- a computable congruence $=_{A,s}$ for each sort s , in order to check the equality of elements in $\llbracket s \rrbracket_A$ (the same element may be represented by different bit-strings); by congruence, we mean a reflexive, symmetric, transitive relation such that $e_1 =_{A,s_1} e'_1, \dots, e_k =_{A,s} e'_k \Rightarrow f_A(e_1, \dots, e_k) =_{A,s} f_A(e'_1, \dots, e'_k)$ (in the remaining we often omit s and write $=_A$ for $=_{A,s}$);
- an effective procedure to draw random elements from $\llbracket s \rrbracket_A$; we denote such a drawing by $x \stackrel{R}{\leftarrow} \llbracket s \rrbracket_A$; the drawing may not follow a uniform distribution, but no $=_{A,s}$ -equivalence class should have probability 0.

Assume a fixed $(\mathcal{S}, \mathcal{F})$ -computational algebra A . We associate to each closed frame $\varphi = \{x_1 = T_1, \dots, x_n = T_n\}$ a distribution $\psi = \llbracket \varphi \rrbracket_A$, of which the drawings $\hat{\psi} \stackrel{R}{\leftarrow} \psi$ are computed as follows:

1. for each name a of sort s appearing in T_1, \dots, T_n , draw a value $\hat{a} \stackrel{R}{\leftarrow} \llbracket s \rrbracket_A$;
2. for each x_i ($1 \leq i \leq n$) of sort s_i , compute $\hat{T}_i \in \llbracket s_i \rrbracket_A$ recursively on the structure of terms: $f(\widehat{T'_1}, \dots, \widehat{T'_m}) = f_A(\widehat{T'_1}, \dots, \widehat{T'_m})$;
3. return the value $\hat{\psi} = \{x_1 = \widehat{T}_1, \dots, x_n = \widehat{T}_n\}$.

Such values $\phi = \{x_1 = e_1, \dots, x_n = e_n\}$ with $e_i \in \llbracket s_i \rrbracket_A$ are called *concrete frames*. We extend the notation $\llbracket \cdot \rrbracket_A$ to (sets of) closed terms in the obvious way. We also generalize the notation to terms or frames with variables, by specifying the concrete values for all of them: $\llbracket \cdot \rrbracket_{A, \{x_1=e_1, \dots, x_n=e_n\}}$. Notice that when a term or a frame contains no names, the translation is deterministic; in this case, we use the same notation to denote the distribution and its unique value.

(Families of) distributions over concrete frames benefit from the usual notion of cryptographic indistinguishability. Let us note $\eta \geq 0$ the complexity parameter. Intuitively, two families (ψ_η) and (ψ'_η) of distributions over concrete frames are *indistinguishable*, written $(\psi_\eta) \approx (\psi'_\eta)$, iff no probabilistic polynomial-time adversary \mathcal{A} can guess whether he is given a sample from ψ_η or ψ'_η with a probability significantly greater than $\frac{1}{2}$. Rigorously, we ask the *advantage* of \mathcal{A} ,

$$\text{Adv}^{\text{IND}}(\mathcal{A}, \eta, \psi_\eta, \psi'_\eta) = \mathbb{P}[\widehat{\psi} \stackrel{R}{\leftarrow} \psi_\eta; \mathcal{A}(\eta, \widehat{\psi}) = 1] - \mathbb{P}[\widehat{\psi} \stackrel{R}{\leftarrow} \psi'_\eta; \mathcal{A}(\eta, \widehat{\psi}) = 1]$$

to be a *negligible* function of η , that is, to remain eventually smaller than any η^{-n} ($n > 0$) for sufficiently large η .

3 Relating Abstract and Computational Algebras

In the previous section we have defined abstract and computational algebras. We now relate formal notions such as equality, (non-)deducibility and static equivalence to their computational counterparts, *i.e.* equality, one-wayness and indistinguishability.

3.1 Soundness and Faithfulness

We introduce the notions of sound, *resp.* faithful, computational algebras with respect to the formal relations studied here: equality, static equivalence and deducibility. In the remaining of the paper we only consider families of computational algebras (A_η) such that each required operation on algebras is feasible by a (uniform) polynomial-time algorithm in the complexity parameter η . We also require that for every sort s , either there exists no name of sort s , or the probability of collision of two random elements in $\llbracket s \rrbracket_A$, $\mathbb{P}[e_1, e_2 \stackrel{R}{\leftarrow} \llbracket s \rrbracket_A ; e_1 =_A e_2]$, is negligible.

Specifically a family of computational algebras (A_η) is

- $=_E$ -*sound* iff for every closed terms T_1, T_2 of the same sort, $T_1 =_E T_2$ implies that $\mathbb{P}[e_1, e_2 \stackrel{R}{\leftarrow} \llbracket T_1, T_2 \rrbracket_A ; e_1 \neq_A e_2]$ is negligible;
- $=_E$ -*faithful* iff for every closed terms T_1, T_2 of the same sort, $T_1 \neq_E T_2$ implies that $\mathbb{P}[e_1, e_2 \stackrel{R}{\leftarrow} \llbracket T_1, T_2 \rrbracket_A ; e_1 =_A e_2]$ is negligible;
- \approx_E -*sound* iff for every closed frames φ_1, φ_2 with the same domain, $\varphi_1 \approx_E \varphi_2$ implies that $(\llbracket \varphi_1 \rrbracket_A) \approx (\llbracket \varphi_2 \rrbracket_A)$;
- \approx_E -*faithful* iff for every closed frames φ_1, φ_2 of the same domain, $\varphi_1 \not\approx_E \varphi_2$ implies that there exists a polynomial-time adversary \mathcal{A} for distinguishing concrete frames, such that $1 - \text{Adv}^{\text{IND}}(\mathcal{A}, \eta, \llbracket \varphi_1 \rrbracket_A, \llbracket \varphi_2 \rrbracket_A)$ is negligible;
- $\not\vdash_E$ -*sound* iff for every closed φ and T , $\varphi \not\vdash_E T$ implies that for each polynomial-time adversary \mathcal{A} , $\mathbb{P}[\phi, e \stackrel{R}{\leftarrow} \llbracket \varphi, T \rrbracket_A ; \mathcal{A}(\phi) =_A e]$ is negligible;
- $\not\vdash_E$ -*faithful* iff for every closed φ and T , $\varphi \vdash_E T$ implies that there exists a polynomial-time adversary \mathcal{A} such that $1 - \mathbb{P}[\phi, e \stackrel{R}{\leftarrow} \llbracket \varphi, T \rrbracket_A ; \mathcal{A}(\phi) =_A e]$ is negligible.

Sometimes, it is possible to prove stronger notions of soundness that hold without restriction on the computational power of adversaries. In particular, (A_η) is *unconditionally* $=_E$ -sound iff for every closed terms T_1, T_2 of the same sort, $T_1 =_E T_2$ implies that $\mathbb{P}[e_1, e_2 \stackrel{R}{\leftarrow} \llbracket T_1, T_2 \rrbracket_A ; e_1 =_A e_2] = 1$; *unconditionally* \approx_E -sound iff for every closed frames φ_1, φ_2 with the same domain, $\varphi_1 \approx_E \varphi_2$ implies $(\llbracket \varphi_1 \rrbracket_A) = (\llbracket \varphi_2 \rrbracket_A)$; *unconditionally* $\not\vdash_E$ -sound iff for every closed φ and T s.t. $\varphi \not\vdash_E T$, the distributions for φ and T are independent: for all ϕ_0, e_0 , $\mathbb{P}[\phi, e \stackrel{R}{\leftarrow} \llbracket \varphi, T \rrbracket_A ; \phi = \phi_0 \text{ and } e = e_0] = \mathbb{P}[\phi \stackrel{R}{\leftarrow} \llbracket \varphi \rrbracket_A ; \phi = \phi_0] \times \mathbb{P}[e \stackrel{R}{\leftarrow} \llbracket T \rrbracket_A ; e = e_0]$.

Generally, (unconditional) $=_E$ -soundness is given by construction. Indeed true formal equations correspond to the expected behavior of primitives and should hold in the concrete world with overwhelming probability. The other criteria are however more difficult to fulfill. Therefore it is often interesting to restrict frames to *well-formed* ones in order to achieve soundness or faithfulness: for instance Abadi and Rogaway [3] do forbid encryption cycles (c.f. Section 5.2).

It is worth noting that the notions introduced above are not independent.

Proposition 1. *Let (A_η) be a $=_E$ -sound family of computational algebras. Then (A_η) is $\not\vdash_E$ -faithful. If moreover (A_η) is $=_E$ -faithful, then it is also \approx_E -faithful.*

For many interesting theories, we have that \approx_E -soundness implies all the other notions of soundness and faithfulness. As an illustration, let us consider an arbitrary theory which includes keyed hash functions.

Proposition 2. *Let (A_η) be a family of \approx_E -sound computational algebras. Assume that free binary symbols $h_s : s \times \text{Key} \rightarrow \text{Hash}$ are available for every sort s , and the sorts Hash and Key have infinitely many names. Then (A_η) is $=_E$ -faithful and $\not\vdash_E$ -sound. Besides, if the implementations for the h_s are collision-resistant, then (A_η) is $=_E$ -sound, \approx_E -faithful and $\not\vdash_E$ -faithful.*

3.2 \approx_E -Soundness Implies Classical Assumptions on Groups

Inspired by the work of Rivest on pseudo-freeness [14], we now study some consequences of \approx_E -soundness on *groups*. Let E_G be the equational theory modeling a free group G with exponents taken over a free commutative ring A . Assume a \approx_{E_G} -sound family of computational algebras (A_η) . Then the static equivalence $\nu g, a, b. \{x_1 = g, x_2 = g^a, x_3 = g^b, x_4 = g^{a \cdot b}\} \approx_{E_G} \nu g, a, b, c. \{x_1 = g, x_2 = g^a, x_3 = g^b, x_4 = g^c\}$ implies the hardness of the decisional Diffie-Hellman problem for this implementation.

In a similar way we prove that \approx_{E_G} -soundness implies the hardness of RSA. More details can be found in [7].

4 A Sufficient (and Often Necessary) Criterion for \approx_E -Soundness

We now present useful results for proving \approx_E -soundness properties in general. Notably, we provide a sufficient criterion for \approx_E -soundness in Section 4.1 and prove it necessary under additional assumptions in Section 4.2.

4.1 Ideal Semantics and \approx_E -Soundness Criterion

Given an implementation of the primitives, what we called the concrete semantics maps every closed frame φ to a distribution $\llbracket \varphi \rrbracket_A$ in the expected way. We now define the *ideal semantics* of a φ , intuitively as the uniform distribution over sequences of bit-strings (in the appropriate space) that pass all the formal tests verified by φ .

Given a closed frame φ , let us write $\text{eq}_E(\varphi)$ for the set of tests that are true in φ : $\text{eq}_E(\varphi) = \{(M, N) \mid \text{var}(M) \cup \text{var}(N) \subseteq \text{dom}(\varphi), (\text{names}(M) \cup \text{names}(N)) \cap \text{names}(\varphi) = \emptyset \text{ and } M\varphi =_E N\varphi\}$. Notice that $\varphi \approx_E \varphi'$ iff $\text{eq}_E(\varphi) = \text{eq}_E(\varphi')$.

We say that (A_η) has *uniform distributions* iff for every η and every sort s , $\llbracket s \rrbracket_A$ is a finite set, $=_A$, ${}_s$ is the usual equality and, the distribution associated to s by A_η is the uniform one over $\llbracket s \rrbracket_A$.

Definition 1 (Ideal semantics). *Let (A_η) be an unconditionally $=_E$ -sound family of computational algebras, having uniform distributions. Let $\varphi = \{x_1 = t_1, \dots, x_n = t_n\}$ be a closed frame and s_i the sort of x_i . The ideal semantics $\llbracket \varphi \rrbracket_A^{\text{ideal}}$ of φ is the uniform distribution over the finite (non-empty) set of concrete frames:*

$$\left\{ \{x_1 = e_1, \dots, x_n = e_n\} \mid (e_1, \dots, e_n) \in \llbracket s_1 \rrbracket_A \times \dots \times \llbracket s_n \rrbracket_A \text{ and } \forall (M, N) \in \text{eq}_E(\varphi) \cdot \llbracket M \rrbracket_A, \{x_1=e_1, \dots, x_n=e_n\} = \llbracket N \rrbracket_A, \{x_1=e_1, \dots, x_n=e_n\} \right\}$$

For instance, let $\varphi = \nu n_1, n_2. \{x_1 = n_1, x_2 = n_2\}$ with n_1 and n_2 of sort s . Then $\text{eq}_E(\varphi) \subseteq \{(M, N) \mid M =_E N\}$ implies that $\llbracket \varphi \rrbracket_A^{\text{ideal}}$ is simply the uniform distribution over $\llbracket s \rrbracket_A \times \llbracket s \rrbracket_A$. A more general definition of the ideal semantics, which does not restrict (A_η) to uniform distributions is given in [7].

We can now state our \approx_E -soundness criterion: intuitively, the two semantics, concrete and ideal, should be indistinguishable.

Theorem 1 (\approx_E -soundness criterion). *Let (A_η) be an unconditionally $=_E$ -sound family of computational algebras. Assume that for every closed frame φ it holds that $(\llbracket \varphi \rrbracket_A) \approx (\llbracket \varphi \rrbracket_A^{\text{ideal}})$. Then (A_η) is \approx_E -sound.*

4.2 Patterns Revisited

Patterns have been introduced by Abadi and Rogaway [3] and used in subsequent work [12, 6] as a way to define computationally sound formal equivalences. Typically frames are mapped to patterns by replacing non-decipherable terms by boxes \square . Two frames are then equivalent iff they yield the same pattern (up to renaming of names). For example, the pattern associated to the frame $\varphi_1 = \{x_1 = \text{enc}(\text{enc}(k_4, k_3), k_1), x_2 = \text{enc}(k_1, k_2), x_3 = k_2\}$ is $\{x_1 = \text{enc}(\square, k_1), x_2 = \text{enc}(k_1, k_2), x_3 = k_2\}$.

In this section we propose a general, novel definition of patterns and study some of their properties. We then use these properties to prove that our soundness criterion is necessary in many cases.

Definition 2. *A closed frame φ is a pattern if each of its subterms is deducible from φ .*

Equivalently a pattern is a closed frame of the form $\varphi = \{x_1 = C_1[a_1, \dots, a_m], \dots, x_n = C_n[a_1, \dots, a_m]\}$ where the $C_1 \dots C_n$ are closed (not necessarily linear) contexts

and the $a_1 \dots a_m$ are distinct deducible names: $\varphi \vdash_E a_i$. For example, φ_1 as defined above is not a pattern, while $\varphi_2 = \{x_1 = \text{enc}(n_1, k_1), x_2 = \text{enc}(k_1, k_2), x_3 = k_2\}$ is.

The following proposition finitely characterizes the equations verified by a pattern.

Proposition 3. *Let $\varphi = \{x_1 = C_1[a_1, \dots, a_m], \dots, x_n = C_n[a_1, \dots, a_m]\}$ be a pattern, using the notations above. For each a_i , let ζ_a be a term such that $\text{var}(\zeta_a) \subseteq \{x_1, \dots, x_n\}$, $\text{names}(\zeta_a) \cap \text{names}(\varphi) = \emptyset$ and $\zeta_a \varphi =_E a_i$. Then every equation which holds in φ is a logical consequence (in the first-order theory of equality) of E and the equations $x_j = C_j[\zeta_{a_1}, \dots, \zeta_{a_m}]$.*

Interestingly the concrete and the ideal semantics of patterns often coincide.

Proposition 4. *Let (A_η) be an unconditionally $=_E$ -sound family of computational algebras, having uniform distributions. Let φ be a pattern. The concrete and the ideal semantics of φ yield the same family of distributions: for all η , $\llbracket \varphi \rrbracket_A = \llbracket \varphi \rrbracket_A^{\text{ideal}}$.*

The idea of the proof is that, using the finite characterization of $\text{eq}_E(\varphi)$ (Proposition 3), one can draw a bijection between the drawing of nonces and the eligible values for the ideal semantics.

A theory E admits patterns iff for every closed frame φ , there exists a (not necessarily unique) pattern $\overline{\varphi}$ such that $\varphi \approx_E \overline{\varphi}$. In practice many theories useful in cryptography satisfy this property, e.g. the theories considered in Section 5. Note that we have proved *en passant* that \approx_E is decidable for equational theories that admit patterns and for which $=_E$ is decidable, provided the construction of patterns is effective. Indeed, given two frames φ_1 and φ_2 , we associate to each of them one of its statically equivalent pattern $\overline{\varphi_1}$ and $\overline{\varphi_2}$, respectively. It is then straightforward to check whether $\overline{\varphi_1}$ and $\overline{\varphi_2}$ are equivalent using the finite characterization of $\text{eq}_E(\overline{\varphi_i})$ by Proposition 3.

The following theorem states that our soundness criterion is actually very tight: whenever a theory admits patterns, our criterion is a necessary condition.

Theorem 2. *Assume that the theory E admits patterns. Let (A_η) be a family of computational algebras, such that (A_η) has uniform distributions, is \approx_E - and unconditionally $=_E$ -sound. Then the soundness criterion of Theorem 1 is satisfied: for every closed frame φ , $(\llbracket \varphi \rrbracket_A) \approx (\llbracket \varphi \rrbracket_A^{\text{ideal}})$.*

5 Examples

We now apply the framework of Sections 3 and 4 to establish two novel \approx_E -soundness results, concerning the theory of exclusive OR and that of ciphers and lists.

5.1 Exclusive OR

We study the soundness and faithfulness problems for the usual theory and implementation of the exclusive OR (XOR).

The formal model consists of a single sort $Data$, an infinite number of names, the infix symbol $\oplus : Data \times Data \rightarrow Data$ and two constants $0, 1 : Data$. Terms are equipped with the equational theory E_\oplus generated by:

$$\begin{array}{ll}
 x \oplus y = y \oplus x & x \oplus x = 0 \\
 (x \oplus y) \oplus z = x \oplus (y \oplus z) & x \oplus 0 = x
 \end{array}$$

As an implementation, we define the computational algebras A_η , $\eta \geq 0$: the concrete domain $\llbracket Data \rrbracket_A$ is $\{0, 1\}^\eta$ equipped with the uniform distribution; \oplus is interpreted by the usual XOR function over $\{0, 1\}^\eta$, $\llbracket 0 \rrbracket_A = 0^\eta$, $\llbracket 1 \rrbracket_A = 1^\eta$.

In this setting, statically equivalent frames enjoy an algebraic characterization. Indeed, let φ and φ' be two frames with $\text{names}(\varphi) \cup \text{names}(\varphi') \subseteq \{a_1, \dots, a_n\}$ and $\text{dom}(\varphi) = \text{dom}(\varphi') = \{x_1, \dots, x_m\}$. We associate to φ a $(m + 1) \times (n + 1)$ -matrix $\alpha = (\alpha_{i,j})$ over the two element field \mathbb{F}_2 : the 0-th row of α is $(1, 0 \dots 0)$ and for $1 \leq i \leq m$, $1 \leq j \leq n$ (*resp.* $j = 0$) $\alpha_{i,j}$ is the number of occurrences of a_j (*resp.* of 1) in $\varphi(x_i)$, taken modulo 2. In the same way, a matrix α' is associated to φ' . Using classical manipulations on matrices, it is easy to show that $\varphi \approx_{E_\oplus} \varphi'$ iff the two associated matrices α and α' have the same image, that is $\alpha(\mathbb{F}_2^{n+1}) = \alpha'(\mathbb{F}_2^{n+1})$.

This characterization is the key point of our main result for the theory of XOR.

Theorem 3. *The usual implementation of the XOR theory is unconditionally $=_{E_\oplus}$ -, \approx_{E_\oplus} - and \forall_{E_\oplus} -sound. It is also $=_{E_\oplus}$ -, \approx_{E_\oplus} - and \forall_{E_\oplus} -faithful.*

This result is comparable to the work of Bana [6], who shows the unconditional soundness of the One-Time Pad encryption in a setting similar to that of Abadi and Rogaway [3]. In some sense our result is more precise as we model the XOR symbol itself and not a particular use of it.

5.2 Symmetric, Deterministic, Length-Preserving Encryption and Lists

We now detail the example of symmetric, deterministic and length-preserving encryption schemes. Such schemes, also known as *ciphers* [13], are widely used in practice, the most famous examples being DES and AES .

Our formal model consists of a set of sorts $\mathcal{S} = \{Data, List_0, List_1 \dots List_n \dots\}$, an infinite number of names for every sort $Data$ and $List_n$, $n \neq 0$, and the symbols:

$$\begin{array}{ll}
 \text{enc}_n, \text{dec}_n : List_n \times Data \rightarrow List_n & \text{encryption, decryption} \\
 \text{cons}_n : Data \times List_n \rightarrow List_{n+1} & \text{list constructor} \\
 \text{head}_n : List_{n+1} \rightarrow Data & \text{head of a list} \\
 \text{tail}_n : List_{n+1} \rightarrow List_n & \text{tail of a list} \\
 \text{nil} : List_0 \quad 0, 1 : Data & \text{empty list, constants}
 \end{array}$$

We consider the equational theory E_{sym} generated by (for every $n \geq 0$)

$$\begin{array}{ll}
 \text{dec}_n(\text{enc}_n(x, y), y) = x & \text{cons}_n(\text{head}_n(x), \text{tail}_n(x)) = x \\
 \text{enc}_n(\text{dec}_n(x, y), y) = x & \text{enc}_0(\text{nil}, x) = \text{nil} \\
 \text{head}_n(\text{cons}_n(x, y)) = x & \text{dec}_0(\text{nil}, x) = \text{nil} \\
 \text{tail}_n(\text{cons}_n(x, y)) = y &
 \end{array}$$

When oriented from left to right, the equations E_{sym} form an (infinite) convergent rewriting system, written \mathcal{R} . The equations $\text{enc}_n(\text{dec}_n(x, y), y) = x$ are characteristic of length-preserving encryption schemes. Indeed, encryption and decryption functions under each key then form a pair of mutually inverse bijections. The concrete meaning of sorts and symbols is given by the computational algebras A_η , $\eta > 0$, defined as follows:

- the carrier sets are $\llbracket \text{Data} \rrbracket_A = \{0, 1\}^\eta$ and $\llbracket \text{List}_n \rrbracket_A = \{0, 1\}^{n\eta}$ equipped with the uniform distribution and the usual equality relation;
- $\text{enc}_n, \text{dec}_n$ are implemented by a cipher for data of size $n\eta$ and keys of size η (we discuss the required cryptographic assumptions later);
- $\llbracket \text{nil} \rrbracket_A$ is the empty bit-string, $\llbracket \text{cons}_n \rrbracket_A$ is the usual concatenation, $\llbracket 0 \rrbracket_A = 0^\eta$, $\llbracket 1 \rrbracket_A = 1^\eta$, $\llbracket \text{head}_n \rrbracket_A$ returns the η first digits of bit-strings (of size $(n + 1)\eta$) whereas $\llbracket \text{tail}_n \rrbracket_A$ returns the last $n\eta$ digits.

Obviously, the above implementation is unconditionally $=_{E_{\text{sym}}}$ -sound. Before studying the $\approx_{E_{\text{sym}}}$ -soundness, we need to characterize statically equivalent frames. Specifically we show that this theory admits patterns, in the sense of Section 3.

Proposition 5. *Let φ be a closed frame. There exists a pattern $\bar{\varphi}$ such that $\varphi \approx_{E_{\text{sym}}} \bar{\varphi}$.*

Proof (outline). We associate a pattern to any frame φ by the following procedure:

1. normalize φ using the rules \mathcal{R} (the result is still denoted φ);
2. while φ is not a pattern, repeat: find any subterm T of the form $T = \text{enc}_n(U, V)$, $T = \text{dec}_n(U, V)$, $T = \text{head}_n(V)$ or $T = \text{tail}_n(V)$, with $\varphi \not\vdash_{E_{\text{sym}}} V$ and replace T everywhere in φ by a fresh name a of the appropriate sort.

We prove in [7] that this procedure always terminates on a pattern statically equivalent to the initial frame.

We now study the $\approx_{E_{\text{sym}}}$ -soundness problem under realistic cryptographic assumptions. Classical assumptions on ciphers include the notions of super pseudo-random permutation (SPRP) and several notions of indistinguishability (IND-Pi-C j , $i, j = 0, 1, 2$). In particular, IND-P1-C1 denotes the indistinguishability against lunchtime chosen-plaintext and chosen-ciphertext attacks. These notions and the relations between them have been studied notably in [13].

Initially, the SPRP and IND-P1-C1 assumptions apply to (block) ciphers specialized to plaintexts of a given size. Interestingly, this is not sufficient to imply $\approx_{E_{\text{sym}}}$ -soundness for frames which contain plaintexts of heterogeneous sizes, encrypted under the same key. Thus we introduce a strengthened version of IND-P1-C1, applying to a *collection* of ciphers $(\mathcal{E}_{\eta,n}, \mathcal{D}_{\eta,n})$, where η is the complexity parameter and $n \geq 0$ is the number of blocks of size η contained in plaintexts and ciphertexts.

We define the ω -IND-P1-C1 assumption by considering the following experiment \mathcal{G}_η involving a 2-stage adversary $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$:

- first a key k is randomly chosen from $\{0, 1\}^\eta$;
- (Stage 1) \mathcal{A}_1 is given access to the encryption oracles $\mathcal{E}_{\eta,n}(\cdot, k)$ and the decryption oracles $\mathcal{D}_{\eta,n}(\cdot, k)$; it outputs two plaintexts $m_0, m_1 \in \{0, 1\}^{n\eta}$ for some n_0 , and possibly some data d ;
- (Stage 2) a random bit $b \in \{0, 1\}$ is drawn; \mathcal{A}_2 receives the data d , the *challenge ciphertext* $c = \mathcal{E}_{\eta,n_0}(m_b, k)$ and outputs a bit b' ;
- \mathcal{A} is *successful* in \mathcal{G}_η iff $b = b'$ and it has never submitted m_0 or m_1 to an encryption oracle, nor c to a decryption oracle.

Define the *advantage* of \mathcal{A} as: $\text{Adv}_{\mathcal{A}}^{\omega\text{-IND-P1-C1}}(\eta) = 2 \times \mathbb{P}[\mathcal{A} \text{ is successful in } \mathcal{G}_\eta] - 1$. The $\omega\text{-IND-P1-C1}$ assumption holds for $(\mathcal{E}_{\eta,n}, \mathcal{D}_{\eta,n})$ iff the advantage of any probabilistic polynomial-time adversary is negligible. It holds for the *inverse* of the encryption scheme, iff it holds for the collection of ciphers $(\mathcal{D}_{\eta,n}, \mathcal{E}_{\eta,n})$.

As in previous work [3, 12, 4, 11], we restrict frames to those with only atomic keys and no encryption cycles. Specifically a closed frame φ has *only atomic keys* if for all subterms $\text{enc}_n(u, v)$ and $\text{dec}_n(u, v)$ of φ , v is a name. Given two (atomic) keys k_1 and k_2 , we say that k_1 *encrypts* k_2 in φ , written $k_1 >_\varphi k_2$, iff there exists a subterm U of φ of the form $U = \text{enc}_n(T, k_1)$ or $U = \text{dec}_n(T, k_1)$ such that k_2 appears in T *not used as a key*, i.e. k_2 appears in T at a position which is not the right-hand argument of an $\text{enc}_{n'}$ or a $\text{dec}_{n'}$. An *encryption cycle* is a tuple $k_1 \dots k_m$ such that $k_1 >_\varphi \dots >_\varphi k_m >_\varphi k_1$.

The effect of the condition “not used as a key” is to allow considering more terms as free of encryption cycles, for instance $\text{enc}_n(\text{enc}_n(a, k), k)$. This improvement is already suggested in [3].

We now state our $\approx_{E_{\text{sym}}}$ -soundness theorem. A closed frame is *well-formed* iff its \mathcal{R} -normal form has only atomic keys, contains no encryption cycles and uses no head and tail symbols.

Theorem 4 ($\approx_{E_{\text{sym}}}$ -soundness). *Let φ_1 and φ_2 be two well-formed frames of the same domain. Assume that the concrete implementations for the encryption and its inverse satisfy both the $\omega\text{-IND-P1-C1}$ assumption. If $\varphi_1 \approx_{E_{\text{sym}}} \varphi_2$ then $(\llbracket \varphi_1 \rrbracket_A) \approx (\llbracket \varphi_2 \rrbracket_A)$.*

Note on the cryptographic assumptions. Cryptographic assumptions of Theorem 4 may appear strong compared to existing work on passive adversaries [3, 12]. Nevertheless if φ_1 and φ_2 contain no decryption symbols, our proofs are easily adapted to work when the encryption scheme is $\omega\text{-IND-P1-C0}$ only, where $\omega\text{-IND-P1-C0}$ is defined similarly to $\omega\text{-IND-P1-C1}$ except that the adversary has no access to the decryption oracle.

Also, it is possible to recover the classical assumptions IND-P1-C1 by modeling the ECB mode (Electronic Code Book). Let us add two symbols $\text{enc} : \text{Data} \times \text{Data} \rightarrow \text{Data}$ and $\text{dec} : \text{Data} \times \text{Data} \rightarrow \text{Data}$, and define the symbols enc_n and dec_n (formally and concretely) recursively by

$$\begin{aligned} \text{enc}_{n+1}(x, y) &= \text{cons}_n(\text{enc}(\text{head}_n(x), y), \text{enc}_n(\text{tail}_n(x), y)) \quad \text{and} \\ \text{dec}_{n+1}(x, y) &= \text{cons}_n(\text{dec}(\text{head}_n(x), y), \text{dec}_n(\text{tail}_n(x), y)). \end{aligned}$$

Define well-formed frames as those of which the normal forms contain no encryption cycles. The $\approx_{E_{\text{sym}}}$ -soundness property holds for well-formed frames as soon as the implementations for enc and dec are both IND-P1-C1, or equivalently [13] enc is SPRP.

6 Conclusion and Future Work

In this paper we developed a general framework for relating formal and computational models of security protocols in the presence of a passive attacker. These are the first results on abstract models allowing arbitrary equational theories. We define the soundness and faithfulness of cryptographic implementations *w.r.t.* abstract models. We also provide a soundness criterion which for a large number of theories—those that admit a

general notion of patterns—is not only sufficient but also necessary. Finally, we provide new soundness results for the exclusive OR and a theory of ciphers and lists.

As future work, we foresee to study the soundness of other theories. An interesting case would be the combination of the two theories considered in this paper: in a theory combining XOR, ciphers and lists, one can precisely model the *Cipher Block Chaining* (CBC) mode, which is commonly used with block ciphers such as DES or AES. Another ambitious extension is to consider the case of an active attacker.

Password-Based Encryption Analyzed

Martín Abadi¹ and Bogdan Warinschi²

Abstract. The use of passwords in security protocols is particularly delicate because of the possibility of off-line guessing attacks. We study password-based protocols in the context of a recent line of research that aims to justify symbolic models in terms of more concrete, computational ones. We offer two models for reasoning about the concurrent use of symmetric, asymmetric, and password-based encryption in protocol messages. In each of the models we define a notion of equivalence between messages and also characterize when passwords are used securely in a message or in a set of messages. Our new definition for the computational security of password-based encryption may be of independent interest. The main results of this paper are two soundness theorems. We show that under certain (standard) assumptions about the computational implementation of the cryptographic primitives, symbolic equivalence implies computational equivalence. More importantly, we prove that symbolically secure uses of passwords are also computationally secure.

1 Introduction

Passwords and other weak secrets sometimes serve as cryptographic keys in security protocols and elsewhere (e.g., [5, 14, 16, 21]). The use of weak secrets is particularly delicate because of the possibility of off-line guessing attacks. In such an attack, data that depends on a weak secret is used in checking guesses of the values of the weak secret. Consider, for example, a protocol where two parties exchange the encryption c of some fixed message, say **OK**, under a shared password pwd . If pwd is picked from a relatively small dictionary, then an attacker that obtains a transcript of the protocol execution can mount the following off-line attack. It decrypts the ciphertext c with the passwords in the dictionary, one by one, until the result of the decryption is the text **Ok**. The password used for this last decryption is likely to be pwd . Guessing attacks such as this one are passive, in the sense that they do not require interaction with the protocol participants, so they are hard to detect. A guessing attack may however be carried out after an active attack, relying on the messages exchanged in the course of the active attack.

Early research on the design and analysis of protocols based on weak secrets focused on techniques for defending against guessing attacks (e.g. [13]). These techniques basically aim to ensure that plaintexts encrypted under passwords do not contain redundancy that can later be used to verify a password guess. While this is a helpful guideline, its informal application need not guarantee security. As experience demonstrates (e.g., [23]), conjecturing the security of a protocol, or arguing it only heuristically, is

not sufficient. Instead, and this is the goal pursued by recent research on the subject, the security of protocols should be rigorously analyzed. Models for carrying out such analyzes have been designed using two different, yet related approaches.

The first approach, known as the symbolic or formal methods approach, adopts an abstract view of executions. Messages are modeled as elements of a term algebra constructed with symbolic operations that represent various cryptographic primitives. Parties operate on terms using a limited number of inference rules, sometimes generically known as the Dolev-Yao rules. The rules reflect a common understanding of the security of cryptographic primitives. For example, they say that the message encrypted in a ciphertext can be recovered only if the appropriate decryption key is known. Quite often, proofs that rely on these rules can be mechanized. Work done on symbolic models for password-based protocol has concentrated on extending the Dolev-Yao rules to guessing attacks [7–9, 18]. Typical formalisms enrich standard symbolic models with an operation that represents encryption under passwords, and they offer a careful account of when a password guess can be verified from a given set of terms (presumably a transcript of a protocol execution). The resulting decision procedure has been automated [7, 8, 18]; a corresponding decision problem has been shown NP-complete [9]. Unfortunately, as remarked by authors of prior work [18], it is quite difficult to determine if a set of formal criteria for the existence of guessing attacks is exhaustive. Hence, the possibility remains that a formal analysis would miss some attacks, and unsoundly conclude that a protocol is secure when in fact it is not.

The second approach, known as the computational approach, uses a concrete (bit level) representation, for protocol executions. The attacker is modeled as a powerful, arbitrary probabilistic polynomial-time Turing machine. Although proofs with this approach tend to be lengthy, difficult, and tedious, it is generally accepted that it provides strong guarantees. For the case of password-based protocols, work with the computational approach seems to have focused almost exclusively on the important use of passwords for authenticated key exchange. This work includes designing models and giving provably secure constructions [4, 6, 10, 11, 15]. Surprisingly, the security of password-based encryption as a stand-alone primitive has not been addressed.

A recent line of research aims to justify the abstractions made by symbolic methods with respect to computational models (e.g., [1, 2, 17, 20, 22]) via soundness theorems. These theorems typically state that, under certain assumptions on the implementation of cryptographic primitives, symbolic security proofs imply security in the computational model. The applications of soundness theorems are quite appealing: simple reasoning techniques and automatic tools, specific to the symbolic setting, can be used to carry out proofs that guarantee strong, computational security.

This paper is a first exploration on the subject of computationally sound symbolic analysis for protocols based on passwords. We concentrate on off-line guessing attacks, because they are the main original concern in the analysis of those protocols and because they appear mostly orthogonal to the standard active attacks. Our framework is an extension of the framework introduced by Abadi and Rogaway [1] to asymmetric and password-based encryption. That framework focuses, as an initial step, on passive attacks; in that respect, it is a good match for our purposes, since off-line guessing attacks are passive by definition (even if they may occur in conjunction with active attacks).

We introduce a language of expressions whose elements are abstract representations of the messages sent during protocol executions. The cryptographic primitives that we consider are symmetric encryption, asymmetric encryption, and encryption that uses passwords as keys. To these expressions we attach two different semantics. The first is symbolic; it is based on an extension of the classical Dolev-Yao inference rules to include password-based encryption. The second is computational; it is based on concrete implementations of the encryption operations. In current protocols, password-based encryption typically serves for achieving authenticity rather than secrecy properties, despite the use of the term “encryption” (which we preserve for historical reasons). Accordingly, our semantics do not require that the encryption of a plaintext under a password ensure the secrecy of the plaintext. Further, we give symbolic and computational definitions for expression equivalence (when two expressions convey the same information to an adversary) and for secure use of passwords (which expressions do not leak passwords despite guessing attacks). The main results of our paper are soundness theorems that link the two models. We prove that if two expressions are equivalent symbolically then they are equivalent computationally. We also prove that if an expression hides a password symbolically then it hides the password computationally.

In Section 2 we give the syntax of the language of expressions. As a counterpart, we introduce a computational setting in Section 4. We define expression equivalence and password hiding, symbolically and computationally, in Sections 3 and 5, respectively. In Section 6 we give our main results; as an example, we show an application to the EKE protocol [5]. We conclude in Section 7. Because of space constraints, we leave many details and proofs to a longer version of this paper.

2 Syntax

In this section we define the language of expressions Exp . We consider messages constructed from bits and cryptographic keys by using pairing, symmetric and asymmetric encryption, as well as encryption that employs passwords as keys. In what follows, Bool is the set of bits $\{0, 1\}$. Keys is the set of cryptographic keys; it is the union of the disjoint sets SKeys , EKeys , DKeys , and Passwd which contain symbols for symmetric keys, asymmetric encryption keys, asymmetric decryption keys, and passwords, respectively. We write EncKeys for $\text{SKeys} \cup \text{EKeys} \cup \text{Passwd}$, the set of keys that can be used for encryption; and write $(\cdot)^{-1} : \text{SKeys} \cup \text{EKeys} \rightarrow \text{SKeys} \cup \text{DKeys}$ for a bijection that maps an encryption key to the associated decryption key. We usually follow the convention that K_1^s, K_2^s, \dots represent symmetric keys, K_1^e, K_2^e, \dots asymmetric encryption keys, and K_1^d, K_2^d, \dots the corresponding asymmetric decryption keys. In this paper we concentrate on the simple setting where expressions use a single password symbol for encryption, so the set Passwd contains a single element W . This setting is sufficient for analyzing multiple concurrent runs of the execution of a protocol between principals that share a password; with some complications, our approach extends to the general case where multiple passwords are used simultaneously.

The set Exp of formal expressions is defined by the grammar:

$$\text{Exp} ::= \text{Bool} \mid \text{Passwd} \mid \text{EKeys} \mid \text{DKeys} \mid \text{SKeys} \mid (\text{Exp}, \text{Exp}) \mid \{\text{Exp}\}_{\text{EncKeys}}$$

For example, expression $\{K^s\}_W, \{(0, 0)\}_K$ represents the encryption of symmetric key K^s under the password W paired with the encryption of $(0, 0)$ under key K^s . The expression $\{K^e\}_K, \{K^s\}_K, \{0\}_K$ represents the encryption of public key K^e under itself, paired with the encryption of symmetric key K^s under K^e and the encryption of the bit 0 under K^s . As we do here, we omit parenthesis when there is no risk of ambiguity or when ambiguity is harmless.

An important subset of Exp is that of *acyclic expressions*. Acyclicity was introduced in previous work [1] for expressions that use only symmetric encryption. Here we generalize this notion to deal also with asymmetric encryption. Given an expression $E \in \text{Exp}$ we build the following directed graph. The nodes of the graph are pairs of encryption and decryption keys $(K, K^{-1}) \in \text{SKeys} \times \text{SKeys} \cup \text{EKeys} \times \text{DKeys}$ for which at least one of the components appears in E . We add an edge between nodes (K_1, K_1^{-1}) and (K_2, K_2^{-1}) , and say that K_1 encrypts K_2 , if there exists $E' \in \text{Exp}$ such that $\{E'\}_{K_1}$ occurs in E and K_2^{-1} occurs in E' . We say that an expression $E \in \text{Exp}$ is acyclic if its associated graph is acyclic. For example, the two expressions $\{K_1^e\}_{K_1}$ and $(\{K_1^e\}_{K_1}, \{K_1^s\}_{K_1})$ are acyclic, and the three expressions $\{K_1^s\}_{K_1}$, $(\{K_1^s\}_{K_2}, \{K_2^s\}_{K_1})$, and $(\{K_1^d\}_{K_1}, \{K_1^s\}_{K_1})$ are not.

3 A Symbolic Model for Expressions

In this section we introduce a symbolic semantics for expressions in Exp . Intuitively, the semantics of an expression is a *pattern* that represents the information that an adversary learns by observing the expression. With this interpretation, we give an equivalence relation on the set of expressions that identifies expressions that convey the same information to the adversary (extending [1]). Furthermore, we use the symbolic semantics to give a characterization of expressions that do not leak a password.

Symbolic semantics and expression equivalence. The inference rules that an adversary can use for deriving new information are formalized by the *entailment* relation $M \vdash N$, which is the least relation that satisfies:

1. $M \vdash 0$ and $M \vdash 1$,
2. $M \vdash M$,
3. if $M \vdash N_1$ and $M \vdash N_2$ then $M \vdash (N_1, N_2)$,
4. if $M \vdash (N_1, N_2)$ then $M \vdash N_1$ and $M \vdash N_2$,
5. if $M \vdash N$ and $M \vdash K$ then $M \vdash \{N\}_K$, for $K \in \text{EncKeys}$,
6. if $M \vdash \{N\}_K$ and $M \vdash K^{-1}$ then $M \vdash N$, for $K \in \text{SKeys} \cup \text{EKeys}$,
7. if $M \vdash \{N\}_W$ then $M \vdash N$, for $W \in \text{Passwd}$.

Most of the rules are self-explanatory: for example, they allow an adversary to pair messages that it knows (rule (3)), recover the components of a pair (rule (4)), and compute the encryption of a message M under a certain key K , provided the adversary can compute both M and K (rule (5)). Rule (6) is the standard rule of Dolev-Yao deduction systems: an adversary can decrypt a ciphertext if it has the right decryption key. For instance, we have: $K_1^d, \{W\}_{K_1} \vdash W$ and $\{\{K_1^s\}_{K_2}, \{K_1^d\}_{K_1}\}_{K_2}, \{W\}_{K_1}, K_2^s \vdash W$.

Rule (7) shows that our definitions make a pessimistic (but perhaps realistic!) assumption about the secrecy of plaintexts encrypted under a password. For instance, we have $K_1^d, \{\{0, K_2^s\}_{K_1}\}_W \vdash K_2^s$. As indicated in the introduction, this assumption is compatible with current uses of passwords for authentication. However, none of the rules allows the recovery of W by simply observing encryptions of messages under W .

Patterns are elements of the language Pat obtained by extending the language Exp with symbols that represent undecryptable (symmetric and asymmetric) ciphertexts. We let $\text{Undec} = \{\square^s, \square^a\}$. The set of patterns is defined by the grammar:

$$\text{Pat} ::= \text{Exp} \mid \text{Undec} \mid (\text{Pat}, \text{Pat}) \mid \{\text{Pat}\}_{\text{EncKeys}}$$

The pattern $p(M, T)$ represents what an adversary can see in an expression $M \in \text{Exp}$ using for decryption the keys in $T \subseteq \text{Keys}$. It is defined inductively by:

$$\begin{aligned} p(M, T) &= M && \text{for } M \in \text{Bool} \cup \text{Keys} \\ p((M, N), T) &= (p(M, T), p(N, T)) \\ p(\{M\}_W, T) &= \{p(M, T)\}_W \\ p(\{M\}_K, T) &= \begin{cases} \{p(M, T)\}_K & \text{if } K^s \in T \\ \square^s & \text{otherwise} \end{cases} \\ p(\{M\}_K, T) &= \begin{cases} \{p(M, T)\}_K & \text{if } K^d \in T \\ \square^a & \text{otherwise} \end{cases} \end{aligned}$$

We let $\text{recoverable}(M) = \{K \in \text{Keys} \mid M \vdash K\}$ be the set of keys that can be recovered from an expression M . The pattern associated to M is the pattern computed from M given the set of keys recoverable from M , that is: $\text{pattern}(M) = p(M, \text{recoverable}(M))$. For instance, in the case of the expression $\{K_1^s\}_W, \{K_1^e\}_W, \{\{K_2^s\}_{K_1}\}_{K_3}, \{0\}_{K_1}, K_2^s, \{\{K_1^d\}_{K_3}, 0\}_{K_1}$, the recoverable keys are K_1^s, K_1^e , and K_2^s , and the pattern is $\{K_1^s\}_W, \{K_1^e\}_W, \square^s, \square^a, K_2^s, \{\square^s, 0\}_{K_1}$.

We use patterns for defining equivalence of expressions: two expressions are equivalent if they have the same pattern. Much as in previous work, this equivalence relation can be a little too restrictive, so we relax it by using key renaming functions. A key renaming function is a bijection on the set Keys that preserves the types of keys: it maps passwords to passwords, asymmetric encryption (decryption) keys to asymmetric encryption (respectively decryption) keys, and symmetric keys to symmetric keys.

Definition 1. $M \equiv N$ if and only if $\text{pattern}(M) = \text{pattern}(N)$, and $M \cong N$ if and only if there exists a key renaming σ such that $M \equiv N\sigma$.

For example, we have $\{0\}_{K_1} \cong \{1\}_{K_2}$ and $\{0\}_{K_1} \cong \{1\}_{K_2}$. These equivalences reflect the standard assumption that symmetric and asymmetric encryption hide plaintexts. We also have $\{0\}_K \not\cong \{0\}_K$: symmetric and asymmetric ciphertexts can in principle be distinguished. Coming to passwords, we have $\{0\}_W \cong \{0\}_W$ and $\{0\}_W \not\cong \{1\}_W$: password-based encryptions of different known plaintexts are inequivalent. On the other hand, we have $\{K_1^s\}_W \cong \{K_2^s\}_W$: encryptions of random keys with a password cannot be distinguished. Finally, in contrast, we have $(\{K_1^s\}_W, \{0\}_{K_1}) \not\cong (\{K_2^s\}_W, \{1\}_{K_2})$: if keys encrypted with a password are used elsewhere, then the two resulting expressions may not be equivalent anymore.

Secure use of passwords, symbolically. Next we identify a set of expressions in which a password is used securely, that is, the password is not subject to a guessing attack. Our definition is in two steps. First we introduce patterns with variables. Then we say that an expression uses passwords securely if its pattern can be obtained from a pattern with variables by instantiating the variables in a certain *appropriate* way.

Let $\text{Var} = \{x_1, x_2, \dots\}$ be a set of variables. The set $\text{Pat}[\text{Var}]$ of patterns with variables from Var is defined by the grammar:

$$\text{Pat}[\text{Var}] ::= \text{Bool} \mid \text{EKeys} \mid \text{DKeys} \mid \text{SKeys} \mid \text{Undec} \mid (\text{Pat}[\text{Var}], \text{Pat}[\text{Var}]) \mid \\ \{\text{Pat}\}_{\text{EKeys}} \mid \{\text{Pat}\}_{\text{SKeys}} \mid \{\text{Var}\}_{\text{Passwd}}$$

Informally, in a pattern with variables, a password may appear only as an encryption key, and only be used for encrypting variables. For example, $(\{x_1\}_W, \{(\{x_2\}_W, 0)\}_K)$ is in $\text{Pat}[\text{Var}]$, but $(W, \{x_1\}_W)$ and $\{W\}_K$ are not. Intuitively, the variables mark places in an expression where we can place concrete subexpressions.

For security, we should ensure that these subexpressions do not offer redundancy that could permit a guessing attack. The subexpressions that we consider benign (in this sense) are ciphertexts and keys that do not themselves appear elsewhere in the pattern. More precisely, an instantiation of a pattern with variables into a pattern is appropriate if variables are mapped to one of the symbols \square^s or \square^a or to (symmetric or asymmetric) encryption keys that do not appear elsewhere in the pattern. For example, the pattern with variables $\{x_1\}_W, \{(\{x_2\}_W, 0)\}_K, K^s$ has occurrences of K^s , so it cannot be instantiated to $\{K^s\}_W, \{(\{\square^s\}_W, 0)\}_K, K^s$. On the other hand, it can be instantiated to $\{\square^a\}_W, \{(\{K^e\}_W, 0)\}_K, K^s$ and to $\{K^e\}_W, \{(\{\square^s\}_W, 0)\}_K, K^s$ via the appropriate instantiations $[x_1 \mapsto \square^a, x_2 \mapsto K^e]$ and $[x_1 \mapsto K^e, x_2 \mapsto \square^s]$. Hence, we define:

Definition 2. Let $p \in \text{Pat}[\text{Var}]$. A mapping $\sigma : \text{Var} \rightarrow \text{Pat}$ is appropriate for p if for all $x \in \text{Var}$ it holds that $\sigma(x) \in \text{SKeys} \cup \text{EKeys} \cup \{\square^s, \square^a\}$ and, if $\sigma(x)$ is a key $K \in \text{SKeys} \cup \text{EKeys}$, then neither K nor K^{-1} occur in p .

Definition 3. An expression $E \in \text{Exp}$ hides passwords symbolically if there exist $p \in \text{Pat}[\text{Var}]$ and a mapping $\sigma : \text{Var} \rightarrow \text{Pat}$ appropriate for p such that $\text{pattern}(E) = p\sigma$.

For example, the expression $\{(\{0, 1\}_K)\}_W, \{(\{K^e\}_W, 0)\}_K, K^s$ hides passwords symbolically: its pattern is $\{\square^a\}_W, \{(\{K^e\}_W, 0)\}_K, K^s$ which, as noted above, can be obtained from a pattern with variables via an appropriate instantiation. On the other hand, neither $\{0\}_W$ nor $\{(K_1^s, K_2^s)\}_W$ hide passwords symbolically. The former is subject to the attack we sketched in the introduction. The same attack may apply to the latter if any kind of fixed delimiters are used to implement pairing. This possibility cannot be ruled out *a priori*, and is in fact quite reasonable, so we chose to consider this expression insecure. Further, $(\{K^s\}_W, \{0\}_K)$ does not hide passwords symbolically either. Although W encrypts the symmetric key K^s (potentially a random string), and therefore the same attack does not seem to apply, the key K^s is also used for encrypting a fixed plaintext, which allows a simple guessing attack: an adversary decrypts the first part with a possible password, then uses the result for decrypting the second part in order to check the password guess. It might appear that the same attack does not apply to

$\{K_1^s\}_W, \{K_2^s\}_{K_1}$, since here the key K_1^s is used for encrypting another symmetric key. We consider this expression insecure because the symmetric encryption scheme may well provide a mechanism for ensuring that decryptions succeed only if the appropriate key is used, as in the case of authenticated encryption (e.g. [3]), thus offering an indirect way to check a password guess.

Our definitions are at the same level of abstraction as those found in the literature on formal analysis of guessing attacks. However, those tend to be, at least superficially, in a somewhat different style. They also model (symmetric and asymmetric) deterministic encryption, while we focus on probabilistic (symmetric and asymmetric) encryption, because this is the standard kind of encryption used in modern cryptography. We expect that a secure expression in the sense defined in this paper is also secure against the symbolic guessing attacks captured by previous work.

4 Computational Security of Encryption Schemes

A password-based encryption scheme II^P is given by a pair of polynomial-time algorithms $(\mathcal{E}^P, \mathcal{D}^P)$ for encryption and decryption, respectively. The scheme is used for encrypting messages in a set $\text{Plaintext}(II^P) \subseteq \{0, 1\}^*$ under passwords from a dictionary $D \subseteq \{0, 1\}^*$. The messages may be chosen according to a probability distribution, part of a distribution ensemble (a parameterized family of distributions). Thus, for generality, we partition the set of plaintexts and the set of passwords according to a security parameter: $\text{Plaintext}(II^P) = \cup_{\eta} \text{Plaintext}(II^P)_{\eta}$ and $D = \cup_{\eta} D_{\eta}$. Furthermore, we require that dictionaries can be sampled efficiently: each dictionary D comes with a probabilistic polynomial-time algorithm that, for security parameter η , returns a sample w from D_{η} ; we write this $w \leftarrow D_{\eta}$. For each η , the encryption function takes as input a password $pwd \in D_{\eta}$ and a plaintext $m \in \text{Plaintext}(II^P)_{\eta}$ and returns an encryption $\mathcal{E}^P(pwd, m)$ of m under pwd . The decryption function \mathcal{D}^P takes as input a password pwd and a ciphertext c and returns the decryption $\mathcal{D}^P(pwd, c)$ of c using pwd . For any security parameter η , any $m \in \text{Plaintext}_{\eta}$, and $pwd \in D_{\eta}$, the equality $m = \mathcal{D}^P(pwd, \mathcal{E}^P(pwd, m))$ must hold.

Before this work, it appears that the security of password-based encryption had not been defined from a computational perspective. We aim to fill this gap. Our definition captures the idea that, given the encryptions of one or more plaintexts under a password, it should be hard to recover the password—and, as suggested in the introduction, our definition does not capture any possible, additional authenticity or secrecy properties. A common assumption is that passwords are selected from a relatively small dictionary that is likely to be known to an adversary; the attack sketched in the introduction indicates that, unless the plaintexts are selected from a distribution with sufficient entropy, there is no hope for the password to be secure. Therefore, in our definition, the plaintexts are chosen according to distributions. Moreover, the distributions are parameterized by a security parameter; we require that it be hard to recover the password asymptotically.

For instance, let us consider a protocol where two parties have exchanged a session key k (for a security parameter η), without authentication, and wish to use a shared password pwd for authenticating k . For this purpose, one party might encrypt a predefined message, say **Ok**, under k , with a symmetric encryption algorithm \mathcal{E}^s , then encrypt it

further under pwd , and transmit the result $\mathcal{E}^p(pwd, \mathcal{E}^s(k, Ok))$. The other party would first decrypt the message that it receives using pwd and then k . It would accept k as valid only if the result of this last decryption is Ok . Ideally, $\mathcal{E}^s(k, Ok)$ should not expose redundancy, so that it can be safely encrypted under pwd . The security of pwd can be guaranteed only for large values of η : for small values, an adversary that sees $\mathcal{E}^p(pwd, \mathcal{E}^s(k, Ok))$ can check a password guess pwd' by decrypting with pwd' and then breaking the inner encryption—a feasible task for small values of η .

The following definition of security uses an adversary A that has access to an encryption oracle $\mathcal{E}^p(pwd, Dist)$. At each query to the oracle, the oracle samples a string d according to distribution $Dist$ and returns $\mathcal{E}^p(pwd, d)$, the encryption of d under pwd . Intuitively, the definition says that A cannot tell which of w_0 and w_1 (two possible values of pwd) is used for creating encryptions of plaintexts selected according to $Dist$.

Definition 4. A dictionary D^0 is a subdictionary of D if $D^0_\eta \subseteq D_\eta$ for all η . A dictionary D^0 is a singleton dictionary if $|D^0_\eta| = 1$ for all η . Let $\Pi^p = (\mathcal{E}^p, \mathcal{D}^p)$ be a password-based encryption scheme. We say that Π^p securely encrypts distribution ensemble $Dist = (Dist_\eta)_\eta$ using passwords from dictionary D , if for any probabilistic polynomial-time adversary A , and any singleton subdictionaries D^0 and D^1 of D ,

$$\text{Adv}_{\Pi, Dist, A}(\eta) \stackrel{\text{def}}{=} \Pr \left[w_0 \leftarrow D^0_\eta, w_1 \leftarrow D^1_\eta : A^{\mathcal{E}^p(w_1, Dist)}(\eta, w_0, w_1) = 1 \right] - \Pr \left[w_0 \leftarrow D^0_\eta, w_1 \leftarrow D^1_\eta : A^{\mathcal{E}^p(w_0, Dist)}(\eta, w_0, w_1) = 1 \right]$$

is negligible (as a function of the security parameter η).

(Recall that a function is negligible if it is smaller than the inverse of any polynomial for all sufficiently large inputs.)

In defining the syntax of password-based encryption, we do not require that the encryption function be randomized. Interestingly, randomization and security appear to be somewhat in conflict for password-based encryption. In order to explain this observation, let us write $\mathcal{E}^p(pwd, m, r)$ for the encryption of m under password pwd with random coins r . Consider an adversary A with access to an encryption oracle as in the definition above, but now with the (reasonable) capability of obtaining several encryptions of the same plaintext using different random coins. When A queries the encryption oracle twice, it obtains ciphertexts $c_0 = \mathcal{E}^p(w_b, m, r_0)$ and $c_1 = \mathcal{E}^p(w_b, m, r_1)$ for some $b \in \{0, 1\}$, some plaintext m , and some fresh random coins r_0 and r_1 . Suppose that $b = 0$, without loss of generality. When A decrypts c_0 and c_1 with w_0 , it obtains m twice. For b to remain secret, it also must be the case that $\mathcal{D}^p(w_1, \mathcal{E}^p(w_0, m, r_0)) = \mathcal{D}^p(w_1, \mathcal{E}^p(w_0, m, r_1))$. In this sense, the use of the random coins is trivial.

In addition to password-based encryption schemes, we rely on symmetric and asymmetric encryption schemes. As usual, a symmetric or asymmetric encryption scheme consists of algorithms $(\mathcal{K}, \mathcal{E}, \mathcal{D})$ for key generation, encryption, and decryption. We require that these satisfy a variant of the standard notion of semantic security [12], called *type-0 security*. This notion was previously introduced for the case of symmetric encryption [1] and extends to the case of asymmetric encryption. We leave precise definitions and constructions for a longer version of this paper.

An *encryption suite* is a triple $\Pi = (\Pi^a, \Pi^s, \Pi^p)$ with an asymmetric encryption scheme Π^a , a symmetric encryption scheme Π^s , and a password-based encryption scheme Π^p . We say that an encryption suite is secure if it provides type-0 secure asymmetric and symmetric encryption schemes, and its password-based encryption scheme securely encrypts keys and ciphertexts:

Definition 5. An encryption suite $\Pi = (\Pi^a, \Pi^s, \Pi^p)$ is secure if $\Pi^a = (\mathcal{K}^a, \mathcal{E}^a, \mathcal{D}^a)$ and $\Pi^s = (\mathcal{K}^s, \mathcal{E}^s, \mathcal{D}^s)$ are type-0 secure encryption schemes and Π^p securely encrypts distribution ensembles *sym key*, *sym ciphertext*, *asym key*, and *asym ciphertext* defined by the algorithms below:

<i>sym key</i> (η)	<i>sym ciphertext</i> (η)	<i>asym key</i> (η)	<i>asym ciphertext</i> (η)
$(k, k) \leftarrow \mathcal{K}^s(\eta)$	$(k, k) \leftarrow \mathcal{K}^s(\eta)$	$(pk, sk) \leftarrow \mathcal{K}^a(\eta)$	$(pk, sk) \leftarrow \mathcal{K}^a(\eta)$
<i>As a sample</i>	<i>As a sample</i>	<i>As a sample</i>	<i>As a sample</i>
<i>return k</i>	<i>return $\mathcal{E}^s(k, \mathbf{0})$</i>	<i>return pk</i>	<i>return $\mathcal{E}^a(pk, \mathbf{0})$</i>

5 A Computational Model for Expressions

In this section we give a computational interpretation to expressions in the form of ensembles of probability distributions, and give computational definitions for expression equivalence and password hiding.

For an encryption suite Π and a dictionary $D = \cup_{\eta} D_{\eta}$, we associate with each expression $M \in \text{Exp}$ a distribution $\llbracket M \rrbracket_{\Pi[\eta], D}$ on strings of bits, and thereby an ensemble $\llbracket M \rrbracket_{\Pi, D}$. The definition is inductive:

- Each key symbol K that occurs in M is mapped to a string $\tau(K)$, via the key generation algorithms of Π^s and Π^a for symmetric and asymmetric keys, respectively, and by selecting at random from D_{η} for passwords.
- The formal bits 0 and 1 are mapped to standard string representations for them.
- The image of a pair (M, N) is obtained by concatenating the images of M and N .
- The image of a formal encryption $\{M\}_K$ is obtained by calculating $\mathcal{E}_{\tau(K)}^{t(K)}(x)$, where x is the image of M and $t(K) \in \{a, s, p\}$ selects the type of encryption.

Definition 6. Two ensembles D^0 and D^1 are indistinguishable ($D^0 \approx D^1$) if for any probabilistic polynomial-time algorithm A ,

$$\text{Adv}_{D^0, D^1, A}^{\text{dist}}(\eta) = \Pr \left[x \leftarrow D_{\eta}^0 : A(x, \eta) = 1 \right] - \Pr \left[x \leftarrow D_{\eta}^1 : A(x, \eta) = 1 \right]$$

is negligible (as a function of the security parameter η).

Definition 7. The expressions $E_0, E_1 \in \text{Exp}$ are computationally equivalent if their associated distribution ensembles are indistinguishable, that is, $\llbracket E_0 \rrbracket_{\Pi, D} \approx \llbracket E_1 \rrbracket_{\Pi, D}$.

Definition 8. Let Π be an arbitrary encryption suite and let D be a dictionary. An expression $E \in \text{Exp}$ hides passwords in D computationally if for all singleton dictionaries D^0 and D^1 , subdictionaries of D , it holds that $\llbracket E \rrbracket_{\Pi, D^0} \approx \llbracket E \rrbracket_{\Pi, D^1}$.

In this definition, intuitively, an adversary is given two singleton dictionaries and a sample from the distribution associated with the expression E . This sample is created by using one of the two singleton dictionaries, and the goal of the adversary is to determine which. The expression hides passwords computationally if the adversary has only a negligible chance of success.

6 Soundness Theorems

Our soundness theorems link the symbolic definitions for expression equivalence and secure use of passwords to their computational counterparts. The theorem on expression equivalence can be regarded as an extension of the main theorem of Abadi and Rogaway [1] to the richer language of expressions of this paper.

Theorem 1 (Soundness for expression equivalence). *Let Π be a secure encryption suite and let D be a dictionary. For any two acyclic expressions $E_0, E_1 \in \text{Exp}$ we have that $E_0 \cong E_1$ implies $\llbracket E_0 \rrbracket_{\Pi, D} \approx \llbracket E_1 \rrbracket_{\Pi, D}$.*

Our main theorem says that, under certain hypotheses, if the use of passwords is secure symbolically, then it is also secure computationally.

Theorem 2 (Soundness of password hiding). *Let Π be a secure encryption suite and let D be a dictionary. For any acyclic expression $E \in \text{Exp}$ if E hides passwords symbolically then E hides passwords in D computationally.*

A question that we do not investigate in this paper is under what conditions the converses of Theorems 1 and 2 hold. However, it seems quite likely that the techniques and the assumptions for proving completeness of symbolic equivalence for the case of symmetric encryption (e.g. [19]) extend to the setting of this paper.

As an example, we show how to apply our results in the case of the influential Encrypted Key Exchange (EKE) protocol [5]. In the language Exp , the flows of the protocol between parties A and B that share a password W are as follows.

1. A generates an asymmetric key pair (K_1^e, K_1^d) and sends $\{K_1^e\}_W$ to B .
2. B decrypts this message using W . Then B generates a symmetric key K_1^s and sends $\{\{K_1^s\}_{K_1}\}_W$ to A .
3. At this point the parties share the key K_1^s , and check if the protocol was executed as expected: A generates a symmetric key K_A^s and sends $\{K_A^s\}_{K_1}$ to B .
4. Upon receiving this message, B obtains K_A^s , generates a new symmetric key K_B^s , and sends $\{(K_A^s, K_B^s)\}_{K_1}$ to A . (In the original protocol, K_A^s and K_B^s are random nonces; for simplicity we model these nonces as random symmetric keys.)
5. A decrypts this message and checks that the first component of the resulting pair is K_A^s . If so, it obtains K_B^s , sends $\{K_B^s\}_{K_1}$ to B , and terminates successfully.
6. Finally, B decrypts this last message, verifies that it contains the key K_B^s it previously sent to A , and if so, it terminates successfully.

A transcript of the execution of the protocol is given by the expression:

$$E = \{K_1^e\}_W, \{\{K_1^s\}_{K_1}\}_W, \{K_A^s\}_{K_1}, \{(K_A^s, K_B^s)\}_{K_1}, \{K_B^s\}_{K_1}$$

Since $pattern(E) = \{K_1^e\}_W, \{\square^a\}_W, \square^s, \square^s, \square^s$ is the instantiation of a pattern in $Pat[Var]$ with an appropriate mapping, by definition, E hides the password symbolically. It follows from Theorem 2 that E also hides the password computationally. Informally, this means that for any probabilistic polynomial-time adversary, the probability that the adversary can determine correctly which of two passwords w_0 and w_1 was used in a given protocol execution is negligible. Once we have Theorem 2, the proof of this fact via the formal definitions is much simpler than a computational proof from scratch.

7 Conclusions

In this paper we investigate the use of password-based encryption schemes in protocols from the perspective of a recent line of research aimed at bridging the gap between the symbolic and computational views of cryptography. We give symbolic and computational interpretations to the elements of a language of formal expressions built using symmetric, asymmetric, and password-based encryption. We then prove that symbolic accounts of expression equivalence and password hiding imply strong, computational formulations of the same properties. We base our results on a new computational security definition for password-based encryption, which may be of independent interest.

Off-line guessing attacks, as typically considered in the literature, are inherently passive: an adversary, with some data about a protocol execution, analyzes the data in an attempt to obtain information about the password in use. Our definitions and theorems focus strictly on the data analysis, and do not consider how the data is obtained. Thus, we neither address nor exclude the possibility that the adversary may play a role in protocol executions, perhaps mounting standard active attacks, and obtaining data from interactions with other participants. For protocols that do not rely on passwords, research on the relations between symbolic and computational models has recently dealt with active attacks (e.g., [2, 20]). In further work, it may be worthwhile to integrate the results of that research with the present analysis of password-based encryption.

On the Cover Time of Random Geometric Graphs

Chen Avin and Gunes Ercal

{avin, ercal}@cs.ucla.edu

Abstract. The cover time of graphs has much relevance to algorithmic applications and has been extensively investigated. Recently, with the advent of ad-hoc and sensor networks, an interesting class of random graphs, namely *random geometric graphs*, has gained new relevance and its properties have been the subject of much study. A random geometric graph $\mathcal{G}(n, r)$ is obtained by placing n points uniformly at random on the unit square and connecting two points iff their Euclidean distance is at most r . The phase transition behavior with respect to the radius r of such graphs has been of special interest. We show that there exists a critical radius r_{opt} such that for any $r \geq r_{\text{opt}}$ $\mathcal{G}(n, r)$ has optimal cover time of $\Theta(n \log n)$ with high probability, and, importantly, $r_{\text{opt}} = \Theta(r_{\text{con}})$ where r_{con} denotes the critical radius guaranteeing asymptotic connectivity. Moreover, since a disconnected graph has infinite cover time, there is a phase transition and the corresponding threshold width is $O(r_{\text{con}})$. We are able to draw our results by giving a tight bound on the electrical resistance of $\mathcal{G}(n, r)$ via the power of certain constructed flows.

1 Introduction

The *cover time* C_G of a graph G is the expected time taken by a simple random walk on G to visit all nodes in G . This property has much relevance to algorithmic applications [1, 2, 3, 4, 5], and methods of bounding the cover time of graphs have been thoroughly investigated [6, 7, 8, 9, 10, 11]. Several bounds on the cover times of particular classes of graphs have been obtained with many positive results [8, 9, 12, 13, 14].

A random geometric graph (RGG) is a graph $\mathcal{G}(n, r)$ resulting from placing n points uniformly at random on the unit square¹ and connecting two points iff their Euclidean distance is at most r . While these graphs have traditionally been studied in relation to subjects such as statistical physics and hypothesis testing [15], random geometric graphs have gained new relevance with the advent of ad-hoc and sensor networks [16, 17] as they are a model of such networks.

¹ We focus on the 2-dimensional, see section 6 for discussion.

Sensor networks have strict energy and memory constraints and in many cases are subject to high dynamics, created by failures, mobility and other factors. Thus, purely deterministic algorithms have disadvantages for such networks as they need to maintain data structures and have expensive recovery mechanism. Recently, questions regarding the random walk properties of such networks have been of interest especially due to the locality, simplicity, low-overhead and robustness to failures of the process [18, 19, 20]. In particular random walk techniques have been proposed for gossiping in random geometric graphs [1], for information collection and query answering [21, 5] and even for routing [22, 23].

In ad-hoc and sensor networks, interference grows with increased communication radius. So, for a desirable property P of random geometric graphs, one wants to find a tight upper bound on the smallest radius r_P , that will guarantee that P holds with high probability. The radius r_P is called *critical radius* if P exhibits a sharp threshold, the difference between the smallest radius for which the property holds with high probability and the radius for which the property holds with very low probability goes to zero as $n \rightarrow \infty$. The critical radius for connectivity, r_{con} , has been of special interest, and it has been shown that if $\pi r^2 \geq \pi r_{\text{con}}^2 = \frac{\log n + \gamma}{n}$ then $\mathcal{G}(n, r)$ is connected with probability going to one as $n \rightarrow +\infty$ iff $\gamma_n \rightarrow +\infty$ [24, 25].

In this paper we study the existence of a critical radius r_{opt} that will guarantee with high probability that $\mathcal{G}(n, r)$ with $r \geq r_{\text{opt}}$ has *optimal cover-time*. That is cover time of $\Theta(n \log n)$ [26], the same order as the complete graph. We show that such a threshold does exist, and, surprisingly, occurs at a radius $r_{\text{opt}} = \Theta(r_{\text{con}})$.

1.1 Discussion of Our Results and Techniques

Our main result can be formalized as follows:

Theorem 1 (Cover Time of RGG). *For $c > 1$, if $r^2 \geq \frac{c8 \log n}{n}$, then w.h.p.² $\mathcal{G}(n, r)$ has cover time $\Theta(n \log n)$. If $r^2 \leq \frac{\log n}{\pi n}$, then $\mathcal{G}(n, r)$ has infinite cover time with positive probability (bounded away from zero).*

The main contribution of this paper is in giving new tight theoretical bounds on the cover time and sharp threshold width associated with cover time for random geometric graphs. Our results improve upon bounds on the cover time obtained through bounding the mixing-time and spectral gap of random geometric graphs [27, 20, 19], as cover time can be bounded by the spectral gap [9]. In particular, the spectral gap method only guarantees optimal cover time of $\mathcal{G}(n, r)$ for $r = \Theta(1)$.

Aside from that, our results also have important implications for applications. Corollaries to our results are that both the *partial cover time* [5], which is the expected time taken by a random walk to visit a constant fraction of the nodes, and the *blanket time* [28], which is the expected time taken by a random walk

² Event \mathcal{E}_n occurs with high probability if probability $P(\mathcal{E}_n)$ is such that $\lim_{n \rightarrow \infty} P(\mathcal{E}_n) = 1$.

to visit all nodes with frequencies according to the stationary distribution, are optimal for random geometric graphs. This demonstrates both the efficiency and quality of random walk approaches and certain token-management schemes for some ad-hoc and sensor networks [29, 1, 5].

In a recent related work Goel *et al.* [30] have proved that any monotonic property of random geometric graphs has a sharp threshold and have bounded the threshold width. While for general graphs optimality of cover time is not a monotonic property (see full version [31]), it follows from our result that optimality of cover time is monotonic for $\mathcal{G}(n, r)$ and has a threshold width of $O(r_{\text{con}})$.

The method that we used to derive our result is by bounding the electrical resistance of $\mathcal{G}(n, r)$, which bounds the cover time by the following result of Chandra *et al.* [8]: for any graph with n nodes and m edges, where R is the the electrical resistance of the graph:

$$mR \leq \text{cover time} \leq O(mR \log n) \tag{1}$$

In turn, we bound the resistance R of $\mathcal{G}(n, r)$ by bounding the power of a unit flow as permitted by Thomson’s Principle which we formalize later. For any pair of points u and v , we construct a flow c in such a manner that the power of the flow satisfies $P(c) = O(\frac{n}{m}) = O(\frac{1}{\delta_{\text{avg}}})$ where δ_{avg} denotes the average degree of a node in $\mathcal{G}(n, r)$. Since $R \leq P(c)$ the above flow together with (1) establish to be sufficient for $\mathcal{G}(n, r)$ to have optimal cover time.

To construct a flow from u to v , we partition the nodes into contour layers based on distance from u and expanding outward until the midpoint between u and v , then from the midpoint line onward contracting towards v in a mirror fashion. The idea of using contour layers that expand with distance from a point is similar to the layering ideas used by Chandra *et al.* [8] for meshes and originally by Doyle and Snell [32] for infinite grids. Layers in our case can be visualized as slices of an isosceles right triangle along the hypotenuse that connects u and v . The flow can thus be thought of as *moving through* consecutive layers, with the total flow on the edges connecting consecutive layers being 1. Just as the variance of a probability function is minimized for the uniform distribution, we minimize the power by allocating flow almost uniformly along the set of edges used between layer l and layer $l + 1$.

The construction of the above flow is based on "nice" properties of random geometric graphs, such as the uniformity of nodes distribution and the regularity of node degree. We formalize this "niceness" using the notion of a *geo-dense* graph: a geometric graph (random or deterministic) with close to uniform node density across the unit square. In *geo-dense* graphs there are no large areas that fail to contain a sufficient number of nodes. To construct the flow we define *bins* as equal size areas that partition the unit square. These bins are used as the building blocks of our layered flow: nodes in neighboring bins are in the same clique, and only edges between neighboring bins contribute to the flow. Finally, We show that *random* geometric graphs are in fact *geo-dense* for radius on the order of $\Theta(r_{\text{con}})$. Note however that *geo-dense* graphs are not necessary dense

graphs in the graph theoretic meaning, i.e have $\Theta(n^2)$ edges. For example RGG are *geo-dense* even with $\Theta(n \log n)$ edges.

1.2 Related Work

There is a vast body of literature on cover times and on geometric graphs, and to attempt to summarize all of the relevant work would not do it justice. We have already mentioned some of the related results previously, however, here we would like to highlight the related literature that has been most influential to our result, namely that of Chandra *et al.* [8] and Doyle and Snell [32].

The work of Doyle and Snell [32] is a seminal work regarding the connection between random walks and electrical resistance. In particular, they proved that while the infinite 2-dimensional grid has infinite resistance, for any $d \geq 3$ the resistance of the d -dimensional grid is bounded from above, and these results were established to be sufficient in re-proving Pólya's beautiful result that a random walk on the infinite 2-dimensional grid is recurrent whereas a random walk on the infinite d -dimensional grid for any $d \geq 3$ is transient. In obtaining this result, essentially thors bounded the power of a unit current flow from the origin out to infinity and found that the power diverges for the 2-dimensional case and converges for every dimension greater than two. The authors used a layering argument, namely partitioning nodes into disjoint contour layers based on their distance from the origin, and the rate of growth of consecutive layers can be seen as the crucial factor yielding the difference between the properties of the different dimensions. Later, Chandra *et al.* [8] proved the tight relation between commute time and resistance, and used that relationship to extend Doyle and Snell's result by bounding the cover time of the *finite* d -dimensional mesh by computing the power and resistance via an expanding contour layers argument. Together with the tight lower bound of Zuckerman [10], they showed that the 2-dimensional torus has cover time of $\Theta(n \log^2 n)$, and for $d \geq 3$ the d -dimensional torus has an optimal cover time of $\Theta(n \log n)$.

While this paper deals with random geometric graphs there are striking similarities between $\mathcal{G}(n, r)$ and a more familiar family of random graphs, the *Bernoulli* graphs $\mathcal{B}(n, p)$ in which each edge is chosen independently with probability p [33]. For example, for critical probability $p_{\text{con}} = \pi r_{\text{con}}^2 = \frac{\log n + \gamma}{n}$, $\mathcal{B}(n, p)$ is connected with probability going to one as $n \rightarrow +\infty$ iff $\gamma_n \rightarrow +\infty$, and both classes of graphs have sharp thresholds for monotone properties [33]. Regarding cover time, Jonasson [12] and Cooper and Frieze [14] gave tight bounds on the cover time and an interesting aspect of our result is that we add another similarity and both classes of graphs have optimal cover time around the same threshold for connectivity. Yet, despite the similarities between $\mathcal{G}(n, r)$ and $\mathcal{B}(n, p)$, *Bernoulli* graphs are not appropriate models for connectivity in wireless networks since edges are introduced independent of the distance between nodes. In wireless networks the event of edges existing between i and j and between j and k is *not* independent of the event of an edge existing between k and i . There are other notable differences between $\mathcal{G}(n, r)$ and $\mathcal{B}(n, p)$ as well. For example, the proof techniques for the above results for $\mathcal{G}(n, r)$ are very different than the

proof techniques for the respective results for $\mathcal{B}(n, p)$. Interestingly, whereas the proof of [14] for optimality of cover time in Bernoulli graphs of $\Theta(\log n)$ average degree depends on the property that Bernoulli graphs do *not* have small cliques (and, in particular that small cycles are sufficiently far apart), in the case of random geometric graphs the existence of many small cliques uniformly distributed over the unit square like bins is essential in our analysis.

Another recent result with a bin-based analysis technique for random geometric graphs is that of Muthukrishnan and Pandurangan [34]. However, as their technique uses large overlapping bins where the overlap is explicitly stated to be essential and there is no direct utilization of cliques.

2 Bounding the Cover Time via Resistance

For a graph $G = (V, E)$ with $|V| = n, |E| = m$, the electrical network $\mathcal{E}(G)$ is obtained by replacing each edge $e \in E$ with a 1 Ohm resistor, and this is the network we analyze when we speak of the resistance properties of G . For $u, v \in V$ let R_{uv} be the *effective resistance* between u and v : the voltage induced between u and v by passing a current flow of one ampere between them. Let R be the electrical resistance of G : the maximum effective resistance between any pair of nodes [32].

Let H_{uv} be the *hitting time*, the expected time for a random walk starting at u to arrive to v for the first time, and let C_{uv} be the *commute time*, the expected time for a random walk starting at u to first arrive at v and then return to u . Chandra *et al.* [8] proved the following equality for the commute time C_{uv} in terms of the effective resistance R_{uv} :

Theorem 2. *For any two vertices u and v in G the commute time $C_{uv} = 2mR_{uv}$*

Using this direct relation between resistance and random walks and Matthews' theorem [6] they introduced the bound of (1) on the cover time for G .

Let H_{\max} be the maximum hitting time over all pairs of nodes in G . Since $H_{uv} \leq C_{uv}$ it follows that $H_{\max} \leq \max_{u,v \in V} C_{uv} = 2mR$. In [5] it has been shown that the partial cover time can be bounded by H_{\max} , so combining:

$$\text{partial cover time} \leq O(mR) \tag{2}$$

Thus, by bounding the resistance R we may obtain tight bounds on the cover time C_G through (1) and on the partial cover time through (2).

A powerful method used to bound resistance is by bounding the power of a current flow in the network. The following definitions and propositions from the literature [8, 32, 35] help to formalize this method.

Definition 1 (Power of a flow). *Given an electrical network (V, E, ρ) , with resistance $\rho(e)$ for each edge e , a flow c from a source u to a sink v is a function from $V \times V$ to \mathbb{R} , having the property that $c(x, y) = 0$ unless $\{x, y\} \in E$, and c is anti-symmetric, i.e., $c(x, y) = -c(y, x)$. The net flow out of a node will be denoted $c(x) = \sum_{y \in V} c(x, y)$ and $c(x) = 0$ if $x \neq u, v$. The flow along an edge e*

is $c(e) = |c(u, v)|$. The power $P(c)$ in a flow is $P(c) = \sum_{e \in E} \rho(e)c^2(e)$. A flow is a current flow if it satisfies Kirchoff's voltage law, i.e., for any directed cycle $x_0, x_1, \dots, x_{k-1}, x_0$, $\sum_{i=0}^{k-1} c(x_i, x_{i+1 \bmod k}) \cdot \rho(x_i, x_{i+1 \bmod k}) = 0$.

Proposition 1. [Thomson Principle [32, 35]] For any electrical network (V, E, ρ) and flow c with only one source u , one sink v , and $c(u) = -c(v) = 1$ (i.e a **unit** flow), we have $R_{uv} \leq P(c)$, with equality when the flow is a current flow.

Finally,

Proposition 2. [Rayleigh's Short/Cut Principle [32]] Resistance is never raised by lowering the resistance on an edge, e.g. by "shorting" two nodes together, and is never lowered by raising the resistance on an edge, e.g. by "cutting" it.

3 The Cover Time and Resistance of Geometric Graphs

Before proving Theorem 1 about *random* geometric graphs we are going to prove a more general Theorem about geometric graphs. A **geometric graph** is a graph $G(n, r) = (V, E)$ with $n = |V|$ such that the nodes of V are embedded into the unit square with the property that $e = (u, v) \in E$ if and only if $d(u, v) \leq r$ (where $d(u, v)$ is the Euclidean distance between points u and v). We say that a geometric graph (either random or deterministic) is **geo-dense** if every square bin of area at least $A = r^2/8$ (in the unit square) has $\Theta(nA) = \Theta(nr^2)$ nodes.

Theorem 3. A geometric graph $G(n, r)$ that is geo-dense and has $r = \Theta(\frac{\log n}{n})$ has optimal cover time of $\Theta(n \log n)$, optimal partial cover time of $\Theta(n)$, and optimal blanket time of $\Theta(n \log n)$.

Let $G(n, r)$ be a geometric graph that is *geo-dense*. We will prove Theorem 3 using the bound on the cover time from Eq. (1) and by bounding the resistance between any two points u, v in $G(n, r)$. Let V be the set of nodes of $G(n, r)$ and $\delta(v)$ denote the degree (i.e number of neighbors) of $v \in V$

Claim 1. $\forall v \in V \delta(v) = \Theta(nr^2)$

Proof. First note that the *geo-dense* property guarantees that if we divide the unit square into square bins of size $\frac{r}{\sqrt{2}} \times \frac{r}{\sqrt{2}}$ each, then the number of nodes in every bin will be $\Theta(nr^2)$. Since, for every bin, the set of nodes in the bin forms a clique, and every node $v \in V$ is in some bin, we have that $\delta(v) = \Omega(nr^2), \forall v \in V$. Similarly, when we divide the area into bins of size $r \times r$ every node may be connected to the nodes of at most nine bins (that is its own bin and the bordering bins), and we have that $\delta(v) = \Theta(nr^2), \forall v \in V$. □

Thus, since we showed that $m = |E| = \Theta(n^2r^2)$, if the resistance R of $G(n, r)$ is $O(\frac{n}{m}) = O(\frac{1}{nr^2})$ then we are done.

Fig. 1. $T(u, v)$ and the flow c between u and v in $G(n, r)$

Theorem 4. *The resistance R_{uv} between $u, v \in V$ is $\Theta(\frac{1}{nr^2} + \frac{\log(d(u, v)/r)}{n^2r^4})$.*

Proof. The proof of the upper bound will be by bounding the power of a unit flow c that we construct between u and v .

Let $T(u, v)$ be an isosceles right triangle such that the line (u, v) is the hypotenuse. It is clear that such a triangle which lies inside the unit square must exist. We divide our flow c into two disjoint flows c_1 and c_2 where c_1 carries a unit flow from u up to the line perpendicular to the midpoint of $d(u, v)$ in increasing layer size, and c_2 forwards the flow in decreasing layer size up to v which is the only sink. By symmetry we can talk only about c_1 since the construction of c_2 mirrors that of c_1 and $P(c) = P(c_1 + c_2) = 2P(c_1)$ since the flows are disjoint. To construct the flow in c_1 we divide the line $(u, \text{midpoint}(u, v))$ into $d(u, v)\sqrt{2}/r$ segments of size $r/\sqrt{8}$, and number them from 0 to $d(u, v)\sqrt{2}/r - 1$ (see Fig 1 (A))³. Let S_l be the largest rectangle of width $r/\sqrt{8}$ included in the intersection of the area perpendicular to the l^{th} segment and $T(u, v)$. S_l will define the l^{th} layer in our flow. Note that the area of S_l is $lr^2/8$ and contains l squares of area $r^2/8$, each of them containing $\Theta(nr^2)$ nodes by the *geo-dense* property.

Let $V_l \subseteq V$ be the set of nodes in layer l . $V_0 = u$, and for $l > 0$ a node v is in layer l if and only if it is located inside S_l . It follows that $|V_l| = \Theta(nr^2l)$. Edges in our flow are only among edges $e = (x, y)$ s.t. $x \in V_l$ and $y \in V_{l+1}$, and all other edges have zero flow. In particular, the set of edges E_l that carries flow from layer l to layer $l + 1$ in c_1 is defined as follows: for the case $l = 0$, E_0 contains all the edges from u to nodes in V_1 , noting that $|E_0| = |V_1| = \Theta(nr^2)$ since $u \cup V_1$ is a clique (i.e the maximum $d(u, x), x \in V_1$ is r). This allows us to make the flow uniform such that each node in V_1 has incoming flow of $1/|V_1|$ and for each edge $e \in E_0$, $c_1(e) = 1/|E_0|$. For $l > 0$ (see again Fig. 1 (A)) we divide S_l into l equal squares A_1, A_2, \dots, A_l each of size $r^2/8$. Let V_A be the set of nodes contained in the area A_i . We then divide S_{l+1} into l equal sized rectangles $B_1, B_2 \dots B_l$ and define V_B similarly, with B_i touching A_i for each i .

³ Assume for simplicity the expression divides nicely, if not, the proof holds by adding one more segment that will end at the midpoint and overlap with the previous segment.

Now let $E_l = \{(x, y) | x \in V_A \text{ and } y \in V_B\}$. Note again that since, for each i , the maximum $d(x, y)$ between nodes in A_i and nodes in B_i is r (see Fig. 1 (B)), $V_A \cup V_B$ is a clique (as the worst case distance occurs between the first two layers). So, the number of edges crossing from A_i to B_i is $|V_A| |V_B| = \Theta(n^2 r^4)$ by *geo-dense* property. The clique construction allows us to easily maintain the uniformity of the flow such that into each node in V_B the total flow is $1/l|V_B|$, and each edge carries a flow of $\Theta(1/n^2 r^4 l) = \Theta(1/E_l)$. All other edges have no flow. Now we compute the power of c :

$$\begin{aligned} R_{uv} &\leq \sum_{e \in c} c(e)^2 = \sum_{e \in c_1} c_1(e)^2 + \sum_{e \in c_2} c_2(e)^2 = \\ &= 2 \sum_{l=0}^{\lfloor \sqrt{2}d(u,v)/r \rfloor} \sum_{e \in E} c_1(e)^2 = 2 \frac{1}{|E_0|} + 2 \sum_{l=1}^{\lfloor \sqrt{2}d(u,v)/r \rfloor} \frac{1}{|E_l|} \\ &= 2O\left(\frac{1}{nr^2}\right) + 2O\left(\frac{1}{n^2 r^4}\right) \sum_{l=1}^{\lfloor \sqrt{2}d(u,v)/r \rfloor} \frac{1}{l} \\ &= O\left(\frac{1}{nr^2} + \frac{\log(d(u,v)/r)}{n^2 r^4}\right) \end{aligned}$$

To prove the lower bound we again follow in the spirit of [32] and use the "Short/Cut" Principle. We partition the graph into $\lfloor d(u,v)/r \rfloor + 1$ partitions by drawing $\lfloor d(u,v)/r \rfloor$ squares perpendicular to the line (u, v) , where the first partition P_0 is only u itself and the l^{th} partition P_l is the area of the l^{th} square excluding the $(l - 1)^{\text{th}}$ square area. The last partition contains all the nodes outside the last square including v (see Fig 2 (A)). We are shorting all vertices in the same partition (see Fig. 2 (B), and following the reasoning of the upper bound, let m_l be the number of edges between partition l and $l + 1$. m_0 is $\Theta(nr^2)$ and for $l > 0$, $m_l = \Theta(n^2 r^4 l)$, so

$$\begin{aligned} R_{uv} &\geq \sum_{l=0}^{\lfloor d(u,v)/r \rfloor} \frac{1}{m_l} \\ &= \Omega\left(\frac{1}{nr^2}\right) + \sum_{l=1}^{\lfloor d(u,v)/r \rfloor} \Omega\left(\frac{1}{n^2 r^4 l}\right) \\ &= \Omega\left(\frac{1}{nr^2} + \frac{\log(d(u,v)/r)}{n^2 r^4}\right) \quad \square \end{aligned}$$

Corollary 1. *The resistance R of $G(n, r)$ is $\Theta\left(\frac{1}{nr^2} + \frac{\log(\sqrt{2}/r)}{n^2 r^4}\right)$.*

This follows directly from the fact that $\max d(u, v) \leq \sqrt{2}$. Now we can prove Theorem 3.

Proof (of Theorem 3). Remember that $m = \Theta(n^2 r^2)$, so all we need is $R = O(n/m) = O(1/nr^2)$ and then the cover time bound will follow by (1), the

Fig. 2. Lower bound for R_{uv} on the $G(n, r)$

partial cover time bound will follow from (2), and the blanket time will follow from [28] and the $\log n$ order difference between the cover time and maximum hitting time. In order to have $R = \Theta(\frac{1}{nr^2})$ we want that $\frac{\log(\sqrt{2}/r)}{n^2r^4} = O(\frac{1}{nr^2})$, which means $\frac{\log(1/r)}{nr^2} \leq \alpha$ for some constant α . Taking $r^2 = \frac{c \log n}{n}$, for a constant β , we get $\frac{\log(n/\beta \log n)}{\beta 2 \log n} = \frac{1}{2\beta} - \frac{\log(\beta \log n)}{2\beta \log n} \leq \frac{1}{2\beta}$. \square

4 Cover Time and Resistance of $\mathcal{G}(n, r)$

After Proving Theorem 3, in order to prove Theorem 1 all we need to show is that for $c > 1$, $r^2 = \frac{c 8 \log n}{n}$ is sufficient to guarantee with high probability that $\mathcal{G}(n, r)$ is *geo-dense*. Note however that the second part of the theorem follows directly from [25] since if $\mathcal{G}(n, r)$ is disconnected with positive probability bounded away from zero when $r^2 \leq \frac{\log n}{\pi n}$, then it has infinite cover time with at least the same probability.

To prove the *geo-dense* property for $\mathcal{G}(n, r)$ we utilize the following lemma which seems to be folklore [28] although we include a proof in the full version since we have not found a reference including a proof of the minimum condition.

Lemma 2 (Balls in Bins). *For a constant $c > 1$, if one throws $n \geq cB \log B$ balls uniformly at random into B bins, then w.h.p both the minimum and the maximum number of balls in any bin is $\Theta(\frac{n}{B})$.*

And, the following lemma easily follows from the Balls in Bins Lemma:

Lemma 3 (Node Density). *For constants $c > 1$ and $a \geq 1$, if $r^2 = \frac{ca \log n}{n}$ then w.h.p any area of size r^2/a in $\mathcal{G}(n, r)$ has $\Theta(c \log n)$ nodes.*

Proof. Let an area of r^2/a be a bin. If we divide the unit square into such equal size bins we have $B = \frac{n}{c \log n}$ bins. For the result to follow we check that Lemma 2 holds by showing that $n \geq c' B \log B$ for some constant $c' > 1$:

$$\begin{aligned}
 B \log B &= \frac{n}{c \log n} \log\left(\frac{n}{c \log n}\right) \\
 &= \frac{n}{c \log n} (\log(n) - \log(c \log n)) \\
 &= \frac{n}{c} - \left(\frac{n}{c \log n}\right) (\log(c \log n)) \\
 &\leq n/c
 \end{aligned}
 \tag*{\square}$$

Now combining the results of Lemmas (2) and (3) we can prove Theorem 1

Proof (of Theorem 1). Clearly from Lemma 3 for $c > 1$, $r^2 = \frac{c8 \log n}{n}$ satisfies the *geo-dense* property w.h.p, and since r^2 is also $\Theta(\frac{\log n}{n})$ the result follows from Theorem 3. □

Corollary 2. *For $c > 1$, if $r^2 \geq \frac{c8 \log n}{n}$, then w.h.p $\mathcal{G}(n, r)$ has optimal partial cover time $\Theta(n)$ and optimal blanket time $\Theta(n \log n)$.*

5 Deterministic Geometric Graphs

As an example of other applications of our results consider the following: for an integer k , let the *k-fuzz* [32] of a graph G be the graph G_k obtained from G by adding an edge xy if x is at most k hops away from y in G . In particular, let $G_1(n)$ denote the 2-dimensional grid of n nodes, and let $G_k(n)$ be the k -fuzz of $G_1(n)$. It is known that the cover time of $G_1(n)$ is $\Theta(n \log^2 n)$. and so we ask what is the minimum k s.t. G_k has an optimal cover time of $\Theta(n \log n)$. Using the results of Theorem 4 and the lower bound method of Zuckerman [10] we can prove the following (see [31]):

Theorem 5. *For any constant k , the cover time of $G_k(n)$ is $\Theta(k^{-2} n \log^2 n)$.*

Corollary 3. *$G_k(n)$ has Cover Time of $\Theta(n \log n)$ if $k = \gamma_n$ and $\lim_{n \rightarrow \infty} \frac{\log n}{\gamma_n^2} \leq c$ for some constant c .*

This means that if each node is neighbor with his $\Omega(\log n)$ closest neighbors, the cover time of the 2-dimensional grid becomes optimal.

6 Conclusions

We have shown that for a two dimensional random geometric graph $\mathcal{G}(n, r)$, if the radius r_{opt} is chosen just on the order of guaranteeing asymptotic connectivity then $\mathcal{G}(n, r)$ has optimal cover time of $\Theta(n \log n)$ for any $r \geq r_{opt}$. We present a similar proof for 1-dimensional random geometric graphs in [31]. We find that the critical radius guaranteeing optimal cover time is $r_{opt} = \Omega(\frac{1}{\sqrt{n}})$ for such graphs, whereas the critical radius guaranteeing asymptotic connectivity is $r_{con} = \frac{\log n}{n}$. So, unlike the 2-dimensional case, we have $r_{opt} = \omega(r_{con})$.

Our proof techniques can be generalized to the d -dimensional random geometric graph $\mathcal{G}^d(n, r)$, yielding that for any given dimension d , $r_{\text{opt}} = \Theta(r_{\text{con}})$ with correspondingly optimal cover time. However, both grow exponentially with d which seems to be a consequence of a separation between average degree and minimum degree for higher dimensions rather than just an artifact of our method. Nevertheless, the case of dimension $d = 2$ is considered to be the hardest one [36]. This can intuitively be seen from the mesh results. The case for $d = 1$ (i.e. the cycle) is easy to analyze. For $d > 2$ the cover time of the d -dimensional mesh is optimal [8], and we can show that for any k the cover time of the k -fuzz is also optimal. On the other hand, as we showed earlier, the cover time of the k -fuzz in 2 dimensions (i.e. $G_k(n)$) for constant k is not optimal making this the most interesting case.

Abstract. Random Intersection Graphs is a new class of random graphs introduced in [5], in which each of n vertices randomly and independently chooses some elements from a universal set, of cardinality m . Each element is chosen with probability p . Two vertices are joined by an edge iff their chosen element sets intersect. Given n, m so that $m = n^\alpha$, for any real α different than one, we establish here, for the first time, tight lower bounds $p_0(n, m)$, on the value of p , as a function of n and m , above which the graph $G_{n,m,p}$ is almost certainly Hamiltonian, i.e. it contains a Hamilton Cycle almost certainly. Our bounds are tight in the sense that when p is asymptotically smaller than $p_0(n, m)$ then $G_{n,m,p}$ almost surely has a vertex of degree less than 2. Our proof involves new, nontrivial, coupling techniques that allow us to circumvent the edge dependencies in the random intersection model. Interestingly, Hamiltonicity appears well below the general thresholds, of [4], at which $G_{n,m,p}$ looks like a usual random graph. Thus our bounds are much stronger than the trivial bounds implied by those thresholds.

Our results strongly support the existence of a threshold for Hamiltonicity in $G_{n,m,p}$.

1 Introduction

E. Marczewski in [8] proved that every graph can be represented by a list of sets where each vertex corresponds to a set and the edges to non-empty intersections of sets. Consider that each vertex chooses randomly the members of its corresponding set from a universal set, each independently of the others. The probability space that is created is the space of random intersection graphs, $G_{n,m,p}$, where n is the number of vertices, m the cardinality of a universal set of elements and p the probability that each vertex chooses each of the elements from the universal set. The random intersection graph model was first introduced by M. Karoński, E. Scheinerman and K. Singer-Cohen in [5]. A rigorous definition of the model of random intersection graphs follows:

* This work has been partially supported by the IST/FET Programme of the European Union under contract number 6FP 001907 (DELIS).

Definition 1. Let n, m be positive integers, $0 \leq p \leq 1$. The random intersection graph $G_{n,m,p}$ is a probability space over the set of graphs on the vertex set $\{1, \dots, n\}$ where each vertex is assigned a random subset from a fixed set of m elements. An edge arises between two vertices when their sets have at least a common element. Each random subset assigned to a vertex is determined by

$$\Pr[\text{vertex } i \text{ chooses element } j] = p$$

with these events mutually independent.

In this work, we find an asymptotically tight lower bound for the probability p of the random intersection graph model $G_{n,m,p}$ so that the graph will be Hamiltonian almost surely. By “almost surely” we mean with probability tending to 1 as $n \rightarrow \infty$.

Definition 2. Consider an undirected graph $G(V, E)$ where V is the set of vertices and E the set of edges. This graph contains a hamiltonian cycle if there is a simple cycle that contains each vertex in V .

The derivation of the lower bound for p is made in two steps. First, we establish a stochastic order relations between the random intersection graph model $G_{n,m,p}$ and the random graph model $G_{n,\hat{p}}$. In particular, we find a function \hat{p} , of the probability p , such that if $G_{n,\hat{p}}$ has an *increasing property*¹, say \mathcal{A} , with probability P , then w.h.p. $G_{n,m,p}$, has the same property, \mathcal{A} , with probability at least P . Then, we calculate the value p , so that no vertex in $G_{n,m,p}$ has degree less than 2, w.h.p.. Finally, because of the stochastic order relation we have established, we conclude that when all degrees in $G_{n,m,p}$ are greater than 2, w.h.p. the graph is Hamiltonian a.s. Note that p will be a function of n, m .

As mentioned in [12], when we study the properties of $G_{n,m,p}$ for large n there are two “parameters” to adjust m, p . When m is very small compared to n , the model is not particularly interesting and when m is exceedingly large (compared to n) the behavior of $G_{n,m,p}$ is essentially the same as the Erdős-Rényi model of random graphs (see [4]). If we take $m = \lfloor n^\alpha \rfloor$, for fixed real $\alpha > 0$, then there is some deviation from the standard models, while allowing for a natural progression from sparse to dense graphs.

The probability for an edge e to arise in $G_{n,m,p}$ is $\Pr[e] = 1 - (1 - p^2)^m$. We will assume $mp^2 \rightarrow 0$ i.e. $\Pr[e] \rightarrow 0$ as $n \rightarrow \infty$ (we have a sparse graph).

1.1 Previous Work

The model of random intersection graphs $G_{n,m,p}$ was first introduced by M. Karoński, E. Scheinerman and K. Singer-Cohen in [5] where they explored the evolution of random intersection graphs by studying the thresholds for the appearance and disappearance of small induced subgraphs. Also, J. A. Fill, E. R.

¹ A graph property A is increasing iff given that A holds for a graph $G(V, E)$ then A holds for any $G(V, E')$: $E' \supseteq E$.

Scheinerman and K. Singer Cohen in [4] proved an equivalence theorem relating the evolution of $G_{n,m,p}$ and $G_{n,p}$, in particular they proved that when $m = n^\alpha$ where $\alpha > 6$, the total variation distance between the graph random variables has limit 0. S. Nikolettseas, C. Raptopoulos and P. Spirakis in [10] studied the existence and the efficient algorithmic construction of close to optimal independent sets in random intersection graphs. No previous work is known to us for the existence of hamiltonian cycles in $G_{n,m,p}$.

There is a vast literature regarding the existence and the discovery of Hamiltonian cycles in random graphs $G_{n,p}$ and random regular graphs $G_{n,r}$ (n nodes with degree r each). The best result, known to us, for the existence of Hamiltonian cycles in random graphs, $G_{n,p}$, first proved by Komlós, Szemerédy in [6] and Korshunov [7], is stated in the following theorem (from [2]).

Theorem 1. (Komlós, Szemerédy, Korshunov) *Let $\omega(n) \rightarrow \infty$, $p = (1/n)(\log n + \log \log n + \omega(n))$. Then, almost every $G_{n,p}$ is Hamiltonian.*

1.2 Our Results and Techniques

The main practical difference between random intersection graphs $G_{n,m,p}$ and the random graphs $G_{n,p}$ is that in the first model, randomness is located on the vertices while in $G_{n,p}$ on the edges. Note, also, that in $G_{n,m,p}$ the existence of an edge affects the probability of existence of its adjacent edges. In this paper, we approximate the set of edges of an instance of $G_{n,m,p}$ with the set of edges of a $G_{n,\hat{p}}$ such that the second set of edges is a subset of the first one. This approximation is achieved by using weak coupling, i.e. we consider a discreet step process that creates, uniformly, an instance of $G_{n,m,p}$ and $G_{n,\hat{p}}$ simultaneously. In each step of this process it is decided which vertices choose a specific element from the universal set of elements. The choice or not of an element by some vertex depends on the degree of this vertex in the instance of $G_{n,p'}$, for a suitable p' , that is created during that step. Each non-isolated vertex is considered to have chosen the corresponding element (coupling). The dependence between the degrees of the vertices of $G_{n,p'}$ is dealt either by using Poisson approximation for the number of non-isolated vertices in $G_{n,p'}$ or by setting the degrees of each vertex independently from the others, which under some conditions (see [9]), satisfied in our case, leads to the creation of an instance of $G_{n,p'}$ in a uniform manner. We finally get a $G_{n,m,p}$ by forming cliques between the vertices that chose the same elements or we get a $G_{n,\hat{p}}$ by taking the union of all the instances of $G_{n,p'}$ that are created in each step.

Having established the stochastic order relation between the random graph models $G_{n,m,p}$ and $G_{n,\hat{p}}$ we show that the moment the vertices of degree less than 2 disappear in $G_{n,m,p}$ is, asymptotically, the moment that the $G_{n,\hat{p}}$ becomes hamiltonian, thus the $G_{n,m,p}$ also becomes hamiltonian. We use Theorem 1 to argue when a random graph $G_{n,p}$ is hamiltonian almost surely. The following theorem is the main result of our paper.

Theorem 9. Let $m = \lfloor n^\alpha \rfloor$, and C_1, C_2 be sufficiently large constants. If

$$\begin{aligned}
 p &\geq C_1 \frac{\log n}{m} && \text{for } 0 < \alpha < 1 && \text{or} \\
 p &\geq C_2 \sqrt{\frac{\log n}{nm}} && \text{for } \alpha > 1
 \end{aligned}$$

then almost all $G_{n,m,p}$ are Hamiltonian. Our bounds are asymptotically tight.

In fact, all our results, conditioned on the Hamiltonicity threshold of $G_{n,p}$, hold with probability at least $1 - n^{-c}$, for some fixed $c > 0$.

2 On the Existence of Degree Less Than 2

If graph G is hamiltonian, then all its vertices must have degree greater than one. In this section we calculate bounds on the probability p for the existence (or not) of vertices with degree less than 2. To prove this, we use the first and second moment methods (see [1]).

Theorem 2. Let $G_{n,m,p}$ be a random intersection graph. When $\alpha > 1$ and $p = C\sqrt{\frac{\log n}{nm}}$, if $C < 1$ then w.h.p. there is at least a vertex with degree less than 2, if $C > 1$ then w.h.p. the vertices with degree less than 2 disappear. When $\alpha \leq 1$ and $p = C\frac{\log n}{m}$, if $1 - \alpha < C < 2 - \alpha$ then w.h.p there is at least a vertex with degree less than 2 and if $C > 2 - \alpha$ vertices with degree less than 2 disappear.

Proof. Let p_0 and p_1 be the probability for a vertex to have degree 0 or 1 respectively and $p_{i,k}^{i,j} = \Pr[\text{deg}(i) = i | \text{deg}(j) = k]$ for $i, j \in \{1, \dots, n\}$, in an instance of $G_{n,m,p}$. Let $X_i, i = 1, \dots, n$ be indicator random variables such that

$$X_i = \begin{cases} 1 & \text{if vertex } i \text{ has degree less than two} \\ 0 & \text{otherwise} \end{cases}$$

It holds that $\Pr[X_i = 1] = (p_0 + p_1)$ where $p_0 = (1 - p + p(1 - p)^{(n-1)})^m$ and $p_1 = nmp^2(1 - \epsilon)(1 - p + p(1 - p)^{(n-2)})^m$ (see full paper [3] for the derivations). Let also $X = \sum_{i=1}^n X_i$. From the Chebyshev inequality it holds

$$\Pr[X = 0] \leq r = \frac{\Delta}{E^2[X]}$$

where the quantity Δ is defined as follows

$$\Delta = \sum_{i \sim j} \Pr[X_i X_j]$$

The symbol $i \sim j$ stands for “for all i, j such that $i \neq j$ ”. Towards calculating Δ first note that

$$\Pr[X_i X_j] = p_0 (p_{0,0}^{i,j} + p_{0,1}^{i,j}) + p_1 (p_{0,1}^{i,j} + p_{1,1}^{i,j})$$

The calculations and asymptotic bounds regarding $p_{k,l}^{i,j}$ can be found in [3]. Finally we get that $\Delta \leq n^2(p_0 + p_1)^2(1 + nmp^2)e^{-mp(1-e^{-\epsilon})+mnp^3}$ and consequently

$$r \leq (1 + nmp^2)e^{-mp(1-e^{-\epsilon})+mnp^3}$$

By linearity of expectation we get

$$\begin{aligned} E[X] &= nE[X_i] = n(p_1 + p_0) \\ &\simeq n(1 + nmp^2)e^{-nmp^2}(1 - \epsilon) \end{aligned}$$

If $nmp^2 = C \log n$ then $E[X] = O(\frac{\log n}{n - \epsilon})$ and $r \leq O(\frac{\log n}{n})$. Taking $C < 1$ we have $E[X] \rightarrow \infty$ and $r \rightarrow 0$ which, by the Second moment method, leads to conclusion that w.h.p. there are vertices of degree less than 2. On the other hand, if $C > 1$ then $E[X] \rightarrow 0$, and by the first moment method, w.h.p. there are no vertices with degree less than 2.

In the case where $\alpha \leq 1$ matters are similar, but now we must have $np \rightarrow \infty$. The derivations of the result can be found in the full version of the paper, [3]. \diamond

3 Weak Coupling

Let $\mathcal{I}(n, m, p)$ be the following process, that creates an instance of $G_{n,m,p}$: There are n vertices and m elements. In step i each vertex chooses element l_i with probability p and independently from the others. Form a clique with the vertices that chose l_i . Repeat the above step for $i = 1, \dots, m$. The union of all cliques is the $G_{n,m,p}$.

We use coupling to establish a stochastic order relation between $G_{n,m,p}$ and $G_{n,\hat{p}}$. Coupling is made by using different processes, but similar to $\mathcal{I}(n, m, p)$. After each step of the processes the result can be interpreted either as a choice of an element from a set of vertices, as in \mathcal{I} , or as the choice of some edges, each independently of the others. In our case we use two processes, the $\mathcal{C}_1(n, m, p)$ and $\mathcal{C}_2(n, m, p)$.

Definition 3. Process $\mathcal{C}_1(n, m, p)$. *The process $\mathcal{C}_1(n, m, p)$ consists of m steps. Choose a value p' from the Normal distribution with mean $\bar{p} = p/(n - 1)$ and variance $\bar{p}\bar{q}/(2N)$ truncated to the unit interval $(0, 1)$, where $\bar{q} = 1 - \bar{p}$ and $N = \binom{n}{2}$. There are n vertices and in step i , vertex j chooses a random integer d_j which is binomially distributed, i.e. as in $B(n - 1, p')$. If in step i , $d_j > 0$ then vertex j is considered to have chosen element l_i .*

Under conditions, which we will analyze in detail, the vector $d = (d_1, \dots, d_n)$, formed in step i , is w.h.p. a degree sequence of a random graph $G_{n,p/(n-1)}$. We choose an instance of $G_{n,p/(n-1)}$ uniformly among those that have degree sequence d . The union of the graphs $G_{n,p/(n-1)}$ that are created in each step is an instance of $G_{n,\hat{p}}$, where $\hat{p} = 1 - (1 - p/(n - 1))^m$ (see subsection 3.1). The

union of cliques between vertices that chose the same elements is an instance of $G_{n,m,p(1-\epsilon)}$, where ϵ is a non-negative constant.

Definition 4. Process $\mathcal{C}_2(n, m, p)$ *The process $\mathcal{C}_2(n, m, p)$ consists of m steps. There are n vertices. In step i : (a) with probability $1 - (1 - p)^{n-1}$, form an instance, H , of $G_{n,p/(n-1)}$ among the n vertices. If $\text{deg}_H(j) > 0$ for vertex j then vertex j is considered to have chosen element l_i . (b) Else, choose uniformly one vertex from the set of vertices. With probability $np(1 - \epsilon)$, where $\epsilon < np$ is a positive real, this vertex chooses element l_i , otherwise it does not.*

Under conditions, which we will see in detail, the choice of the elements from the vertices can be considered independent for each vertex. The union of cliques between vertices that chose the same elements is an instance of $G_{n,m,p(1-\epsilon)}$, where ϵ non-negative constant. The union of the graphs $G_{n,p/(n-1)}$ that are created during $\mathcal{C}_2(n, m, p)$, is an instance of $G_{n,\hat{p}}$, where $\hat{p} = E[1 - (1 - p/(n - 1))^{m^*}]$ and m^* is a random variable following the Binomial distribution $B(n, 1 - (1 - p)^{n-1})$ that indicates the number of $G_{n,p/(n-1)}$ instances that were created during $\mathcal{C}_2(n, m, p)$ (see subsection 3.2).

Corollary 1. *After the execution of either $\mathcal{C}_1(n, m, p)$ or $\mathcal{C}_2(n, m, p)$ the instance of $G_{n,\hat{p}}$ is a subgraph of $G_{n,m,p(1-\epsilon)}$.*

3.1 Analysis of $\mathcal{C}_1(n, m, p)$

We present, here some results from the work of McKay and Wormald in [9] that will be useful to understand $\mathcal{C}_1(n, m, p)$.

Consider a random vector $d \in I_n$, where $I_n = \{0, 1, \dots, n-1\}^n$ and d has components d_1, \dots, d_n . Define $m(d) = \sum_{i=1}^n d_i$ and $E_n = \{d \in I_n \mid m(d) \text{ is even}\}$. We also have $\bar{d} = m(d)/n$, $\lambda = \bar{d}/(n - 1)$ and $\gamma_2 = (n - 1)^{-2} \sum_{i=1}^n (d_i - \bar{d})^2$. We create d according to the following models:

Weighted Even Sum binomial models, \mathcal{E}_p and \mathcal{E}'_p Model \mathcal{E}_p has domain E_n , each component d_i is independently distributed according to binomial distribution, $B(n-1,p)$, with the restriction that $m(d)$ is even. The model \mathcal{E}'_p is constructed from \mathcal{E}_p by weighting each $d \in E_n$ with weight depending on $m(d)$, such that $\frac{1}{2}m$ has distribution $B(N, p)$, where $N = \binom{n}{2}$.

Integrated model \mathcal{I}_p Model \mathcal{I}_p has domain E_n . To generate a vector d in this model we first choose a value p' from the normal distribution with mean p and variance $pq/(2N)$, where $q = 1 - p$, truncated to the unit interval $(0, 1)$. Then we generate a variant of model $\mathcal{E}_{p'}$

Graph model \mathcal{D}_p Model \mathcal{D}_p has domain E_n . A variant d in this model is the degree sequence of a random graph with n vertices and each edge is selected with probability p .

Theorem 3. (McKay-Wormald) *If $\omega(n) \log n/n^2 \leq pq \leq o(n^{-1/2})$ then there is a set-valued function $R_P(n) \subseteq E_n$ and a real function $\delta(n) \rightarrow 0$ such that the following condition is satisfied*

1. For each $d \in R_p(n)$ there is a number δ_d such that $|\delta_d| \leq \delta(n)$ and

$$P_D(d) = P_{\mathcal{E}'}(d) \exp \left\{ \frac{1}{4} - \frac{\gamma_2^2}{4\lambda^2(1-\lambda)^2} + \delta_d \right\}$$

2. In each of the models \mathcal{E}_p and D_p , we have $\Pr[R_p(n)] = 1 - n^{-\omega(n)}$

Theorem 4. (McKay-Wormald) *If $\omega(n) \cdot \log n/n^2 \leq pq \leq o(n^{-1/2})$ then $\gamma_2 = \lambda(1-\lambda)(1+o(1))$ with probability $1 - n^{-\omega(n)}$ for both \mathcal{E}'_p and D_p models.*

Theorem 5. (McKay-Wormald) *If $pqN \rightarrow \infty$ and $y = o((pqN)^{(1/6)})$, then*

$$P_I(d) = P_{\mathcal{E}'}(d) \left(1 + O \left(\frac{1 + |y|^3}{\sqrt{pqN}} \right) \right)$$

uniformly over all $d \in E_n$ such that $|\frac{1}{2}m - pN| \leq y\sqrt{pqN}$

Corollary 2. *If $\omega(n) \log n/n^2 \leq pq \leq o(n^{-1/2})$, where $q = 1 - p$, we can approximate the model D_p by the model I_p . More particularly, for fixed reals $\epsilon > 0$ and ϵ' and sufficiently large n , for the random vector d we have that w.h.p.*

$$Pr_D(d) = Pr_I(d)(1 + \epsilon') \quad \text{where } |\epsilon'| \leq \epsilon$$

Proof. See full version of this paper [3]. ◊

The next theorem shows that $\mathcal{C}_1(n, m, p)$ generates either a $G_{n,m,p(1-\epsilon)}$, with ϵ a non-negative constant, or a $G_{n,\hat{p}}$, under some conditions regarding p .

Theorem 6. *If $\omega(n) \log n/n^2 \leq \bar{p}\bar{q} \leq o(n^{-1/2})$, where $\bar{p} = p/(n-1)$, $\bar{q} = 1 - \bar{p}$ for sufficiently large n , the execution of process $\mathcal{C}_1(n, m, p)$ results in either an instance of a random intersection graph $G_{n,m,p(1-\epsilon)}$, where ϵ is small non-negative number, or an instance of random graph $G_{n,\hat{p}}$ where $\hat{p} = 1 - (1 - p/(n-1))^m$.*

Proof. For $\bar{p} = p/(n-1)$, $\bar{q} = 1 - \bar{p}$ and $N = \binom{n}{2}$, if $\bar{p}\bar{q}N = \omega(n) \log n$, then, by Corollary 2, in step i of the process $\mathcal{C}_1(n, m, p)$ the vector d is w.h.p. the degree sequence of a random graph $G_{n,p/(n-1)}$. We choose one graph uniformly among those that have degree sequence d . Taking the union of all $G_{n,p/(n-1)}$ created in each step, we have a random graph $G_{n,\hat{p}}$ where $\hat{p} = 1 - (1 - p/(n-1))^m$.

After each step of $\mathcal{C}_1(n, m, p)$, an instance of $G_{n,p/(n-1)}$ is created w.h.p. and each non-isolated vertex, in step i is considered to have chosen element l_i . This happens with probability $1 - (1 - p/(n-1))^{n-1}$. By the fact that $(n-1)p/(n-1) = p \rightarrow 0$ and using the binomial expansion of $(1 - p/(n-1))^{(n-1)}$ it holds:

$$\Pr[\text{vertex } i \text{ is non isolated in } G_{n,\bar{p}}] = p(1 - \epsilon)$$

where $0 \leq \epsilon \leq p$. Note that $\epsilon \rightarrow 0$ as $n \rightarrow \infty$, thus given a fixed value for ϵ we can find a sufficiently large n_0 such that $\Pr[\text{vertex } i \text{ is non isolated in } G_{n,\bar{p}}] \geq p(1 - \epsilon)$ when $n \geq n_0$. But this probability is the probability for a vertex to choose element l_i in step i of $\mathcal{C}_1(n, m, p)$. The choice of each element l_i is independent for each vertex because each vertex's degree is set independently from the others' (we used model I_p to create the instance of the degree sequence). ◊

3.2 Analysis of \mathcal{C}_2

The process $\mathcal{C}_2(n, m, p)$ consists of m steps. There are n vertices. In step i : (a) with probability $1 - (1 - p)^{n-1}$, form an instance, H , of $G_{n,p/(n-1)}$ among the n vertices. If $\text{deg}_H(j) > 0$ for vertex j then vertex j is considered to have chosen element l_i . (b) Else, choose uniformly one vertex from the set of vertices. With probability $np(1 - \epsilon)$, where $\epsilon < np$ is a positive real, this vertex chooses element l_i , otherwise it does not.

Someone could object saying that in random intersection graphs each vertex should choose each element independently of the others. In $\mathcal{C}_2(n, m, p)$, this condition is violated, because the event that a vertex has degree greater than zero affects also other vertices' degrees. However, we will show that this dependence is weak for some range of probability p , and its effects weakens as n gets large.

We approximate the distribution of the number of non-isolated vertices in each step of $\mathcal{C}_2(n, m, p)$ by the Poisson distribution. To show that the approximation is precise we use the *Stein-Chen Method* to bound the error in the approximation. The following theorem states the *Stein-Chen Method* (see [11]).

Theorem 7. (*Stein-Chen Method*) Let $X_i, i = 1, \dots, n$ be random indicator variables such that

$$X_i = \begin{cases} 1 & \text{with probability } \lambda_i \\ 0 & \text{with probability } 1 - \lambda_i \end{cases}$$

and $W = \sum_{i=1}^n X_i$. Also, let V_i be any random variable that is distributed as the conditional distribution of $\sum_{j \neq i} X_j$ given that $X_i = 1, i = 1, \dots, n$. That is, for each i, V_i is such that

$$\Pr [V_i = k] = \Pr \left[\sum_{j \neq i} X_j = k \mid X_i = 1 \right], \quad \text{for all } k$$

Setting $\lambda = \sum_{i=1}^n \lambda_i$, for any set A of nonnegative integers we have

$$\left| \Pr [W \in A] - \sum_{i \in A} e^{-\lambda} \lambda^i / i! \right| \leq \min(1, 1/\lambda) \sum_{i=1}^n \lambda_i \cdot E[|W - V_i|]$$

Lemma 1. Let $G_{n,p}$ be a random graph and W be random variable that indicates the number of non-isolated vertices in that graph. If $n^2p \rightarrow 0$ then the distribution of the random variable W can be approximated by a Poisson distribution with mean $\lambda = n(1 - (1 - p)^{n-1})$, more specifically

$$|\Pr [W = i] - e^{-\lambda} \lambda^i / i!| \leq n^2p$$

Proof. Let $G_{n,p}$ be a random graph and X_1, \dots, X_n be indicator random variables such that:

$$X_i = \begin{cases} 1 & \text{if vertex } i \text{ is non-isolated in } G_{n,p} \\ 0 & \text{otherwise} \end{cases}$$

Let $W = \sum_{i=1}^n X_i$, W is a random variable that counts the non-isolated vertices in $G_{n,p}$. We show that W is Poisson distributed with mean $\lambda = n(1 - (1 - p)^{n-1})$.

For the proof we use the *Stein-Chen Method* (Theorem 7). First calculate $E[|V_i - W|]$, V_i is a random variable that counts the non-isolated vertices in $G_{n,p}$ given that vertex i is non-isolated, vertex i is not counted by V_i . To simplify the calculations, we will use coupling.

Coupling. Let $G_{n,p}^1$ and $G_{n,p}^2$ be two random graphs. In G^1 , all edges but these that are adjacent to vertex i , are selected with probability p , independently of each other. Each edge that is selected in G^1 is also selected in G^2 . Then, for the graph G^2 set the degree of vertex i according to binomial distribution, $B(n-1, p)$ but with the restriction that the degree should be greater than zero. In G^1 , the vertex i chooses the same edges as in G^2 , with probability $1 - (1 - p)^{(n-1)}$ otherwise it remains isolated.

W is the number of non-isolated vertices in G^1 while the number of non-isolated vertices in G^2 is $1 + V_i$. If vertex i is non-isolated in G^1 then $W = V_i + 1$, otherwise $V_i \geq W$. We have

$$E[|W - V_i|] = \Pr [deg_{G^1}(i) > 0] + E[V_i - W | deg_{G^1}(i) = 0] \Pr [deg_{G^1}(i) = 0] \tag{1}$$

In the full version of this paper [3] we calculate $E[V_i - W | deg_{G^1}(i) = 0]$ and we get

$$E[V_i - W | deg_{G^1}(i) = 0] \leq \frac{1}{1 - (n - 1)p}$$

We also have that

$$\Pr [deg_{G^1}(i) > 0] = 1 - (1 - p)^{(n-1)} \leq np \tag{2}$$

Finally, by equation 1, $E[|V_i - W|] \leq np + \frac{1}{1-np}$.

From Theorem 7 we get

$$|\Pr [W = i] - e^{-\lambda} \lambda^i / i!| = \min(1, 1/\lambda) \sum_{i=1}^n \lambda_i E[|W - V_i|]$$

Because of equation 2 and the assumption that $n^2p \rightarrow 0$ as $n \rightarrow \infty$, for sufficiently large n , we have that $\min(1, 1/\lambda) = 1$ Thus:

$$\begin{aligned} |\Pr [W = i] - e^{-\lambda} \lambda^i / i!| &\leq n^2p(np + \frac{1}{1-np}) \\ &= n^2p(1 + o(1)) \rightarrow 0 \quad \text{as } n \rightarrow \infty \quad \diamond \end{aligned}$$

It is well known that the binomial distribution, $B(n, p)$, under some range of p , can be approximated by the *Poisson* distribution with mean $\lambda = np$. This is stated in detail by the following lemma.

Lemma 2. *Let Q be a random variable which is binomially distributed, $B(n, p)$. If $np \rightarrow 0$ as $n \rightarrow \infty$ the distribution of the random variable Q can be approximated by a Poisson distribution with mean $\lambda = np$*

$$|\Pr [Q = i] - e^{-\lambda} \lambda^i / i!| \leq np^2$$

Proof. See full version of paper [3]. ◇

From lemmas 1 and 2 we can deduce that the non isolated vertices in a $G_{n,p}$ (under conditions that we study in the following corollary), can be regarded, (with a negligible error) as independent. The following Corollary states it in detail.

Corollary 3. *Let W be the number of non-isolated vertices in an instance of $G_{n,p}$ and Q be a random variable that is binomially distributed, $B(n, 1 - (1 - p)^{(n-1)})$. If $n^2p \rightarrow 0$ as $n \rightarrow \infty$ then for sufficiently large n*

$$|\Pr[W = i] - \Pr[Q = i]| \leq n^2p + n^3p^2(1 - \epsilon) \rightarrow 0$$

where ϵ is a fixed real positive and $i \in \{0, \dots, n\}$.

Proof. See full version of paper [3] ◇

Theorem 8. *If $n^2p \rightarrow 0$ as $n \rightarrow \infty$, for sufficiently large n , the execution of the process $\mathcal{C}_2(n, m, p)$ results in either an instance of a random intersection graph $G_{n,m,p(1-\epsilon)}$, where ϵ is a small number, or an instance of random graph $G_{n,\hat{p}}$ where $\hat{p} = E[1 - (1 - p/(n - 1))^{m^*}]$. m^* is a random variable binomially distributed as in $B(m, 1 - (1 - p)^{n-1})$.*

Proof. The case of $G_{n,\hat{p}}$ is easily shown. In each step of $\mathcal{C}_2(n, m, p)$ an instance of $G_{n,p/(n-1)}$ is created with probability $1 - (1 - p)^{n-1}$. So, after the m -th step of the process the probability of an edge to be created, i.e. \hat{p} , is the probability of the edge to be created during, at least, one step of the process. Let m^* be the number of instances of $G_{n,p/n-1}$ that are created during $\mathcal{C}_2(n, m, p)$ then, conditioning on m^* , we get

$$\begin{aligned} \hat{p} &= \sum_{i=0}^m \Pr[m^* = i] \left(1 - \left(1 - \frac{p}{n-1}\right)^i\right) \\ &= E\left[1 - \left(1 - \frac{p}{n-1}\right)^{m^*}\right] \end{aligned}$$

On the other hand, if an instance of $G_{n,p/(n-1)}$ is created, from Corollary 3, we see that the number of non-isolated vertices in this step tend to be distributed as if each was chosen independently from the others. The probability for a vertex i to be non-isolated, in $G_{n,p/(n-1)}$, is $\Pr[\text{degree}(i) > 0] = 1 - \left(1 - \frac{p}{n-1}\right)^{(n-1)}$ Using the binomial expansion of $(1 - p/n)^n$ and the fact that $p \rightarrow 0$, we get

$$\Pr[\text{degree}(i) > 0] = p(1 - \epsilon) \quad \text{where } 0 \leq \epsilon \leq p$$

For fixed ϵ we can find n_0 such that $\Pr[\text{degree}(i) > 0] \geq p(1 - \epsilon)$ if $n \geq n_0$. The probability for a vertex j to choose element l_i is thus

$$\begin{aligned} \Pr[j \text{ chooses } l_i] &= \frac{1}{n}np(1 - \epsilon)(1 - p)^{(n-1)} + (1 - (1 - p)^{n-1})p(1 - \epsilon) \\ &= p(1 - \epsilon) \end{aligned}$$

Considering the above we indeed form an instance of $G_{n,m,p(1-\epsilon)}$. ◇

4 The Emergence of a Hamiltonian Cycle

In this section, we show that almost every random intersection graph $G_{n,m,p}$ becomes hamiltonian, asymptotically, at the moment that every vertex in the graph acquires degree greater than 1. To prove this we use the stochastic order relations we established in Section 3.

Case $0 < \alpha < 1$. By Theorem 2, if $p = C \frac{\log n}{m}$, for $C > 2 - \alpha$, an instance of $G_{n,m,p}$ has every vertex with degree greater than one w.h.p.. Also, note that for this p , $\frac{p}{n-1}$ satisfies the conditions of $\mathcal{C}_1(n, m, p)$. Thus, using process $\mathcal{C}_1(n, m, p)$, where $p = C' \frac{\log n}{m}$ and $C'(1 - \epsilon) > 2 - \alpha$ we create an instance of $G_{n,m,p(1-\epsilon)}$ and an instance of $G_{n,\hat{p}}$, where $\hat{p} = 1 - [1 - p/(n - 1)]^m$ or

$$\begin{aligned} \hat{p} &= 1 - (1 - p/(n - 1))^m = \frac{mp}{n}(1 - \epsilon') \\ &= (1 - \epsilon')C' \frac{\log n}{n} \end{aligned}$$

where $0 \leq \epsilon' \leq \frac{mp}{n}$. The second equality is derived from the fact that $\frac{mp}{n} \rightarrow 0$ and the binomial expansion of $(1 - p/(n - 1))^m$. Note that $\epsilon' \rightarrow 0$ as $n \rightarrow \infty$. We can fix ϵ' and take sufficiently large n so as $\hat{p} \geq \frac{mp}{n}(1 - \epsilon')$. Substituting p we get $\hat{p} = K \frac{\log n}{n}$, for sufficiently large C' , we get $K > 1$. By Theorem 1 and Corollary 1 the instances of $G_{n,\hat{p}}$ and $G_{n,m,p(1-\epsilon)}$ are almost surely Hamiltonian.

Case $\alpha > 1$. By Theorem 2, if $p = C \sqrt{\frac{\log n}{nm}}$, for $C > 1$ an instance of $G_{n,m,p}$ has every vertex with degree greater than one w.h.p.. We also note that in this case $p/(n - 1)$ satisfies the conditions of $\mathcal{C}_2(n, m, p)$. Thus using the process $\mathcal{C}_2(n, m, p)$ where $p = C' \sqrt{\frac{\log n}{nm}}$ and $C'(1 - \epsilon) > 1$ we can create either $G_{n,m,p(1-\epsilon)}$ or $G_{n,\hat{p}}$, where $\hat{p} = E[1 - (1 - p/(n - 1))^{m^*}]$.

The random variable m^* , indicates the number of instances of $G_{n,p/(n-1)}$ that are created during $\mathcal{C}_2(n, m, p)$. In the full version of paper [3] we find that $\hat{p} = mp^2(1 - \epsilon')$. Substituting p we get $\hat{p} = K \frac{\log n}{n}$, for sufficiently large C' , we get $K > 1$. By Theorem 1 and Corollary 1 the instances of $G_{n,\hat{p}}$ and $G_{n,m,p(1-\epsilon)}$ are almost surely Hamiltonian. In view of Theorem 2 our bounds are asymptotically tight. Thus, we have proved our main result:

Theorem 9. *Let $m = \lfloor n^\alpha \rfloor$, C_1 and C_2 be sufficiently large positive constants. If*

$$\begin{aligned} p &\geq C_1 \frac{\log n}{m} && \text{for } 0 < \alpha < 1 \\ p &\geq C_2 \sqrt{\frac{\log n}{nm}} && \text{for } \alpha > 1 \end{aligned}$$

then almost all $G_{n,m,p}$ is Hamiltonian. Our bounds are asymptotically tight.

Note: The probability of the events that Theorem 9 implies, is at least, that of Theorem 1 multiplied by the probability of the similarity between the models D_p and I_p . This, in fact, gives stronger probability bounds than simple convergence to certainty as n grows.

Optimal Cover Time for a Graph-Based Coupon Collector Process

Nedialko B. Dimitrov* and C. Greg Plaxton**

Abstract. In this paper we study the following covering process defined over an arbitrary directed graph. Each node is initially uncovered and is assigned a random integer rank drawn from a suitable range. The process then proceeds in rounds. In each round, a uniformly random node is selected and its lowest-ranked uncovered outgoing neighbor, if any, is covered. We prove that if each node has in-degree $\Theta(d)$ and out-degree $O(d)$, then with high probability, every node is covered within $O(n + \frac{n \log n}{d})$ rounds, matching a lower bound due to Alon. Alon has also shown that, for a certain class of d -regular expander graphs, the upper bound holds no matter what method is used to choose the uncovered neighbor. In contrast, we show that for arbitrary d -regular graphs, the method used to choose the uncovered neighbor can affect the cover time by more than a constant factor.

1 Introduction

One of the most commonly discussed stochastic processes in computer science is the so-called coupon collector process [7]. In that process, there are n distinct coupons and we proceed in rounds, collecting one uniformly random coupon (with replacement) in each round. Are $O(n)$ rounds sufficient to collect all of the coupons? Put differently, is picking coupons with replacement as efficient, to within a constant factor, as picking them without replacement? No, it is a well-known fact that with high probability the number of rounds required to collect all of the coupons is $\Theta(n \log n)$.

This shortcoming has motivated Adler et al. [1] and Alon [2] to study a similar graph-based covering process. The nodes of the graph nodes represent the coupons and covering a node represents collecting a coupon. In each round, a uniformly random node w is selected. If an uncovered neighbor of w exists, choose one such uncovered neighbor and cover it. We refer to this process as process CC.

Process CC can use a variety of different *covering methods* to decide which uncovered neighbor to cover. If our ultimate goal is to minimize cover time, certainly the most powerful covering method available is an offline method with knowledge of the entire

sequence of node selections and with infinite computing power. We refer to this powerful cover time minimizing version of process CC as process MIN. To achieve our $O(n)$ goal, it is natural to consider $\log n$ -regular graphs since the work of Alon implies process MIN has an expected cover time of $\Omega(n + \frac{n \log n}{d})$ rounds on d -regular graphs [2].

1.1 Logarithmic-Degree Graphs

Another natural version of process CC — in which the covering method chooses a uniformly random uncovered neighbor, if any — was studied by Adler et al. [1] and by Alon [2]. We refer to this version of process CC as process UNI. Alon shows that for logarithmic-degree Ramanujan expander graphs, process UNI completes in $O(n)$ time, matching the lower bound for process MIN.

Adler et al. show that for the hypercube, which has a weak expansion property but is not an expander, process UNI takes $O(n)$ time, also matching the lower bound for process MIN [1]. They also show that for arbitrary logarithmic-degree graphs, process UNI completes in $O(n \log \log n)$ time. Furthermore, Adler et al. present an application of process UNI to load balancing in a hypercubic distributed hash table (DHT).

A process that is intuitively similar to process UNI is one where we initially assign a rank to each node using a uniformly random permutation of the nodes, and the covering method covers the minimum-rank uncovered neighbor, if any. We refer to this permutation-based version of process CC as process P-RANK. In this paper, we show that process P-RANK completes in $O(n)$ time on arbitrary logarithmic-degree graphs.

In fact, we analyze a more general and local version of process CC in which each node initially chooses a uniformly random rank in a suitable range, and the covering method covers the minimum-rank uncovered neighbor of the selected node. (We assume that the nodes are numbered from 1 to n , and that ties in rank are broken in favor of the lower-numbered node.) We refer to this random rank version of process CC as process R-RANK. We show that the more general and local process R-RANK completes in $O(n)$ time on arbitrary logarithmic-degree graphs.

1.2 Results for General Graphs

Alon shows that process MIN on any d -regular graph has expected cover time at least $n - \frac{n}{d} + \frac{n}{d} \ln(\frac{n}{d})$ [2]. Alon also shows that process UNI completes in time $n + (1 + o(1)) \frac{n \ln n}{d}$ for random nearly d -regular graphs. Alon further shows that on any (n, d, λ) -expander graph the expected cover time of process UNI is at most $n + n(\frac{\lambda}{d})^2 (\ln n + 1)$. In particular, this implies that on Ramanujan graphs process UNI completes in $(1 + o(1))n$ time, matching the lower bound for process MIN.

If our goal is to maximize cover time, certainly the most powerful covering method available is an offline adversary with knowledge of the entire sequence of node selections and with infinite computing power. We refer to this powerful cover time maximizing version of process CC as process MAX. Alon notes that the upper bounds for expanders hold even if after every round an adversary “is allowed to shift the uncovered nodes to any place he wishes, keeping their number.” In particular, this shows that on Ramanujan graphs, the cover time for process MAX matches the cover time for process MIN, up to constant factors. In effect, the covering method does not matter for this class of graphs.

Another previously studied variant of process CC favors covering the selected node. In this variant, we check — immediately after selecting a uniformly random node — if the selected node is uncovered. If it is, we cover it and move to the next selection. Only otherwise do we consider the neighbors of the selected node. We refer to the selection-biased variants of processes UNI, P-RANK, and R-RANK as UNI', P-RANK', and R-RANK', respectively.

Adler et al. show that for all d -regular graphs, processes UNI and UNI' finish in $O(n + n(\log n)(\log d)/d)$ time[1]. They also show that for random d -regular graphs only $O(n + \frac{n \log n}{d})$ steps are needed. Furthermore, they exhibit an application of process UNI' to load balancing in DHTs.

All of the results matching Alon's lower bound for process MIN presented prior to this work have used some expansion properties of the underlying graph. In contrast, our proof techniques do not require the underlying graph to have any particular structure. Thus, we show the following general result: for directed graphs, with self-loops but no parallel edges, where each node has in-degree at least δ_{in} and at most Δ_{in} , and out-degree at most Δ_{out} , both process R-RANK and process R-RANK' cover all nodes in $O(n \max(\Delta_{in} \Delta_{out} / \delta_{in}^2, (\log n) / \delta_{in}))$ rounds with high probability. This result matches Alon's lower bound for $\delta_{in} = \Delta_{in} = \Delta_{out} = \Theta(d)$, and is thus optimal under these conditions.

Furthermore, Alon's results for Ramanujan graphs raise the question whether there is any separation between the cover times for process MAX and process MIN. In other words, are there any graphs for which the choice of covering method matters? We define a weakly adversarial process, process A-RANK, that is similar to process P-RANK. In process A-RANK, instead of picking a uniformly random permutation, an adversary is initially allowed to fix the permutation used to assign ranks to the nodes. We then proceed as in process P-RANK. In addition, we define the selection-biased variant of process A-RANK as process A-RANK'. We establish that there exists a logarithmic-degree graph on which process A-RANK and process A-RANK' each take $\omega(n)$ rounds to complete. This implies that in general there is separation between the cover times of process MIN and process MAX. In other words, the covering method does matter. Due to space limitations, the proofs of our $\omega(n)$ lower bounds for processes A-RANK and A-RANK' are omitted from this paper; these proofs may be found in [4].

1.3 Proof Outline

The proof of our theorem is inspired by the delay sequence argument used by Ranade for the analysis of a certain packet routing problem on the butterfly [8] (see also [6]). In a delay sequence argument, we identify certain combinatorial structures that exist whenever the random process lasts for a long time. Then, we show that the probability any of these structures exist is small. This in turn implies an upper bound on the running time of the random process.

There are significant differences between our proof and that of Ranade. For example, in our problem, the connection between the running time and the length of a delay sequence is not clear-cut, while in the butterfly routing problem analyzed by Ranade, the length of the delay sequence is equal to the running time. But let us begin by giving the notion of a delay sequence in our problem.

Consider the node that was covered last, say w_1 . Why wasn't w_1 covered earlier? It was not covered earlier because at the last opportunity to cover w_1 — that is, the last selection in w_1 's neighborhood — we covered some other node, w_2 , instead. In such a case we consider w_1 to be delayed by w_2 . Similarly, w_2 may be delayed by some node w_3 , et cetera, until finally we reach a node w_k that is not delayed, i.e., w_k is covered at the first opportunity. The sequence of nodes w_1, \dots, w_k corresponds to our notion of a delay sequence.

In analyzing process R-RANK, we find it useful to first analyze a much simpler process, process SELECT, in which we repeatedly select a uniformly random node, never covering anything. After establishing several lemmas for the simpler process, we proceed to analyzing process R-RANK. This is the bulk of the proof, and includes a technical lemma to work around the difficulties in linking cover time to delay sequence length. Finally, we reduce process R-RANK' to process R-RANK to show that the same bounds hold.

Due to space limitations, we omit our analysis of process R-RANK' from the present paper. In [4], we analyze process R-RANK' via a reduction from process R-RANK; in addition, we establish the existence of a logarithmic-degree graph on which processes A-RANK and A-RANK' each take $\omega(n)$ rounds to complete, establishing that the covering method does matter.

The rest of this paper is structured as follows. In Section 2, we present a number of useful definitions and lemmas related to standard probability distributions. In Section 3, we analyze process SELECT. In Section 4, we analyze process R-RANK using the results in Section 3.

2 Preliminaries

We use the term ℓ -sequence to refer to a sequence of length ℓ . For any ℓ -sequence σ of elements of a given type, and any element x of the same type, we let $\sigma : x$ denote the $(\ell + 1)$ -sequence obtained by appending element x to σ .

For any nonnegative integer n and probability p , we use the notation $X \sim \text{Bin}(n, p)$ to denote that the random variable X has a binomial distribution with n trials and success probability p . Similarly, we write $X \sim \text{Geo}(p)$ to indicate that the random variable X has a geometric distribution with success probability p , and we write $X \sim \text{NegBin}(r, p)$ to indicate that the random variable X has a negative binomial distribution with r successes and success probability p . Due to space limitations, we include proofs for only two of the lemmas stated in this section. The other lemmas follow from simple arguments involving independence of random variables or tail bounds for the binomial distribution [4].

Lemma 1. *Let p denote an arbitrary probability, let ℓ denote an arbitrary nonnegative integer, and let $X \sim \text{NegBin}(\ell, p)$. For any integer j such that $1 \leq j \leq \ell$, let p_j denote an arbitrary probability such that $p_j \geq p$, let $Y_j \sim \text{Geo}(p_j)$, and let $Y = \sum_{1 \leq j \leq \ell} Y_j$. Then for any nonnegative integer i , $\Pr(X \geq i) \geq \Pr(Y \geq i)$.*

Proof. Note that if $p_j = p$ for all j , then the random variables X and Y have the same distribution. Furthermore, increasing any of the p_j 's can only decrease Y . \square

Lemma 2. For any nonnegative integers r and n , and any probability p , we have $\Pr(X < r) = \Pr(Y > n)$, where $X \sim \text{Bin}(n, p)$ and $Y \sim \text{NegBin}(r, p)$.

Proof. The random variables X and Y can be seen as different views of the same experiment where we successively flip coins with probability of success p . With Y , we ask “How many flips are required for r successes?” With X , we ask “How many successes are in the first n flips?” In this experiment, the event of seeing less than r successes in the first n flips ($X < r$) corresponds to the event that we have to wait more than n flips for the first r successes ($Y > n$). This gives the result. \square

Lemma 3. For any integer $r \geq 2$, $\Pr(X \geq 2E[X]) = \Pr(X \geq 2r/p) \leq \exp(-r/8)$, where $X \sim \text{NegBin}(r, p)$.

Proof. Let $j = \left\lfloor \frac{2r}{p} \right\rfloor - 1$ and let $Y \sim \text{Bin}(j, p)$. By Lemma 2, we know that $\Pr(X \geq \frac{2r}{p}) \leq \Pr(X \geq \left\lfloor \frac{2r}{p} \right\rfloor) = \Pr(X > \left\lfloor \frac{2r}{p} \right\rfloor - 1) = \Pr(Y < r) = \Pr(Y \leq r - 1)$.

$$\begin{aligned} \Pr\left(Y \leq \frac{jp}{2}\right) &= \Pr\left(Y \leq r - (\eta + 1)\frac{p}{2}\right) \\ &= \Pr(Y \leq r - 1) \end{aligned}$$

where $\frac{2r}{p} = \left\lfloor \frac{2r}{p} \right\rfloor + \eta$ and the last equality holds because $0 < (\eta + 1)\frac{p}{2} < 1$.

Recall the Chernoff bounds in the form $\Pr(Y \leq (1 - \lambda)jp) \leq \exp(-\lambda^2 jp/2)$ for $0 < \lambda < 1$ (see [3, 5]).

We apply this bound with $\lambda = \frac{1}{2}$ to get

$$\begin{aligned} \Pr(Y \leq r - 1) &= \Pr(Y \leq jp/2) \\ &\leq \exp(-jp/8) \\ &\leq \exp\left(\frac{-2r + (\eta + 1)p}{8}\right) \\ &\leq \exp(-r/8) \end{aligned}$$

where η is as previously defined and the last inequality holds because $r \geq 2$. \square

Lemma 4. Let p be an arbitrary probability and let X be the sum of n independent Bernoulli variables X_1, \dots, X_n , where X_j has success probability $p_j \geq p$. Then $\Pr(X \leq np/2) \leq \exp(-np/12)$.

Proof. The result follows from Chernoff bounds (see, e.g., [3, 5]). \square

Lemma 5. Suppose we repeatedly throw balls independently and uniformly at random into n bins, and let the random variable X denote the number of throws required for every bin to receive at least n balls. Then X is $O(n^2)$ with high probability, that is, with failure probability that is an arbitrary inverse polynomial in n .

Proof. The result follows from Lemma 4. \square

3 Process SELECT

Throughout the remainder of the paper, we fix an arbitrary directed graph $G = (V, E)$ where $|V| = n > 0$. We say that an event holds “with high probability” if the probability that it fails to occur is upper bounded by an arbitrary inverse polynomial in n . We let δ_{in} , Δ_{in} , and Δ_{out} denote the minimum in-degree, maximum in-degree, and maximum out-degree of any node, respectively. For ease of exposition, we assume throughout the paper that $\delta_{\text{in}} > 0$. The edge set E is allowed to contain loops but not parallel edges. For any node v , we define $\Gamma_{\text{in}}(v)$ as $\{w \mid (w, v) \in E\}$. For any sequence of edges $\sigma = (u_1, v_1), \dots, (u_\ell, v_\ell)$, we define the two sequences of nodes $\text{src}(\sigma) = u_1, \dots, u_\ell$ and $\text{dst}(\sigma) = v_1, \dots, v_\ell$.

In this section, we analyze a simple stochastic process, process SELECT, defined as follows. Initially, we fix a positive integer r and independently assign each node in V a uniformly random integer rank between 1 and r . Process SELECT then proceeds in an infinite number of rounds, indexed from 1. In each round, one node is selected uniformly at random, with replacement. The following definitions are central to our analysis of this process.

A node sequence is said to be *rank-sorted* if the associated sequence of node ranks is nondecreasing.

For any node sequence σ , we inductively define a nonnegative integer $\text{duration}(\sigma)$ and a node sequence $\text{select}(\sigma)$ as follows. If σ is empty, then $\text{duration}(\sigma)$ is 0 and $\text{select}(\sigma)$ is empty. Otherwise, σ is of the form $\tau : v$ for some shorter node sequence τ and node v . Let i denote the least i such that $i > \text{duration}(\tau)$ and the node selected in round i belongs to $\Gamma_{\text{in}}(v)$. Let u denote the node selected in round i . Then we define $\text{duration}(\sigma)$ as i , and $\text{select}(\sigma)$ as $\text{select}(\tau) : u$.

Lemma 6. *For any ℓ -sequence of distinct nodes σ , $\Pr(\sigma \text{ is rank-sorted}) = \binom{\ell+r-1}{\ell} r^{-\ell}$.*

Proof. There are $\binom{\ell+r-1}{\ell}$ ways that ranks can be assigned to the ℓ distinct nodes so that the resulting ℓ -sequence is rank-sorted. The result follows since each such assignment occurs with probability $r^{-\ell}$. □

Lemma 7. *For any ℓ -sequence of nodes $\sigma = v_1, \dots, v_\ell$ and any nonnegative integer i , we have*

$$\Pr(\text{duration}(\sigma) = i) \leq \Pr(X \geq i), \text{ where } X \sim \text{NegBin} \left(\ell, \frac{\delta_{\text{in}}}{n} \right).$$

Proof. We proceed by proving that

$$\Pr(\text{duration}(\sigma) = i) = \Pr \left(\sum_{k=1}^{\ell} Y_k = i \right)$$

where $Y_k \sim \text{Geo} \left(\frac{d_k}{n} \right)$ and d_k denotes the in-degree of v_k . The desired bound then follows by Lemma 1.

We prove the foregoing claim by induction on ℓ . If $\ell = 0$, the claim holds since $\text{duration}(\sigma) = \sum_{k=1}^{\ell} Y_k = 0$.

For $\ell > 0$, we let τ denote the node sequence $v_1, \dots, v_{\ell-1}$ and assume inductively that

$$\Pr(\text{duration}(\tau) = i) = \Pr\left(\sum_{k=1}^{\ell-1} Y_k = i\right).$$

Thus,

$$\begin{aligned} \Pr(\text{duration}(\sigma) = i) &= \sum_{j=0}^{i-1} \Pr(\text{duration}(\tau) = j) \cdot \Pr(\text{duration}(\sigma) - \text{duration}(\tau) \\ &= i - j \mid \text{duration}(\tau) = j) \\ &= \sum_{j=0}^{i-1} \Pr(\text{duration}(\tau) = j) \cdot \Pr(\text{duration}(\sigma) - \text{duration}(\tau) \\ &= i - j) \\ &= \sum_{j=0}^{i-1} \Pr(\text{duration}(\tau) = j) \cdot \Pr(Y_\ell = i - j) \\ &= \sum_{j=0}^{i-1} \Pr\left(\sum_{k=1}^{\ell-1} Y_k = j\right) \cdot \Pr(Y_\ell = i - j) \\ &= \Pr\left(\sum_{k=1}^{\ell-1} Y_k = i\right). \end{aligned}$$

The second equality holds because each selection is independent of previous selections. The third equality holds because the waiting time to obtain a selection in $\Gamma_{\text{in}}(v_\ell)$ is distributed as Y_ℓ . \square

Lemma 8. For any ℓ -sequence of edges σ , $\Pr(\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)) \leq \delta_{\text{in}}^{-\ell}$.

Proof. We proceed by induction on ℓ . For $\ell = 0$, $\Pr(\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)) = 1 = \delta_{\text{in}}^0$ since we have assumed that $\delta_{\text{in}} > 0$.

For $\ell > 0$, σ can be written in the form $\tau : (u, v)$, where we inductively assume that the claim of the lemma holds for τ . Let A denote the event that the first node selected in $\Gamma_{\text{in}}(v)$ after round $\text{duration}(\text{dst}(\tau))$ is u . We have

$$\begin{aligned} \Pr(\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)) &= \Pr(\text{select}(\text{dst}(\tau)) = \text{src}(\tau)) \cdot \Pr(A \mid \text{select}(\text{dst}(\tau)) = \text{src}(\tau)) \\ &= \Pr(\text{select}(\text{dst}(\tau)) = \text{src}(\tau)) \cdot \Pr(A) \\ &\leq \delta_{\text{in}}^{-\ell}. \end{aligned}$$

The second step follows from the independence of the events A and $\text{select}(\text{dst}(\sigma')) = \text{src}(\sigma')$. (These two events are independent since each selection is independent of previous selections.) The third step follows from the induction hypothesis and the observation that $\Pr(A)$ is equal $1/\Gamma_{\text{in}}(v)$, which is at most $1/\delta_{\text{in}}$. \square

Lemma 9. For any ℓ -sequence of edges σ and nonnegative integer i , the events $A =$ “ $\text{dst}(\sigma)$ is rank-sorted”, $B =$ “ $\text{duration}(\text{dst}(\sigma)) = i$ ”, and $C =$ “ $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$ ” are mutually independent.

Proof. Note that event A depends only on the rank assignments, while events B and C depend only on the selections. Thus event A is independent of events B and C . Below we argue that events B and C are independent.

Let $\sigma = (u_1, v_1), \dots, (u_\ell, v_\ell)$ and let σ_j denote the length- j prefix of σ , $0 \leq j \leq \ell$. Define a selection to be j -special, $1 \leq j \leq \ell$, if it is the first selection after round $\text{duration}(\sigma_{j-1})$ in $\Gamma_{\text{in}}(v_j)$. A selection is *special* if it is j -special for some j . Note that event B depends only on the timing of the special events; in particular, B occurs if and only if the ℓ -special selection occurs in round i . Suppose we run process SELECT, but at each step, instead of revealing the selected node, we reveal only whether the selection is special. This information is sufficient to determine the unique i for which B occurs, but does not bias the distribution of $\text{select}(\text{dst}(\sigma))$. Since event C only depends on $\text{select}(\text{dst}(\sigma))$, it is independent of B . \square

Lemma 10. Let σ be an ℓ -sequence of edges so that the nodes of $\text{dst}(\sigma)$ are distinct, let $X \sim \text{NegBin}(\ell, \frac{\delta_{\text{in}}}{n})$, let i be a nonnegative integer, and let events A , B , and C be defined as in the statement of Lemma 9. Then $\Pr(A \cap B \cap C) \leq \binom{\ell+r-1}{\ell} \cdot \Pr(X \geq i) \cdot (r\delta_{\text{in}})^{-\ell}$.

Proof. By Lemma 6, $\Pr(A) \leq \binom{\ell+r-1}{\ell} r^{-\ell}$. By Lemma 7, $\Pr(B) \leq \Pr(X \geq i)$. By Lemma 8, $\Pr(C) \leq \delta_{\text{in}}^{-\ell}$. The claim then follows by Lemma 9. \square

4 Process R-RANK

In the section we analyze an augmented version of process SELECT, referred to as Process R-RANK, in which we maintain a notion of a “covered subset” of the nodes. Initially, all of the nodes are uncovered. Process R-RANK then proceeds in rounds in exactly the same manner as process SELECT, except that in any given round, if one or more outgoing neighbors of the selected node are uncovered, we cover the uncovered outgoing neighbor with minimum rank. (As indicated in Section 1, ties are broken according to some arbitrary numbering of the nodes.)

Note that process R-RANK simply augments process SELECT by also covering nodes; rank assignment and selections are performed in exactly the same manner in the two processes. Thus all of the definitions and lemmas presented in Section 3 are applicable to process R-RANK. The following additional definitions are useful for our analysis of process R-RANK.

The *cover time* of process R-RANK is defined as the number of rounds required to cover all of the nodes.

We inductively define the notion of a *linked* sequence of edges. For ℓ equal to 0 or 1, any ℓ -sequence of edges is linked. For $\ell > 1$, an ℓ -sequence of edges of the form $\sigma : (u, v) : (u', v')$ is linked if the $(\ell - 1)$ -sequence $\sigma : (u, v)$ is linked and (u, v') belongs to E .

For any node v , we define $\text{parent}(v)$ as follows. Let i denote the round in which node v is covered. If i is the first round in which some node in $\Gamma_{\text{in}}(v)$ is selected, then $\text{parent}(v)$ is defined to be nil. Otherwise, $\text{parent}(v)$ is the node covered in the first round prior to round i in which the selected node belongs to $\Gamma_{\text{in}}(v)$.

We inductively define the notion of a *chronological* sequence of nodes as follows. Any ℓ -sequence of nodes with $\ell \leq 1$ is chronological. An ℓ -sequence of nodes of the form $\sigma : v : v'$ is chronological if $\sigma : v$ is chronological and node v is covered before node v' .

We inductively define the notion of an *active* node sequence as follows. The empty node sequence is active. A singleton node sequence consisting of the node v is active if $\text{parent}(v) = \text{nil}$. An ℓ -sequence of nodes of the form $\sigma : v : v'$ is active if $\sigma : v$ is active and $\text{parent}(v') = v$.

We call an ℓ -sequence of edges σ *active* if $\text{dst}(\sigma)$ is active and $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$.

We call an ℓ -sequence of edges σ *i -active* if it is active and either $\ell = i = 0$ or $\ell > 0$, σ is of the form $\sigma : (u, v)$, and v is the node covered in round i .

Lemma 11. *For any nonnegative integer ℓ , there are at most $n\Delta_{\text{out}}^\ell \Delta_{\text{in}}^{\ell-1}$ linked ℓ -sequences of edges.*

Proof. We proceed by induction on ℓ , treating $\ell = 0$ and $\ell = 1$ as the base cases. For $\ell = 0$, the empty sequence is the only linked 0-sequence, and the claim holds since $n/\Delta_{\text{in}} \geq 1$. (Note that Δ_{in} is at most n since we do not allow parallel edges.) For $\ell = 1$, the number of linked 1-sequences is at most $|E| \leq n\Delta_{\text{out}}$.

Now let ℓ be greater than 1 and inductively assume that the number of linked $(\ell - 1)$ -sequences of edges is at most $n\Delta_{\text{out}}^{\ell-1} \Delta_{\text{in}}^{\ell-2}$. Recall that any linked ℓ -sequence of edges is of the form $\sigma : (u, v) : (u', v')$ where the $(\ell - 1)$ -sequence of edges $\sigma : (u, v)$ is linked and (u, v') belongs to E . Observe that for any linked $(\ell - 1)$ -sequence of edges $\sigma : (u, v)$, there are at most Δ_{out} nodes v' such that (u, v') belongs to E , and for each such choice of v' , there are at most Δ_{in} nodes u' such that (u', v') belongs to E . Thus the number of linked ℓ -sequences is at most $\Delta_{\text{out}} \Delta_{\text{in}}$ times the number of linked $(\ell - 1)$ -sequences, and the desired bound follows from the induction hypothesis. \square

Lemma 12. *Suppose we run two instances of process R-RANK in parallel using the same random ranks and the same sequence of random selections, but in the second instance, we allow an arbitrary subset of the covered nodes to be uncovered after each round. Then the cover time of the first instance is at most the cover time of the second instance.*

Proof. By a straightforward induction on the number of rounds, at all times, the set of covered nodes in the first instance contains the set of covered nodes in the second instance. The claim of the lemma follows. \square

Lemma 13. *For any rank assignment, the expected cover time of process R-RANK is $O(n^2)$.*

Proof. It follows from Lemma 5 that the cover time is $O(n^2)$ with high probability since in that time each vertex is selected at least n times, implying that all of its neighbors are covered.

We can then consider a modified version of process R-RANK in which the infinite sequence of rounds is partitioned into epochs of $O(n^2)$ rounds, and where at the end of each epoch, if the nodes are not all covered, all nodes are uncovered before proceeding to the next epoch. Since each epoch covers all the nodes with high probability, the expected cover time of this modified version of process R-RANK is $O(n^2)$. By Lemma 12, for any rank assignment, the expected cover time of process R-RANK is $O(n^2)$. \square

Lemma 14. *Assume that v is the node covered in round i and let u be the node selected in round i . Then there is an i -active edge sequence σ terminating in edge (u, v) and such that $\text{duration}(\text{dst}(\sigma)) = i$.*

Proof. Observe that u belongs to $\Gamma_{\text{in}}(v)$. Furthermore, if $\text{parent}(v) = \text{nil}$, then the singleton node sequence v is active with $\text{duration}(v) = i$. Thus the singleton edge sequence $\sigma = (u, v)$ is i -active with $\text{duration}(\text{dst}(\sigma)) = i$.

We prove the claim by induction on i . For $i = 1$, we have $\text{parent}(v) = \text{nil}$ and so the claim follows by the observations of the previous paragraph.

For $i > 1$, if $\text{parent}(v) = \text{nil}$, the claim once again follows from the foregoing observations. Otherwise, $\text{parent}(v) = v'$ where v' is the node covered in round j with $j < i$. Let u' denote the node selected in round j . Since $j < i$, we can inductively assume that there is a j -active edge sequence, call it τ , terminating in edge (u', v') and such that $\text{duration}(\text{dst}(\tau)) = j$. Since τ is active, the node sequence $\text{dst}(\tau)$ is active and $\text{select}(\text{dst}(\tau)) = \text{src}(\tau)$. Let $\sigma = \tau : (u, v)$. Thus $\text{src}(\sigma) = \text{src}(\tau) : u$ and $\text{dst}(\sigma) = \text{dst}(\tau) : v$. Since $\text{parent}(v) = v'$ and $\text{dst}(\tau)$ is an active node sequence terminating in node v' , $\text{dst}(\sigma)$ is active. Since $\text{duration}(\text{dst}(\tau)) = j$, $\text{select}(\text{dst}(\tau)) = \text{src}(\tau)$, u was selected in round i , and i is the least integer greater than j such that the node selected in round i belongs to $\Gamma_{\text{in}}(v)$, we have $\text{duration}(\text{dst}(\sigma)) = i$ and $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$. Since $\text{dst}(\sigma)$ is active and $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$, σ is active. Since σ is active and v is the node covered in round i , σ is i -active. Thus the edge sequence σ satisfies all of the requirements of the lemma. \square

Lemma 15. *Any active node sequence is rank-sorted, chronological, and consists of distinct nodes.*

Proof. Note that any chronological node sequence consists of distinct nodes. Thus, in what follows, it is sufficient to prove that any active node sequence is rank-sorted and chronological.

We proceed by induction on the length of the sequence. For the base case, note that any node sequence of length 0 or 1 is rank-sorted and chronological. For the induction step, consider an active node sequence σ of the form $\tau : v : v'$. Since σ is active, $\tau : v$ is active and $\text{parent}(v') = v$. Since $\tau : v$ is active, the induction hypothesis implies that it is also rank-sorted and chronological. Since $\text{parent}(v') = v$, $\text{rank}(v) \leq \text{rank}(v')$ and v is covered before v' . Hence σ is rank-sorted and chronological. \square

Lemma 16. *For any nonempty active edge sequence σ , if the last edge in σ is (u, v) , then v is the node covered in round $\text{duration}(\text{dst}(\sigma))$ and node u is selected in the same round.*

Proof. We prove the claim by induction on the length of the active edge sequence σ .

If σ consists of a single edge (u, v) , then by the definition of an active edge sequence, the singleton node sequence $\text{dst}(\sigma)$ is active and $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$. Since $\text{dst}(\sigma)$ is active, $\text{parent}(v) = \text{nil}$, that is, v is the node covered in the first round in which a node in $\Gamma_{\text{in}}(v)$ is selected, which is round $\text{duration}(\text{dst}(\sigma))$. Since $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$, node u is selected in the same round.

Now assume that σ is an active edge sequence of the form $\tau : (u, v)$, where τ is of the form $\tau' : (u', v')$. Since σ is active, the node sequence $\text{dst}(\sigma)$ is active and $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$. It follows that $\text{dst}(\tau)$ is active and $\text{select}(\text{dst}(\tau)) = \text{src}(\tau)$, that is, τ is also active. Since τ is active and shorter than σ , we can inductively assume that v' is the node covered in round $\text{duration}(\text{dst}(\tau))$ and node u' is selected in the same round. Since $\text{dst}(\sigma)$ is active, $\text{parent}(v) = v'$, that is, v is the node covered in the first round after round $\text{duration}(\text{dst}(\tau))$ in which a node in $\Gamma_{\text{in}}(v)$ is selected. Applying the definition of $\text{duration}(\text{dst}(\sigma))$, we conclude that v is the node covered in round $\text{duration}(\text{dst}(\sigma))$. Since $\text{select}(\text{dst}(\sigma)) = \text{src}(\sigma)$, node u is selected in the same round. □

Lemma 17. *If σ is an active sequence of edges, then σ is linked.*

Proof. We proceed by induction on the length of σ . If the length of σ is 0 or 1, then σ is linked by definition.

Now assume that σ is an edge sequence of the form $\tau : (u, v)$, where τ is of the form $\tau' : (u', v')$ and σ is active. Since σ is active, $\text{dst}(\sigma)$ is active. Since $\text{dst}(\sigma)$ is active, $\text{dst}(\tau)$ is also active. Since $\text{dst}(\tau)$ is active and τ is shorter than σ , we can inductively assume that τ is linked. Therefore, in order to establish that σ is linked, it is sufficient to prove that (u', v) is an edge. Since $\text{dst}(\sigma)$ is active, $\text{parent}(v) = v'$. Hence, letting i denote the round in which node v is covered, we find that v' is the node covered in the first round prior to round i in which the selected node belongs to $\Gamma_{\text{in}}(v)$. By Lemma 16, v' is covered in a round in which node u' is selected. Thus u' belongs to $\Gamma_{\text{in}}(v)$, that is, (u', v) is an edge, as required. □

Lemma 18. *If an edge sequence σ is i -active, then $\text{duration}(\text{dst}(\sigma)) = i$.*

Proof. If σ is empty, then the claim holds since $i = 0$ and $\text{duration}(\text{dst}(\sigma)) = 0$. Otherwise, σ is of the form $\tau : (u, v)$, and by the definition of an i -active edge sequence, v is the node covered in round i . By Lemma 16, v is the node covered in round $\text{duration}(\text{dst}(\sigma))$, so $\text{duration}(\text{dst}(\sigma)) = i$. □

Lemma 19. *For any ℓ -sequence of edges σ , and any nonnegative integer i , the probability that σ is i -active is at most $\binom{\ell+r-1}{\ell} \cdot \Pr(X \geq i) \cdot (r\delta_{\text{in}})^{-\ell}$, where $X \sim \text{NegBin}(\ell, \frac{\delta_{\text{in}}}{n})$.*

Proof. If the nodes in $\text{dst}(\sigma)$ are not all distinct, then $\Pr(\sigma \text{ is } i\text{-active}) = 0$ by Lemma 15 and the claimed inequality holds since the right-hand side is nonnegative.

Now assume that $\text{dst}(\sigma)$ consists of distinct nodes, and let events A, B , and C be as defined in the statement of Lemma 9. Below we prove that if σ is i -active, then events A, B , and C all occur. The claimed inequality then follows by Lemma 10.

Assume that σ is i -active. Thus event B occurs by Lemma 18. Furthermore, σ is active, so $\text{dst}(\sigma)$ is active and event C occurs by the definition of an active edge sequence. Since $\text{dst}(\sigma)$ is active, event A occurs by Lemma 15. \square

Lemma 20. *For any nonnegative integers i and ℓ , the probability that some ℓ -sequence of edges is i -active is at most*

$$n\Delta_{\text{out}}^\ell \Delta_{\text{in}}^{\ell-1} \binom{\ell+r-1}{\ell} \frac{\Pr(X \geq i)}{(r\delta_{\text{in}})^\ell}$$

where $X \sim \text{NegBin}(\ell, \frac{\delta_{\text{in}}}{n})$.

Proof. By Lemma 17, if an edge sequence σ is not linked, then $\Pr(\sigma \text{ is } i\text{-active}) = 0$. A union bound then implies that the probability some ℓ -sequence of edges is i -active is at most the number of linked ℓ -sequences of edges multiplied by the maximum probability that any particular ℓ -sequence is i -active. The desired inequality then follows by Lemmas 11 and 19. \square

Lemma 21. *For nonnegative integers i , ℓ , and r such that $i \geq 64n \max(\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}^2, (\ln n)/\delta_{\text{in}})$ and $r \geq \min(\lceil 2e^2\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}} \rceil, \ell)$, we have*

$$\Delta_{\text{out}}^\ell \Delta_{\text{in}}^{\ell-1} \binom{\ell+r-1}{\ell} \frac{\Pr(X \geq i)}{(r\delta_{\text{in}})^\ell} \leq \exp(-i\delta_{\text{in}}/(32n))$$

where $X \sim \text{NegBin}(\ell, \frac{\delta_{\text{in}}}{n})$.

Proof. First, we show that the LHS of the claimed inequality is a nonincreasing function of r .

It is sufficient to prove that the expression $\binom{\ell+r-1}{\ell} r^{-\ell}$ is a nonincreasing function of r . Fix ℓ and let $f(r)$ denote the preceding expression. Note that

$$\begin{aligned} \frac{f(r+1)}{f(r)} &= \frac{r+\ell}{r} \left(\frac{r}{r+1}\right)^\ell \\ &= \left(1 + \frac{\ell}{r}\right) \left(1 + \frac{1}{r}\right)^{-\ell} \\ &\leq 1, \end{aligned}$$

where the last inequality holds since the binomial theorem implies $(1 + \frac{1}{r})^\ell \geq 1 + \frac{\ell}{r}$.

Since we have established that the LHS of the claimed inequality is a nonincreasing function of r , we can assume in what follows that $r = \min(\lceil 2e^2\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}} \rceil, \ell)$.

Let us rewrite the LHS of the claimed inequality as $\lambda \cdot \Pr(X \geq i)$, where

$$\begin{aligned} \lambda &= \Delta_{\text{out}}^\ell \Delta_{\text{in}}^{\ell-1} \binom{\ell+r-1}{\ell} (r\delta_{\text{in}})^{-\ell} \\ &\leq \Delta_{\text{out}}^\ell \Delta_{\text{in}}^\ell \left(\frac{e(\ell+r-1)}{lr\delta_{\text{in}}}\right)^\ell \\ &\leq \left(\frac{e\Delta_{\text{out}}\Delta_{\text{in}}(\ell+r)}{lr\delta_{\text{in}}}\right)^\ell. \end{aligned} \tag{1}$$

We begin by establishing two useful upper bounds on λ , namely, Equations (2) and (4) below.

If $r = \lceil 2e^2 \Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}} \rceil$, then since $r = \min(\lceil 2e^2 \Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}} \rceil, \ell)$, we have $r \leq \ell$. Substituting the value of r into Equation (1), we find that

$$\begin{aligned} \lambda &\leq \left(\frac{e(\ell + r)}{2e^2 \ell} \right)^\ell \\ &\leq \left(\frac{2e\ell}{2e^2 \ell} \right)^\ell \\ &\leq e^{-\ell}. \end{aligned} \tag{2}$$

If $r = \ell$, then Equation (1) implies

$$\lambda \leq \left(\frac{2e \Delta_{\text{out}} \Delta_{\text{in}}}{\ell \delta_{\text{in}}} \right)^\ell. \tag{3}$$

Let $h(\ell)$ denote the natural logarithm of the RHS of Equation (3), that is, $h(\ell) = \ell \ln(2e \Delta_{\text{out}} \Delta_{\text{in}} / (\ell \delta_{\text{in}}))$. Using elementary calculus, it is straightforward to prove that the derivative of $h(\ell)$ with respect to ℓ is positive for $\ell < 2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}$, is 0 when $\ell = 2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}$, and is negative for $\ell > 2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}$. It follows that $h(\ell) \leq h(2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}) = 2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}$. Since \ln is monotonic, the RHS of Equation (3) is also maximized when $\ell = 2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}$. Combining this result with Equation (2), we find that for any r

$$\lambda \leq \exp(2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}). \tag{4}$$

(Note that $\exp(2\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}) \geq 1$ and Equation (2) implies $\lambda \leq 1$ when $r = \lceil 2e^2 \Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}} \rceil$.)

We are now ready to proceed with the proof of the lemma. We consider the two cases $\ell > \lceil i\delta_{\text{in}} / (2n) \rceil$ and $\ell \leq \lceil i\delta_{\text{in}} / (2n) \rceil$ separately.

If $\ell > \lceil i\delta_{\text{in}} / (2n) \rceil$, then $\ell > 2ec \max(\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}, \ln n)$ where $c = 16/e > e$. Thus $\ell > \lceil 2e^2 \Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}} \rceil$ and so $r = \lceil 2e^2 \Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}} \rceil$. It follows from Equation (2) that $\lambda \leq e^{-\ell} \leq \exp(-i\delta_{\text{in}} / (2n)) \leq \exp(-i\delta_{\text{in}} / (64n))$, and hence the claim holds since $\Pr(X \geq i) \leq 1$.

Now assume that $\ell \leq \lceil i\delta_{\text{in}} / (2n) \rceil$. Let $Y \sim \text{NegBin}(\lfloor \frac{i\delta_{\text{in}}}{2n} \rfloor, \frac{\delta_{\text{in}}}{n})$ and $Z \sim \text{NegBin}(\lfloor \frac{i\delta_{\text{in}}}{2n} \rfloor - \ell, \frac{\delta_{\text{in}}}{n})$. By the definition of the negative binomial distribution, $\Pr(Y \geq i) = \Pr(X + Z \geq i)$. And, since Z is nonnegative, $\Pr(X + Z \geq i) \geq \Pr(X \geq i)$. Thus

$$\Pr(X \geq i) \leq \Pr(Y \geq i). \tag{5}$$

Since $E[Y] \leq \frac{i}{2}$ and $\lfloor i\delta_{\text{in}} / (2n) \rfloor \geq \lfloor 32 \max(\Delta_{\text{out}} \Delta_{\text{in}} / \delta_{\text{in}}, \ln n) \rfloor > 2$, Lemma 3 implies $\Pr(Y \geq i) \leq \Pr(Y \geq 2E[Y]) \leq \exp(-\frac{i\delta_{\text{in}}}{16n} + \frac{1}{8})$. The claim follows since

$$\begin{aligned}
 \lambda \cdot \Pr(X \geq i) &\leq \exp\left(\frac{2\Delta_{\text{out}}\Delta_{\text{in}}}{\delta_{\text{in}}}\right) \cdot \Pr(Y \geq i) \\
 &\leq \exp\left(\frac{-i\delta_{\text{in}}}{16n} + \frac{1}{8} + \frac{2\Delta_{\text{out}}\Delta_{\text{in}}}{\delta_{\text{in}}}\right) \\
 &\leq \exp\left(\frac{-i\delta_{\text{in}}}{32n} + \frac{1}{8}\right) \\
 &\leq \exp\left(\frac{-i\delta_{\text{in}}}{64n}\right).
 \end{aligned}$$

(The first step follows from Equations (4) and (5). For the third step and fourth steps, note that the assumption $i \geq 64n \max(\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}^2, (\ln n)/\delta_{\text{in}})$ implies $i\delta_{\text{in}}/(32n) \geq 2\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}$ and $i\delta_{\text{in}}/(64n) \geq 1/8$, respectively.) \square

Lemma 22. *If $r \geq \min(\lceil 2e^2 \Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}} \rceil, n)$, then every active edge sequence is, with high probability, $O(n \max(\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}^2, (\log n)/\delta_{\text{in}}))$ -active.*

Proof. Let c denote an arbitrary positive real greater than or equal to 1, and let i denote the positive integer $\lceil 64cn \max(\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}^2, (\ln n)/\delta_{\text{in}}) \rceil$.

For any nonnegative integer j , let p_j denotes the probability that there is a j -active edge sequence. Any j -active edge sequence σ is active, so the associated node sequence $\text{dst}(\sigma)$ is active. It follows from Lemma 15 that any j -active sequence has length at most n . In other words, $\ell \leq n$ for any j -active ℓ -sequence of edges. Furthermore, if $j > 0$ then the length of a j -active sequence is nonzero. Since any j -active ℓ -sequence of edges satisfies $\ell \leq n$, the condition $r = \min(\lceil 2e^2 \Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}} \rceil, n)$ allows us to apply Lemmas 20 and 21. Applying these two lemmas, together with a union bound, we obtain $p_j \leq n^2 \exp(-j\delta_{\text{in}}/(64n))$ for $j > i$.

Let p denote the probability that there is a j -active edge sequence for some $j \geq i$. By a union bound, $p \leq \sum_{j \geq i} p_j$. Using the upper bound on p_j derived in the preceding paragraph, we find that p is upper bounded by an infinite geometric sum with initial term $n^2 \exp(-i\delta_{\text{in}}/(64n))$ and ratio $\exp(-\delta_{\text{in}}/(64n))$. Thus

$$\begin{aligned}
 p &= O((n^3/\delta_{\text{in}}) \exp(-i\delta_{\text{in}}/(64n))) \\
 &= O(n^3 \exp(-c \max(\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}, \log n))) \\
 &= O(n^{3-c}).
 \end{aligned}$$

By setting c to a sufficiently large positive constant, we can drive p below any desired inverse polynomial threshold. The claim of the lemma follows. \square

Lemma 23. *If $r \geq \min(\lceil 2e^2 \Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}} \rceil, n)$, then the cover time of process R-RANK is, with high probability, $O(n \max(\Delta_{\text{out}}\Delta_{\text{in}}/\delta_{\text{in}}^2, (\log n)/\delta_{\text{in}}))$. The same asymptotic bound holds for the expected cover time.*

Proof. The high probability claim is immediate from Lemmas 14 and 22. The bound on the expected cover time then follows by Lemma 13. \square

Theorem 1. *If both Δ_{in} and Δ_{out} are $O(\delta_{\text{in}})$, then there is an r in $O(\delta_{\text{in}})$ such that the cover time of process R-RANK is $O(n + \frac{n \log n}{\delta_{\text{in}}})$ with high probability. The same asymptotic bound holds for the expected cover time.*

Proof. Immediate from Lemma 23. □

The result of Theorem 1 matches the lower bound proved by Alon for process MIN and is thus optimal [2].

Note that as r tends to infinity, the behavior of process R-RANK converges to that of process P-RANK. Thus, the bounds of Theorem 1 also hold for process P-RANK.

Abstract. Recently, there has been a surge of research activity in the area of *Link Analysis Ranking*, where hyperlink structures are used to determine the relative *authority* of Web pages. One of the seminal works in this area is that of Kleinberg [15], who proposed the HITS algorithm. In this paper, we undertake a theoretical analysis of the properties of the HITS algorithm on a broad class of random graphs. Working within the framework of Borodin et al. [7], we prove that on this class (a) the HITS algorithm is stable with high probability, and (b) the HITS algorithm is similar to the INDEGREE heuristic that assigns to each node weight proportional to the number of incoming links. We demonstrate that our results go through for the case that the expected in-degrees of the graph follow a power-law distribution, a situation observed in the actual Web graph [9]. We also study experimentally the similarity between HITS and INDEGREE, and we investigate the general conditions under which the two algorithms are similar.

1 Introduction

In the past years there has been increasing research interest in the analysis of the Web graph for the purpose of improving the performance of search engines. The seminal works of Kleinberg [15] and Brin and Page [8] introduced the area of *Link Analysis Ranking*, where hyperlink structures are used to rank the results of search queries. Their work was followed by a plethora of modifications, generalizations and improvements (see [7] and references within). As a result, today there exists a wide range of Link Analysis Ranking (LAR) algorithms, many of which are variations of each other.

The multitude of LAR algorithms creates the need for a formal framework for assessing and comparing their properties. Borodin et al., introduced such a theoretical framework in [7]. In this framework an LAR algorithm is defined as a function from a class of graphs of size n to an n -dimensional real vector that assigns an *authority weight* to each node in the graph. The nodes are ranked in decreasing order of their

^{*} Partially supported by the EU under contract 001907 (DELIS) and 33555 (COSIN), and by the Italian MIUR under contract ALGO-NEXT.

weights. Borodin et al. [7] define various properties of LAR algorithms. In this work we focus on *stability* and *similarity*. Stability considers the effect of small changes in the graph to the output of an LAR algorithm. Similarity studies how close the outputs of two algorithms are on the same graph.

Borodin et al. [7] considered the question of stability and similarity over an unrestricted class of graphs. They studied a variety of algorithms, and they proved that no pair of these algorithms is similar, and almost all algorithms are unstable. It appears that the class of all possible graphs is too broad to allow for positive results. This raises naturally the question whether it is possible to prove positive results if we restrict ourselves to a smaller class of graphs. Since the explosion of the Web, various stochastic models have been proposed for the Web graph [4, 5, 16, 3]. The model we consider, which was proposed by Azar et al. [4], is the following: assume that every node i in the graph comes with two parameters a_i and h_i which take values in $[0, 1]$. For some node i , the value h_i can be thought of as the probability of node i to be a good *hub*, while the value a_i is the probability of the node i to be a good *authority*. We then generate an edge from i to j with probability proportional to $h_i a_j$. We will refer to this model as the *product model*, and the corresponding class of graphs as the class of *product graphs*. The product graph model generalizes the traditional random graph model of Erdős and Rényi [13] to include graphs where the *expected* degrees follow specific distributions. This is of particular interest since it is well known [16, 9] that the in-degrees of the nodes in the Web graph follow a power law distribution.

Our contribution. In this paper we study the behavior of the HITS algorithm, proposed by Kleinberg [15], on the class of product graphs. The study of HITS on product graphs was initiated by Azar et al. [4] who showed that under some assumptions the HITS algorithm returns weights that are very close to the authority parameters. We formalize the findings of Azar et al. [4] in the framework of Borodin et al. [7]. We extend the definitions of stability and similarity for classes of random graphs, and we demonstrate the link between stability and similarity. We then prove that, with high probability, under some restrictive assumptions, the HITS algorithm is stable on the class of product graphs, and similar to the INDEGREE heuristic that ranks pages according to their in-degree. This similarity result is the main contribution of the paper. The implication of the result is that on product graphs, with high probability, the HITS algorithm reduces to simple in-degree count. We show that our assumptions are general enough to capture graphs where the expected degrees follow a power law distribution as the one observed on the real Web. We also analyze the correlation between INDEGREE and HITS on a large sample of the Web graph. The experimental analysis reveals that similarity between HITS and INDEGREE can also be observed on the real Web. We conclude with a discussion on the conditions that guarantee similarity of HITS and INDEGREE for the class of all possible graphs.

2 Related Work

Link Analysis Ranking Algorithms: Let P be a collection of n Web pages that need to be ranked. This collection may be the whole Web, or a query dependent subset of the Web. We construct the underlying *hyperlink graph* $G = (P, E)$ by creating a node for

each Web page in the collection, and a directed edge for each hyperlink between two pages. The input to a LAR algorithm is the $n \times n$ adjacency matrix W of the graph G . The output of the algorithm is an n -dimensional *authority weight vector* w , where w_i , the i -th coordinate of w , is the authority weight of node i .

We now describe the two LAR algorithms we consider in this paper: the INDEGREE algorithm, and the HITS algorithm. The INDEGREE algorithm is the simple heuristic that assigns to each node weight equal to the number of incoming links in the graph G . The HITS algorithm was proposed by Kleinberg [15] in the seminal paper that introduced the hubs and authorities paradigm. In this framework, every page can be thought of as having a *hub* and an *authority* weight. Let h and a denote the n -dimensional hub and authority weight vectors. Kleinberg proposed an iterative algorithm, termed HITS, for computing the vectors h and a ; the algorithm is essentially a power method computation of the principle eigenvectors of the matrices WW^T and W^TW respectively. These are the principal *singular vectors* of the matrix W . The HITS algorithm returns the vector a , the right singular vector of matrix W .

Independently from Kleinberg, Brin and Page developed the celebrated PAGERANK algorithm [8], which outputs the stationary distribution of a random walk on the Web graph. The works of Kleinberg [15] and Brin and Page [8] were followed by numerous modifications and extensions (see [7] and references within). Of particular interest is the SALSA algorithm by Lempel and Moran [18], which performs a random walk that alternates between hubs and authorities.

Theoretical study of LAR algorithms: Borodin et al. [7], in the paper that introduced the theoretical framework for the analysis of LAR algorithms, considered various algorithms, including HITS, SALSA, INDEGREE, and variants of HITS defined in their paper. They proved that, on the class of all possible graphs, no pair of algorithms is similar, and only the INDEGREE algorithm is stable. They also defined the notion of *rank stability* and *rank similarity*, where they considered the ordinal rankings induced by the weight vectors. The same results carry over in this case. Their work was extended by Lempel and Moran [19], and Lee and Borodin [17]. The stability of HITS and PAGERANK has also been studied elsewhere [22, 6].

The product graph model: Product graphs (also known as random graphs with given expected degrees) were first considered as a model for the Web graph by Azar et al. [4]. The undirected case, where the $h_i = a_i$ and the edges are undirected, has been studied extensively [20, 10, 11, 12]. The focus of these works is on the case where the parameters follow a power law distribution, as it is the case with most real-life networks.

3 The Theoretical Framework

In this section we review the definitions of Borodin et al. [7], and we extend them for classes of random graphs. Let \mathcal{G}_n denote the set of all possible graphs of size n . The size of a graph is the number of nodes in the graph. Let $\overline{\mathcal{G}}_n \subseteq \mathcal{G}_n$ denote a collection of graphs in \mathcal{G}_n . Following the work of Borodin et al. [7], we define a link analysis algorithm \mathcal{A} as a function $\mathcal{A} : \overline{\mathcal{G}}_n \rightarrow \mathbb{R}^n$ that maps a graph $G \in \overline{\mathcal{G}}_n$ to an n -dimensional real vector. The vector $\mathcal{A}(G)$ is the authority weight vector produced by the algorithm

\mathcal{A} on graph G . The weight vector $\mathcal{A}(G)$ is normalized under some chosen norm L , that is, the algorithm maps the graphs in $\overline{\mathcal{G}}_n$ onto the unit L -sphere. Typically, the weights are normalized under some L_p norm. The L_p norm of a vector \mathbf{w} is defined as $\|\mathbf{w}\|_p = (\sum_{i=1}^n |w_i|^p)^{1/p}$.

Distance measures: In order to compare the behavior of different algorithms, or the behavior of the same algorithm on different graphs, Borodin et al. [7] defined various distance measures between authority weight vectors. The distance functions we consider are defined using the L_q norm. The d_q distance between two weight vectors $\mathbf{w}_1, \mathbf{w}_2$ is defined as follows.

$$d_q(\mathbf{w}_1, \mathbf{w}_2) = \min_{\gamma_1, \gamma_2 \geq 1} \|\gamma_1 \mathbf{w}_1 - \gamma_2 \mathbf{w}_2\|_q$$

The constants γ_1 and γ_2 serve the purpose of alleviating differences due to different normalization factors. When using distance d_q we will assume that the vectors are normalized in the L_q norm. In this paper we consider mainly the d_2 distance measure. We can prove that the $d_2(\mathbf{a}, \mathbf{b}) = \|\mathbf{a} - \mathbf{b}\|$, and thus the d_2 distance is a metric. The proof appears in the full version of the paper.

Similarity: Borodin et al. [7] give the following general definition of similarity for any distance function d and any normalization norm L . In the following we define $M_n(d, L) = \sup_{\|\mathbf{w}_1\|=\|\mathbf{w}_2\|=1} d(\mathbf{w}_1, \mathbf{w}_2)$ to be the maximum distance between any two n -dimensional vectors with unit norm $L = \|\cdot\|$.

Definition 1. Algorithms \mathcal{A}_1 and \mathcal{A}_2 are (L, d) -similar on the class $\overline{\mathcal{G}}_n$ if as $n \rightarrow \infty$

$$\max_{G \in \overline{\mathcal{G}}} d(\mathcal{A}_1(G), \mathcal{A}_2(G)) = o(M_n(d, L))$$

Consider now the case that the class $\overline{\mathcal{G}}_n$ is a class of random graphs, generated according to some random process. That is, we define a probability space $(\overline{\mathcal{G}}_n, \mathcal{P})$, where \mathcal{P} is a probability distribution over the class $\overline{\mathcal{G}}_n$. We extend the definition of similarity on the class $\overline{\mathcal{G}}_n$ as follows.

Definition 2. Algorithms \mathcal{A}_1 and \mathcal{A}_2 are (L, d) -similar with high probability on the class of random graphs $\overline{\mathcal{G}}_n$ if for a graph G drawn from $\overline{\mathcal{G}}_n$, as $n \rightarrow \infty$

$$d(\mathcal{A}_1(G), \mathcal{A}_2(G)) = o(M_n(d, L))$$

with probability $1 - o(1)$.

We note that when we consider (L_q, d_q) -similarity we have that $M_n(d_q, L_q) = \Theta(1)$. Furthermore, if the distance function d is a metric, or a near metric¹, then the transitivity property holds. It is easy to show that if algorithms \mathcal{A}_1 and \mathcal{A}_2 are similar

¹ A near metric [14] is a distance function that is reflexive, and symmetric, and there exists a constant c independent of n , such that for all $k > 0$, and all vectors $\mathbf{u}, \mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_k, \mathbf{v}$, $d(\mathbf{u}, \mathbf{v}) \leq c(d(\mathbf{u}, \mathbf{w}_1) + d(\mathbf{w}_1, \mathbf{w}_2) + \dots + d(\mathbf{w}_k, \mathbf{v}))$.

(with high probability), and algorithms \mathcal{A}_2 and \mathcal{A}_3 are similar (with high probability), then algorithms \mathcal{A}_1 and \mathcal{A}_3 are also similar (with high probability).

Stability: Let $\bar{\mathcal{G}}_n$ be a class of graphs, and let $G = (P, E)$ and $G' = (P, E')$ be two graphs in $\bar{\mathcal{G}}_n$. The *link distance* d_ℓ between graphs G and G' is defined as $d_\ell(G, G') = |(E \cup E') \setminus (E \cap E')|$. That is, $d_\ell(G, G')$ is the minimum number of links that we need to add and/or remove so as to change one graph into the other.

Given a class of graphs $\bar{\mathcal{G}}_n$, let $\mathcal{C}_k(G) = \{G' \in \bar{\mathcal{G}}_n : d_\ell(G, G') \leq k\}$ denote the set of all graphs that have link distance at most k from graph G . Borodin et al. [7] give the following generic definition of stability.

Definition 3. An algorithm \mathcal{A} is (L, d) -stable on the class of graphs $\bar{\mathcal{G}}_n$ if for every fixed positive integer k , we have as $n \rightarrow \infty$

$$\max_{G \in \bar{\mathcal{G}}} \max_{G' \in \mathcal{C}(G)} d(\mathcal{A}(G), \mathcal{A}(G')) = o(M_n(d, L))$$

Given a class of random graphs $\bar{\mathcal{G}}_n$ we define stability with high probability as follows.

Definition 4. An algorithm \mathcal{A} is (L, d) -stable with high probability on the class of random graphs $\bar{\mathcal{G}}_n$ if for every fixed positive integer k , for a graph G drawn from $\bar{\mathcal{G}}_n$ we have as $n \rightarrow \infty$

$$\max_{G' \in \mathcal{C}(G)} d(\mathcal{A}(G), \mathcal{A}(G')) = o(M_n(d, L))$$

with probability $1 - o(1)$.

Stability and Similarity: The following lemma shows the connection between stability and similarity. The lemma is a generalization of a lemma by Borodin et al. [7]. The proof appears in the full version of the paper.

Lemma 1. Let d be a metric or near metric distance function, L a norm, and $\bar{\mathcal{G}}_n$ a class of random graphs. If algorithm \mathcal{A}_1 is (L, d) -stable with high probability on the class $\bar{\mathcal{G}}_n$, and algorithm \mathcal{A}_2 is (L, d) -similar to \mathcal{A}_1 with high probability on the class $\bar{\mathcal{G}}_n$, then \mathcal{A}_2 is (L, d) -stable with high probability on the class $\bar{\mathcal{G}}_n$.

4 Stability and Similarity on the Class of Product Graphs

The class of product graphs $\mathcal{G}_n^p(\mathbf{h}, \mathbf{a})$ (or, for brevity, \mathcal{G}_n^p) is defined with two parameters \mathbf{h} and \mathbf{a} , which are two n -dimensional real vectors, with h_i and a_i taking values in $[0, 1]$. These can be thought of as the *latent* hub and authority vectors. A link is generated from node i to node j with probability $h_i a_j$.

Let $G \in \mathcal{G}_n^p$, and let W be the adjacency matrix of the graph G . The matrix W can be written as $W = \mathbf{h}\mathbf{a}^T + R$, where R is a random matrix, such that

$$R[i, j] = \begin{cases} -h_i a_j & \text{with probability } 1 - h_i a_j \\ 1 - h_i a_j & \text{with probability } h_i a_j \end{cases}$$

We refer to matrix R as the *rounding* matrix, that rounds the entries of M to 0 or 1. We can think of the matrix W as a perturbation of the matrix $M = \mathbf{h}\mathbf{a}^T$ by the rounding matrix R . The matrix M is a rank-one matrix. If we run HITS on the matrix M (assuming a small modification of the algorithm so that it runs on weighted graphs), the algorithm will reconstruct the latent vectors \mathbf{a} and \mathbf{h} , which are the singular vectors of matrix M . Note also that if we run the INDEGREE algorithm on the matrix M (assuming again that we take the weighted in-degrees), the algorithm will also output the latent vector \mathbf{a} . So, on rank-one matrices the two algorithms are identical. The question is how the addition of the rounding matrix R affects the output of the two algorithms. We will show that it has only a small effect, and the two algorithms remain similar.

More formally, let LATENT denote the (imaginary) LAR algorithm which, for any graph G in the class $\mathcal{G}_n^p(\mathbf{h}, \mathbf{a})$, outputs the vector \mathbf{a} . We will show that both HITS and INDEGREE are similar to LATENT with high probability. This implies that the two algorithms are similar with high probability. Furthermore, we will show that it also implies the stability of the HITS algorithm.

4.1 Mathematical Tools

We now introduce some mathematical tools that we will use for the remaining of this section.

Perturbation Theory: Perturbation theory studies how adding a perturbation matrix E to a matrix M affects the eigenvalues and eigenvectors of M . Let G and G' be two graphs, and let W and W' denote the respective adjacency matrices. The matrix W' can be written as $W' = W + E$, where E is a matrix with entries in $\{-1, 0, 1\}$. The entry $E[i, j]$ is 1 if we add a link from i to j , and -1 if we remove a link from i to j . Therefore, we can think of the matrix W' as a perturbation of the matrix W by a matrix E . Note that if we assume that only a constant number of links is added and removed, then both the Frobenius and the L_2 norms of E are bounded by a constant.

We now introduce an important lemma that we will use in the following. The proof of the lemma appears in the full version of the paper.

Lemma 2. *Let W be a matrix, and let $W + E$ be a perturbation of the matrix. Let \mathbf{u} and \mathbf{v} denote the left and right principal singular vectors of the matrix W , and \mathbf{u}' and \mathbf{v}' the principal singular vectors of the perturbed matrix. Let σ_1, σ_2 denote the first and second singular values of the matrix W . If $\sigma_1 - \sigma_2 = \omega(\|E\|_2)$, then $\|\mathbf{u}' - \mathbf{u}\|_2 = o(1)$ and $\|\mathbf{v}' - \mathbf{v}\|_2 = o(1)$.*

Norms of random matrices: We also make use of the following theorem for concentration bounds on the L_2 norm of random symmetric matrices. We state the theorem as it appears in [1].

Theorem 1. *Given an $m \times n$ matrix A and any $\epsilon > 0$, let \hat{A} be any random matrix such that for all i, j : $E[\hat{A}_{ij}] = A_{ij}$, $Var(\hat{A}_{ij}) \leq \sigma^2$, and $|\hat{A}_{ij} - A_{ij}| \leq K$, where*

$$K = \left(\frac{4\epsilon}{4 + 3\epsilon} \right)^3 \frac{\sigma\sqrt{m+n}}{\log^3(m+n)}$$

For any $\alpha > 0$, and $m + n \geq 20$, with probability at least $1 - (m + n)^{-\alpha^2}$,

$$\|\widehat{A} - A\|_2 < (2 + \alpha + \epsilon)\sigma\sqrt{m + n}$$

Chernoff bounds: We will make use of standard Chernoff bounds. The following theorem can be found in the textbook of Motwani and Raghavan [21].

Theorem 2. *Let X_1, X_2, \dots, X_n be independent Poisson trials such that, for $1 \leq i \leq n$, $\Pr[X_i = 1] = p_i$, where $0 \leq p_i \leq 1$. Let $X = \sum_{i=1}^n X_i, \mu = E[X] = \sum_{i=1}^n p_i$. Then, for $0 < \delta \leq 1$, we have that*

$$\Pr[X < (1 - \delta)\mu] < \exp(-\mu\delta^2/2) \tag{1}$$

$$\Pr[X > (1 + \delta)\mu] < \exp(-\mu\delta^2/4) \tag{2}$$

4.2 Conditions for the Stability of HITS

We first provide general conditions for the stability of the HITS algorithm. Let \mathcal{G}_n^σ denote the class of graphs with adjacency matrix W that satisfies $\sigma_1(W) - \sigma_2(W) = \omega(1)$. The proof of the following theorem follows directly from Lemma 2, and the fact that the perturbation matrix E has L_2 norm bounded by a constant.

Theorem 3. *The HITS algorithm is (L_2, d_2) -stable on the class of graphs \mathcal{G}_n^σ .*

Theorem 3 provides a sufficient condition for the stability of HITS on general graphs and it will be useful when considering stability on the class of product graphs. The class \mathcal{G}_n^σ is actually a subset of the class defined by the result of Ng et al. [22]. Translating their result in the framework of Borodin et al. [7], they prove that the HITS algorithm is stable on the class of graphs with $\sigma_1(W)^2 - \sigma_2(W)^2 = \omega(\sqrt{d})$, where d is the maximum out-degree.

4.3 Similarity of HITS and LATENT

We now turn our attention to product graphs, and we prove that HITS and LATENT are similar on this class. A result of similar spirit is shown in the work of Azar et al. [4]. We make the following assumption for the vectors \mathbf{a} and \mathbf{h} .

Assumption 1. *For the class $\mathcal{G}_n^p(\mathbf{h}, \mathbf{a})$, the latent vectors \mathbf{a} and \mathbf{h} satisfy $\|\mathbf{a}\|_2\|\mathbf{h}\|_2 = \omega(\sqrt{n})$.*

As we show below, Assumption 1 places a direct lower bound on the principal singular value of the matrix $M = \mathbf{h}\mathbf{a}^T$. Also, let $A = \sum_{i=1}^n a_i$, denote the sum of the authority values, and let $H = \sum_{j=1}^n h_j$ the sum of the hub values. Since the values are positive, we have $A = \|\mathbf{a}\|_1$ and $H = \|\mathbf{h}\|_1$. The product HA is equal to expected number of edges in the graph. We have that $HA \geq \|\mathbf{a}\|_2\|\mathbf{h}\|_2$, thus, from Assumption 1, $HA = \omega(\sqrt{n})$. This implies that the graph is not too sparse.

Lemma 3. *The algorithms HITS and LATENT are (L_2, d_2) -similar with high probability on the class \mathcal{G}_n^p , subject to Assumption 1.*

Proof. The singular vectors of the matrix M are the L_2 unit vectors $\mathbf{a}_2 = \mathbf{a}/\|\mathbf{a}\|_2$ and $\mathbf{h}_2 = \mathbf{h}/\|\mathbf{h}\|_2$. The matrix M can be expressed as $M = \mathbf{h}_2^T \|\mathbf{h}\|_2 \|\mathbf{a}\|_2 \mathbf{a}_2$. Therefore, the principal singular value of M is $\sigma_1 = \|\mathbf{h}\|_2 \|\mathbf{a}\|_2 = \omega(\sqrt{n})$. Since M is rank-one, $\sigma_i = 0$, for all $i = 2, 3, \dots, n$. Therefore, for matrix M we have that $\sigma_1 - \sigma_2 = \omega(\sqrt{n})$.

Matrix R is a random matrix, where each entry is a independent random variable with mean 0, and maximum value and variance bounded by 1. Using Theorem 1, we observe that $K = 1$, and $\sigma = 1$. Setting $\epsilon = 1$ and $\alpha = 1$, we get that $Pr[\|R\|_2 \leq 8\sqrt{n}] \geq 1 - o(1/n)$, thus $\|R\|_2 = O(\sqrt{n})$ with high probability.

Therefore, we have that $\sigma_1 - \sigma_2 = \omega(\|R\|_2)$ with probability $1 - o(1)$. If \mathbf{w}_2 is the right singular vector of matrix W normalized in the L_2 norm, then, using Lemma 2, we have that $\|\mathbf{w}_2 - \mathbf{a}_2\|_2 = o(1)$ with probability $1 - o(1)$. \square

Assumption 1 guarantees also the stability of HITS on \mathcal{G}_n^p . The proof follows from the fact that if $G \in \mathcal{G}_n^p$, then $G \in \mathcal{G}_n^\sigma$, with high probability.

Theorem 4. *The HITS algorithm is (L_2, d_2) -stable with high probability on the class of graphs \mathcal{G}_n^p , subject to Assumption 1.*

4.4 Similarity of INDEGREE and LATENT

We now consider the (L_q, d_q) -similarity of INDEGREE and LATENT, for all $1 \leq q < \infty$. Again, let $A = \sum_{i=1}^n a_i$, and let $H = \sum_{j=1}^n h_j$. Also, let \mathbf{d} denote the vector of the INDEGREE algorithm before any normalization is applied. That is, d_i is the in-degree of node i . For some node i , we have that

$$d_i = \sum_{j=1}^n W[j, i] = \sum_{j=1}^n M[j, i] + \sum_{j=1}^n R[j, i]$$

We have that $\sum_{j=1}^n M[j, i] = Ha_i$. Furthermore, let $r_i = \sum_{j=1}^n R[j, i]$, and let $\mathbf{r} = [r_1, \dots, r_n]^T$. Vector \mathbf{d} can be expressed as $\mathbf{d} = H\mathbf{a} + \mathbf{r}$.

We first prove the following auxiliary lemma.

Lemma 4. *For every $q \in [1, \infty)$, if $H\|\mathbf{a}\|_q = \omega(n^{1/q} \ln n)$, then $\|\mathbf{r}\|_q = o(H\|\mathbf{a}\|_q)$ with high probability.*

Proof. For the following we will use $\|\cdot\|$ to denote the L_q norm, for some $q \in [1, \infty)$. We will prove that $\|\mathbf{r}\| = o(H\|\mathbf{a}\|)$ with probability at least $1 - 1/n$. We have assumed that $H\|\mathbf{a}\| = \omega(n^{1/q} \ln n)$, so it is sufficient to show that $\|\mathbf{r}\| = O(n^{1/q} \ln n)$, or equivalently that for all $1 \leq i \leq n$, $|r_i| = O(\ln n)$ with probability at least $1 - 1/n^2$. Note that $r_i = d_i - Ha_i$, so essentially we need to bound the deviation of d_i from its expectation.

We partition the nodes into two sets S and B . Set S contains all nodes such that $Ha_i = O(\ln n)$, that is, nodes with “small” expected in-degree, and set B contains all nodes such that $Ha_i = \omega(\ln n)$, that is, node with “big” expected in-degree.

Consider a node $i \in S$. We have that $Ha_i \leq c \ln n$, for some constant c . Using Theorem 2, Equation 2, we set $\delta = k \ln n / (Ha_i)$, where k is a constant such that $k \geq \sqrt{8c}$, and we get that $Pr[d_i - Ha_i \geq k \ln n] \leq \exp(-2 \ln n)$. Therefore, for all

nodes in S we have that $|r_i| = O(\ln n)$ with probability at least $1 - 1/n^2$. This implies that $\sum_{i \in S} |r_i|^q = O(n \ln^q n) = o(H^q \|\mathbf{a}\|^q)$, with probability $1 - 1/n$.

Consider now a node $i \in B$. We have that $Ha_i = \omega(\ln n)$, thus, $Ha_i = (\ln n)/s(n)$, where $s(n)$ is a function such that $s(n) = o(1)$. Using Theorem 2, we set $\delta = k\sqrt{s(n)}$, where k is a constant such that $k \geq \sqrt{8}$, and we get that $\Pr[|d_i - Ha_i| \geq \delta Ha_i] \leq \exp(-2 \ln n)$. Therefore, for the nodes in B , we have that $|r_i| = o(Ha_i)$ with probability at least $1 - 1/n^2$. Thus, $\sum_{i \in B} |r_i|^q = o(H^q \|\mathbf{a}\|^q)$, with probability $1 - 1/n$.

Putting everything together we have that $\|\mathbf{r}\|^q = \sum_{i \in S} |r_i|^q + \sum_{i \in B} |r_i|^q = o(H^q \|\mathbf{a}\|^q)$, with probability $1 - 2/n$. Therefore, $\|\mathbf{r}\| = o(H\|\mathbf{a}\|)$ with probability $1 - 2/n$. This concludes our proof. \square

We are now ready to prove the similarity of INDEGREE and LATENT. The following lemma follows from Lemma 4. The details of the proof appears in the full version of the paper.

Lemma 5. *For every $q \in [1, \infty)$, the INDEGREE and LATENT algorithms are (L_q, d_q) -similar with high probability on the class \mathcal{G}_n^p , when the latent vectors \mathbf{a} and \mathbf{h} satisfy $H\|\mathbf{a}\|_q = \omega(n^{1/q} \ln n)$.*

We now make the following assumption for vectors \mathbf{a} and \mathbf{h} .

Assumption 2. *For the class $\mathcal{G}_n^p(\mathbf{h}, \mathbf{a})$, the latent vectors \mathbf{a} and \mathbf{h} satisfy $H\|\mathbf{a}\|_2 = \omega(\sqrt{n} \ln n)$.*

Assumption 2 implies that the expected number of edges in the graph satisfies $HA = \omega(\sqrt{n} \ln n)$. Note that we can satisfy Assumption 2 by requiring $HA = \omega(n \ln n)$, that is, the graph is dense enough. We can satisfy both Assumption 1 and 2 by requiring that $\sigma_1(M) = \|\mathbf{h}\|_2 \|\mathbf{a}\|_2 = \omega(\sqrt{n} \ln n)$.

The INDEGREE and LATENT algorithms are (L_2, d_2) -similar subject to Assumption 2. The following theorem follows from the transitivity property of similarity.

Theorem 5. *The HITS and INDEGREE algorithms are (L_2, d_2) -similar with high probability on the class \mathcal{G}_n^p , subject to Assumptions 1 and 2.*

4.5 Power Law Graphs

A discrete random variable X follows a power law distribution with parameter α , if $\Pr[X = x] \propto x^{-\alpha}$. Closely related to the power-law distribution is the Zipfian distribution, also known as Zipf's law [24]. Zipf's law states that the r -th largest value of the random variable X is proportional to $r^{-\beta}$. It can be proved [2] that if X follows a Zipfian distribution with exponent β , then it also follows a power law distribution with parameter $\alpha = 1 + 1/\beta$. We will now prove that Assumptions 1 and 2 are general enough to include graphs with *expected* in-degrees that follow Zipf's law with parameter $\beta < 1$.

Without loss of generality we assume that $a_1 \geq a_2 \geq \dots \geq a_n$. For some constant $c \leq 1$ the i -th authority value is defined as $a_i = ci^{-\beta}$, for $\beta < 1$. This implies a power law distribution on the *expected* in-degrees with exponent $\alpha > 2$. This is typical for most real-life graphs. The exponent of the in-degree distribution for the Web graph is

Fig. 1. INDEGREE and HITS distributions on the Web graph

2.1 [9]. For the hub values we assume that $h_i = \Theta(1)$, for all $1 \leq i \leq n$. Therefore, we have that $H = \Theta(n)$, and $\|\mathbf{h}\|_2 = \Theta(\sqrt{n})$. Furthermore, it is easy to show that for $\beta < 1$, $\|\mathbf{a}\|_2^2 = \sum_{i=1}^n \frac{c}{i^2} = \omega(1)$.

Therefore, $\|\mathbf{a}\|_2 \|\mathbf{h}\|_2 = \omega(\sqrt{n})$, and $H\|\mathbf{a}\|_2 = \omega(n)$, thus satisfying Assumptions 1 and 2. Therefore, we can conclude that HITS and INDEGREE are similar with high probability when the expected degrees follow a power law distribution. Note that on this graph we have that the expected number of edges is $HA = \omega(n \ln n)$.

5 Experimental Analysis

In this section we study experimentally the similarity of HITS and INDEGREE on a large sample of the Web. We analyze a sample of 136M vertices and about 1,2 billion edges of the Web graph collected in 2001 by the WebBase project² at Stanford. Figures 1(a) and 1(b) show the distributions of the INDEGREE and HITS authority values. The in-degree distribution, as it is well known, follows a power law distribution. The HITS authority weights also follow a “fat” power law distribution in the central part of the plot. Table 1 summarizes our findings on the relationship between INDEGREE and HITS. Since we only have a single graph and not a sequence of graphs, the distance measures are not very informative, so we also compute the correlation coefficient between the two weight vectors. We observe a strong correlation between the authority weights of HITS and the in-degrees, while almost no correlation between the hub weights and the out-degrees.

Table 1. Similarity between HITS and INDEGREE

	authority/in-degree	hub/out-degree
d_2 distance	0.36	1.23
correlation coefficient	0.93	0.005

² <http://www-diglib.stanford.edu/~testbed/doc2/WebBase/>

Similar trends are observed for the d_2 distance, where the distance between hub weights and out-degrees is much larger than that between authority weights and in-degrees. These results suggest that although the Web, as expected, is not a product graph, the HITS authority weights can be well approximated by the in-degrees.

6 Similarity of HITS and INDEGREE

In this section we study the general conditions under which the HITS and INDEGREE algorithms are similar. Consider a graph $G \in \mathcal{G}_n$ and the corresponding adjacency matrix W . Let $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n$ be the singular values of W , and let $\mathbf{a}_1, \dots, \mathbf{a}_n$ and $\mathbf{h}_1, \dots, \mathbf{h}_n$ denote the right (authority) and left (hub) singular vectors respectively. All vectors are unit vectors in the L_2 norm. The HITS algorithm outputs the vector $\mathbf{a} = \mathbf{a}_1$. Let \mathbf{w} denote the output of the INDEGREE algorithm (normalized in L_2). Also, let $H_i = \sum_{j=1}^n h_i(j)$ be the sum of the entries of the i -th hub vector. We can prove the following proposition. The proof appears in the full version of the paper.

Proposition 1. *For a graph $G \in \overline{\mathcal{G}}_n$, the d_2 distance between HITS and INDEGREE is*

$$d_2(\mathbf{a}, \mathbf{w}) = \sqrt{\left(\frac{\sigma_2 H_2}{\sigma_1 H_1}\right)^2 + \dots + \left(\frac{\sigma_n H_n}{\sigma_1 H_1}\right)^2} \tag{3}$$

We now study the conditions under which $d_2(\mathbf{a}, \mathbf{w}) = o(1)$. Since the values of \mathbf{h}_1 are positive, we have that $H_1 = \|\mathbf{h}_1\|_1$, and $1 \leq H_1 \leq \sqrt{n}$. For every $i > 1$, we have that $|H_i| \leq \|\mathbf{h}_i\|_1$ and $|H_i| \leq \sqrt{n}$. The following conditions guarantee the similarity of HITS and INDEGREE: (a) $\sigma_2/\sigma_1 = o(1/\sqrt{n})$, and there exists a constant k such that $\sigma_{k+1}/\sigma_1 = o(1/n)$; (b) $H_1 = \Theta(\sqrt{n})$, and $\sigma_2/\sigma_1 = o(1)$, and there exists a constant k such that $\sigma_{k+1}/\sigma_1 = o(1/n)$; (c) $H_1 = \Theta(\sqrt{n})$, and $\sigma_2/\sigma_1 = o(1/\sqrt{n})$.

Assume now that $|H_i|/(\sigma_1 H_1) = o(1)$, for all $i \geq 2$. One possible way to obtain this bound is to assume that $\sigma_1 = \omega(\sqrt{n})$, or that $H_1 = \Theta(\sqrt{n})$ and $\sigma_1 = \omega(1)$. Then, we can obtain the following characterization of the distance between HITS and INDEGREE. From Equation (3) we have that $d_2(\mathbf{a}, \mathbf{w}) = o\left(\sqrt{\sigma_2^2 + \dots + \sigma_n^2}\right)$. Let $W_1 = \sigma_1 \mathbf{h}_1 \mathbf{a}_1^T$ denote the rank-one approximation of W . The matrix $R = W - W_1$ is called the residual matrix, and it has singular values $\sigma_2, \dots, \sigma_n$. We have that

$$d_2(\mathbf{a}, \mathbf{w}) = o(\|W - W_1\|_F) \quad \text{and} \quad d_2(\mathbf{a}, \mathbf{w}) = o\left(\sqrt{\|W\|_F^2 - \|W_1\|_F^2}\right) \tag{4}$$

Equation (4) says that the similarity of HITS and INDEGREE algorithms depends on the Frobenius norm of the residual matrix. Furthermore, the similarity of the HITS and INDEGREE algorithms depends on the difference between the Frobenius and the spectral (L_2) norm of matrix W . The L_2 norm measures the strength of the strongest linear trend in the matrix, while the Frobenius norm captures the sum of the strengths of all linear trends in the matrix [1]. The similarity of the HITS and INDEGREE algorithms depends upon the contribution of the strongest linear trend to the sum of linear trends.

7 Conclusions

In this paper we studied the behavior of the HITS algorithm on the class of product graphs. We proved that under some assumptions the HITS algorithm is stable, and it is similar to the INDEGREE algorithm. Our assumptions include graphs with expected degrees that follow a power law distribution.

Our work opens a number of interesting directions for future work. First, it would be interesting to determine a necessary condition for the stability of the HITS algorithm. Also, it would be interesting to study the stability and similarity of other LAR algorithms on product graphs, such as the PAGERANK and the SALSA algorithms. Finally, it would be interesting to study other classes of random graphs [5, 16].

Up-to Techniques for Weak Bisimulation

Damien Pous

ENS Lyon

Abstract. Up-to techniques have been introduced to enhance the bisimulation proof method for establishing bisimilarity results. While up-to techniques for strong bisimilarity are well understood, in the weak case they come as a collection of unrelated results, and lack a unified presentation. We propose a uniform and modular theory of up-to techniques for weak bisimulation that captures existing proof technology and introduces new techniques. Some proofs rely on non trivial – and new – commutation results based on termination guarantees.

Introduction

Bisimilarity is a widely used behavioural equivalence in concurrency theory. It can be seen as the finest extensional equivalence that enjoys a natural formulation and nice mathematical properties. Bisimilarity can be defined as the greatest *bisimulation*. Given a *labelled transition system* (LTS), allowing one to write transitions between states of the form $P \xrightarrow{\alpha} P'$ (meaning that a state P can perform an action α and evolve to P'), we say that a relation \mathcal{R} between states is a bisimulation whenever the leftmost diagram below holds: if P and Q are related by \mathcal{R} and $P \xrightarrow{\alpha} P'$, there is Q' such that $Q \xrightarrow{\alpha} Q'$ and \mathcal{R} relates P' and Q' , and symmetrically for the transitions of Q .

$$\begin{array}{ccc} P & \mathcal{R} & Q \\ \alpha \downarrow & & \downarrow \alpha \\ P' & \mathcal{R} & Q' \end{array} \quad \begin{array}{ccc} P & \mathcal{R} & Q \\ \alpha \downarrow & & \downarrow \alpha \\ P' & \mathcal{F}(\mathcal{R}) & Q' \end{array} \quad \begin{array}{ccc} P & \mathcal{R} & Q \\ \alpha \downarrow & & \downarrow \alpha \\ P' & \mathcal{S} & Q' \end{array} \quad \begin{array}{ccc} P & \mathcal{R} & Q \\ \alpha \downarrow & & \downarrow \alpha \\ P' & \mathcal{R} & Q' \end{array}$$

Bisimulation is the most popular technique to establish bisimilarity results: to prove that P and Q are bisimilar (written $P \sim Q$), exhibit a bisimulation \mathcal{R} such that $P \mathcal{R} Q$. *Up-to techniques for bisimulation* have been introduced to alleviate the task of bisimulation proofs, by working with smaller relations. The proof scheme is shown on the second diagram above: a correct up-to technique is given by a function \mathcal{F} from relations to relations such that if we prove that \mathcal{R} ‘evolves to’ $\mathcal{F}(\mathcal{R})$, then we know that $\mathcal{R} \subseteq \sim$. The advantage is that \mathcal{R} need not be a bisimulation (and can be ‘much smaller’ than a bisimulation). The notion of evolution of relations (depicted on the third diagram, where \mathcal{R} evolves to \mathcal{S} — its informal meaning is made precise below) serves as the basis of [8], where a general theory of up-to techniques for bisimulation is presented. The corresponding framework gives a unified and modular view of known up-to techniques, that can be combined together to yield powerful proof techniques for bisimilarity.

Up to now, we have implicitly been referring to *strong* bisimulation. When analysing nontrivial systems, however, one is often interested in the *weak* version, where a special action, called τ , is isolated, and the game of bisimulation is redefined by abstracting over τ transitions (τ is treated as a *silent* action, while other actions are *visible*). In the weak version of the bisimulation game, as shown on the rightmost diagram above, Q responds to $P \xrightarrow{\alpha} P'$ by performing an $\xrightarrow{\alpha}$ transition: this means that Q can do zero or several silent steps before and after the transition along α , or even not move at all in the case where $\alpha = \tau$ (and symmetrically when Q offers a challenge). One might then want to follow the same path as above: redefine the evolution of relations, and look for some functions \mathcal{F} that yield correct up-to proof techniques for weak bisimilarity (written \approx). An important motivation for doing so is that in general, weak bisimulation proofs tend to be much larger than strong bisimulation proofs, so that having up-to techniques for the weak case is at least as important as in the strong case.

Unfortunately, in the weak case, irregularities appear, the paradigmatic example being given by the unsoundness of the ‘weak bisimulation up to weak bisimilarity’ proof technique. We recall the counterexample, from [9]. We suppose that the reader is familiar with CCS, and define $\mathcal{R} \triangleq \{(\tau.a, 0)\}$. Let us show that \mathcal{R} is a weak bisimulation up to \approx , i.e., that \mathcal{R} evolves to $\approx \mathcal{R} \approx$ (we use juxtaposition to denote relation composition). The right process, 0, cannot move. The only move the left process can do is a τ transition to a , to which the right process answers by no move, and we get the pair $(a, 0)$. Now since we are reasoning up to \approx , and since $a \approx \tau.a$, we are allowed to replace this pair with $(\tau.a, 0)$, and we are back in \mathcal{R} . Nevertheless, we obviously cannot conclude that $\tau.a$ and 0 are bisimilar processes.

Novel and useful proof techniques have been introduced to circumvent this difficulty [9, 3], notably based on the expansion preorder [1], that allows one to avoid situations where one can ‘undo a τ transition’ as in the example above. However, as we have experienced in a recent study [4], in some cases reasoning up to expansion is not possible. The intuitive reason can be formulated as follows: when a process P expands a process Q , P has to be more efficient (in terms of internal computations, represented by silent transitions) than Q *at every step*. Typically, expansion is a well suited relation to get rid of intermediate computation steps that do not affect the behaviour of the system. However, it is common (in particular, it is the case in [4]) that along such transitions, an increased efficiency is achieved at the cost of some initial computation. Because of its ‘very controlled’ nature, expansion fails in handling this kind of pre-calculation techniques.

In the present work, we develop a theory of up-to techniques for weak bisimulation that enjoys nice properties in terms of generality and modularity, and we introduce new useful proof techniques for weak bisimilarity that can be used in that framework.

We start by adapting the work of [7] to the weak case, yielding the notion of *monotonic function* over relations. We explore the class of monotonic functions, and argue that it is too restrictive. We are thus led to relax the notion of monotonicity, and introduce *weakly monotonic* functions, for which up-to techniques

can be applied only to reason about visible actions (those that cannot be undone by \approx). We then show under which conditions monotonic and weakly monotonic functions can be combined together to obtain sound proof techniques. The resulting framework gives a unified and modular account of existing technology for weak bisimulation proofs. Beyond that, we validate some proof principles, such as ‘up to bisimilarity and transitivity on visible actions’, that to our knowledge had not been proposed before.

We then attack the question of finding alternatives to the expansion relation to handle τ transitions in weak bisimulation proofs. We propose an *up to controlled bisimulation* technique. The notion of controlled bisimulation intuitively captures the idea of avoiding ‘going back in time’ in bisimulation proofs. We introduce *relaxed expansion*, a co-inductively defined relation that is a controlled bisimulation and is coarser than expansion. We also propose two new proof principles for which the control on τ steps exploits a different kind of argument, based on termination guarantees. The corresponding correctness proofs are best formulated as rewriting results, that are technically difficult and may be of interest *per se*; we therefore describe them in that setting in a dedicated section. All our results have been formally checked using the Coq proof assistant [7]. For the lack of space, most are omitted in this extended abstract. They can be found in [5].

Outline of the paper. In Sect. 1, we introduce some necessary background and show where the approach of [8] breaks when adapted to the weak case. We develop our theory of up-to techniques for weak bisimulation in Sect. 2, introducing monotonic and weakly monotonic functions. In Sect. 3 we introduce controlled simulations and present new up-to techniques based on this notion. The correctness of some of these techniques is supported by the proofs given in Sect. 4, which are formulated in the setting of commutation results. We give final remarks in Sect. 5.

1 The Problem of “Weak Bisimulation Up to”

1.1 Labelled Transition Systems, Relations, Evolution

We consider a labelled transition system (LTS) $(\mathcal{P}, \mathcal{L}, \rightarrow)$, with domain \mathcal{P} , labels or actions in \mathcal{L} and transition relation $\rightarrow \subseteq \mathcal{P} \times \mathcal{L} \times \mathcal{P}$. The elements of \mathcal{P} are called *processes* and are denoted by P, Q . We distinguish a *silent action*, $\tau \in \mathcal{L}$. We let α, β (resp. a, b) range over actions, in \mathcal{L} (resp. *visible actions*, in $\mathcal{L} \setminus \{\tau\}$). We write $P \xrightarrow{a} Q$ when $(P, a, Q) \in \rightarrow$ (so that $P \xrightarrow{a} Q$ stands for a transition of P along a visible action a).

We let $\mathcal{R}, \mathcal{S}, \mathcal{B}, \mathcal{E}$ range over binary relations (simply called *relations* in the sequel) on processes, and denote respectively by $\mathcal{R}^+, \mathcal{R}^-, \mathcal{R}^*$ the transitive, reflexive, transitive and reflexive closure of the relation \mathcal{R} . $P \mathcal{R} Q$ stands for $(P, Q) \in \mathcal{R}$. The composition of two relations \mathcal{R} and \mathcal{S} , written $\mathcal{R}\mathcal{S}$, is defined by $\mathcal{R}\mathcal{S} \triangleq \{(P, Q) \text{ s.t. } P \mathcal{R} T \text{ and } T \mathcal{S} Q \text{ for some process } T\}$. We will also need the inverse of a relation: $\mathcal{R}^{-1} \triangleq \{(P, Q) \text{ s.t. } Q \mathcal{R} P\}$. \mathcal{I} will denote the identity relation. We say that \mathcal{R} *contains* \mathcal{S} (alternatively, that \mathcal{S} is contained in \mathcal{R}),

written $S \subseteq \mathcal{R}$, if $P S Q$ implies $P \mathcal{R} Q$. A relation \mathcal{R} *terminates* if there is no infinite sequence $P_1, P_2 \dots$ such that $\forall i, P_i \mathcal{R} P_{i+1}$.

Definition 1.1 (weak transitions). *The weak transition relation, written $\overset{\alpha}{\rightsquigarrow}$, is defined as the reflexive transitive closure of $\overset{\alpha}{\rightarrow}$ when $\alpha = \tau$, and the composition $\overset{\alpha}{\rightarrow} \overset{\beta}{\rightarrow} \overset{\gamma}{\rightarrow}$ for $\alpha = a \in \mathcal{L} \setminus \{\tau\}$.*

Definition 1.2 (evolution). *Let α be an action and \mathcal{R}, \mathcal{S} two relations. We say that \mathcal{R} α -evolves to \mathcal{S} , if whenever $P \mathcal{R} Q$, $P \overset{\alpha}{\rightarrow} P'$ implies $Q \overset{\alpha}{\rightsquigarrow} Q'$ and $P' S Q'$ for some Q' . Given two relations \mathcal{R} and \mathcal{S} , we say that:*

- \mathcal{R} evolves to \mathcal{S} , denoted by $\mathcal{R} \rightsquigarrow \mathcal{S}$, if \mathcal{R} α -evolves to \mathcal{S} for all $\alpha \in \mathcal{L}$,
- \mathcal{R} evolves silently to \mathcal{S} , denoted by $\mathcal{R} \rightsquigarrow_{\tau} \mathcal{S}$, if \mathcal{R} τ -evolves to \mathcal{S} ,
- \mathcal{R} evolves visibly to \mathcal{S} , denoted by $\mathcal{R} \rightsquigarrow_{\neq \tau} \mathcal{S}$, if \mathcal{R} a -evolves to \mathcal{S} for all $a \in \mathcal{L} \setminus \{\tau\}$.

Our notion of evolution is the ‘asymmetric’ version of *progression* in [8]: \mathcal{R} progresses to \mathcal{S} in the sense of [8] iff \mathcal{R} evolves to \mathcal{S} and \mathcal{R}^{-1} evolves to \mathcal{S}^{-1} .

In the following, we build a theory of up-to techniques to reason about simulations. This leads to simpler developments, and we show at the end of each section how to use the results to obtain proof techniques for bisimulation.

In the definition below, and in the remainder of the paper, we implicitly refer to *weak* relations. There are several equivalent definitions of bisimilarity. The following directly gives the standard way to prove a bisimilarity result between two processes P and Q : exhibit a bisimulation \mathcal{R} containing the pair (P, Q) .

Definition 1.3 (simulation, bisimulation, expansion). *Let \mathcal{R} be a relation, \mathcal{R} is a simulation (resp. silent simulation) if $\mathcal{R} \rightsquigarrow \mathcal{R}$ (resp. $\mathcal{R} \rightsquigarrow_{\tau} \mathcal{R}$). \mathcal{R} is a bisimulation if \mathcal{R} and \mathcal{R}^{-1} are simulations. Two processes P and Q are bisimilar, written $P \approx Q$, if $P \mathcal{R} Q$ for some bisimulation \mathcal{R} .*

Expansion, denoted by \succsim , is the largest relation such that \succsim^{-1} is a simulation, and, whenever $P \succsim Q$,

1. $P \overset{\tau}{\rightarrow} P'$ implies $Q \overset{\tau}{\rightarrow} Q'$ and $P' \succsim Q'$ for some Q' , or $P' \succsim Q$;
2. $P \overset{a}{\rightarrow} P'$ implies $Q \overset{a}{\rightarrow} Q'$ and $P' \succsim Q'$ for some Q' .

1.2 The Difficulty in the Weak Case

We now adapt the theory of up-to techniques of [8] to the weak case, and show where the difficulties arise. We let \mathcal{F}, \mathcal{G} range over *functions* from relations to relations. We say that \mathcal{F} *contains* \mathcal{G} , written $\mathcal{G} \subseteq \mathcal{F}$, if $\mathcal{G}(\mathcal{R}) \subseteq \mathcal{F}(\mathcal{R})$ for any relation \mathcal{R} . Given a relation \mathcal{S} , we define *identity* (\mathcal{U}), *constant-to- \mathcal{S}* ($\tilde{\mathcal{S}}$), *\mathcal{S} -left-chaining* ($\mathcal{S}\bullet$) and *\mathcal{S} -right-chaining* ($\bullet\mathcal{S}$) as follows:

$$\mathcal{U}(\mathcal{R}) \triangleq \mathcal{R} \quad \tilde{\mathcal{S}}(\mathcal{R}) \triangleq \mathcal{S} \quad \mathcal{S}\bullet(\mathcal{R}) \triangleq \mathcal{S}\mathcal{R} \quad \bullet\mathcal{S}(\mathcal{R}) \triangleq \mathcal{R}\mathcal{S}$$

We define four *constructors*, i.e., functions from functions to functions: *composition* (\circ), *union* (\cup), *iteration* ($*$) and *chaining* (\frown), as follows:

$$\begin{aligned} (\mathcal{F} \circ \mathcal{G})(\mathcal{R}) &\triangleq \mathcal{F}(\mathcal{G}(\mathcal{R})) & (\mathcal{F}^0)(\mathcal{R}) &\triangleq \mathcal{R} \\ (\mathcal{F} \cup \mathcal{G})(\mathcal{R}) &\triangleq \mathcal{F}(\mathcal{R}) \cup \mathcal{G}(\mathcal{R}) & (\mathcal{F}^{n+1})(\mathcal{R}) &\triangleq \mathcal{F}^n(\mathcal{R}) \cup \mathcal{F}(\mathcal{F}^n(\mathcal{R})) \\ (\mathcal{F} \frown \mathcal{G})(\mathcal{R}) &\triangleq \mathcal{F}(\mathcal{R})\mathcal{G}(\mathcal{R}) & (\mathcal{F}^*)(\mathcal{R}) &\triangleq \bigcup_{n \geq 0} \mathcal{F}^n(\mathcal{R}) \end{aligned}$$

Definition 1.4 (monotonicity). A function \mathcal{F} is monotonic if $\mathcal{R} \subseteq \mathcal{S}$ entails $\mathcal{F}(\mathcal{R}) \subseteq \mathcal{F}(\mathcal{S})$ and the following conditions hold:

$$(1) \left\{ \begin{array}{l} \mathcal{R} \rightsquigarrow \mathcal{S} \\ \mathcal{R} \subseteq \mathcal{S} \end{array} \right. \Rightarrow \mathcal{F}(\mathcal{R}) \rightsquigarrow \mathcal{F}(\mathcal{S}) \qquad (2) \left\{ \begin{array}{l} \mathcal{R} \succ \mathcal{S} \\ \mathcal{R} \subseteq \mathcal{S} \end{array} \right. \Rightarrow \mathcal{F}(\mathcal{R}) \succ \mathcal{F}(\mathcal{S})$$

This slightly strengthens the notion of *respectfulness* found in [8], in which the two kinds of transitions are treated uniformly. While the results of this section would hold using respectful functions, we will need this separation between silent and visible actions in Sect. 2.2.

Proposition 1.5 (correctness of monotonic functions). Let \mathcal{F} be a monotonic function. If $\mathcal{R} \succ \mathcal{F}(\mathcal{R})$, then $\mathcal{F}^*(\mathcal{R})$ is a simulation.

This proposition ensures that a monotonic function provides a sound up-to technique: whenever we can prove that \mathcal{R} evolves to $\mathcal{F}(\mathcal{R})$, then \mathcal{R} is contained in $\mathcal{F}^*(\mathcal{R})$, which is a simulation. We now exhibit some monotonic functions, and show how to combine them to obtain more powerful techniques.

Lemma 1.6. Let \mathcal{S} be a simulation, \mathcal{U} , $\tilde{\mathcal{S}}$, $\bullet\mathcal{S}$ and $\succ\bullet$ are monotonic functions.

In the sequel, we will say that a constructor *respects* a predicate P over functions, if, given arguments that satisfy P, it returns a function satisfying P.

Lemma 1.7. Constructors \circ , \cup and $*$ respect monotonicity.

We can now apply our framework to reason about bisimulation relations, and revisit a result from [9]. We show that the proof becomes elementary.

Theorem 1.8. If $\mathcal{R} \succ \succsim \mathcal{R} \approx \approx$ and $\mathcal{R}^{-1} \succ \succsim (\mathcal{R}^{-1}) \approx \approx$, then $\mathcal{R} \subseteq \approx$.

Proof. Using the previous results, $\mathcal{F}(\mathcal{R}) \triangleq \succ \mathcal{R} \approx \approx$ is monotonic, and $\mathcal{F}^*(\mathcal{R})$ and $\mathcal{F}^*(\mathcal{R}^{-1})$ are simulations. Then $\approx \mathcal{F}^*(\mathcal{R})$ and $\mathcal{F}^*(\mathcal{R}^{-1}) \approx$ are simulations. We check that $(\approx \mathcal{F}^*(\mathcal{R}))^{-1} = \mathcal{F}^*(\mathcal{R}^{-1}) \approx$, so that $\mathcal{R} \subseteq \approx \mathcal{F}^*(\mathcal{R}) \subseteq \approx$. \square

The transitivity problem. The \approx -left-chaining function is not monotonic. As a consequence, the chaining constructor does not respect monotonicity in general. Indeed, when trying to prove the monotonicity of $\approx\bullet$, we lack some hypotheses about silent transitions to close the corresponding diagram.

2 A Smooth Theory for the Weak Case

2.1 A Weaker Notion of Monotonicity

When looking at the counterexample given in the Introduction, we can observe that the problem is related to silent transitions: unlike visible transitions, they can be cancelled by \approx . We now exploit this observation to relax the definition of monotonicity, which leads to a smoother theory, where reasoning *up to weak bisimilarity* is allowed, but on visible actions only.

Definition 2.1 (weak monotonicity). A function \mathcal{F} is weakly monotonic if $\mathcal{R} \subseteq \mathcal{S}$ entails $\mathcal{F}(\mathcal{R}) \subseteq \mathcal{F}(\mathcal{S})$ and the following conditions hold:

$$(1) \mathcal{R} \rightsquigarrow \mathcal{R} \Rightarrow \mathcal{F}(\mathcal{R}) \rightsquigarrow \mathcal{F}(\mathcal{R}) \qquad (2) \begin{cases} \mathcal{R} \rightsquigarrow \mathcal{R}, \mathcal{R} \rightsquigarrow \mathcal{S} \\ \mathcal{S} \rightsquigarrow \mathcal{S}, \mathcal{R} \subseteq \mathcal{S} \end{cases} \Rightarrow \mathcal{F}(\mathcal{R}) \rightsquigarrow \mathcal{F}(\mathcal{S})$$

The main difference w.r.t. Definition 1.4 is in clause (1): instead of respecting silent evolutions, a weakly monotonic function has to respect silent simulations. On the visible side (2), we suppose that \mathcal{R} and \mathcal{S} are silent simulations. The immediate consequence of these modifications appears in the following result: the up-to function may only be used on visible evolutions, and the candidate relation \mathcal{R} has to be a silent simulation.

Proposition 2.2 (correctness of weakly monotonic functions). Let \mathcal{F} be weakly monotonic. If $\mathcal{R} \rightsquigarrow \mathcal{R}$, and $\mathcal{R} \rightsquigarrow \mathcal{F}(\mathcal{R})$, then $\mathcal{F}^*(\mathcal{R})$ is a simulation.

Now we study the class of weakly monotonic functions: the following lemma ensures that the functions given by Lemma 1.6 can be used in the setting of weakly monotonic functions. Furthermore, weakly monotonic functions can be composed using the most important constructors:

Lemma 2.3. Any monotonic function is weakly monotonic. Composition (\circ), union (\cup), iteration ($*$) and chaining (\frown) respect weak monotonicity.

The closure under the chaining constructor naturally suggests the use of interesting up-to techniques, and in particular *up to transitivity*, given by $\mathcal{F}(\mathcal{R}) = \mathcal{R}^*$, and *up to weak bisimilarity*, using $\mathcal{F}(\mathcal{R}) = \approx \mathcal{R} \approx$.

2.2 Combining Monotonicity and Weak Monotonicity

In introducing weakly monotonic functions, we have restricted the use of up-to techniques to visible steps. We show how to develop further this approach by combining a monotonic function and a weakly monotonic function so as to employ constrained up-to techniques on silent steps, and full-fledged up-to techniques on visible steps.

Proposition 2.4 (unified up-to technique). Let \mathcal{F} be monotonic and \mathcal{G} be weakly monotonic, and suppose further that $\mathcal{F} \subseteq \mathcal{G}$.

If $\mathcal{R} \rightsquigarrow \mathcal{F}(\mathcal{R})$ and $\mathcal{R} \rightsquigarrow \mathcal{G}(\mathcal{R})$, then $(\mathcal{G}^*)^*(\mathcal{R})$ is a simulation.

In this result, we have to iterate \mathcal{G} twice for technical reasons (see [5] for details). The following theorem is the counterpart of Theorem 1.8 in the richer setting we have introduced:

Theorem 2.5. If $\begin{cases} \mathcal{R} \rightsquigarrow \gtrsim \mathcal{R}^{\approx} \approx \\ \mathcal{R} \rightsquigarrow (\mathcal{R} \cup \approx)^* \end{cases}$ and $\begin{cases} \mathcal{R}^{-1} \rightsquigarrow \gtrsim \mathcal{R}^{-1} \approx \\ \mathcal{R}^{-1} \rightsquigarrow (\mathcal{R}^{-1} \cup \approx)^* \end{cases}$ then $\mathcal{R} \subseteq \approx$.

We thus have a modular theory of up-to techniques for weak bisimulation that follows the approach for the strong case in [8]. Technically, the main improvement over previous works is the ability to exploit weaker hypotheses when reasoning about visible steps: for instance, *up to transitivity* ($\mathcal{R} \rightsquigarrow \mathcal{R}^*$) and *up to weak bisimilarity* ($\mathcal{R} \rightsquigarrow \approx \mathcal{R} \approx$) techniques entail valid proof methods.

3 Beyond Expansion

3.1 Controlled Relations

In this section, we enrich our framework with the possibility to use alternatives to \succsim (which is the best we can do using Theorem 2.5) to handle τ transitions in bisimulation proofs. We define a class of relations that are controlled w.r.t. silent transitions, meaning that they prevent silent steps from being cancelled in an up-to bisimulation game.

The left-chaining functions associated to such relations are not weakly monotonic, and we thus have to depart from the theory we have developed so far. Roughly, a controlled relation is defined as a relation that induces a correct proof technique when used as a left-chaining up-to technique. The following technical definition introduces a uniform way to plug a non weakly monotonic left-chaining function into our setting.

Definition 3.1 (controlled relation). *We say that \mathcal{B} is a controlled relation if the following holds for all relations \mathcal{R}, \mathcal{S} :*

$$(1) \mathcal{R} \succ_{\tau} \mathcal{B}^*\mathcal{R} \Rightarrow \mathcal{B}^*\mathcal{R} \succ_{\tau} \mathcal{B}^*\mathcal{R} \quad (2) \begin{cases} \mathcal{R} \succ_{\tau} \mathcal{B}^*\mathcal{R} \\ \mathcal{R} \succ_{\nu} \mathcal{S}, \mathcal{S} \succ_{\tau} \mathcal{S} \end{cases} \Rightarrow \mathcal{B}^*\mathcal{R} \succ_{\nu} \mathcal{B}^*\mathcal{S}.$$

Remark 3.2. Note that a controlled relation need not be a simulation. However, by taking $\mathcal{R} = \mathcal{S} = \mathcal{I}$, we see that if \mathcal{B} is controlled, then \mathcal{B}^* is a simulation. Also, the union of two controlled relations is not necessarily a controlled relation. Thus, this does not a priori induce a notion of *controlled bisimilarity*.

We say that \mathcal{B} is a *controlled bisimulation* if it is a controlled relation contained in bisimilarity.

We now show how controlled relations can be used in simulation proofs.

Definition 3.3 (transparency). *Given a relation \mathcal{B} and a function \mathcal{F} , \mathcal{F} is \mathcal{B} -transparent if $\mathcal{F}(\mathcal{B}^*\mathcal{R}) \subseteq \mathcal{B}^*\mathcal{F}(\mathcal{R})$ for any relation \mathcal{R} .*

\mathcal{F} is transparent if it is \mathcal{B} -transparent for any relation \mathcal{B} .

Proposition 3.4 (up to controlled relation). *Let \mathcal{F} and \mathcal{G} be two functions, and \mathcal{B} a relation such that: \mathcal{B} is a controlled relation, \mathcal{F} is monotonic and \mathcal{B} -transparent, \mathcal{G} is weakly monotonic. Suppose moreover that \mathcal{G} contains \mathcal{F} and $\mathcal{B}^*\bullet$. If $\mathcal{R} \succ_{\tau} \mathcal{B}^*\mathcal{F}(\mathcal{R})$ and $\mathcal{R} \succ_{\nu} \mathcal{G}(\mathcal{R})$, then $(\mathcal{G}^*)^*(\mathcal{R})$ is a simulation.*

Lemma 3.5. *The identity and all \mathcal{S} -right-chaining functions are transparent. If $\mathcal{B} \subseteq \mathcal{S}$ then the constant-to- \mathcal{S} function is \mathcal{B} -transparent.*

The composition, union and iteration constructors respect \mathcal{B} -transparency.

In practise, we will work with $\mathcal{S} = \approx$ and require that $\mathcal{B} \subseteq \approx$, so that condition $\mathcal{B} \subseteq \mathcal{S}$ will be satisfied.

Also notice that $\succsim\bullet$, the expansion-left-chaining function, is not transparent in general. This hence prevents us from encompassing the up to expansion proof technique in the statement of the following theorem.

Theorem 3.6. *Let \mathcal{B} be a controlled bisimulation.*

$$\text{If } \left\{ \begin{array}{l} \mathcal{R} \succ\!\!\succ \mathcal{B}^* \mathcal{R} = \approx \\ \mathcal{R} \succ\!\!\succ (\mathcal{R} \cup \approx)^* \end{array} \right. \text{ and } \left\{ \begin{array}{l} \mathcal{R}^{-1} \succ\!\!\succ \mathcal{B}^* \mathcal{R}^{-1} = \approx \\ \mathcal{R}^{-1} \succ\!\!\succ (\mathcal{R}^{-1} \cup \approx)^* \end{array} \right. \text{ then } \mathcal{R} \subseteq \approx.$$

This theorem is the counterpart of Theorem 2.5 using a controlled bisimulation instead of $\succ\!\!\succ$. A refined version of this result, in which two distinct controlled bisimulations are used for the silent evolutions of \mathcal{R} and \mathcal{R}^{-1} , also holds. This can be useful in particular because the class of controlled bisimulations is not closed under union, as explained in Remark 3.2.

The remainder of the section is devoted to the construction of controlled relations.

3.2 Relaxed Expansion

Definition 3.7 (relaxed expansion). *A relation \mathcal{E} is a relaxed expansion if whenever $P \mathcal{E} Q$,*

1. $P \xrightarrow{\tau} P'$ implies $Q \xrightarrow{\tau} Q'$ and $P' \mathcal{E} Q'$ for some Q' or $P' \mathcal{E} Q$,
2. $P \xrightarrow{a} P'$ implies $Q \xrightarrow{a} \xrightarrow{\tau} Q'$ and $P' \mathcal{E} Q'$ for some Q' .

Relaxed expansion, denoted by $\succ\!\!\succ$, is the union of all relaxed expansions \mathcal{E} such that \mathcal{E}^{-1} is a simulation.

When $P \succ\!\!\succ Q$ and $P \xrightarrow{a} P'$, Q has to do immediately a transition along a , but then can do as many silent transitions as necessary. The intuition behind the definition of relaxed expansion is that, using this possibility, Q can do some ‘preliminary internal computation’ in order to be able to remain faster than P until the next visible action.

Lemma 3.8. *$\succ\!\!\succ$ is a relaxed expansion, and we have: $\succ\!\!\succ \subseteq \preceq \subseteq \approx \subseteq \approx$.*

Proof. The first point and the inclusions are straightforward. We illustrate the strictness of the inclusions using CCS processes: $a.b \succ\!\!\succ a.\tau.b$ holds but not $a.b \preceq a.\tau.b$, and $a \approx \tau.a$ holds but not $a \succ\!\!\succ \tau.a$. □

Theorem 3.9. *A relaxed expansion is a controlled relation. $\succ\!\!\succ$ is a controlled bisimulation.*

In general, $\succ\!\!\succ$ is not a congruence: for instance, in CCS, $a.b \succ\!\!\succ a.\tau.b$ holds but not $\bar{a} \mid a.b \succ\!\!\succ \bar{a} \mid a.\tau.b$. We remark that $\succ\!\!\succ$ is very close to *almost weak bisimilarity*, defined in [9]; the definition of $\succ\!\!\succ$ only fits better to our setting.

3.3 Introducing Termination Guarantees

We now show how to obtain controlled relations using termination guarantees. The theorems below follow from general results about commuting diagrams, presented in Sect. 4. Their proofs are thus deferred to that section.

Theorem 3.10. *Let \mathcal{B} be a relation such that $\mathcal{B} \rightarrow \mathcal{B}^+$ and \mathcal{B} terminates. Then \mathcal{B} is a controlled relation.*

Theorem 3.11. *Let \mathcal{B} be a relation such that $\mathcal{B} \mapsto \mathcal{B}^*$ and $\mathcal{B}^+ \dashv\vdash^+$ terminates. Then \mathcal{B} is a controlled relation.*

Unlike \approx , where the control on silent moves is fixed by the co-inductive definition of the relation, in these two results we start with a relation that roughly respects the – too permissive – weak bisimulation game, and constrain it a posteriori, in such a way that it cannot cancel silent steps indefinitely. For example, the erroneous up-to relation $\mathcal{B} = \{(a, \tau.a)\}$ is rejected because \mathcal{B} evolves to $\mathcal{I} = \mathcal{B}^0$, and $\mathcal{B}^+ \dashv\vdash^+ = \{(a, a)\}$ obviously does not terminate.

There are processes that are not related by \approx , but by a relation satisfying the conditions of the previous theorems: consider $(a \mid (\nu b)b, \tau.a)$ or $(a + a, \tau.a)$.

Like for controlled relations, there is no direct way to define the greatest relation satisfying the requirements in Theorems 3.10 and 3.11, the main reason being that the union of terminating relations does not terminate in general. Also remark that the termination of $\mathcal{B}^+ \dashv\vdash^+$ does not entail the termination of \mathcal{B} or $\dashv\vdash$. Theorem 3.11 can thus be applied to systems exhibiting infinite chains of τ transitions (e.g., π or CCS with replication).

We can use the up-to techniques we have defined previously to show the evolution condition in the above theorems ($\mathcal{B} \mapsto \mathcal{B}^+$ or $\mathcal{B} \mapsto \mathcal{B}^*$). However one has to be careful, because the simulation relation obtained with these techniques is $\mathcal{F}^*(\mathcal{B})$. Depending on \mathcal{F} , this relation may be reflexive, which discards Theorem 3.10, or just quite complex, so that proving the termination of $\mathcal{F}^*(\mathcal{B})$ or $\mathcal{F}^*(\mathcal{B})^+ \dashv\vdash^+$ may be delicate.

4 Results About Commuting Diagrams

In this section, we work in the more general setting of *diagrams*, commonly found in rewriting theory. In addition to \mathcal{R}, \mathcal{S} we let $\rightarrow, \leftrightarrow$ and \rightsquigarrow range over relations. As before, \rightarrow^+ (resp. \rightsquigarrow) is the transitive (resp. reflexive transitive) closure of \rightarrow . We shall say that four relations $(\mathcal{R}, \rightarrow, \mathcal{S}, \leftrightarrow)$ form a *diagram*, denoted $(\mathcal{R}, \rightarrow) \gg (\mathcal{S}, \leftrightarrow)$, if whenever $P \mathcal{R} Q$ and $P \rightarrow P'$, there is Q' such that $P' \mathcal{S} Q'$ and $Q \leftrightarrow Q'$ (in our proofs, we shall sometimes adopt the usual graphical notation for diagrams). We say that two relations \mathcal{R} and \rightarrow *commute* if $(\mathcal{R}, \rightarrow) \gg (\mathcal{R}, \rightarrow)$. Notice that a relation \mathcal{R} is a simulation iff \mathcal{R} commutes with \rightsquigarrow for all $\alpha \in \mathcal{L}$.

4.1 A First Termination Argument

Lemma 4.1. *Let \mathcal{B}, \rightarrow be two relations such that \mathcal{B} terminates. If $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^+, \rightsquigarrow)$, then \mathcal{B}^+ and \rightsquigarrow commute.*

Remark 4.2. The commutation hypothesis $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^+, \rightsquigarrow)$ cannot be weakened to $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^*, \rightsquigarrow)$, or to “whenever $P \mathcal{B} Q$ and $P \rightarrow P', P' = Q$ or there is Q' such that $P' \mathcal{B}^+ Q'$ and $Q \rightsquigarrow Q'$ ”. Indeed, if we define

$$\begin{aligned} \mathcal{B} &\triangleq \{ (2, 3), (3, 4), (1, 0) \} & 0 &\xleftarrow{\mathcal{B}} 1 \leftarrow 2 \begin{array}{c} \xrightarrow{\mathcal{B}} \\ \xleftarrow{\mathcal{B}} \end{array} 3 \xrightarrow{\mathcal{B}} 4 \\ \rightsquigarrow &\triangleq \{ (3, 2), (2, 1), (1, 0) \} \end{aligned}$$

\mathcal{B} terminates and satisfies the two alternative hypotheses; $2 \mathcal{B}^* 4$ and $2 \rightarrow 1$, but there is no i s.t. $4 \rightarrow i$ and $1 \mathcal{B}^* i$.

A similar result: “if \mathcal{B} terminates and $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^+, \rightarrow)$, then \mathcal{B}^* and \rightarrow commute” is given in [10–Exercise 1.3.2]. However we are interested in showing the stronger result below, in which diagrams can be composed with other relations (this is necessary to obtain controlled simulations).

Lemma 4.3. *Let $\mathcal{B}, \rightarrow, \leftrightarrow$ be three relations such that \mathcal{B} terminates.*

If $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^+, \rightarrow)$ and $(\mathcal{B}, \leftrightarrow) \gg (\mathcal{B}^+, \rightarrow\leftrightarrow)$, then \mathcal{B}^ and $\rightarrow\leftrightarrow$ commute.*

Proof. By induction over the well-founded relation \mathcal{B}^{-1} with the predicate $\phi(P')$: “For all P, Q such that $P \rightarrow\leftrightarrow P'$ and $P \mathcal{B}^+ Q$, there is Q' such that $Q \rightarrow\leftrightarrow Q'$ and $P' \mathcal{B}^+ Q'$ ”. \square

Proposition 4.4. *Let $\mathcal{B}, \rightarrow, \leftrightarrow, \mathcal{R}, \mathcal{S}, \rightsquigarrow$ be six relations such that \mathcal{B} terminates.*

If $\left\{ \begin{array}{l} (\mathcal{B}, \rightarrow) \gg (\mathcal{B}^+, \rightarrow) \\ (\mathcal{B}, \leftrightarrow) \gg (\mathcal{B}^+, \rightarrow\leftrightarrow) \end{array} \right.$ and $\left\{ \begin{array}{l} (\mathcal{R}, \rightarrow) \gg (\mathcal{B}^\mathcal{R}, \rightarrow) \\ (\mathcal{R}, \leftrightarrow) \gg (\mathcal{B}^*\mathcal{S}, \rightarrow\rightsquigarrow) \end{array} \right.$*

then $(\mathcal{B}^\mathcal{R}, \rightarrow\leftrightarrow) \gg (\mathcal{B}^*\mathcal{S}, \rightarrow\rightsquigarrow)$.*

We can now give the first deferred proof from the previous section:

Proof (of Theorem 3.10).

1. Suppose $\mathcal{R} \rightsquigarrow \mathcal{B}^*\mathcal{R}$, we apply Proposition 4.4, taking \rightsquigarrow for \rightarrow , and the identity relation for $\leftrightarrow, \rightsquigarrow$, and \mathcal{S} .
2. Suppose furthermore $\mathcal{R} \rightsquigarrow \mathcal{S}$ and $\mathcal{S} \rightsquigarrow \mathcal{S}$. Lemma 4.1 ensures that \mathcal{B}^* is a silent simulation. We close the diagram marked with a (*) below with a simple induction.

$$\begin{array}{ccc}
 \begin{array}{c} \mathcal{B} \\ a \downarrow \\ \mathcal{B}^+ \\ \tau \downarrow \\ \mathcal{B}^+ \end{array} & \begin{array}{c} (H) \\ \downarrow a \\ (Lem. 4.1) \downarrow \tau \end{array} & \begin{array}{c} \mathcal{R} \\ a \downarrow \\ \mathcal{S} \\ \tau \downarrow \\ \mathcal{S} \end{array} \\
 & & \begin{array}{c} (H) \\ \downarrow a \\ (*) \\ \downarrow \tau \end{array}
 \end{array}$$

We then apply Proposition 4.4, using \rightsquigarrow for \rightarrow , $\rightsquigarrow \rightsquigarrow$ for \leftrightarrow and \rightsquigarrow . \square

4.2 A Generalisation of Newman’s Lemma

Lemma 4.5. *Let $\mathcal{B}, \rightarrow, \mathcal{R}$ be three relations such that $\mathcal{B}^+ \rightarrow^+$ terminates.*

If $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^, \rightarrow)$ and $(\mathcal{R}, \rightarrow) \gg (\mathcal{B}^*\mathcal{R}, \rightarrow)$, then $\mathcal{B}^*\mathcal{R}$ and \rightarrow commute.*

Proof. It suffices to prove $(\mathcal{B}^*\mathcal{R}, \rightarrow) \gg (\mathcal{B}^*\mathcal{R}, \rightarrow)$: the commutation result then follows by a simple induction. We use an induction over the well-founded order induced by the termination of $\mathcal{B}^+ \rightarrow^+$, with the predicate $\phi(P)$: “For all P', Q such that $P \rightarrow P'$ and $P \mathcal{B}^*\mathcal{R} Q$, there is Q' such that $Q \rightarrow Q'$ and $P' \mathcal{B}^*\mathcal{R} Q'$ ” (IH_1). Then we do a second induction on the derivation of $P \mathcal{B}^*\mathcal{R} Q$ (IH_2). From the first hypothesis, we get P_n such that the leftmost diagram below holds (we show the interesting case where $P_0 \rightarrow^+ P_n$). We use the internal induction

to obtain Q_1 in the central diagram; this is possible since any process P'' such that $P_0 \mathcal{B}^+ \rightarrow^+ P''$ satisfies $P \mathcal{B}^+ \rightarrow^+ P''$: the external induction hypothesis is preserved. Finally, using a third induction on the derivation $P_1 \rightarrow P_n$, we close the diagram by applying $n - 1$ times the external induction hypothesis (all processes between P_1 and P_n satisfy $P \mathcal{B}^+ \rightarrow^+ P_i$).

$$\begin{array}{ccccccccc}
 P & \mathcal{B} & P_0 & \mathcal{B}^* \mathcal{R} & Q & P & \mathcal{B} & P_0 & \mathcal{B}^* \mathcal{R} & Q & P & \mathcal{B} & P_0 & \mathcal{B}^* \mathcal{R} & Q \\
 \downarrow & & \downarrow & & & \downarrow & & \downarrow & & & \downarrow & & \downarrow & & \downarrow \\
 & (H) & P_1 & & & & & P_1 & \mathcal{B}^* \mathcal{R} & Q_1 & & & P_1 & \mathcal{B}^* \mathcal{R} & Q_1 \\
 \downarrow & & \downarrow & & & \downarrow & & \downarrow & & & \downarrow & & \downarrow & & \downarrow \\
 P' & \mathcal{B}^* & P_n & & & P' & \mathcal{B}^* & P_n & & & P' & \mathcal{B}^* & P_n & \mathcal{B}^* \mathcal{R} & Q'
 \end{array}$$

□

By taking $\mathcal{R} = \mathcal{I}$ in this lemma, we obtain the following corollary:

Corollary 4.6. *Let \mathcal{B}, \rightarrow be two relations such that $\mathcal{B}^+ \rightarrow^+$ terminates. If $(\mathcal{B}, \rightarrow) \gg (\mathcal{B}^*, \rightarrow)$, then \mathcal{B}^* and \rightarrow commute.*

By taking $\mathcal{B} = \rightarrow$, we get Newman’s lemma: “Local confluence and termination entail confluence”. A different generalisation of this confluence lemma to commutation can be found in [2–Lemma 4.26]. However, the latter result is weaker than ours since it requires the termination of $\mathcal{B} \cup \rightarrow$, and thus the termination of both \mathcal{B} and \rightarrow .

Remark 4.7 (up-to techniques and commuting diagrams). The previous corollary admits a direct and elegant proof using the decreasing diagram techniques of van Oostrom et al. [2–Theorem 4.25]. The details of this proof are given in [5]. However, results like Lemma 4.5 and Proposition 4.8 cannot be proved within the setting of [2], because they express properties beyond ‘pure commutation’.

Fournet [3] and others have been using results from [2] to validate up-to techniques for *barbed equivalences*. This is not directly comparable to the present work, since in that setting, commutation results apply directly (visible actions are not taken into account). Moreover, these works do not exploit results based on termination guarantees on the relations between processes.

Proposition 4.8. *Let $\mathcal{B}, \rightarrow, \mathcal{R}, \leftrightarrow, \mathcal{S}, \rightsquigarrow$ be six relations s.t. $\mathcal{B}^+ \rightarrow^+$ terminates. If $\left\{ \begin{array}{l} (\mathcal{B}, \rightarrow) \gg (\mathcal{B}^*, \rightarrow) \\ (\mathcal{B}, \leftrightarrow) \gg (\mathcal{B}^*, \rightarrow \leftrightarrow) \end{array} \right.$ and $\left\{ \begin{array}{l} (\mathcal{R}, \rightarrow) \gg (\mathcal{B}^* \mathcal{R}, \rightarrow) \\ (\mathcal{R}, \leftrightarrow) \gg (\mathcal{B}^* \mathcal{S}, \rightarrow \rightsquigarrow) \end{array} \right.$ then $(\mathcal{B}^* \mathcal{R}, \rightarrow \leftrightarrow) \gg (\mathcal{B}^* \mathcal{S}, \rightarrow \rightsquigarrow)$.*

Like in the proof of Theorem 3.10, we use Proposition 4.8 and Corollary 4.6 to establish Theorem 3.11.

5 Concluding Remarks

Applications of our proof techniques. We have analysed two example systems where existing methods do not really help in establishing bisimilarity results, while the techniques we have presented are applicable, and indeed simplify

the proofs. One of these examples comes from the work reported in [4] (which presents a direct bisimilarity proof). For lack of space, we do not present these here; the interested reader can refer to the long version of this paper [5]. More experience on case studies has to be developed in order to have a better understanding of how our techniques can be best combined, and how to tune the distinction between visible and internal computation steps.

A theorem prover formalisation of our results. All results in this paper have been formally checked in the Coq proof assistant [7], and the descriptions of the proofs we give actually closely follow the proof scripts (available from [6]). This is of particular interest for the proofs in Sect. 4, which require non trivial and error-prone reasoning, especially when reasoning about nested inductions.

Results about decreasing diagrams. Due to the presence of labelled transitions, results about decreasing diagrams from [2] are not applicable directly in our setting. We plan to study how the theory of [2] can be adapted to keep track of visible actions. This could be a way to provide an abstract approach for the definition of ‘up to transitivity’ techniques based on termination guarantees.

Acknowledgements. We would like to thank Davide Sangiorgi for his comments and suggestions, and Daniel Hirschhoff for helpful discussions and a great help during the redaction process.

Abstract. The firing rule of Petri nets relies on a residuation operation for the commutative monoid of natural numbers. We identify a class of residuated commutative monoids, called Petri algebras, for which one can mimic the token game of Petri nets to define the behaviour of generalized Petri net whose flow relation and place contents are valued in such algebraic structures. We show that Petri algebras coincide with the positive cones of lattice-ordered commutative groups and constitute the subvariety of the (duals of) residuated lattices generated by the commutative monoid of natural numbers. We introduce a class of nets, termed lexicographic Petri nets, that are associated with the positive cones of the lexicographic powers of the additive group of real numbers. This class of nets is universal in the sense that any net associated with some Petri algebras can be simulated by a lexicographic Petri net. All the classical decidable properties of Petri nets however are undecidable on the class of lexicographic Petri nets. Finally we turn our attention to bounded nets associated with Petri algebras and show that their dynamics can be reformulated in term of MV-algebras.

1 Introduction

The Petri net model is a graphical and mathematical modeling tool that, since its introduction in the early sixties, have come to play a pre-eminent role in the formal study of concurrent discrete-event dynamic systems. A Petri net $(P, T, Pre, Post)$ consists of a finite set P of places, a finite set T of transitions (disjoint from P), and flow relations $Pre, Post : P \times T \rightarrow \mathbb{N}$. Places can contain some tokens representing the resources available in this place for the current configuration. A configuration of a Petri net is given as a vector $M : P \rightarrow \mathbb{N}$, called marking, indicating the number of tokens available in each place. Tokens are consumed and produced by the firing of transitions according to the so-called token game

$$M[t] M' \Leftrightarrow (\forall p \in P) M(p) \sqsupseteq Pre(p, t) \wedge M'(p) = (M(p) - Pre(p, t)) + Post(p, t)$$

The token game of Petri net says that in order for a transition t to fire in marking M it should be the case that each place contains enough resources as it is expressed by the condition $M(p) \sqsupseteq Pre(p, t)$ where \sqsupseteq is the usual order relation on \mathbb{N} . Then the firing of transition t proceeds in two stages : a consumption of resources ($Pre(p, t)$ tokens are removed from place p) followed by a production of resources ($Post(p, t)$ tokens are added to place p). The notation $M[t] M'$ expresses the fact that transition t is allowed to fire in marking M and that firing t in marking M produces the new marking M' . Numerous techniques, supported and automated by software tools, can be used to verify that some required properties are met for systems specified using Petri nets. For instance reachability, coverability, place-boundedness, deadlock and liveness can be decided on the class of Petri nets [13].

Numerous extensions of this basic model of Petri nets have been introduced over the years. Some of them are high level nets that allow for more compact representations but do not increase the expressive power of Petri nets: these high level nets can be unfolded into equivalent, even though in general much larger, Petri nets. Some extensions however change more dramatically the semantics of the original model. For instance timing constraints may be added, as in timed Petri nets or stochastic Petri nets for the purpose of enabling performance analysis. With continuous Petri nets the discrete state transition rule is replaced by a notion of trajectory using a continuum of intermediate states. In Fuzzy Petri nets one has a possibilistic measure of the firing of a transition in the given marking thus enabling to deal with uncertainty. Our purpose in this paper is to put forward an axiomatisation of the token game of Petri nets. More precisely we identify a class of commutative residuated monoids, called Petri algebras, for which one can mimic the token game of Petri nets to define the behaviour of generalized Petri nets whose flow relations and place contents are valued in such algebraic structures. The sum and its associated residuation capture respectively how resources within places are produced and consumed through the firing of a transition. The class of usual Petri nets is associated with the commutative monoid of natural numbers. We show that Petri algebras coincide with the positive cones of lattice-ordered commutative groups and constitute the subvariety of the (duals of) residuated lattices generated by the commutative monoid of natural numbers. The basic Petri net model is thus associated with the generator of the variety of Petri algebras which shows that these extended nets share all algebraic properties of Petri nets, in particular they have the same equational and inequational theory. We however exhibit a Petri algebra whose corresponding class of nets is strictly more expressive than the class of Petri nets, i.e. their class of marking graphs is strictly larger. More precisely, we introduce a class of nets, termed lexicographic Petri nets, that are associated with the positive cones of the lexicographic powers of the additive group of real numbers. This class of nets is proved to be universal in the sense that any net associated with some Petri algebra can be simulated by a lexicographic Petri net. All the classical decidable properties of Petri nets how-

ever (termination, covering, boundedness, structural boundedness, accessibility, deadlock, liveness ...) are proved to be undecidable on the class of lexicographic Petri nets. Finally we turn our attention to bounded nets associated with Petri algebras and show that their dynamics can be reformulated in term of MV-algebras.

2 An Axiomatisation of the Token Game

In order to obtain an axiomatisation of the token game of Petri nets we represent the marking of a net as a map $M : P \rightarrow \bigsqcup_{p \in P} A_p$ that associates with each place $p \in P$ the local value of the current configuration $M(p) \in A_p$ in this place. Content of places are resources that are consumed and produced according to the token game. Thus we assume that each place $p \in P$ is associated with a commutative divisibility monoid $A_p = (A_p, \oplus, 0)$, i.e. a monoid such that

$$\text{the relation } a \sqsupseteq b \Leftrightarrow \exists c \cdot a = b \oplus c \text{ is an order relation} \tag{1}$$

The constant 0 represents the absence of resource and the binary operator \oplus the accumulation of resources in places. Immediate consequences of condition (1) are the following:

$$\begin{aligned} a \oplus b &\sqsupseteq a, b \\ 0 &\sqsubseteq a \\ a \oplus b = 0 &\Rightarrow a = b = 0 \end{aligned}$$

Moreover we need to have a residuation operation \ominus such that $a \ominus b$ represents the residual resource obtained by subtracting b from a when $b \sqsubseteq a$. Thus the following should hold true:

$$b \sqsubseteq a \Rightarrow a = (a \ominus b) \oplus b \tag{2}$$

Usual Petri nets corresponds to the situation where, for every place p , $A_p = (\mathbb{N}, +, 0)$ is the commutative monoid of natural numbers with the truncated difference $n \ominus m = \max(0; n - m)$ as residuation. This operation is characterized by the universal property that for every natural numbers n, m and p

$$n + m \sqsupseteq p \Leftrightarrow n \sqsupseteq p \ominus m$$

Up to the reversal of the order relation, it is a *commutative residuated monoid* i.e. a commutative monoid $(A, \oplus, 0)$ with an order relation \leq and a residuation operation \ominus which is a right adjoint to the addition, in the sense that

$$a \oplus b \leq c \Leftrightarrow a \leq c \ominus b \tag{3}$$

It follows immediately from this definition that a commutative monoid is residuated if and only if its addition is order preserving in each argument and the inequation $a \oplus b \leq c$ has a largest solution for a (namely $c \ominus b$). In particular the residual is uniquely determined by the addition and the order relation.

When the monoid is a divisibility monoid the order relation itself is defined in terms of the addition and thus the whole structure is characterized by its monoid reduct.

Proposition 1. *Let $(A, \oplus, 0, \sqsubseteq)$ be a commutative monoid where the neutral element is also the least element for the order relation, we assume that this monoid is co-residuated in the sense that there exists a residuation operation \ominus such that*

$$a \oplus b \sqsubseteq c \Leftrightarrow a \sqsubseteq c \ominus b \tag{4}$$

then the following conditions are equivalent

- (i) *It is a divisibility monoid: $a \sqsubseteq b \Leftrightarrow \exists c \cdot a = b \oplus c$*
- (ii) *It is an upper semi-lattice with: $a \sqcup b = (a \ominus b) \oplus b$*
- (iii) *$b \sqsubseteq a \Rightarrow a = (a \ominus b) \oplus b$*

Definition 2. *A Petri pre-structure is a commutative monoid equipped with a residuation operation $(M, \oplus, 0, \ominus)$ satisfying the conditions (1) and (4).*

The firing of a transition proceeds in two stages: a consumption of resources in the input places followed by a production of resources in the output places. More precisely, the transition relation $M [t] M'$ stating that transition t can fire in marking M and leads, when it is fired, to the new marking M' is given by:

$$M [t] M' \Leftrightarrow \forall p \in P \ M(p) \sqsupseteq Pre(p, t) \wedge M'(p) = (M(p) \ominus Pre(p, t)) \oplus Post(p, t)$$

A net is called *homogeneous* if all the algebras A_p are identical. We will stick to homogeneous nets until Section 3 where it will be noticed that the "multi-sorted" case adds in fact no extra generality. By the way we also restrict our attention in this paper to commutative algebras. With non commutative monoids it would be possible [1] for example to take fifo nets [11] into account.

For any non empty sequence of transitions $u = a_0 \dots a_{n-1} \in T^+$ we let $M [u] M'$ state the existence of markings $M = M_0, M_1, \dots, M_n = M'$ such that $M_i [a_i] M_{i+1}$ for every $0 \leq i < n$. Moreover we set $M [\varepsilon] M$ where $\varepsilon \in E^*$ is the empty sequence and M an arbitrary marking. We use $M [u]$ (respectively $[u] M'$) as a shorthand for $\exists M' \ M [u] M'$ (resp. $\exists M \ M [u] M'$). If $a, b \in T$ are transitions in a (n usual) Petri net we have the following equivalences (using the vectorial notations $\mathcal{P}(t) = (\mathcal{P}(p, t); p \in P) \in \mathbb{N}^P$ for $\mathcal{P} \in \{Pre, Post\}$)

$$\begin{aligned} M [ab] &\Leftrightarrow M \sqsupseteq Pre(a) \text{ and } (M - Pre(a)) + Post(a) \sqsupseteq Pre(b) \\ &\Leftrightarrow M \sqsupseteq \max(Pre(a); Pre(a) + (Pre(b) - Post(a))) \\ &\Leftrightarrow M \sqsupseteq Pre(a) + \max(0; Pre(b) - Post(a)) \\ &\Leftrightarrow M \sqsupseteq Pre(a) \oplus (Pre(b) \ominus Post(a)) \end{aligned}$$

This suggests to let $Pre(uv) = Pre(u) \oplus (Pre(v) \ominus Post(u))$ for any sequences $u, v \in T^*$ and symmetrically $Post(uv) = (Post(u) \ominus Pre(v)) \oplus Post(v)$. For these definitions to make sense however, it remains to show that they do not depend

upon the specific chosen decomposition $w = uv$; otherwise stated, the product defined on $A \times A$ by $(x, y) \otimes (x', y') = (x \oplus (x' \ominus y), (y \ominus x') \oplus y')$ should be associative.

Theorem 3. *For any Petri pre-structure, the following conditions are equivalent:*

- (i) *Operation \otimes is associative,*
- (ii) *the identity $(b \oplus c) \ominus a = (b \ominus (a \ominus c)) \oplus (c \ominus a)$ holds,*
- (iii) *the monoid is cancellable: $a \oplus b = a \oplus c \Rightarrow b = c$, and*
- (iv) *the identity $(a \oplus b) \ominus b = a$ holds.*

Definition 4. *A Petri algebra is a Petri pre-structure with a cancellable monoid reduct.*

Corollary 5. *Petri algebras satisfy the following equivalence*

$$a \sqsupseteq b \oplus c \iff a \sqsupseteq b \text{ and } a \ominus b \sqsupseteq c \tag{5}$$

Identity (ii) of Theorem 3 is an internalization of (5) using the axiomatization of the order relation: $a \sqsubseteq b \iff a \ominus b = 0$.

Let us consider a net over a Petri algebra A , then we can inductively define the applications $Pre, Post : P \times T^* \rightarrow A$ by letting $\varphi(p, u) = (Pre(p, u), Post(p, u))$ where $\varphi(p, -) : T^* \rightarrow A \times A$ is the unique monoid morphism such that the images $\varphi(p, t) = (Pre(p, t), Post(p, t))$ of the generators $t \in T$ be given by the flow relations of the net. Then the following holds:

$$\begin{aligned} Pre(p, \varepsilon) &= Post(p, \varepsilon) = 0 \\ Pre(p, uv) &= Pre(p, u) \oplus (Pre(p, v) \ominus Post(p, u)) \\ Post(p, uv) &= (Post(p, u) \ominus Pre(p, v)) \oplus Post(p, v) \end{aligned}$$

Theorem 6. *The generalized transition relation $M[u] M'$ stating the existence of a sequence u of transitions leading from M to M' is given by any of the three following equivalent conditions*

1. $\forall p \in P \ M(p) \sqsupseteq Pre(p, u)$ and $M'(p) = (M(p) \ominus Pre(p, u)) \oplus Post(p, u)$
2. $\forall p \in P \ M'(p) \sqsupseteq Post(p, u)$ and $M(p) = (M'(p) \ominus Post(p, u)) \oplus Pre(p, u)$
3. $\forall p \in P \ M(p) \sqsupseteq Pre(p, u) ; M'(p) \sqsupseteq Post(p, u)$ and $M(p) \ominus Pre(p, u) = M'(p) \ominus Post(p, u)$

We have so far identified the set of conditions that should be fulfilled by Petri algebras so that we can play the token game and the resulting firing rule is associative. To sum up, these structures are duals of commutative residuated lattices whose joins and meets are given by the formulas $a \sqcup b = a \ominus (a \ominus b)$ and $a \sqcap b = b \oplus (a \ominus b)$. Moreover this lattice is integral in the sense that the neutral element for the sum is also the least element of the lattice. Finally the underlying monoid is cancellable and this condition is equivalent to the identity $(a \oplus b) \ominus b = a$.

Using [3,9] we can conclude that Petri algebras coincide with the (duals of) *integral, cancellative and commutative GMV-algebras*. These algebras form a sub-variety of the variety of residuated lattices and the following result is a direct consequence of [10–Theorem 5.6 and corollaries].

Theorem 7. *Petri algebras coincide with the positive cones of lattice-ordered abelian groups. Moreover lattice-ordered abelian groups constitute the subvariety of lattice-ordered groups generated by the group \mathbb{Z} of integer, and their positive cones (i.e. Petri algebras) is the subvariety of residuated lattices generated by \mathbb{N} .*

3 Lexicographic Petri Nets

We define a (generalized) Petri net as a structure $\mathcal{N} = (P, T, Pre, Post, M_0)$ where P is a finite set of places with a Petri algebra A_p associated with each place $p \in P$, T is a finite set of transitions disjoint from P and $Pre, Post : P \times T \rightarrow \bigsqcup_{p \in P} A_p$, the flow relations, are such that $\forall p \in P \forall t \in T \quad Pre(p, t), Post(p, t) \in A_p$. A marking is a map $M : P \rightarrow \bigsqcup_{p \in P} A_p$ that associates with each place $p \in P$ the local value of the current configuration $M(p) \in A_p$ in this place. M_0 is some fixed marking, called the *initial marking*. The transition relation $M[t] M'$ stating that transition t can fire in marking M and leads, when it is fired, to the new marking M' is given by:

$$M[t] M' \Leftrightarrow \forall p \in P \quad M(p) \supseteq Pre(p, t) \wedge M'(p) = (M(p) \ominus Pre(p, t)) \oplus Post(p, t)$$

This relation can be extended inductively to sequences $u \in T^*$ of transitions by letting $M[\varepsilon] M$ for every marking M and $M[t \cdot u] M'$ if and only if there exists some marking M'' such that $M[t] M''$ and $M''[u] M'$ for every $t \in T$ and $u \in T^*$. The set of *reachable markings* is $Reach(\mathcal{N}) = \{M \mid \exists u \in T^* \quad M_0[u] M\}$, and the *marking graph* of a generalized net $\mathcal{N} = (P, T, Pre, Post, M_0)$ is the labelled graph $\Gamma_{\mathcal{N}} = (V, \Lambda, v_0)$ whose set of vertices is given by the set $V = Reach(\mathcal{N})$ of reachable markings with $v_0 = M_0$ and whose set of arcs $\Lambda \subseteq V \times T \times V$ is the restriction of the transition relation to the set of reachable markings: $\Lambda = \{(M, t, M') \mid M, M' \in V \wedge M[t] M'\}$. Two generalized Petri nets are termed *equivalent* when they have isomorphic marking graphs.

We immediately see that a place p whose type A_p is a sub-algebra of a product of Petri algebras ($A_p \subseteq A_1 \times \dots \times A_n$) can be replaced by n places p_1, \dots, p_n with respective types A_1, \dots, A_n without changing the marking graph (at least up to isomorphism). A classical result of universal algebra says that any algebra of a variety is a sub-direct product of sub-directly irreducible algebras. Thus we can assume without loss of generality that all algebras A_p are sub-directly irreducible algebras in the variety of Petri algebras. Now any $M(p)$ belongs to the sub-algebra of A_p generated by the set $\{M_0(p)\} \cup \bigcup_{t \in T} \{Pre(p, t), Post(p, t)\}$. Thus:

Theorem 8. *Every generalized Petri net is equivalent to a generalized Petri net all of whose types are sub-directly irreducible and finitely generated Petri algebras.*

Let $Irr(V)$ denote the set of sub-directly irreducible algebras of a variety V , then if V is a subvariety of W one has $Irr(W) \cap V = Irr(V)$; using the fact

that the sub-directly irreducible commutative GMV-algebras are chains (totally ordered sets) we deduce that

Proposition 9. *sub-directly irreducible Petri algebras are chains.*

An algebra is sub-directly irreducible if and only if it admits a least non trivial congruence [4]. Now we know [5, 6] that the congruences of Petri algebras are in bijective correspondance with their convex sub-monoids. On the one hand we can associate each congruence θ of a Petri algebra A with the class of the neutral element which is a convex sub-monoid $M_\theta = [0]_\theta$ of A . Conversely we associate each such monoid M to the congruence $\theta_M = \{(a, b) \in A^2 \mid b \ominus a, a \ominus b \in M\}$. The correspondances $\theta \mapsto M_\theta$ and $M \mapsto \theta_M$ are inverses to each other and they establish an isomorphism between the lattice of congruences of A and the lattice of the convex sub-monoids of A . Moreover for every $a \in A$, the principal congruence generated by the equation $a = 0$ corresponds to the convex sub-monoid generated by a . A Petri algebra is then sub-directly irreducible if and only if it admits a least non trivial convex sub-monoid. Let us assume that A is a totally ordered Petri algebra. Let

$$M(x) = \{y \in A \mid \exists k \in \mathbb{N} \cdot y \sqsubseteq k \cdot x = \underbrace{x \oplus \dots \oplus x}_{k \text{ times}}\}$$

denote the principal convex sub-monoid generated by $x \in A$. $M(x)$ is non-trivial if and only if $x \neq 0$. Now if x is some element of a convex sub-monoid M of A one necessarily has $M(x) \subseteq M$; thus a minimal convex sub-monoid is principal and is generated by any of its non null elements. Since A is totally ordered and $x \leq y \Rightarrow M(x) \subseteq M(y)$ we deduce that A admits at most one minimal non trivial sub-monoid. $M(x)$ is minimal if and only if $y \ll x \Rightarrow y = 0$ where relation \ll is given by $y \ll x \Leftrightarrow \forall k \in \mathbb{N} \cdot k \cdot y \sqsubset x$. Otherwise stated $y \ll x$ if and only if $y \sqsubset x$ and $M(y)$ is strictly included in $M(x)$. Therefore A has no non trivial minimal sub-monoid if and only if for every $x \in A \setminus \{0\}$ one can find some $y \in A \setminus \{0\}$ such that $y \ll x$. Under that condition one can form an infinite strictly decreasing chain thus proving that the order relation \ll is not well-founded. Conversely if this order is well-founded then any non empty subset of A , and thus in particular $A \setminus \{0\}$ if A is not trivial, admits a least element for this order which shows the existence of a minimal non trivial sub-monoid. We thus have established the following:

Theorem 10. *A Petri algebra is sub-directly irreducible if and only if it is a chain and the order relation $y \ll x \Leftrightarrow \forall k \in \mathbb{N} \cdot k \cdot y \sqsubset x$ is well-founded.*

The lexicographic product $\mathbb{G} \circ \mathbb{H}$ of two ordered groups \mathbb{G} and \mathbb{H} is the product group $\mathbb{G} \times \mathbb{H}$ equipped with the lexicographic order relation:

$$(x, y) \leq_{\mathbb{G} \circ \mathbb{H}} (x', y') \Leftrightarrow x <_{\mathbb{G}} x' \text{ or } (x = x' \text{ and } y \leq_{\mathbb{H}} y')$$

If \mathbb{G} and \mathbb{H} are simply ordered abelian groups then the same holds for their lexicographic product. This product is associative and we can define inductively

$L_n(\mathbb{G}) = (\mathbb{G}^n)^+$ for every simply ordered abelian group \mathbb{G} and integer $n \in \mathbb{N}$ by letting $\mathbb{G}^0 = \{0\}$ be the trivial group and $\mathbb{G}^{n+1} = \mathbb{G}^n \circ \mathbb{G}$, and where \mathbb{G}^+ denote the positive cone of group \mathbb{G} . The group \mathbb{G}^n naturally embeds into \mathbb{G}^m when $n \leq m$; the projective limit of this sequence of embeddings is the group \mathbb{G}^ω whose elements are the infinite sequences of elements in \mathbb{G} , with componentwise composition and the lexicographic order relation defined as follows: $u \leq_{lex} v \Leftrightarrow u <_{lex} v$ or $u = v$ where $u <_{lex} v \Leftrightarrow \exists n \in \mathbb{N} \forall m \leq n \ u_m = v_m$ and $u_n <_{\mathbb{G}} v_n$. The inductive limit, or "union" $\bigcup_{n < \omega} \mathbb{G}^n$, is the subgroup of \mathbb{G}^ω consisting of the sequences u of finite support ($supp(u) = \sup \{k \in \mathbb{N} \mid u_k \neq 0\} < \omega$) with \mathbb{G}^n identified with the subgroup of $u \in \mathbb{G}^\omega$ such that $supp(u) \leq n$.

Definition 11. *The set $Lex(\mathbb{G})$ of lexicographic Petri nets based on a totally ordered abelian group \mathbb{G} is the set of (homogeneous) generalized Petri net of type $(\mathbb{G}^\omega)^+$. $Lex(\mathbb{G}, n) \subseteq Lex(\mathbb{G})$ is the set of n -dimensional lexicographic Petri nets with type $L_n(\mathbb{G}) = (\mathbb{G}^n)^+ \subseteq (\mathbb{G}^\omega)^+$, i.e. all flow arc inscriptions and initial place contents, and hence all place contents in every accessible marking, are elements in $(\mathbb{G}^n)^+$.*

If \mathcal{K} and \mathcal{L} are subclasses of generalized Petri nets we let $\mathcal{K} \lesssim \mathcal{L}$ when every net in \mathcal{K} is equivalent to some net in \mathcal{L} . This is a pre-order relation, we let \approx denote its associated equivalence relation and \lesssim the corresponding strict relation: $\mathcal{K} \lesssim \mathcal{L}$ when every net in \mathcal{K} is equivalent to some net in \mathcal{L} but there exists some net in \mathcal{L} not equivalent to any net in \mathcal{K} . Notice that $Lex(\mathbb{G}, n) \lesssim Lex(\mathbb{H}, m)$ when $\mathbb{G} \subseteq \mathbb{H}$ and $n \leq m$; and that $Lex(\mathbb{Z}, 1)$ is the class of Petri nets.

Lemma 12. *Any finitely generated sub-directly irreducible Petri algebra A is isomorphic to a sub-algebra of the positive cone of some finite power of the additive group of real numbers: $A \subseteq (\mathbb{R}^n)^+$.*

By Theorem 8 we deduce the following result.

Theorem 13. *Every generalized Petri net is equivalent to some lexicographic Petri net, more precisely : $GenPetri \approx Lex(\mathbb{R})$*

We provide an example showing that $Lex(\mathbb{Z}, 1) \lesssim Lex(\mathbb{Z}, 2)$, i.e. that lexicographic Petri nets based on the group of integers of dimension 2 are already strictly more expressive than the class of Petri nets. Let us consider the net of type $L_2 = (\mathbb{Z} \circ \mathbb{Z})^+ = \{(n, m) \mid (n = 0 \text{ and } m \geq 0) \text{ or } (n > 0 \text{ and } m \in \mathbb{Z})\}$.

From the initial marking $(1, 0)$ transition a can fire once $(1, 0) [a] (0, 0)$ and transition b can fire an infinite number of time leading to the infinite firing sequence $(1, 0) [b] (1, -1) [b] (1, -2) \dots [b] (1, -n) \dots$ and there are no other transitions in

the marking graph of the net. Suppose there exists some Petri net with an isomorphic marking graph. Since transition b can fire an infinite number of time, and

$$M_0 [b^n] M_n \Rightarrow \forall p \in P M_n(p) = M_0(p) - n \times (Pre(p, b) - Post(p, b))$$

we deduce that for every place p it is the case that $Post(p, b) \supseteq Pre(p, b)$ and thus $M_n(p) \supseteq M_0(p)$. By monotony of the firing rule, any transition that can fire in the initial marking M_0 can also fire in any of the markings M_n obtained by firing b . Transition a is in contradiction with this property. Thus

Proposition 14. $Petri = Lex(\mathbb{Z}, 1) \not\approx GenPetri$

It can also be shown that $Lex(\mathbb{Z}, n) \not\approx Lex(\mathbb{Z}, m) \not\approx Lex(\mathbb{Z})$ for $n < m < \omega$, and $Lex(\mathbb{Z}, n) \approx Lex(\mathbb{Q}, n) \not\approx Lex(\mathbb{R}, n)$.

It appears to be difficult to obtain strict extensions of the class of Petri nets that preserve all of its decidable properties. Many of these extensions, like the class of Petri nets with inhibitor arcs, are indeed Turing-powerful. We recall that an inhibitor arc from a place p to a transition t (one such arc is depicted in Fig. 1) is intended to inhibit the firing of transition t as long as place p is not empty.

Theorem 15. *Lexicographic Petri nets are a strict extension of the class of Petri nets with inhibitor arcs. Thus Reachability, Coverability, Place-boundedness, Boundedness, Deadlock and Liveness are undecidable for the class of lexicographic Petri nets.*

The translation of a Petri net with inhibitor arcs \mathcal{N} into an equivalent lexicographic Petri net $\bar{\mathcal{N}}$, illustrated in Fig. 1, consists in splitting every place p with

Fig. 1. A translation from Petri nets with inhibitor arcs into lexicographic Petri nets

initial marking $m \in \mathbb{N}$ of the original net into two places denoted p and p' with initial markings $(0, m) \in (\mathbb{Z} \circ \mathbb{Z})^+$ and $(1, -m) \in (\mathbb{Z} \circ \mathbb{Z})^+$ respectively.

4 Bounded Nets

A net is bounded if we can find an upper bound on the possible values of places in any accessible marking. Let us start our study on the algebraization of the dynamic of bounded nets by the following observation.

Proposition 16. *Any non trivial commutative Petri algebra is an unbounded lattice.*

However we can enforce boundedness by modifying the rule of the token game. Let us consider first the case of the usual Petri nets: assume that each place $p \in P$ is associated with a capacity $k_p \in \mathbb{N}$ and that we want to ensure that the value of a place p of a Petri net be bounded from above by its capacity k_p . For that purpose we modify the firing rule as follows (where all computations are performed in \mathbb{Z})

$$M [t] M' \Leftrightarrow \forall p \in P \begin{cases} M(p) \sqsupseteq Pre(p, t) \wedge (M(p) - Pre(p, t)) + Post(p, t) \sqsubseteq k_p \\ M'(p) = (M(p) - Pre(p, t)) + Post(p, t) \end{cases}$$

this rule can be reformulated as:

$$M [t] M' \Leftrightarrow \forall p \in P \begin{cases} Pre(p, t) \sqsubseteq M(p) \sqsubseteq (k_p + Pre(p, t)) - Post(p, t) \\ M'(p) = (M(p) - Pre(p, t)) + Post(p, t) \end{cases}$$

Petri algebras are the positive cones G^+ of lattice-ordered abelian groups $G = (G, +, 0, \sqcup, \sqcap)$. It is an algebra with the following operations: the sum (restriction of the group operation $x \oplus y = x + y$), and the truncated difference ($x \ominus y = (x - y) \sqcup 0$).

Let $k \sqsupseteq 0$ be some element of this positive cone; we suppose that it is a *strong unit* in the sense that $\forall g \in G \exists n \in \mathbb{N} \cdot n \cdot k \sqsupseteq g$. We can by modifying the firing rule ensure that the values of places stay within the interval $I = [0, k] = \{g \in G \mid 0 \sqsubseteq g \sqsubseteq k\}$. This interval with induced order is a bounded lattice that can be equipped with the following operations: the truncated sum ($x \boxplus y = (x + y) \sqcap k$), the truncated difference ($x \ominus y = (x - y) \sqcup 0$), the product ($x \bullet y = ((x + y) - k) \sqcup 0$), the implication ($x \rightarrow y = ((y + k) - x) \sqcap k$), and the negation ($\neg x = (x \rightarrow 0) = k \ominus x$).

Such a structure is called an MV-algebra. MV-algebras are generalizations of boolean algebras used in the algebraic analysis of Lukasiewicz infinite-valued propositional logic and this class of algebras admits several equivalent definitions [7, 12]. We then state that the firing relation of a so-called bounded net associated with some MV-algebras is given by:

$$M [t] M' \Leftrightarrow \forall p \in P \begin{cases} Pre(p, t) \sqsubseteq M(p) \sqsubseteq Post(p, t) \rightarrow Pre(p, t) \\ M'(p) = (M(p) \ominus Pre(p, t)) \boxplus Post(p, t) \end{cases}$$

The boolean algebra $2 = \{0, 1\}$ is an MV-algebra where $x \boxplus y = x \sqcup y$ and $x \bullet y = x \sqcap y$. Let P be the set of places of a net and $B = 2^P = \wp(P)$ the corresponding product structure, the preceding firing rule can be reformulated as:

$$M[a]M' \Leftrightarrow M \supseteq \text{Pre}(a) \wedge M \cap \text{Post}(a) \subseteq \text{Pre}(a) \wedge M' = (M \setminus \text{Pre}(a)) \cup \text{Post}(a)$$

which is the usual firing rule of 1-safe nets. If we replace the boolean algebra $2 = \{0, 1\}$ by the interval $[0, 1]$ of the additive group of real numbers, i.e. with $x \boxplus y = \min(1, x + y)$ and $x \bullet y = \max(0, x + y - 1)$ then we obtain the firing rule of some kind of 1-safe "fuzzy" nets :

$$M[a]M' \Leftrightarrow \forall p \in P \begin{cases} \text{Pre}(a, p) \sqsubseteq M(p) \sqsubseteq \text{Pre}(a, p) + 1 - \text{Post}(a, p) \\ M'(p) = \min(1, M(p) + \text{Post}(a, p) - \text{Pre}(a, p)) \end{cases}$$

Mundici [12] proved that MV-algebras coincide with $[0, k]$ intervals of abelian lattice-ordered groups where k is a strong unit. More precisely if $G = (G, +, 0)$ is an abelian lattice-ordered group with strong unit k then $\Gamma(G, k) = (A, \boxplus, 0, \bullet, k, \neg)$ where $A = [0, k] = \{x \in G \mid 0 \sqsubseteq x \sqsubseteq k\}$, $x \boxplus y = (x + y) \sqcap k$, $x \bullet y = ((x + y) - k) \sqcup 0$, and $\neg x = k - x$ is an MV-algebra such that the restriction of the order relation of the group on the unit interval $[0, k]$ coincides with the order relation of the MV-algebra: $x \sqsubseteq y \Leftrightarrow x \ominus y = 0$ (where $x \ominus y = x \bullet \neg y = (x - y) \sqcup 0$). Moreover Γ extends into an equivalence between the respective categories, i.e. it induces a bijective correspondence between isomorphism classes of abelian lattice-ordered groups with strong unit and isomorphism classes of MV-algebras. Now we have seen that Petri algebras corresponds bijectively, up to isomorphism, to the positive cones of abelian lattice-ordered groups, we thus have a Petri algebra canonically associated with each MV-algebra. The following result shows that, by using complementary places, we can simulate a bounded Petri net by a generalized Petri net defined on the associated Petri algebra.

Theorem 17. *Any bounded net can be simulated by a generalized Petri net.*

The translation of a bounded net \mathcal{N} into an equivalent generalized Petri net $\overline{\mathcal{N}}$, illustrated in Fig. (2), consists in splitting every place p with initial marking $m \in A_p$ of the bounded net into two places denoted p and p' with initial markings $m \in (\mathbb{G}_p)^+$ and $k_p - m \in (\mathbb{G}_p)^+$ respectively where (\mathbb{G}_p, k_p) is the lattice-ordered abelian group with strong unit associated with the MV-algebra $A_p \simeq \Gamma(\mathbb{G}_p, k_p)$.

Fig. 2. Translation from bounded nets to generalized Petri nets

5 Conclusion

In this paper we have put forward an axiomatization of the token game of Petri nets by identifying a class of commutative residuated monoids, called Petri algebras, for which one can generalize the rule of token game of Petri nets to define the behaviour of generalized Petri net whose flow relation and place contents are valued in such algebras. In this way we have put the basis for a uniform presentation of various families of Petri nets by recasting them as particular instances of a generic class of Petri nets parametric in algebraic structures representing some concrete notion of resources. We thus have followed the line of research best illustrated in [8], a special issue of *Advances in Petri nets*, dedicated to the development of uniform approaches to Petri nets. However the present approach, centered on the notion of resources, is probably too concrete to be of practical interest in many situations. For instance even though one can describe continuous Petri nets in this framework the obtained semantics is too much extensional. We see two directions that can be used in order to derived more abstract representations for the behaviour of these generic nets. First, one can abstract of the flow arc inscriptions. Such an inscription takes its value in some algebra of abstract properties. A precondition then appears as a guard stating that some property has to be satisfied by the resources contained in the corresponding place and a postcondition is interpreted as adding resources to enforce some property. Second, one can abstract on the firing relation itself by giving the measure in some adequate semiring of the "firability" of a transition in some marking.

Abstract. We present a finite ω -complete axiomatization for the process algebra BCCSP modulo failure semantics, in case of a finite alphabet. This solves an open question by Groote [12].

1 Introduction

Labeled transition systems model processes by explicitly describing their states and their transitions from state to state, together with the actions that produce these transitions. Several notions of behavioral equivalence have been proposed, with the aim to identify those states of labeled transition systems that afford the same observations.

Van Glabbeek [10, 11] presented the linear time - branching time spectrum of behavioral equivalences for finitely branching, concrete, sequential processes. In this paper we focus on *failure semantics* [6, 7], which distinguishes a process by its “failure pairs”, which consist of a finite (partial) trace together with a set of actions that cannot be executed at the ultimate state of this trace. Other semantics in the spectrum are based on (bi)simulation and on (decorated) traces. Figure 1 depicts the linear time - branching time spectrum, where a directed edge from one equivalence to another means that the source of the edge is finer than the target.

Van Glabbeek [10, 11] studied the semantics in his spectrum in the setting of the process algebra BCCSP, which contains only basic process algebraic operators from CCS and CSP, but is sufficiently powerful to express all finite synchronization trees. Van Glabbeek gave (sound and complete) axiomatizations for semantics in the spectrum, meaning that two *closed* BCCSP terms (i.e., terms that do not contain variables) can be equated if and only if they are equivalent.

An axiomatization E is ω -complete when an equation can be derived from E if (and only if) all its closed instantiations can be derived from E . In theorem proving applications, it is convenient if an axiomatization has this property, because it means that proofs by (structural) induction can be avoided in favor

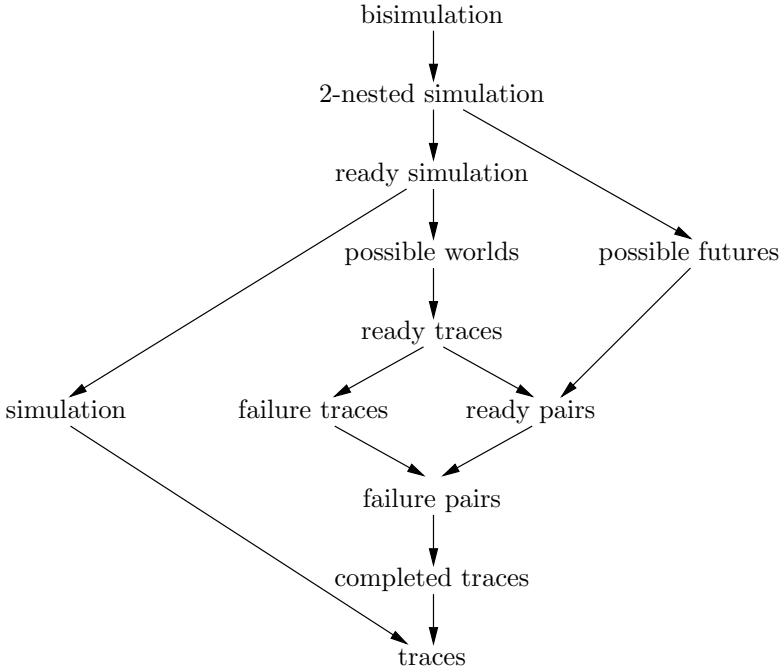

Fig. 1. The linear time - branching time spectrum

of purely equational reasoning; see [16]. In [14] it was argued that ω -completeness is desirable for the partial evaluation of programs.

Notable examples of ω -incomplete axiomatizations in the literature are the $\lambda K\beta\eta$ -calculus (see [27]) and the equational theory of CCS [20]. Therefore laws such as commutativity of parallelism, which are valid in the initial model but which cannot be derived, are often added to the latter equational theory. For such extended equational theories, ω -completeness results were presented in the setting of CCS [22] and ACP [8]. Another negative result, for basic process algebra with the binary Kleene star, was reported in [2]: semantics no coarser than completed trace equivalence and no finer than ready simulation equivalence have no finite (sound and complete) axiomatization, so by default no finite ω -complete axiomatization.

A number of positive and negative results regarding finite ω -complete axiomatizations for BCCSP occur in the literature. Moller [22] proved that the finite axiomatization for BCCSP modulo bisimulation equivalence is ω -complete. Groote [12] presented a similar result for completed trace equivalence, for trace equivalence (in case of an alphabet with more than one element), and for readiness, failure and failure trace equivalence (in case of an infinite alphabet). Blom, Fokkink and Nain [4] proved that in case of an infinite alphabet, BCCSP modulo ready trace equivalence does not have a finite (sound and complete) axiomatization. Aceto, Fokkink and Ingólfssdóttir [3] proved a similar negative result

for 2-nested simulation equivalence, independent of the cardinality of the alphabet.¹ Fokkink and Nain [9] showed that in case of a finite alphabet with more than one element, BCCSP modulo any semantics no coarser than readiness equivalence and no finer than possible worlds equivalence does not have a finite ω -complete axiomatization.

A *basis* of an equational theory is a set of axioms from which all equations in the theory can be derived. The existence of a finite basis for an equational theory is a classic topic of study in universal algebra (see, e.g., [19]), dating back to Lyndon [17]. Murskiĭ [24] proved that “almost all” finite algebras (namely all quasi-primal ones) are finitely based, while in [23] he presented an example of a three-element algebra that has no finite basis. Henkin [15] showed that the algebra of naturals with addition and multiplication is finitely based, while Gurevič [13] showed that after adding exponentiation the algebra is no longer finitely based. McKenzie [18] settled Tarski’s Finite Basis Problem in the negative, by showing that the general question whether a finite algebra is finitely based is undecidable.

In this paper we present a finite ω -complete axiomatization for BCCSP modulo failure semantics. This provides a positive answer to an open question from [12]. The axiomatization consists of the standard axioms A1-4 for bisimulation, two standard axioms F1-2 for failure semantics, and a new axiom F3 that requires a finite alphabet. The latter axiom was obtained by considering *cover equations*, which aim to obtain a full coverage of the equational theory for (in this case) failure semantics. The central idea is that it is sufficient to only consider equations of the form $at + u \approx u$ and $x + u \approx u$ (where a denotes an action, x a variable, and t, u BCCSP terms). We classified the sound equations of this form, which we call *cover equations*. Now one can proceed in two ways. Either one can determine an infinite family of cover equations that obstructs a finite basis; this approach we took in [9] to prove the absence of a finite basis for a range of process semantics. Or one can determine a finite basis among the cover equations; this approach is followed in the current paper. We only present A1-4 and F1-3 together with a proof that this axiomatization is ω -complete, as the full classification of cover equations is quite involved and not needed for the proof.

We also present a proof that A1-4 together with F1-2 are ω -complete in case of an infinite alphabet. This proof is considerably simpler than the proof in [12], and moreover it is a sub-proof of the proof that A1-4 together with F1-3 are ω -complete in case of a finite alphabet. Last but not least, our axioms F1-2 are simplifications with respect to the axioms for failure equivalence as presented in [11, 12].

Groote [12] also asked whether in case of a finite alphabet, BCCSP modulo failure trace semantics has a finite ω -complete axiomatization. This question remains open.

¹ In case of an infinite alphabet, occurrences of action names in axioms should be interpreted as variables, as else most of the axiomatizations mentioned in this paragraph would be infinite.

2 Preliminaries

Syntax of BCCSP. $BCCSP(A)$ is a basic process algebra for expressing finite process behavior. Its syntax consists of closed (process) terms p, q that are constructed from a constant $\mathbf{0}$, a binary operator $+$ called *alternative composition*, and unary *prefix* operators $a\cdot$, where a ranges over a nonempty set A of actions, called the *alphabet* (with typical elements a, b, c). Open terms t, u can moreover contain variables from a countably infinite set V (with typical elements x, y, z). A (closed) substitution maps variables in V to (closed) terms. For every term t and substitution σ , the term $\sigma(t)$ is obtained by replacing every occurrence of a variable x in t by $\sigma(x)$.

Transition rules. Intuitively, closed terms represent finite process behaviors, where $\mathbf{0}$ does not exhibit any behavior, $p + q$ is the nondeterministic choice between the behaviors of p and q , and ap executes action a to transform into p . This intuition is captured, in the style of Plotkin [26], by the transition rules below, which give rise to A -labeled transitions between closed terms.

$$\frac{}{ax \xrightarrow{a} x} \quad \frac{x \xrightarrow{a} x'}{x + y \xrightarrow{a} x'} \quad \frac{y \xrightarrow{a} y'}{x + y \xrightarrow{a} y'}$$

The *depth* of a term t , denoted by $depth(t)$, is the maximal number of transitions in sequence that t can exhibit. It is defined by: $depth(\mathbf{0}) = 0$, $depth(x) = 0$, $depth(t + u) = \max\{depth(t), depth(u)\}$, and $depth(at) = depth(t) + 1$.

For a closed term p , $\mathcal{I}(p)$ denotes the set of actions a for which there exists a transition $p \xrightarrow{a} p'$.

Definition 1. A pair $(a_1 \cdots a_k, B)$ with $B \subseteq A$ and $k \geq 0$ is a failure pair of p_0 if $p_0 \xrightarrow{a_1} p_1 \cdots \xrightarrow{a_k} p_k$ with $\mathcal{I}(p_k) \cap B = \emptyset$. Two closed terms p and q are failure equivalent, denoted by $p \sim_F q$, if they have exactly the same failure pairs.

Failure equivalence is a *congruence* for $BCCSP(A)$, meaning that $p_1 \sim_F q_1$ and $p_2 \sim_F q_2$ implies $ap_1 \sim_F aq_1$ for $a \in A$ and $p_1 + p_2 \sim_F q_1 + q_2$. This follows from the fact that the transition rules above are in the failure format from [5].

Axiomatization. An (equational) axiomatization E for $BCCSP(A)$ is a collection of equations $t \approx u$. We write $E \vdash t \approx u$ if this equation can be derived from the equations in E using the standard rules of equational logic, and $E \vdash F$ if $E \vdash t \approx u$ for all $t \approx u \in F$. An axiomatization E is *sound* modulo an equivalence \sim on closed terms if $(E \vdash p \approx q) \Rightarrow p \sim q$, and it is *complete* modulo \sim if $p \sim q \Rightarrow (E \vdash p \approx q)$, for all closed terms p and q . An axiomatization E is ω -complete if for each equation $t \approx u$ with $E \vdash \sigma(t) \approx \sigma(u)$ for all closed substitutions σ , we have $E \vdash t \approx u$.

The core axioms A1-4 below from [20] are sound and complete for $BCCSP(A)$ modulo bisimulation equivalence [25], which is the finest semantics in the linear time - branching time spectrum (see Figure 1).

- A1 $x + y \approx y + x$
- A2 $(x + y) + z \approx x + (y + z)$
- A3 $x + x \approx x$
- A4 $x + \mathbf{0} \approx x$

In the remainder of this paper, process terms are considered modulo A1-4.

We use *summation* $\sum_{i=1}^k t_i$ or $\sum_{i \in \{1, \dots, k\}} t_i$, with $k \geq 0$, to denote $t_1 + \dots + t_k$, where the empty sum denotes $\mathbf{0}$. Each process term is of the form $\sum_{i=1}^k a_i t_i + \sum_{j=1}^\ell x_j$. The $a_i t_i$ and x_j are called the *summands* of this process term.

As binding convention, alternative composition and summation bind weaker than prefixing.

3 A Finite Basis for Failure Semantics

3.1 Cover Equations

The central idea is that for bisimulation semantics, and thus for all process semantics in the linear time - branching time spectrum, axiom A3 is sound. So if an equation $t \approx u$ is sound, then $u + t \approx t$ and $t + u \approx u$ are sound too; and from the last two equations one can derive $t \approx u$, using axiom A1. Hence, by A2 and A4, it is sufficient to only consider sound equations of the form $at + u \approx u$ and $x + u \approx u$. We call these the *cover equations*. We present three lemmas that limit the form that cover equations can have.

Lemma 1. *If $t \approx u$ is sound modulo \sim_F , then t and u have the same variable summands.*

Proof. Let $x \in V$ be a summand of t . We define $\sigma(x) = a^{\text{depth}(u)+1}\mathbf{0}$ for some $a \in A$, and $\sigma(y) = \mathbf{0}$ for $y \neq x$. Then $(a^{\text{depth}(u)+1}, A)$ is a failure trace of $\sigma(t)$, so it must be a failure trace of $\sigma(u)$. This implies that x is a summand of u . \square

Remark 1. Lemma 1 fails for trace equivalence. Namely, let $A = \{a\}$. Then $x + ax \approx ax$ is sound modulo trace equivalence. Lemma 1 does hold for completed trace equivalence.

Lemma 2. *If $at + u + bv \approx u + bv$ with $a \neq b$ is sound modulo \sim_F , then $at + u \approx u$ is sound modulo \sim_F .*

Proof. Since $at + u + bv \approx u + bv$ is sound modulo \sim_F and $a \neq b$, for each closed substitution σ :

- $\mathcal{I}(\sigma(at + u)) = \mathcal{I}(\sigma(u))$, and
- each failure pair $(ab_1 \dots b_k, B)$ of $a\sigma(t)$ is a failure pair of $\sigma(u)$.

So $at + u \approx u$ is sound modulo \sim_F . \square

Lemma 3. *If $t + x \approx u + x$ is sound modulo \sim_F , and x is not a summand of $t + u$, then $t \approx u$ is sound modulo \sim_F .*

Proof. Suppose that $t \approx u$ is not sound modulo \sim_F ; we prove that then $t + x \approx u + x$ is not sound modulo \sim_F .

$\sigma(t) \not\sim_F \sigma(u)$ for some closed substitution σ . Without loss of generality we can assume that some failure pair $(b_1 \cdots b_k, B_0)$ of $\sigma(t)$ is not a failure pair of $\sigma(u)$. The (fixed) set B_0 will play a crucial role in the construction below. We distinguish two cases.

1. $k = 0$.

Then $\mathcal{I}(\sigma(t)) \neq \mathcal{I}(\sigma(u))$. Let $\sigma'(x) = \mathbf{0}$ and $\sigma'(y) = \sigma(y)$ for $y \neq x$. Since x is not a summand of $t + u$, $\mathcal{I}(\sigma'(t + x)) = \mathcal{I}(\sigma(t))$ and $\mathcal{I}(\sigma'(u + x)) = \mathcal{I}(\sigma(u))$. Then $\mathcal{I}(\sigma'(t + x)) \neq \mathcal{I}(\sigma'(u + x))$, and so $\sigma'(t + x) \not\sim_F \sigma'(u + x)$.

2. $k > 0$.

We define a substitution σ' such that $\sigma'(y) = \sigma(y)$ for $y \neq x$, and $\sigma'(x)$ has the same failure pairs $(c_1 \cdots c_\ell, B_0)$ as $\sigma(x)$ for $\ell < k$, while it does not have failure pairs $(c_1 \cdots c_k, B_0)$. We obtain $\sigma'(x)$ from $\sigma(x)$ by replacing subterms ap at depth $k - 1$ by $\mathbf{0}$ if $a \notin B_0$, or by $aa\mathbf{0}$ if $a \in B_0$. That is,

$$\sigma'(x) = chop_{k-1}(\sigma(x))$$

where

$$\begin{aligned} chop_m(\mathbf{0}) &= \mathbf{0} \\ chop_m(p + q) &= chop_m(p) + chop_m(q) \\ chop_0(ap) &= \begin{cases} \mathbf{0} & \text{if } a \notin B_0 \\ aa\mathbf{0} & \text{if } a \in B_0 \end{cases} \\ chop_{m+1}(ap) &= a chop_m(p) \end{aligned}$$

We prove the two desired properties concerning the failure pairs of $chop_m(p)$, for $m \geq 0$ and closed terms p . Let c_1, \dots, c_{m+1} range over A .

I For $\ell \leq m$, p and $chop_m(p)$ have the same failure pairs $(c_1 \cdots c_\ell, B_0)$.

We use induction on ℓ . *Base case:* Since the summands of $chop_0(p)$ are $aa\mathbf{0}$ with $a \in \mathcal{I}(p) \cap B_0$, $\mathcal{I}(p) \cap B_0 = \emptyset$ if and only if $\mathcal{I}(chop_0(p)) \cap B_0 = \emptyset$. *Inductive case:* Let $\ell + 1 \leq m$. By induction, for closed terms q , q and $chop_{m-1}(q)$ have the same failure pairs $(c_2 \cdots c_{\ell+1}, B_0)$. Since $m > 0$, the transitions of $chop_m(p)$ are $chop_m(p) \xrightarrow{c_1} chop_{m-1}(p')$ for $p \xrightarrow{c_1} p'$. Hence p and $chop_m(p)$ have the same failure pairs $(c_1 \cdots c_{\ell+1}, B_0)$.

II $chop_m(p)$ does not have failure pairs $(c_1 \cdots c_{m+1}, B_0)$.

We use induction on m . *Base case:* Since the summands of $chop_0(p)$ are $aa\mathbf{0}$ with $a \in \mathcal{I}(p) \cap B_0$, $chop_0(p)$ does not have a failure pair (c_1, B_0) . *Inductive case:* By induction, for closed terms q , $chop_m(q)$ does not have failure pairs $(c_2 \cdots c_{m+2}, B_0)$. Since the transitions of $chop_{m+1}(p)$ are $chop_{m+1}(p) \xrightarrow{c_1} chop_m(p')$ for $p \xrightarrow{c_1} p'$, it follows that $chop_{m+1}(p)$ does not have failure pairs $(c_1 \cdots c_{m+2}, B_0)$.

We proceed to relate the failure pairs of $\sigma(t_0)$ and $\sigma'(t_0)$, for terms t_0 .

III For $\ell < k$, $\sigma(t_0)$ and $\sigma'(t_0)$ have the same failure pairs $(c_1 \cdots c_\ell, B_0)$.

We apply induction on ℓ . *Base case:* Clearly, $\sigma(x) \cap B_0 = \emptyset$ if and only if $\sigma'(x) \cap B_0 = \emptyset$, and moreover $\sigma(y) = \sigma'(y)$ for $y \neq x$. This implies that $\mathcal{I}(\sigma(t_0)) \cap B_0 = \emptyset$ if and only if $\mathcal{I}(\sigma'(t_0)) \cap B_0 = \emptyset$. *Inductive case:*

Let $\ell + 1 < k$. We prove for each summand of t_0 that applying σ or σ' gives rise to the same failure pairs $(c_1 \cdots c_{\ell+1}, B_0)$. By property I, $\sigma(x)$ and $\sigma'(x)$ have the same failure pairs $(c_1 \cdots c_{\ell+1}, B_0)$. Moreover, $\sigma(y) = \sigma'(y)$ for $y \neq x$. Furthermore, by induction, for each summand $c_1 t_1$ of t_0 , $\sigma(t_1)$ and $\sigma'(t_1)$ have the same failure pairs $(c_2 \cdots c_{\ell+1}, B_0)$; so $\sigma(c_1 t_1)$ and $\sigma'(c_1 t_1)$ have the same failure pairs $(c_1 \cdots c_{\ell+1}, B_0)$.

IV If t_0 does not have the summand x , then $\sigma(t_0)$ and $\sigma'(t_0)$ have the same failure pairs $(c_1 \cdots c_k, B_0)$.

We prove for each summand of t_0 that applying σ or σ' gives rise to the same failure pairs $(c_1 \cdots c_k, B_0)$. $\sigma(y) = \sigma'(y)$ for $y \neq x$. Furthermore, by property III, for each summand $c_1 t_1$ of t_0 , $\sigma(t_1)$ and $\sigma'(t_1)$ have the same failure pairs $(c_2 \cdots c_k, B_0)$; so $\sigma(c_1 t_1)$ and $\sigma'(c_1 t_1)$ have the same failure pairs $(c_1 \cdots c_k, B_0)$.

Recall that $(b_1 \cdots b_k, B_0)$ is a failure pair of $\sigma(t)$ and not of $\sigma(u)$. Since x is not a summand of $t + u$, by property IV, $(b_1 \cdots b_k, B_0)$ is a failure pair of $\sigma'(t)$ and not of $\sigma'(u)$. Since $k > 0$, $(b_1 \cdots b_k, B_0)$ is a failure pair of $\sigma'(t + x)$. By property II, $\sigma'(x) = \text{chop}_{k-1}(\sigma(x))$ does not have the failure pair $(b_1 \cdots b_k, B_0)$, so $(b_1 \cdots b_k, B_0)$ is not a failure pair of $\sigma'(u + x)$. Hence $\sigma'(t + x) \not\sim_{\text{F}} \sigma'(u + x)$.

We conclude that $t + x \approx u + x$ is not sound modulo \sim_{F} . \square

Remark 2. The condition in Lemma 3 that x is not a summand of $t + u$ is essential. For instance, $x + x \approx \mathbf{0} + x$ is sound modulo \sim_{F} , but $x \approx \mathbf{0}$ is not.

Remark 3. There exist equivalences in between bisimulation and partial traces that are a congruence for $\text{BCCSP}(A)$, but for which Lemma 2 and/or Lemma 3 fail. So these lemmas have to be proved for each equivalence in the linear time - branching time spectrum individually.

3.2 ω -Complete Axiomatizations for Failure Semantics

We present two axioms for failure semantics.²

$$\begin{aligned} \text{F1} \quad & a(x + y) + ax + a(y + z) \approx ax + a(y + z) \\ \text{F2} \quad & a(x + by) + a(x + by + bz) \approx a(x + by + bz) \end{aligned}$$

It is not hard to see that F1 and F2 are sound for $\text{BCCSP}(A)$ modulo \sim_{F} .

Theorem 1. [10] *A1-4+F1-2 is complete for $\text{BCCSP}(A)$ modulo \sim_{F} .*

Theorem 2. [12] *If $|A| = \infty$, then A1-4+F1-2 is ω -complete.*

In case of a finite alphabet, A1-4+F1-2 is not ω -complete. Let $A = \{a_1, \dots, a_n\}$ for some $n > 0$. Then the following axiom is sound for $\text{BCCSP}(A)$ modulo \sim_{F} .

² Van Glabbeek [11] and Groote [12] presented a somewhat more complicated version of F2. In [11] it takes the form $a(bx + u) + a(by + v) \approx a(bx + by + u) + a(by + v)$.

$$F3_n \quad a(x + \sum_{i=1}^n a_i z_i) + a(x + y + \sum_{i=1}^n a_i z_i) \approx a(x + y + \sum_{i=1}^n a_i z_i)$$

$F3_n$ cannot be derived from A1-4+F1-2. This follows from the fact that A1-4+F1-2 are sound for $BCCSP(A)$ modulo \sim_F in case of an infinite alphabet, while $F3_n$ is not.

Theorem 3. *If $A = \{a_1, \dots, a_n\}$, then A1-4+F1-2+F3_n is ω -complete.*

The main aim of this paper is to present a proof of Theorem 3. Furthermore, although Theorems 1 and 2 have already been proved in earlier papers, we provide new proofs here. First of all, since axiom F2 is presented in a simpler form here than in [11, 12], strictly speaking Theorems 1 and 2 have not been proved in [10, 12], but are immediate corollaries from results in those papers and the fact that the earlier axiom $a(bx + u) + a(by + v) \approx a(bx + by + u) + a(by + v)$ can be derived from A1-4+F1-2. More important, Theorems 1 and 2 follow immediately from our proof of Theorem 3. So we obtain the new proofs for free, and moreover they are considerably simpler than the old proofs. In particular, the new proofs are fully equational, and more direct than the old proofs, which involve term rewriting and normal forms.

By abuse of notation, we let a finite set $X \subset V$ denote the term $\sum_{x \in X} x$. From now on, X, Y (possibly subscripted) denote finite subsets of V .

Proof. We derive all equations $t \approx u$ that are sound modulo \sim_F , by induction on $\max\{\text{depth}(t), \text{depth}(u)\}$. Clearly $u + t \approx t$ and $t + u \approx u$ are sound too; and from the last two equations one can derive $t \approx u$. So it suffices to derive all sound equations of the form $at + u \approx u$ and $x + u \approx u$. In view of Lemma 1, soundness of $x + u \approx u$ implies that x is a summand of u , so that $x + u \approx u$ follows from A3. So it suffices to derive all sound equations of the form $at + u \approx u$. In view of Lemmas 2 and 3, we can take u to be of the form $\sum_{j \in J} au_j$. (Note that the equations to-be-proved, which are thus obtained from the original equation $t \approx u$, involve terms with a depth $\leq \max\{\text{depth}(t), \text{depth}(u)\}$; so the induction order is respected.)

Hence, to prove Theorems 1, 2 and 3, it suffices to prove that each equation $at + \sum_{j \in J} au_j \approx \sum_{j \in J} au_j$ that is sound modulo \sim_F can be derived from A1-4+F1-2 in case of an infinite alphabet, and from A1-4+F1-2+F3_n in case of a finite alphabet with n elements. Consider such a sound equation modulo \sim_F :

$$a(X + \sum_{i \in I} b_i t_i) + \sum_{j \in J} a(Y_j + \sum_{k \in K} c_k u_k) \approx \sum_{j \in J} a(Y_j + \sum_{k \in K} c_k u_k) \quad (1)$$

As said before, we apply induction on the depth of the terms in the equation. In the base case of the induction, $I = \emptyset$ and $K_j = \emptyset$ for $j \in J$.

The main idea of the proof will be to restrict the syntactic form that the summands in equation (1) can have, by exploiting the fact that it is sound modulo \sim_F . Thus the application of a suitable closed substitution can provide information on syntactic relations between the summands.

Suppose, towards a contradiction, that $X \not\subseteq \cup_{j \in J} Y_j$. Let $x \in X \setminus (\cup_{j \in J} Y_j)$. Let σ be a closed substitution with $\sigma(x) = a^\ell \mathbf{0}$ where ℓ is greater than the depth

of the terms in (1), and $\sigma(y) = \mathbf{0}$ for all $y \neq x$. Then clearly $(a^{\ell+1}, A)$ is a failure pair of $\sigma(a(X + \sum_{i \in I} b_i t_i))$, but not of $\sigma(\sum_{j \in J} a(Y_j + \sum_{k \in K} c_k u_k))$ for $j \in J$, contradicting the soundness of (1). Hence $X \subseteq \cup_{j \in J} Y_j$.

Suppose, towards a contradiction, that $\{b_i \mid i \in I\} \not\subseteq \cup_{j \in J} \{c_k \mid k \in K_j\}$. Let $b \in \{b_i \mid i \in I\} \setminus \cup_{j \in J} \{c_k \mid k \in K_j\}$. Let σ be the closed substitution with $\sigma(y) = \mathbf{0}$ for all $y \in V$. Then clearly (ab, \emptyset) is a failure pair of $\sigma(a(X + \sum_{i \in I} b_i t_i))$, but not of $\sigma(a(Y_j + \sum_{k \in K} c_k u_k))$ for $j \in J$, contradicting the soundness of (1). Hence $\{b_i \mid i \in I\} \subseteq \cup_{j \in J} \{c_k \mid k \in K_j\}$.

Since (1) is sound, clearly

$$X + \sum_{i \in I} b_i t_i + \sum_{j \in J} (Y_j + \sum_{k \in K} c_k u_k) \approx \sum_{j \in J} (Y_j + \sum_{k \in K} c_k u_k) \quad (2)$$

is also sound modulo $\sim_{\mathbb{F}}$. Let $L_j = \{k \in K_j \mid c_k \in \{b_i \mid i \in I\}\}$. By Lemmas 2 and 3, (2) implies that

$$\sum_{i \in I} b_i t_i + \sum_{j \in J} \sum_{k \in L} c_k u_k \approx \sum_{j \in J} \sum_{k \in L} c_k u_k \quad (3)$$

is sound modulo $\sim_{\mathbb{F}}$. Hence, by induction on depth (or, in the base case, because $I = \emptyset$ and $L_j = \emptyset$ for $j \in J$), it can be derived from A1-4, F1-2 and, in case of a finite alphabet with n elements, F3 _{n} .

We consider two cases.

1. $\{b_i \mid i \in I\} \neq A$.

Suppose, towards a contradiction, that for all $j \in J$, either $Y_j \not\subseteq X$ or $\{c_k \mid k \in K_j\} \not\subseteq \{b_i \mid i \in I\}$. Let $c \in A \setminus \{b_i \mid i \in I\}$. Let σ be the closed substitution with $\sigma(x) = \mathbf{0}$ for $x \in X$ and $\sigma(y) = c$ for $y \notin X$. Then clearly $(a, A \setminus \{b_i \mid i \in I\})$ is a failure pair of $\sigma(a(X + \sum_{i \in I} b_i t_i))$, but not of $\sigma(a(Y_j + \sum_{k \in K} c_k u_k))$ for $j \in J$, contradicting the soundness of (1). Hence there is a $j_0 \in J$ such that $Y_{j_0} \subseteq X$ and $\{c_k \mid k \in K_{j_0}\} \subseteq \{b_i \mid i \in I\}$.

We start with the term $\sum_{j \in J} a(Y_j + \sum_{k \in K} c_k u_k)$. Since $Y_{j_0} \subseteq X \subseteq \cup_{j \in J} Y_j$ and $K_{j_0} = L_{j_0}$, we can use F1 to convert the summand $a(Y_{j_0} + \sum_{k \in K} c_k u_k)$ into $a(X + \sum_{j \in J} \sum_{k \in L} c_k u_k)$. By (3) we convert this into $a(X + \sum_{i \in I} b_i t_i + \sum_{j \in J} \sum_{k \in L} c_k u_k)$. Finally, since $c_k \in \{b_i \mid i \in I\}$ for $k \in L_{j_0}$ and $j_0 \in J$, we can use F2 to convert this into $a(X + \sum_{i \in I} b_i t_i)$. Thus we have derived (1).

2. $\{b_i \mid i \in I\} = A$. Note that in this case A is finite.

We start with the term $\sum_{j \in J} a(Y_j + \sum_{k \in K} c_k u_k)$. Using F1 we can create the summand $a(\sum_{j \in J} Y_j + \sum_{j \in J} \sum_{k \in K} c_k u_k)$. Note that $K_j = L_j$ for $j \in J$, because $\{b_i \mid i \in I\} = A$. So we can use (3) to convert this summand into $a(\sum_{j \in J} Y_j + \sum_{i \in I} b_i t_i + \sum_{j \in J} \sum_{k \in K} c_k u_k)$. Finally, since $X \subseteq \cup_{j \in J} Y_j$ and $\{b_i \mid i \in I\} = A$, we can use F3 _{$|A|$} to convert this into $a(X + \sum_{i \in I} b_i t_i)$. Thus we have derived (1).

We note that in case of an infinite alphabet, the axioms F3 _{n} were not used in the derivation of (1). \square

Spatial Logics for Bigraphs[★]

² Università Ca' Foscari di Venezia

³ University of Sussex

Abstract. Bigraphs are emerging as an interesting model for concurrent calculi, like CCS, pi-calculus, and Petri nets. Bigraphs are built orthogonally on two structures: a hierarchical place graph for locations and a link (hyper-)graph for connections. With the aim of describing bigraphical structures, we introduce a general framework for logics whose terms represent arrows in monoidal categories. We then instantiate the framework to bigraphical structures and obtain a logic that is a natural composition of a place graph logic and a link graph logic. We explore the concepts of separation and sharing in these logics and we prove that they generalise some known spatial logics for trees, graphs and tree contexts.

1 Introduction

To describe and reason about structured, distributed, dynamic resources is one of the main goals of global computing research. Recently, many *spatial logics*, in different contexts, have been studied to fulfill this goal. The term ‘spatial,’ as opposed to ‘temporal,’ refers to the use of modal operators inspecting the structure of the terms in the considered model. Spatial logics are usually equipped with a separation/composition binary operator that *splits* a term into two parts, in order to ‘talk’ about them separately. Looking closely, we observe that the notion of *separation* is interpreted differently in different logics. In ‘separation’ logics [18], it is used to reason about dynamic update of heap-like structures, and it is *strong* in that it forces names of resources in separated components to be disjoint. As a consequence, term composition is usually partially defined. In static spatial logics (e.g., for trees [2], graphs [4] or trees with hidden names [5]), the separation/composition does not require any constraint on terms, and names are usually shared between separated parts. Similarly in dynamic spatial logics (for, e.g., ambients [6] or π -calculus [1]), where the separation is intended only for location in space. Context tree logic, introduced in [3], integrates the first approach above with a spatial logic for trees. The result is a logic able to express properties of tree-shaped structures (and contexts) with pointers, and it is used as an assertion language for Hoare-style program specifications in a tree memory model.

Bigraphs [12, 14] are an emerging model for structures in global computing, which can be instantiated to model several well-known examples, including CCS [17], π -calculus [12], and Petri nets [16]. Bigraphs consist essentially of two graphs sharing the same nodes. The first graph, the *place graph*, is tree structured and expresses a hierarchical relationship on nodes (viz. locality in space and nesting of locations). The second graph, the *link graph*, is an hyper-graph and expresses a generic “*many-to-many*” relationship among nodes (e.g. data link, sharing of a channel). The two structures are orthogonal, so links between nodes can cross locality boundaries. Thus, bigraphs make clear the difference between structural separation (i.e., separation in the place graph) and name separation (i.e., separation on the link graph).

In this paper we introduce a spatial logic for bigraphs as a natural composition of a place graph logic (for tree contexts) and a link graph logic (for name linkings). The main point is that a resource has a spatial structure as well as a link structure associated to it. Suppose for instance to be describing a tree-shaped distribution of resources in locations. We may use formulae like $\text{PC}(A)$ and $\text{PC}_x(A)$ to describe a resource in an unnamed location, respectively location x , of ‘type’ PC (e.g. a computer) whose contents satisfy A . We can then write $\text{PC}(\mathbf{T}) \otimes \text{PC}(\mathbf{T})$ to characterise terms with two unnamed PC resources whose contents satisfy the tautological formula (i.e., with anything inside). Using named locations, as e.g. in $\text{PC}_a(\mathbf{T}) \otimes \text{PC}_b(\mathbf{T})$, we are able to express name separation, i.e., that names a and b are different. Furthermore, using link expressions we can force name-sharing between resources with formulae like:

$$\text{PC}_a(\text{in}_c \otimes \mathbf{T}) \overset{c}{\otimes} \text{PC}_b(\text{out}_c \otimes \mathbf{T})$$

This describes two PC with different names, a and b , sharing a link on a distinct name c , which models, e.g., a communication channel. Name c is used as input (in) for the first PC and as an output (out) for the second PC . No other names are shared and c cannot be used elsewhere inside the PC s.

A bigraphical structure is, in general, a context with several holes and open links that can be filled by composition. This means that the logic can describe contexts for resources at no additional cost. We can then express formulae like $\text{PC}_a(\mathbf{T} \otimes \text{HD}(id_1))$ that describes a modular computer PC , where id_1 represents a ‘pluggable’ hole in the hard disc HD . Contextual resources have many important applications. In particular, the contextual nature of bigraphs is useful to specify reaction rules, but it can also be used as a general mechanism to describe contexts of bigraphical data structures (cf. [8, 10]).

As bigraphs are establishing themselves as a truly general (meta)model of global systems, our bigraph logic, *BiLog*, aims at achieving the same generality as a description language: as bigraphs specialise to particular models, we expect *BiLog* to specialise to powerful logics on these. In this sense, the contribution of this paper is to propose *BiLog* as a unifying language for the description of global resources. We will explore this path in future work, fortified by the positive preliminary results obtained for semistructured data [8] and CCS [9].

2 An Informal Introduction to Bigraphs

Bigraphs formalise distributed systems by focusing on two of their main characteristics: locality and interconnections. A bigraph consists of a set of *nodes*, which may be nested in a hierarchical tree structure (the so-called *place graph*), and have ports that may be connected to each other (and to names) by *links* (the so-called *link graph*). Place graphs express locality, i.e., the physical arrangement of the nodes. Link graphs are hypergraphs and formalise connections among nodes. The orthogonality of the two structures dictates that nestings impose no constrain upon interconnections.

The bigraph G of Fig. 1 represents a system where people and things interact. We imagine two offices with employees logged on PCs. Every entity is represented by a node, shown with bold outlines, and every node is associated with a *control* (either PC, U, R1, R2). Controls represent kinds of nodes, and have fixed *arities* that determine their number of ports. Control PC marks nodes representing computers, and its arity is 3: in clockwise order, these ports represent a keyboard interacting with an employee U, a LAN to an other PC and open to the outside network, and a plug connecting the computer to the electrical mains of office R. Employees U may communicate with each other via the upper port in the picture. The nesting of nodes (place graph) is shown by the inclusion of nodes into each other; the connections (link graph) are drawn like lines.

At the top level of the nesting structure sit the *regions*. In Fig. 1 there is one sole region (the dotted box). Inside nodes there may be ‘context’ *holes*, drawn as shaded boxes, which are uniquely identified by ordinals. In figure the hole marked by 1 represents the possibility for another user U to get into office R1 and sit in front of a PC. The hole marked by 2 represents the possibility to plug a subsystem inside office R2.

Place graphs can be seen as *arrows* over a symmetric monoidal category whose objects are finite ordinals. We write $P : m \rightarrow n$ to indicate a place graph P with m holes and n regions. In Fig. 1, the place graph of G is of type $2 \rightarrow 1$. Given place graphs P_1, P_2 , their composition $P_1 \circ P_2$ is defined only if the holes of P_1 are as many as the regions of P_2 , and amounts to *filling* holes with regions, according to the number each carries. The tensor product $P_1 \otimes P_2$ is not commutative, as it ‘renumbers’ regions and holes ‘from left to right’.

Link graphs are arrows of a partial monoidal category whose objects are (finite) sets Λ of names, that we assume to be *denumerable*. A link graph is an arrow $X \rightarrow Y$,

Fig. 1. A bigraph $G : \langle 2, \{x, y, z, v, w\} \rangle \rightarrow \langle 1, \{x, y\} \rangle$

Fig. 2. Bigraphical composition, $H \equiv G \circ (F_1 \otimes F_2)$

with $X, Y \subseteq \Lambda$. The set X represents the *inner* names (drawn at the bottom of the bi-graph) and Y represents the set of *outer* names (drawn on the top). The link graph connects ports to names or to *edges*, in any finite number. A link to a name is *open*, i.e., it may be connected to other nodes as an effect of composition. A link to an edge (represented in Fig. 1 by a line between nodes) is *closed*, as it cannot be further connected to ports. Thus, edges are *private*, or hidden, connections. The composition of link graphs $W \circ W'$ corresponds to *linking* the inner names of W with the corresponding outer names of W' and forgetting about their identities. As a consequence, the outer names of W' (resp. inner names of W) are not necessarily inner (resp. outer) names of $W \circ W'$, and the link graphs can perform substitution and renaming. The tensor product of link graphs is defined in the obvious way only if their inner (resp. outer) names are disjoint.

Combining ordinals with names we obtain *interfaces*, i.e., pairs $\langle m, X \rangle$ where m is an ordinal and X is a set of names. Combining the notion of place graph and link graphs on the same nodes we obtain the notion of bigraphs, i.e., arrows $G : \langle m, X \rangle \rightarrow \langle n, Y \rangle$.

Fig. 2 represents a more complex situation. At the top left-hand side is the system of Fig. 1, At the bottom left-hand side F_1 represents a user U ready to interact with a PC or with some other users, F_2 represents a user logged on its laptop, ready to communicate with other users. The system with F_1 and F_2 represents the tensor product $F = F_1 \otimes F_2$. The right-hand side of Fig. 2 represents the composition $G \circ F$. The idea is to insert F into the context G . The operation is partially defined, since it requires the inner names and the number of holes of G to match the outer names and the number of regions of F , respectively. Shared names create the new links between the two structures.

3 BiLog: Syntax and Semantics

As place and link graphs are arrows of a (partial) monoidal category, we first introduce a logic having monoidal categories as models and then we adapt it to model the orthogonal structures of place and link graphs. Each of these is expressive enough to model and generalise (e.g. by means of contexts) well-known spatial logics. Finally we apply the logic to model the whole structure of abstract bigraphs.

Table 1. BiLog($M, \otimes, \epsilon, \Theta, \equiv, \tau$)

$\Omega ::= id_I \mid \dots$	a constant formula for every Ω s.t. $\tau(\Omega)$
$A, B ::= \mathbf{F}$	false $A \Rightarrow B$ implication
\mathbf{id}	identity Ω Constant for a simple term
$A \otimes B$	tensor product $A \circ B$ composition
$A \circ\!-\! B$	left comp. adjunct $A \circ\!-\! B$ right comp. adjunct
$A \otimes\!-\! B$	left prod. adjunct $A \otimes\!-\! B$ right prod. adjunct
$G \models \mathbf{F}$	$\stackrel{def}{=} \text{never}$
$G \models A \Rightarrow B$	$\stackrel{def}{=} G \models A$ implies $G \models B$
$G \models \Omega$	$\stackrel{def}{=} G \equiv \Omega$
$G \models \mathbf{id}$	$\stackrel{def}{=} \exists I. G \equiv id_I$
$G \models A \otimes B$	$\stackrel{def}{=} \exists G_1, G_2. G \equiv G_1 \otimes G_2$ and $G_1 \models A$ and $G_2 \models B$
$G \models A \circ B$	$\stackrel{def}{=} \exists G_1, G_2. G \equiv G_1 \circ G_2$ and $\tau(G_1)$ and $G_1 \models A$ and $G_2 \models B$
$G \models A \circ\!-\! B$	$\stackrel{def}{=} \forall G'. G' \models A$ and $\tau(G')$ and $(G' \circ G) \downarrow$ implies $G' \circ G \models B$
$G \models A \circ\!-\! B$	$\stackrel{def}{=} \tau(G)$ implies $\forall G'. G' \models A$ and $(G \circ G') \downarrow$ implies $G \circ G' \models B$
$G \models A \otimes\!-\! B$	$\stackrel{def}{=} \forall G'. G' \models A$ and $(G' \otimes G) \downarrow$ implies $G' \otimes G \models B$
$G \models A \otimes\!-\! B$	$\stackrel{def}{=} \forall G'. G' \models A$ and $(G \otimes G') \downarrow$ implies $G \otimes G' \models B$

The models are categories built on a (possibly partial) monoid (M, \otimes, ϵ) , whose elements are dubbed *interfaces* and denoted by I, J . The elements of a BiLog model are arrows on the corresponding (partial) monoid. Given a set of term constructors Θ , ranged over by Ω , the arrows are defined by the term language $G ::= G \otimes G' \mid G \circ G' \mid \Omega$. Each Ω in Θ has a type $\Omega : I \rightarrow J$. For each interface I , we assume a distinguished construct $id_I : I \rightarrow I$. The types of constructors, together with the obvious rules [9] determine the type of each term. Terms of type $\epsilon \rightarrow J$ are called *ground*.

We consider terms up to a structural congruence \equiv , which subsumes the axioms of monoidal categories [9]. Later on, the congruence will be refined to model specialised structures, such as place graphs or bigraphs. All axioms are required to hold only when both sides are well typed. Throughout the paper, when using $=$ or \equiv we imply that both sides are defined and we write $(G) \downarrow$ to say that G is defined.

BiLog internalises the term constructors in the style of the ambient logic [6]. Constructors are represented in the logic as constant formulae, while tensor product and composition are expressed by connectives. We thus have two binary spatial operators. This contrasts with other spatial logics, which have only one: ambient-like logics, with parallel composition $A \mid B$, Separation Logic [18], with separating conjunction $A * B$, and Context Tree Logic [3], with application $K(P)$. Our logic is parameterised on a transparency predicate τ , reflecting that not every term can be directly observed in the logic: some are opaque and do not allow inspection of their contents. We will see that when all terms are observable (i.e. $\tau(G)$ for all G), logical equivalence corresponds to \equiv . Otherwise, it can be less discriminating. We assume that id_I and ground terms are always transparent, and τ preserves \equiv , hence \otimes and \circ , in particular.

The logic BiLog($M, \otimes, \epsilon, \Theta, \equiv, \tau$) is formally defined in Table 1 and the meaning of formulae is given in terms of a satisfaction relation. It features a logical constant

Ω for each *transparent* construct Ω . The satisfaction of logical constants is simply the congruence to the corresponding constructor. The *horizontal decomposition* formula $A \otimes B$ is satisfied by a term that can be decomposed as the tensor product of terms satisfying A and B respectively. The degree of separation enforced by \otimes between terms plays a fundamental role in the various fragments of the logic (notably link graph and place graph). The *vertical decomposition* formula $A \circ B$ is satisfied by terms that can be seen as the composition of terms satisfying A and B . We shall see that both connectives correspond in some cases to well known spatial connectives. We define the *left* and *right adjuncts* for composition and tensor to express extensional properties. The left adjunct $A \circ\text{-} B$ expresses the property of a term to satisfy B whenever inserted in a context satisfying A . Similarly, the right adjunct $A \text{-}\circ B$ expresses the property of a context to satisfy B whenever filled with a term satisfying A . A similar description for $\otimes\text{-}$ and $\text{-}\otimes$, the adjoints of \otimes . Observe that these collapse if the tensor is commutative in the model.

Derived Operators and Logical Properties. In Table 2 we outline some interesting operators that can be derived in BiLog. The operators constraining the interfaces are self-explanatory. The ‘dual’ operators have the following semantics: $A \ominus B$ is satisfied by terms G such that for every possible decomposition $G_1 \otimes G_2$ either $G_1 \models A$ or $G_2 \models B$. For instance, $A \ominus A$ describes terms where A is true in (at least) one part of each \otimes -decomposition. Similarly, the composition $A \bullet B$ expresses structural properties universally quantified on every \circ -decomposition. Both these connectives are useful to specify security properties or types. The adjuncts work as usual. The formulae $A^{\exists\otimes}$, $A^{\forall\otimes}$, $A^{\exists\circ}$, and $A^{\forall\circ}$ correspond to quantifications on the horizontal/vertical structure of terms. The equality between interfaces $I = J$ is easily derivable using \otimes and $\otimes\text{-}$.

We can extend the idea of *sublocation* (\sqsubseteq) defined in [7] to our terms. The inductive definition of \sqsubseteq specifies that $G \sqsubseteq G$, and $G' \sqsubseteq G$ if either $G \equiv G_1 \otimes G_2$, with $G' \sqsubseteq G_1$ (and symmetrically $G' \sqsubseteq G_2$) or $G \equiv G_1 \circ G_2$, with $\tau(G_1)$ and $G' \sqsubseteq G_2$. Exploiting this relation between ground terms, we define a *somewhere* modality. Intuitively, we say that a term satisfies $\diamond A$ whenever one of its sublocations satisfies A . Quite surprisingly, $\diamond A$ is expressible in the logic, as described in [9].

The lemma below states that the relation \models is well defined w.r.t. the congruence and that the interfaces for transparent terms can be observed.

Lemma 3.1 (Type and Congruence preservation).

For every couple of term G, G' , it holds: $G \models A$ and $G \equiv G'$ implies $G' \models A$.

For every term G , it holds: $G \models A_{I \rightarrow J}$ if and only if $G : I \rightarrow J$, $G \models A$, and $\tau(G)$.

BiLog induces a logical equivalence $=_L$ on terms in the usual sense, that is $G_1 =_L G_2$ if $G_1 \models A$ implies $G_2 \models A$ and vice versa, for every formula A .

Theorem 3.2 (Logical equivalence and congruence). *If the transparency predicate is always true, then for every term G, G' , it holds: $G =_L G'$ if and only if $G \equiv G'$.*

Place Graph Logic (PGL). Place graphs are essentially ordered lists of regions hosting unordered labelled trees with holes. The labels of the trees correspond to controls K belonging to the fixed signature \mathcal{K} . We consider the monoid $(\omega, +, 0)$ of finite ordinals

Table 2. Derived Operators

$\mathbf{T}, \wedge, \vee, \Leftrightarrow, \Leftarrow, \neg$	Classical operators
$A_I \stackrel{\text{def}}{=} A \circ \mathbf{id}_I$	Constraining the source to be I
$A_{\rightarrow J} \stackrel{\text{def}}{=} \mathbf{id}_J \circ A$	Constraining the target to be J
$A_{I \rightarrow J} \stackrel{\text{def}}{=} (A_I)_{\rightarrow J}$	Constraining the type to be $I \rightarrow J$
$A \circ_I B \stackrel{\text{def}}{=} A \circ \mathbf{id}_I \circ B$	Composition with interface I
$A \circ_{\rightarrow J} B \stackrel{\text{def}}{=} A_{\rightarrow J} \circ B$	Contexts with J as target guaranteee
$A \circ_{\rightarrow I} B \stackrel{\text{def}}{=} A_I \circ B$	Composing with terms with I as source guaranteee
$A \otimes B \stackrel{\text{def}}{=} \neg(\neg A \otimes \neg B)$	Dual of tensor product
$A \bullet B \stackrel{\text{def}}{=} \neg(\neg A \circ \neg B)$	Dual of composition
$A \bullet\leftarrow B \stackrel{\text{def}}{=} \neg(\neg A \circ_{\rightarrow} \neg B)$	Dual of composition left adjunct
$A \rightarrow\bullet B \stackrel{\text{def}}{=} \neg(\neg A \circ_{\leftarrow} \neg B)$	Dual of composition right adjunct
$A^{\exists\otimes} \stackrel{\text{def}}{=} \mathbf{T} \otimes A \otimes \mathbf{T}$	Some horizontal term satisfies A
$A^{\forall\otimes} \stackrel{\text{def}}{=} \mathbf{F} \otimes A \otimes \mathbf{F}$	Every horizontal term satisfies A
$A^{\exists\circ} \stackrel{\text{def}}{=} \mathbf{T} \circ A \circ \mathbf{T}$	Some vertical term satisfies A
$A^{\forall\circ} \stackrel{\text{def}}{=} \mathbf{F} \bullet A \bullet \mathbf{F}$	Every vertical term satisfies A
$I = J \stackrel{\text{def}}{=} \mathbf{T} \otimes (id_\epsilon \wedge id_I \otimes id_J)$	Equality between interfaces
$\diamond A \stackrel{\text{def}}{=} (\mathbf{T} \circ A)_\epsilon$	Somewhere modality (on ground terms)
$\sqsupset A \stackrel{\text{def}}{=} \neg\diamond\neg A$	Anywhere modality (on ground terms)

m, n . Interfaces here represent the number of holes and regions of place graphs. Place graph terms are generated from the set $\Theta = \{1 : 0 \rightarrow 1, id_n : n \rightarrow n, join : 2 \rightarrow 1, \gamma_{m,n} : m + n \rightarrow n + m, K : 1 \rightarrow 1 \text{ for } K \in \mathcal{K}\}$. The main structural term is K , that represents a region containing a single node with a hole inside. Other simple terms are *placings*, representing trees $m \rightarrow n$ with no nodes; the constructor 1 represents a barren region; *join* is a mapping of two regions into one; $\gamma_{m,n}$ is a permutation that interchanges the first m regions with the following n . The structural congruence \equiv for place graph terms is refined by the usual axioms for symmetry of $\gamma_{m,n}$ and by the place axioms that essentially turn the operation $join \circ (- \otimes -)$ in a commutative monoid with neutral element 1 . Hence, the places generated by composition and tensor product from $\gamma_{m,n}$ are *permutations*. A place graph is *prime* if it has type $I \rightarrow 1$ (i.e., with a single region).

Defined the transparency predicate τ on each control in \mathcal{K} , the Place Graph Logic $\text{PGL}(\mathcal{K}, \tau)$ is $\text{BiLog}(\omega, +, 0, \equiv, \mathcal{K} \cup \{1, join, \gamma_{m,n}\}, \tau)$. We assume the τ to be true for *join* and $\gamma_{m,n}$. It follows from Theorem 3.2 that PGL can describe place graphs precisely. The logic resembles a propositional spatial tree logic, like [2]. The main differences are that PGL models contexts of trees and that the tensor product is not commutative, allowing us to model the order of regions. We can define a commutative separation using **join** and the tensor product, the *parallel composition* $A \mid B \stackrel{\text{def}}{=} \mathbf{join} \circ (A_{\rightarrow 1} \otimes B_{\rightarrow 1})$. This separation is purely structural, and corresponds at term level to $join \circ (P \otimes P')$ that is a total operation on all prime place graphs.

We show that BiLog restricted to prime ground place graphs (with the always-true transparency predicate) is equivalent to the propositional spatial tree logic of [2] (STL in the following). The logic STL expresses properties of unordered labelled trees T

Table 3. Encoding STL in PGL over prime ground place graphs

Trees into Prime Ground Place Graphs		
$\llbracket 0 \rrbracket \stackrel{\text{def}}{=} 1$	$\llbracket a[T] \rrbracket \stackrel{\text{def}}{=} K(a) \circ \llbracket T \rrbracket$	$\llbracket T_1 T_2 \rrbracket \stackrel{\text{def}}{=} \text{join} \circ (\llbracket T_1 \rrbracket \otimes \llbracket T_2 \rrbracket)$
STL formulae into PGL formulae		
$\llbracket \mathbf{0} \rrbracket \stackrel{\text{def}}{=} 1$		$\llbracket a[A] \rrbracket \stackrel{\text{def}}{=} \mathbf{K}(a) \circ_1 \llbracket A \rrbracket$
$\llbracket \mathbf{F} \rrbracket \stackrel{\text{def}}{=} \mathbf{F}$		$\llbracket A@a \rrbracket \stackrel{\text{def}}{=} \mathbf{K}(a) \circ_{-1} \llbracket A \rrbracket$
$\llbracket A \Rightarrow B \rrbracket \stackrel{\text{def}}{=} \llbracket A \rrbracket \Rightarrow \llbracket B \rrbracket$		$\llbracket A B \rrbracket \stackrel{\text{def}}{=} \llbracket A \rrbracket \llbracket B \rrbracket$
$\llbracket A \triangleright B \rrbracket \stackrel{\text{def}}{=} (\llbracket A \rrbracket \mathbf{id}_1) \circ_{-1} \llbracket B \rrbracket$		

constructed from the empty tree 0 , the labelled node containing a tree $a[T]$, and the parallel composition of trees $T_1 | T_2$. It is a static fragment of the ambient logic [6] characterised by propositional connectives, spatial connectives (i.e., 0 , $a[A]$, $A | B$), and their adjuncts (i.e., $A@a$, $A \triangleright B$).

In Table 3 we encode the tree model of STL into prime ground place graphs, and STL operators into PGL operators. We assume a bijective encoding between labels and controls, and associate every label a with a distinct control $K(a)$. The monoidal properties of parallel composition are guaranteed by the symmetry and unit axioms of *join*. The equations are self-explanatory once we remark that: (i) the parallel composition of STL is the structural commutative separation of PGL; (ii) tree labels can be represented by the corresponding controls of the place graph; and (iii) location and composition adjuncts of STL are encoded in terms of the left composition adjunct, as they add logically expressible contexts to the tree. This encoding allows us to prove the following.

Theorem 3.3 (Encoding STL). *For each tree T and formula A of STL we have that $T \models_{SL} A$ if and only if $\llbracket T \rrbracket \models (\llbracket A \rrbracket)_{0 \rightarrow 1}$.*

Differently from STL, PGL can also describe structures with several holes and regions. In [8] we show how PGL describes contexts of tree-shaped semistructured data. In particular multi-contexts can be useful to specify properties of web-services. Consider for instance a function taking two trees and returning the tree obtained by merging their roots. Such function is represented by the term *join*, which solely satisfies the formula **join**. Similarly, the function that takes a tree and encapsulates it inside a node labelled by K , is represented by the term K and captured by the formula **K**. Moreover, the formula **join** \circ (**K** \otimes (**T** \circ **id**₁)) expresses all contexts of form $2 \rightarrow 1$ that place their first argument inside a K node and their second one as a sibling of such node.

Link Graph Logic (LGL). For Λ a denumerable set of names, we consider the monoid of interfaces $(\mathcal{P}_{fin}(\Lambda), \uplus, \emptyset)$, where $\mathcal{P}_{fin}(\cdot)$ is the finite powerset operator and \uplus is the union on disjoint pairs of sets and undefined otherwise. The structures that arise from such a monoid are the link graphs discussed in §2. They can describe nominal resources common in many areas, such as object identifiers, location names in memory structures, channel names, and ID attributes in XML documents.

Wiring terms are a structured way to map a set of inner names X into a set of outer names Y . They are generated by the constructors: $/a : \{a\} \rightarrow \emptyset$ and $^a/_X : X \rightarrow a$. The

closure $/a$ hides the inner name a in the outer face. The substitution $^a/_X$ associates all the names in the set X to the name a . We denote wirings by ω , substitutions by σ, τ , and *renamings* (i.e., bijective substitutions) by α, β . Substitutions can be specialised in:

$$a \stackrel{\text{def}}{=} a/_\emptyset; \quad a \leftarrow b \stackrel{\text{def}}{=} a/_\{b\}; \quad a \Leftarrow b \stackrel{\text{def}}{=} a/_\{a,b\}.$$

Constructor a represents the introduction of a name a , term $a \leftarrow b$ the renaming of b to a , and finally $a \Leftarrow b$ links (or fuse) a and b in the name a .

Given a signature \mathcal{K} of controls K with corresponding ports $ar(K)$ we generate link graphs from wirings and the constructor $K_{\vec{a}} : \emptyset \rightarrow \vec{a}$ with $\vec{a} = a_1, \dots, a_k$, $K \in \mathcal{K}$, and $k = ar(K)$; $K_{\vec{a}}$ represents a resource of kind K with named ports \vec{a} . Any ports may be connected to other node ports via wiring compositions.

The structural congruence \equiv for link graphs is refined with obvious axioms for links, modelling α -conversion and extrusion of closed names, cf. [9]. We assume the transparency predicate τ to be true for wiring constructors.

Given the transparency τ for each control in \mathcal{K} , the Link Graph Logic $\text{LGL}(\mathcal{K}, \tau)$ is $\text{BiLog}(\mathcal{P}_{\text{fin}}(\Lambda), \uplus, \emptyset, \equiv, \mathcal{K} \cup \{ /a, ^a/_X \}, \tau)$. By Theorem 3.2, LGL describes the link graphs precisely. The logic expresses structural spatiality for resources and strong spatiality (separation) for names, and it can therefore be viewed as a generalisation of Separation Logic for contexts and multi-ports locations. On the other side the logic can describe resources with local (hidden/private) names between resources, and in this sense the logic is a generalisation of Spatial Graph Logic [4], considering the edges as resources.

In LGL the formula $A \otimes B$ describes a decomposition into two *separate* link graphs (i.e., sharing no resources, names, nor connections) satisfying respectively A and B . Observe that in this case, horizontal decomposition inherits the commutativity property from the monoidal tensor product. If we want a name a to be shared between separated resources, we need the sharing to be made explicit, and the sole way to do that is through the link operation. We therefore need a way to first separate the names occurring in two wirings in order to apply the tensor, and then link them back together.

As a shorthand if $W : X \rightarrow Y$ and $W' : X' \rightarrow Y'$ with $Y \subset X'$, we write $[W']W$ for $(W' \otimes id_{X \setminus Y}) \circ W$ and if $\vec{a} = a_1, \dots, a_n$ and $\vec{b} = b_1, \dots, b_n$, we write $\vec{a} \leftarrow \vec{b}$ for $a_1 \leftarrow b_1 \otimes \dots \otimes a_n \leftarrow b_n$ (and similarly for $\vec{a} \Leftarrow \vec{b}$). It is possible to derive from the tensor product a product with sharing on \vec{a} . Given $G : X \rightarrow Y$ and $G' : X' \rightarrow Y'$ with $X \cap X' = \emptyset$, we choose a list \vec{b} (with the same length as \vec{a}) of fresh names. The composition with sharing \vec{a} is:

$$G \otimes G' \stackrel{\text{def}}{=} [\vec{a} \Leftarrow \vec{b}]((\vec{b} \leftarrow \vec{a}) \circ G) \otimes G'$$

By extending this sharing to all names we can define the parallel composition $G \mid G'$ as a total operation. However, such an operator does not behave “well” with respect to the composition, as shown in [15]. In addition a direct inclusion of a corresponding connective in the logic would impact the satisfaction relation by expanding the finite horizontal decompositions to the boundless possible name-sharing decompositions.

As a matter of fact, without name quantification it is not possible to build formulae that explore a link, since the latter has the effect of hiding names. For this task, we employ the name variables x_1, \dots, x_n and a fresh name quantification in the style of Nominal Logic [19].

$$G \models \mathbb{N}x_1, \dots, x_n. A \stackrel{\text{def}}{=} \exists a_1 \dots a_n \notin \text{fn}(G) \cup \text{fn}(A). G \models A\{x_1, \dots, x_n \leftarrow a_1 \dots a_n\}$$

Using fresh name quantification we can define a notion of \vec{d} -linked name quantification for fresh names, whose purpose is to identify names that are linked to \vec{d} :

$$\vec{d} \mathbf{L} \vec{x}. A \stackrel{\text{def}}{=} \mathbb{N} \vec{x}. ((\vec{d} \leftarrow \vec{x}) \otimes \mathbf{id}) \circ A.$$

The formula above expresses that variables in \vec{x} denote in A names that are linked in the term to \vec{d} , and the role of $(\vec{d} \leftarrow \vec{x})$ is to link the fresh names \vec{x} with \vec{d} , while \mathbf{id} deals with names not in \vec{d} . We also define a *separation-upto*, namely the decomposition in two terms that are separated apart from the link on the specific names in \vec{d} , which crosses the separation line.

$$A \otimes B \stackrel{\vec{d}}{\text{def}} \vec{d} \mathbf{L} \vec{x}. (((\vec{x} \leftarrow \vec{d}) \otimes \mathbf{id}) \circ A) \otimes B.$$

The idea of the formula above is that the shared names \vec{d} are renamed in fresh names \vec{x} , so that the product can be performed and finally \vec{x} is linked to \vec{d} in order to actually have the sharing. The corresponding parallel composition operator is not directly definable using separation-upto, since we do not know a priori the name shared in arbitrary decompositions. However, we will show that a careful encoding is possible for the parallel composition of spatial logics with nominal resources.

We show that LGL can be seen as a contextual (and multi-edge) version of Spatial Graph Logic (SGL) [4]. The logic SGL expresses properties of directed edge labelled graphs G built from the empty graph nil , the edge labelled a from x to y nodes $a(x, y)$, the parallel composition of graphs $G_1 \mid G_2$, and the binding for local names of nodes $(\nu x)G$. We consider a \mathcal{K} such that: there is a bijective function associating every edge label a to a distinct control $K(a)$ and the arity of every control is 2 (the ports represent the starting and arrival node respectively). The resulting link graphs can be interpreted as contextual edge labelled graphs and the resulting class of ground link graphs is isomorphic to the graph model of SGL. In Table 4 we encode the graphs modelling SGL into ground link graphs and SGL formulae into LGL formulae. The encoding is parametric on a finite set X of names containing the free names of the graph under consideration. Observe that when we force the outer face of the graphs to be a fixed finite set X , the encoding of parallel composition is simply the separation-upto \vec{d} , where \vec{d} is a list of all the elements in X . Notice also how local names are encoded into name closures (and identity).

Theorem 3.4 (Encoding SGL). *For each graph G , finite set X containing $\text{fn}(G)$, and formula ϕ of the propositional fragment of SGL, we have that $G \models_{GL} \phi$ if and only if $\llbracket G \rrbracket_X \models (\llbracket \phi \rrbracket_X)_{0 \rightarrow X}$.*

In LGL is also possible to encode the Separation Logics on heaps: names used as identifiers of location will be forcibly separated by tensor product, while names used for pointers will be shared/linked.

Bigraphs as a Model for BiLog. We combine the structures of link graphs and place graphs to generate all (*abstract pure*) *bigraphs* of [12]. We take as monoid the product of link and place interfaces, i.e. $(\omega \times \mathcal{P}_{\text{fn}}(\Lambda), \otimes, \epsilon)$ where $\langle m, X \rangle \otimes \langle n, Y \rangle \stackrel{\text{def}}{=} \langle m + n, X \uplus Y \rangle$

Table 4. Encoding Propositional SGL in LGL over two ported ground link graphs

Spatial Graphs into Two-ported Ground Link Graphs	
$\llbracket \text{nil} \rrbracket_X \stackrel{\text{def}}{=} X$	$\llbracket a(x, y) \rrbracket_X \stackrel{\text{def}}{=} K(a)_{x,y} \otimes X \setminus \{x, y\}$
$\llbracket G \mid G' \rrbracket_X \stackrel{\text{def}}{=} \llbracket G \rrbracket_X \otimes^{\vec{a}} \llbracket G' \rrbracket_X$	$\llbracket (\nu x)G \rrbracket_X \stackrel{\text{def}}{=} ((/x \otimes id_{X \setminus \{x\}}) \circ \llbracket G \rrbracket_{\{x\} \cup X}) \otimes (\{x\} \cap X)$
SGL formulae into LGL formulae	
$\llbracket \text{nil} \rrbracket_X \stackrel{\text{def}}{=} X$	$\llbracket a(x, y) \rrbracket_X \stackrel{\text{def}}{=} \mathbf{K}(a)_{x,y} \otimes (X \setminus \{x, y\})$
$\llbracket \mathbf{F} \rrbracket_X \stackrel{\text{def}}{=} \mathbf{F}$	$\llbracket \phi \Rightarrow \psi \rrbracket_X \stackrel{\text{def}}{=} \llbracket \phi \rrbracket_X \Rightarrow \llbracket \psi \rrbracket_X$
$\llbracket \phi \mid \psi \rrbracket_X \stackrel{\text{def}}{=} \llbracket \phi \rrbracket_X \otimes^{\vec{a}} \llbracket \psi \rrbracket_X$	

and $\epsilon \stackrel{\text{def}}{=} \langle 0, \emptyset \rangle$. We will use X for $\langle 0, X \rangle$ and n for $\langle n, \emptyset \rangle$. As constructors for bigraphical terms we have the union of place and link graph constructors apart from the controls $K : 1 \rightarrow 1$ and $K_{\vec{a}} : \emptyset \rightarrow \vec{a}$, which are replaced by the new *discrete ion* constructor, which we note $K_{\vec{a}} : 1 \rightarrow \langle 1, \vec{a} \rangle$; this is a prime bigraph containing a single node with ports named \vec{a} and an hole inside. Bigraphical terms thus are defined w.r.t. a control signature \mathcal{K} and a set of names Λ , cf. [15] for details.

PGL excels at expressing properties of *unnamed* resources, i.e., resources accessible only by following the structure of the term. On the other hand, LGL characterises names and their links to resources, but it has no notion of locality. A combination of them ought to be useful to model spatial structures, either private or public. BiLog promises to be a good (contextual) spatial logic for (semi-structured) resources with nominal links, thanks to bigraphs' orthogonal treatment of locality and connectivity. To witness this we have proved in [9] that also the recently proposed Context Logic for Trees [3] can be encoded into bigraphs. The idea of the encoding is to extend the one of STL with contexts and identified nodes. Essentially, in [9] we show that the model of [3] is a particular class of prime bigraphs with one port for each node and a number of holes and regions limited to one. Since [3] is more general than separation logic, and is used to reason about programs that manipulate tree structured memories, it is possible to generalise separation logic as well.

4 Conclusion and Future Work

In this paper we moved a first step towards describing global resources by focusing on bigraphs. Our final objective is to design a general dynamic logic able to cope uniformly with all the models bigraphs have been proved useful for, as of today these include CCS [17], pi-calculus [12] and Petri-nets [13, 16]. We introduced BiLog, a logic for bigraphs (and more generally for monoidal categories), with two main spatial connectives: composition and tensor product. Our main technical results are the embedding and comparison with other spatial logics previously studied. Moreover, we have shown that BiLog is expressive enough to internalise the somewhere modality. In §3 we observed that the induced logical equivalence can be forced to coincide with the structural congruence of terms. This property is fundamental in order to describe, query and reason about bigraphical data structures. For a more detailed discussion we refer to [8].

In [9] we study how BiLog can deal with dynamics. A natural solution is to add a temporal *next step* modality basically describing bigraphs that can compute (*react*) according to a Bigraphical Reactive System [12]. When the transparency predicate τ enables the inspection of ‘dynamic’ controls, BiLog is ‘*intensional*’ in the sense of [11], namely it can observe internal structures. In several cases, notably the bigraphical system describing CCS [17], this can be to the extent that the next step modality can be expressed directly by using the static fragment of BiLog. Notice that τ specifies what structure the logic can directly observe, while the next step modality, along with the spatial connectives, allows to deduce the structure by observing the behaviour. It would be interesting to investigate how the transparency predicate influences the expressiveness and intentionality of significant fragments of the dynamic logic.

The ‘separation’ plays differently in various fragments of the logic. For instance, in the case of *Place Graph Logic*, where the model is the class of bigraphs without names, the separation is purely structural and coincides with the notion of parallel composition in Spatial Tree Logic. The separation in the *Link Graph Logic* is disjointness of nominal resources. Finally, for *Bigraph Logic* it is a combination that can be seen as separation in a structured term with nominal resources (e.g. the trees with pointers of [3] and trees with hidden names [5]). In the paper we have not addressed logical operators for hidden names (e.g. \mathbb{R} , \mathbf{H} , \mathbb{C} of ambient logic). We can encode them easily using, in particular, \mathbb{I} and $/a$. The decidability of BiLog is an open question, we are working on extending the results of [2], and we are isolating decidable fragments of BiLog.

We are currently developing a proof theory for Bilog in order to complete the robust logical setting provided by the model theory presented here. Besides aiming at a generalise existing proof systems, this will allow direct comparisons between BiLog and other spatial logics also from the proof-theoretic point of view.

Acknowledgment. We would like to thank Philippe Bidinger, Annalisa Bossi, Rohit Chadha, Murdoch Gabbay, Giorgio Ghelli, Robin Milner, Peter O’Hearn and all the anonymous referees for useful comments and discussions.

Completely Non-malleable Schemes

(Extended Abstract)

Marc Fischlin*

Institute for Theoretical Computer Science, ETH Zürich, Switzerland
marc.fischlin@inf.ethz.ch
<http://www.fischlin.de/>

Abstract. An encryption scheme is non-malleable if the adversary cannot transform a ciphertext into one of a related message under the given public key. Although providing a very strong security property, some application scenarios like the recently proposed key-substitution attacks yet show the limitations of this notion. In such settings the adversary may have the power to transform the ciphertext *and* the given public key, possibly without knowing the corresponding secret key of her own public key. In this paper we therefore introduce the notion of completely non-malleable cryptographic schemes withstanding such attacks. We show that classical schemes like the well-known Cramer-Shoup DDH encryption scheme become indeed insecure against this stronger kind of attack, implying that the notion is a strict extension of chosen-ciphertext security. We also prove that, unless one puts further restrictions on the adversary's success goals, completely non-malleable schemes are hard to construct (as in the case of encryption) or even impossible (as in the case of signatures). Identifying the appropriate restrictions we then show how to modify well-known constructions like RSA-OAEP and Fiat-Shamir signatures yielding practical solutions for the problem in the random oracle model.

1 Introduction

According to the seminal paper by Dolev et al. [7] an encryption scheme is called non-malleable if giving a ciphertext to an adversary does not significantly help this adversary to produce a ciphertext of a related message under the same public key. Analogous requirements can be formulated for other cryptographic primitives like signatures or commitments. While this definition of non-malleability is already quite strong and suffices in most settings it yet leaves open if there are cases where refined notions are needed and, if so, whether they can be achieved at all.

* This work was supported by the Emmy Noether Programme Fi 940/1-1 of the German Research Foundation (DFG). Part of this work done while visiting University of California, San Diego, USA.

Motivation. A possible stronger definition of non-malleability, introduced here as complete non-malleability, basically allows the adversary to transform the public key as well. That is, in case of encryption the adversary may output a ciphertext of a related message *under an adversarial chosen public key*. For this, the adversary does not even need to know the matching secret key to the chosen public key.

Our initial interest in completely non-malleable schemes stems from the area of (regular) non-malleable commitments. Previous constructions of such non-malleable commitments usually require a common reference string [4, 8, 5, 9], or are rather theoretical in terms of efficiency [7, 1]. Coming up with an efficient non-malleable commitment protocol in the plain model is still an open problem.

Early in cryptography it has been observed that efficient commitment schemes can be derived from encryption schemes. To commit, the sender creates a key pair and sends a ciphertext of the message together with the public key. To decommit, the sender transmits the message with the random bits used to create the ciphertext, or simply sends the secret key (if appropriate). Now, if the encryption scheme was *completely* non-malleable then the resulting commitment scheme in this basic construction would be non-malleable in the ordinary sense. And the derived commitment scheme would be non-interactive and would not rely on public parameters either.

In addition to the application to commitment schemes, it turns out that, recently, the problem of complete non-malleability also appeared in similar flavors in related areas like signatures or hash functions [3, 13, 12]. For example, Blake-Wilson and Menezes [3] show how to deploy unknown key-share attacks to show weaknesses in the station-to-station key agreement protocol. In their case, the adversary is given a signature s for message m under some public verification key vk and her task is to find a different key pair (sk^*, vk^*) such that s is also a valid signature for m under vk^* .

Our Results. In this work we discuss the issue of complete non-malleability for public-key encryption and signatures. We first show that most of the well-known encryption and signature schemes fall prey to complete non-malleability attacks. Specifically, we propose attacks against the Cramer-Shoup DDH encryption scheme, RSA-OAEP and signatures of the Fiat-Shamir type like Schnorr signatures (of which only the first one appears in this version). This shows that the security notion of complete non-malleability is not covered by chosen-ciphertext security and by unforgeability against chosen-message attacks, respectively.

Then we give a formal framework for complete non-malleability of public-key encryption and signatures. There are two major differences to the basic definition of non-malleability. First, the adversary's goal in the definition of [7] for encryption is to relate the original secret message m to a chosen message m^* via a relation $R(m, m^*)$. Here we extend the relation to include the given public key pk . For message-only relations it remains for example unclear if it is easy to modify a ciphertext of some message m under some RSA-based non-malleable encryption with random RSA-exponent e into a ciphertext of the related message $m^* = m+e$ under the same public key. We answer this in the affirmative, showing

that this is indeed easy for general schemes. Namely, we present a scheme which is non-malleable for relations over messages, but for which the adversary can easily produce a ciphertext c^* of a message m^* under pk such that a specific relation $R(pk, m, m^*)$ is satisfied. We stress that the adversary does not even take advantage of the possibility to select her own public key for this attack.

Our separating example for relations $R(m, m^*)$ over messages shows that (regular) non-malleable commitments constructed by means of encryption schemes in the common reference string model (as in [5]) may not provide adequate security for the classical Internet auction example. In the auction case the users' bids are encrypted with a public key published in the reference string. Now, an adversarial bidder may be able to transform such a sealed bid of an honest user into one which is related via this public key, and may thus overbid this user easily with a reasonably small amount (e.g., by $m^* = m + e$).

The second, and more significant extension of the [7] framework for encryption is that the adversary now has the power to tamper the public key. Consequently, the relations now also range over the given public key pk , the adversarial chosen public key pk^* and, for sake of generality, also over adversary's ciphertext. Similarly, for signatures we let the relation include the given verification key vk , the adversarial key vk^* , message m^* and signature s^* .

Concerning constructions of completely non-malleable schemes, the bad news is that schemes for *general relations* are hard to derive or even impossible. We show that there are relations where complete non-malleability cannot be proven via black-box proofs for both encryption and signatures. Even worse, for more complex relations we prove that completely non-malleable signature schemes do not exist at all.

On the positive side, we can show that practical schemes like RSA-OAEP and Fiat-Shamir signatures can be made completely non-malleable *in the random oracle model* (while the basic versions do not achieve this goal, not even in the random oracle model). Security holds for a broad class of relations which, roughly, excludes only such relations for which we are able to show our unconditional impossibility results. Also, our solutions are essentially as efficient as the original schemes, thus giving us complete non-malleability almost for free.

However, we remark that the completely non-malleable versions of the schemes above are proven secure in the random oracle model only. A closer look reveals why this model provides a useful countermeasure: Random oracles are by nature highly non-malleable constructs, because outputs of related inputs are completely uncorrelated and because all users in the system use the *same* hash function oracle as a common anchor. The advantage of giving security of these schemes in terms of complete non-malleability, even in the random oracle model, is that security now follows for a vast number of attacks, including for example so-called key-substitution and strong-unforgeability attacks. That is, any attack where the adversary's goal can be cast through such relations provably fails; extra security proofs become obsolete. An interesting open question is whether there are secure schemes in the plain model for interesting relations or not.

Organization. To provide some intuition about the power of complete non-malleability attack we start with the attack on the Cramer-Shoup encryption scheme in Section 2. Then we define completely non-malleable schemes formally in Section 3. Because of the complexity of the topic we mainly focus on the definitions. Our impossibility and positive results are outlined in Section 4, further details appear in the full version.

2 Attack on Cramer-Shoup Encryption Scheme

The Cramer-Shoup encryption scheme [6] is semantically secure against adaptive chosen-ciphertext attacks under the decisional Diffie-Hellman assumption. It is thus also non-malleable (in the classical sense) with respect to such attacks.

Key Generation: The public key is given by the description of a group \mathcal{G}_q of prime order q for which the decisional Diffie-Hellman problem is believed to be intractable, two random generators g_1, g_2 of this group as well as c, d and h where

$$c = g_1^{x_1} g_2^{x_2}, \quad d = g_1^{y_1} g_2^{y_2}, \quad h = g_1^{z_1} g_2^{z_2}$$

for random values $x_1, x_2, y_1, y_2, z_1, z_2 \leftarrow \mathbb{Z}_q$. The public key also contains a collision-intractable hash function H . The secret key is $(x_1, x_2, y_1, y_2, z_1, z_2)$.

Encryption: To encrypt a message $m \in \mathcal{G}_q$ pick a random $r \leftarrow \mathbb{Z}_q$ and compute

$$u_1 = g_1^r, \quad u_2 = g_2^r, \quad e = h^r m, \quad \alpha = H(u_1, u_2, e), \quad v = c^r d^{r\alpha}$$

The ciphertext is given by (u_1, u_2, e, v) .

Decryption: To decrypt a ciphertext (u_1, u_2, e, v) compute $\alpha = H(u_1, u_2, e)$ and verify that $v = u_1^{x_1 + \alpha y_1} u_2^{x_2 + \alpha y_2}$. If so, then output $m = e / u_1^{z_1} u_2^{z_2}$.

The attack showing that the scheme fails to provide complete non-malleability now proceeds as follows. Given a public key $(\mathcal{G}, g_1, g_2, H, c, d, h)$ and a ciphertext (u_1, u_2, e, v) first recompute $\alpha = H(u_1, u_2, e)$. With overwhelming probability $\alpha \not\equiv 0 \pmod q$ and we can invert α in \mathbb{Z}_q^* ; else, if a random ciphertext maps to 0 with noticeable probability, collisions for H could be found easily. Next compute

$$u_1^* = u_1^2, \quad u_2^* = u_2^2, \quad e^* = e^2, \quad \alpha^* = H(u_1^*, u_2^*, e^*), \quad v^* = v^{2\alpha^* / \alpha}$$

and finally prepare the public key as

$$c^* = c^{\alpha^* / \alpha}, \quad d^* = d, \quad h^* = h.$$

A simple calculation shows that

$$v^* = v^{2\alpha^* / \alpha} = c^{2r\alpha^* / \alpha} d^{2r\alpha\alpha^* / \alpha} = (c^*)^{2r} (d^*)^{2r\alpha^*}$$

Hence, the tuple (u_1^*, u_2^*, e^*, v^*) is a valid ciphertext of $m^* = m^2 \in \mathcal{G}$ under randomness $r^* = 2r \bmod q$ and public key $(\mathcal{G}, g_1, g_2, H, c^*, d^*, h^*)$.¹

The attack shows that the encryption scheme cannot be used as a non-malleable commitment scheme, as explained in the introduction. With this attack the adversary would be able to open her commitment correctly with $(2r, m^2)$ after seeing the decommitment (m, r) of the original sender. Analogously, if the adversary is given the original secret key $(x_1, x_2, y_1, y_2, z_1, z_2)$ she can modify it to $(x_1\alpha^*/\alpha, x_2\alpha^*/\alpha, y_1, y_2, z_1, z_2)$. We stress that the scheme still satisfies its designated security goal of chosen-ciphertext security.

3 Definitions

In this section we define completely non-malleable public-key encryption and signature schemes. Our approach follows the line of Dolev et al. [7] and also investigates the non-malleability question of an encryption or signature scheme merely with respect to itself. Achieving non-malleability between different schemes is in general impossible, even in the basic case.

3.1 Encryption

An obvious problem with defining completely non-malleable encryption schemes lies in the adversary's possibility to choose her own public key and the uniqueness of ciphertexts. With a fake, yet valid-looking public key the adversary might be able to produce ciphertexts which can be decrypted ambiguously. We consider this to be a characteristic of the encryption scheme, and not an issue of complete non-malleability. Specifically, we allow the adversary to produce such phony keys if the scheme supports it, i.e., if one cannot distinguish good keys from fake ones. We note that, for the application to non-malleable commitments as explained in the introduction, verifying the validity of keys is for example necessary.

Relations. As mentioned in the introduction, regular non-malleability says that it is hard to transform a given ciphertext of message m into one of a related message m^* under the same key. There, related messages are designated according to an efficiently computable (probabilistic) algorithm R which basically takes the messages m and m^* as input.² But here we are interested in more general attacks where, as in the examples of non-malleable commitments or key-substitution attacks on signatures, finding a related public key pk^* or ciphertext c^* to the given

¹ At first glance it seems that replacing h by $h^* = h^a$ (or similar substitutions), and leaving the other ciphertext components untouched, would work as well. But then the adversary would encrypt a message $m^* = e/(h^*)^r = mh^{r(1-a)}$. This, however, would be a random message (over the choice of r) and would be thus unlikely to be related to m in a reasonable way.

² The definition in [7] lets the relations include another string chosen by the adversary, mainly to deal with the case of symmetric encryption schemes. All our positive and negative results for public-key encryption and signatures remain valid for this extension.

key pk may be considered a success. Hence, we let the relations in general also depend on pk and pk^*, c^* .

Our approach of allowing the relation to depend on other parameters than the messages introduces an interesting issue for non-malleable encryption schemes in the “ordinary” sense. In the original definition of [7] the relation $R(m, m^*)$ does not range over the user’s public key pk . Hence, it remains unclear if it is infeasible to find a ciphertext of a message m^* to a given ciphertext of some unknown m such that m^* is related to m via the public key pk for such schemes. We discuss this in more detail in the final version, presenting an example which is malleable if the relation includes the public key, but which is provably non-malleable if the relations are defined over messages only.

To capture both the original definition of relations over messages only and the more general approach including public keys, we look at classes \mathcal{R} of relations and define complete non-malleability with respect to such classes. The class for the basic definition then spans over relations $R(pk, m, pk^*, m^*, c^*) = R_0(m, m^*) \wedge pk = pk^*$, for example.

Message Distributions. We assume that the distribution of the user’s message is determined according to some efficiently computable probabilistic algorithm M from some class \mathcal{M} . The message distribution M may depend on the given public key. Dolev et al. [7] let the adversary and the simulator determine the message distribution after seeing the public key and having queried the decryption oracle in a preprocessing phase. This can be subsumed in our model by letting these two algorithms output some parameter μ before the ciphertext is created. Unless stated differently all our results, positive and negative ones, remain valid in the setting where the adversary and simulator select such values; yet, we usually do not include them here for sake of simplicity.

Attack Model. In the first stage of the actual attack the adversary \mathcal{A} is given a public key pk and access to a decryption oracle $DEC(sk, \cdot)$, where $(sk, pk) \leftarrow KGEN(1^k)$ have been produced by the key generator. The adversary also gets a description of the relation R and the message distribution M . A message m is sampled according to the distribution $M(m) \in \mathcal{M}$ and encrypted under pk to ciphertext $c \leftarrow ENC(pk, m; r)$. The adversary starts the attack on the ciphertext c , the decryption oracle and some information about the message m in form of the value $h \leftarrow hist(m)$ of an efficiently computable probabilistic function $hist$. This function can be formally regarded of part of the distribution M . The adversary finally outputs a public key pk^* , possibly for a different yet polynomially related security parameter, and a ciphertext c^* .

Let $\pi_{enc}(\mathcal{A}, M, R)$ be the probability that $(pk, c) \neq (pk^*, c^*)$ and that there exists some m^*, r^* such that $c^* = ENC(pk^*, m^*; r^*)$ and $R(pk, m, pk^*, m^*, c^*)$ for the relation R . We call this a related-ciphertext attack. Here, as usual for non-malleability definitions, R may implicitly depend on the encryption scheme itself and some security parameter. However, we do not demand that $m \neq m^*$; it suffices to produce a different key/ciphertext pair.

As explained in the introduction, the usage of the encryption scheme as a commitment may result in different attacks and success goals, e.g., the adver-

	\mathcal{A} gets pk, c , oracle $\text{DEC}(sk, \cdot)$ and . . .	\mathcal{S} gets pk [and possibly oracle $\text{DEC}(sk, \cdot)$] and. . .
$\pi_{\text{enc}}^{(r)}$	\mathcal{A} outputs pk^*, c^*	\mathcal{S} outputs pk', c', m', r'
$\pi_{\text{open}}^{(r)}$	\mathcal{A} outputs pk^*, c^* , then m^*, r^* after m, r	\mathcal{S} outputs pk', c', m', r'
$\pi_{\text{sk-open}}^{(r)}$	\mathcal{A} outputs pk^*, c^* , then sk^* after sk	\mathcal{S} outputs pk', c', m', r', sk'

Fig. 1. Overview of Attack and Simulation Modes for Encryption

sary may be obliged to actually open her ciphertext after seeing the opening of the original ciphertext. Therefore, let $\pi_{\text{open}}(\mathcal{A}, \mathbf{M}, \mathbf{R})$ denote the probability that \mathcal{A} after the first stage, on input α^* and values m, r , also returns m^*, r^* such that $c^* = \text{ENC}(pk^*, m^*; r^*)$ and $\mathbf{R}(pk, m, pk^*, m^*, c^*) = 1$. This is called a related-opening attack. Write $\pi_{\text{sk-open}}(\mathcal{A}, \mathbf{M}, \mathbf{R})$ for the probability that \mathcal{A} for input α^* and the secret key sk returns sk^* such that $\text{DEC}(sk^*, c^*) = m^*$ and $\mathbf{R}(pk, m, pk^*, m^*, c^*) = 1$ in a so-called related-key-opening attack. The three cases are described informally in the middle column in Figure 1.

Simulation Model. To capture the idea of the user’s ciphertext not helping to produce a ciphertext of a related message we define a simulator \mathcal{S} which is supposed to be as successful as the adversary but without seeing the ciphertext. \mathcal{S} gets as input a public key pk and descriptions of the relation and the message distribution, but does not get access to a decryption oracle. Then, a message m is sampled according to $\mathbf{M}(pk)$ and algorithm \mathcal{S} receives $h \leftarrow \text{hist}(m)$ as input.

Depending on the adversary’s attack mode, the simulator’s task becomes increasingly challenging such that a successful simulator for a security level automatically constitutes a simulator for a lower level. Precisely, the simulator is supposed to output a key pk' , a ciphertext c' , a message m' and randomness r' (if the adversary runs a related-ciphertext or a related-opening attack),³ and a key pk' , a ciphertext c' , a message m' , a random string r' and a secret key sk' (if the adversary runs a related-key-opening attack). Again, see Figure 1 for an overview.

Concerning the auxiliary power of the simulator there are two possibilities. One version is to give the simulator, like the adversary, additional access to the decryption oracle. We call this an *assisted* simulator. This reflects the approach that the simulator should have comparable power as the adversary. The other possibility is to deny the simulator access to DEC . We call such simulators *stand-alone* simulators. This approach follows the definition of [7].

Although the definition with assisted simulators appears to be more intuitive at first, it is not clear that giving the simulator access to DEC captures the “right flavor” of complete non-malleability. The additional power may for

³ For some of our negative results we use a milder requirement and let the simulator only output pk', c' . This even strengthens these results.

example allow to prove schemes to be secure which are completely malleable in a natural sense. While this question has somewhat been settled for chosen-ciphertext security, where this additional power is acceptable, our separation of complete non-malleability from chosen-ciphertext security means that these arguments cannot be transferred without precautions. Instead, a conservative approach for designing schemes is therefore to rely on stand-alone simulators, as it suffices for our solutions in the random oracle model for example. We note that our impossibility results hold for both cases, although in a slightly weaker sense for assisted simulators.

Let both $\pi'_{\text{enc}}(\mathcal{S}, \mathcal{M}, \mathcal{R})$ and $\pi'_{\text{open}}(\mathcal{S}, \mathcal{M}, \mathcal{R})$ denote the probability that $c' = \text{ENC}(pk', m'; r')$ and that $\mathbf{R}(pk, m, pk', m', c') = 1$ in the first and second simulation experiment, respectively. Similarly, $\pi'_{\text{sk-open}}(\mathcal{S}, \mathcal{M}, \mathcal{R})$ stands for the probability that $c' = \text{ENC}(pk', m'; r')$, $m' = \text{DEC}(sk', c')$ and $\mathbf{R}(pk, m, pk', m', c') = 1$ in the third simulation experiment.

Definition 1. *A public-key encryption scheme is completely non-malleable (for stand-alone or assisted simulator) with respect to kind $\in \{\text{enc}, \text{open}, \text{sk-open}\}$, distribution class \mathcal{M} and relation class \mathcal{R} , if for any adversary \mathcal{A} there exists a (stand-alone or assisted) simulator \mathcal{S} such that for any distribution $\mathbf{M} \in \mathcal{M}$ and any relation $\mathbf{R} \in \mathcal{R}$ the absolute difference $|\pi_{\text{kind}}(\mathcal{A}, \mathbf{M}, \mathbf{R}) - \pi'_{\text{kind}}(\mathcal{S}, \mathbf{M}, \mathbf{R})|$ is negligible.*

In the sequel, when speaking of completely non-malleable encryption schemes we refer to related-ciphertext attacks and $\pi_{\text{enc}}(\mathcal{A}, \mathbf{M}, \mathbf{R})$, $\pi'_{\text{enc}}(\mathcal{S}, \mathbf{M}, \mathbf{R})$. The definitions for completely non-malleable encryption (and signatures in the next section) can be extended in a straightforward way to the random oracle model.

3.2 Signatures

The attack scenario for completely non-malleable signature schemes resembles the setting of adaptive chosen-message attacks known from regular signature schemes.

Discussion. Defining the attack model for completely non-malleable signature schemes as outlined above, it seems that the adversary can always generate a new signature under a new public key, i.e., the adversary can naturally generate a new key pair and sign some message with the self-generated secret key. As explained, this attack can be confined as in the example of unknown-key attacks [3] where the adversary is supposed to find a matching key pair for a given message and a given signature. Here we do not restrict the adversary's goal in such a way. First, we do not want to give up generality and exclude certain application scenarios, e.g., signatures encrypted together with the message under a malleable encryption scheme, where the message is not known but the signature may still be transformable by permeating the malleable ciphertext. Second, if the adversary can trivially output a signature, i.e., without relying on the original signature, then this does not violate the idea of (complete) non-malleability and we should therefore be able to prove this formally as well.

	\mathcal{A} gets vk , oracle $\text{SIG}(sk, \cdot)$ and \dots	\mathcal{S} gets vk and \dots
$\pi_{\text{sig}}^{(\prime)}$	\mathcal{A} outputs vk^*, m^*, s^*	\mathcal{S} outputs vk', m', s'

Fig. 2. Overview of Attack and Simulation Mode for Signatures

Attack and Simulation Model. At the outset of the complete non-malleability attack the adversary \mathcal{A} gets as input the description of the relation R and a verification key vk , generated together with the secret signing key sk by $\text{KGEN}(1^k)$. The adversary is then allowed to query a signature oracle $\text{SIG}(sk, \cdot)$ about messages of her choice. For definitional reasons we let the signature oracle prepend the verification key vk and the message m to each signature reply s for such a query. The adversary finally outputs some verification key vk^* , a message m^* and some signature s^* . Define $\pi_{\text{sig}}(\mathcal{A}, R)$ as the probability that s^* is a valid signature for m^* under vk^* , i.e., $\text{VF}(vk^*, m^*, s^*) = 1$, that (vk^*, m^*, s^*) is different from any previously given answer (vk, m, s) of the signature oracle, and that $R(vk, vk^*, m^*, s^*)$ holds for relation R from the class \mathcal{R} .

The simulator only gets vk and the relation as input and is supposed to output a triple (vk', m', s') without having oracle access to $\text{SIG}(sk, \cdot)$. Let $\pi'_{\text{sig}}(\mathcal{S}, R)$ be the probability that s' is a valid signature for m' under vk' and that $R(vk, vk', m', s')$ is satisfied. The attack and simulation model is outlined in Figure 2.

Similar to the encryption case one could also distinguish between stand-alone simulators (as defined here) and assisted simulators (which additionally get access to the signature oracle). In the latter case one would have to unorthodoxly extend the model to allow the adversary to ask for a “challenge signature” which the simulator is denied. We do not follow this approach here as our negative results would hold for this case as well, and our constructions in the random oracle already work for stand-alone simulators.

Security Definition. The idea is now to say that for any adversary there is a simulator such that the success probabilities differ only insignificantly. But with this definition a signature scheme could be completely non-malleable and yet be insecure in the sense of unforgeability, e.g., if it is easy to derive the secret key from the verification key. Therefore, we also throw in the mild assumption that the signature scheme must be unforgeable under key-only attacks, i.e., it must be infeasible on input vk (but no signature oracle) to find some message together with a valid signature under vk .

Definition 2. *A signature scheme is completely non-malleable for relation class \mathcal{R} if it is existentially unforgeable under key-only attacks and if for any adversary \mathcal{A} there exists a simulator \mathcal{S} such that for any relation $R \in \mathcal{R}$ the absolute difference $|\pi_{\text{sig}}(\mathcal{A}, R) - \pi'_{\text{sig}}(\mathcal{S}, R)|$ is negligible.*

We briefly discuss some consequences of the definition, showing that the definition is powerful to reflect the notions of strong unforgeability (i.e., where the adversary is also considered victorious if she finds a new signature under the

original verification key to a message previously signed by the signature oracle) or key-substitution attacks (where the adversary tries to find another key vk^* to a valid triple (vk, m, s) , both under adaptive chosen-message attacks. For this, let $R_{\text{str-unf}}(vk, vk^*, m^*, s^*)$ be the relation such that $R_{\text{str-unf}}(vk, vk^*, m^*, s^*) = 1$ iff $vk = vk^*$; let $R_{\text{key-sub}}$ be the relation such that $R_{\text{key-sub}}(vk, vk^*, m^*, s^*) = 1$ iff $\text{VF}(vk, m^*, s^*) = 1$. The proof is omitted.

Proposition 1. *Let $(\text{KGEN}, \text{SIG}, \text{VF})$ be a signature scheme which is completely non-malleable with respect to $\mathcal{R} \ni R_{\text{str-unf}}$ resp. $\mathcal{R} \ni R_{\text{key-sub}}$. Then the scheme is strongly unforgeable under adaptive chosen-message attacks resp. secure against key-substitution attacks.*

4 Summary of Results

In this section we summarize our (positive and negative) results. For better comprehensibility the results are stated in an informal way. The formal results and technical details can be found in the full version.

Regular Non-Malleability and Relations over Messages Only. We show that extending the relations in the definition of [7] for regular non-malleability, i.e., where the adversary does not tamper the public key, to include the given public key pk (in addition to the messages m, m^*) can be fatal to security:

Theorem 1 (informal). *There is an encryption scheme which is non-malleable with respect to $\mathcal{R}_{\text{msg}} = \{R(m, m^*)\}$ but which is malleable with respect to some relation $R_{pk}(pk, m, m^*)$.*

Hardness of Constructions for General Relations. Here we discuss our negative results for constructions of completely non-malleable schemes where, in contrast to the previous case, the adversary is allowed to output another key pk^* . We show that there are relations for which completely non-malleable schemes are hard to construct. Although we prove this result for a specific set of “bad” relations, we note that the implication carries over to any class where such relations can be “somehow embedded” in relations of the class.

Theorem 2 (informal). *Public-key encryption schemes which are completely non-malleable according to black-box stand-alone simulators and general relations, do not exist.*

Note that the previous theorem assumes that the simulator is stand-alone. For assisted simulators, which are granted access to DEC , we can show the same result for relations which are efficiently computable relative to an oracle. We note that the black-box simulator does not have access to this oracle directly, but only through the relation. This corresponds to the case that the simulator can efficiently compute the relation (via black-box access) but is denied the description of the relation.

Theorem 3 (informal). *Public-key encryption schemes which are completely non-malleable according to black-box assisted simulators and general relations (relative to an oracle), do not exist.*

The results about encryption easily transfers to signatures:

Proposition 2 (informal). *Signature schemes which are completely non-malleable according to black-box simulations for general relations, do not exist.*

Yet, for signatures we can show that completely non-malleable systems for general relations are impossible at all, even when allowing non-black-box constructions or if the simulator depends on the relation.

Theorem 4 (informal). *There do not exist completely non-malleable signature schemes with respect to general relations.*

Constructions in the Random Oracle Model. On the positive side, solutions in the random oracle for completely non-malleable schemes exist. And while OAEP encryption [2] and Fiat-Shamir signatures [11] provably do not have this property, slight variations of these schemes work. The basic idea to simply include the public encryption or signature key, respectively, to each hash function evaluation. We append the term “with public-key hashing” to such modified schemes:

Proposition 3 (informal). *RSA-OAEP with public-key hashing is completely non-malleable with respect to stand-alone simulators and any relations, in the random oracle model.*

A similar result holds for Fiat-Shamir signatures:

Proposition 4 (informal). *Fiat-Shamir signatures with public-key hashing are completely non-malleable with respect to general relations (except for essentially those relations, for which the unconditional impossibility results of Theorem 4 holds), in the random oracle model.*

In both cases the proofs rely on the original results [2, 10, 14] about the security against regular chosen-ciphertext attacks and chosen-message attacks.

`d.galindo@cs.ru.nl`

Abstract. The first practical identity based encryption (IBE) scheme was proposed by Boneh and Franklin in [BF03]. In this work we point out that there is a flawed step in the security reduction exhibited by the authors. Fortunately, it is possible to fix it without changing the scheme or the underlying assumption.

In the second place, we introduce a variant of the seminal IBE scheme which allows a more efficient security reduction. This variant is simpler, and has more compact ciphertexts than Boneh-Franklin's proposal, while keeping the computational cost.

Finally, we observe that the flawed step pointed out here is present in several works, and that our techniques can be applied to obtain tighter reductions for previous relevant schemes.

Keywords: provable security, identity-based encryption, exact security, bilinear maps.

1 Introduction

The concept of Identity Based Encryption (IBE) was proposed by Shamir in [Sha84], aimed at simplifying certificate management in e-mail related systems. The idea is that an arbitrary string such as an e-mail address or a telephone number could serve as a public key for an encryption scheme. Once a user U receives a communication encrypted using its identity ID_U , the user authenticates itself to a Private Key Generation Center (KGC) from which it obtains the corresponding private key d_{ID} .

The problem was not satisfactorily solved until the work by Boneh and Franklin [BF03]. They proposed formal security notions for IBE systems and designed a fully functional secure IBE scheme using bilinear maps. The security is based on a variant of the Computational Diffie-Hellman assumption, called Bilinear Diffie-Hellman assumption. This scheme and the tools developed in its design have been successfully applied in numerous cryptographic settings, transcending by far the identity based cryptography framework.

On the other hand, an important concern when exhibiting a security reductionist proof is that of the efficiency of the reduction. One of the goals pursued

is to preserve as much as possible the strength of the underlying hard problem which is used in the protocol's design. An inefficient security reduction would imply the use of larger key sizes to attain a given security level.

Our contributions. In the first place, we show there is a flawed step in the security reduction exhibited in [BF03] for the scheme proposed for chosen ciphertext security. Fortunately, the reduction can be changed without modifying the original scheme or the underlying hard problem used to state the security. The efficiency of the new security reduction is a bit worse than the previous one. This is just another example in which a well-known and widely used construction turns out to have an unnoticed flawed security reduction.

In the second place, we modify the scheme by Boneh and Franklin towards obtaining a more efficient security reduction. Indeed, it is possible to show a tighter security reduction for a modified scheme which uses one less random oracle. The new proposal also presents more compact ciphertexts than the original scheme.

Finally, since Boneh-Franklin IBE scheme has been used as a building block for numerous protocols, the corrections and/or improvements we present here are likely to be applied to further schemes. For instance, this is the case for the schemes in [GS02, HL02, Gen03, AP03, YFDL04, CC05].

2 Preliminaries

We begin by fixing some notation. If A is a non-empty set, then $x \leftarrow A$ denotes that x has been uniformly chosen in A . If A is a finite set, then $|A|$ denotes its cardinality.

2.1 Definitions for IBE Schemes

Identity based encryption (IBE). An IBE is specified by four probabilistic polynomial time (PPT) algorithms:

Setup takes a security parameter 1^ℓ and returns the system parameters **params** and **master-key**. The system parameters include the description of sets \mathcal{M}, \mathcal{C} , which denote the set of messages and ciphertexts respectively. **params** is publicly available, while the **master-key** is kept secret by the KGC.

Extract takes as inputs **params**, **master-key** and an arbitrary string $ID \in \{0, 1\}^*$ and returns a private key d_{ID} to the user with identity ID . This must be done over a secure channel, since d_{ID} enables to decrypt ciphertexts under the identity ID .

Encrypt takes as inputs **params**, $ID \in \{0, 1\}^*$ and $M \in \mathcal{M}$. It returns a ciphertext $C \in \mathcal{C}$.

Decrypt takes as inputs **params**, $C \in \mathcal{C}$ and a private key d_{ID} , and it returns $M \in \mathcal{M}$ or rejects.

Chosen ciphertext security. An IBE scheme is said to have indistinguishability against an adaptive chosen ciphertext attack (IND-ID-CCA) if any PPT algorithm \mathcal{A} has a negligible advantage in the following game:

Setup The challenger takes a security parameter 1^ℓ and runs the **Setup** algorithm. It gives **params** to the adversary. It keeps the **master-key** to itself.

Phase 1 The adversary issues queries of the form

- Extraction query $\langle \text{ID}_i \rangle$. The challenger runs algorithm **Extract** to generate the private key d_i corresponding to ID_i . It sends d_i to the adversary.
- Decryption query $\langle \text{ID}_i, C_i \rangle$. The challenger generates the private key d_i . It then runs **Decrypt** to decrypt C_i under ID_i .

These queries may be asked adaptively, that is, each query may depend on the answers obtained to the previous queries.

Challenge The adversary outputs equal length plaintexts $M_0, M_1 \in \mathcal{M}$ and an identity ID_{ch} . The only constraint is that the private key for ID_{ch} was not requested in Phase 1. The challenger picks $\beta \leftarrow \{0, 1\}$ and sets $C = \text{Encrypt}(\text{params}, \text{ID}_{\text{ch}}, M_\beta)$. It sends C to the adversary.

Phase 2 The adversary issues extraction and decryption queries as in Phase 1, with the restriction $\langle \text{ID}_i \rangle \neq \langle \text{ID}_{\text{ch}} \rangle$ and $\langle \text{ID}_i, C_i \rangle \neq \langle \text{ID}_{\text{ch}}, C \rangle$.

Guess The adversary outputs a guess $\beta' \in \{0, 1\}$.

Such an adversary is called an IND-ID-CCA adversary \mathcal{A} , and its advantage is defined as $\text{Adv}_{\mathcal{E}, \mathcal{A}}^{\text{CCA}}(1^\ell) = |\Pr[\beta = \beta'] - 1/2|$.

Similarly, indistinguishability against passive adversaries (IND-ID-CPA) can also be defined. In this case, the game between the challenger and the adversary is similar to the IND-ID-CCA case, but disallowing decryption queries. The advantage of an adversary in this game is defined as $\text{Adv}_{\mathcal{E}, \mathcal{A}}^{\text{CPA}}(1^\ell) = |\Pr[\beta = \beta'] - 1/2|$.

Definition 1. *An IBE system \mathcal{E} is secure under chosen ciphertext attacks (resp. chosen plaintext attacks) if for any probabilistic polynomial time IND-ID-CCA (resp. IND-ID-CPA) adversary \mathcal{A} the function $\text{Adv}_{\mathcal{E}, \mathcal{A}}^{\text{CCA}}(1^\ell)$ (resp. $\text{Adv}_{\mathcal{E}, \mathcal{A}}^{\text{CPA}}(1^\ell)$) is negligible.*

2.2 Bilinear Maps and Bilinear Groups

Let $\mathbb{G}_1, \mathbb{G}_2$ and \mathbb{G}_T be finite abelian groups in which the discrete logarithm is believed to be hard. We use additive notation for $\mathbb{G}_1, \mathbb{G}_2$ whereas multiplicative notation is used for \mathbb{G}_T . Thus, $\mathbb{G}_1^* = \mathbb{G}_1 \setminus \{O_1\}$ and $\mathbb{G}_T^* = \mathbb{G}_T \setminus \{1_T\}$, where O_1 and 1_T are the identity elements in \mathbb{G}_1 and \mathbb{G}_T respectively. By a *pairing* or *bilinear map* we will refer to a non-degenerate bilinear function $\hat{e} : \mathbb{G}_1 \times \mathbb{G}_2 \rightarrow \mathbb{G}_T$. In some protocols the existence of a computable isomorphism $\psi : \mathbb{G}_2 \rightarrow \mathbb{G}_1$ is assumed. In particular, this implies that $\psi(aP_2) = a\psi(P_2)$. By a *bilinear group* we refer to a tuple $(\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, \hat{e}, \psi)$ with the properties described above.

Bilinear maps are usually implemented using the Weil or modified Tate pairings on an elliptic curve. In general, the elements in \mathbb{G}_1 allow more compact representation than those in \mathbb{G}_2 . In the following it is assumed that $|\mathbb{G}_1| = |\mathbb{G}_2| = |\mathbb{G}_T| = p$, where p is prime; $\mathbb{G}_1, \mathbb{G}_2$ are cyclic groups generated by P_1, P_2

respectively and $\psi(P_2) = P_1$. In this context, the map \hat{e} is non-degenerate if and only if $\hat{e}(P_1, P_2) \neq 1_G$. We refer to [BF03] for further details.

Bilinear Diffie-Hellman (BDH) Problem on $(\mathbb{G}_1, \mathbb{G}_2)$. Given $aP_2, bP_2 \in \mathbb{G}_2^*$ and $cP_1 \in \mathbb{G}_1^*$, where $P_2 \leftarrow \mathbb{G}_2^*$, $P_1 = \psi(P_2)$, $a, b, c \leftarrow \mathbb{Z}_p^*$; compute $W = \hat{e}(P_1, P_2)^{abc} \in \mathbb{G}_T$.

We say that an algorithm $\mathcal{B}(t, \varepsilon)$ breaks BDH on $(\mathbb{G}_1, \mathbb{G}_2)$ if it runs in time at most t and has advantage at least ε , that is,

$$\Pr[\mathcal{B}(P_2, aP_2, bP_2, cP_1) = \hat{e}(P_1, P_2)^{abc}] \geq \varepsilon,$$

where the probability is taken over the random choices of the parameters, and the random bits of \mathcal{B} .

Bilinear Decision Diffie-Hellman (BDDH) Problem on $(\mathbb{G}_1, \mathbb{G}_2)$. Let $aP_2, bP_2 \in \mathbb{G}_2^*$, $cP_1 \in \mathbb{G}_1^*$, and $T \leftarrow \mathbb{G}_T$, where $P_2 \leftarrow \mathbb{G}_2^*$, $P_1 = \psi(P_2)$, $a, b, c \leftarrow \mathbb{Z}_p^*$. We say that an algorithm $\mathcal{B}(t, \varepsilon)$ breaks BDDH on $(\mathbb{G}_1, \mathbb{G}_2)$ if it runs in time at most t and

$$|\Pr[\mathcal{B}(P_2, aP_2, bP_2, cP_1, \hat{e}(P_1, P_2)^{abc}) = 1] - \Pr[\mathcal{B}(P_2, aP_2, bP_2, cP_1, T) = 1]| \geq \varepsilon,$$

where the probability is computed over the random choices of the parameters, and the random bits of \mathcal{B} . Hereafter, the distribution on the left side is called *BDH distribution* and is denoted by \mathcal{P}_{BDH} , while the distribution on the right is called *random BDH distribution* and is denoted by \mathcal{R}_{BDH} .

3 Security Proof of Boneh-Franklin Identity Based Encryption Scheme Revisited

In this section we consider the identity based encryption (IBE) scheme by Boneh and Franklin [BF03]. In the first place, we point out and fix a flaw in the security reduction given by the authors. In repairing the proof, we do not need to change the security assumption neither the specification of the scheme. However, the security reduction is a bit worse than the original one.

3.1 Boneh-Franklin IBE Scheme

We will not directly use the original description of the BF scheme, because it is phrased with bilinear group pairs where $\mathbb{G}_1 = \mathbb{G}_2$, so we must adapt their scheme to the more general case $\mathbb{G}_1 \neq \mathbb{G}_2$. In choosing how to use \mathbb{G}_1 and \mathbb{G}_2 , we preferred to minimize the length of the ciphertexts. This means we use \mathbb{G}_2 as the set of private keys and then ciphertexts are elements in $\mathbb{G}_1^* \times \{0, 1\}^n$. Here follows the description of the BF scheme, which is called *Full-Ident* in [BF03].

Full-Ident

Setup. Let $(\mathbb{G}_1, \mathbb{G}_2, G_T, \widehat{e}, \psi)$ a bilinear group. Choose a generator $P_2 \leftarrow \mathbb{G}_2$ and set $P_1 = \psi(P_2)$. Next pick $s \leftarrow \mathbb{Z}_p^*$ and set $Q_{pub} = sP_2 \in \mathbb{G}_2^*$, $P_{pub} = sP_1 \in \mathbb{G}_1^*$. Choose cryptographic hash functions $H_1 : \{0, 1\}^* \rightarrow \mathbb{G}_2^*$, $H_2 : \mathbb{G}_T \rightarrow \{0, 1\}^n$, $H_3 : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \mathbb{Z}_p^*$, $H_4 : \{0, 1\}^n \rightarrow \{0, 1\}^n$. The message space is $\mathcal{M} = \{0, 1\}^n$ and the ciphertext space is $\mathcal{C} = \mathbb{G}_1^* \times \{0, 1\}^n \times \{0, 1\}^n$.

Extract. For a given string $ID \in \{0, 1\}^*$, compute $Q_{ID} = H_1(ID) \in \mathbb{G}_2^*$ and set the private key d_{ID} to be $d_{ID} = sQ_{ID} \in \mathbb{G}_2^*$.

Encrypt. To encrypt $M \in \{0, 1\}^n$ under identity ID , compute $Q_{ID} = H_1(ID) \in \mathbb{G}_2^*$, choose $\sigma \leftarrow \{0, 1\}^n$, set $r = H_3(\sigma, M) \in \mathbb{Z}_p^*$ and finally $C = \langle rP_1, \sigma \oplus H_2(g_{ID}^r), M \oplus H_4(\sigma) \rangle$ where $g_{ID} = \widehat{e}(P_{pub}, Q_{ID}) \in \mathbb{G}_T$.

Decrypt. Let $C = \langle U, V, W \rangle \in \mathcal{C}$ be a ciphertext under the identity ID . To decrypt C using the private key $d_{ID} \in \mathbb{G}_2^*$ do:

1. Compute $V \oplus H_2(\widehat{e}(U, d_{ID})) = \sigma$.
2. Compute $W \oplus H_4(\sigma) = M$.
3. Set $r = H_3(\sigma, M)$. Check that $U = rP$. If not, reject the ciphertext.
4. Output M .

This completes the description of Full-Ident. This IBE scheme is sound since

$$\widehat{e}(U, d_{ID}) = \widehat{e}(rP_1, sQ_{ID}) = \widehat{e}(P_1, Q_{ID})^{sr} = \widehat{e}(P_{pub}, Q_{ID})^r = g_{ID}^r.$$

In [BF03] it is proven that the above scheme is IND-ID-CCA secure under the BDH assumption in the Random Oracle model. That scheme uses Fujisaki and Okamoto transformation [FO99] from a one-way encryption scheme into an IND-CCA encryption scheme in the ROM (we refer to [BDPR98] for public key encryption security notions). If we denote by $E_{pk}(M, r)$ the encryption of M using the random bits r under the public key pk , the transformation by Fujisaki and Okamoto is the hybrid scheme¹

$$E_{pk}^{hy}(M) = \langle E_{pk}(\sigma, H_3(\sigma, M)), H_4(\sigma) \oplus M \rangle \tag{1}$$

where σ is random and H_3, H_4 are random oracles. To decrypt (C_1, C_2) , one first obtains σ' decrypting C_1 using the original scheme, next computes M' and finally checks if $E_{pk}(\sigma', H_3(\sigma', M)) = C_1$. If this is so, outputs M ; otherwise outputs reject.

Two additional schemes are needed in order to exhibit the security proof in [BF03]. These schemes are not IBE schemes but merely public key encryption schemes. They are called BasicPub and BasicPub^{hy}. Here follows the description of

¹ In the case where the symmetric encryption scheme is the one-time pad.

BasicPub

KeyGen. Let $(\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, \hat{e}, \psi)$ a bilinear group. Choose a generator $P_2 \leftarrow \mathbb{G}_2$ and set $P_1 = \psi(P_2)$. Next pick $s \leftarrow \mathbb{Z}_p^*$, $Q \leftarrow \mathbb{G}_2^*$ and set $Q_{pub} = sP_2 \in \mathbb{G}_2^*$, $P_{pub} = sP_1 \in \mathbb{G}_1^*$. Choose $H_2 : \mathbb{G}_T \rightarrow \{0, 1\}^n$. Then $\mathcal{M} = \{0, 1\}^n$ and $\mathcal{C} = \mathbb{G}_1^* \times \{0, 1\}^n$. The public key is

$$\text{pk} = \langle p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, \hat{e}, P_1, P_2, P_{pub}, Q_{pub}, Q, H_2 \rangle.$$

The private key is $\text{sk} = d = sQ \in \mathbb{G}_2^*$.

Encrypt. To encrypt $M \in \{0, 1\}^n$ choose $r \leftarrow \mathbb{Z}_p^*$ and set the ciphertext to be

$$C = \langle rP_1, M \oplus H_2(g^r) \rangle \quad \text{where } g = \hat{e}(P_{pub}, Q) \in \mathbb{G}_T$$

Decrypt. Let $C = \langle U, V \rangle \in \mathcal{C}$ be a ciphertext under the public key pk. To decrypt C using the private key $d \in \mathbb{G}_2^*$, compute $V \oplus H_2(\hat{e}(U, d)) = M$.

Finally, the scheme BasicPub^{hy} is the result of applying Fujisaki-Okamoto transformation (1) to the above scheme. The security reduction for Full-Ident scheme under the BDH assumption follows the diagram below

The following results are shown in [BF03]. Hereafter, q_E, q_D, q_H denote the number of extraction, decryption and random oracle H_i queries respectively.

Result 1. Let \mathcal{A}_1 an IND-ID-CCA adversary that has advantage ε_2 against Full-Ident making at most q_E, q_D and q_{H_1} queries. Then there is an IND-CCA adversary \mathcal{A}_2 that has advantage at least $\frac{\varepsilon_1}{\varepsilon(1+q + q)}$ against BasicPub^{hy} . Its running time is $t_2 \leq t_1 + c_{\mathbb{G}_2}(q_D + q_{H_1} + q_E)$, where $c_{\mathbb{G}_2}$ denotes the time of computing a random multiple in \mathbb{G}_2 .

Result 2. Let \mathcal{A}_2 an IND-CCA adversary that has advantage ε_2 against BasicPub^{hy} making at most q_D, q_{H_3} and q_{H_4} queries. Then there is an IND-CPA adversary \mathcal{A}_3 that has advantage at least $\frac{1}{2(q + q + q)} [(\varepsilon_2 + 1)(1 - 2/p)^q - 1]$ against BasicPub. Its running time is $t_3 \leq t_2 + \mathcal{O}((q_{H_3} + q_{H_4}) \cdot (n + \log p))$.

Result 3. Let \mathcal{A}_3 an IND-CPA adversary that has advantage ε_3 against BasicPub making at most q_{H_2} queries. Then there is an algorithm \mathcal{B} breaking the BDH problem on $(\mathbb{G}_1, \mathbb{G}_2)$ with advantage at least $\frac{2\varepsilon_3}{q_{H_2}}$ and running time $t' \approx t_3$.

In order to come up with the total concrete security, we can bound any q_H with a single q_H , and assume that $q_E = q_D$, since extraction and decryption operations have roughly the same computational complexity. Then, taking the above reductions, we obtain that the BF scheme is $(t_1, q_H, q_D, \varepsilon_1)$ IND-ID-CCA secure if the BDH problem on $(\mathbb{G}_1, \mathbb{G}_2)$ is

$$\left(t_1 + c_{\mathbb{G}_1}(2q_D + q_H) + 2q_H(n + \log p), \frac{\varepsilon_1}{8eq_H^2q_D} \right)\text{-secure.} \quad (2)$$

Therefore, the security reduction is far from tight, mainly because of the $q_H^2q_D$ factor relating the advantages against the scheme and the underlying problem.

3.2 A Flaw in the Security Reduction

In this section we point out a flaw in the reduction used to state Result 1, which is Lemma 4.6 in [BF03].

The goal of that reduction is to construct an IND-CCA adversary \mathcal{B} with advantage $\varepsilon/e(1 + q_E + q_D)$ against BasicPub^{hy} by using an IND-ID-CCA adversary \mathcal{A} with advantage ε against Full-Ident . \mathcal{B} receives a public key

$$K_{pub} = \langle p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, \hat{e}, P_1, P_2, P_{pub}, Q, Q_{pub}, H_2, H_3, H_4 \rangle$$

from its challenger. Then \mathcal{B} simulates the challenger for \mathcal{A} as follows:

Setup \mathcal{B} gives \mathcal{A} the parameters $\langle p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, \hat{e}, P_1, P_2, P_{pub}, Q_{pub}, H_1, H_2, H_3, H_4 \rangle$, where H_1 is an oracle controlled by \mathcal{B} as indicated in the following:

H_1 -queries To respond to \mathcal{A} queries, algorithm \mathcal{B} maintains a list H_1^{list} of tuples $\langle \text{ID}_i, Q_i, b_i, c_i \rangle$ as explained below. When \mathcal{A} queries H_1 at an unrepeated ID_i , \mathcal{B} generates a random coin $c_i \in \{0, 1\}$ such that $\Pr[c_i = 0] = \delta$, and a random $b_i \leftarrow \mathbb{Z}_p^*$. If $c_i = 0$ it computes $Q_i = b_i P_2 \in \mathbb{G}_2^*$, and if $c_i = 1$ it computes $Q_i = b_i Q \in \mathbb{G}_2^*$. Finally, \mathcal{B} adds the tuple $\langle \text{ID}_i, Q_i, b_i, c_i \rangle$ to the H_1^{list} and sends $H_1(\text{ID}_i) = Q_i$ to \mathcal{A} .

The idea is that tuples with $c_i = 0$ enable \mathcal{B} to answer private key queries for identity ID_i , while \mathcal{B} can only take profit of \mathcal{A} 's advantage when \mathcal{A} chooses a challenge identity ID_{ch} such that $c_{\text{ch}} = 1$.

Phase 1 - Extraction queries When \mathcal{A} asks for the private key associated to ID_i , \mathcal{B} runs the algorithm for responding H_1 -queries and gets $H_1(\text{ID}_i) = Q_i$, where $\langle \text{ID}_i, Q_i, b_i, c_i \rangle$ is the corresponding entry in H_1^{list} . If $c_i = 1$ then \mathcal{B} aborts the game and the attack against BasicPub^{hy} failed. Otherwise, $c_i = 0$ and therefore $Q_i = b_i P_2$. It turns out that d_i can be computed as $d_i := b_i Q_{pub}$, since by definition $d_i = sQ_i$. Finally, \mathcal{B} gives d_i to algorithm \mathcal{A} .

Phase 1 - Decryption queries \mathcal{B} answers to a decryption query $\langle \text{ID}_i, C_i \rangle$ as follows. It runs H_1 -queries algorithm and let $\langle \text{ID}_i, Q_i, b_i, c_i \rangle \in H_1^{\text{list}}$. If $c_i = 0$, then \mathcal{B} retrieves the private key d_i and decrypts C_i using the decryption algorithm. If $c_i = 1$, then $Q_i = b_i Q$. Recall that the unknown private key is $d_i = sQ_i = sb_i Q$. Set $C'_i = \langle b_i U_i, V_i, W_i \rangle$, where $C_i = \langle U_i, V_i, W_i \rangle$. Then, the authors claim that the Full-Ident decryption of C_i is equal to the BasicPub^{hy} decryption of C'_i . The reason given is that

$$\hat{e}(b_i U_i, d) = \hat{e}(b_i U_i, sQ) = \hat{e}(U_i, sb_i Q) = \hat{e}(U_i, sQ_i) = \hat{e}(U_i, d_i),$$

which implies that the values σ and M obtained by decrypting C_i with Full-Ident and by decrypting C'_i with BasicPub^{hy} are equal. However, BasicPub^{hy} will output the reject symbol when decrypting C'_i with overwhelming probability. To see this, remember that $b_i U_i = b_i r_i P_1$, and at least $b_i \leftarrow \mathbb{Z}_p^*$, which implies that $b_i r$ is uniformly random in \mathbb{Z}_p^* . On the other hand, we have that H_3 is a random oracle not controlled by \mathcal{B} . These facts imply that $H_3(\sigma, M) \neq b_i r$ with probability $1 - 1/p$, and therefore the decryption algorithm of BasicPub^{hy} will reject the ciphertext. Thereby, we can not use the decryption oracle for BasicPub^{hy} to decrypt ciphertexts under any ID_i such that $H_1(ID_i) \neq Q$. Therefore, the reduction in [BF03] is not valid.

3.3 Fixing the Security Reduction

Due to the ciphertext integrity checking in FO transformation [FO99], we can only answer decryption queries $\langle ID_i, C_i \rangle$ such that:

- $H_1(ID_i) = b_i P_2$, since we can use the private key d_i , or
- $H_1(ID_i) = Q$, since in this case, the decryption of C_i under such ID_i is equal to the decryption of C_i by BasicPub^{hy}.

This remark enables us to fix the flawed reduction shown above. In the following we describe the new answers delivered by \mathcal{B} .

Setup As in Section 3.2.

H_1 -queries Before initializing H_1^{list} , \mathcal{B} selects at random $j \leftarrow \{1, \dots, q_{H_1}\}$. When \mathcal{A} queries H_1 at ID_i , algorithm \mathcal{B} proceeds as follows: if $i \neq j$, it picks $b_i \leftarrow \mathbb{Z}_p^*$, sets $Q_i = b_i P_2$, adds $\langle ID_i, Q_i, b_i \rangle$ to the list and gives back Q_i to \mathcal{A} . If $i = j$, it sets $Q_j = Q$, adds $\langle ID_i, Q_i, * \rangle$ to the list and sends Q_j to \mathcal{A} . Here $*$ denotes a special symbol. Note that the outputs of H_1 are uniformly distributed in \mathbb{G}_2^* and independent of \mathcal{A} 's current view, since Q is unknown to \mathcal{A} and is uniformly distributed in \mathbb{G}_2^* .

Phase 1 - Extraction queries When \mathcal{A} asks for the private key for ID_i , \mathcal{B} runs the algorithm for responding H_1 -queries and gets $H_1(ID_i) = Q_i$, where $\langle ID_i, Q_i, b_i \rangle$ is the corresponding entry in H_1^{list} . If $i = j$, then \mathcal{B} aborts the game and the attack against BasicPub^{hy} failed. Otherwise, it sets $d_i := b_i Q_{pub}$. Finally, \mathcal{B} gives d_i to algorithm \mathcal{A} .

Phase 1 - Decryption queries \mathcal{B} answers to a decryption query $\langle ID_i, C_i \rangle$ as follows. It runs H_1 -queries algorithm and let $\langle ID_i, Q_i, b_i \rangle \in H_1^{\text{list}}$. If $i \neq j$, then \mathcal{B} retrieves the private key d_i and decrypts C_i using the decryption algorithm. If $i = j$, then $Q_i = Q$, and the decryption of $\langle ID_j, C_j \rangle$ is the same as the decryption of C_j under BasicPub^{hy}. Then, \mathcal{B} asks its challenger to decrypt C_j and relays the answer to \mathcal{A} .

Challenge \mathcal{A} outputs a public key ID_{ch} and two equal length plaintexts M_0, M_1 . Algorithm \mathcal{B} proceeds as follows. If $ID_{ch} \neq ID_j$, it aborts the game and the attack against BasicPub^{hy} failed. Otherwise, it sends M_0, M_1 to its own challenger and gets back C , the encryption of M_β for a random bit β under BasicPub^{hy}. Finally, \mathcal{B} relays C to \mathcal{A} , which is an also encryption of M_β under ID_{ch} for Full-Ident.

Phase 2 - Extraction queries Algorithm \mathcal{B} proceeds as in Phase 1, except for the extraction query for ID_{ch} , which is rejected.

Phase 2 - Decryption queries Algorithm \mathcal{B} proceeds as in Phase 1, except for the decryption query $\langle ID_{ch}, C_\beta \rangle$, which is rejected.

Guess Algorithm \mathcal{A} outputs a guess β' for β . \mathcal{B} outputs β' as its guess.

Using this algorithm \mathcal{B} , we are able to state the following:

Result 4. *Let \mathcal{A} an IND-ID-CCA adversary that has advantage ε against Full-Ident making at most q_E, q_D and q_{H_1} queries. Then there is an IND-CCA adversary \mathcal{B} that has advantage at least $\frac{\varepsilon}{q-1} \left(1 - \frac{q}{q-1}\right) \approx \frac{\varepsilon}{q-1}$ against BasicPub^{hy}. Its running time is $t_2 \leq t_1 + c_{\mathbb{G}_2}(q_D + q_{H_1} + q_E)$, where $c_{\mathbb{G}_2}$ denotes the time of computing a random multiple in \mathbb{G}_2 .*

Proof: The proof appears in the full version of the paper. □

Therefore, joining Results 2, 3 and 4, an IND-ID-CCA advantage ε_1 against Full-Ident is turned into an algorithm with advantage roughly $\varepsilon_1/(q_H^3)$ in solving the BDH problem. Compared to the original flawed reduction, where the advantage obtained against BDH was roughly $\varepsilon_1/(q_H^2 q_D)$, the new reduction is a bit worse, since in general $q_D \ll q_H$. In the next section we show a modification of Full-Ident which allows a tighter security reduction.

4 A New Identity Based Encryption Scheme with Improved Tightness

In this section we design a new IBE scheme using the scheme Basic-Ident from the previous section and a second general transformation also due to Fujisaki and Okamoto [FO00]. This conversion starts from an IND-CPA encryption scheme and builds an IND-CCA scheme in the ROM. If we denote by $E_{pk}(M, r)$ the encryption of M using the random bits r under the public key pk , with set of messages $\mathcal{M} = \{0, 1\}^n$, set of coins \mathcal{R} and set of ciphertexts \mathcal{C} , the new transformation is the scheme

$$E_{pk}^{hyNew}(M) = E_{pk}(M||r, H(M||r)) \tag{3}$$

where $M||r \in \{0, 1\}^{n-k_0} \times \{0, 1\}^{k_0}$ and $H : \{0, 1\}^* \rightarrow \mathcal{R}$ is a hash function. Then, $\mathcal{M}^{hyNew} = \{0, 1\}^{n-k_0}$, $\mathcal{R}^{hyNew} = \{0, 1\}^{k_0}$ and $\mathcal{C}^{hyNew} = \mathcal{C}$. To decrypt C , one first obtains $M'||r'$ using the original decryption algorithm, and next checks if $E_{pk}(M'||r', H(M'||r')) = C$. If this is so, outputs M ; otherwise outputs reject.

Let us describe the new IBE scheme thereby obtained.

NewFull-Ident

Setup. Let $(\mathbb{G}_1, \mathbb{G}_2, G_T, \hat{e}, \psi)$ a bilinear group. Choose a generator $P_2 \leftarrow \mathbb{G}_2$ and set $P_1 = \psi(P_2)$. Next pick $s \leftarrow \mathbb{Z}_p^*$ and set $Q_{pub} = sP_2 \in \mathbb{G}_2^*, P_{pub} = sP_1 \in \mathbb{G}_1^*$. Choose hash functions $H_1 : \{0, 1\}^* \rightarrow \mathbb{G}_2^*, H_2 : \mathbb{G}_T \rightarrow \{0, 1\}^n$ and $H_3 : \{0, 1\}^* \rightarrow \mathbb{Z}_p^*$. Now $\mathcal{M} = \{0, 1\}^{n-k_0}, \mathcal{C} = \mathbb{G}_1^* \times \{0, 1\}^n$ and $\text{params} = \langle p, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, \hat{e}, P_1, P_2, P_{pub}, Q_{pub}, H_1, H_2, H_3 \rangle$. The master-key is $s \in \mathbb{Z}_p^*$.

Extract. For a given $\text{ID} \in \{0, 1\}^*$, compute $Q_{\text{ID}} = H_1(\text{ID}) \in \mathbb{G}_2^*$ and set $d_{\text{ID}} = sQ_{\text{ID}} \in \mathbb{G}_2^*$ where s is the master key.

Encrypt. To encrypt $M \in \{0, 1\}^{n-k_0}$ under ID , compute $Q_{\text{ID}} = H_1(\text{ID}) \in \mathbb{G}_2^*$, choose $\sigma \leftarrow \{0, 1\}^{k_0}$, set $r = H_3(M, \sigma) \in \mathbb{Z}_p^*$ and finally

$$C = \langle rP_1, (M || \sigma) \oplus H_2(g_{\text{ID}}^r) \rangle \quad \text{where} \quad g_{\text{ID}} = \hat{e}(P_{pub}, Q_{\text{ID}}) \in \mathbb{G}_T$$

Decrypt. Let $C = \langle U, V \rangle \in \mathcal{C}$ be a ciphertext under the public key ID . To decrypt C using the private key $d_{\text{ID}} \in \mathbb{G}_2^*$ do:

1. Compute $V \oplus H_2(\hat{e}(U, d_{\text{ID}})) = M || \sigma$.
2. Parse $M || \sigma$ and compute $r = H_3(M, \sigma)$. Check that $U = rP$. If not, reject the ciphertext.
4. Output M .

On the basis of the proof sketched in the previous section, we define in a similar fashion a public key encryption scheme **NewBasicPub^{hy}**, which is obtained applying the conversion from expression (3) to **Basic-Pub**. Then the following results hold:

Result 5. *Let \mathcal{A}_1 an IND-ID-CCA adversary with advantage ε_1 against **NewFull-Ident** making at most q_E private key extraction queries, q_D decryption queries and q_{H_1} hash queries. Then there is an IND-CCA adversary \mathcal{A}_2 that has advantage at least $\frac{\varepsilon}{q_1} \left(1 - \frac{q}{q_1}\right) \approx \frac{\varepsilon}{q_1}$ against **NewBasicPub^{Hy}**. Its running time is $t_2 \leq t_1 + c_{\mathbb{G}_1}(q_D + q_{H_1} + q_E)$.*

Proof: Use the same reduction as for Result 4 in Section 3.3.

Result 6. *Let \mathcal{A}_2 an IND-CCA adversary with advantage ε_2 against **NewBasicPub^{hy}** making at most q_D decryption queries and at most q_{H_2} hash queries. Then there is an IND-CPA adversary \mathcal{A}_3 that has advantage at least*

$$\left(\varepsilon_2 - q_{H_2} \cdot 2^{-(k_0-1)}\right) \left(1 - \frac{1}{p}\right)^q \approx \varepsilon_2$$

*against **BasicPub**. Its running time is $t_3 \leq t_2 + q_{H_2}(T_{\text{BasicPub}} + \log p)$, where T_{BasicPub} is the running time of **Encrypt** algorithm in **BasicPub**.*

Proof: This result is obtained as a special case of Theorem 5.4 in [FO00].

Finally, taking into account these new reductions, we obtain that **NewFull-Ident** scheme is $(t_1, q_H, q_D, \varepsilon_1)$ IND-ID-CCA secure if the BDH problem on $(\mathbb{G}_1, \mathbb{G}_2)$ is

$$\left(t_1 + c_{\mathbb{G}_1}(2q_D + q_H) + q_H \mathcal{O}(\log^3 p + \log p), \frac{\varepsilon_1}{q_H^2} \right)\text{-secure}$$

The last expression has been simplified replacing any of the hash queries q_H by q_H and setting $q_D = q_E$. Then, we get rid of a q_H factor in the BDH advantage with respect to the reduction in expression (2).

Compared to **Full-Ident** scheme, which is the result of using FO transformation in expression (1), the **NewFull-Ident** scheme presents several advantages:

- It provides more compact ciphertexts. In fact, **Full-Ident** scheme adds a n -bits component to a **Basic-Ident** ciphertext to get chosen ciphertext security, while **NewFull-Ident** achieves this preserving **Basic-Ident** ciphertext’s structure.
- It presents a tighter security reduction to the BDH problem.
- It uses one less hash function than **Full-Ident**.

We can obtain a second tightness improvement using a stronger assumption, namely, the BDDH assumption. In this case, we have the following result:

Result 7. *Let \mathcal{A}_3 an IND-CPA adversary that has advantage ε_3 against **BasicPub** making at most q_{H_2} hash queries. Then there is an algorithm \mathcal{B} breaking the BDDH problem on $(\mathbb{G}_1, \mathbb{G}_2)$ with advantage roughly ε_3 and running time $t' \approx t_3$.*

Proof: The proof appears in the full version of the paper. □

With this second tightness improvement, we obtain that **NewFull-Ident** scheme is $(t_1, q_H, q_D, \varepsilon_1)$ IND-ID-CCA secure if the BDDH problem on $(\mathbb{G}_1, \mathbb{G}_2)$ is

$$\left(t_1 + c_{\mathbb{G}_1}(2q_D + q_H) + q_H \mathcal{O}(\log^3 q + \log q), \frac{\varepsilon_1}{q_H} \right)\text{-secure}$$

Then, we get rid of a q_H factor in the security reduction at the cost of relying on a stronger assumption.

5 Conclusions

In this work, we have shown there is a flawed step in the security reduction exhibited in [BF03] for the so called Boneh-Franklin IBE scheme. We have provided a new reduction without modifying the original scheme neither the underlying hard problem used to state the security.

In the second place, we have proposed a new IBE scheme slightly changing the original scheme. The proposal presents a tighter reduction than BF scheme, uses one less random oracle and has more compact ciphertexts.

Finally, we point out that it is still an open problem to design an IND-ID-CCA IBE scheme with a tight security reduction under a reasonable assumption either in the standard or the random oracle models.

Single-Database Private Information Retrieval with Constant Communication Rate

Craig Gentry and Zulfikar Ramzan

DoCoMo Communications Laboratories USA, Inc.
{cgentry, ramzan}@docomolabs-usa.com

Abstract. We present a single-database private information retrieval (PIR) scheme with communication complexity $\mathcal{O}(k+d)$, where $k \geq \log n$ is a security parameter that depends on the database size n and d is the bit-length of the retrieved database block. This communication complexity is better asymptotically than previous single-database PIR schemes. The scheme also gives improved performance for practical parameter settings whether the user is retrieving a single bit or very large blocks. For large blocks, our scheme achieves a constant “rate” (e.g., 0.2), even when the user-side communication is very low (e.g., two 1024-bit numbers). Our scheme and security analysis is presented using general groups with hidden smooth subgroups; the scheme can be instantiated using composite moduli, in which case the security of our scheme is based on a simple variant of the “ Φ -hiding” assumption by Cachin, Micali and Stadler [2].

1 Introduction

PROBLEM STATEMENT AND BACKGROUND. Private Information Retrieval (PIR) schemes allow a user to retrieve the i^{th} bit of an n -bit database, without revealing to the database the value of i . The “trivial” solution is for the user to retrieve the entire database, but this approach may incur enormous communication costs. A good PIR scheme, on the other hand, should have considerably lower (certainly sub-linear) communication complexity. Private Block Retrieval (PBR) is a natural and more practical extension of PIR in which, instead of retrieving only a single bit, the user retrieves a d -bit block that begins at index i .

PIR and PBR have been studied extensively; here, we only mention the work most relevant to us. The notion of PIR was introduced by Chor et al. [5], who focused on the *information-theoretic* case, where one requires that the user’s query give absolutely no information about i . They proved that if only a single database is used, then n bits must be communicated. On the other hand, if the database is replicated in k servers, and if the user is allowed to give a separate query to each server, one can construct a PIR scheme with k user queries each being $\mathcal{O}(n^{1/k})$ -bits and k single-bit server responses.¹ However, to ensure user privacy in the multi-server setting, the servers must be trusted not to collude.

¹ Currently, the lowest asymptotic total communication complexity for information-theoretic PIR is $\mathcal{O}(n^{\log \log k / k \log k})$ [1].

Chor et al. also introduced PBR. They showed that any PIR scheme with $\alpha_k(n)$ -bit queries and $\beta_k(n)$ -bit responses can be converted into a PBR scheme for d -bit blocks with $\alpha_k(n)$ -bit queries and $d\beta_k(n)$ -bit responses. This means that, for a constant $k \geq 2$ of servers, the above information-theoretic PIR scheme can be converted into a PBR scheme with an asymptotically constant “rate” of $1/k$ – i.e., the ratio of bits retrieved (i.e., d) versus total communication complexity (i.e., $kd + \mathcal{O}(n^{1/k})$) tends towards $1/k$ as n and d increase appropriately. Increasing the rate to 1 in the information-theoretic setting seems difficult.

Chor and Gilboa studied the problem of whether one could achieve better communication complexity for multi-server PIR by using computational assumptions [4]. Subsequently, Kushilevitz and Ostrovsky showed that one can achieve *single database* PIR under the Quadratic Residuosity assumption with communication $2^{\mathcal{O}(\sqrt{\log n \log l})}$, where l_m is the bit length of a composite modulus m . Like all current single-database PIR schemes, the server needs $\Omega(n)$ computation to generate a query response. Since the number field sieve [10] can factor an l_m -bit composite number in time $2^{\mathcal{O}(1)l^{1/3}(\log l)^{2/3}}$ (and hence solve quadratic residuosity), and since it seems reasonable that the server should need at least as much computation to break user privacy as to generate a response, one should set $l_m = \Omega(\log^{3-o(1)} n)$ to ensure adequate security.

Cachin, Micali, and Stadler [2] constructed the first single-database PIR scheme with *poly-logarithmic* communication complexity (about $\mathcal{O}(\log^8 n)$ for their suggested parameters), addressing an open problem left by Kushilevitz and Ostrovsky. The security of their scheme (CMS) is based on the “ Φ -hiding” assumption – roughly, that is hard to distinguish which of two primes divides $\phi(m)$ for composite modulus m . Essentially, the scheme works as follows. Each index $j \in [1, n]$ is mapped to a distinct prime p_j . To recover bit b_i from database $B = b_1 \cdots b_n$, the user sends a composite (hard-to-factor) modulus m such that p_i divides $\phi(m)$ and a generator $x \in \mathbb{Z}_m^*$ with order divisible by p_i . The server sends back $r = x^P \pmod{m}$ for $P = \prod_j p_j^b$. The user concludes that $b_i = 1$ if r is a p -residue modulo m ; otherwise, $b_i = 0$. The communication complexity of (this simplified version of) CMS is $3l_m$ to recover 1 database bit. Again, $l_m = \Omega(\log^{3-o(1)} n)$ for adequate security, though [2] recommends an even larger value of l_m ($\mathcal{O}(\log^8 n)$).

Recently, Lipmaa [11] gave a PBR scheme with stated $\Theta(l_m \cdot \log^2 n + d \cdot \log n)$ communication complexity for d -bit blocks, where again $l_m = \Omega(\log^{3-o(1)} n)$. Thus, Lipmaa’s scheme has a better “rate” – namely $1/(\log n)$ – than CMS for large blocks. In fact, as we describe in the full version of this paper, one can apply Chor et al.’s [5] abovementioned conversion from PIR to PBR to Lipmaa’s scheme to get a PBR scheme with rate arbitrarily close to 1. However, for Lipmaa’s scheme to achieve a good rate in practice, n and d must be quite large (on the order of gigabits and megabits, respectively) before they begin to offset the large one-time cost represented by the $l_m \cdot \log^2 n$ term.

OUR RESULTS. We present a single-database PBR scheme that has, to the best of our knowledge, the lowest asymptotic communication complexity of

$\Theta(k + d)$. The scheme is somewhat similar to CMS [2], but the scheme is described (and its security proven) with respect to general groups that have “hidden subgroups” of smooth order. Our scheme also transforms the CMS technique to *maximize* the number of database bits the user can recover from a short server response. The essential technique is to associate each *block* of bits with a distinct *small* prime (or power of a small prime), rather than allocating a (largish) prime to each bit. The database’s response protocol uses the Chinese Remainder Theorem to encode each database chunk modulo its associated prime power. To decode, the user computes a discrete logarithm, but in a subgroup whose order is *smooth* – i.e., a product of small primes. We can carry out this step efficiently in a (somewhat surprising) *constructive* application of the Pohlig-Hellman method [14]. In the full version of the paper, we show that our scheme is secure against generic attacks even when $k = \mathcal{O}(\log n)$ and when the rate of the scheme approaches 1. We provide an oblivious transfer scheme with similar performance characteristics by using the Naor-Pinkas transformation [13].

We describe an instantiation of our scheme that, like CMS, uses a (e.g., 1024-bit) composite modulus m . In CMS as described above, a user sends a $2l_m$ -bit query and gets back a l_m -bit response that allows the user to retrieve a single bit; in our scheme, with the same communication complexity, the user can recover $c \cdot l_m$ bits for $c < 1/4$; this is a fairly high constant “rate” – i.e., the communication of the PBR scheme is only a small constant times more than the communication needed to transmit the block with *no privacy at all*. This instantiation has the best known asymptotic communication complexity $\Theta(\log^{3-o(1)} n, d)$ in terms of n and d among single-database PIR schemes and has the lowest complexity for most practical parameters (until it is overtaken by the modified version of Lipmaa’s scheme with rate approaching 1). However, this instantiation does not perform as well as our scheme *could* perform according to the generic group model, since it is vulnerable to the number field sieve unless $k = \Omega(\log^{3-o(1)} n)$ and to Coppersmith’s attack [6, 7] when $c \geq 1/4$. We speculate on approaches to instantiating the scheme that may achieve better performance.

2 Preliminaries

In the sequel, n denotes the database size in bits. If S is a set of elements, and D is a sampleable probability distribution on S , we let $s \stackrel{D}{\leftarrow} S$ denote the process of picking an element s from S according to distribution D . Throughout, π will denote a prime power. We say that an integer m Φ -hides π if π divides $\phi(m)$.

If A is an algorithm, we let $A(\cdot, \dots, \cdot)$ denote that A may take one or more inputs. By $\Pr[y \leftarrow A(x) : b(y)]$, we denote the probability that $b(y)$ is true after y was generated by A on input x . By $A^{(B)}(\cdot)$, we denote an algorithm that can make oracle queries to B . For $a, b \in \mathbb{Z}$ with $a \leq b$, let $[a, b]$ denote the set of integers between a and b inclusive. Let $[b]$ denote $[1, b]$.

Now, we define polylogarithmic private information retrieval as in [2].

Definition 1 (Polylogarithmic CPIR). Let $Q(\cdot, \cdot, \cdot)$, $D(\cdot, \cdot, \cdot)$ and $R(\cdot, \cdot, \cdot, \cdot, \cdot)$ be polynomial-time algorithms. We say that (Q, D, R) is a fully polylogarithmic CPIR scheme if there exists constants $a, b, c, d > 0$ such that:

- (Correctness) $\forall n \in \mathbb{N}, \forall B \in \{0, 1\}^n, \forall i \in [1, n],$ and $\forall k' \in \mathbb{N},$

$$\Pr[(q, s) \stackrel{R}{\leftarrow} Q(n, i, 1^{k'}); r \stackrel{R}{\leftarrow} D(B, q, 1^{k'}) : R(n, i, (q, s), r, 1^{k'}) = B_i] > 1 - 2^{-ak'}$$
- (User Privacy) $\forall n \in \mathbb{N}, \forall i, j \in [1, n], \forall k' \in \mathbb{N}$ such that $2^{k'} > n^b,$ and $\forall 2^{ck'}$ -gate circuits $A,$

$$\left| \Pr[(q, s) \stackrel{R}{\leftarrow} Q(n, i, 1^{k'}) : A(n, q, 1^{k'}) = 1] - \Pr[(q, s) \stackrel{R}{\leftarrow} Q(n, j, 1^{k'}) : A(n, q, 1^{k'}) = 1] \right| < 2^{-dk'}$$

Here a, b, c, d are the fundamental constants of the CPIR scheme; B is the contents of the database, D is the database’s response algorithm; Q is the user’s query-generating algorithm; R is the user’s response reconstruction algorithm; q is the user’s actual query; s is the user’s secret (associated with q); r is the database’s response; and k' is a security parameter.

Notice that we have mentioned two security parameters – namely, $k' > b \log n$ above, and k in the Introduction (which may be, e.g., the bit-length of a composite modulus). The two parameters are related by $k = \mathcal{O}(f(k'))$ for some polynomial f . For example, for the modulus-based instantiation, we may have $k = \max\{1024, Ck'^3\}$ for some constant C to ensure that no $(2^{ck'} = \text{poly}(n))$ -gate circuits A (e.g., a circuit running NFS) can break user privacy with probability $1/\text{poly}(n)$. Against generic attacks, $k = k'$ suffices to ensure user privacy. In short, the security parameter k' is useful because it ensures (above) that no algorithms A that are polynomial in n can break user privacy, while allowing us to separately define the security parameter k in the “common parlance” of a particular instantiation. (For example, for cryptosystems related to factoring, the security parameter k is typically defined as the modulus bit-length, even though such schemes have only $\exp(\mathcal{O}(1)k^{1/3}(\log k)^{2/3})$ security against NFS.)

3 Our General Private Block Retrieval Scheme

We now describe our PIR scheme using general groups with hidden smooth-order subgroups; afterwards, once the essential strategy of our scheme has been laid out, we will describe the computational assumption on which user privacy is based (which, by then, will seem relatively natural).

First, we give a high-level description of the scheme. The scheme has some public parameters known to all users, including the database size n , an integer parameter ℓ , a set of $t = \lceil n/\ell \rceil$ (small) distinct prime numbers $\{p_1, \dots, p_t\}$, and a set $\mathcal{S} = \{\pi_1, \dots, \pi_t\}$ of prime powers $\pi_i = p_i^{c_i}$, where $c_i = \lceil \ell / \log_2 p_i \rceil$ (i.e., so that $p_i^{c_i} \geq 2^\ell$). The server partitions the database B into t blocks $B = C_1 \| C_2 \| \dots \| C_t$ of size at most ℓ . In our scheme, the user will retrieve the entire ℓ -bit block that

contains its desired bit. Each block C_i is associated to a prime power π_i . Using the Chinese Remainder Theorem, the server can express the entire database B as an integer e that satisfies $e \equiv C_i \pmod{\pi_i}$, where the ℓ -bit block C_i is treated as an integer satisfying $0 \leq C_i < 2^\ell \leq \pi_i$. Notice that to retrieve C_i , it suffices to retrieve $e \pmod{\pi_i}$.

Roughly speaking, to query the value of $e \pmod{\pi_i}$, the user generates an appropriate cyclic group $G = \langle g \rangle$ with order $|G| = q\pi_i$ for some suitable integer q . It sends (G, g) to the server and keeps q private. Notice that G contains a subgroup H of order π_i , and that $h = g^q$ is a generator of H . (For technical reasons, in the actual scheme below, $\langle g \rangle$ may be a proper subgroup of G .)

The server responds with $g_e = g^e \in G$. The user then obtains $e \pmod{\pi_i}$ by setting $h_e = g_e^q \in H$ and performing a (tractable) discrete logarithm computation: $\log_h h_e \equiv e \pmod{\pi_i}$. This discrete logarithm computation, which occurs entirely in the subgroup H of order π_i , can actually be quite efficient if π_i is small. Correctness is demonstrated below. Now, we give a more precise description of the general scheme.

For some parameter choices, the user can select G such that $|G|$ is divisible by multiple π_i 's. In this case, the user can recover multiple ℓ -bit blocks (note that this does not contradict the security requirements for PIR schemes). However, for simplicity, we focus on the single-block case.

SPECIFICATION OF THE SCHEME. Let B be an n -bit database. Let $f_1(x, y)$ and $f_2(x, y)$ be functions. Let $k' = \Theta(\log n)$ and $k = f_2(k', \log n)$ be security parameters. Set $\ell = \lfloor f_1(k, \log n) \rfloor$ and $t = \lceil n/\ell \rceil$. For primes $\mathcal{P} = \{p_1, \dots, p_t\}$, set $\pi_i = p_i^c$ for $c_i = \lceil \ell/(\log_2 p_i) \rceil$, and $\mathcal{S} = \{\pi_i\}$. Let \mathcal{G}_i be the set of cyclic groups whose order is a number in $[2^k, 2^{k+1}]$ that is divisible by π_i . Let D_i be a distribution under which elements of \mathcal{G}_i can be efficiently sampled. We assume that for $G \xleftarrow{D_i} \mathcal{G}_i$, each $g \in G$ has a unique “normal” representation. (We will discuss the security considerations involved in choosing k' , f_1 , f_2 and $\{D_i\}$ later.)

Query Generation: Given input $(n, f_1, f_2, \mathcal{S}, \{D_i\}, 1^{k'})$, the user determines the index i of its desired block, and generates a query for block C_i as follows:

1. Generate $G \xleftarrow{D_i} \mathcal{G}_i$ and a uniformly random “quasi-generator” g of G – i.e., g is a random element of G such that $\text{GCD}(|G : \langle g \rangle|, \prod_{j=1}^t p_j) = 1$;
2. Output query (G, g) ; keep $q = |G|/\pi_i$ private; store $h = g^q$ for future use.

Database Response Generation: Given the input $(B, f_1, f_2, \mathcal{S}, G, g, 1^{k'})$, the server responds to the user’s query as follows:

1. Express each ℓ -bit database block C_j (after appending zeros to C_t if needed) as a number in $[0, 2^\ell - 1]$ in the obvious fashion;
2. Set e to be the smallest positive integer such that $e \equiv C_j \pmod{\pi_j}$ for all j ;
3. Output the response $g_e = g^e \in G$.

Note that steps 1 and 2 are independent of the query, and can be precomputed.

Response Retrieval: Given the input $(\pi_i, g_e, G, q, h, 1^{k'})$, the user retrieves block C_i as follows:

1. Compute $h_e = g_e^q$;
2. Compute C_i as the discrete logarithm $\log_h h_e$ within the subgroup $H \subset G$ of order $\pi_i = p_i^c$ using Pohlig-Hellman.

Notice that we need p_i to be small (unlike CMS) for the discrete logarithm computation using Pohlig-Hellman to be efficient. Fortunately, as we show below, the Prime Number Theorem will help us ensure that $\max\{p_i\}$ is small, and that response retrieval is efficient.

CORRECTNESS OF RESPONSE RETRIEVAL. Let $e_\pi \in [0, \pi_i - 1]$ satisfy $e_\pi \equiv e \pmod{\pi_i}$; observe that e_π is equal to C_i . So, it suffices to show that e_π is the discrete logarithm of h_e with respect to base h . Write $e = e_\pi + \pi_i \cdot E$, for some $E \in \mathbb{Z}$. Now:

$$h_e = g_e^{\langle g \rangle / \pi} = g^{e \langle g \rangle / \pi} = g^{e_\pi \langle g \rangle / \pi} = h^{e_\pi} .$$

Remark 1. The above scheme has some similarities to CMS, particularly if one instantiates the group G using a composite modulus m . However, for recovering *blocks* of data (a more realistic scenario anyway), our scheme is much more communication efficient; the server’s $(\log m)$ -bit response uses the Chinese Remainder Theorem to give the user ℓ bits instead of 1 bit. Later, we will see that ℓ can equal $(\log m)/C$ for reasonably small constant C .

CHOOSING THE SET \mathcal{P} WISELY. Recall that $\mathcal{P} = \{p_1, \dots, p_t\}$ is the set of primes that the scheme uses; let p_t be the largest. As mentioned above, p_t must be reasonably small to ensure efficient response retrieval. Also, since we must have $\log |G| \geq \max\{\pi_i\} \geq p_t$, the size of p_t also affects communication complexity. The following result of Rosser and Schoenfeld related to the Prime Number Theorem [15] gives an upper bound on p_t .

Theorem 1 (Rosser and Schoenfeld). *For $t > 20$, let $\mathcal{P} = \{p_1, \dots, p_t\}$ be the first t primes, with p_t the largest. Then, $p_t < t(\ln t + \ln \ln t - 1/2)$.*

For technical reasons in the security proof, we need $p_1 \geq 2t$. Nonetheless, in terms of n and ℓ , we easily get that $p_t < 16(n/\ell) \log_2(n/\ell)$ suffices. For the performance analysis below, we assume for convenience that ℓ is chosen so that $2^\ell \geq p_t$.

COMPUTATIONAL COMPLEXITY. The dominant component of the querier’s computation is in computing the discrete logarithm of h_e for base h . This step involves solving c_i discrete logarithm sub-problems in groups of order p_i for $p_i^c \in [2^\ell, 2^\ell p_t]$. Assuming that each sub-problem involves $\sqrt{p_i}$ group operations – e.g., using baby-step giant-step – the entire discrete logarithm problem requires about $c_i \sqrt{p_i}$ group operations. Considering the curve $y^x = 2^\ell p_t$ for $y \leq p_t$, we see that $x \sqrt{y} = (\sqrt{y} / \log y)(x \log y) = (\sqrt{y} / \log y)(\log(2^\ell p_t))$ takes its maximum at $y = p_t$. As a very rough upper bound, $\sqrt{p_i} / \log p_t < 2\sqrt{n/\ell}$ and $\log(2^\ell p_t) < 2\ell$, so the querier’s computation is no more than $4\sqrt{n\ell}$ group operations, where ℓ must be less than $\log |G|$ (which will be polylogarithmic in n). This does not seem

unreasonable given that the database’s computation in single-database PIR is *unavoidably linear* in n (since otherwise the database has not included every database bit in the computation, which would imply that it knows at least one bit that the user did not request).

The dominant component of the database’s computation is in computing $g^e \bmod m$. This requires (roughly) $\log e$ group operations. Since e is a number modulo $\prod_{i=1}^t \pi_i$, we have $\log e \leq \sum_{i=1}^t \log \pi_i$. Since, $p_i \leq 2^\ell$ for all i , $\pi_i = p_i^{c_i} < 2^{2\ell}$ for all $c_i = \lceil \ell / (\log p_i) \rceil$. Thus, we have $\sum_{i=1}^t \log \pi_i < 2t\ell = 2\ell \lceil n/\ell \rceil$ – i.e., the database needs $\Theta(n)$ group operations, which is about the best we can hope for in single-database PIR.

COMMUNICATION COMPLEXITY. Suppose that the group G and any element of G can be described in $l_G = \Omega(\log |G|)$ bits. (For example, the group generated by g modulo m for composite modulus m can be described in $\mathcal{O}(\log \phi(m))$ bits.) Then, the total communication complexity is $3l_G$. The size of l_G depends, in part, on security considerations pertaining to the particular instantiation of our general scheme; so, we obviously cannot give a general upper bound for l_G . Here, we merely note that, in terms of the scheme’s *correctness*, the only constraint on $|G|$ is that it be divisible by (and, hence, at least as large as) π_i . Above, we saw that when $2^\ell > p_t$, $\pi_i < 2^{2\ell}$ for all i . Thus, if we set $\ell = \lceil \log p_t \rceil$, then $\max\{\log \pi_i\} < 2\ell < 4 \log p_t < 8 \log n$. Thus, the mechanics of the scheme do not prevent $\log |G| = \Theta(\log n)$ or $l_G = \Theta(\log n)$.

We stress that l_G may need to be larger to ensure user privacy. However, in our analysis of the scheme’s security in the generic group model in Section 6, we find that generic attacks do not prevent our scheme with $l_G = \Theta(\log n)$ from having the security required by CMS’s definition of polylogarithmic PIR; any attack that forces l_G to be larger must exploit the encoding of the group or its elements.

PRIVATE BLOCK RETRIEVAL. In our scheme, the user already recovers ℓ -bit blocks. This scheme can be converted, using the general transformation described in [5], into a scheme that recovers d ℓ -bit blocks with total communication complexity $(2+d)l_G$, as follows. The user generates a query (G, g) for the ℓ -bit block beginning with index i . To allow the user to retrieve the ℓ -bit block with index $i + x\ell$ for $x \in [0, d-1]$, the server temporarily relabels the database, giving the database bit with index j (for $j \in [n]$) the “temporary index” $j - x\ell \pmod{n}$; it then responds to the user’s query (G, g) using the temporary indices, rather than the actual ones. The “rate” of our scheme – i.e., the ratio of the number of bits that the user retrieves over the total communication complexity – is $d\ell / (d+2)l_G$, which approaches ℓ/l_G as d increases. We will see that our general scheme is secure against generic group attacks for ℓ/l_G arbitrarily close to 1. When we instantiate the scheme using Φ -hiding and a composite modulus m in the natural way, however, an attack by Coppersmith [7] forces $\ell/l_G < 1/4$.

OBLIVIOUS TRANSFER. Naor and Pinkas [13] describe how to construct 1-out-of- n OT scheme from a PIR scheme for n -bit databases and $\log n$ invocations of a 1-out-of-2 OT scheme. Since the transformation is generic, we omit the

details, except to mention that 1-out-of-2 OT can be accomplished fairly efficiently through the ElGamal encryption scheme. If k'' is the bit-length of group elements in the ElGamal group (e.g., $k'' = 160$), the transformation only adds $6k''(\log n)$ bits to our PIR scheme, regardless of the block size d .

4 Our General Computational Assumption

In our PIR scheme, the server is given not only a description of G (and generator g), but also a promise that one of the prime powers in \mathcal{S} – i.e., the one associated to the user’s target block index i – actually divides $|G|$. For our PIR scheme to be user-private, the server should be unable to distinguish which of π_0 or π_1 divides $|G|$ – or, equivalently, to distinguish whether the “smooth” subgroup H hidden inside G has order π_0 or π_1 . So, our computational assumption is roughly that, given (π_0, π_1, G) and the promise that π_b divides $|G|$ for one $b \in \{0, 1\}$, it is computationally hard (if G is generated appropriately) to distinguish the value of b , even if π_0 and π_1 are not “much smaller” than $|G|$, and even if π_0 and π_1 are “special” integers such as powers of small primes. We formalize this assumption in terms of the following problem.

Definition 2 (The Decision Subgroup Problem). *Let ℓ be an integer and k a parameter. Let $\pi_0, \pi_1 \in [2^\ell, 2^{2\ell} - 1]$ be distinct integers. Let \mathcal{G}_i be the set of cyclic groups whose order is a number in $[2^k, 2^{k+1}]$ that is divisible by π_i . Let D_i be a distribution on \mathcal{G}_i . We say that algorithm A has advantage ϵ against the $(\ell, k, \pi_0, \pi_1, D_0, D_1)$ -Decision Subgroup Problem if*

$$\left| \Pr \left[b \stackrel{R}{\leftarrow} \{0, 1\}, G_b \stackrel{D}{\leftarrow} \mathcal{G}_b : A(G_b, \ell, k, \pi_0, \pi_1, \{D_i\}, \{\mathcal{G}_i\}) = b \right] - \frac{1}{2} \right| \geq \epsilon.$$

A solves the problem if it guesses b correctly.

In our PIR scheme, we want the above problem to be hard for each pair $\pi_{i_0}, \pi_{i_1} \in \mathcal{S}$, a set of prime powers. Thus, we state our computational assumption as follows.

Definition 3 (The (Extended) Decision Subgroup Assumption). *Let $f_1(x, y)$ and $f_2(x, y)$ be functions. Let \mathcal{S} be a set of $t \geq 2$ powers of distinct primes. The (f_1, f_2, \mathcal{S}) -Extended Decision Subgroup Assumption is that there exist constants $b, c, d > 0$ such that, for all $n \in \mathbb{N}$ and all $k' > b \log n$ with $\ell = \lfloor f_1(k', \log n) \rfloor$ and $k = f_2(k', \log n)$, there exist efficiently sampleable distributions $\{D_i : i \in [t]\}$ such that, for all $i_0, i_1 \in [t]$, all circuits \mathcal{A} with $(2^{ck'} + t \cdot f_2(k', \log n) \cdot C_{\{\mathcal{D}\}})$ gates have advantage at most $2^{-dk'}$ against the $(\ell, k, \pi_{i_0}, \pi_{i_1}, D_{i_0}, D_{i_1})$ -Decision Subgroup Problem, where $C_{\{\mathcal{D}\}}$ is an upper bound on the circuit complexity of a group multiplication in groups drawn according to D_i for $i \in [t]$.*

5 Security Proof for Our PIR Scheme

We base the security of our scheme on the extended decision subgroup assumption. The proof is done in the standard model.

Theorem 2. *Suppose that a circuit \mathcal{A} with $2^{ck'}$ gates can break user privacy with advantage $2^{-dk'}$. Then, there is an \mathcal{A}' with $\mathcal{O}(2^{ck'} + t \cdot f_2(k', \log n) \cdot C_{\{\mathcal{D}\}})$ gates that solves the extended decision subgroup problem with advantage $\frac{1}{5}2^{-dk'}$.*

Proof. Suppose that the privacy condition fails for (Q, D, R) . Then for all $b, c, d > 0$, there exist $n, k' > b \log n$, $B \in \{0, 1\}^n$, block indices $i \neq j$, and a circuit \mathcal{A} with $2^{ck'}$ gates, such that $|\alpha_{i,0} - \alpha_{j,0}| \geq 2^{-dk'}$, where:

$$\begin{aligned}\alpha_{i,\bar{v}} &\triangleq \Pr[((G, g), q) \leftarrow Q(i, T) : \mathcal{A}((G, g^{\prod_{=1}^p}), T) = 1], \\ \alpha_{j,\bar{v}} &\triangleq \Pr[((G, g), q) \leftarrow Q(j, T) : \mathcal{A}((G, g^{\prod_{=1}^p}), T) = 1],\end{aligned}$$

where \bar{v} is a t -element integer vector and 0^t is the zero vector, and where we define $T = (n, f_1, f_2, \mathcal{S}, \{D_i\}, 1^{k'})$ for convenience. We now define two probabilities representing \mathcal{A} 's output when g is chosen uniformly at random from G (as opposed to being a random quasi-generator of G):

$$\begin{aligned}\beta_{i,\bar{v}} &\triangleq \Pr[G \xleftarrow{D_i} \mathcal{G}_i; g \xleftarrow{R} G : \mathcal{A}((G, g^{\prod_{=1}^p}), T) = 1], \\ \beta_{j,\bar{v}} &\triangleq \Pr[G \xleftarrow{D_j} \mathcal{G}_j; g \xleftarrow{R} G : \mathcal{A}((G, g^{\prod_{=1}^p}), T) = 1].\end{aligned}$$

Let \bar{e}_x be the unit vector in dimension x . If p_x^v is greater than $2^{f_2(k, \log n)+1}$ (the maximum possible group order), then $\alpha_{i,\bar{v}} = \alpha_{i,\bar{v}-\bar{e}}$ since the distributions of the element given to \mathcal{A} are identical. Let \bar{v}_0 be s.t. $\epsilon_{\alpha\alpha} = |\alpha_{i,\bar{v}_0} - \alpha_{j,\bar{v}_0}|$ is maximal and s.t. $p_x^{v_0} \leq 2^{f_2(k, \log n)+1}$ for all $x \in [t]$. Set $\epsilon_{\beta\beta} \triangleq |\beta_{i,\bar{v}_0} - \beta_{j,\bar{v}_0}|$. Then, \mathcal{A}' can solve the decision subgroup problem instance for prime powers π_i, π_j with advantage $\epsilon_{\beta\beta}$ simply by generating random $g \in G$ and passing $(G, g^{\prod_{=1}^p})$ to \mathcal{A} , and then outputting “ i ” if \mathcal{A} outputs 1 and outputting “ j ” otherwise.

Let $\bar{w} \geq \bar{v}$ denote $\forall x \in [t], w_x \geq v_x$. We express $\beta_{i,\bar{v}}$ in terms of $\{\alpha_{i,\bar{w}} : \bar{w} \geq \bar{v}\}$ by noting that choosing an element of G uniformly at random is equivalent to choosing a uniformly random quasi-generator and then exponentiating it by $\prod_{x=1}^t p_x^{w_x - v_x}$ with probability $(\prod_{x=1}^t \frac{p_x - 1}{p}) / (\prod_{x=1}^t p_x^{w_x - v_x})$. We obtain:

$$\beta_{i,\bar{v}} = \left(\prod_{x=1}^t \frac{p_x - 1}{p_x} \right) \left(\sum_{\bar{w} \geq \bar{v}} \alpha_{i,\bar{w}} / \left(\prod_{x=1}^t p_x^{w_x - v_x} \right) \right).$$

Since $p_1 > 2t$, $\sum_{\bar{w} \geq \bar{v}_0} \alpha_{i,\bar{w}} / (\prod_{x=1}^t p_x^{w_x - v_0}) < \epsilon_{\alpha\alpha} \prod_{x=1}^t \frac{p}{p-1} < \epsilon_{\alpha\alpha} e^{t/(p_1-1)} < \epsilon_{\alpha\alpha} \sqrt{e}$. By the triangle inequality, $|\beta_{i,\bar{v}_0} - \beta_{j,\bar{v}_0}| \geq (\epsilon_{\alpha\alpha} - (\sqrt{e}-1)\epsilon_{\alpha\alpha}) (\prod_{x=1}^t \frac{p-1}{p}) \geq \epsilon_{\alpha\alpha} (2 - \sqrt{e}) / (\sqrt{e}) > \epsilon_{\alpha\alpha} / 5$. So, \mathcal{A} has $\epsilon_{\beta\beta} \geq \epsilon_{\alpha\alpha} / 5 \geq (1/5)2^{-dk'}$ advantage against the Decision Subgroup Problem for (π_i, π_j) . The circuit complexity of \mathcal{A}' is basically that of \mathcal{A} , plus that needed to compute $g^{\prod_{=1}^p}$. \square

6 Lessons from the Generic Group Model

To gain confidence in our computational assumption, we can consider the Decision Subgroup Problem’s vulnerability to generic attacks. The following theorem, which is quite similar to a result by Damgard and Koprowski [8] on root extraction in generic groups, roughly states that, as long as the distributions D_0 and D_1 each tend to output a group whose order is divisible by a large evenly-distributed prime, the Decision Subgroup Problem is hard against generic attacks. In other words, the security of the Decisional Subgroup Problem against generic attacks depends less on the value of $|H|$ (the order of the subgroup hidden in G) than it does on the distribution of $|G : H|$.

Theorem 3. *Let A be a generic algorithm for solving the Decision Subgroup Problem on $(\ell, k, \pi_0, \pi_1, D_0, D_1)$ that makes at most m oracle queries. Let S be a set of bit strings of cardinality at least $2^{2\ell}$. For group G_i , let $\theta(G_i)$ be the largest prime divisor of $|G_i|$ that does not divide $\pi_0\pi_1$. Let $\alpha(D_i) = \max_q \{\Pr[\theta(G_i) = q \mid G_i \xleftarrow{D} \mathcal{G}_i]\}$. Let $\beta(D_i, M)$ be the probability that $\theta(G_i) \leq M$ for distribution D_i ; let $\beta(D, M) = \max\{\beta(D_0, M), \beta(D_1, M)\}$. Now, randomly choose $b \xleftarrow{R} \{0, 1\}$, $G_b \xleftarrow{D} \mathcal{G}_b$, and a random mapping $\sigma_b : G_b \rightarrow S$. Then,*

$$\left| \Pr \left[A^{(O)}(S, \ell, k, \pi_0, \pi_1, D_0, D_1) = b \right] - \frac{1}{2} \right| \leq m^2 \left(m\alpha(D) + \beta(D, M) + \frac{1}{M} \right) / 2,$$

where the probability is over the random bits of the oracle and A .

Proof. See full version of this paper.

Let’s choose parameters to give Theorem 3 meaning. Suppose $2^k / \max\{\pi_i\} \geq 2^{k'}$, and define D_i to choose $|G_i|$ as follows: choose a uniformly random prime q from $[2^{k'}, 2^{k'+1}] \setminus P$ (where P is the set of primes dividing $\pi_0\pi_1$) and an integer d from the set of integers in the interval $[2^k/q\pi_i, 2^{k+1}/q\pi_i]$ whose prime divisors are all less than q ; set $|G_i| = \pi_iqd$. Then, by the Prime Number Theorem, $\alpha(D) \approx 2^{-k'+\log k'} \ln 2$. If we set $M = 2^{k'}$, then $\beta(D, M) = 0$. Once we insert these values into Theorem 3, we find that a generic algorithm for solving the Decision Subgroup Problem for such D_i takes $\Omega(2^{(k'-\log k')/3})$ oracle queries. Thus, when $2^k / \max\{\pi_i\} \geq 2^{k'}$, the Extended Decision Subgroup Assumption is absolutely true in the generic group model.

Now, let’s consider how well our scheme could perform, if generic attacks were the only security concern. First, consider the rate of our scheme. If we set $k = \lceil k' + \ell + \log p_t \rceil$, then $2^k / \max\{\pi_i\} \geq 2^{k'}$ as required above, while the rate $f_1(k', \log n) / f_2(k', \log n) = k/\ell$ can be arbitrarily close to 1. Also, since $k' = b \log n$, $\log p_t = \mathcal{O}(\log n)$, and ℓ can be chosen to be $\mathcal{O}(\log n)$, k can also be purely logarithmic in n . Thus, generic attacks do not prevent our scheme from achieving an optimal rate (approaching 1) for blocks, and minimal communication $\mathcal{O}(\log n)$ for private bit retrieval.

7 Instantiating Groups with Hidden Smooth Subgroups

Up to this point, we have discussed our PIR scheme and its performance and security properties in a general way, without discussing in detail how to instantiate the group G securely. One way to instantiate G is using a composite modulus, as in [2]. For example, to construct a modulus m that Φ -hides π , one may choose a random “semi-safe” prime $Q_0 = 2q_0\pi + 1$ for prime q_0 and a random semi-safe prime $Q_1 = 2dq_1 + 1$ for prime q_1 and d chosen uniformly from a large interval, and set $m = Q_0Q_1$. Then, m should have good uniformity properties, even modulo the primes dividing π .

Cachin, Micali and Stadler [2] note that when a divisor $\pi \geq m^{1/4}$ of $(Q_0 - 1)$ is known, however, it is easy to decide whether π divides $\phi(m)$; in particular, given $m = Q_0Q_1$ and divisor $\pi \geq m^{1/4}$ of $(Q_0 - 1)$, one can factor m using Coppersmith’s method [7], [6] – a lattice-based attack. An abundance of work relating to Coppersmith’s method has appeared in the literature, the most recent being May’s Eurocrypt 2005 paper [12], which provides a unifying framework for most of the results. His Corollary 14 applies to the Φ -hiding situation; it states:

Corollary 14 (A. May). *Let $f(x) \in \mathbb{Z}[X]$ be a polynomial of degree δ . Let m be a composite number of unknown factorization with divisor $Q_0 \geq m^\beta$. Then, we can find all points $x_0 \in \mathbb{Z}$ satisfying $f(x_0) = Q_0$ in time polynomial in $\log m$ and δ if $|x_0| \leq m^{\beta^2}$.*

Setting $\beta = 1/2$ and $f(x) = \pi x + 1$, the algorithm will give us the divisor $Q_0 = \pi c + 1$ in polynomial time, since $c \approx Q_0/\pi < m^{1/4}$ for $\pi > m^{1/4}$. As May notes, this $|x_0| \leq m^{1/4}$ bound occurs frequently in the literature on Coppersmith’s method. Since the algorithm works well (in polynomial time) when $\pi > m^{1/4}$, one might expect that the algorithm’s performance declines only gradually – e.g., so that for $\pi > m^{1/5}$, the algorithm (while not polynomial-time) would be only slightly super-polynomial, perhaps because of the inefficiency of lattice reduction. However, this is not true; when $(\log m)/(\log \pi)$ is larger than 4, the target vector (i.e., the one that would help us factor m) is not even the shortest vector in the lattice; thus, even perfect lattice reduction algorithms would not, by themselves, make the attack work.

These considerations give us confidence that, as long as $(\log m)/(\log \pi) > 4$ (perhaps by a “comfortable” margin), then the Φ -hiding assumption, as outlined above, is hard. Thus, it seems plausible that the bit-length of m only needs to be a constant factor greater than $\log \pi$. This allows our PIR scheme to achieve constant rate when instantiated with groups modulo composite numbers. A drawback of using composite moduli is that, as mentioned before, we need $\log m = \Omega(\log^{3-o(1)} n)$, due to the number field sieve [10]. This makes our PIR scheme somewhat communication-inefficient for short block sizes d , even though it is most efficient among the single-database PIR schemes that currently exist.

Of course, it would be preferable to instantiate our scheme using groups for which the number field sieve is inapplicable if this could be done securely. For example, one might try elliptic curve groups. However, algorithms exist to find the orders of elliptic curves over finite fields; when we try using the compositum of

finite fields, we seem to be reverting back to a factorization problem. Class groups are another interesting alternative, since currently the best known algorithms for attacking class groups (e.g., determining their order) have quadratic-sieve-type complexity. Unfortunately, in our scheme, the user generating the group must know its order for response retrieval; currently, there are no efficient algorithms that would allow the user to generate a class group with known partially-smooth order, as required by our scheme.

8 Conclusion and Open Problems

We described single-database computational block retrieval schemes based on the decision subgroup problem with communication complexity $\mathcal{O}(k + d)$, where d is the size of the block to be retrieved and k is the security parameter. Asymptotically, this is about as good as one might expect since there is only an additive communication overhead of the security parameter k . Indeed, our scheme has better asymptotic performance compared to previous schemes.

We leave it as an open problem to construct an instantiation of our scheme that achieves rate arbitrarily close to 1, while circumventing Coppersmith's attack. Clearly, based on our analysis of the Decision Subgroup Problem in the generic group model, any attack that prevents the scheme from achieving rate close to 1 must exploit the encoding of the elements.

Acknowledgments. We thank Phil Mackenzie, David Woodruff, Helger Lipmaa, Yuval Ishai, and the anonymous referees for fruitful comments.

Abstract. The concurrent setting for Zero-Knowledge protocols is very challenging as it requires protocols to remain secure even when several parties execute the same protocol concurrently. Indeed, it has been proved that achieving concurrent security for (black-box-simulation) zero-knowledge protocols in standard models requires a non-constant number of rounds, thus severely limiting efficiency. As a result, a few models with additional setup or network assumptions have been introduced to present constant-round concurrently-secure zero-knowledge protocols for all languages in \mathcal{NP} .

In this paper we consider the bare public-key model, which is known to have very minimal setup assumptions, and we present the first constant round and concurrently secure zero-knowledge argument for any languages in \mathcal{NP} , under standard intractability assumptions. In fact, our protocol requires 4 rounds and is therefore round-optimal, is a proof of knowledge, and is time-efficient, in the sense that it is based on a transformation that does not require any expensive \mathcal{NP} reduction from prover or verifier. One 5-round variant of our protocol can be based on the minimal assumption of the existence of a one-way function.

1 Introduction

The classical notion of a zero knowledge proof (a proof that reveals no additional information other than the theorem being true, even to malicious verifiers) was introduced in [20] and, since its introduction, it has been widely used to prove the security of distributed protocols for several applications. Motivated by the use of such protocols in networks like the Internet, several researchers recently realized the need of extending the security properties of zero-knowledge protocols to multi-party and asynchronous settings. In particular, the notion of concurrent zero-knowledge considers the case where several concurrent executions of the same protocol can take place and a malicious adversary may control the scheduling of the messages and corrupt multiple provers or verifiers in order to vi-

olate the soundness or zero-knowledge properties. This notion is being studied in a (standard) model without additional setup infrastructures or network assumptions, where several protocols have been proposed [26, 21, 25], but super-constant lower bounds on the round complexity have been given (see, e.g. [6]). As these bounds severely limit the applicability of these protocols and this notion, other models are being studied to achieve efficient, and, in particular, constant-round concurrent zero-knowledge protocols. Specifically, a model with synchronous network assumptions is studied in [8]; the timing model [15, 16, 18] makes other assumptions on the network asynchronicity; the preprocessing model [11] requires an interactive preprocessing stage involving all parties; the common random string model [3], and its various extensions, require a trusted party or a trusted public auxiliary string. The model that seems to have the minimal set-up or network assumptions is the bare public-key (BPK) model [5], where verifiers register their public key in a public file during a set-up stage, and there is no interactive preprocessing stage, trusted third party, trusted string, or assumption on the asynchronicity of the network. In this model, both the concurrent soundness and zero-knowledge notions are harder to achieve than their non-concurrent variants, as noted in [22], who discussed four distinct and increasingly stronger soundness notions: one-time, sequential, concurrent and resettable soundness. Indeed, the constant-round concurrent zero-knowledge (in fact, resettable zero-knowledge, a stronger notion from [5]) protocols in the BPK model presented in [5, 22] only enjoy sequential soundness while it is conjectured that they do not satisfy concurrent soundness. Recently, [12] shows constant-round concurrently sound resettable zero-knowledge arguments in the BPK model, under non-standard assumptions on the hardness of computational problems against subexponential adversaries; and [13] shows 3-round resettable zero-knowledge arguments in a public-key model requiring stronger set-up assumptions.

Our results. We obtain the first constant-round argument in the BPK model with concurrent security (both soundness and zero-knowledge) under standard intractability assumptions. Our protocol is based on number-theoretic hardness assumptions, and is time-efficient, in the sense that it is based on a transformation not requiring inefficient \mathcal{NP} reductions. Moreover, it has desirable round-complexity and security in the BPK model, with respect to the black-box simulation model, as:

1. it is a 4-round protocol and therefore optimal among concurrently sound or concurrent zero-knowledge arguments (see [22, 19]), unless \mathcal{NP} is in \mathcal{BPP} ;
2. it is a concurrent zero-knowledge argument of knowledge and the stronger notion of resettable zero-knowledge arguments of knowledge only exists for trivial relations (see [5]);
3. it is concurrently sound and the stronger notion of resettable sound zero-knowledge protocols can only be obtained for languages in \mathcal{BPP} (see [22, 1]).

One 5-round variant of our protocol can be based on the minimal assumption of the existence of a one-way function. Both our constructions are arguments of

knowledge and crucially use equivocal commitment schemes in the BPK model that withstand certain types of malleability attacks.

2 Definitions

Model description. The BPK model can be seen as a relaxed version of two well-known models in Cryptography: the Public-Key Infrastructure model, (one main difference being in that the BPK model does not deal with certification issues and therefore we do not discuss certification authorities) and the Preprocessing model (one main difference being in that in the BPK model the preprocessing is reduced to users non-interactively posting public keys on a public file). Formally, this model assumes that: 1) there exists a public file F that is a collection of records, each containing a public key; 2) an (honest) prover is an interactive deterministic polynomial-time Turing machine that takes as input a security parameter 1^n , F , an n -bit string x , such that $x \in L$, for some language L , an auxiliary input y , a reference to an entry of F and a random tape; 3) an (honest) verifier V is an interactive deterministic polynomial-time Turing machine that works in the following two stages: (a) on input a security parameter 1^n and a random tape, V generates a key pair $(\mathbf{pk}, \mathbf{sk})$ and stores the public key \mathbf{pk} in one entry of the file F ; (b) later, V takes as input the secret key \mathbf{sk} , a statement $x \in L$ and a random string, and outputs “accept” or “reject” after performing an interactive protocol with a prover; 4) the first interaction between a prover and a verifier starts after all verifiers have completed their first stage.

Malicious provers in the BPK model. Let s be a positive polynomial. We say that P^* is an s -concurrent malicious prover if it is a probabilistic polynomial-time Turing Machine that, on input 1^n and PK , can perform the $s(n)$ interactive protocols with V as follows: 1) if P^* is already running i protocols $0 \leq i < s(n)$ he can choose a new statement x_i to be proved and start a new protocol with V with $x_i \in L$ as statement; 2) he can output a message for any running protocol, receive immediately the response from V and continue. (We assume that each message is unambiguously associated with only one of the protocols.) Given an s -concurrent malicious prover P^* and an honest verifier V , an s -concurrent attack is performed as follows: 1) the first stage of V is run on input 1^n and a random string to obtain pair $(\mathbf{pk}, \mathbf{sk})$; 2) P^* is run on input 1^n and \mathbf{pk} so to obtain an n -bit string x_1 ; 3) whenever P^* starts a new protocol choosing an n -bit string x_i , V uses inputs x_i , a new random string r_i and \mathbf{sk} , and interacts with P^* .

Malicious verifiers in the BPK model. We say that V^* is an s -concurrent malicious verifier if it is probabilistic polynomial-time Turing Machine that, on input 1^n and PK , can perform the following $s(n)$ interactive protocols with P : 1) if V^* is already running i protocols $0 \leq i < s(n)$ he can decide the i -th protocol to be started with P ; 2) he can output a message for any running protocol, receive immediately the next message from P and continue. Given an s -concurrent malicious verifier V^* and an honest prover P , an s -concurrent attack is performed as follows: 1) in its first stage, V^* , on input 1^n and a random string, generates

a public file F ; 2) V^* is run on input 1^n and F so to start the first protocol with P ; 3) whenever V^* starts a new protocol, P uses a new statement, a new random string, and interacts with V^* .

We now define concurrently sound and zero-knowledge protocols in the BPK model.

Definition 1. *Given a language $L \in \mathcal{NP}$, and its corresponding relation R_L , we say that a pair $\langle P, V \rangle$ is complete for L , if for all n -bit strings $x \in L$ and any witness y such that $(x, y) \in R_L$, the probability that V , at the end of the interaction with P on input y , outputs “reject”, is negligible in n . We say that $\langle P, V \rangle$ is concurrently-sound over L if, for any false statement “ $x \in L$ ”, for all positive polynomials s , for all s -concurrent malicious provers P^* , the probability that in an execution of an s -concurrent attack V outputs “accept” for such a statement is negligible in n . Finally, we say that $\langle P, V \rangle$ is concurrently-zero-knowledge over L if for all positive polynomials s , for any s -concurrent malicious verifiers V^* , there exists a probabilistic polynomial-time algorithm S_V , called the simulator, such that for all $x_1, \dots, x_{s(n)} \in L$, the probability distributions $\{\text{view}_V^P(\bar{x})\}$ and $\{S_V(\bar{x})\}$ are computationally indistinguishable, where $\{\text{view}_V^P(\bar{x})\}$ is the distribution of the transcript seen by V^* on its input tape (i.e., $\bar{x} = x_1, \dots, x_{s(n)}$), random tape and communication tape during its interaction with P .*

3 Equivocal Commitments in the BPK Model

Crucial tools towards our main results are equivocal commitment schemes in the BPK model that maintain security properties against certain concurrent adversaries. We now describe these schemes after reviewing the notions of (conventional) commitment schemes and equivocal commitment schemes.

Commitment schemes. Informally speaking, a *commitment scheme* (sen, rec) is a two-phase interactive protocol between two probabilistic polynomial time parties sen and rec , called the sender and the receiver, respectively, such that the following is true. sen commits to a bit b in the first phase (called the commitment phase); in the second phase (called the decommitment phase) sen convinces rec of the value of the bit b committed in the first phase. A commitment scheme has three requirements. First, if sen and rec behave honestly, then at the end of the decommitment phase rec is convinced that sen committed to bit b with high probability (this is the *correctness* requirement). Then, no matter which polynomial-time computable strategy rec^* uses in the commitment phase, rec^* is not able to guess such a bit with probability significantly better than its a priori probability before such phase (this is the *hiding* property). Finally, for any strategy played by a polynomial-time sen^* , the probability that sen^* can later decommit both as 0 and as 1 is negligible (this is the *binding* property).

Equivocal commitment schemes. Informally speaking, a commitment scheme (sen, rec) is *equivocal* if there exists an efficient equivocator algorithm returning a transcript leading to a faked commitment key such that: (a) this commitment

can be decommitted both as 0 and as 1, (the *key equivocation* property) and (b) the transcript is indistinguishable from a real execution (the *transcript indistinguishability* property). The advantage of the equivocator algorithm over a real committer is usually realized by rewinding of the receiver, or auxiliary information about a common reference string. Equivocal commitment schemes are a strict generalization of trapdoor commitment schemes [4] and have been already applied in several works towards the construction of various types of commitments and zero-knowledge proofs. In particular, [11] uses equivocal commitment schemes to construct concurrent zero-knowledge protocols in the preprocessing model.

Constructing equivocal commitments in the BPK model. Following [11], a first natural step towards our goal of constructing concurrently zero-knowledge and concurrently sound protocols in the BPK model could be that of constructing an equivocal commitment scheme in this model. As we will see, this both requires some work and turns out not to be enough due to a subtle malleability attack by a concurrent adversary. A first candidate for such a construction could be the perfectly-hiding commitment scheme in [24], which we now describe.

Let p, q be primes such that $p = 2q + 1$ and let G_q denote the only subgroup of Z_p^* of order q . We note that it can be efficiently decided whether an integer a is in G_q , by checking that $a^q \equiv 1 \pmod{p}$. Moreover, any element of G_q different from 1 generates such a subgroup. For any $a, b \in G_q$, if $b \neq 1$ the *discrete logarithm of a in base b* is the integer x such that $b^x = a \pmod{p}$. In order to commit to an integer $z \in Z_q$, the committer uniformly chooses $r \in Z_q$, computes $\text{com} = g^z h^r \pmod{p}$, and sends com to the receiver. In order to decommit com as z , the committer sends the pair (z, r) to the receiver, who checks that $\text{com} = g^z h^r \pmod{p}$. The hiding property of this scheme follows from the fact that com is uniformly distributed in G_q for any z ; the binding property follows from the fact that if a committer is able to successfully decommit a string com both as z and z' with $z' \neq z$, then he can be used to compute the discrete logarithm of h in base g . A simulator recovering, either through rewinding or as an auxiliary input, the value α such that $g^\alpha = h$, can open a commitment $\text{com} = g^z h^r \pmod{p}$ of z as z' by sending pair $(z', r' = r + (z - z')\alpha^{-1} \pmod{q})$ as a decommitment.

One way to use this scheme in the BPK model goes as follows. The receiver sets her public key equal to values (p, q, g, h) chosen as above, and proves, using well-known 3-round witness-indistinguishable proofs of knowledge (e.g., [27]), that he knows the discrete logarithm of h modulo p . The committer computes the commitment key com and the decommitment key (z, r) as above. While the commitment is equivocal as an equivocator can extract α from the proof of knowledge, it is unclear how to prove the binding property because of the conflicting requirements of computing the discrete logarithm of h from a dishonest committer, and simulating the proof of knowledge to the dishonest committer.

Achieving the binding property. A first idea to fix the above problem, based on an approach of [23], is to extend the previously discussed commitment scheme so that the receiver's public key has two integers h_0, h_1 instead of one. The receiver's

public key is then a tuple (p, q, g, h_0, h_1) where p, q, g are as before, $h_0, h_1 \in G_q$, and $h_i = g^{\alpha_i} \bmod p$, for $i = 0, 1$ and some α_0, α_1 . In this case, the receiver proves, using well-known 3-round witness-indistinguishable proofs of knowledge (e.g., [7]), that he knows the discrete logarithm modulo p of one among h_0, h_1 . A commitment to a string z can be obtained by randomly choosing $u, v \in Z_q$, and computing $\text{com} = g^u h_0^v h_1^{z-v} \bmod p$ and the decommitment is implemented by sending (u, v, z) and verifying that $\text{com} = g^u h_0^v h_1^{z-v} \bmod p$. We will refer to this scheme as EQ_{dlog} .

The correctness and hiding properties of EQ_{dlog} directly follow from the analogue properties of the scheme in [24]. To see that the scheme enjoys the equivocation property, consider an equivocator that extracts one of the two values α_0, α_1 from the receiver's proof of knowledge, and then computes a commitment com as $\text{com} = g^u h_0^v h_1^{z-v} \bmod p$. Later, on input one of the two trapdoors α_0, α_1 , it can compute a decommitment (u', v', z') as $z' \in Z_q$ as follows:

1. on input α_0 such that $g^{\alpha_0} = h_0$, set $v' = z' + v - z \bmod q$ and $u' = u + \alpha_0(z - z') \bmod q$;
2. on input α_1 such that $g^{\alpha_1} = h_1$, set $v' = v$ and $u' = u + \alpha_1(z - z') \bmod q$.

It can be seen that in both cases (u', v', z') is a valid decommitment of com as z' and that the distribution of the tuples (com, u', v', z') is perfectly indistinguishable from that produced by a honest committer on input z' .

To see that EQ_{dlog} is computationally binding, we show an efficient algorithm DLbreak that can randomly choose $b \in \{0, 1\}$ and use α_b to compute the prover's messages in the witness-indistinguishable proofs of knowledge. Later, for any two different decommitments $(u, v, z), (u', v', z')$ of a commitment com (i.e., $z \neq z'$), it can succeed in computing α_{1-b} on input α_b , with probability at least $1/2$. Specifically, we consider the following two cases:

1. $v = v' \bmod q$: notice that $z \neq z' \bmod q$ and thus $z' - v' \neq z - v \bmod q$; since $g^{u+\alpha_0 v+\alpha_1(z-v)} = g^{u'+\alpha_0 v'+\alpha_1(z'-v')} \bmod p$, if $b = 0$ then DLbreak computes $\alpha_1 = (u - u')(z' - v' - z + v)^{-1} \bmod q$;
2. $v \neq v' \bmod q$: since $g^{u+\alpha_0 v+\alpha_1(z-v)} = g^{u'+\alpha_0 v'+\alpha_1(z'-v')} \bmod p$, if $b = 1$ then DLbreak computes $\alpha_0 = (u' - u + \alpha_1(z' - v' - z + v))(v - v')^{-1} \bmod q$.

A variant based on any one-way function. A variant of EQ_{dlog} , denoted as EQ_{oway} , can be based on the (minimal) assumption of the existence of a one-way function f . We now only sketch the main ideas behind scheme EQ_{oway} . The receiver computes a public key $pk = (y_0, y_1)$, where $y_j = f(x_j)$, for x_j randomly chosen in $\{0, 1\}^n$ and $j = 0, 1$. The receiver proves, using a 3-round witness-indistinguishable system (such as a parallel repetition of the protocol with soundness error $1/2$ from [2]), that he knows at least one of (x_0, x_1) . The committer uses the same language and the same atomic proof system with soundness error $1/2$, as follows. For this protocol, there exists a simulator that, on input $b \in \{0, 1\}$, can compute a first message from the prover and an answer to the verifier's challenge, if equal to b . We use the first message returned by the simulator as a commitment key and the answer as a decommitment key. We can prove the following

Theorem 1. *EQ_{dlog} (resp. EQ_{oway}) is an equivocal commitment scheme in the BPK model for which the correctness, hiding, and equivocation property hold unconditionally, and the binding property holds assuming the hardness of computing discrete logarithms modulo primes p of the form $p = 2q + 1$, for q prime (resp., assuming the existence of a one-way function).*

Malleability attacks during concurrent executions. Both schemes from Theorem 1 are not enough to construct concurrently sound and zero-knowledge arguments in the BPK model, as their properties may not hold under concurrent attacks when the scheme is used as a subprotocol in a larger protocol. Assume, for instance, that we use a constant-round honest-verifier zero-knowledge proof system for an \mathcal{NP} language L , denoted as BL, such as the one in [2], and implement the commitment scheme necessary in this protocol by using, say, scheme EQ_{dlog} . The resulting protocol has 4 messages: m_1 (containing the first message from the proof of knowledge in EQ_{dlog}), m_2 (containing the second message from the proof of knowledge and the commitment keys for BL computed as com in EQ_{dlog}), m_3 (containing the third message from the proof of knowledge in EQ_{dlog} and the challenge message from BL), and m_4 (containing the decommitments as in EQ_{dlog} and the answer message from BL). While one would expect the hiding and equivocation property of the commitment to still hold, this may not be true for the binding property. In fact, we show an example of two concurrent executions between a malicious prover P^* and two incarnations of the same verifier V, V' , where it is unclear how to prevent a malleability attack from P^* in the execution with V using the public key and the proof of knowledge from the execution with V' . Specifically, the schedule decided by a malicious prover P^* is $(m_1, m_1', m_2, m_3, m_2', m_3', m_4, m_4')$, and P^* might decide to compute the commitments in m_2 with some malleability attack over m_1' and the public key of V' . Now, assume P^* tries to prove a false statement to V ; we then see that the known approach in proving that P^* only succeeds with negligible probability, fails. Indeed, in trying to extract two different decommitments from the proof given by P^* on a false statement to V , the rewind performed on P^* while interacting with V and possibly changing message m_3 , also rewinds the proof given by V' to P^* and may change message m_2' (as m_2' is carefully scheduled by P^* to happen after m_3). As a consequence, the secret key α_b extracted from P^* could always be the same used by V' in its witness indistinguishable proof of knowledge, just due to a successful malleability attack, and thus not violating the witness indistinguishability of the proof of knowledge used.¹

Our atomic commitment scheme. Even if we will not use EQ_{dlog} or EQ_{oway} as a black box in our main construction, we will crucially use their components and properties. To avoid the above malleability attack, we cannot use known round-efficient non-malleable commitment schemes, as some of these solutions do not preserve their security when executed in a concurrent setting (e.g., [17]), or are designed in the stronger public random string model (e.g., [10]). Instead,

¹ We note that a similar problem applies to (unrefereed) protocols in [28], that consequently do not seem to satisfy concurrent soundness.

we observe that we do not need the full power of non-malleability, and avoid the above attacks by requiring that the committer, after computing an equivocal commitment key \mathbf{eqcom} and its decommitment key \mathbf{eqdec} as in scheme \mathbf{EQ}_{dlog} (resp., \mathbf{EQ}_{oway}), additionally commits to \mathbf{eqdec} at commitment stage and using a statistically-binding commitment scheme, that can be implemented as a simple application of the El-Gamal encryption scheme (resp., starting from any one-way function). To prevent the loss of the equivocation property, we extend an idea of [9] so that it can be applied to the BPK model, again using statistically-binding commitments. Formally, we define an atomic commitment scheme ($\mathbf{sen,rec}$) using discrete logarithms (the analogue description using one-way functions is similarly obtained), as follows. The common input to \mathbf{sen} and \mathbf{rec} is public key (p, q, g, h_0, h_1) , the private input of \mathbf{sen} is the bit or string z to be committed.

Commitment Phase:

1. \mathbf{sen} checks that $p = 2q + 1$, that p, q are primes, that g is a generator of G_q and that h_0, h_1 are in G_q .
2. \mathbf{sen} commits to z by randomly choosing $u, v \in Z_q$ and by computing the commitment $\mathbf{com} = (\mathbf{eqcom}, \mathbf{sbc}_{\mathbf{com}_0}, \mathbf{sbc}_{\mathbf{com}_1})$, where $\mathbf{eqcom} = g^u h_0^v h_1^{z-v} \bmod p$, $\mathbf{sbc}_{\mathbf{com}_{1-b}}$ is a statistically-binding commitment of a random chosen string while $\mathbf{sbc}_{\mathbf{com}_b}$ is a statistically-binding commitment of (u, v) for $b \in \{0, 1\}$.

Decommitment Phase:

1. \mathbf{sen} decommits z by sending (u, v, z) and the decommitment that corresponds to the statistically-binding commitment $\mathbf{sbc}_{\mathbf{com}_b}$ (instead $\mathbf{sbc}_{\mathbf{com}_{1-b}}$ is not opened).
2. \mathbf{rec} returns z if $\mathbf{eqcom} = g^u h_0^v h_1^{z-v} \bmod p$ and one between $\mathbf{sbc}_{\mathbf{com}_0}$ and $\mathbf{sbc}_{\mathbf{com}_1}$ has been correctly opened and corresponds to a commitment of (u, v) .

We note that a polynomial-time malicious committer cannot change the committed bit unless he both knows two valid decommitments for opening \mathbf{eqcom} and commits to them in $\mathbf{sbc}_{\mathbf{com}_b}$ and $\mathbf{sbc}_{\mathbf{com}_{1-b}}$ at commitment phase. In particular, the previously described concurrent scheduling does not help a malicious committer in computing the decommitted value at decommitment phase.

4 Concurrent Zero Knowledge and Soundness

We now present our concurrently sound and concurrently zero-knowledge argument system for any \mathcal{NP} -language in the BPK model. Most importantly, it only uses hardness assumptions with respect to polynomial-time adversaries, while [12] obtains the same result (in fact, a stronger one) with hardness assumptions against subexponential-time adversaries. We obtain the following

Theorem 2. *Let L be a language in \mathcal{NP} . Assuming the intractability of the DDH problem for integers of the form $p = 2q + 1$, for p, q primes, in the BPK model, there exists (constructively) a 4-round concurrently sound and concurrently zero-knowledge argument system for L . Moreover, this protocol is also an argument of knowledge for the relation R_L associated with L .*

The above result is obtained using tools from commitment scheme EQ_{dlog} . If, instead, we start from EQ_{oway} , we can reduce the assumption to the existence of a one-way function, but we obtain a 5-round and less efficient protocol.

Construction of our argument system. Our protocol (P, V) , depicted in Figure 1, uses the following tools:

1. The atomic commitment scheme (sen, rec) constructed in Section 3 to compute commitments $\text{atcom} = (\text{eqcom}, \text{sbc}_{\text{com}_0}, \text{sbc}_{\text{com}_1})$.
2. A 3-round witness indistinguishable proof of knowledge π_v given by the verifier in order to prove knowledge of one of the two secret keys corresponding to his public key. We further need a *partial witness-independence* property from π_v : the message sent at its first round should have distribution independent from the value of any witness for the theorem proved. We can obtain such a protocol using [27, 7]. (For the variant based on one-way functions we can use [2], requiring 4 rounds.)
3. A 3-round public-coin honest-verifier zero-knowledge argument of knowledge π_p for any \mathcal{NP} -complete language L with the following special structure and property. We denote by (a, c, z) the three messages exchanged by prover P and verifier V and assume that (a, c, z) is an l -times parallel iteration of a basic protocol with soundness $1/2$, and a single-bit challenge. Then we assume that π_p satisfies a *special witness-extraction* property (specifically, an extractor, given two accepting transcripts (a, c, z) and (a, c', z') with $c' \neq c$, can compute a witness y for x). We can obtain such a protocol from [2].

Properties of our argument system. The completeness follows by the completeness of protocols π_p, π_v and the correctness of scheme (sen, rec) . Witness extraction also follows from the witness extraction of protocol π_p , the completeness of π_v and the binding property of (sen, rec) . For the concurrent zero-knowledge property (when a concurrent malicious verifier is considered), we show a simulator S that extracts the secret keys from the arguments of knowledge π_v given by the adversarial verifier V^* and later uses them in order to compute equivocal commitments. Note that since S performs a rewind, he could run in exponential-time when concurrent executions are performed. We show that after an expected polynomial number of rewinds S can complete the simulation without any further rewinds and thus run in expected polynomial-time.

The most interesting part of our proof is verifying the concurrent soundness property. Assume by contradiction that the protocol is not concurrently sound, thus there exists a malicious s -concurrent prover P^* that in a concurrent attack succeeds with non-negligible probability in completing a proof for a false statement “ $x \in L$ ”. We show a probabilistic polynomial-time algorithm \mathcal{A} that, using black-box access to P^* , breaks the discrete logarithm assumption.

We now describe algorithm \mathcal{A} . On input as challenge a discrete logarithm instance (p, q, g, h) \mathcal{A} randomly chooses $\alpha \in Z_q, b \in \{0, 1\}$, and the session number $s_j \in \{1, \dots, s\}$ (trying to guess the index of the proof in which P^* will succeed in cheating), and stores public key $\text{pk}_i = (p, q, g, h_0, h_1)$, where $h_b = g^\alpha, h_{1-b} = h$. Note that \mathcal{A} knows the secret key corresponding to pk_i .

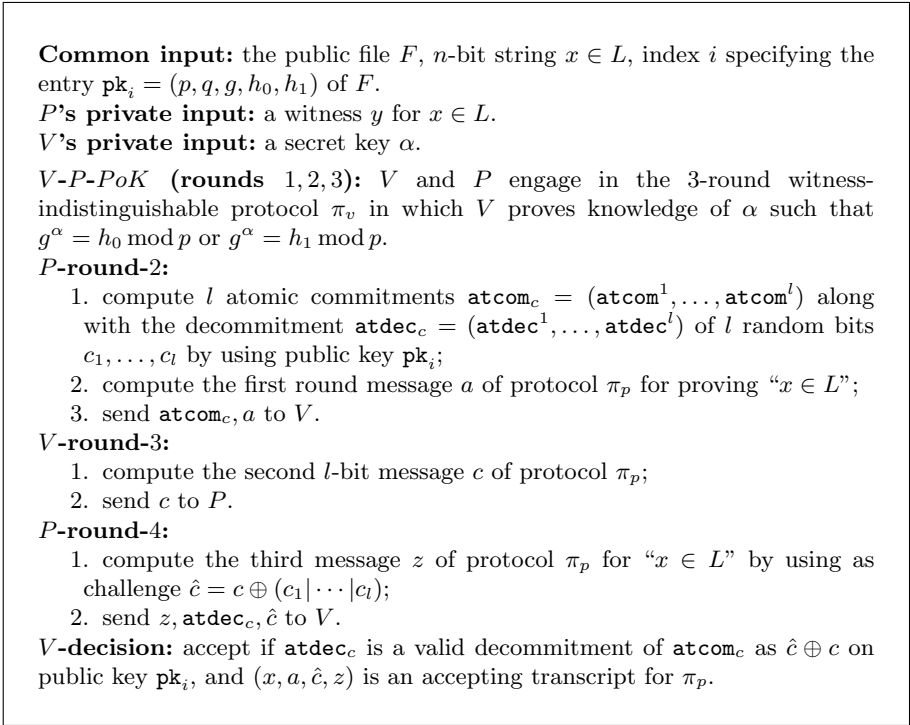

Fig. 1. The four-round concurrently sound and concurrently zero-knowledge argument of knowledge for any \mathcal{NP} language in the BPK model

For all the proof sessions, \mathcal{A} interacts with an s -concurrent malicious prover P^* during a concurrent attack. In particular in all but the s_j -th session, \mathcal{A} works as an honest verifier, by using α to run the prover's algorithm of π_v . In correspondence with the s_j -th session, \mathcal{A} uses the following rewind strategy.

1. The first time that \mathcal{A} runs the session, he works as an honest verifier. After the 4-th round \mathcal{A} logs the accepting transcript (a, \hat{c}, z) of the honest-verifier zero-knowledge proof π_p given by the prover. Then \mathcal{A} rewinds the prover so that round V -round-3 can be played again.
2. \mathcal{A} plays round V -round-3, by choosing random challenges $c' \neq c$ until he obtains an accepting transcript (a, \hat{c}', z') for protocol π_p by the prover.

If $\hat{c} \neq \hat{c}'$, by the special witness extraction property of the honest-verifier zero-knowledge proof of knowledge π_p , \mathcal{A} obtains a witness for $x \in L$ and this contradicts the assumption that " $x \notin L$ ". If instead $\hat{c} = \hat{c}'$ then for each $t \in \{1, \dots, l\}$ such that the t -th bit of c' is different from the t -th bit of c , the corresponding t -th commitment atcom^t in atcom_c has been opened as both 0 and 1. We note that the probability that this happens because P^* reveals two decommitments of any among commitments $\text{sbc}_{\text{com}0}, \text{sbc}_{\text{com}1}$ contained in atcom_c is exponentially

small because the commitment scheme used is statistically binding. Therefore P^* opens in two different ways commitment eqcom . Then \mathcal{A} selects the pairs that correspond to different openings and for each of them, say the t -th, \mathcal{A} runs DLbreak on input α, eqcom^t and the t -th pair of decommitments. For $j = 0, 1$, let $sk_{i,j}$ be such that $g^{sk_{i,j}} = h_j \bmod p$ and $sk_{i,b} = \alpha$ in pk_i . In case the output of DLbreak is at least once secret key $sk_{i,1-b}$, then \mathcal{A} obtains the discrete logarithm of h in base g and thus we reach a contradiction.

Therefore we have only to deal with the case that DLbreak always outputs $sk_{i,b}$, that is the same secret key that \mathcal{A} knows. Notice that \mathcal{A} uses the secret key as witness to compute the third round of the witness indistinguishable proofs of knowledge. Let m be the number of sessions played until the end of session s_j . We now use hybrid arguments to contradict the assumed witness indistinguishability of the proof of knowledge. We know that using m times $sk_{i,0}$, DLbreak outputs $sk_{i,0}$ and using m times $sk_{i,1}$, DLbreak outputs $sk_{i,1}$. Then there must be $\gamma \in \{1, \dots, m\}$ such that by using $sk_{i,0}$ for the first $\gamma - 1$ times and $sk_{i,1}$ for the last $m - \gamma$ times, the witness used in the γ -th proof is the same that will be extracted by DLbreak . Now we distinguish two different cases, according to whether the γ -th proof has been completed before or after P -round-2 of session s_j :

1. “before”: here the γ -th proof is not affected by rewinds performed so far, and we can use this session to break the witness indistinguishability of π_v ;
2. “after”: here, rewinds to P^* may rewind the γ -th proof. Then we can flip a bit j to use one of the two $sk_{i,j}$ as witness in the γ -th proof and the same discrete logarithm is also given as input to DLbreak ; as assumed so far, the same discrete logarithm will be also given as output by DLbreak . However, because of the statistical binding property of the commitment scheme sbcom , except with exponentially small probability, all values decommitted by P^* at step P -round-4 of the γ -th proof are already fixed at step P -round-2 of the same proof. Furthermore, at this step P^* has seen at most step V -round-1 of the γ -th proof, and, by the partial witness-independence property of π_v , the message sent by \mathcal{A} at this step has distribution independent from bit j . Therefore, except with exponentially small probability, P^* can guess j with probability at most $1/2$, which contradicts our assumptions so far.

Acknowledgments. We thank Pino Persiano and Yunlei Zhao for many interesting discussions on zero knowledge protocols in various models.

Abstract. We consider the problem of scheduling n independent jobs on m unrelated parallel machines without preemption. Job i takes processing time p_{ij} on machine j , and the total time used by a machine is the sum of the processing times for the jobs assigned to it. The objective is to minimize makespan. The best known approximation algorithms for this problem compute an optimum fractional solution and then use rounding techniques to get an integral 2-approximation.

In this paper we present a combinatorial approximation algorithm that matches this approximation quality. It is much simpler than the previously known algorithms and its running time is better. This is the first time that a combinatorial algorithm always beats the interior point approach for this problem. Our algorithm is a generic minimum cost flow algorithm, without any complex enhancements, tailored to handle unsplittable flow. It pushes unsplittable jobs through a two-layered bipartite generalized network defined by the scheduling problem. In our analysis, we take advantage from addressing the approximation problem directly. In particular, we replace the classical technique of solving the LP-relaxation and rounding afterwards by a completely integral approach. We feel that this approach will be helpful also for other applications.

1 Introduction

We consider the scheduling problem where n independent jobs have to be assigned to a set of m unrelated parallel machines without preemption. Processing

job i on machine j takes time p_{ij} . For each machine j , the total time used by machine j is the sum of processing times p_{ij} for the jobs that are assigned to machine j . The makespan of a schedule is the maximum total time used by any machine. The objective is to find a schedule (assignment) that minimizes makespan. This problem has many applications. Typically, they arise in the area of scheduling multiprocessor computers and industrial manufacturing systems (see [18, 28]).

Related Work. There is a large amount of literature on scheduling independent jobs on parallel machines (a collection of several approximation algorithms can be found in [10]). A good deal of these publications concentrate on scheduling jobs on unrelated machines. Horowitz and Sahni [11] presented a (non-polynomial) dynamic programming algorithm to compute a schedule with minimum makespan. Lenstra et al. [17] proved that unless $\mathcal{P} = \mathcal{NP}$, there is no polynomial-time approximation algorithm for the optimum schedule with approximation factor less than $\frac{3}{2}$. They also presented a polynomial-time 2-approximation algorithm. This algorithm computes an optimal fractional solution and then uses rounding to obtain a schedule for the discrete problem with approximation factor 2. Shmoys and Tardos [23] generalized this technique to obtain the same approximation factor for the generalized assignment problem. They also generalized the rounding technique to hold for any fractional solution.

The fractional unrelated scheduling problem can also be formulated as a *generalized maximum flow* problem, where the network is defined by the scheduling problem and the capacity of some edges, that corresponds to the makespan, is minimized. This generalized maximum flow problem is a special case of *linear programming*. Using techniques of Kapoor and Vaidya [14] and by exploiting the special structure of the problem, an optimum fractional solution can be found with the interior point algorithm of Vaidya [27] in time $O(|E|^{1.5}|V|^2 \log(U))$, where U denotes the maximal p_{ij} .

In contrast to the linear programming methods, the aforementioned generalized maximum flow problem can also be solved with a purely *combinatorial* approach. Here, the makespan minimization is done by binary search. Computing generalized flows has a rich history, going back to Dantzig [2]. The first combinatorial algorithms for the generalized maximum flow problem were exponential time augmenting path algorithms by Jewell [13] and Onaga [19]. Truemper [26] showed that the generalized maximum flow problem and the *minimum cost flow* problem are closely related. More specifically, he transformed a generalized maximum flow problem into some minimum cost flow problem by setting the cost of an edge to be the logarithm of the gain from the generalized maximum flow problem. Goldberg et al. [6] designed the first polynomial-time combinatorial algorithms for the generalized maximum flow problem. Their algorithms were further refined and improved by Goldfarb, Jin and Orlin [7] and later by Radzik [22]. Radzik's algorithm is so far the fastest combinatorial algorithm with a running time of $O(|E| |V| (|E| + |V| \log |V|) \log U)$. In order to minimize makespan, this algorithm has to be called at most $O(\log(nU))$ times.

There exist fast fully polynomial-time approximation schemes for computing a fractional solution [4, 12, 20, 21, 25]. Using the rounding technique from [23],

this leads to a $(2 + \varepsilon)$ -approximation for the discrete problem. The approximation schemes can be divided into those that approximate generalized maximum flows [4, 21, 25] and those that directly address the scheduling problem [12, 20].

Unrelated machine scheduling is a very important problem and many heuristics and exact methods have been proposed. Techniques used here range from combinatorial approaches with partial enumeration to integer programming with branch-and-bound and cutting planes. For a selection we refer to [18, 24, 28] and references therein.

Finding a discrete solution for the unrelated scheduling problem can be formulated as an *unsplittable* generalized maximum flow problem. Several authors [3, 15, 16] have studied the unsplittable flow problem for usual flow networks. Kleinberg [15] formulated the problem of finding a solution with minimum makespan for the restricted scheduling problem as an unsplittable flow problem. Here the restricted scheduling problem is a special case of our problem, in which each job i has some weight w_i , each machine j has some speed s_j and $p_{ij} = \frac{w}{s}$ or $p_{ij} = \infty$ holds for all i, j . Gairing et al. [5] exploited the special structure of the network, gave a 2-approximation algorithm for the restricted scheduling problem based on preflow-push techniques and also an algorithm for computing a Nash equilibrium for the restricted scheduling problem on identical machines.

Contribution. The algorithm presented in this paper computes an assignment for the unrelated scheduling problem with makespan at most twice the optimum. We prove that a 2-approximative schedule can be computed in $O(m^2 A \log(m) \log(nU))$ time, where A is the number of pairs (i, j) with $p_{ij} \neq \infty$. This is better than the previously known best time bounds of Vaidya's [27] and Radzik's [22] algorithms. In particular, this is the first time that a combinatorial algorithm always beats the interior point approach for this problem.

An essential element of our approximation algorithm is the procedure Unsplittable-Blocking-Flow from [5]. This procedure was designed to solve the unsplittable maximum flow problem in a bipartite network, which is defined by the *restricted* scheduling problem. In this paper the connection to flow is more tenuous. We solve an unsplittable flow problem in a *generalized* bipartite network, which is defined by the *unrelated* scheduling problem. The generalized flow problem can be transformed to a minimum cost flow problem. Our algorithm uses the primal-dual approach combined with a gain scaling technique to obtain a polynomial running time. To compute a flow among the edges with zero reduced cost it uses the procedure Unsplittable-Blocking-Flow from [5] in the inner loop.

Given some candidate value for the makespan, our algorithm finds an approximate solution for the generalized flow problem in the two-layered bipartite network. Throughout execution the algorithm always maintains an integral assignment of jobs to machines. Each assignment defines a partition of the machines into underloaded, medium loaded and overloaded machines. Our overloaded machines are heavily overloaded, that is, their load is at least twice as large as the candidate makespan.

The main idea of our algorithm is to utilize the existence of overloaded machines in conjunction with the fact that we are looking for an approximate integral solution. We use this idea twice. On the one hand this allows us to show an improved lower bound on the makespan of an optimum schedule and thus to overcome the $(1 + \varepsilon)$ error usually induced by the gain scaling technique. On the other hand this is also used to reduce the number of outer loops to $O(m \log m)$, which is the main reason for the substantial running time improvement. Our algorithm is a generic minimum cost flow algorithm without any complex enhancements for generalized flow computation. Overloaded and underloaded machines are treated as sources and sinks, respectively. The height of a node is its minimum distance to a sink. In our algorithm the admissible network, used for the unsplittable maximum flow computation, consists only of edges and nodes which are on shortest paths from overloaded machines with minimum height to underloaded machines. This modification to the primal-dual approach is important to show the improved lower bound on the makespan of an optimum schedule.

Our algorithm is simpler and faster than the previously known algorithms. For the unrelated scheduling problem we have replaced the classical technique, i.e., computing first a fractional solution and rounding afterwards, by a completely integral approach. Our algorithm takes advantage from addressing the approximation problem directly. In particular, this allows us to benefit from an unfavorable preliminary assignment. We feel that this might be helpful also in other applications.

Identifying the connection to flow might be the key for obtaining combinatorial (approximation) algorithms for problems for which solving the LP-relaxation and rounding is currently the (only) alternative. Our techniques and results do not improve upon the approximation factor for the unrelated scheduling problem, however, we expect more exciting improvements for other hard problems.

Comparison of Running Times. We compare the running time of our algorithm with the so far fastest algorithms of Vaidya [27] and Radzik [22]. Both of the former approaches have been designed to solve the fractional generalized maximum flow problem on a graph with node set V and edge set E . Rounding the fractional solution yields the 2-approximation.

Technique and running time for computing a 2-approximative schedule:

- $O(|E|^{1.5}|V|^2 \log(U))$: Interior Point approach for generalized flow problem and rounding [27]
- $O(|E||V|(|E| + |V| \log |V|) \log U \log(nU))$: Combinatorial algorithm for generalized flow problem and rounding [22]
- $O(m^2 A \log(m) \log(nU))$: The integral approach presented in this paper

To compare these bounds, note that in our bipartite network $A = |E| = O(nm)$ and $|V| = n + m$. Our algorithm is linear in A . It clearly outperforms the previous algorithms if $n + m = o(A)$. In the case $A = \Theta(n + m)$ our algorithm is better by a factor of $\Omega(\frac{(n+m)^{0.5}}{\log(n) \log(m)})$ than Vaidya’s algorithm and by a factor of $\Omega(\log U)$ faster than Radzik’s algorithm. This is the first time that a com-

binatorial algorithm always beats the interior point approach for this problem. The heuristics [18, 24, 28] consider instances where $A = \Theta(nm)$. In this case our algorithm outperforms both former approaches by a factor almost linear in n .

The $(1+\epsilon)$ -approximation algorithms for the generalized maximum flow problem in [4, 21, 25] have all running time $\tilde{O}(\log \epsilon^{-1}|E|(|E| + |V| \log \log U))$, where the $\tilde{O}()$ notation hides a factor polylogarithmic in $|V|$. Again, an extra factor of $O(\log(nU))$ is needed for the makespan minimization. This running time is not always better than ours. The fastest approximation scheme that directly addresses the scheduling problem is due to Jansen and Porkolab [12] and has a running time of $O(\epsilon^{-2}(\log \epsilon^{-1})mn \min\{m, n \log m\} \log m)$. Clearly, for constant ϵ this algorithm is faster than our algorithm. However, for ϵ in the order of $\frac{1}{m}$ and $\log(U) = O(n)$ their running times become comparable.

Roadmap. The rest of the paper is organized as follows. In Section 2, we introduce notation and model. Section 3.1 presents our approximation algorithm and Section 3.2 shows the analysis.

2 Notation

2.1 The Scheduling Problem

We consider the problem of scheduling a set J of n independent *jobs* on a set M of m *machines*. The *processing time* of job i on machine j is denoted by p_{ij} . Define the $n \times m$ matrix of processing times \mathbf{P} in the natural way. Throughout the paper we assume that p_{ij} is either an integer or ∞ for all $i \in J$ and $j \in M$. Define $U = \max_{i \in J, j \in M} \{p_{ij} \neq \infty\}$. Furthermore, define A as the number of pairs (i, j) with $p_{ij} \neq \infty$. An *assignment* of jobs to machines is denoted by a function $\alpha : J \mapsto M$. We denote $\alpha(i) = j$ if job i is assigned to machine j . For any assignment α , the *load* δ_j on machine j for a matrix of processing times \mathbf{P} is the sum of processing times for the jobs that are assigned to machine j , thus $\delta_j(\mathbf{P}, \alpha) = \sum_{i \in J, \alpha(i)=j} p_{ij}$. We omit \mathbf{P} in the notation of δ_j if \mathbf{P} is clear from the context.

Define the *makespan* of an assignment α for a processing time matrix \mathbf{P} , denoted $\text{Cost}(\mathbf{P}, \alpha)$, as the maximum load on a machine, hence $\text{Cost}(\mathbf{P}, \alpha) = \max_{j \in M} \delta_j(\alpha)$. Associated with a matrix of processing times \mathbf{P} is the *optimum makespan*, which is the least possible makespan of an assignment α , that is $\text{OPT}(\mathbf{P}) = \min_{\alpha} \text{Cost}(\mathbf{P}, \alpha)$. Following Graham’s notation [9], our problem is equivalent to $R|C_{\max}$.

2.2 Generalized Maximum Flows and Minimum Cost Flows

The generalized maximum flow problem is a generalization of the maximum flow problem, where each edge (i, j) has some gain factor μ_{ij} . If f_{ij} units of flow are sent from node i to node j along edge (i, j) , then $\mu_{ij} f_{ij}$ units arrive at j . More specifically, let $G = (V, E)$ be a directed graph of the generalized flow problem, $\mu : E \mapsto \mathbb{R}^+$ a gain function, and s and t source and sink node, respectively. Furthermore, there

is a capacity function on the edges. A generalized flow $f : E \mapsto \mathbb{R}$ is a function on the edges that satisfies the capacity and antisymmetry constraints on all edges, and the conservation constraints $\sum_{(j,i) \in E} \mu_{ji} f_{ji} - \sum_{(i,j) \in E} f_{ij} = 0$ on all nodes $i \in V \setminus \{s, t\}$. The value of the flow f is defined as the amount of flow into the sink. Among all generalized flows of maximum value, the goal is to find one that minimizes the flow out of the source.

The fractional version of the scheduling problem can be converted into a generalized maximum flow problem [20]. In order to check whether a fractional schedule of length w exists, one can construct a bipartite graph with nodes representing jobs and machines and introduce an edge from machine node i to job node j with gain $1/p_{ij}$. There is a source which is connected to all the machine nodes with edges of unit gain and capacity w , and the job nodes are connected to a sink with edges of unit gain and unit capacity. A generalized flow in this network that results in an excess of n at the sink corresponds to a solution of the fractional scheduling problem. If the maximum excess that can be generated at the sink is below n , then the fractional scheduling problem is infeasible, i.e., the current value of w is too small.

Truemper [26] established a relationship between the generalized maximum flow problem and the minimum cost flow problem. In his construction, he defined the cost for each arc in the minimum cost flow problem as the logarithm of the gain in the generalized maximum flow problem. In order to transform the generalized maximum flow problem to a minimum cost flow problem with integral arc costs, a gain rounding technique can be used (see e.g. [25]). Gains are rounded down to integer powers of some base $b > 1$. The rounded gain of each residual arc (i, j) is defined as $\gamma_{ij} = b^{c_{ij}}$ where $c_{ij} = \lfloor \log_b \mu_{ij} \rfloor$. Antisymmetry is maintained by setting $\gamma_{ij} = 1/\gamma_{ji}$ and $c_{ij} = -c_{ji}$. The cost of arc (i, j) in the resulting minimum cost flow problem equals c_{ij} . Using a potential function $\pi : V \mapsto \mathbb{R}^+$, the reduced costs c_{ij}^π of an arc (i, j) are defined as $c_{ij}^\pi = c_{ij} - \pi(i) + \pi(j)$ (see [1]). The PRIMAL-DUAL approach [1] for minimum cost flows can be used to compute a generalized maximum flow (see e.g. [25]). The PRIMAL-DUAL approach preserves the *reduced cost optimality condition*, i.e., $c_{ij}^\pi \geq 0$ for each edge (i, j) in the residual network. Because of the rounding, an optimum solution of the minimum cost flow problem gives only a $(1 + \epsilon)$ -approximation of the generalized (fractional) maximum flow problem. Using techniques from [23], the fractional solution can be transformed to an integral solution. This approach leads to a $(2 + \epsilon)$ -approximation algorithm for the scheduling problem.

2.3 Our Model

We also formulate the scheduling problem as a generalized maximum flow problem. However, we use a different construction as in [20]. We construct a bipartite graph with nodes representing jobs and machines. There is an arc from job node i to machine node j with unit capacity and gain $\mu_{ij} = p_{ij}$ if $p_{ij} \leq w$. The parameter w will be determined by binary search. Each job node i has supply 1. A generalized flow f is a solution to the fractional version of the scheduling prob-

lem, if in f all supplies are sent to the machines. In this case, we call f a *feasible* flow. A generalized flow in such a network creates excess on the machine nodes. An excess on machine j corresponds to the load on machine j . Define $\delta_j(\mathbf{P}, f)$ as the load on machine j under the generalized flow f with gains defined by \mathbf{P} . If we require that the supply of each job is sent to exactly one machine, then we get an integral solution to the scheduling problem. In this case, we call f a generalized unsplittable flow and f corresponds to an assignment α , i.e., assigning job i to machine j corresponds to sending one unit of flow along edge (i, j) . We are interested in finding a generalized unsplittable flow f such that the maximum excess over all machines is at most $2w$. This is not always possible, however, if we can't find such a flow, we can still derive the lower bound $\text{OPT}(\mathbf{P}) \geq w + 1$.

Following the construction from Section 2.2, we formulate this generalized maximum unsplittable flow problem as a minimum cost flow problem. For the gain rounding, we choose $b = (1 + z)$ where $z = \frac{1}{m}$. If (i, j) is an edge from job node i to machine node j then the cost c_{ij} and the rounded gain γ_{ij} is defined by $c_{ij} = \lfloor \log_b(p_{ij}) \rfloor$, and $\gamma_{ij} = b^c$. For any path W , we define $\gamma(W) = \prod_{(i,j) \in W} \gamma_{ij}$. In the same way we define $\gamma(K)$ for some cycle K . In the following, denote $\mathbf{C} = (c_{ij})$ and $\mathbf{\Gamma} = (\gamma_{ij})$. In order to solve the minimum cost flow problem we use the well known PRIMAL-DUAL approach [1].

For a given assignment α , a positive integer w and a matrix of processing times \mathbf{P} , we now define the residual network $G_\alpha(w)$ (Definition 1) and we partition the machines, with respect to their loads, into three subsets (Definition 2).

Definition 1. Let α be an assignment and $w \in \mathbb{N}$. We define a directed bipartite graph $G_\alpha(w) = (V, E_\alpha(w))$ where $V = M \cup J$ and each machine is represented by a node in M , whereas each job defines a node in J . Furthermore, $E_\alpha = E_\alpha^1 \cup E_\alpha^2$ with $E_\alpha^1 = \{(j, i) : j \in M, i \in J, \alpha(i) = j, p_{ij} \leq w\}$ and $E_\alpha^2 = \{(i, j) : j \in M, i \in J, \alpha(i) \neq j, p_{ij} \leq w\}$.

Definition 2. Let $w \in \mathbb{N}$ and α be an assignment. We partition the set of machines M into three subsets:

$$\begin{aligned} M^-(\alpha) &= \{j : \delta_j(\mathbf{P}, \alpha) \leq w\} \\ M^0(\alpha) &= \{j : w + 1 \leq \delta_j(\mathbf{P}, \alpha) \leq 2w\} \\ M^+(\alpha) &= \{j : \delta_j(\mathbf{P}, \alpha) \geq 2w + 1\} \end{aligned}$$

In our setting, at each time, nodes from M^- can be interpreted as sink nodes, whereas nodes from M^+ as source nodes.

We now give a lemma that generalizes the path decomposition theorem to generalized flows. The proof of a similar decomposition theorem can be found in [8]. Note, that a fractional generalized flow on a path is defined as a flow that fulfills the flow conservation constraints on the inner nodes. Similarly, a generalized flow on a cycle fulfills the flow conservation constraints on all nodes in the cycle except one.

Lemma 1 (Decomposition theorem). Let f and g be two generalized feasible flows in $G = (J \cup M, E)$. Then g equals f plus fractional flow: on some directed

cycles in G_f , and on some directed paths in G_f with end points in M and with the additional property that no end point of some path is also the starting point of some other path.

2.4 Unsplittable Blocking Flows

Our approximation algorithm will make use of the algorithm UNSPLITTABLE-BLOCKING-FLOW introduced in [5]. UNSPLITTABLE-BLOCKING-FLOW was designed for a restricted scheduling problem on identical machines. Here, each job i has some weight w_i and is only allowed to use a subset A_i of the machines. This is a special case of the unrelated scheduling problem considered in this paper, where $p_{ij} = w_i$ if $j \in A_i$ and $p_{ij} = \infty$ otherwise. Given an assignment α and an integer w , UNSPLITTABLE-BLOCKING-FLOW(α, w) computes an assignment β , where there is no path from $M^+(\beta)$ to $M^-(\beta)$ in $G_\beta(w)$.

We use UNSPLITTABLE-BLOCKING-FLOW for arbitrary processing times p_{ij} . In order to make clear that UNSPLITTABLE-BLOCKING-FLOW runs on the original processing times (p_{ij}) we include \mathbf{P} in the parameter list. Furthermore, we allow UNSPLITTABLE-BLOCKING-FLOW only to reassign jobs according to some graph $G_\alpha^0(w)$, which can be any subgraph of $G_\alpha(w)$. These adaptations do not influence the correctness and the running time of algorithm UNSPLITTABLE-BLOCKING-FLOW.

Lemma 2 and Theorem 1 are derived from [5] and state properties of algorithm UNSPLITTABLE-BLOCKING-FLOW that are used in the discussion of our approximation algorithm.

Let $G_\alpha^0(w)$ be any subgraph of $G_\alpha(w)$. Let β be the assignment computed by UNSPLITTABLE-BLOCKING-FLOW($\alpha, G_\alpha^0(w), \mathbf{P}, w$). In this call jobs are reassigned by pushing them through edges of $G_\alpha^0(w)$. We define $G_\beta^0(w)$ as the graph that results from $G_\alpha^0(w)$ after this reassignments.

Lemma 2 ([5, Lemma 4.2]). *Let β be the assignment computed by UNSPLITTABLE-BLOCKING-FLOW($\alpha, G_\alpha^0(w), \mathbf{P}, w$). Then*

- (a) $j \in M^-(\alpha) \Rightarrow \delta_j(\mathbf{P}, \beta) \geq \delta_j(\mathbf{P}, \alpha)$
- (b) $j \in M^0(\alpha) \Rightarrow w + 1 \leq \delta_j(\mathbf{P}, \beta) \leq 2w$
- (c) $j \in M^+(\alpha) \Rightarrow \delta_j(\mathbf{P}, \beta) \leq \delta_j(\mathbf{P}, \alpha)$.

Theorem 1 ([5, Lemma 4.4/Theorem 4.5]). UNSPLITTABLE-BLOCKING-FLOW($\alpha, G_\alpha^0(w), \mathbf{P}, w$) takes time $O(mA)$ and computes an assignment β , having the property, that there is no path from $M^+(\beta)$ to $M^-(\beta)$ in $G_\beta^0(w)$.

3 Approximation Algorithm

We now present our approximation algorithm, UNSPLITTABLE-TRUEMPER, which will be used to compute an assignment α where $\text{Cost}(\mathbf{P}, \alpha) \leq 2 \cdot \text{OPT}(\mathbf{P})$. We always maintain an *unsplittable* flow, i.e., an integral solution. We loose a factor of 2 by allowing some gap for the machine loads. The special structure of our algorithm allows us to compensate the error, introduced by the gain scaling technique, by a better lower bound on $\text{OPT}(\mathbf{P})$. We stop the computation as soon as we get this better lower bound. This improves also the running time.

3.1 Algorithm Unsplittable-Truemper

We formulate the scheduling problem as a generalized maximum unsplittable flow problem with rounded gain factors as described in Section 2.2. In order to solve this generalized unsplittable flow problem we use the PRIMAL-DUAL approach for computing a minimum cost flow [1]. Our algorithm maintains the reduced cost optimality condition. In our setting this means that it does not create negative cost cycles in the residual network. In order to achieve this, UNSPLITTABLE-TRUEMPPER iteratively computes a shortest path graph $G_\alpha^0(w)$, which we define below, and uses UNSPLITTABLE-BLOCKING-FLOW to compute a blocking flow on this shortest path graph. While the costs in UNSPLITTABLE-TRUEMPPER refer to the rounded processing times, it operates on the original processing times. It is important to note, that both the costs as well as the original processing times are integer. Because of Theorem 1, there is no path from a machine from M^+ to a machine from M^- in $G_\alpha^0(w)$ after termination of UNSPLITTABLE-BLOCKING-FLOW. We stop this procedure, when we can either derive a *good* lower bound on OPT(P) (see Theorem 2) or we found an assignment α with $M^+ = \emptyset$.

```

UNSPLITTABLE-TRUEMPPER( $\alpha, \mathbf{P}, \mathbf{C}, w$ )
Input: assignment  $\alpha$  with each job  $i$  assigned to a machine from  $B(i)$ ,
         matrix of processing times  $\mathbf{P}$ , matrix of edge costs  $\mathbf{C}$ ,
         positive integer  $w$ 
Output: assignment  $\beta$ 

//  $G_\alpha(w)$  is the graph corresponding to  $\alpha$  and  $w$ .
 $\pi := 0$ ;
while  $\exists$  machine in  $M^+$  with a path to some machine in  $M^-$  in  $G_\alpha(w)$ 
      and  $\forall u \in M^+ : \pi(u) < \log_b(m)$ 
{
  determine shortest path distances  $d(\cdot)$  from all nodes to the set
    of sinks  $M^-$  in  $G_\alpha(w)$  with respect to the reduced costs  $c_{ij}^\pi$ ;
  update  $\pi := \pi + d$ ;
  define  $M_{\min}^+$  as the set of machines from  $M^+$  with minimum distance
    to a node in  $M^-$  with respect to the costs  $c_{ij}$ ;
  define  $G_\alpha^0(w)$  as the admissible graph, consisting only of edges on
    shortest paths from  $M_{\min}^+$  to  $M^-$  in  $G_\alpha(w)$ ;
   $\beta :=$  UNSPLITTABLE-BLOCKING-FLOW( $\alpha, G_\alpha^0(w), \mathbf{P}, w$ );
  update  $\alpha := \beta$ ;
}
return  $\alpha$ ;

```

We now describe our algorithm in more detail. UNSPLITTABLE-TRUEMPPER starts with an assignment α . In α , each job $i \in J$ is assigned to some machine $j \in B(i)$, where its processing time is minimum, i.e., $B(i) = \{j \in M : p_{ij} \leq p_{ik}, \forall k \in M\}$. Arc capacities are given by \mathbf{P} whereas arc costs are given by \mathbf{C} (as defined in

Section 2). Furthermore, UNSPLITTABLE-TRUEMPER gets as input an integer w . Assignment α and integer w define a graph $G_\alpha(w)$ as in Definition 1, and a partition of the machines as in Definition 2. At all times, UNSPLITTABLE-TRUEMPER maintains a total assignment, that is all jobs are always assigned to some machine. If a job gets unassigned from a machine, it is immediately assigned to some other machine.

Our algorithm iteratively computes shortest path distances $d(u)$ from each node u to the set of sinks M^- , with respect to the reduced costs c_{ij}^π . Then π is updated, such that all arcs on shortest paths have zero reduced costs. For each node $u \in M$, $\pi(u)$ never decreases. After the update of π , $\pi(u)$ holds the minimum distance from u to M^- for each node u with respect to the costs c_{ij} . We define M_{\min}^+ as the set of machines from M^+ with minimum distance to a node in M^- with respect to the costs c_{ij} . Note, that M_{\min}^+ consists of all machines $u \in M^+$ where $\pi(u)$ is minimum. $G_\alpha^0(w)$ is then defined as the admissible graph, consisting only of edges on shortest paths from M_{\min}^+ to M^- in $G_\alpha(w)$. We will see in Section 3.2 that this is essential for our algorithm. Note, that $G_\alpha^0(w)$ consists only of arcs with zero reduced costs. Afterwards, UNSPLITTABLE-BLOCKING-FLOW is applied to the admissible graph $G_\alpha^0(w)$. It reassigns jobs from the admissible graph, such that after UNSPLITTABLE-BLOCKING-FLOW returns, there is no longer a path from a machine in M_{\min}^+ to a machine in M^- in the admissible graph $G_\alpha^0(w)$. Therefore, $\min\{\pi(u); u \in M^+\}$ increases in the next iteration of the while loop. The residual network $G_\alpha(w)$ is then updated accordingly. The while-loop terminates when there exists no machine from M^+ with a path to a machine from M^- in $G_\alpha(w)$ or there exists a machine $u \in M^+$ with $\pi(u) \geq \log_b(m)$.

3.2 Analysis

We now analyze the behavior of our algorithm. The main result in this section is Theorem 2. A call of UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w$) terminates if $M^+(\alpha) = \emptyset$. In this case, we know that $\text{Cost}(\mathbf{P}, \alpha) \leq 2w$. We will see, that we can take also some advantage from an assignment α which is still unfavorable, i.e., for which $M^+(\alpha) \neq \emptyset$ holds.

The reduced cost optimality condition $c_{ij}^\pi \geq 0$ holds for all $(i, j) \in E_\alpha(w)$ during the whole computation. It implies $\gamma(K) \geq 1$ for each cycle K in $G_\alpha(w)$. This property does not necessarily hold for every path. Lemma 3 is of crucial importance in our analysis. It shows that $\gamma(W) \geq 1$ holds for every path W connecting some node from $M^+(\alpha)$ to any other node from M in $G_\alpha(w)$. For proving this result, we need that $G_\alpha^0(w)$ was defined only by shortest paths from nodes in M_{\min}^+ to nodes in M^- .

Lemma 3. UNSPLITTABLE-TRUEMPER maintains the property, that for each path W in $G_\alpha(w)$ from any machine in M^+ to any other machine in M , we have $\gamma(W) \geq 1$.

The following lemma will be used to derive a lower bound on $\text{OPT}(\mathbf{P})$.

Lemma 4. Let (G, Γ) denote a generalized maximum unsplittable flow problem defined by network G and matrix of processing times Γ . Let f be a generalized feasible unsplittable flow in (G, Γ) , and let $s, t \in \mathbb{R}^+$. Suppose $\forall u \in M : \delta_u(\Gamma, f) \geq s$, and $\exists \hat{u} \in M : \delta_{\hat{u}}(\Gamma, f) \geq s + t$, and for each cycle K in G_f , $\gamma(K) \geq 1$. If on every path W in G_f from \hat{u} to any other machine $u \in M$, $\gamma(W) \geq 1$, then $\text{OPT}(\Gamma) \geq s + \frac{t}{m}$.

Theorem 2. UNSPLITTABLE-TRUEMPER takes time $O(m^2 A \log(m))$. Furthermore, if UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w$) terminates with $M^+ \neq \emptyset$ then $\text{OPT}(\mathbf{P}) \geq w + 1$.

We will now show how to use UNSPLITTABLE-TRUEMPER to approximate a schedule with minimum makespan. We do series of calls to UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w$) where, by a binary search on $w \in [1, nU]$, we identify the smallest w such that a call to UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w$) returns an assignment with $M^+ = \emptyset$. Afterwards we have identified a parameter w , such that UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w$) returns an assignment where $M^+ \neq \emptyset$ and UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w + 1$) returns with $M^+ = \emptyset$.

Theorem 3. UNSPLITTABLE-TRUEMPER can be used to compute a schedule α with $\text{Cost}(\mathbf{P}, \alpha) \leq 2 \cdot \text{OPT}(\mathbf{P})$ in time $O(m^2 A \log(m) \log(nU))$.

Proof. We use UNSPLITTABLE-TRUEMPER as described above. Let β_1 be the assignment returned by UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w$) where $M^+ \neq \emptyset$. Let β_2 be the assignment returned by UNSPLITTABLE-TRUEMPER($\alpha, \mathbf{P}, \mathbf{C}, w + 1$) where $M^+ = \emptyset$. From β_1 we follow by Theorem 2 that $\text{OPT}(\mathbf{P}) \geq w + 1$ and in β_2 we have $\text{Cost}(\mathbf{P}, \beta_2) \leq 2(w + 1)$. Thus, $\text{Cost}(\mathbf{P}, \beta_2) \leq 2 \cdot \text{OPT}(\mathbf{P})$. It remains to show the running time of $O(m^2 A \log(m) \log(nU))$. Due to Theorem 2, one call to UNSPLITTABLE-TRUEMPER takes time $O(m^2 A \log(m))$. The binary search contributes a factor $\log(nU)$. This completes the proof of the theorem. \square

Polynomial Time Preemptive Sum-Multicoloring on Paths

Annamária Kovács

panni@mpi-sb.mpg.de

Abstract. The *preemptive Sum-Multicoloring (pSMC)* problem is a scheduling problem where pairwise conflicting jobs are represented by a conflict graph. The time demands of jobs are given by integer weights on the nodes. The goal is to schedule the jobs in such a way that the *sum* of their finish times is minimized. We give an $\mathcal{O}(n \cdot \min(n, \log p))$ time algorithm for pSMC on paths and cycles, where n is the number of nodes and p is the largest time demand. This is the first polynomial algorithm for this problem. It answers the question raised in [8] about the hardness of this problem. In this respect our result identifies a gap between binary-tree conflict graphs – where the question is NP-hard – and paths. Furthermore, our time bound gets very close to that of $\mathcal{O}(n \cdot \log p / \log \log p)$ for the *non-preemptive* SMC on paths [8]. A detailed version of this paper is available at [3].

1 Introduction

In the paper we consider the *preemptive Sum-Multicoloring (pSMC)* problem. In spite of the name “multicoloring”, we prefer to discuss it from a scheduling point of view. The input is given by a simple undirected *conflict graph* $G(V, E)$, where the nodes model different jobs, and by integer weights on the nodes $x : V \rightarrow \mathbb{N}^+$, i.e., *time demands* for each job. The edges of the graph represent pairwise conflicts between certain jobs, meaning that they cannot be processed at the same time, e.g., due to some non-shareable resource they use. The goal is to schedule the jobs, i.e., to determine a function $\Phi : V \rightarrow 2^{\mathbb{N}}$ that assigns a set of time units to each job, so that the sets assigned to conflicting jobs do not intersect, and $\forall v \in V : |\Phi(v)| = x(v)$. Let $f(v) = \max \Phi(v)$ be the finish time of node v . In the Sum-Multicoloring problems, the *average* finish time, or equivalently, the *sum* of finish times $\sum_{v \in V} f(v)$ has to be minimized. In the *non-preemptive* version of SMC (*npSMC*) the assigned sets $\Phi(v)$ must be contiguous, whereas in *preemptive* SMC they are arbitrary.

Scheduling jobs with pairwise conflicts is a classical problem, with applications in diverse areas like traffic intersection control, VLSI routing, session management in local area networks, operating systems, etc. (see [7]). From the jobs’ point of view, it is a natural goal to minimize the average completion time.

The concern of this paper is the pSMC problem on path conflict graphs. The path has n nodes, and the nodes are numbered by $1, \dots, n$, from left to right. Let $p := \max_{1 \leq i \leq n} x(i)$ be the largest demand in the input. We provide the first polynomial algorithm for pSMC on paths. It runs in time $\mathcal{O}(n \cdot \min(n, \log p))$. Moreover, our result easily carries over to cycle conflict graphs.

Related work. For a comprehensive history of the SMC problems see, e.g., [2, 8]. The Sum-Multicoloring problem was introduced by Bar-Noy et al. in [7], as a generalization of the *Sum-Coloring* problem (the latter was studied by Kubicka in [5]). Even the Sum-Coloring problem was shown to be NP-hard on several conflict graph classes, like e.g., on planar graphs [2]; it is hard to approximate within a constant factor $c > 1$ on bipartite graphs [1].

The SMC problem on trees was studied by Halldórsson et al. in [8] and some of the results were generalized to partial k -trees in [2]. In [8] an $\mathcal{O}(n^2)$ and an $\mathcal{O}(np)$ algorithm was provided for the *non-preemptive* SMC on trees. The first one runs in time $\mathcal{O}(n \cdot \log p / \log \log p)$ on paths. For the *preemptive* SMC on trees a PTAS was given. The hardness of pSMC on trees or paths was posed as an open question. Marx [6] showed, that pSMC is NP-hard on binary trees, even for polynomially bounded p . Thus, the preemptive problem on trees turned out to be essentially harder than the non-preemptive version. In [4] we gave a pseudo-polynomial algorithm, running in time $\mathcal{O}(n^3 p)$ for pSMC on paths.

Our result. We provide an $\mathcal{O}(n \cdot \min(n, \log p))$ time algorithm for the pSMC problem on paths which immediately implies an $\mathcal{O}(n \cdot \min(n, \log p))$ time solution for cycles. This is the first polynomial algorithm for this problem. It improves substantially on our previous $\mathcal{O}(n^3 p)$ -time result, and answers the question raised in [8], whether pSMC is efficiently solvable on paths. Thus, we identify a major difference between the solvability of the problem on binary trees – where it is NP-hard [6] – and graphs of maximum degree 2. More interestingly, compared to the results on the *non-preemptive* SMC problem in [8], our result gets very close to the time-bound of $\mathcal{O}(n \cdot \log p / \log \log p)$ for paths, whereas for very large p , our $\mathcal{O}(n^2)$ bound matches the $\mathcal{O}(n^2)$ bound for npSMC on paths (or trees in general). Our method is an improved version of the algorithm in [4]. The core of this improvement is a result about the structure of some “nice” optimal schedules, which we will briefly sketch here.

Without loss of generality, we add nodes 0 and $n + 1$ to the path, with demands $x(0) = x(n + 1) = 0$. We denote by $\langle i, j \rangle$ the subpath i, \dots, j . In a fixed schedule Φ , we distinguish so called local minimum (*loc-min*), and local maximum (*loc-max*) nodes on the path: a loc-min node has smaller finish time, resp. a loc-max has larger finish time than any of its two neighbors. The rest is called *stair* node. Restricted to optimal schedules with maximum value of $\sum_{v \in V} f^2(v)$, the following hold: The schedule of a loc-min node determines the schedule of the stairs on its two sides in a greedy fashion, and a loc-max node receives the first time units idle on both sides. The hardness of this problem lies in the fact that loc-mins are not always *compact*, i.e., in general $f(i) \neq x(i)$ for a loc-min i . Let’s denote by $r(i)$ and $\ell(i)$ the first nodes to the right and to the left of loc-min i with finish time less than $f(i)$ (see Fig. 1). The main idea of [4]

Fig. 1. Minimum-tree of a block

was that any “simultaneous permutation” of the time units in $\Phi(i)$ and $\Phi(r(i))$ results in the same optimum sum on the subpath strictly between i and $r(i)$. As a further consequence, $f(i)$ alone determines the optimum $F(f(i)) := \sum_{j=i+1}^{r(i)-1} f(j)$ on this subpath. This observation facilitates a dynamic programming algorithm: Two scheduled subpaths are glued at a loc-min, proceeding from short subpaths to longer ones, from large loc-mins to smaller ones. However, on the subpath $\langle i+1, r(i)-1 \rangle$ the optimum $F(f(i))$ for every possible $f(i)$ has to be determined (since $f(i)$ depends also on what will be glued to the left of i).

Our new result is that the possible changes in $f(i)$ cannot modify the structure on $\langle i, r(i) \rangle$, i.e., the order of the finish times remains the same. Moreover, by increasing $f(i)$ to $f(i) + \Delta$, we increase the finish time of all the loc-mins and decrease the finish time of all the loc-max’s on $\langle i+1, r(i)-1 \rangle$ by Δ . In total we decrease $F(f(i))$ by Δ . The optimum on $\langle i+1, r(i)-1 \rangle$ is a simple linear function of the form $F(f(i)) = C - f(i)$. The only question for the dynamic algorithm is the constant C in this function and the range of possible $f(i)$ values.

What is the explanation for this determined structure on $\langle i, r(i) \rangle$? A subpath between nearest compact loc-mins will be called a *block*. (Note that blocks are easy to connect.) Inside a block, the loc-mins are non-compact, and there must be “large” differences between their demands. They form a binary tree (see Fig. 1), and the finish times on growing levels of this tree grow exponentially. In other words, if there are many loc-mins of similar demands, not separated by nodes of smaller demands, then some (e.g. the odd ones) will be compact. The exponential growth within a block implies that for fixed i there are just a constant number of candidates for $r(i)$, and just a few candidates to be the loc-min finished next, i.e., the child of i in the minimum-tree.

The fast growth within a block is quite intuitive. However, the order of finish times must remain the same already on the lowest levels above $f(i)$, meaning roughly, that even the smallest differences between finish times should exceed potential changes in $f(i)$. The proof of these results is lengthy and technical; it makes use of a handful of simple operations, and a tricky induction argument.

Overview. In Section 2 we characterize the type of optimal schedules we will look for, based on [4]. There we also try to provide more insight into the spirit of our improvement. Section 3 contains the key result that facilitates a polynomial-time algorithm. The proofs can be found at [3]. In Section 4 we present our fast algorithm. We conclude with a few words about cycle conflict graphs, and potential future work.

2 Definitions and Basic Facts

We will refer to time units as to **levels**. Given a schedule Φ , we say that i is **black** on level a , if $a \in \Phi(i)$, and i is **white** on level a if $a \notin \Phi(i)$. For $i < j$ we will also say, that the ordered pair (i, j) is **black-white, black-black,... etc.** on level a . Note that $(i, i + 1)$ cannot be black-black on any level.

Definition 1. *An (i, j) pair has a conflict or is conflicting on level a , if i and j are of the same parity and (i, j) is black-white, or white-black, or i and j are of opposite parity and (i, j) is black-black, or white-white.*

Obviously, if (i, j) is conflicting on level a , then $\exists k \in \langle i, j - 1 \rangle$ s.t. $(k, k + 1)$ is white-white on level a .

Definition 2. *For any ordered pair of nodes (i, j) and any fixed schedule Φ , we may consider the number of levels under some fixed level Γ , where (i, j) is black-black, white-black, white-white and black-white, respectively. We call the 4-tuple of these numbers the **scheme of (i, j) under Γ** .*

Definition 3. *Given a schedule, we say that node i is*
*a **loc-min**, if $f(i - 1) > f(i)$ and $f(i) < f(i + 1)$, or $i = 0$, or $i = n + 1$;*
*a **loc-max**, if $f(i - 1) < f(i)$ and $f(i) > f(i + 1)$;*
*a **stair** otherwise, in particular a **stair-up**, if $f(i - 1) < f(i) < f(i + 1)$, and*
*a **stair-down**, if $f(i - 1) > f(i) > f(i + 1)$;*
compact, if $f(i) = x(i)$. Note that 0 and $n + 1$ are compact.
 If both i and j are compact with no compact nodes between them, then we call $\langle i, j \rangle$ or (i, j) a **block**.

We provide with notation the following 4 nodes concerning a loc-min i :

Definition 4. *If i is a loc-min in a schedule, then we denote by $r(i)$ the first node to the right of i s.t. $f(r(i)) < f(i)$ and we denote by $\ell(i)$ the first node to the left of i s.t. $f(\ell(i)) < f(i)$. Furthermore, $R(i) := r(i) - 1$ and $L(i) := \ell(i) + 1$.*

Note that $R(i)$ ($L(i)$) is either a stair-down (stair-up) or a loc-max.

We would like to restrict our attention to schedules of the simplest possible structure. In [4] we have shown that for any instance of the pSMC problem, a schedule exists with properties (P1)–(P5) below. For example, among schedules of minimum $\sum_{i=1}^n f(i)$ those of maximum $\sum_{i=1}^n f^2(i)$ fulfil (P1)–(P5).

- (P1) the sum of finish times $\sum_{i=1}^n f(i)$ is minimum over all proper schedules;
- (P2) stairs and loc-max's are scheduled "greedily": e.g., a stair-up i is black on the first possible levels where $i - 1$ is white; a loc-max m is black on the first levels where both $m - 1$ and $m + 1$ are white;
- (P3) if i is a non-compact loc-min and $\ell(i) \leq k \leq r(i)$ then i has no conflict with k on the level $f(i)$ and on any level where i is white; therefore there are no compact nodes inside $\langle \ell(i), r(i) \rangle$, since any node is white either on level $f(i)$ or on the levels where i is white.
- (P4) if i is a non-compact loc-min and k is a loc-min $i < k < r(i)$, then there is no level where k (is black and) has conflict on both sides (with $\ell(k)$ and with $r(k)$).
- (P5) if $i < j$ are loc-mins, $j < r(i)$ and $f(i) = f(j)$, then i and j are compact.

Definition 5. A schedule Φ is called **optimal schedule** or a **solution** if properties (P1)–(P5) hold.

Corollary 1. The schedule of a loc-min determines the schedules of stairs leading up to the next loc-max's on both sides. If, e.g., i is a stair-up, then $f(i) = x(i - 1) + x(i)$.

Corollary 2. Let i be a non-compact, even loc-min. (P2), (P3) and (P4) imply the following on $\langle i, r(i) \rangle$: If $(i, r(i))$ have no conflict on level b , then exactly the odd or exactly the even nodes are black on level b . If $(i, r(i))$ have a conflict on level b , then there is a loc-max m , s.t. on $\langle i, m - 1 \rangle$ exactly the even nodes, on $\langle m + 1, r(i) \rangle$ exactly the odd nodes are black on level b .

Corollary 3. Let i be a non-compact loc-min. $(i, r(i))$ is black-white on level $f(i)$, so i and $r(i)$ are of different parity, and $i + 3 \leq r(i)$ (resp. $\ell(i) \leq i - 3$).

Definition 6. Let i be a non-compact loc-min. We denote by $pit(i, r(i))$ the loc-min of smallest finish time between i and $r(i)$. If there is no loc-min between them, then $pit(i, r(i)) = \emptyset$ and $top(i, r(i))$ denotes the unique loc-max in $\langle i, r(i) \rangle$. The nodes $pit(\ell(i), i)$ and $top(\ell(i), i)$ are defined analogously.

Due to (P5), the $pit()$ is well-defined. Note that if $k = pit(i, r(i))$ then $\langle i + 1, \ell(k) \rangle$ is a series of stair-ups and $\langle r(k), r(i) - 1 \rangle$ is a series of stair-downs, and (P3) implies that $k = pit(i, r(i))$ is non-compact.

If g is a compact loc-min, then – instead of $\langle g, r(g) \rangle$ –, the block $\langle g, h \rangle$ is of relevance, where h is the nearest compact node. Blocks can be regarded as maximal $(i, r(i))$ or $(\ell(i), i)$ pairs, and we can define $pit(g, h)$ similarly to Definition 6.

If $\langle g, h \rangle$ is a block then the (non-compact) loc-mins inside form a binary tree in the following way: $i = pit(g, h)$ is the root of the tree, and its two children are $pit(\ell(i), i)$ and $pit(i, r(i))$, etc. The loc-max's can be regarded as the leaves of this tree. We will call this tree the **minimum-tree** of (g, h) (see Fig. 1). We say that the root i is on the **1st floor**, the children of i are on the **2nd floor**, etc. of the minimum-tree. Having the minimum-tree fixed, the root i is the only loc-min that can have (black) levels conflicting with both $\ell(i)$ and $r(i)$, and so $f(i)$ is

not automatically determined by (P3), (P4). But once we have $f(i)$ ($\Phi(i)$), it determines the schedule of all the other loc-mins (by (P3), (P4)), consequently of all other nodes in the block (by (P2)).

Suppose we know that i is a non-compact loc-min and $j = r(i)$. In [4] we have shown that the optimum sum of finish times $F := \sum_{k=i+1}^{r(i)-1} f(k)$ depends only on $f(i)$. This fact is based on the following simple observations: The optimum on $\langle i + 1, r(i) - 1 \rangle$ depends only on the scheme of $(i, r(i))$ and not on the exact schedule of i and $r(i)$. And, since there are no conflicting white-white levels of $(i, r(i))$ under $f(i)$, fixing the scheme of $(i, r(i))$ boils down to fixing the number of conflicting black-black levels under $f(i)$ or equivalently, to fixing $f(i)$ itself.

Let α denote the number of levels where $(i, r(i))$ is black-black. In this paper we consider the optimum F as a function of α . Our goal is to show that for the range of feasible α values, the order of finish times on $\langle i, r(i) \rangle$ is fixed. As a consequence, $F(\alpha)$ is a simple linear function, namely $F(\alpha - \Delta) = F(\alpha) - \Delta$. This result in turn, allows us to modify our previous algorithm: in the previous version, for each potential $(i, r(i))$ we had to test the $F(\alpha)$ value for each α one by one. Now it is sufficient to compute dynamically the domain and one value of $F(\alpha)$ for each possible $(i, r(i))$ (resp. $(\ell(i), i)$).

From a more global perspective, observe that inside a block $\langle i, j \rangle$, or inside $\langle i, r(i) \rangle$, there is one more loc-max than loc-mins. On the whole, we will derive that increasing the finish time of the root in a minimum-tree by Δ increases every other loc-min and decreases every loc-max by the same value, resulting in an improvement of Δ on the whole block. However, each increase must mean exchanging a black level below the finish time for a white level above the finish time of a loc-min, both having conflicts on both sides. This condition bounds from above the potential values of Δ in a recursive manner. The *rung* of a stair is the topmost set of contiguous black levels of the stair. The rungs of consecutive stairs partition the set of levels above the loc-min.

Definition 7. Let s be a stair-up (stair-down) in a fixed solution Φ . The **rung** of s is the set of levels $S := [f(s - 1) + 1, f(s)]$, (resp. $S := [f(s + 1) + 1, f(s)]$). For simplicity, we use the respective capital letters to denote rungs.

Definition 8. We say that s is a 2nd **stair** resp. S is a 2nd **rung** if $s - 1$ or $s + 1$ is a loc-min. We call a stair or rung **high stair**, resp. **high rung** otherwise. Let i be a non-compact loc-min, $c = L(i)$ and $d = R(i)$. Now C and D are the rungs of c and d , respectively, and $f(i) \in C \cap D$. We say that i (or $f(i)$) **ends in C on the left and in D on the right**.

3 The Main Theorem

Let $\langle i, j \rangle$ be a subpath, and $x(i), x(i + 1), \dots, x(j)$ a fixed (partial) instance of the pSMC problem. Regard all cases when this is part of an instance on a longer path, and all solutions (if existent) where i is a *non-compact* loc-min and $j = r(i)$.

Let's take all $f(i)$ that ever occur in such a situation, and fix one solution on $\langle i, r(i) \rangle$ for each of them. We can only talk about fixed solutions modulo permutation of the levels below $f(i)$, but with fixed finish times on $\langle i, r(i) - 1 \rangle$.

From here on we discuss the case of potential $(i, r(i))$ pairs. Case $(\ell(i), i)$ can be handled symmetrically. Instead of considering the optimum as a function of $f(i)$, we will look at it as follows: Let α be the number of black-black conflicts of $(i, r(i))$, and $F(\alpha)$ be the sum of finish times on $\langle i + 1, r(i) - 1 \rangle$ in the corresponding fixed solution Φ_α . Since $\alpha = x(i) + x(r(i)) - f(i)$ (see (P3)), this makes just a tiny technical difference. Those α values that correspond to an occurrence of $f(i)$ constitute the **domain** \mathcal{D}_F of $F(\alpha)$.

We fix a level $\Gamma := \min(x(i) + x(i + 1), x(r(i)) + x(r(i) - 1))$. We claim that Γ separates the set of levels into two parts: For any of the fixed solutions on $\langle i, r(i) \rangle$, $f(i) \leq \Gamma$, and $f(\text{pit}(i, r(i))) > \Gamma$. (The latter holds, because i and $r(i)$ are of different parity, and $\text{pit}(i, r(i))$ ends in rungs of the same parity.) In the rest of the paper Γ denotes this level.

For fixed α , the optimum is indifferent to the permutation (exchange) of levels below Γ (or even to change of roles of i and $r(i)$). Since $f(\text{pit}(i, r(i))) > \Gamma$, such a permutation does not interfere with finish times inside the subpath.

Decreasing $f(i)$ by Δ corresponds to the following change in the scheme of $(i, r(i))$ below Γ : α increases by Δ , and equivalently, the number of white-white conflicts increases by Δ , the number of black-white levels and white-black levels both decrease by Δ . Theorem 1 serves as an illustration of what we would like to show in general, and as the base step of an induction proof of the general case:

Theorem 1. *Let $i, r(i), \alpha$, etc. be as defined above. If for all $\alpha \in \mathcal{D}_F$, $\text{pit}(i, r(i)) = \emptyset$ in Φ_α , then*

- (I.) *we may assume wlog. that $\text{top}(i, r(i))$ is the same node m in every Φ_α and*
- (II.) $F(\alpha - \Delta) = F(\alpha) - \Delta$.

We will state a similar theorem about the general case, i.e. when for some α in Φ_α there is a $\text{pit}(i, r(i)) \neq \emptyset$. In the full version [3] we show that independent of $f(i)$, the solutions on $\langle i, r(i) \rangle$ have the same minimum-tree. The reason for this is roughly as follows: Within $\langle i, r(i) \rangle$ the loc-mins end in different (pairs of) rungs, and the sizes of these rungs are large compared to possible differences in $f(i)$. Consequently, the demands of nodes in $\langle i, r(i) \rangle$ differ too much to be alternative candidates for, e.g., $\text{pit}(i, r(i))$. We could not exclude a few potential exceptions to this rule (although we did not find any example for such an exception), but fortunately these might appear only on the first two floors of a minimum-tree. For example, we have more than one candidate for $\text{pit}(i, r(i))$ when $r(i)$ is compact. The notions of *irregular* vs. *regular* partial solutions on $\langle i, r(i) \rangle$ were introduced in order to handle the possible exceptional solutions separately [3].

Let $\mathcal{D}'_F \subseteq \mathcal{D}_F$ be the set of α for which a regular solution exists, and let Φ_α be regular for $\alpha \in \mathcal{D}'_F$. Now we state the generalized theorem:

Theorem 2. *Let $i, r(i), \alpha, \Phi_\alpha$, etc. and the partial instance on $\langle i, r(i) \rangle$ be as defined above.*

- (I.) Either $m := \text{top}(i, r(i))$ can be fixed to be the same node; or $k := \text{pit}(i, r(i))$ is the same, $L(k)$ is the same, resp. $R(k)$ is the same node in every Φ_α ($\alpha \in \mathcal{D}'_F$).
- (II.) $F(\alpha - \Delta) = F(\alpha) - \Delta$ on \mathcal{D}'_F .

Theorem 3 below characterizes the candidate nodes for $k, L(k)$, and $R(k)$. Recall that the potential finish time $f_\alpha(k)$ of any possible $k = \text{pit}(i, r(i))$ is determined by α (see (P3) and (P4)).

Theorem 3. *Suppose that the unique $\text{pit}(i, r(i))$ of Theorem 2 is known to be even. Let $i < c$ and $d < r(i)$ be the lowest even stairs s.t. $\exists \alpha, \exists k \in \langle c+2, d-2 \rangle$ so that k is even, and $f_\alpha(k) \in C \cap D$. Then $L(k) = c, R(k) = d$, and $k = \text{pit}(i, r(i))$ in any regular partial solution. Moreover, for all $\alpha \in \mathcal{D}'_F$ there is no even $k' \neq k$ s.t. $f_\alpha(k') \in C \cap D$. Similar statement holds for odd k .*

Corollary 4. *Let $x(i), \dots, x(r(i))$ be a given (partial) instance. When restricted to regular solutions, there is at most one even and at most one odd node in $\langle i, r(i) \rangle$ to be a candidate for $\text{pit}(i, r(i))$, independent of α .*

4 The Algorithm

Let $x(1), x(2), \dots, x(n)$ be an instance of the pSMC problem on the path (or cycle) $1, 2, \dots, n$. Recall that $p = \max_i x(i)$. Theorem 2 allows us to get rid of the factor p that was there in the $\mathcal{O}(n^3 p)$ algorithm of [4]. By the following lemmas we can improve on the factor n^3 and obtain an algorithm that runs in $\mathcal{O}(n \cdot \min(n, \log p))$ time. The lemmas are quite intuitive: they reflect the fact that within one block the finish times exhibit exponential growth.

In a fixed schedule, let the **rungs of a loc-min** mean the maximal sets of contiguous black or contiguous white levels of the loc-min. Let I_1, I_2, \dots, I_η be the rungs of a loc-min i and S_1, S_2, \dots, S_ζ ($\zeta \geq 0$) be the rungs of any number of consecutive stair-ups $i = s_o, s_1, s_2, \dots, s_\zeta$ following i . Now all of these sets I_τ and S_ρ are disjoint and $[1, f(s_\zeta)] = \bigcup_{\tau=1}^\eta I_\tau \cup \bigcup_{\rho=1}^\zeta S_\rho$.

Lemma 1. *If η and ζ are numbers of rungs as described above, then $\eta + \zeta < 5 \log f(s_\zeta)$.*

Lemmas 2 and 3 imply that for given non-compact i , there is a constant number of candidate nodes for $r(i)$ and $\text{pit}(i, r(i))$:

Definition 9. *Let*

$$\begin{aligned} \chi(i) &:= \min(x(i) + x(i + 1), 2x(i)); \\ \chi(r(i)) &:= \min(x(r(i)) + x(r(i) - 1), 2x(r(i))). \end{aligned}$$

Lemma 2. *If i is a loc-min, then $x(r(i)) \leq \chi(i)$.*

Lemma 3. *Let i be a non-compact loc-min. A constant $C \leq 30$ exists, such that if i is even,*

- (a.) there are $\leq C$ odd nodes l , and $\leq C$ even nodes k in $\langle i, r(i) \rangle$ s.t. $x(l) \leq \chi(i)$, resp. $x(k) \leq \chi(r(i))$.
- (b.) there are $\leq C$ even nodes $k \in \langle i, r(i) \rangle$, s.t. $x(k) \leq 2x(i)$.

We did not provide the definition of *irregular* partial solutions on $\langle i, r(i) \rangle$ in this short version. We will also omit the details concerning irregular solutions from the algorithm description. We include here two hints, why these potential exceptions to Theorem 2 do not blow up the running time. On the one hand, the following claim, together with Lemma 3, imply that possible $pit(i, r(i))$ nodes of irregular solutions can be found in constant time:

Claim 1. Suppose i is even, and $k = pit(i, r(i))$ in an irregular solution. If k is odd, then $x(k) \leq \chi(i)$; if k is even, then $x(k) \leq \chi(r(i))$.

On the other hand, recall that irregular partial solutions on $\langle i, r(i) \rangle$ may appear only if i is on ≤ 2 nd floor of a minimum-tree. Although we have to deal with irregular solutions in the dynamic programming algorithm, fortunately they do not propagate: We have to take the minimum function of $F(\alpha)$ functions resulted by irregular solutions, which may be a non-linear function due to breaks or holes in the domain. However, we can forget these solutions as soon as we stepped down at least two floors in the minimum-tree. This implies, that we will never have to deal with more than $\approx C^2$ breaks in the optimum function.

Proposition 1. For any node i in a solution, unless i has compact neighbours on both sides, $f(i) \leq 4x(i)$.

The algorithm has two phases. In Phase 1. the blocks, and the minimum-tree of each block are determined. In Phase 2. the schedule is determined.

Phase 1. We group the nodes into $\log p$ groups: nodes of demand in $[2^{t-1}, 2^t - 1]$ belong to group \mathcal{G}_t . First we traverse the path from right to left, and from a node k in \mathcal{G}_t we set pointers to the nearest nodes of each of $\mathcal{G}_{t+2}, \mathcal{G}_{t+1}, \mathcal{G}_t, \dots, \mathcal{G}_1$ to the right of k . After that we do the same from left to right. This preprocessing takes $\mathcal{O}(n \cdot \min(n, \log p))$ time.

We test for every node $1 \leq i \leq n$, if it can be a *non-compact* loc-min, and every potential $r(i)$ (and $\ell(i)$). Let i be a fixed even node. By Corollary 3 and Lemma 2, $r(i)$ must be an odd node s.t. $x(r(i)) \leq \chi(i)$. According to Lemma 3, we have to test at most C odd nodes of demand $\leq \chi(i)$, both on the left and on the right of i . However, we may stop earlier if we find a node of demand $< x(i)/4$. Because of the preprocessing, finding these $2C$ candidate nodes for all i , takes overall $\mathcal{O}(n)$ time. We partition all these candidate $(i, r(i))$ and $(\ell(i), i)$ pairs into sets depending on their distances. In the testing process, we have to determine the optimum dynamically, and therefore we proceed from pairs of short distances to pairs of long ones. We start with the possible $r(i) = i + 3$ and $\ell(i) = i - 3$ values for every $i \in \langle 1, n \rangle$.

Suppose we have i and $r(i)$ fixed. Let α and $F(\alpha)$ be as defined in Section 3. Now we have to compute $F(\alpha)$ dynamically, for every potential $(i, r(i))$ (and $(\ell(i), i)$) pairs. When we set the domain \mathcal{D}'_F of the possible α values, we must

take care that each α and $F(\alpha)$ can be realized on $\langle i, r(i) \rangle$, and that *all* realizable α are considered. It is straightforward to show that the nonnegative part of $[x(i) + x(r(i)) - \Gamma, \min(x(r(i)), x(i) - 1)]$ is an enclosing interval of all α . Later we cut this domain as required by the connecting step of the dynamic algorithm.

Next, we search for $k = \text{pit}(i, r(i))$ or $m = \text{top}(i, r(i))$. Corollary 4 says that there is not more than one even and one odd potential $\text{pit}(i, r(i))$. As for the number of possible $\text{top}(i, r(i))$ nodes, there are obviously always ≤ 2 even and ≤ 2 odd candidates, since $x(m-1) > x(m-3) > \dots$, resp. $x(m+1) > x(m+3) > \dots$, must hold. The potential k or m nodes we find as described in Claim 2:

Claim 2. For given i and $r(i)$ it takes $\mathcal{O}(\min(n, \log p))$ steps to find the ≤ 2 candidates for $\text{pit}(i, r(i))$ or ≤ 4 candidates for $\text{top}(i, r(i))$ in a regular solution.

Sketch of proof. We proceed upwards along the stairs on the two sides of $\langle i, r(i) \rangle$. The potential finish time $f(k)$ of a loc-min k , is calculated by summing up the number of (potential) black levels of k : say k is even, these are the levels, where on at least one side there is an even rung (see (P3)). Finally, $f(k)$ is the level where the sum totals to $x(k)$. By Theorem 3, the even candidate is the node k of the least possible $f(k)$. Consequently, $x(k)$ is minimum over all demands *inside* $\langle L(k), R(k) \rangle$. The starting value of the summation is the number of black levels below Γ , this depends on α . Large α values yield small $f(k)$ values, and we search for minimum $f(k)$, so we fix $\alpha := \min(x(r(i)), x(i) - 1)$.

In order to find potential nodes k of minimum $x(k)$, we can check the linked lists of each group \mathcal{G}_t , starting nodes might be the stairs on the left. Applying Lemma 3 (b.) to k implies that in the lowest group that is nonempty between stairs on the two sides, there are at most $2\mathcal{C}$ nodes. So, by Lemma 1 we find the candidate k in $\mathcal{O}(\min(n, \log p))$ steps. If stairs on the two sides meet before we find a possible $\text{pit}(i, r(i))$, then the topmost stairs are candidates for $\text{top}(i, r(i))$.

If we have found an appropriate node k of minimum $x(k)$, we have to restrict the domain of α values to those for which $f(k)$ ends in an even rung on both sides. Should there be two different *pairs* of even rungs, where $f(k)$ might end, the higher pair does not provide optimal solutions by Theorem 3. Thus, the restricted set of α values is an interval. \square

First suppose that the process of Claim 2 yields possible $\text{top}(i, r(i))$ nodes. Such $(i, r(i))$ pairs constitute the starting steps in the dynamic process. It is trivial to check, which subinterval of the starting domain of α values allows that m is a local maximum (it is easy to show that for $m = \text{top}(i, r(i))$ all of the starting α are realizable). Moreover, each potential m provides a function $F_m(\alpha) = \alpha + C_m$, where C_m is a constant, computable in $\mathcal{O}(\min(n, \log p))$ time along with the procedure of Claim 2. Finally, $F(\alpha) = \alpha + C$ where $C = \min_m C_m$.

Second, suppose we have a candidate $k = \text{pit}(i, r(i))$. How do we compute the optimum function $F_k(\alpha)$ for this k ? Claim 2 settled a restricted interval domain for α s.t. $f(k)$ ends in a fixed pair of even rungs. We only search for “hereditarily” regular solutions. In this case the optimum function on $\langle \ell(k) + 1, k - 1 \rangle$ has the form $F'(\beta) = \beta + C'$ and the optimum function on $\langle k + 1, r(k) - 1 \rangle$ has the form $F''(\gamma) = \gamma + C''$, where β and γ are the numbers of black-black conflicts of

$(\ell(k), k)$ resp. $(k, r(k))$ below $f(k)$. These functions we computed earlier. Now we further restrict the domain of α so that the β and γ values stay within the domains of F' , resp. F'' . Since we take intersection of intervals, we have the following:

- (1) the restricted domain of $F(\alpha)$ is an interval $[\alpha_0, \alpha_0 + \Delta]$.
- (2) the corresponding finish times range from $f_0(k)$ to $f_0(k) - \Delta$.
- (3) β ranges from β_0 , to $\beta_0 + \Delta$ and γ ranges from γ_0 , to $\gamma_0 + \Delta$.

The stairs $\langle i + 1, \ell(k) \rangle$ and $\langle r(k), r(i) - 1 \rangle$ have constant finish times, that total up to some S (see Corollary 1).

So, we have $F_k(\alpha_0 + \delta) = F'(\beta_0 + \delta) + f_0(k) - \delta + F''(\gamma_0 + \delta) + S = \beta_0 + \delta + C' + f_0(k) - \delta + \gamma_0 + \delta + C'' + S = \alpha_0 + \delta + C_k$. That is, $F_k(\alpha) = \alpha + C_k$, where $C_k := \beta_0 + C' + f_0(k) + \gamma_0 + C'' + S - \alpha_0$.

The even k , and the odd l candidate for $\text{pit}(i, r(i))$ yield the optimum functions $F_k(\alpha)$ and $F_l(\alpha)$. Theorem 2 makes sure, that the function of smaller constant (C_k or C_l) is the better one overall.

The last steps of this dynamic process are calculating the optimum on $\langle i, r(i) \rangle$, $(\langle \ell(i), i \rangle)$ when i is compact. We also include here the case when $\langle i, j \rangle$ is a block and $x(i) = x(j)$. Suppose that node i is fixed, then node $r(i)$ (in this broader sense) may be a node of arbitrary parity, s.t. $x(r(i)) \leq x(i)$. By Lemma 3 (a.), it is enough to test $\leq 2\mathcal{C}$ such nodes of both parity in both directions to be $r(i)$.

A natural variant of Theorem 3 holds for compact i . The 2 potential k (or 4 potential $m = \text{top}(i, r(i))$) nodes can be found as described in Claim 2. Since (P4) does not apply to such a k , $f(i)$ does not determine $f(k)$. Let k be fixed and even, and let $f_0(k)$ be the potential finish time of k as determined by $f(i) = x(i)$ like in Claim 2. The starting domain of possible $f(k)$ values is $f(k) \in [x(k), f_0(k)]$. This domain is trimmed further so that $f(k)$ ends in rungs of some even $L(k)$ and $R(k)$. (There are ≤ 3 different pairs of $L(k)$ and $R(k)$ to be considered.) We fix $L(k)$ and $R(k)$ as well. Now the possible $f(k)$ values constitute an interval \mathcal{I} .

We have the optimum functions $F'_k(\beta)$ on $\langle \ell(k) + 1, k - 1 \rangle$ and $F''_k(\gamma)$ on $\langle k + 1, r(k) - 1 \rangle$. The domains of these two functions correspond to two intervals of possible $f(k)$ values. We take the intersection of these two intervals and \mathcal{I} . The maximum possible $f(k)$ will provide the optimum sum of finish times on $\langle i + 1, j \rangle$ for this $k, L(k)$ and $R(k)$.

We conclude Phase 1. with searching for (potential) blocks (i, j) (resp. (j, i)) assuming that $f(i) \geq f(j)$. Let i be fixed. Since $x(r(i)) = x(i)$ was allowed, we may assume that $r(i) \leq j$. Claim 3 shows that for a fixed $(i, r(i))$ pair, any possible j is within the first $< 2 \log p$ nodes to the right of $r(i)$.

Claim 3. Let (i, j) be a block in a solution Φ , s.t. $x(i) > x(j)$. Let $r(i) = s_\eta < \dots < s_2 < s_1 < j$ be the series of consecutive stair-downs leading from $r(i)$ to j . Then $\forall \tau \ x(s_{\tau+2}) \geq 2x(s_\tau)$.

Let $F(i, j)$ denote the optimum sum of finish times on $\langle i + 1, j \rangle$. Calculating $F(i, j)$ is straightforward from the optimum on $\langle i, r(i) \rangle$. We can define a graph $G(V, E)$ on the nodes $V := \{0, 1, \dots, n, n + 1\}$ having $\leq 8 \cdot \mathcal{C} \cdot n \min(2 \log p, n)$ edges. An edge leads between i and j if (i, j) is a potential block. The edge

can be weighted by $F(i, j)$. Finally, we determine the optimum and the blocks on $\langle 0, n+1 \rangle$ dynamically: if i is compact, then $F(i)$, the optimum on $\langle 0, i \rangle$ is determined by $F(i) = \min\{F(i-t) + F(i-t, i) \mid (i-t, i) \in E\}$. The running time is proportional to the number of edges in G .

Phase 2. Now we have the blocks, and the minimum-tree for each block in an optimal solution. Let (i, j) be a block of t nodes and $x(i) > x(j)$. First we schedule the stairs $\langle r(i), j \rangle$. Next we schedule $k = \text{pit}(i, r(i))$ and the stairs $\langle i, \ell(k) \rangle$ and $\langle r(k), r(i) \rangle$, and so on. (The root k of the minimum-tree has black levels conflicting with both sides of the block (determined by $f(k)$). These levels can be arbitrary, e.g. the lowest possible such levels.)

The scheduling procedure is basically the same as described in Claim 2. The preemption levels in $\Phi(k)$ are obtained by way of merging the finish-times of stairs on the two sides. Lemma 1 implies that a node has $\mathcal{O}(\min(t, \log p))$ preemption levels. Scheduling the whole block takes $\mathcal{O}(\min(t^2, t \log p))$ time.

5 Concluding Remarks

Since on cycles there is always at least one compact node i , the overlapping path $i, i+1, \dots, i+n, i+n+1 = i \pmod{n}$ constitutes one or more blocks. Let's take the first two nonempty groups of $\mathcal{G}_1, \dots, \mathcal{G}_t$. By Lemma 3, there must be a compact node among the first $\leq 2\mathcal{C}$ nodes of these groups. Testing these possible starting nodes one by one, yields the same $\mathcal{O}(n \cdot \min(n, \log p))$ time bound.

Due to the observation, that the *total* number of different preemption levels is $\leq 2n$ (see [4]), the lower bound for pSMC on paths is $\mathcal{O}(n)$. If we may assign a certain preemption level to a whole set of nodes at once (e.g., in $\langle i, m \rangle$ the odd jobs should be started, and even jobs should be stopped at time a), then it is not excluded that by way of a better analysis or an improved algorithm the time-bound could be reduced. It could also be investigated, what our results imply for conflict graphs with just one, or very few nodes of higher degree.

The Generalized Deadlock Resolution Problem

Kamal Jain¹, MohammadTaghi Hajiaghayi², and Kunal Talwar¹

hajiagha@csail.mit.edu

Abstract. In this paper we initiate the study of the AND-OR directed feedback vertex set problem from the viewpoint of approximation algorithms. This AND-OR feedback vertex set problem is motivated by a practical deadlock resolution problem that appears in the development of distributed database systems¹. This problem also turns out to be a natural generalization of the directed feedback vertex set problem. Awerbuch and Micali [1] gave a polynomial time algorithm to find a minimal solution for this problem. Unfortunately, a minimal solution can be arbitrarily more expensive than the minimum cost solution. We show that finding the minimum cost solution is as hard as the directed Steiner tree problem (and thus $\Omega(\log^2 n)$ hard to approximate). On the positive side, we give algorithms which work well when the number of writers (AND nodes) or the number of readers (OR nodes) are small.

We also consider a variant that we call *permanent deadlock resolution* where we cannot specify an execution order for the surviving processes; they should get completed even if they were scheduled adversarially. When all processes are writers (AND nodes), we give an $O(\log n \log \log n)$ approximation for this problem.

Finally we give an LP-rounding approach and discuss some other natural variants.

1 Introduction

One of the best ways to understand deadlocks in databases is the dining philosophers problem. Say there are five philosophers sitting on a circular table to eat spaghetti, with a fork between every two of them. Each philosopher needs two forks to eat. But everybody grabs the fork on the right, hence everybody has one fork and is waiting for another to be freed. This wait will be never ending unless one of the philosophers gave up and freed up his fork. This never ending is an example of a *deadlock*. Picking up a philosopher who can give up on eating the spaghetti is an example of *deadlock resolution*. Now suppose that these philosophers have different likings for the spaghetti and hence different inherent costs of giving up eating it. In this case we want to pick the philosopher who likes spaghetti the least. This is called the *minimum cost deadlock resolution* problem.

In databases, philosophers correspond to independent agents e.g., transactions and processes. Forks correspond to shared resources, e.g., shared memory. Eating spaghetti

¹ Thanks to Ondrej Such from Microsoft for asking an algorithm for this problem.

corresponds to actions which these independent agents want to perform on the shared resources e.g., reading or writing a memory location. So in general besides asking for two forks these philosophers may ask for two spoons too, while they have grabbed only one each. These spoons and forks can be of different kinds (e.g., plastic or metallic). In general demands for resources can be very complicated and it can be represented by a monotonic binary function, called *demand function*. A demand function takes a vector of resources as an input and outputs whether it can satisfy the demand or not.

When a process does not get all the resources to satisfy its demand then it has to wait. Like any other protocol involving waiting, there is a risk of deadlock. There are ways to avoid deadlock, like putting a total order on all the resources and telling to the users to ask them in the same order. In big or distributed databases, such solutions are difficult to implement. Moreover such a solution works when the demand functions consist of only ANDs. In essence deadlocks do happen and they need to be resolved at a small cost. In practice one of the convenient solution is to time out on wait, i.e., if it takes too long for a transaction to acquire further resources then it aborts and frees up the resources held so far. This solution does not have any guarantee on the cost incurred. For notational convenience, aborting a transaction will also be referred as *killing* it. We assume that there is an associated cost of killing a process (this cost can also be the cost of restarting it). The cost of a solution is the total cost of all the processes killed. For the minimum cost deadlock resolution problem we want to kill the least expensive set of processes to resolve the deadlock.

An instance of a generalized deadlock detection problem is captured by a *waits-for-graph* (WFG) on transactions. An old survey by Knapp [17] mentions many relevant models of WFG graphs. In the AND model, formally defined by Chandy and Misra [5], transactions are permitted to request a set of resources. A transaction is blocked until it gets all the resources it has requested. In the OR model, formally defined by Chandy et al. [6], a request for numerous resources are satisfied by granting any requested resource, such as satisfying a read request for a replicated data item by reading any copy of it. In a more generalized AND-OR model, defined by Gray et al. [12] and Herman et al. [15], requests of both kinds are permitted. A node making an AND request is called an AND node and a node making an OR request is called an OR node. An advantage of using both these kinds of nodes is that one can express² arbitrary demand functions e.g., if a philosopher wants any one fork and any one spoon then we can create two sub-agents for this philosopher, one responsible for getting a fork and the other for getting a spoon. This philosopher then becomes an AND node and the two sub-agents become two OR nodes. From the perspective of algorithm design, detecting deadlocks in all these models is not a difficult task (see e.g. [11, 21, 23]). The difficult task is to resolve it once detected and that too at a minimum cost (for some heuristics and surveys on the generalized AND-OR model see e.g. [1, 3, 4, 14]). In the next section we formally model the problem as an AND-OR directed feedback vertex set problem.

Often it may not be possible for the deadlock resolving algorithm to specify a schedule for the remaining processes, and when the cost of calling the deadlock resolution algorithm is large (as one would expect in a distributed setting), we would like that

² This expression may be of exponential size. See [17] for more models of waits-for-graphs.

no matter in what order the surviving transactions are scheduled, they do not deadlock again. This motivates the *permanent deadlock resolution* problem. For the case when the transactions are all writers (the AND only case), we show a polynomial-time approximation algorithm for the problem.

1.1 Our Results

When all the nodes are OR nodes then the problem can be solved in polynomial time via strongly connected components decomposition. But the problem quickly becomes at least as hard as the set-cover problem even in the presence of a single AND node. Our reduction has deadlock cycles of length 3 capturing the special case mentioned by Jim Gray, who says in practice deadlocks happen because of cycles of length 2 or 3. We give an $O(n_a \log(n_o))$ factor approximation algorithm, where n_o is the number of OR nodes and n_a is the number of AND nodes. On the other hand if all the nodes are AND nodes, the problem is the well-studied directed feedback vertex set problem. There are approximation algorithms with polylog approximation factor for this problem due to Leighton-Rao [18] and Seymour [22]. We generalize those algorithms to destroy all the *handles* at a pivot vertex. We define handles later in the paper and there we also show that destroying handles is a more general problem than destroying cycles. We use this generalization as a subroutine to develop an $O(n_o \log(n_a) \log \log(n_a))$ factor approximation algorithm.

From the hardness point of view, we show that the problem is as hard as the directed Steiner tree problem, which was shown to be hard to approximate better than a factor of $O(\log^{2-\epsilon} n)$ by Halperin and Krauthgamer [13], and has no known polynomial time polylogarithmic approximation algorithm. One difficulty in designing an approximation algorithm for our problem is that we do not know any good LP relaxation. The natural LP relaxation itself is at least as hard as the directed Steiner tree problem, even for the case of one OR node. It will be interesting to interpret our algorithms in terms of LP rounding. We do that in case there is one (or a constant number of) OR nodes. The size of this LP is exponential in the number of OR nodes.

For the *permanent deadlock resolution* problem, we show that the case with only AND nodes is reducible to the feedback vertex set problem in mixed graphs. Acyclicity implies schedulability for both undirected and directed graphs - acyclic undirected graphs have leaves and acyclic directed graphs have sinks. Corresponding theorem for mixed graphs is not clear. We develop a corresponding theorem for bipartite mixed graphs. This leads to an $O(\log n \log \log n)$ approximation algorithm for this problem. We leave open the approximability of this problem in the general case.

This problem was also studied in theoretical computer science by Awerbuch and Micali [1]. In their paper, they mentioned that the ideal goal is to kill a set of processes with minimum cost, but the problem is a generalization of feedback vertex set and seems very hard. Thus they gave a distributed algorithm for finding a minimal solution. Unfortunately, a minimal solution can be arbitrarily more expensive than the minimum cost solution. We study this problem from approximation algorithm point of view. We are excited with the fact that the problem has such a rich mathematical structure. It allows use of many results, which were discovered after the paper due to Awerbuch and Micali. In this paper we try to find a proper place for the problem in the vast area of

approximation algorithms. We show that this problem blends naturally with feedback vertex and arc set problems. From hardness point of view it blends naturally with the directed Steiner tree and set cover problems. In the discussion section we mention an alternative approach to design approximation algorithms for the directed Steiner tree problem. This approach is suggested by interpreting our algorithm for the case of one OR node in terms of linear programming. This approach does not seem to be based upon the standard LP for the directed Steiner tree problem, which some researchers suspect to have integrality ratio worse than polylogarithmic.

Due to interest of space, we omit several proofs in this extended abstract and defer them to the journal version of this paper.

2 Problem Definition and Preliminary Results

All the graphs in this paper are directed without loops or multiple edges, unless stated otherwise. Our graph terminology is as follows. A graph G is represented by $G = (V, E)$, where V (or $V(G)$) is the set of vertices (or nodes) and E (or $E(G)$) is the set of edges. We denote an edge e from u to v by (u, v) , and we call it an *outgoing* edge for u and an *incoming* edge for v . We say node u can *reach* node v (or equivalently v is *reachable* from u) if there is a path from u to v in the graph. We shall use the notation $u \rightsquigarrow v$ to denote that v is reachable from u . We define n to be the number of vertices of a graph when this is clear from context. We denote the maximum out-degree by Δ_{out} and the maximum in-degree by Δ_{in} . We assume that the node set V is partitioned into two sets V_a and V_o . Nodes in V_a and V_o are referred to as AND nodes and OR nodes respectively. We let $n_a = |V_a|$ and $n_o = |V_o|$. With this terminology we now define the wait-for-graphs (WFG).

Each node of a wait-for-graph, $G = (V, E)$, represents a transaction. An edge (u, v) denotes that transaction u has made a request for a resource currently held by transaction v . There are two kinds of nodes. An AND node represents a transaction which has made an AND request on a set of resources, which are held by other transactions. An OR node represents a transaction which has made an OR request on a set of resources. Without loss of generality we assume that a transaction is allowed to make only one request. If a transaction makes multiple requests then we can create a sub-transaction for each request and put the necessary dependency edges. Each transaction has an associated weight. We denote the weight of a transaction u by w_u .

An AND transaction can be scheduled if it gets all the resources it has requested. An OR transaction can be scheduled if it gets at least one of the resources it has requested. Once a transaction is scheduled, it gives up all its locks, potentially allowing other processes to get scheduled. A wait-for-graph is called *deadlock free* if there exist an ordering of the transactions in which they can be executed successfully. If no such ordering exist then we say that the graph has a deadlock. The *minimum cost generalized deadlock resolution problem (GDR)* is to kill the minimum weight set of transactions to free up the resources held by them so that the remaining transactions are deadlock free. In other words, there exists an order on the remaining transactions so that for each AND transaction, each of its children is either killed or can be completed before it and for each OR transaction at least one of its children is either killed or can be completed before it.

2.1 Some Special Cases

We show some simple propositions which give us some intuition about the problem.

Proposition 1. *The GDR problem when there is no OR node has an approximation algorithm with ratio $O(\log n \log \log n)$.*

Proposition 2. *The GDR problem with all OR nodes can be solved in polynomial time.*

In fact, we can strengthen Proposition 2 as follows:

Proposition 3. *The GDR problem, when the reachability graph on the AND nodes is a directed acyclic graph, can be solved in polynomial time.*

Proposition 4. *The GDR problem with uniform weights and $O(\log n)$ AND nodes can be solved in polynomial time.*

Using ideas of Propositions 3 and 4, we can show the following theorem.

Theorem 1. *The GDR problem with uniform weights and n_a AND nodes has an $O(n_a)$ -approximation algorithm.*

3 Hardness Results and Natural LP

In this section, we consider the hardness of the GDR problem. First, we show a simple approximation preserving reduction from the set cover problem to this problem. Recall that the set cover problem is to find a minimum collection \mathcal{C} of sets from a family $\mathcal{F} \subseteq 2^U$, such that \mathcal{C} covers U , i.e. $\cup_{S \in \mathcal{C}} S = U$. From the results of Lund and Yannakakis [20] and Feige [10], it follows that no polynomial time algorithm approximates the set cover problem better than a factor of $\ln n$ unless $NP \subseteq \text{DTIME}(n^{\log \log n})$. Our reduction then implies a similar hardness for the GDR problem. There is no similar inapproximability result known for the directed feedback vertex set problem.

Theorem 2. *There exists an approximation preserving reduction from (unweighted) set cover to GDR with only one AND node.*

It is worth mentioning that in the reduction of Theorem 2, there is only one AND node whose weight is $m + 1$ and the rest of the vertices are OR nodes with weight one. Moreover, the one AND node of high weight can be replaced by $m + 1$ AND nodes of unit weight placed “in parallel”. Thus the uniform weight case is also hard to approximate better than a factor of $\Omega(\log n)$.

Now the question is that whether it is possible to get a better inapproximability result. To answer this question, we use a recent result of Halperin and Krauthgamer [13] on the inapproximability of the *directed Steiner tree* problem. In the directed Steiner tree problem, given a directed graph $G = (V, E)$, a root $r \in V$ and a set of terminals $T \in V$, our goal is to find a minimum subset $E' \subseteq E$ such that in graph $G' = (V, E')$ there is a path from r to every $t \in T$. Halperin and Krauthgamer [13] show that the *directed Steiner tree* problem is hard to approximate better than a factor of $\Omega(\log^2 n)$, unless

$NP \subseteq ZTIME(n^{\text{polylog } n})$. So far, no polynomial-time polylogarithmic approximation algorithm is known for this problem. We show a similar non-approximability result in Theorem 3 for GDR by giving an approximation preserving reduction from directed Steiner tree.

Theorem 3. *There exists an approximation preserving reduction from directed Steiner tree to GDR.*

Proof. We consider an instance of directed Steiner tree given by a directed graph $G = (V, E)$, a set of terminals $T \subseteq V$ and a root node $r \in V$. The goal is to find a minimum cost subset E' of edges containing a path from r to every terminal $t \in T$. The reduction is as follows. For each vertex $v \in V - \{r\}$, we create an OR node v of weight ∞^3 in our GDR instance. For r , we create an OR node r of weight zero. In addition, we have an AND node a of weight ∞ which has an edge (a, t) for each $t \in T$ and an edge (v, a) for each $v \in V$. For each edge $e \in E$, we put an AND-OR gadget shown in Figure 1, with the weight of each node as shown in the figure. Recall that a is the global AND node introduced before and o_e and a_e are new OR and AND nodes corresponding to e respectively. Intuitively, using an edge e in the Steiner tree corresponds to killing the OR node o_e in this gadget.

Next we show that the cost of an optimum Steiner tree is equal to the minimum cost of nodes to be killed such that the remaining graph is deadlock-free. First consider a Steiner tree S in G . We kill all OR nodes corresponding to edges in S . For each edge $e = (u, v) \in S$, killing o_e allows v to be complete after u . Thus, first complete node r , then complete nodes according to the directed Steiner tree. Since the Steiner tree solution contains a path to each terminal, we can complete all terminals. Now, after completing all terminals, we can complete the global AND node a and then complete every other node in the graph.

On the other hand, since the only nodes with finite weight are the OR nodes corresponding to edges and the node corresponding to root r , any feasible solution of finite weight for GDR kills only such nodes. It is easy to check that the set of edges for which the OR nodes are killed contain a directed Steiner tree. □

Again, we might replace each node of weight ∞ with several nodes of unit weight, say $|E(G)|$, in order to reduce the directed Steiner tree problem to the uniform weighted case.

3.1 Natural LP and Hardness

We end this section by considering a natural LP for the GDR problem, which is a generalization of the LP for feedback vertex set (see e.g. [9]). We say a set of nodes H forms a *Minimal Deadlocked Structure (MDS)* if

Fig. 1. Edge $e = (u, v)$ in graph G and its AND-OR gadget in the new instance of GDR

³ As usual, the ∞ weights can be replaced by a (polynomially) large weight.

1. For any OR node $u \in H$, all its outneighbors are in H .
2. For any AND node $u \in H$, at least one of its outneighbors is in H .
3. H is minimal⁴ amongst sets satisfying (1) and (2).

We now write a linear program (called *LP 1*) is as follows: minimize $\sum_{v \in V} w_v x_v$ such that $\sum_{v \in H} x_v \geq 1$ for any *MDS* H and $x_v \geq 0$ for all $v \in V$

Clearly an integral solution to this linear program is a feasible solution to the underlying GDR instance and hence this is a relaxation. However, this linear program can potentially have exponentially many constraints. Note that if the graph G does not have any OR node, *MDS*s are exactly the minimal directed cycles and our LP is the same as the LP considered in [18,22,9] for applying region growing techniques for the feedback vertex set problem. In this special case of feedback vertex set, this LP has a simple separation oracle which enables us to solve it using Ellipsoid method. However, we now show that even the separation oracle for LP 1 is as hard as the directed Steiner tree problem.

Theorem 4. *The separation oracle for LP 1 is as hard as solving directed Steiner tree.*

Proof. A separation oracle for LP 1 solves the following problem: given a vector \vec{x} , is there an *MDS* H for which $\sum_{v \in H} x_v < 1$. We shall reduce the directed Steiner tree problem to this problem

We consider an instance of directed Steiner tree: given a root r and a set of terminals T in a directed graph $G = (V, E)$, is there is Steiner tree of weight at most 1 (by scaling). Without loss of generality we assume G is a directed acyclic graph (DAG), since the directed Steiner tree problem on DAGs is as hard as the one on general directed graphs (see e.g. [7]). Also without loss of generality assume we have weights on vertices instead of edges (again the two problems are equivalent). Now we are ready to demonstrate the reduction. For each vertex $v \in V$, we place an AND node v with x_v equal to its weight in the Steiner instance. For each edge (u, v) in G , we place an edge (v, u) in our new graph. In addition, we add an OR node with $x_o = 0$ which has an outgoing edge (o, t) for each terminal $t \in T$ and an incoming edge (r, o) (r is the root node). Call the new graph G' . It is easy to check that $H \cup \{o\}$ is an *MDS* in G' if and only if H is a directed Steiner tree in G . Hence the claim follows. \square

As shown by Jain et. al. [16], for these kinds of problems optimizing LP 1 is equivalent to solving the separation oracle problem. Furthermore, these reductions are approximation preserving. Thus if we can optimize LP 1 within some factor then we can solve its separation oracle for the same factor. Hence by Theorem 4, we can solve the directed Steiner tree problem within the same factor.

Corollary 1. *Optimizing LP 1 is at least as hard as the directed Steiner tree problem.*

Finally, notice that finding the integrality gap of LP 1 is an interesting open problem.

⁴ With respect to set inclusion.

4 Approximation Algorithms

In this section, we give an $O(\min\{n_a \log n, n_o \log n \log \log n\})$ algorithm for this problem, where n_a is the number of AND nodes and n_o is the number of OR nodes in the instance. Thus, when either of n_a or n_o is small, the problem is well approximable.

In subsection 4.1 we show how to use region growing to solve a slight generalization of feedback vertex set. We use this to get an $O(n_o \log n \log \log n)$ algorithm in subsection 4.2. In subsection 4.3, we give an $O(n_a \log n)$ approximation algorithm for the problem. Thus the better of these two algorithms gives the claimed performance guarantee.

4.1 Handle Removal Algorithm

In this section, we consider the following handle removal problem which plays an important role in the algorithm for the case of few OR nodes (see Section 4.2): Given a directed graph G , and a designated vertex r , delete the smallest number (weight) of vertices such that the remaining graph has no cycles reachable from r . For ease of exposition, we shall replace each vertex by a pair of vertices joined by an edge, and transfer the weight to this edge. The edges in the original graph are given an infinite weight. The problem then reduces to finding the smallest cost set of edges whose removal eliminates all cycles reachable from r .

We shall write this problem as an integer program, and consider its linear programming relaxation. We first formally define a *handle*.

Definition 1. Let $H = (r = u_0, u_1, \dots, u_k)$ be a simple path in G . We call H a handle if for some $p : 0 \leq p < k$, there is an edge (u_k, u_p) . We refer to u_p as the pivot of the handle H . The edges on the path along with the edge $\{u_k, u_p\}$ constitute the edges of the handle.

Let \mathcal{H} be the set of all handles in G . We can write the following linear programming relaxation for this problem: minimize $\sum_{e \in E} w_e x_e$ such that $\sum_{e \in H} x_e \geq 1$ for all $H \in \mathcal{H}$ and $x_e \geq 0$ for all $e \in E$.

Note that the above linear program has an exponential number of constraints. The separation oracle for this LP requires us to find a violated handle in a given fractional solution. Note that we can find in polynomial time, for each $u \in V$, the smallest cycle passing through u , and the shortest path from r to u . The shortest handle in the graph is then just the minimum, over all u , of the sum of the above two quantities. Thus the LP has a polynomial time separation oracle, and hence can be solved by Ellipsoid method.

Given a solution to this linear program, we shall now argue that the techniques used by Seymour [22] and Even et.al. [9] for the feedback arc set problem apply here to give an $O(\log n \log \log n)$ -approximation algorithm to the problem. Given a graph G , and a non negative length function x_e on the edges, we can define the shortest path function d_x on the vertices of G . A modification of the algorithm of Seymour implies the following theorem:

Theorem 5. Given a weighted graph G , a special vertex r and non-negative length function x_e , let $W = \sum_e w_e x_e$. There exists a set of edges C such that:

- $\sum_{e \in C} w_e \leq O(\log n \log \log n) \cdot W$
- For any vertex v with $d_x(r, v) \geq \frac{1}{4}$, C is an r - v cut.
- For any pair of vertices u and v such that $d_x(u, v) \geq \frac{1}{4}$, C contains either a u - v cut or a v - u cut.

We now argue that the rounding described in the theorem applied to a feasible LP solution, gives a feasible solution to the handle removal problem.

Claim. Let x be a feasible solution to the linear program above and d be the shortest path function defined accordingly. Then for any handle H with pivot u , either $d(r, u) \geq \frac{1}{4}$, Or there exists $v \in H$ such that $d(u, v) \geq \frac{1}{4}$.

From the above claim, and theorem 5, it follows that the handle removal problem is approximable within a factor of $O(\log n \log \log n)$.

4.2 Few OR Nodes Algorithm

Using the algorithm for the handle removal problem in section 4.1, we are now ready to prove the following theorem.

Theorem 6. *There is an $O(n_o \log(n_a) \log \log(n_a))$ -approximation algorithm for the Generalized Deadlock Resolution Problem.*

Proof. We first assume that the OR nodes in the graph have infinite cost, and thus are all scheduled. We shall give an $O(\alpha n_o)$ solution where α is the approximability of the handle removal problem.

Let u be the first OR node to be scheduled. Since this node is scheduled, one of its outneighbors, say v , is killed/scheduled before any other OR node. Since no cycle of AND nodes can be scheduled, no such cycle reachable from v survives in the optimum solution. OPT thus includes a solution to the handle removal problem with root v . Let O_v be the optimum of the handle removal problem with root v , when all OR nodes are removed. Hence $OPT \geq \min_{u \in V} \min_{v: (u,v) \in E} O_v$.

Our algorithm is as follows. Using an α -approximation algorithm for the handle removal problem, we compute solutions to handle removal problems rooted at $\{v : (u, v) \in E, u \in V_O\}$. We pick the cheapest of these and kill the nodes in this solution. The cost of killing these nodes is at most αOPT . Now the OR node u can be scheduled, and consequently some more nodes can be scheduled. We remove all such nodes along with their incoming edges, and recur. In the base case, when there are no OR nodes, we have the feedback vertex set problem, which is also approximable within α (by a simple reduction to the handle removal problem). Thus we get obtain $(n_o + 1)\alpha$ approximation.

We now show how to remove the assumption about OR node removal. To each OR node u in the graph, we add a new outneighbor u_a which is an AND node with cost equal to the original OR node. We add another AND node v of infinite cost to the graph, with edges to all the original vertices of the graph. Finally, we add an edge from u_a to the vertex v , and increase the costs of all OR nodes to infinity.

For any solution to the original instance that kills an OR node u , we can get a solution to the new instance by killing u_a . This lets us schedule u instead of killing u . Moreover, after scheduling/killing all original nodes, the node v can be scheduled, after

which any unkilld u_a can be scheduled. Finally, the cost of the new solution is the same as the original one.

A solution to the new instance immediately gives a solution to the original instance: kill OR node u whenever the new solution killed u_a . It is easy to see that this transformation preserves feasibility and cost. □

4.3 Few AND Nodes Algorithm

In this section, we present an $O(n_a \log n)$ -approximation algorithm for this problem. We note that in the reduction of set cover to generalized deadlock resolution (mentioned in Theorem 2), we have only one AND node and thus our result is tight in this case. However, in the reduction of directed Steiner tree to this problem, the number of AND nodes is linear and the best non-approximability result is in $\Omega(\log^2 n)$.

The algorithm is as follows. We start with the original graph G and in each iteration we update it. More precisely, if in an iteration graph G does not have any AND node, we can obtain the optimal solution for G by the procedure mentioned in Proposition 2 (and thus we stop). Otherwise, for each AND node a whose outgoing edges are $(a, c_1), (a, c_2), \dots, (a, c_{\Delta})$ in graph G and all c_i 's, $1 \leq i \leq \Delta_{out}$, are OR nodes, we construct the following hitting set instance (note that the hitting set problem is the dual of the set cover problem). For each c_i , $1 \leq i \leq \Delta_{out}$, we form a set S_i which contains all OR nodes reachable via OR nodes from c_i (i.e. paths from c_i to S_i do not use any AND nodes). Now, the collection \mathcal{C} contains all sets $S_i \subseteq S$, where S is the set of all OR nodes. Using the $(1 + \ln \Delta_{out}) = O(\log n)$ approximation for hitting set, we obtain a set S_a^* of weight w_a^* of OR nodes which hit every set. Let $W_a = \min\{w_a, w_a^*\}$ (w_a is the weight of node a). Choose the AND node a with minimum W_a over all AND nodes. Kill AND node a or all the OR nodes in the corresponding hitting set solution (the one with minimum weight). Clear graph G , i.e., remove every AND/OR node which can be completed after killing the aforementioned nodes, and repeat the above iteration for G . The final solution contain all AND/OR nodes killed during the iterations.

We finish by showing that

Theorem 7. *The above algorithm kills a set of AND/OR nodes such that the remaining graph is deadlock free and the weight of the solution is at most $(1 + \ln \Delta_{out})n_a + 1 = O(n_a \log n)$ times optimum.*

Proof. The correctness of the solution can be easily seen from the description of the algorithm. Thus, we only show the approximation factor here. To this end, we prove that in each iteration, except the case in which there is no AND node, we kill nodes of total weight at most $(1 + \ln \Delta_{out})$ times optimum weight for the updated graph G in that iteration. In the last iteration, we kill nodes of total weight at most OPT according to the description of the algorithm. Using these facts and that OPT in each iteration is at most the original optimum, we obtain the desired approximation factor.

Consider an optimum solution and let a be the first AND node which is completed or killed in the optimum resolution. Thus either we have killed a or we have completed a by killing at least one OR node from the OR nodes reachable from each of its children. Hence for at least one AND node, the weight of the solution to the corresponding hitting set instance is at most the weight of optimum. Since the approximation factor of hitting

set is $1 + \ln \Delta_{out}$ and we try all AND nodes and then take the minimum, the total weight of the killed nodes is at most $(1 + \ln \Delta_{out})$ times optimum, as desired. \square

5 Permanent Deadlock Resolution

Here we consider another version of the deadlock resolution problem where it is not possible for the algorithm to specify a feasible schedule on the remaining processes. In particular, we want to kill enough processes, such that if the remaining processes try to acquire locks in any order, they cannot deadlock. We then say that the remaining processes are *adversarially schedulable*.

We consider the special case of this problem when all processes are writers (AND nodes). In this case, we show that this problem can be reduced to the feedback vertex set problem on mixed graphs (i.e. graphs with both directed and undirected edges). Since this problem yields to the same techniques as those used for feedback vertex set of directed graphs, we get an $O(\log n \log \log n)$ -approximation.

We are given a set of resources R and a set of processes P , each holding a lock on some subset of resources, and waiting to get locks on another subset of resources. We construct a bipartite mixed graph as follows: create a vertex v_r for every resource r with infinite cost, and a vertex v_p for every process p . Whenever process p holds the lock on resource r , we add a directed edge from v_p to v_r . Moreover, we add an undirected edge between v_p and $v_{r'}$ whenever process p is waiting to get a lock on resource r' .

Theorem 8. *An instance is adversarially schedulable if and only if the corresponding graph is acyclic.*

Proof. We first argue that greedily schedulability implies acyclicity. Assume the contrary, and let the graph have a cycle $p_1, r_1, p_2, r_2, \dots, p_k, r_k, p_1$. Now consider the schedule in which p_i grabs a lock on r_i (or already holds it, in case the edge is directed). Note that p_i waits for a lock on r_{i-1} and p_1 waits on r_k . this entails a cyclic dependency amongst processes p_1, \dots, p_k : p_i cannot finish unless p_{i-1} finishes and releases r_{i-1} . This configuration is therefore deadlocked. Since we have shown how to reach a deadlocked state from the initial state, the initial state was not adversarially schedulable, which contradicts the assumption. Hence the claim follows.

Now suppose that the graph is acyclic. We claim that the initial configuration is adversarially schedulable. Suppose not. Then there is a sequence of lock acquisition that lead to a deadlocked configuration. Clearly, a deadlocked configuration corresponds to processes p_1, p_2, \dots, p_k such that p_{i+1} is waiting for p_i to release some resource r_i . Since p_i holds r_i in this configuration, (p_i, r_i) must be directed/undirected edge in the graph. Moreover, since p_{i+1} is waiting for r_i , (r_i, p_{i+1}) is an undirected edge in the graph. However, we have just shown that $p_1, r_1, p_2, r_2, \dots, p_k, r_k, p_1$ is a cycle in G , which contradicts the acyclicity of G . Thus the claim follows. \square

Theorem 9. *The permanent deadlock resolution problem for AND nodes has an $O(\log n \log \log n)$ approximation algorithm.*

Acknowledgement

We would like to thank, Ondrej Such, a developer at Microsoft for asking his question on the Algorithm's email list. The first author would also like to thanks Joseph Cheriyan and Laci Lovasz for many initial and fruitful discussions. He would also like to thank David Shmoys for a very short but helpful discussion. The last author would like to thank Christos Papadimitriou and Joe Hellerstein for very useful discussions.

Abstract. In this paper we present a randomized constant factor approximation algorithm for the problem of computing the optimal *cost* of the metric Minimum Facility Location problem, in the case of uniform costs and uniform demands, and in which every point can open a facility. By exploiting the fact that we are approximating the optimal cost without computing an actual solution, we give the first algorithm for this problem with running time $O(n \log^2 n)$, where n is the number of metric space points. Since the size of the representation of an n -point metric space is $\Theta(n^2)$, the complexity of our algorithm is *sublinear* with respect to the input size.

We consider also the general version of the metric Minimum Facility Location problem and we show that there is no $o(n^2)$ -time algorithm, even a randomized one, that approximates the optimal solution to within any factor. This result can be generalized to some related problems, and in particular, the cost of minimum-cost matching, the cost of bichromatic matching, or the cost of $n/2$ -median cannot be approximated in $o(n^2)$ -time.

1 Introduction

The design of algorithms operating on massive data sets has received a lot of attention in recent years. The practical motivation of this study is that polynomial-time algorithms that are efficient in relatively small inputs, may become impractical for input sizes of several gigabytes. For example, when we consider approximation algorithms for clustering problems in metric spaces then they typically

* Research supported in part by NSF grant ITR-CCR-0313219.

** Research supported in part by DFG grant Me 872/8-2 and by the IST program of EC under contract no. IST-2002-001-907 (DELIS).

have $\Omega(n^2)$ running time where n is the number of input points. Clearly, such a running time is not feasible for massive data sets. But for many problems — like the facility location problem considered in this paper — such a running time is provably unavoidable. Surprisingly, these lower bounds do not necessarily hold when one wants to estimate the *cost* of an optimal solution. In this paper we will indeed show that one can find a constant factor approximation algorithm for the metric uncapacitated facility location problem with uniform costs and in which every point can open a facility, that runs in $O(n \log^2 n)$ time, that is, in time *sublinear* in the input size.

Our approach is motivated by the fact that in many applications it suffices to know an *approximate cost* of the facility location problem rather than to find an approximate solution to the facility location problem. Let us consider the example that a company wants to invest money and it can relate the cost of the facility location problem to the possible return on investment. Then it would first solve an instance of the problem for every market to find out the most profitable one. In such a situation it is sufficient to know the return on investment before one decides which market to enter. It is not (yet) necessary to know how to achieve it. Finally, when one knows which market to enter one only has to compute a solution to a single instance of the problem. Therefore, if one could approximate the *cost* of an optimal solution significantly faster than finding such a particular approximate solution this would significantly speed up the market analysis.

Similar arguments hold for another popular application of facility location algorithms, that of clustering data sets. In particular, it is good to know if the data can be “well-clustered” before actually attempting to find the clustering.

1.1 Our Results

In this paper we consider the metric Minimum Facility Location problem with uniform opening costs and demands, and in which every point can open a facility. We give a randomized $O(1)$ -approximation algorithm for this problem that runs in time $O(n \log^2 n)$, where n is the number of metric space points. Since the size of the representation of an n -point metric space is $\Theta(n^2)$, the complexity of our algorithm is *sublinear* with respect to the input size. No $o(n^2)$ -time approximation algorithm for this problem was known before. It has been known that any constant factor approximation algorithm that returns not only the cost, but also a solution itself, requires the running time of $\Omega(n^2)$ [14].

Next, we prove that if the set of facilities and the cities (points that are to be connected to the facilities) are allowed to be disjoint, then any, *even randomized*, approximation algorithm for the cost of the Minimum Facility Location that guarantees any bounded approximation ratio for the cost, requires time $\Omega(n^2)$. This bound holds even when the opening costs and demands are uniform. Furthermore, our proof can be extended to the problems of estimating the *cost of minimum-cost matching*, the *cost of bi-chromatic matching*, and the *cost of k -median* for $k = n/2$; all these problems require $\Omega(n^2)$ to estimate the cost of their optimal solution to within any factor. We feel that these results

demonstrate that most optimization problems for metric instances do not have sublinear-time algorithms even to estimate well the cost of the optimal solution; results like our sublinear-time algorithm for a $O(1)$ -factor approximation of the cost of the optimum solution for the metric uniform Minimum Facility Location problem are rare (see however, [4, 6, 7]).

1.2 Our Techniques

Our analysis of a sublinear-time algorithm consists of two principal steps: we first prove the existence of an appropriated estimator for the cost of the Minimum Facility Location problem and then we show how such an estimator can be approximated in time $O(n \log^2 n)$. Our estimator is obtained by extending the primal-dual approach from [12]: for each point we define an approximation of the contribution of that point to the total cost, and then we prove that the sum of the contributions for all the points approximates the cost of the Minimum Facility Location problem. An important property of our estimator is that it can be efficiently approximated by *adaptive sampling*. We first prove that the individual value of an estimator for any single point can be efficiently approximated by sampling with the running time depending on the value of the estimator, and then we apply another adaptive sampling scheme to efficiently approximate the sum of the estimators. A similar approach has been used in recent sublinear-time algorithms for estimating the cost of the minimum spanning tree problem in [2] and [4].

1.3 Definition of the Problem

The formal definition of the general form of the (Metric) *Minimum Facility Location* problem is as follows: We are given a metric (P, D) , and a subset $\mathcal{F} \subseteq P$ of *facilities*. For each facility $v \in \mathcal{F}$, we are given a nonnegative *cost* $f(v)$, and for each point $u \in P$, a nonnegative *demand* $d(u)$. The problem consists of finding a set $F \subseteq \mathcal{F}$, so as to minimize

$$\sum_{v \in F} f(v) + \sum_{u \in P} d(u) \cdot D(u, F) ,$$

where $D(u, F) = \min_{v \in F} D(u, v)$.

In this paper we focus on the variant of the facility location problem with $\mathcal{F} = P$ and in which the costs as well as the demands are uniform. That is, for each $v \in \mathcal{F}$, $f(v) = c$ for some $c > 0$, and for each $u \in P$, $d(u) = 1$. Observe that we can assume that $c = 1$, if we re-scale the given metric, by dividing all the distances by c . In what follows, we will refer to this variant of the facility location problem as *uniform*.

The key property of our formulation, is that we are interested in computing the cost of the optimal solution, without computing a solution itself. Thus, in what follows, our task is to approximate the value:

$$\min_{F \subseteq P} |F| + \sum_{u \in P} D(u, F) .$$

In the final part of the paper we also consider a more general variant of the problem when P and \mathcal{F} do not have to be the same. We prove in Theorem 2 that in that case there is no hope to obtain a sublinear-time algorithm.

1.4 Previous Work

The *Minimum Facility Location* problem is one of the most extensively studied problems in combinatorial optimization. The problem is known to be \mathcal{NP} -hard and the first constant factor approximation algorithm was given by Shmoys et al. [13]. Several other approximation algorithms are given in [1, 3, 8]. The best approximation ratio of 1.52, is due to Madhian, Ye, and Zhang [10], while the best lower bound of 1.463 for the approximation ratio is due to Guha and Khuller [5].

The first constant factor approximation algorithm with almost linear running time (that is, the running time of $O(n^2 \log n)$) was given by Jain and Vazirani [9]; Mettu and Plaxton [12] gave a simple $O(n^2)$ -time constant approximation ratio algorithm. Thorup [14] considered the facility location problem in metric spaces defined by a graph. If the underlying graph has m edges, then even though the metric space is of size $\Theta(n^2)$, Thorup gives a constant-factor approximation algorithm running in time $\tilde{O}(m)$; this is a sublinear time for sparse graphs. On the other hand, it has been shown [14] that for general metric spaces, any constant factor approximation algorithm, even a randomized one, requires running time of $\Omega(n^2)$. Notice that this does not exclude the possibility of approximating the *cost* of the Minimum Facility Location problem in sublinear time, in particular, in time $O(n \text{ polylog}(n))$.

2 Estimating the Cost of Uniform Minimum Facility Location

In this section we present an $O(n \log^2 n)$ time algorithm that approximates the cost of the Minimum Facility Location in the uniform case, that is, when the costs as well as the demands are uniform.

2.1 Preliminaries

Let (P, D) be a metric with a point set $P = \{p_1, \dots, p_n\}$. For any point $p_i \in P$, and for any $r \geq 0$, we denote by $B(p_i, r)$ the set of points in P which are at distance at most r from p_i . For each i , $1 \leq i \leq n$, let $r_i > 0$ be the number satisfying

$$\sum_{p \in B(p_i, r)} (r_i - D(p_i, p)) = 1 .$$

Observe that the value $\sum_{p \in B(p_i, r)} (r - D(p_i, p))$ is continuous and strictly monotonically increasing with r . Thus, there exists a unique value r_i satisfying the above equality. Moreover, for any i , $1 \leq i \leq n$, we have $1/n \leq r_i \leq 1$.

We begin with a lemma that establishes the relation between the value of r_i and the size of $B(p_i, r_i)$.

Lemma 1. *For every i , with $1 \leq i \leq n$, we have $\frac{1}{|B(p, r)|} \leq r_i \leq \frac{2}{|B(p, r/2)|}$.*

Proof. By the definition of r_i , we have $\sum_{p \in B(p, r)} (r_i - D(p_i, p)) = 1$, which implies $\sum_{p \in B(p, r)} r_i \geq 1$, and thus $r_i \geq 1/|B(p_i, r_i)|$. The other inequality follows directly from the following,

$$1 = \sum_{p \in B(p, r)} (r_i - D(p_i, p)) \geq \sum_{p \in B(p, r/2)} (r_i - D(p_i, p)) \geq |B(p_i, r_i/2)| \cdot r_i/2. \quad \square$$

MP algorithm. In our analysis we will use a simple approximation algorithm for the Minimum Facility Location problem due to Mettu and Plaxton [12]; we will refer to that algorithm as the *MP algorithm*.

1. Compute the value of r_i for every $p_i \in P$.
2. Sort the input such that $r_1 \leq r_2 \leq \dots \leq r_n$.
3. For $i = 1$ to n : if there is no open facility in $B(p_i, 2r_i)$ then open the facility at p_i .

Mettu and Plaxton [12] proved that this simple algorithm will return a set of open facilities for which the total cost is at most 3 times the minimum.

2.2 Cost Estimation

In this section, we show that the sum of the radii approximates the optimal cost of the facility location to within a constant factor. Our analysis uses the relation between the sum $\sum_{p \in P} r_i$ and the cost of optimal solution and that of the solution obtained by the MP algorithm discussed above.

Let C_{OPT} be the cost of an optimal solution. Let also F_{MP} be the set of facilities computed by the MP algorithm. For this solution given by the MP algorithm, we define C_{MP} , C_{MP}^c , and C_{MP}^f to be the total cost, the connection cost, and the facility cost respectively.

The following lemma shows that the sum of the radii estimates well C_{OPT} .

Lemma 2. $\frac{1}{4} \cdot C_{OPT} \leq \sum_{p \in P} r_i \leq 6 \cdot C_{OPT}$.

Proof. We first prove the lower bound that $C_{OPT} \leq 4 \cdot \sum_{p \in P} r_i$ and then the upper bound that $\sum_{p \in P} r_i \leq 6 \cdot C_{OPT}$.

Lower bound: Since in the MP algorithm for every $p_i \in P$ there is an open facility within distance at most $2r_i$ (for if not, then the algorithm would open the facility at p_i), we get that $2 \sum_{p \in P} r_i \geq C_{MP}^c$.

It remains to show that $\sum_{p \in P} r_i$ is an upper bound for C_{MP}^f . We first observe that every $p_i \in P$ is contained in at most one ball $B(p_j, r_j)$, for some $p_j \in F_{MP}$. Indeed, if $p_i \in B(p_j, r_j) \cap B(p_k, r_k)$ for some $p_j, p_k \in F_{MP}$, $j < k$, then since

$r_j \leq r_k$, we would have $p_j \in B(p_k, 2r_k)$. But this implies that the MP algorithm would not open the facility at p_k , a contradiction.

This observation yields:

$$\sum_{p \in P} r_i \geq \sum_{p \in F} \sum_{p \in B(p, r)} r_k . \tag{1}$$

Next, we observe that if $p_j \in F_{MP}$ and $p_k \in B(p_j, r_j)$, then we must have $r_j \leq 2r_k$. Indeed, for if not, then we would have $B(p_k, 2r_k) \subseteq B(p_k, r_j) \subseteq B(p_k, r_j + D(p_j, p_k)) \subseteq B(p_j, 2r_j)$, and thus the MP algorithm would not open the facility at p_j , a contradiction. This observation can be now combined with (1) to conclude:

$$\begin{aligned} \sum_{p \in P} r_i &\geq \sum_{p \in F} \sum_{p \in B(p, r)} r_k \geq \sum_{p \in F} \sum_{p \in B(p, r)} r_j/2 \\ &= \frac{1}{2} \cdot \sum_{p \in F} r_j \cdot |B(p_j, r_j)| \geq \frac{1}{2} \cdot \sum_{p \in F} 1 = \frac{1}{2} \cdot C_{MP}^f , \end{aligned}$$

where the second inequality follows from the fact that $r_j \geq 1/|B(p_j, r_j)|$ (Lemma 1). Thus, we have $2 \cdot \sum_{p \in P} r_i \geq C_{MP}^c/2 + C_{MP}^f/2 \geq C_{MP}/2 \geq C_{OPT}/2$.

Upper bound: Next, we show that the sum of the radii is not much bigger than the cost of optimal solution. Before we proceed, we introduce one definition from [12]. For a set $X \subseteq P$ and a point $p_i \in P$, we define

$$charge(p_i, X) = D(p_i, X) + \sum_{p \in X} \max\{0, r_j - D(p_i, p_j)\} .$$

Mettu and Plaxton proved [12] that $C_{MP} = \sum_{p \in P} charge(p_i, F_{MP})$.

Now we are ready to prove that $\sum_{p \in P} r_i \leq 2 \cdot C_{MP}$ what will imply that $\sum_{p \in P} r_i \leq 6 \cdot C_{OPT}$. We have,

$$\begin{aligned} 2 \cdot C_{MP} &= 2 \cdot \sum_{p \in P} charge(p_i, F_{MP}) \\ &\geq 2 \cdot \left(\sum_{p \in F} r_i + \sum_{p \in P \setminus F} \max\{r_{\delta(j)}, D(p_j, p_{\delta(j)})\} \right) , \end{aligned}$$

where $\delta(j)$ denotes the index of the facility in F_{MP} that is closest to p_j . We want to show

$$2 \cdot \left(\sum_{p \in F} r_i + \sum_{p \in P \setminus F} \max\{r_{\delta(j)}, D(p_j, p_{\delta(j)})\} \right) \geq \sum_{p \in P} r_i .$$

We will show that $r_j \leq D(p_j, p_{\delta(j)}) + r_{\delta(j)}$, which immediately implies the above inequality because then $\max\{r_{\delta(j)}, D(p_j, p_{\delta(j)})\} \geq r_j/2$. Assume $r_j > D(p_j, p_{\delta(j)}) + r_{\delta(j)}$. In this case we have $B(p_{\delta(j)}, r_{\delta(j)}) \subseteq B(p_j, r_j)$. We get

$$\begin{aligned} \sum_{p \in B(p_j, r_j)} (r_j - D(p_j, p)) &\geq \sum_{p \in B(p_j, r_j)} (r_j - D(p_j, p)) \\ &> \sum_{p \in B(p_j, r_j)} (r_{\delta(j)} - D(p_{\delta(j)}, p)) = 1. \end{aligned}$$

This is a contradiction because the definition of r_j requires

$$\sum_{p \in B(p_j, r_j)} (r_j - D(p_j, p)) = 1.$$

To summarize, we have proven that $2 \cdot C_{MP} \geq \sum_{p \in P} r_i$, and now the lower bound follows from the fact that $C_{MP} \leq 3 \cdot C_{OPT}$ [12]. □

2.3 Estimating the Cost of the Facility Location Problem

From the previous section we know that to approximate the cost of the facility location problem it suffices to estimate the sum $\sum_i r_i$ of the radii r_1, \dots, r_n of the points p_1, \dots, p_n . A standard approach to this problem would be to sample a set of s points (for a suitable s), determine (possibly approximately) their radii, and then output n times their average radius as an approximation for $\sum_i r_i$. However, this approach cannot lead to a sublinear-time algorithm for the following reason. In general, the time to determine the radius of a point in $\Omega(n)$. For example, this might be the case when the radius is constant, because there is only a constant number of points within the radius. Therefore, to certify that a point has constant radius the algorithm must be able to certify that no more than a constant number of points are within the radius. This task cannot be done in $o(n)$ time (even if one aims at an approximation and uses randomization). We also note that, in general, $s = \Omega(n)$, if we need a constant factor approximation of $\sum_i r_i$. This follows from standard Chernoff-Hoeffding bounds (which are essentially tight in this setting) and the fact that the average radius can be as small as $1/n$. Therefore, this standard sampling approach would not give us a sublinear time algorithm.

In the following we will show that an *adaptive sampling* algorithm can estimate the size of r_i in $O(r_i n \log n)$ time (recall that $r_i < 1$). We start with a constant size sample of points and determine their average radius. If our sample is too small we double it and continue until we have found a sample of sufficient size. For the analysis we will parameterize the sample size s by the average value of the r_i . Combining this with the running time of the adaptive algorithm leads to a sublinear algorithm. Details follow in the next two subsections.

2.4 Estimating r_i

In this section we present an algorithm that for a given i , in time $O(r_i n \log n)$ approximate the value of r_i to within a constant factor, with high probability.

Let us fix i . Our approach of estimating the value of r_i is by approximating the value of r for which $B(p_i, r)$ contains approximately $1/r$ points. This is formalized in the following lemma.

Lemma 3. *Let j_0 be the maximum integer j , with $1 \leq j \leq \log n$, such that $|B(p_i, 2^{-j})| \geq 2^j$. Then, we have $2^{-(j_0+1)} \leq r_i \leq 2^{-j_0+1}$.*

Proof. We will use Lemma 1. By our assumption about j_0 we have $|B(p_i, 2^{-(j_0+1)})| < 2^{j_0+1}$ and $|B(p_i, 2^{-j_0})| \geq 2^{j_0}$. The first inequality implies that for any $r < 2^{-(j_0+1)}$, $|B(p_i, r)| \leq |B(p_i, 2^{-(j_0+1)})| < 2^{j_0+1} < 1/r$. This bound together with the lower bound in Lemma 1 yield that $r_i \geq 2^{-(j_0+1)}$. On the other hand, the inequality $|B(p_i, 2^{-j_0})| \geq 2^{j_0}$ implies that for any $r > 2^{-j_0+1}$, $|B(p_i, r/2)| \geq |B(p_i, 2^{-j_0})| \geq 2^{j_0} > 2/r$. Therefore, by the upper bound in Lemma 1 we must have $r_i \leq 2^{-j_0+1}$. \square

Lemma 3 implies that in order to estimate r_i , it suffices to estimate the value of j_0 . Our algorithm to estimate j_0 runs as follows: We begin with setting $j = \log n$, and then we are decreasing j by one until for the first time $|B(p_i, 2^{-j})| \geq 2^j$. Since computing $|B(p_i, 2^{-j})|$ exactly requires $\Omega(n)$ time, we only approximate $|B(p_i, 2^{-j})|$ by *random sampling*. This reduces the running time. At each step, we pick uniformly at random, and with replacement, $K_j = c 2^{-j} n \log n$ sample points to estimate the value of $|B(p_i, 2^{-j})|$, where c is a sufficiently large constant. Let N_j be the number of sample points that are inside the ball $B(p_i, 2^{-j})$. We return $\beta_j = n N_j / K_j$ as the estimator of $|B(p_i, 2^{-j})|$.

In the following three lemmas we first analyze the quality of the estimator β_j and then discuss the running time of this sampling scheme.

Lemma 4. *If $j \geq j_0 + 2$, then $\Pr[\beta_j \geq 2^j] < 1/\text{poly}(n)$.*

Proof. Since $j \geq j_0 + 2$, it follows that $B(p_i, 2^{-j}) \subseteq B(p_i, 2^{-(j_0+1)})$. Let q be the probability that a randomly chosen sample point is in $B(p_i, 2^{-j})$. We have $q \leq |B(p_i, 2^{-(j_0+1)})|/n$. By the choice of j_0 , we have $|B(p_i, 2^{-(j_0+1)})| < 2^{j_0+1}$, and thus $q < 2^{j_0+1}/n \leq 2^{j-1}/n$.

The expected number of sample points that fall inside $B(p_i, 2^{-j})$ is $\mathbf{E}[N_j] = qK_j < \frac{c \log n}{2}$. Applying the Chernoff bound, we obtain

$$\Pr[\beta_j \geq 2^j] = \Pr[N_j \geq c \log n] < 1/\text{poly}(n) . \quad \square$$

Lemma 5. *If $j \leq j_0 - 1$, then $\Pr[\beta_j \geq 2^j] > 1 - 1/\text{poly}(n)$.*

Proof. Since $j \leq j_0 - 1$, it follows that $|B(p_i, 2^{-j})| \geq |B(p_i, 2^{-j_0})| \geq 2^{j_0} \geq 2^{j+1}$. Let q be the probability that a randomly chosen sample point is in $B(p_i, 2^{-j})$. We have that $q \geq 2^{j+1}/n$.

The expected number of sample points that fall inside $B(p_i, 2^{-j})$ is $\mathbf{E}[N_j] = qK_j \geq 2c \log n$. Applying the Chernoff bound, we obtain

$$\Pr[\beta_j \geq 2^j] = \Pr[N_j \geq c \log n] > 1 - 1/\text{poly}(n) . \quad \square$$

Lemma 6. *The described procedure estimates the value of r_i to within a constant factor in time $O(r_i n \log n)$, with high probability.*

Proof. Let j'_0 be the estimated value of j_0 . By Lemmas 4 and 5, it follows that with high probability, $j_0 \leq j'_0 \leq j_0 + 1$. If we use the value $r'_i = 2^{-j'_0}$ as an estimation of r_i , then by Lemma 3 we obtain that $r_i/2 \leq r'_i \leq 4r_i$.

Moreover, with high probability, the running time of the procedure is at most $\sum_{j=j_0}^{\log n} O(K_j) = O(r_i n \log n)$. □

2.5 Estimating the Sum of the Radii

In this section we show how to estimate $\sum_i r_i$ in time almost linear in n . Let us first assume that we know the cost of the solution c , and we sample a set of s points independently and uniformly at random, where $s = \Theta(\frac{n}{c} \log n)$. Since by Lemma 6, the running time to estimate a radius r_i is $O(r_i n \log n)$, the total expected running time of the algorithm is

$$\mathbf{E}[\text{time}] = s \cdot \mathbf{E}[\text{one step}] = s \cdot O\left(\frac{1}{n} \cdot \sum_i r_i n \log n\right) = O(n \log^2 n) .$$

Let x_i , for $i \in \{1, 2, \dots, s\}$, be the radii of the sample points taken by the algorithm. We have

$$\mathbf{E}[x_i] = \frac{\sum_j r_j}{n} .$$

Let $S = \sum_{i=1}^s x_i$ and hence, $\mathbf{E}[S] = \frac{s \cdot \sum r}{n} = \frac{\Theta(-\log n) \cdot \sum r}{n} = \Theta\left(\frac{\sum r}{c} \cdot \log n\right) = \Theta(\log n)$. Let $\epsilon > 0$ be arbitrary. Our goal is to use the value of S as the estimator of $\frac{n}{s} \sum_i r_i$. To show the quality of this estimator we will bound $\Pr[|S - \mathbf{E}[S]| \geq \epsilon \cdot \mathbf{E}[S]]$. By using the fact that $0 \leq x_i \leq 1$ for every i , we apply a variant of the Hoeffding inequality, see [11, Theorem 2.3], to obtain

$$\Pr[S \geq (1 + \epsilon) \cdot \mathbf{E}[S]] \leq e^{-\frac{2 \cdot \mathbf{E}[S]}{2(1 + \frac{1}{3})}} ,$$

$$\Pr[S \leq (1 - \epsilon) \cdot \mathbf{E}[S]] \leq e^{-\frac{1}{2} \cdot \epsilon^2 \cdot \mathbf{E}[S]} .$$

This immediately implies the following bound for any $0 < \epsilon \leq 1$,

$$\Pr[|S - \mathbf{E}[S]| \geq \epsilon \cdot \mathbf{E}[S]] \leq 2e^{-\Theta(\epsilon^2 \cdot \mathbf{E}[S])} = 2e^{-\Theta(\epsilon^2 \cdot \log n)} .$$

We now show how to remove the assumption that we know the cost of the solution. We run the algorithm in phases: we start in the first phase by “guessing” $c = n$, because we know that the cost of the optimal solution is not bigger than n . If $S < \frac{s}{n} \cdot c$, then we start a new phase with estimated cost $c/2$, and so on. If $S \geq \frac{s}{n} \cdot c$, we return $S \cdot n/s$ as the approximation of the cost. The probability that the algorithm ends in a bad phase (when S far away from $\frac{s}{n} \cdot c$) is low, because $\Pr[S \geq (1 + \epsilon) \cdot \mathbf{E}[S]] < 1/\text{poly}(n)$, as shown above. Since we need to have at least one facility in a solution, we have $c \geq 1$, therefore we have at most a logarithmic number of phases.

Note that we only get a constant slowdown by running these phases to guess c , because the last phase, for the smallest c , dominates the running time of all the other phases. Thus we obtain the following theorem.

Theorem 1. *There exists a constant factor approximation algorithm for the uniform case of the Minimum Facility Location problem which runs in time $O(n \log^2 n)$ with high probability.*

3 Lower Bounds: Estimating the Cost in the General Case of the Uniform Minimum Facility Location Problem Requires $\Omega(n^2)$ Time (Even for Randomized Algorithms)

In this section, we consider a general case of the Minimum Facility Location problem in which we do not impose the restriction that $\mathcal{F} = P$ (that is, we allow only for a subset of points to be able to open a facility). We focus again on the uniform case, and the goal is to minimize the following cost:

$$\min_{F \subseteq \mathcal{F}} \left(|F| + \sum_{p \in P} d(p, F) \right) .$$

Our main result is the following theorem.

Theorem 2. *For any $\rho \geq 1$, every approximation algorithm (even a randomized one) with approximation ratio ρ for the cost of the Minimum Facility Location problem as defined above requires time $\Omega(n^2)$.*

Proof. We show the existence of two instances of the metric spaces which are undistinguishable by any $o(n^2)$ -time algorithms and such that the cost of the

Fig. 1. Two metric spaces undistinguishable by any $o(n^2)$ -time algorithms whose costs of the Minimum Facility Location differ by factor ρ . The perfect matching connecting \mathcal{F} with P is selected at random and the edge e is selected as a random edge from the matching. We set $Q = 2n(\rho - 1) + 2$. The distances not shown are all equal to $n^3 \rho$

Minimum Facility Location in one instance is greater than ϱ times than the one in the other instance (see Fig. 1).

Let us consider the metric space with $2n$ points: n points in P and n points in \mathcal{F} . Take a random perfect matching \mathbb{M} between the points in P and \mathcal{F} , and choose an edge $e \in \mathbb{M}$ at random. Now, we define the distances in $(P \cup \mathcal{F}, D)$ according to the following:

- for any $e^* \in \mathbb{M} \setminus \{e\}$, $D(e^*) = 1$,
- $D(e)$ is either 1 or $Q = 2n(\varrho - 1) + 2$, and
- for any pair of points x, y not connected by an edge from \mathbb{M} , $D(x, y) = n^3 \varrho$.

It is easy to see that both instances define properly a metric space $(P \cup \mathcal{F}, D)$. Furthermore, that for such problem instances, the solution to the Minimum Facility Location will open all facilities and the cost of the Minimum Facility Location problem will depend on the choice of $D(e)$: if $D(e) = Q$ then the cost will be $2n - 1 + Q > 2n\varrho$, and if $D(e) = 1$, then the cost will be $2n$. Hence, any ϱ -factor approximation algorithm for the matching problem must distinguish between these two problem instances. However, this requires to find if there is an edge of length Q , and this is known to require time $\Omega(n^2)$, even if a randomized algorithm is used. \square

3.1 Extensions

It is not difficult to see that almost an identical proof will also work for estimating the cost of *minimum-cost matching*, the cost of *minimum-cost bi-chromatic matching*, and also the cost of *k-median* for $k = n/2$; all these problems require $\Omega(n^2)$ to estimate the cost of their optimal solution to within any factor. No such lower bounds have been previously known.

Theorem 3. *For any $\varrho \geq 1$, every approximation algorithm (even a randomized one) with approximation ratio ϱ for each of the following problems requires time $\Omega(n^2)$:*

- *estimating the cost of minimum-cost matching for a set of n points in a metric space,*
- *estimating the cost of minimum-cost bi-chromatic matching for a set of n points in a metric space,*
- *estimating the cost of metric k-median for $k = n/2$.*

Abstract. The theory of graph games with ω -regular winning conditions is the foundation for modeling and synthesizing reactive processes. In the case of stochastic reactive processes, the corresponding stochastic graph games have three players, two of them (System and Environment) behaving adversarially, and the third (Uncertainty) behaving probabilistically. We consider two problems for stochastic graph games: the *qualitative* problem asks for the set of states from which a player can win with probability 1 (*almost-sure winning*); the *quantitative* problem asks for the maximal probability of winning (*optimal winning*) from each state. We show that for Rabin winning conditions, both problems are in NP. As these problems were known to be NP-hard, it follows that they are NP-complete for Rabin conditions, and dually, coNP-complete for Streett conditions. The proof proceeds by showing that pure memoryless strategies suffice for qualitatively and quantitatively winning stochastic graph games with Rabin conditions. This insight is of interest in its own right, as it implies that controllers for Rabin objectives have simple implementations. We also prove that for every ω -regular condition, optimal winning strategies are no more complex than almost-sure winning strategies.

1 Introduction

A stochastic graph game [5] is played on a directed graph with three kinds of states: player-1, player-2, and probabilistic states. At player-1 states, player 1 chooses a successor state; at player-2 states, player 2 chooses a successor state; and at probabilistic states, a successor state is chosen according to a given probability distribution. The result of playing the game forever is an infinite path through the graph. If there are no probabilistic states, we refer to the game as a *2-player graph game*; otherwise, as a *2^{1/2}-player graph game*. There has been a long history of using 2-player graph games for modeling and synthesizing reactive processes [1, 14, 16]: a reactive system and its environment represent the

** Full proofs are available in [2].

two players, whose states and transitions are specified by the states and edges of a game graph. Consequently, $2^{1/2}$ -player graph games provide the theoretical foundation for modeling and synthesizing processes that are both reactive and stochastic [9, 15].

For the modeling and synthesis (or “control”) of reactive processes, one traditionally considers ω -regular winning conditions, which naturally express the temporal specifications and fairness assumptions of transition systems [11]. This paper focuses on the complexity of solving $2^{1/2}$ -player graph games with respect to two important normal forms of ω -regular winning conditions: *Rabin conditions* and *Streett conditions* [17]. Rabin and Streett conditions are dual (i.e., complementary), and their practical relevance stems from the fact that their form corresponds to the form of fairness conditions for transition systems.

In the case of 2-player graph games, where no randomization is involved, a fundamental determinacy result ensures that, given an ω -regular winning condition, at each state, either player 1 has a strategy to ensure that the condition holds, or player 2 has a strategy to ensure that the condition does not hold [10]. Thus, the problem of solving 2-player graph games consists in finding the set of *winning states*, from which player 1 can ensure that the condition holds. This problem is known to be in $\text{NP} \cap \text{coNP}$ for parity conditions, to be NP-complete for Rabin conditions [8], and consequently, to be coNP-complete for Streett conditions. The proofs of inclusion in NP rely on the existence of pure (i.e., deterministic) memoryless winning strategies, which act as polynomial witnesses. The existence of pure memoryless winning strategies is also of independent interest, as such strategies can be simply and effectively implemented by a controller. Note that for Streett conditions, winning strategies in general require memory.

In the case of $2^{1/2}$ -player graph games, where randomization is present in the transition structure, the notion of winning needs to be clarified. Player 1 is said to *win surely* if she has a strategy that guarantees to achieve the winning condition against all player-2 strategies. While this is the classical notion of winning in the 2-player case, it is less meaningful in the presence of probabilistic states, because it makes all probabilistic choices adversarial (it treats them analogously to player-2 choices). To adequately treat probabilistic choice, we consider the *probability* with which player 1 can ensure that the winning condition is met. We thus define two solution problems for $2^{1/2}$ -player graph games: the *qualitative* problem asks for the set of states from which player 1 can ensure winning with probability 1; the *quantitative* problem asks for the maximal probability with which player 1 can ensure winning from each state (this probability is called the *value* of the game at a state) [7]. Correspondingly, we define *almost-sure winning strategies*, which enable player 1 to win with probability 1 whenever possible, and *optimal strategies*, which enable player 1 to win with maximal probability. The main result of this paper is that, in $2^{1/2}$ -player graph games, both the qualitative and the quantitative solution problems are NP-complete in the case of Rabin conditions, and coNP-complete in the case of Streett conditions. The NP-hardness for Rabin conditions follows from the NP-hardness of 2-player games with Rabin conditions [8]; we establish the membership in NP. Both questions

are known to be in $\text{NP} \cap \text{coNP}$ for the more restrictive, self-dual case of parity conditions [4, 13, 18], whose exact complexity is an important open problem.

Our proof of membership in NP for stochastic Rabin games relies on establishing the existence of pure memoryless almost-sure winning and optimal strategies. The corresponding result for stochastic parity games has been proved only recently [4, 13, 18], and these proofs rely on the self-duality of parity conditions. For Rabin conditions, a new proof approach is required. First, we show the existence of pure memoryless almost-sure winning strategies in stochastic Rabin games by a reduction from $2^{1/2}$ -player games to 2-player. The reduction preserves the ability of player 1 to win with probability 1, but it does not preserve the maximal probability of winning. The proof technique is combinatorial and uses graph-theoretic arguments to account for the fact that Rabin conditions are not closed under complementation. Second, to show the existence of pure memoryless optimal strategies in stochastic Rabin games, we partition the game graph into value classes, each consisting of states where the value of the game is identical. We prove that if the players play according to optimal strategies, then the game leaves every intermediate value class (in which the value is neither 0 nor 1) with probability 1. We then use the qualitative result on almost-sure winning to establish the existence of pure memoryless optimal strategies.

We emphasize that, as mentioned earlier, the existence of pure memoryless strategies is relevant in its own right, as such strategies consist in mappings that associate with each player-1 state a unique successor, without need for randomization or memory; such mappings are easily implemented in controllers. Furthermore, our techniques lead us to a more general result, which states a strong connection between certain qualitative and quantitative games: we show that for every ω -regular winning condition in a $2^{1/2}$ -player game graph, if a restricted family of strategies suffices for almost-sure winning, then it suffices also for optimality. Hence future research on $2^{1/2}$ -player games with ω -regular conditions can focus on qualitatively (i.e., almost-sure) winning strategies, and our result generalizes these strategies to quantitatively winning (i.e., optimal) strategies.

2 Definitions

We consider several classes of turn-based games, namely, two-player turn-based probabilistic games ($2^{1/2}$ -player games), two-player turn-based deterministic games (2-player games), and Markov decision processes ($1^{1/2}$ -player games).

Game graphs. A *turn-based probabilistic game graph* ($2^{1/2}$ -player game graph) $G = ((S, E), (S_1, S_2, S_\circ), \delta)$ consists of a directed graph (S, E) , a partition (S_1, S_2, S_\circ) of the finite set S of states, and a probabilistic transition function $\delta: S_\circ \rightarrow \mathcal{D}(S)$, where $\mathcal{D}(S)$ denotes the set of probability distributions over the state space S . The states in S_1 are the *player-1* states, where player 1 decides the successor state; the states in S_2 are the *player-2* states, where player 2 decides the successor state; and the states in S_\circ are the *probabilistic* states, where the

successor state is chosen according to the probabilistic transition function δ . We assume that for $s \in S_{\circlearrowleft}$ and $t \in S$, we have $(s, t) \in E$ iff $\delta(s)(t) > 0$, and we often write $\delta(s, t)$ for $\delta(s)(t)$. For technical convenience we assume that every state in the graph (S, E) has at least one outgoing edge. For a state $s \in S$, we write $E(s)$ to denote the set $\{t \in S \mid (s, t) \in E\}$ of possible successors.

A set $U \subseteq S$ of states is called δ -closed if for every probabilistic state $u \in U \cap S_{\circlearrowleft}$, if $(u, t) \in E$, then $t \in U$. The set U is called δ -live if for every nonprobabilistic state $s \in U \cap (S_1 \cup S_2)$, there is a state $t \in U$ such that $(s, t) \in E$. A δ -closed and δ -live subset U of S induces a *subgame graph* of G , indicated by $G \upharpoonright U$.

The *turn-based deterministic game graphs (2-player game graphs)* are the special case of the $2^{1/2}$ -player game graphs with $S_{\circlearrowleft} = \emptyset$. The *Markov decision processes (1^{1/2}-player game graphs)* are the special case of the $2^{1/2}$ -player game graphs with $S_1 = \emptyset$ or $S_2 = \emptyset$. We refer to the MDPs with $S_2 = \emptyset$ as *player-1 MDPs*, and to the MDPs with $S_1 = \emptyset$ as *player-2 MDPs*.

Plays and strategies. An infinite path, or *play*, of the game graph G is an infinite sequence $\omega = \langle s_0, s_1, s_2, \dots \rangle$ of states such that $(s_k, s_{k+1}) \in E$ for all $k \in \mathbb{N}$. We write Ω for the set of all plays, and for a state $s \in S$, we write $\Omega_s \subseteq \Omega$ for the set of plays that start from the state s .

A *strategy* for player 1 is a function $\sigma: S^* \cdot S_1 \rightarrow \mathcal{D}(S)$ that assigns a probability distribution to all finite sequences $\mathbf{w} \in S^* \cdot S_1$ of states ending in a player-1 state (the sequence represents a prefix of a play). Player 1 follows the strategy σ if in each player-1 move, given that the current history of the game is $\mathbf{w} \in S^* \cdot S_1$, she chooses the next state according to the probability distribution $\sigma(\mathbf{w})$. A strategy must prescribe only available moves, i.e., for all $\mathbf{w} \in S^*$, $s \in S_1$, and $t \in S$, if $\sigma(\mathbf{w} \cdot s)(t) > 0$, then $(s, t) \in E$. The strategies for player 2 are defined analogously. We denote by Σ and Π the set of all strategies for player 1 and player 2, respectively.

Once a starting state $s \in S$ and strategies $\sigma \in \Sigma$ and $\pi \in \Pi$ for the two players are fixed, the outcome of the game is a random walk $\omega_s^{\sigma, \pi}$ for which the probabilities of events are uniquely defined, where an *event* $\mathcal{A} \subseteq \Omega$ is a measurable set of paths. Given strategies σ for player 1 and π for player 2, a play $\omega = \langle s_0, s_1, s_2, \dots \rangle$ is *feasible* if for every $k \in \mathbb{N}$ the following three conditions hold: (1) if $s_k \in S_{\circlearrowleft}$, then $(s_k, s_{k+1}) \in E$; (2) if $s_k \in S_1$, then $\sigma(s_0, s_1, \dots, s_k)(s_{k+1}) > 0$; and (3) if $s_k \in S_2$ then $\pi(s_0, s_1, \dots, s_k)(s_{k+1}) > 0$. Given two strategies $\sigma \in \Sigma$ and $\pi \in \Pi$, and a state $s \in S$, we denote by $\text{Outcome}(s, \sigma, \pi) \subseteq \Omega_s$ the set of feasible plays that start from s given strategies σ and π . For a state $s \in S$ and an event $\mathcal{A} \subseteq \Omega$, we write $\text{Pr}_s^{\sigma, \pi}(\mathcal{A})$ for the probability that a path belongs to \mathcal{A} if the game starts from the state s and the players follow the strategies σ and π , respectively. In the context of player-1 MDPs we often omit the argument π , because Π is a singleton set.

We classify strategies according to their use of randomization and memory. The strategies that do not use randomization are called pure. A player-1 strategy σ is *pure* if for all $\mathbf{w} \in S^*$ and $s \in S_1$, there is a state $t \in S$ such that $\sigma(\mathbf{w} \cdot s)(t) = 1$. We denote by $\Sigma^P \subseteq \Sigma$ the set of pure strategies for player 1. A

strategy that is not necessarily pure is called *randomized*. Let M be a set called *memory*. A player-1 strategy can be described as a pair of functions: a *memory-update* function $\sigma_u: S \times M \rightarrow M$ and a *next-move* function $\sigma_m: S_1 \times M \rightarrow \mathcal{D}(S)$. The strategy (σ_u, σ_m) is *finite-memory* if the memory M is finite. We denote by Σ^F the set of finite-memory strategies for player 1, and by Σ^{PF} the set of *pure finite-memory* strategies; that is, $\Sigma^{PF} = \Sigma^P \cap \Sigma^F$. The strategy (σ_u, σ_m) is *memoryless* if $|M| = 1$; that is, the next move does not depend on the history of the play but only on the current state. A memoryless player-1 strategy can be represented as a function $\sigma: S_1 \rightarrow \mathcal{D}(S)$. A *pure memoryless strategy* is a pure strategy that is memoryless. A pure memoryless strategy for player 1 can be represented as a function $\sigma: S_1 \rightarrow S$. We denote by Σ^M the set of memoryless strategies for player 1, and by Σ^{PM} the set of pure memoryless strategies; that is, $\Sigma^{PM} = \Sigma^P \cap \Sigma^M$. Analogously we define the corresponding strategy families $\Pi^P, \Pi^F, \Pi^{PF}, \Pi^M$, and Π^{PM} for player 2.

Given a finite-memory strategy $\sigma \in \Sigma^F$, let G_σ be the game graph obtained from G under the constraint that player 1 follows the strategy σ . The corresponding definition G_π for a player-2 strategy $\pi \in \Pi^F$ is analogous, and we write $G_{\sigma,\pi}$ for the game graph obtained from G if both players follow the finite-memory strategies σ and π , respectively. Observe that given a $2^{1/2}$ -player game graph G and a memoryless player-1 strategy σ , the result G_σ is a player-2 MDP. Similarly, for a player-1 MDP G and a memoryless player-1 strategy σ , the result G_σ is a Markov chain. Hence, if G is a $2^{1/2}$ -player game graph and the two players follow memoryless strategies σ and π , the result $G_{\sigma,\pi}$ is a Markov chain. These observations will be useful in the analysis of $2^{1/2}$ -player games.

Objectives. An *objective* for a player consists of an ω -regular set of *winning plays* $\Phi \subseteq \Omega$ [17]. In this paper we study zero-sum games [9, 15], where the objectives of the two players are complementary; that is, if the objective of one player is Φ , then the objective of the other player is $\Omega \setminus \Phi$. We consider ω -regular objectives specified in Rabin or Streett normal forms. For a play $\omega = \langle s_0, s_1, s_2, \dots \rangle$, let $\text{Inf}(\omega)$ be the set $\{s \in S \mid s = s_k \text{ for infinitely many } k \geq 0\}$ of states that occur infinitely often in ω . We use colors to define objectives independent of game graphs. For a set C of colors, we write $\llbracket \cdot \rrbracket: C \rightarrow 2^S$ for a function that maps each color to a set of states. Inversely, given a set $U \subseteq S$ of states, we write $\llbracket U \rrbracket = \{c \in C \mid \llbracket c \rrbracket \cap U \neq \emptyset\}$ for the set of colors that occur in U . Note that a state can have multiple colors.

A *Rabin objective* is specified as a set $P = \{(e_1, f_1), \dots, (e_d, f_d)\}$ of pairs of colors $e_i, f_i \in C$. Intuitively, the Rabin condition P requires that for some $1 \leq i \leq d$, all states of color e_i be visited finitely often and some state of color f_i be visited infinitely often. Let $\llbracket P \rrbracket = \{(E_1, F_1), \dots, (E_d, F_d)\}$ be the corresponding set of so-called *Rabin pairs*, where $E_i = \llbracket e_i \rrbracket$ and $F_i = \llbracket f_i \rrbracket$ for all $1 \leq i \leq d$. Formally, the set of winning plays is $\text{Rabin}(P) = \{\omega \in \Omega \mid \exists 1 \leq i \leq d. (\text{Inf}(\omega) \cap E_i = \emptyset \wedge \text{Inf}(\omega) \cap F_i \neq \emptyset)\}$. Without loss of generality, we require that $(\bigcup_{i \in \{1, 2, \dots, d\}} (E_i \cup F_i)) = S$. The *parity* (or *Rabin-chain*) objectives are the special case of Rabin objectives such that $E_1 \subset F_1 \subset E_2 \subset F_2 \dots \subset E_d \subset F_d$. A *Streett objective* is again specified as a set $P = \{(e_1, f_1), \dots, (e_d, f_d)\}$

of pairs of colors. The Streett condition P requires that for each $1 \leq i \leq d$, if some state of color f_i is visited infinitely often, then some state of color e_i be visited infinitely often. Formally, the set of winning plays is $\text{Streett}(P) = \{ \omega \in \Omega \mid \forall 1 \leq i \leq d. (\text{Inf}(\omega) \cap E_i \neq \emptyset \vee \text{Inf}(\omega) \cap F_i = \emptyset) \}$, for the set $\llbracket P \rrbracket = \{(E_1, F_1), \dots, (E_d, F_d)\}$ of so-called *Streett pairs*. Note that the Rabin and Streett objectives are dual; i.e., the complement of a Rabin objective is a Streett objective, and vice versa. Moreover, every parity objective is both a Rabin objective and a Streett objective.

Sure winning, almost-sure winning, and optimality. Given a player-1 objective Φ , a strategy $\sigma \in \Sigma$ is *sure winning* for player 1 from a state $s \in S$ if for every strategy $\pi \in \Pi$ for player 2, we have $\text{Outcome}(s, \sigma, \pi) \subseteq \Phi$. The strategy σ is *almost-sure winning* for player 1 from the state s for the objective Φ if for every player-2 strategy π , we have $\text{Pr}_s^{\sigma, \pi}(\Phi) = 1$. The sure and almost-sure winning strategies for player 2 are defined analogously. Given an objective Φ , the *sure winning set* $\langle\langle 1 \rangle\rangle_{\text{sure}}(\Phi)$ for player 1 is the set of states from which player 1 has a sure winning strategy. The *almost-sure winning set* $\langle\langle 1 \rangle\rangle_{\text{almost}}(\Phi)$ for player 1 is the set of states from which player 1 has an almost-sure winning strategy. The sure winning set $\langle\langle 2 \rangle\rangle_{\text{sure}}(\Omega \setminus \Phi)$ and the almost-sure winning set $\langle\langle 2 \rangle\rangle_{\text{almost}}(\Omega \setminus \Phi)$ for player 2 are defined analogously. It follows from the definitions that for all $2^{1/2}$ -player game graphs and all objectives Φ , we have $\langle\langle 1 \rangle\rangle_{\text{sure}}(\Phi) \subseteq \langle\langle 1 \rangle\rangle_{\text{almost}}(\Phi)$. Computing sure and almost-sure winning sets and strategies is referred to as the *qualitative* analysis of $2^{1/2}$ -player games [7].

Given ω -regular objectives $\Phi \subseteq \Omega$ for player 1 and $\Omega \setminus \Phi$ for player 2, we define the *value* functions $\langle\langle 1 \rangle\rangle_{\text{val}}$ and $\langle\langle 2 \rangle\rangle_{\text{val}}$ for the players 1 and 2, respectively, as the following functions from the state space S to the interval $[0, 1]$ of reals: for all states $s \in S$, let $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s) = \sup_{\sigma \in \Sigma} \inf_{\pi \in \Pi} \text{Pr}_s^{\sigma, \pi}(\Phi)$ and $\langle\langle 2 \rangle\rangle_{\text{val}}(\Omega \setminus \Phi)(s) = \sup_{\pi \in \Pi} \inf_{\sigma \in \Sigma} \text{Pr}_s^{\sigma, \pi}(\Omega \setminus \Phi)$. In other words, the value $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s)$ gives the maximal probability with which player 1 can achieve her objective Φ from state s , and analogously for player 2. The strategies that achieve the value are called *optimal*: a strategy σ for player 1 is *optimal* from the state s for the objective Φ if $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s) = \inf_{\pi \in \Pi} \text{Pr}_s^{\sigma, \pi}(\Phi)$. The optimal strategies for player 2 are defined analogously. Computing values is referred to as the *quantitative* analysis of $2^{1/2}$ -player games. The set of states with value 1 is called the *limit-sure winning set* [7]. For $2^{1/2}$ -player game graphs with ω -regular objectives the almost-sure and limit-sure winning sets coincide [3].

Let $\mathcal{C} \in \{P, M, F, PM, PF\}$ and consider the family $\Sigma^{\mathcal{C}} \subseteq \Sigma$ of special strategies for player 1. We say that the family $\Sigma^{\mathcal{C}}$ *suffices* with respect to a player-1 objective Φ on a class \mathcal{G} of game graphs for *sure winning* if for every game graph $G \in \mathcal{G}$ and state $s \in \langle\langle 1 \rangle\rangle_{\text{sure}}(\Phi)$, there is a player-1 strategy $\sigma \in \Sigma^{\mathcal{C}}$ such that for every player-2 strategy $\pi \in \Pi$, we have $\text{Outcome}(s, \sigma, \pi) \subseteq \Phi$. Similarly, the family $\Sigma^{\mathcal{C}}$ *suffices* with respect to the objective Φ on the class \mathcal{G} of game graphs for *almost-sure winning* if for every game graph $G \in \mathcal{G}$ and state $s \in \langle\langle 1 \rangle\rangle_{\text{almost}}(\Phi)$, there is a player-1 strategy $\sigma \in \Sigma^{\mathcal{C}}$ such that for every player-2 strategy $\pi \in \Pi$, we have $\text{Pr}_s^{\sigma, \pi}(\Phi) = 1$; and for *optimality*, if for every

game graph $G \in \mathcal{G}$ and state $s \in S$, there is a player-1 strategy $\sigma \in \Sigma^c$ such that $\langle\langle 1 \rangle\rangle_{val}(\Phi)(s) = \inf_{\pi \in \Pi} \Pr_s^{\sigma, \pi}(\Phi)$.

For sure winning, the $1^{1/2}$ -player and $2^{1/2}$ -player games coincide with 2-player (deterministic) games where the random player (who chooses the successor at the probabilistic states) is interpreted as an adversary, i.e., as player 2. Theorem 1 and Theorem 2 state the classical determinacy results for 2-player and $2^{1/2}$ -player game graphs with ω -regular objectives.

Theorem 1 (Qualitative determinacy [8, 10]). *For all 2-player game graphs and Rabin or Streett objectives Φ , we have $\langle\langle 1 \rangle\rangle_{sure}(\Phi) \cap \langle\langle 2 \rangle\rangle_{sure}(\Omega \setminus \Phi) = \emptyset$ and $\langle\langle 1 \rangle\rangle_{sure}(\Phi) \cup \langle\langle 2 \rangle\rangle_{sure}(\Omega \setminus \Phi) = S$. Moreover, on 2-player game graphs, the family of pure memoryless strategies suffices for sure winning with respect to Rabin objectives, and the family of pure finite-memory strategies suffices for sure winning with respect to Streett objectives.*

Theorem 2 (Quantitative determinacy [12]). *For all $2^{1/2}$ -player game graphs, all Rabin or Streett objectives Φ , and all states s , we have $\langle\langle 1 \rangle\rangle_{val}(\Phi)(s) + \langle\langle 2 \rangle\rangle_{val}(\Omega \setminus \Phi)(s) = 1$.*

3 Qualitative Analysis

We show that the pure memoryless strategies suffice for almost-sure winning with respect to Rabin objectives on $2^{1/2}$ -player game graphs. The result is achieved by a reduction to 2-player Rabin games. The reduction also allows us to apply algorithms for solving 2-player Rabin games to the qualitative analysis of $2^{1/2}$ -player Rabin games. Furthermore, in the next section, we will use the existence of pure memoryless almost-sure winning strategies to prove the existence of pure memoryless optimal strategies.

End components of MDPs. We review some facts about *end components* [6] which are needed for the further development of the paper. We consider player-1 MDPs and hence strategies for player 1. Let $G = ((S, E), (S_1, S_2, S_\circ), \delta)$ with $S_2 = \emptyset$ be a $1^{1/2}$ -player game graph.

Definition 1 (End components). *A set $U \subseteq S$ of states is an end component if U is δ -closed and the subgame graph $G \upharpoonright U$ is strongly connected.*

We denote by $\mathcal{E} \subseteq 2^S$ the set of all end-components of G . The next lemma states that, under every strategy (memoryless or not), with probability 1 the set of states visited infinitely often along a play is an end component. This lemma allows us to derive conclusions on the (infinite) set of plays in an MDP by analyzing the (finite) set of end components in the MDP. In particular, the lemma implies that to show that a set $\{(E_1, F_1), \dots, (E_d, F_d)\}$ of Rabin pairs is satisfied with probability 1, it suffices to show that for each reachable end component U , there exists a $1 \leq i \leq d$ such that $U \cap E_i = \emptyset$ and $U \cap F_i \neq \emptyset$. To state the lemma, for $s \in S$ and $U \subseteq S$, we define $\Omega_s^U = \{\omega \in \Omega_s \mid \text{Inf}(\omega) = U\}$.

Fig. 1. Gadget for the reduction of $2^{1/2}$ -player Rabin games to 2-player Rabin games

Lemma 1. [6] *For all states $s \in S$ and strategies $\sigma \in \Sigma$, $\Pr_s^\sigma(\bigcup_{U \in \mathcal{E}} \Omega_s^U) = 1$.*

Reduction. Given a $2^{1/2}$ -player game graph $G = ((S, E), (S_1, S_2, S_\circ), \delta)$, a set $C = \{e_1, f_1, \dots, e_d, f_d\}$ of colors, and a color map $[\cdot]: S \rightarrow 2^C \setminus \emptyset$, we construct a 2-player game graph $\bar{G} = ((\bar{S}, \bar{E}), (\bar{S}_1, \bar{S}_2), \bar{\delta})$ together with a color map $[\cdot]: \bar{S} \rightarrow 2^{\bar{C}} \setminus \emptyset$ for the extended color set $\bar{C} = C \cup \{e_{d+1}, f_{d+1}\}$. The construction is specified as follows. For every nonprobabilistic state $s \in S_1 \cup S_2$, there is a corresponding state $\bar{s} \in \bar{S}$ such that (1) $\bar{s} \in \bar{S}_1$ iff $s \in S_1$, and (2) $[\bar{s}] = [s]$, and (3) $(\bar{s}, \bar{t}) \in \bar{E}$ iff $(s, t) \in E$. Every probabilistic state $s \in S_\circ$ is replaced by the gadget shown in Figure 1. In the figure, diamond-shaped states are player-2 states (in \bar{S}_2), and square-shaped states are player-1 states (in \bar{S}_1). From the state \bar{s} with $[\bar{s}] = [s]$, the players play the following 3-step game in \bar{G} . First, in state \bar{s} player 2 chooses a successor $(\bar{s}, 2k)$, for $k \in \{0, 1, \dots, d\}$. For every state $(\bar{s}, 2k)$, we have $[(\bar{s}, 2k)] = [s]$. For $k > 1$, in state $(\bar{s}, 2k)$ player 1 chooses from two successors: state $(\hat{s}, 2k - 1)$ with $[(\hat{s}, 2k - 1)] = e_k$, or state $(\hat{s}, 2k)$ with $[(\hat{s}, 2k)] = f_k$. The state $(\hat{s}, 0)$ has only one successor $(\hat{s}, 0)$, with $[(\hat{s}, 0)] = f_{d+1}$. Note that no state in \bar{S} is labeled by the new color e_{d+1} , that is, $[e_{d+1}] = \emptyset$. Finally, in each state (\hat{s}, j) the choice is between all states \bar{t} such that $(s, t) \in E$, and it belongs to player 1 if k is odd, and to player 2 if k is even.

We consider the $2^{1/2}$ -player game played on the graph G with the Rabin condition $P = \{(e_1, f_1), \dots, (e_d, f_d)\}$ for player 1. Let \bar{U}_1 and \bar{U}_2 be the sure winning sets for players 1 and 2, respectively, in the constructed 2-player game graph \bar{G} with the modified Rabin condition $\bar{P} = \{(e_1, f_1), \dots, (e_{d+1}, f_{d+1})\}$ for player 1. Define the sets U_1 and U_2 in the original $2^{1/2}$ -player game graph G by $U_1 = \{s \in S \mid \bar{s} \in \bar{U}_1\}$ and $U_2 = \{s \in S \mid \bar{s} \in \bar{U}_2\}$. From the determinacy of 2-player Rabin games (Theorem 1), it follows that $\bar{U}_1 = \bar{S} \setminus \bar{U}_2$, and hence $U_1 = S \setminus U_2$.

Lemma 2. *In the $2^{1/2}$ -player game graph G with the Rabin condition P for player 1, there exists a pure memoryless strategy σ for player 1 such that for all player-2 strategies π and all states $s \in U_1$, we have $\Pr_s^{\sigma, \pi}(\text{Rabin}(P)) = 1$.*

Proof. We define a pure memoryless strategy σ for player 1 in the game G from a strategy $\bar{\sigma}$ in the game \bar{G} as follows: for all states $s \in S_1$, if $\bar{\sigma}(\bar{s}) = \bar{t}$, then

set $\sigma(s) = t$. Consider a pure memoryless sure winning strategy $\bar{\sigma}$ in the game \bar{G} from every state $\bar{s} \in \bar{U}_1$. Our goal is to establish that σ is an almost-sure winning strategy from every state in U_1 .

For the Rabin objective $\text{Rabin}(P)$, let the set Rabin pairs be $\llbracket P \rrbracket = \{(E_1, F_1), (E_2, F_2), \dots, (E_d, F_d)\}$. A strongly connected component (s.c.c.) W in a graph G_1 is winning for player 1, if there exists $i \in \{1, 2, \dots, d\}$ such that $W \cap F_i \neq \emptyset$ and $W \cap E_i = \emptyset$; otherwise W is winning for player 2. If G_1 is a MDP, then an end component W in G_1 is winning for player 1, if there exists $i \in \{1, 2, \dots, d\}$ such that $W \cap F_i \neq \emptyset$ and $W \cap E_i = \emptyset$; otherwise W is winning for player 2.

We prove that every end component in the player-2 MDP $(G \upharpoonright U_1)_\sigma$ is winning for player 1. It would follow from Lemma 1 that σ is an almost-sure winning strategy. We argue that if there is an end component W in $(G \upharpoonright U_1)_\sigma$ that is winning for player 2, then we can construct an s.c.c. in the subgraph $(\bar{G} \upharpoonright \bar{U}_1)_{\bar{\sigma}}$ that is winning for player 2, which is impossible because $\bar{\sigma}$ is a sure winning strategy for player 1 from the set \bar{U}_1 in the 2-player Rabin game \bar{G} . Let W be an end component in $(G \upharpoonright U_1)_\sigma$ that is winning for player 2. We denote by \bar{W} the set of states in the gadget of states in W . Hence for all $i \in \{1, 2, \dots, d\}$ we have if $F_i \cap W \neq \emptyset$, then $W \cap E_i \neq \emptyset$. Let us define the set $I = \{i_1, i_2, \dots, i_j\}$ such that $E_i \cap W \neq \emptyset$. Thus for all $i \in (\{1, 2, \dots, d\} \setminus I)$ we have $F_i \cap W = \emptyset$. Note that $I \neq \emptyset$, as every state has at least one color. We now construct a sub-game in $\bar{G}_{\bar{\sigma}}$ as follows:

1. For a state $\bar{s} \in \bar{W} \cap \bar{S}_2$ keep all the edges (\bar{s}, \bar{t}) such that $\bar{t} \in \bar{W}$.
2. For a state $\bar{s} \in \bar{W} \cap \bar{S}_\circ$ the sub-game is defined as follows:
 - At state \bar{s} choose the edges to state $(\tilde{s}, 2i)$ such that $i \in I$.
 - For a state $s \in W$, let $\text{dis}(s, W \cap E_i)$ denote the shortest distance (BFS distance) from s to $W \cap E_i$ in the graph of $(G \upharpoonright W)_\sigma$. At state $(\hat{s}, 2i)$, which is a player 2 state, player 2 chooses a successor \hat{s}_1 such that $\text{dis}(s_1, W \cap E_i) < \text{dis}(s, W \cap E_i)$ (i.e., shorten distance to the set $\bar{W} \cap E_i$ in \bar{G}).

We now prove that every terminal s.c.c. is winning for player 2 in the subgame thus constructed in $(\bar{G} \upharpoonright \bar{W})_{\bar{\sigma}}$, where \bar{W} is the set of states in the gadget of states in W . Consider any arbitrary terminal s.c.c. \bar{Y} in the subgame constructed in $(\bar{G} \upharpoonright \bar{W})_{\bar{\sigma}}$. It follows from the construction that for every $i \in (\{1, 2, \dots, d\} \setminus I)$, we have $F_i \cap \bar{Y} = \emptyset$. Suppose for a $i \in I$ we have $F_i \cap \bar{Y} \neq \emptyset$, we show that $E_i \cap \bar{Y} \neq \emptyset$. There are two cases:

1. If there is at least one state $(\tilde{s}, 2i)$ such that the strategy $\bar{\sigma}$ chooses the successor $(\hat{s}, 2i - 1)$, then $E_i \cap \bar{Y} \neq \emptyset$, since $[(\tilde{s}, 2i - 1)] = e_i$.
2. Else for every state $(\tilde{s}, 2i)$ the strategy for player 1 chooses the successor $(\hat{s}, 2i)$. At state $(\hat{s}, 2i)$, which is a player 2 state, player 2 chooses a successor \hat{s}_1 that shortens distance to the set $\bar{Y} \cap E_i$. Hence the terminal s.c.c. \bar{Y} must contain a state \bar{s} such that $[\bar{s}] = e_i$. Hence $E_i \cap \bar{Y} \neq \emptyset$.

We argue that for every probabilistic state $s \in S_\circ \cap U_1$, all of its successors are in U_1 . Otherwise, player 2 in the state \bar{s} of the game \bar{G} can choose the

successor $(\tilde{s}, 0)$ and then a successor to its winning set \overline{U}_2 , which contradicts the assumption that the strategy $\bar{\sigma}$ is a sure winning strategy for player 1 in the game \overline{G} from \overline{U}_1 . It follows from Lemma 1 that for all strategies π , for all states $s \in U_1$, with probability 1 the set of states visited infinitely often along the play $\omega_s^{\sigma, \pi}$ is an end component in U_1 . Since every end component in $(G \upharpoonright U_1)_\sigma$ is winning for player 1 the strategy σ is an almost-sure winning strategy for player 1 from U_1 . ■

Lemma 3. *In the $2^{1/2}$ -player game graph G with the Rabin condition P for player 1, there exists a finite-memory strategy π for player 2 such that for all player-1 strategies σ and all states $s \in U_2$, we have $\Pr_s^{\sigma, \pi}(\Omega \setminus \text{Rabin}(P)) > 0$.*

From Lemma 2, it follows that $U_1 \subseteq \langle\langle 1 \rangle\rangle_{\text{almost}} \text{Rabin}(P)$. From Lemma 3, it follows that $\langle\langle 1 \rangle\rangle_{\text{almost}} \text{Rabin}(P) \subseteq U_1$. Therefore $U_1 = \langle\langle 1 \rangle\rangle_{\text{almost}} \text{Rabin}(P)$. The proof of Lemma 2 also establishes the existence of pure memoryless almost-sure winning strategies for Rabin objectives.

Theorem 3. *The family of pure memoryless strategies suffices for almost-sure winning with respect to Rabin objectives on $2^{1/2}$ -player game graphs.*

4 Quantitative Analysis

We extend sufficiency results for families of strategies from almost-sure winning to optimality with respect to all ω -regular objectives. In the following, we fix a $2^{1/2}$ -player game graph G . Given an ω -regular objective Φ , for every real $r \in \mathbb{R}$ the *value class* with value r is $\text{VC}(r) = \{s \in S \mid \langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s) = r\}$. Proposition 1 states that there exist optimal strategies for player 1 such that they never choose an edge to a lower value class.

Proposition 1. *For all ω -regular objectives Φ , there exists an optimal strategy σ for player 1 such that for all $\mathbf{w} \in S^*$, $s \in S_1$, and $t \in S$, if $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(t) < \langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s)$, then $\sigma(\mathbf{w} \cdot s)(t) = 0$.*

Definition 2 (Boundary probabilistic states). *Given an ω -regular objective Φ , a probabilistic state $s \in S_\circ$ is a boundary probabilistic state if there exists a successor $t \in E(s)$ such that $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(t) \neq \langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s)$. Observe that for every boundary probabilistic state s , there exist $t_1, t_2 \in E(s)$ such that $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(t_1) < \langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s)$ and $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(t_2) > \langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s)$.*

Lemma 4. *Consider a $2^{1/2}$ -player game G with an ω -regular objective Φ . Given a value class $\text{VC}(r)$ with $0 < r < 1$, let $B(r)$ be the set of boundary probabilistic states in the value class $\text{VC}(r)$. Convert each state in $B(r)$ into a sink state that is winning for player 1. Let the new game be G' . Then player 1 wins almost-surely from all states in the subgame with game graph $G' \upharpoonright \text{VC}(r)$ and objective Φ .*

Proof. Assume that player 1 does not win almost-surely from every state in $G' \upharpoonright \text{VC}(r)$. Then there exists a state where player 2 wins with positive bounded probability. It follows from Corollary 1 of [7] that there exist a non-empty set $U \subseteq \text{VC}(r)$ such that that player 2 wins almost-surely from U in $G' \upharpoonright \text{VC}(r)$. Consider an optimal strategy σ that never chooses an edge with positive probability to a lower value class (such a strategy exists from Proposition 1). Since player 2 wins almost-surely from U it follows that for every state $s \in U \cap S_1$, for every successor t of s in $\text{VC}(r)$ we have $t \in U$. It follows that every move of the strategy σ exists in U . Hence player 2 wins almost-surely from U against σ . This is a contradiction to the assumption that $r > 0$ and that σ is an optimal strategy. ■

Definition 3 (Qualitatively optimal strategies). *A strategy σ is qualitatively optimal for player 1, for an ω -regular objective Φ , if the following conditions hold: (a) for every state $s \in \langle\langle 1 \rangle\rangle_{\text{almost}}(\Phi)$, the strategy σ is almost-sure winning, and (b) for every state $s \in \text{VC}(r)$ such that $0 < r < 1$, there is a constant $c > 0$ such that $\inf_{\pi \in \Pi} \text{Pr}_s^{\sigma, \pi}(\Phi) \geq c$.*

Lemma 4 shows that in every value class, if the boundary probabilistic states are assumed to be winning for player 1, then player 1 wins almost-surely. We call such an almost-sure winning strategy a *conditional* almost-sure winning strategy. We compose conditional almost-sure winning strategies in value classes to obtain an optimal strategy. If a strategy σ is conditional almost-sure winning, it follows that for all player-2 strategies π that are optimal against σ , the play $\omega_s^{\sigma, \pi}$ reaches the boundary probabilistic states with positive probability, for $s \in \text{VC}(r)$ and $r > 0$. From every boundary probabilistic state the game proceeds to a higher value class with positive probability. An induction on the number of value classes yields Lemma 5.

Lemma 5. *For every ω -regular objective Φ , if a player-1 strategy σ is almost-sure winning from every state $s \in \langle\langle 1 \rangle\rangle_{\text{almost}}(\Phi)$, and is conditionally almost-sure winning from every state $s \notin \langle\langle 2 \rangle\rangle_{\text{almost}}(\Omega \setminus \Phi)$, then σ is qualitatively optimal for Φ .*

Definition 4 (Locally optimal strategies). *A strategy σ is locally optimal for player 1, for an ω -regular objective Φ , if for all $\mathbf{w} \in S^*$, $s \in S_1$, and $t \in S$, if $\langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(t) < \langle\langle 1 \rangle\rangle_{\text{val}}(\Phi)(s)$, then $\sigma(\mathbf{w} \cdot s)(t) = 0$.*

Note that by definition, a conditional almost-sure winning strategy is locally optimal. The following Lemma generalizes Lemma 5.3 of [4]. Theorem 4 follows from Lemma 6. Since pure memoryless strategies suffice for almost-sure winning with respect to Rabin objectives on $2^{1/2}$ -player game graphs (Theorem 3), Theorem 5 is immediate from Theorem 4.

Lemma 6. *Consider a $2^{1/2}$ -player game G with an ω -regular objective Φ for player 1. Let σ be a finite-memory strategy such that σ is both qualitatively optimal and locally optimal for Φ . Then σ is an optimal strategy for Φ from all states of G .*

Theorem 4. *If a family Σ^C of strategies suffices for almost-sure winning with respect to an ω -regular objective Φ on $2^{1/2}$ -player game graphs, then Σ^C suffices for optimality with respect to Φ on $2^{1/2}$ -player game graphs.*

Theorem 5. *The family of pure memoryless strategy suffices for optimality with respect to Rabin objectives on $2^{1/2}$ -player game graphs.*

The existence of pure memoryless optimal strategies for $2^{1/2}$ -player game graphs with Rabin objectives, and of polynomial-time algorithms for computing the values of MDPs with Streett objectives [2], establishes that the $2^{1/2}$ -player games with Rabin objectives can be decided (qualitatively and quantitatively) in NP. The NP-hardness follows from the hardness of 2-player Rabin games.

Theorem 6. *Given a $2^{1/2}$ -player game graph G , an objective Φ for player 1, a state s of G , and a rational r , the complexity of determining whether $\langle\langle 1 \rangle\rangle_{val}(\Phi)(s) \geq r$ is as follows: NP-complete if Φ is a Rabin objective; coNP-complete if Φ is a Streett objective; and in $NP \cap coNP$ if Φ is a parity objective.*

Recursive Markov Decision Processes and Recursive Stochastic Games

Kousha Etessami¹ and Mihalis Yannakakis²

² Department of Computer Science, Columbia University

Abstract. We introduce Recursive Markov Decision Processes (RMDPs) and Recursive Simple Stochastic Games (RSSGs), and study the decidability and complexity of algorithms for their analysis and verification. These models extend Recursive Markov Chains (RMCs), introduced in [EY05a, EY05b] as a natural model for verification of probabilistic procedural programs and related systems involving both recursion and probabilistic behavior. RMCs define a class of denumerable Markov chains with a rich theory generalizing that of stochastic context-free grammars and multi-type branching processes, and they are also intimately related to probabilistic pushdown systems. RMDPs & RSSGs extend RMCs with one controller or two adversarial players, respectively. Such extensions are useful for modeling nondeterministic and concurrent behavior, as well as modeling a system's interactions with an environment.

We provide upper and lower bounds for deciding, given an RMDP (or RSSG) A and probability p , whether player 1 has a strategy to force termination at a desired exit with probability at least p . We also address “qualitative” termination, where $p = 1$, and model checking questions.

1 Introduction

Markov Decision Processes (MDPs) are a fundamental formalism for modeling control optimization problems in sequential stochastic environments. They have found widespread applications in many fields (see, e.g., [Put94, FS02]). They have also been studied extensively in recent years for verification of probabilistic systems. Stochastic games generalize MDPs with multiple players, and in their 2-player zero-sum version are also known as Competitive MDPs (see [FV97]). Simple Stochastic Games (SSGs) [Con92] are a special class of 2-player zero-sum stochastic games, where the goal of one player is to reach a given terminal state, while the other aims to avoid it. SSGs generalize parity games and other important games for model checking, and the termination problem for finite SSGs already presents a well-known algorithmic challenge: it is in $\text{NP} \cap \text{coNP}$, but no P-time algorithm is known ([Con92]).

Recursive Markov Chains (RMCs) were introduced and studied in our earlier work ([EY05a, EY05b]) as a natural model of probabilistic procedural programs and systems exhibiting both recursion and probabilistic behavior. There we provided strong upper and lower bounds for both reachability and ω -regular model

checking questions for RMCs. Informally, a RMC consists of a (finite) collection of finite state Markov chains that can call each other in a potentially recursive manner. RMCs define a class of denumerable Markov chains with a rich theory generalizing that of Stochastic Context-Free Grammars (SCFGs) (see, e.g., [MS99]) and Multi-Type Branching Processes ([Har63]), both of which correspond to 1-exit RMCs: RMCs in which each component Markov chain has 1 terminating exit state where it can return control back to a component that called it. RMCs are also intimately related to probabilistic Pushdown Systems (pPDSs), which have also been studied recently in connection to verification of probabilistic programs ([EKM04, BKS05]).

For verification, it is natural and useful to extend RMCs with nondeterministic choice, where some states are controlled by the system while others exhibit probabilistic behavior. Indeed, finite MDPs have been studied extensively for verification of probabilistic systems, and optimized verification tools already exist for them (see, e.g., [CY98, Var85, dAKN⁺00, Kwi03]; [Kwi03] is a recent survey). SSGs extend MDPs with a second (adversarial) player. Like non-probabilistic game graphs, they can also be used to model and analyze the interactions between a controlled (but probabilistic) system and an (adversarial) environment.

In this paper we focus on precisely such extensions of RMCs: we introduce *Recursive Markov Decision Processes* (RMDPs) and *Recursive Simple Stochastic Games* (RSSGs), which define natural classes of countable MDPs and SSGs, respectively. In the stochastic dynamic programming literature, MDPs are studied under many different reward criteria, such as average reward, discounted reward, etc. Our focus here is on verification of probabilistic systems, and for this purpose we study RMDPs and RSSGs under reachability criteria which are central to any analysis like model checking. In particular, we ask the *quantitative termination* question: given an RMDP (or RSSG) A and a probability p , is there a strategy for the controller where (regardless of the strategy used by the adversary, in the case of RSSGs) the process terminates at a desired exit with probability at least p (or at most p)? We also ask the *qualitative* question of whether the controller has a strategy to force termination with probability 1. Lastly, we address model checking questions.

Our positive results apply primarily to 1-exit RMDPs and 1-exit RSSGs, which correspond to controlled and game extensions, respectively, of both SCFGs and Multi-Type Branching Processes (MT-BPs). Branching processes are an important class of stochastic processes, dating back to the early work of Galton and Watson in the 19th century (they studied the single-type case, a subcase of 1-exit 1-entry 1-component RMCs), and continuing in the 20th century in the work of Kolmogorov, Sevastianov, Harris and others for MT-BPs and beyond (see, e.g., [Har63]). These have been used to model a wide variety of applications, including in population genetics ([Jag75]), nuclear chain reactions, and RNA modeling in computational biology (based on SCFGs) ([SBH⁺94]). SCFGs are also fundamental models in statistical natural language processing (see, e.g., [MS99]). 1-exit RMDPs correspond to a controlled version of MT-BPs (and SCFGs): the reproduction of some types can be controlled, while the dynamics of other types

is probabilistic as in ordinary MT-BPs. This model would also be suitable for analysis of population dynamics under worst-case (or best-case) assumptions for some types and probabilistic assumptions for others. Such controlled MT-BPs can be readily translated to 1-entry, 1-exit RMDPs, where the number of components is bounded by the number of types (a reverse translation is possible, but will not in general preserve the number of components, i.e., 1-entry, 1-exit RMDPs with a bounded number of components are more general than MT-BPs with a bounded number of types). Thus, our results on 1-exit RMDPs apply, among other things, to such controlled MT-BPs; these do not appear to have been studied in the rich Branching Process literature. Indeed, even some basic algorithmic problems about SCFGs and MT-BPs had received limited attention prior to our work in [EY05a, EY05b].

We now outline our main results in this paper:

- We show that the Least Fixed Point solution of certain systems of nonlinear min/max equations captures optimal termination probabilities for 1-exit RMDPs & 1-exit RSSGs. These equations generalize linear Bellman’s equations for finite MDPs (see, e.g., [Put94, FV97]) and also generalize the monotone systems of nonlinear equations for RMCs that we studied in ([EY05a]).
- We show a quite nontrivial *Stackless & Memoryless (S&M) Determinacy* result for 1-exit RSSG termination, whereas we observe this fails badly even for 2-exit RMDPs (namely, optimal strategies of any kind do not always exist for 2-exit RMDP termination; one must make do with ϵ -optimal strategies).
- Using the equations, we show that quantitative termination for 1-exit RMDPs and 1-exit RSSGs is decidable in PSPACE. This matches our PSPACE upper bound for the special case of 1-exit RMCs in [EY05a] and, as shown there, it can not be improved without resolving a long standing open problem in the complexity of numerical computation, namely the square-root sum problem.
- Using S&M-determinacy, we show qualitative termination (where $p = 1$) can be decided in NP for 1-exit RMDPs, and in $\Sigma_2^P \cap \Pi_2^P$ for 1-exit RSSGs.
- For the special case of *linearly recursive* 1-exit RMDPs (RSSGs), we show that the exact optimal, and rational, termination probabilities can be computed in polynomial time (in $\text{NP} \cap \text{co-NP}$, respectively).
- Lastly, and unfortunately, we show that for multi-exit RMDPs & RSSGs the situation is far worse: even qualitative termination for general RMDPs is undecidable, even when the number of exits is bounded by a fixed constant and the RMDP is restricted to be linearly-recursive. It is even undecidable, for any fixed $\epsilon > 0$, to distinguish whether the optimal value is 1 or $< \epsilon$. So optimal probabilities can not be approximated in a strong sense, with any resources. Furthermore, we show undecidability applies already to qualitative model checking of 1-exit RMDPs, against regular or LTL properties. Our undecidability results are derived from classic and recent undecidability results for Probabilistic Finite Automata (PFA) [Paz71, CL89, BC03]. We show PFAs can be viewed as essentially a special case of multi-exit RMDPs.

Related work. Both MDPs and Stochastic Games have a vast literature, dating back to Bellman and Shapley (see, e.g., [Put94, FS02, FV97]). MDPs are studied

in both finite state and infinite state variants. Verification of finite state MDPs, also called concurrent Markov chains, has been studied for a long time (see, e.g., [CY98, CY95, Var85, HSP83]). [CY98] provides efficient algorithms for ω -regular model checking of finite MDPs. Model checking tools like PRISM contain optimized implementations of branching-time model checkers for finite MDPs (see, e.g., [dAKN⁺00, Kwi03]).

Our earlier work [EY05a, EY05b] developed the basic theory of RMCs and studied efficient algorithms for both their reachability analysis and model checking. We showed, among many results, that qualitative model checking of ω -regular properties for 1-exit RMCs can be decided in polynomial time in the size of the RMC, and that quantitative model checking of RMCs can be done in PSPACE in the size of the RMC. As mentioned, 1-exit RMCs correspond to both MT-BPs and SCFGs (see, e.g., [Har63] and [MS99]), while general RMCs are intimately related to probabilistic Pushdown Systems (pPDSs). Model checking questions for pPDSs, for both linear and branching time properties, have also been recently studied in [EKM04, BKS05]. RMDPs and RSSGs are natural extensions of RMCs, introducing nondeterministic and game behavior. Countable state MDPs are studied extensively in the MDP literature (see, e.g., [Put94, FS02]), but the concise representations afforded by RMDPs and its algorithmic properties, appear not to have been studied prior to our work.

2 Basics

A *Recursive Simple Stochastic Game (RSSG)*, A , is a tuple $A = (A_1, \dots, A_k)$, where each *component graph* $A_i = (N_i, B_i, Y_i, En_i, Ex_i, \mathbf{pl}_i, \delta_i)$ consists of:

- A set N_i of *nodes*. Let $N = \bigcup_{i=1}^k N_i$ be the (disjoint) union of all nodes of A .
- A distinguished subset of *entry nodes* $En_i \subseteq N_i$, and a disjoint subset of *exit nodes* $Ex_i \subseteq N_i$. Let $En = \bigcup_{i=1}^k En_i$ and $Ex = \bigcup_{i=1}^k Ex_i$.
- A set B_i of *boxes*. Let $B = \bigcup_{i=1}^k B_i$ be the (disjoint) union of all boxes of A .
- A mapping $Y_i : B_i \mapsto \{1, \dots, k\}$ that assigns to every box (the index of) of a component. Let $Y = \bigcup_{i=1}^k Y_i$ be the map $Y : B \mapsto \{1, \dots, k\}$ where $Y|_B = Y_i$, for $1 \leq i \leq k$.
- To each box $b \in B_i$, we associate a set of *call ports*, $Call_b = \{(b, en) \mid en \in En_{Y(b)}\}$, and a set of *return ports*, $Return_b = \{(b, ex) \mid ex \in Ex_{Y(b)}\}$. Let $Call^i = \bigcup_{b \in B} Call_b$ and let $Call = \bigcup_{i=1}^k Call^i$ denote all calls in A . Similarly, define $Return^i$ and $Return$.
- We let $Q_i = N_i \cup Call^i \cup Return^i$, denote collectively the nodes, call ports, and return ports, We will use the term *vertex* of A_i to refer to elements of Q_i . We let $Q = \bigcup_{i=1}^k Q_i$ be the set of all vertices of the RSSG A .
- A mapping $\mathbf{pl}_i : Q_i \mapsto \{0, 1, 2\}$ that assigns to every vertex a player (Player 0 represents “chance” or “nature”). We assume $\mathbf{pl}_i(ex) = 0$ for all $ex \in Ex_i$. Let $\mathbf{pl} = \bigcup_{i=1}^k \mathbf{pl}_i$ denote $\mathbf{pl} : Q \mapsto \{0, 1, 2\}$ where $\mathbf{pl}|_Q = \mathbf{pl}_i$, for $1 \leq i \leq k$.
- A transition relation $\delta_i \subseteq (Q_i \times (\mathbb{R} \cup \{\perp\})) \times Q_i$, where for each tuple $(u, x, v) \in \delta_i$, the source $u \in (N_i \setminus Ex_i) \cup Return^i$, the destination $v \in$

$(N_i \setminus En_i) \cup Call^i$, and x is either (i) a real number $p_{u,v} \in [0, 1]$ (the transition probability) if $\mathbf{pl}(u) = 0$, or (ii) $x = \perp$ if $\mathbf{pl}(u) = 1$ or 2 . For computational purposes we assume that the given probabilities $p_{u,v}$ are rational. Furthermore they must satisfy the consistency property: for every $u \in \mathbf{pl}^{-1}(0)$, $\sum_{\{v' | (u,p, \cdot, v') \in \delta\}} p_{u,v'} = 1$, unless u is a call port or exit node, neither of which have outgoing transitions, in which case by default $\sum_{v'} p_{u,v'} = 0$. Let $\delta = \cup_i \delta_i$ be the set of all transitions of A .

An RSSG A defines a global denumerable Simple Stochastic Game (SSG) $M_A = (V = V_0 \cup V_1 \cup V_2, \Delta, \mathbf{pl})$ as follows. The global states $V \subseteq B^* \times Q$ of M_A are pairs of the form $\langle \beta, u \rangle$, where $\beta \in B^*$ is a (possibly empty) sequence of boxes and $u \in Q$ is a vertex of A . More precisely, the states $V \subseteq B^* \times Q$ and transitions Δ are defined inductively as follows:

1. $\langle \epsilon, u \rangle \in V$, for $u \in Q$. (ϵ denotes the empty string.)
2. if $\langle \beta, u \rangle \in V$ & $(u, x, v) \in \delta$, then $\langle \beta, v \rangle \in V$ and $(\langle \beta, u \rangle, x, \langle \beta, v \rangle) \in \Delta$.
3. if $\langle \beta, (b, en) \rangle \in V$ & $(b, en) \in Call_b$, then $\langle \beta b, en \rangle \in V$ & $(\langle \beta, (b, en) \rangle, 1, \langle \beta b, en \rangle) \in \Delta$.
4. if $\langle \beta b, ex \rangle \in V$ & $(b, ex) \in Return_b$, then $\langle \beta, (b, ex) \rangle \in V$ & $(\langle \beta b, ex \rangle, 1, \langle \beta, (b, ex) \rangle) \in \Delta$.

Item 1 corresponds to the possible initial states, item 2 corresponds to control staying within a component, item 3 is when a new component is entered via a box, item 4 is when control exits a box and returns to the calling component. The mapping $\mathbf{pl} : V \mapsto \{0, 1, 2\}$ is given as follows: $\mathbf{pl}(\langle \beta, u \rangle) = \mathbf{pl}(u)$ if u is in $Q \setminus (Call \cup Ex)$, and $\mathbf{pl}(\langle \beta, u \rangle) = 0$ if $u \in Call \cup Ex$. The set of vertices V is partitioned into V_0 , V_1 , and V_2 , where $V_i = \mathbf{pl}^{-1}(i)$.

We consider M_A with various *initial states* of the form $\langle \epsilon, u \rangle$, denoting this by M_A^u . Some states of M_A are *terminating states* and have no outgoing transitions. These are states $\langle \epsilon, ex \rangle$, where ex is an exit node.

An RSSG where $V_2 = \emptyset$ ($V_1 = \emptyset$) is called a *maximizing* (minimizing, respectively) *Recursive Markov Decision Process* (RMDP); an RSSG where $V_1 \cup V_2 = \emptyset$ is called a *Recursive Markov Chain* (RMC) ([EY05a, EY05b]); an RSSG where $V_0 \cup V_2 = \emptyset$ is called a *Recursive Graph* ([AEY01]); an RSSG where $V_0 = \emptyset$ is called a *Recursive Game Graph* (see [ATM03, Ete04]). We use *1-exit RSSG* to refer to RSSGs where every component has 1 exit. W.l.o.g., we can assume every component has 1 entry, because multi-entry RSSGs can be transformed to equivalent 1-entry RSSGs with polynomial blowup (similar to RSM transformations [AEY01]). This is decidedly not so for exits: 1-exit RSSGs form an important sub-class of RSSGs and are the main focus of our upper bounds. We shall call a RSSG (RMDP, RMC, etc.) *linearly-recursive* (denoted **1r**-RSSG, etc.) if there is no path of transitions in any component from any return port to a call port. **1r**-RMCs are much easier to analyse than general RMCs: reachability probabilities are rational and both reachability analysis and model checking can be performed with the same complexity as for finite Markov chains, using the decomposed Newton's method [EY05a] and techniques we developed in [EY05a, EY05b] (although **1r**-RMCs were not mentioned explicitly in [EY05a, EY05b]).

A basic goal is to answer termination questions for RSSGs: “Does player 1 have a strategy to force the game to terminate at ex (i.e., reach state $\langle \epsilon, ex \rangle$),

starting at $\langle \epsilon, u \rangle$, with probability $\geq p$, regardless of how player 2 plays?”. A strategy σ for player i , $i \in \{1, 2\}$, is a function $\sigma : V^*V_i \mapsto V$, where, given the history $ws \in V^*V_i$ of play so far, with $s \in V_i$ (i.e., it is player i ’s turn to play a move), $\sigma(ws) = s'$ determines the next move of player i , where $(s, \perp, s') \in \Delta$. (We could also allow randomized strategies.)

Let Ψ_i denote the set of all strategies for player i . A pair of strategies $\sigma \in \Psi_1$ and $\tau \in \Psi_2$ induce in a straightforward way a Markov chain $M_A^{\sigma, \tau} = (V^*, \Delta')$, whose set of states is the set V^* of histories. Given initial vertex u , a final exit ex in the same component, and a $k \geq 0$, let $q_{(u,ex)}^{k, \sigma, \tau}$ be the probability that, in $M_A^{\sigma, \tau}$, starting at initial state $\langle \epsilon, u \rangle$, we will reach a state $w \langle \epsilon, ex \rangle$ in at most k “steps” (i.e., where $|w| \leq k$). Let $q_{(u,ex)}^{*, \sigma, \tau} = \lim_{k \rightarrow \infty} q_{(u,ex)}^{k, \sigma, \tau}$ be the probability of ever terminating at ex , i.e., reaching $\langle \epsilon, ex \rangle$ (the limit exists: the sequence is monotonically non-decreasing & bounded by 1). Let $\mathbf{q}_{(u,ex)}^k = \max_{\sigma \in \Psi_1} \min_{\tau \in \Psi_2} q_{(u,ex)}^{k, \sigma, \tau}$ and let $\mathbf{q}_{(u,ex)}^* = \sup_{\sigma \in \Psi_1} \inf_{\tau \in \Psi_2} q_{(u,ex)}^{*, \sigma, \tau}$. Next, for a strategy $\sigma \in \Psi_1$, let $q_{(u,ex)}^{k, \sigma} = \min_{\tau \in \Psi_2} q_{(u,ex)}^{k, \sigma, \tau}$, and let $q_{(u,ex)}^{*, \sigma} = \inf_{\tau \in \Psi_2} q_{(u,ex)}^{*, \sigma, \tau}$. Lastly, given instead a strategy $\tau \in \Psi_2$, let $q_{(u,ex)}^{k, \tau} = \max_{\sigma \in \Psi_1} q_{(u,ex)}^{k, \sigma, \tau}$, and let $q_{(u,ex)}^{*, \tau} = \sup_{\sigma \in \Psi_1} q_{(u,ex)}^{*, \sigma, \tau}$.

From very general determinacy results (eg. Martin’s “Blackwell determinacy” [Mar98]) it follows that the games M_A are *determined*, meaning that $\sup_{\sigma \in \Psi_1} \inf_{\tau \in \Psi_2} q_{(u,ex)}^{*, \sigma, \tau} = \inf_{\tau \in \Psi_2} \sup_{\sigma \in \Psi_1} q_{(u,ex)}^{*, \sigma, \tau}$. Of course, finite SSGs are even *memorylessly determined* ([Con92]), meaning that the strategies of either player can be restricted to *memoryless strategies* which ignore the history prior to the current position, without harming the optimal outcome. As we shall see, 1-exit RSSGs exhibit memoryless determinacy in an even stronger sense, namely, the strategy is also independent of the call stack. This fails badly for multi-exit RMDPs, as we will see. We are interested in the following questions:

- (1) The *qualitative* termination problem: Is $\mathbf{q}_{(u,ex)}^* = 1$?
- (2) The *quantitative* termination problems: Given $r \in [0, 1]$, is $q_{(u,ex)}^* \geq r$? Is $q_{(u,ex)}^* = r$? Or we may wish to compute or approximate probabilities $q_{(u,ex)}^*$.

More generally, we can ask model checking questions, where, given a Σ -labeling of vertices, and e.g., an LTL formula φ over Σ , we ask what is the supremum probability with which player 1 can force the satisfaction of property φ ? We refrain from formal definitions due to space (see, e.g., [CY98, EY05b]). Our results for model checking will be negative: undecidability, stemming from the undecidability of termination problems for general RMDPs.

3 Systems of Nonlinear Min-max Equations for 1-Exit RSSGs

We generalize the monotone nonlinear system of equations for RMCs ([EY05a]) to monotone nonlinear min-max systems for 1-exit RSSGs, whose Least Fixed Point yields the desired probabilities $q_{(u,ex)}^*$. Let us use a variable $x_{(u,ex)}$ for

each unknown $q_{(u,ex)}^*$. We will often find it convenient to index the variables $x_{(u,ex)}$ according to a fixed order (say lexicographical), so we can refer to them also as x_1, \dots, x_n , with each $x_{(u,ex)}$ identified with x_j for some j . In this way we obtain a vector of variables: $\mathbf{x} = (x_1 \ x_2 \ \dots \ x_n)^T$.

Definition 1. *Given 1-exit RSSG $A = (A_1, \dots, A_k)$, we define a system of polynomial/min-max equations, S_A , over the variables $x_{(u,ex)}$, where $u \in Q_i$ and $ex \in Ex_i$, for $1 \leq i \leq k$. The system contains one equation of the form $x_{(u,ex)} = P_{(u,ex)}(\mathbf{x})$, for each variable $x_{(u,ex)}$. There are 5 cases to distinguish, based on what “type” of vertex u is:*

1. *Type I: $u = ex$. In this case: $x_{(ex,ex)} = 1$.*
2. *Type II: $\mathbf{pl}(u) = 0 \ \& \ u \in (N_i \setminus \{ex\}) \cup \text{Return}^i$: $x_{(u,ex)} = \sum_{\{v|(u,p, \cdot, v) \in \delta\}} p_{u,v} x_{(v,ex)}$. (If u has no outgoing transitions, this equation is by definition $x_{(u,ex)} = 0$.)*
3. *Type III: $u = (b, en)$ is a call port: $x_{((b,en),ex)} = x_{(en,ex')} \cdot x_{((b,ex'),ex)}$, where $ex' \in Ex_{Y(b)}$ is the unique exit of $A_{Y(b)}$.*
4. *Type IV: $\mathbf{pl}(u) = 1 \ \& \ u \in (N_i \setminus \{ex\}) \cup \text{Return}^i$: $x_{(u,ex)} = \max_{\{v|(u,\perp,v) \in \delta\}} x_{(v,ex)}$. (If u has no outgoing transitions, we define $\max(\emptyset) = 0$.)*
5. *Type V: $\mathbf{pl}(u) = 2$ and $u \in (N_i \setminus \{ex\}) \cup \text{Return}^i$: $x_{(u,ex)} = \min_{\{v|(u,\perp,v) \in \delta\}} x_{(v,ex)}$. (If u has no outgoing transitions, we define $\min(\emptyset) = 0$.)*

In vector notation, we denote $S_A = (x_j = P_j(\mathbf{x}) \mid j = 1, \dots, n)$ by: $\mathbf{x} = P(\mathbf{x})$.

Given 1-exit RSSG A , we can easily construct $\mathbf{x} = P(\mathbf{x})$ in linear time. We now identify a particular solution to $\mathbf{x} = P(\mathbf{x})$, called the *Least Fixed Point* (LFP) solution, which gives precisely the termination game values. For vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$, define the partial-order $\mathbf{x} \preceq \mathbf{y}$ to mean $x_j \leq y_j$ for every coordinate j . For $D \subseteq \mathbb{R}^n$, we call a mapping $H : \mathbb{R}^n \mapsto \mathbb{R}^n$ *monotone* on D , if: for all $\mathbf{x}, \mathbf{y} \in D$, if $\mathbf{x} \preceq \mathbf{y}$ then $H(\mathbf{x}) \preceq H(\mathbf{y})$. Define $P^1(\mathbf{x}) = P(\mathbf{x})$, and define $P^k(\mathbf{x}) = P(P^{k-1}(\mathbf{x}))$, for $k > 1$. Let $\mathbf{q}^* \in \mathbb{R}^n$ denote the n -vector $q_{(u,ex)}^*$ (using the same indexing as used for \mathbf{x}). For $k \geq 0$, let \mathbf{q}^k denote, similarly, the n -vector $q_{(u,ex)}^k$. Let $\mathbf{0}$ ($\mathbf{1}$) denote the n -vector consisting of 0 (respectively, 1) in every coordinate. Define $\mathbf{x}^0 = \mathbf{0}$, and for $k \geq 1$, define $\mathbf{x}^k = P(\mathbf{x}^{k-1}) = P^k(\mathbf{0})$.

Theorem 1. *Let $\mathbf{x} = P(\mathbf{x})$ be the system S_A associated with 1-exit RSSG A .*

1. *$P : \mathbb{R}^n \mapsto \mathbb{R}^n$ is monotone on $\mathbb{R}_{\geq 0}^n$. Hence, for $k \geq 0$, $\mathbf{0} \preceq \mathbf{x}^k \preceq \mathbf{x}^{k+1}$.*
2. *For all $k \geq 0$, $\mathbf{q}^k \preceq \mathbf{x}^{k+1} \preceq \mathbf{q}^2$.*
3. *$\mathbf{q}^* = P(\mathbf{q}^*)$. In other words, \mathbf{q}^* is a fixed point of the map P .*
4. *For all $k \geq 0$, $\mathbf{x}^k \preceq \mathbf{q}^*$.*
5. *For all $\mathbf{q}' \in \mathbb{R}_{\geq 0}^n$, if $\mathbf{q}' = P(\mathbf{q}')$, then $\mathbf{q}^* \preceq \mathbf{q}'$.*
In other words, \mathbf{q}^ is the Least Fixed Point, LFP(P), of $P : \mathbb{R}_{\geq 0}^n \mapsto \mathbb{R}_{\geq 0}^n$.*
6. *$\mathbf{q}^* = \lim_{k \rightarrow \infty} \mathbf{x}^k = \lim_{k \rightarrow \infty} \mathbf{q}^k$.*

The proofs are omitted due to space. They are similar to those of an analogous theorem in [EY05a] for nonlinear systems associated with RMCs, but some parts

are substantially more tricky because of the players. We sketch here the idea for part (5). Consider any fixpoint \mathbf{q}' of the equations, i.e., $\mathbf{q}' = P(\mathbf{q}')$. Let τ' be the (S&M) strategy for player 2 that always picks, at any state $\langle \beta, u \rangle$, for vertex $u \in \text{pl}^{-1}(2)$, the particular successor v of u such that $v = \arg \min_{\{v | (u, \perp, v) \in \delta\}} \mathbf{q}'_{(v, ex)}$ (breaking ties, say, lexicographically). Then we prove a lemma stating that, for all strategies $\sigma \in \Psi_1$ of player 1, and for all $k \geq 0$, $\mathbf{q}^{k, \sigma, \tau'} \preceq \mathbf{q}'$. The lemma implies that $\mathbf{q}^{*, \sigma, \tau'} = \lim_{k \rightarrow \infty} \mathbf{q}^{k, \sigma, \tau'} \preceq \mathbf{q}'$. This holds for any strategy $\sigma \in \Psi_1$. Therefore, $\sup_{\sigma \in \Psi_1} q_{(u, ex)}^{*, \sigma, \tau'} \leq \mathbf{q}'_{(u, ex)}$, for every vertex u . Thus, by the determinacy of RSSG games, it follows that $\mathbf{q}^*_{(u, ex)} = \inf_{\tau \in \Psi_2} \sup_{\sigma \in \Psi_1} q_{(u, ex)}^{*, \sigma, \tau} \leq \sup_{\sigma \in \Psi_1} q_{(u, ex)}^{*, \sigma, \tau'} \leq \mathbf{q}'_{(u, ex)}$, for all vertices u . In other words, $\mathbf{q}^* \preceq \mathbf{q}'$. \square

4 S&M Determinacy

We now identify a very restricted kind of strategy that suffices as an optimal strategy in 1-exit RSSGs. Call a strategy *Stackless & Memoryless (S&M)* if it is not only independent of the history of the game, but also independent of the current call stack, i.e., only depends on the current vertex. (See also [ATM03], where such strategies are called *modular* strategies.)

Corollary 1. *In every 1-exit RSSG termination game, player 2 (the minimizer) has an optimal S&M strategy.*

Proof. Consider the strategy τ' in the proof of part (5) of Theorem 1, chosen not for just any fixed point \mathbf{q}' , but for \mathbf{q}^* itself. \square

Far less trivially, we establish next that player 1 (the maximizer) also has an optimal S&M strategy and thus the game is *S&M-determined*, meaning both players have optimal S&M strategies. (Note that the game is not symmetric with respect to the two players.)

Theorem 2. *Every 1-exit RSSG termination game is S&M-determined.*

Although the statement is intuitive, the proof is quite nontrivial and delicate; the full proof is given in the full paper. We sketch the approach here. By Corollary 1, we only need to show that player 1 has an optimal S&M strategy. Let σ be any S&M strategy for player 1, and let $\mathbf{q}^{*, \sigma} = \inf_{\tau \in \Psi_2} \mathbf{q}^{*, \sigma, \tau}$. If $\mathbf{q}^{*, \sigma}$ is a fixpoint of the equations then it follows that it is the least fixpoint and σ is optimal. On the other hand, it can be shown that $\mathbf{q}^{*, \sigma}$ satisfies all the equations except possibly for some type IV equations. We argue that if u is such a vertex (belonging to player 1) whose equation is violated, then switching to another strategy σ' where u picks another successor leads to a strictly better strategy than σ (for any strategy of player 2). This is the heart of the proof. We parameterize the game with respect to the value t at vertex u , and we express the optimal values of the other vertices z (for all strategies τ of player 2) as functions $f_z(t)$. We then carefully analyze the properties of these functions, which are power series in t

Fig. 1. 2-exit RMDPs: no optimal strategy exists for terminating at ex_1

with non-negative coefficients, and we analyze their fixpoints, and conclude that switching the choice at vertex u leads to a strategy σ' that has at least as great value as σ at every vertex, and strictly better at u . We repeat the process until we arrive at a S&M strategy σ^* whose probabilities satisfy all the equations, and hence it is optimal. We refer to the full paper for the details. \square

Already for 2-exit RMDP termination, not only are there no optimal S&M strategies for player 1, there are in general no optimal strategies at all! Figure 1 illustrates this. In this 2-exit maximizing RMDP the *supremum* probability of terminating at exit ex_1 starting from en is 1. However, no strategy player 1 achieves this. Specifically, for $n \geq 0$, the strategy $L^n R$ terminates at ex_1 with probability $(1 - \frac{1}{2}^n)$. Note that any S&M strategy for player 1 would yield probability 0 of terminating at ex_1 , so such strategies are the worst possible.

5 Termination Problems for 1-Exit RMDPs & RSSGs

Using Corollary 1 and Theorem 2, and results from [EY05a], we can show the following results for qualitative termination of 1-exit RMDPs and 1-exit RSSGs:

Theorem 3.

1. We can decide in P -time if the value of a 1-exit RSSG termination game (and optimal termination probability in a maximizing or minimizing 1-exit RMDP) is exactly 0.
2. We can decide in NP whether the maximum probability of termination in a maximizing 1-exit RMDP is exactly 1, and in $coNP$ whether the minimum probability of termination in a minimizing 1-exit RMDP is exactly 1.
3. Deciding whether a 1-exit RSSG termination game has value 1 is in $\Sigma_2^P \cap \Pi_2^P$.
4. For 1-exit $1r$ -RMDPs we can compute the exact optimal (rational) termination probability in P -time, and for 1-exit $1r$ -RSSGs we can compute the exact optimal (rational) value of the termination game in $NP \cap co-NP$.

Part (1) is done via a fixpoint algorithm; parts (2) and (3) involve guessing the optimal S&M strategies and verifying the optimality with the appropriate complexity using techniques from [EY05a]; part (4) exploits the fact that for 1-exit $1r$ -RMDPs & $1r$ -RSSGs the non-linear system $\mathbf{x} = P(\mathbf{x})$ can be decomposed

into linear parts that can be solved sequentially by linear programming (and by guessing strategies for RSSGs); see the full paper. \square

We next show that quantitative termination questions for 1-exit RMDPs and 1-exit RSSGs can be answered in PSPACE by appealing to the deep algorithms for deciding the *Existential Theory of Reals*, $\mathbf{ExTh}(\mathbb{R})$. A first-order sentence in the theory of reals is formed from quantifiers and boolean connectives over a vocabulary with “atomic predicates” of the form: $f_i(\mathbf{x})\Delta 0$, where the f_i , are multi-variate polynomials with rational coefficients over the variables $\mathbf{x} = x_1, \dots, x_n$, and Δ is any comparison operator: $=, <, \text{ or } \leq$. The *existential theory of reals*, $\mathbf{ExTh}(\mathbb{R})$, consists of prenex sentences: $\exists x_1, \dots, x_n R(x_1, \dots, x_n)$, where R is a boolean combination of “atomic predicates”. Beginning with Tarski, algorithms for deciding the theory of reals and fragments such as $\mathbf{ExTh}(\mathbb{R})$ have been deeply investigated. Current, it is known that $\mathbf{ExTh}(\mathbb{R})$ can be decided in PSPACE [Can88, Ren92, BPR96]. Furthermore, it can be decided in exponential time where the exponent depends (linearly) only on the number of variables; hence for a fixed number of variables the time is polynomial.

Suppose we want to decide whether a vector $\mathbf{c} = [c_1, \dots, c_n]^T$ of rational numbers is $\text{LFP}(P)$, where $\mathbf{x} = P(\mathbf{x})$ is the system of equations for a given 1-exit RSSG. Consider the sentence:

$$\varphi \equiv \exists x_1, \dots, x_n \bigwedge_{i=1}^n (P_i(x_1, \dots, x_n) = x_i) \wedge \bigwedge_{i=1}^n (x_i = c_i)$$

φ is true iff $\mathbf{c} = P(\mathbf{c})$. For type I, II, and III nodes, P_i is a polynomial. It remains to show how to encode, in arithmetic, the predicate “ $P_i(x_1, \dots, x_n) = x_i$ ” in the case (IV) where $P_i(x_1, \dots, x_n) = \max_{j \in J} x_j$, and in the case (V) where $P_i(x_1, \dots, x_n) = \min_{j \in J} x_j$, for some subset $J \subseteq \{1, \dots, n\}$. For type IV nodes, note that $x_i = \max_{j \in J} x_j$ iff $\bigwedge_{j \in J} x_i \geq x_j \wedge (\bigvee_{j \in J} x_i \leq x_j)$. Likewise, for type V nodes, $x_i = \min_{j \in J} x_j$ iff $\bigwedge_{j \in J} x_i \leq x_j \wedge (\bigvee_{j \in J} x_i \geq x_j)$. Thus, we can encode the predicates $x_i = P_i(x_1, \dots, x_n)$ as a boolean combination of quantifier-free predicates, and we can encode the sentence φ in $\mathbf{ExTh}(\mathbb{R})$. To guarantee that $\mathbf{c} = \text{LFP}(P)$, we need in addition to check the following sentence:

$$\psi \equiv \exists x_1, \dots, x_n \bigwedge_{i=1}^n (P_i(x_1, \dots, x_n) = x_i) \wedge \bigwedge_{i=1}^n (0 \leq x_i) \wedge \bigvee_{i=1}^n (x_i < c_i)$$

ψ is false iff there is no solution $\mathbf{z} \in \mathbb{R}_{\geq 0}^n$ to $\mathbf{x} = P(\mathbf{x})$ such that $\mathbf{c} \not\leq \mathbf{z}$. Hence, to decide whether $\mathbf{c} = \text{LFP}(P)$, we only need two queries to $\mathbf{ExTh}(\mathbb{R})$. Namely, we check that φ is true, and hence $\mathbf{c} = P(\mathbf{c})$, and that ψ is false, and hence $\mathbf{c} = \text{LFP}(P)$. If we only want to check an inequality $\mathbf{q}_j^* \leq c_j$, then let φ' be φ with the last conjunction of equations replaced by $\bigwedge_{i=1}^n (0 \leq x_i) \wedge (x_j \leq c_j)$. Applying the results on $\mathbf{ExTh}(\mathbb{R})$, we obtain the following:

Theorem 4. *Given a 1-exit RSSG A and a vector of rational probabilities \mathbf{c} , there is a PSPACE algorithm to decide whether $\mathbf{q}^* = \mathbf{c}$, as well as to decide whether $\mathbf{q}_j^* \Delta c_j$, for any comparison operator Δ . Moreover, the running time is $O(|A|^{O(1)} \cdot 2^{O(n)})$ where n is the number of variables in $\mathbf{x} = P(\mathbf{x})$. Hence the running time is polynomial if n is bounded.*

Since $\mathbf{0} \leq \text{LFP}(P) \leq \mathbf{1}$, we can use such queries to $\mathbf{ExTh}(\mathbb{R})$ in a “binary search” to “narrow in” on the value of each coordinate of $\text{LFP}(P)$. Via obvious modifications of sentences like ψ , we can gain one extra bit of precision on the exact value of each c_i with one extra query to $\mathbf{ExTh}(\mathbb{R})$. This yields:

Theorem 5. *Given 1-exit RSSG A and a number j in unary, there is an algorithm that approximates every coordinate of \mathbf{q}^* to within j bits of precision in PSPACE. Moreover, the running time is $O(j \cdot |A|^{O(1)} \cdot 2^{O(n)})$, where n is the number of variables in $\mathbf{x} = P(\mathbf{x})$.*

6 Multi-exit RMDP Termination and 1-Exit RMDP Model Checking: Undecidability

We next show strong undecidability results for RMDPs, and thus for RSSGs.

Theorem 6. *Given a multi-exit linearly-recursive RMDP, A , entry en and exit ex , it is undecidable whether $q_{(en,ex)}^* = 1$. This is so even when the number of exits in each component of A is bounded by a fixed constant. Furthermore, there is no algorithm that approximates the probability $q_{(en,ex)}^*$ within any constant (multiplicative) factor. In particular:*

1. *For any fixed rational ϵ with $0 < \epsilon < 1$, given 1r-RMDP A with only one component such that either $q_{(en,ex)}^* > 1 - \epsilon$ or $q_{(en,ex)}^* < \epsilon$, it is undecidable to distinguish which is the case.*
2. *For any fixed rational ϵ with $0 < \epsilon < 1$, given a 1r-RMDP A with only two components such that either $q_{(en,ex)}^* = 1$ or $q_{(en,ex)}^* < \epsilon$, it is undecidable to distinguish which is the case.*

We have two proofs: one is a reduction from the halting problem for 2-counter machines. The second is a reduction from the emptiness problem for Probabilistic Finite Automata (PFAs). The latter reduction is simpler and connects RMDPs to the well-studied area of PFAs, allowing us to leverage extensive research in that area [Paz71, CL89, BC03]. We show that PFAs are, in effect, a special case of RMDPs. Recall, a PFA is a FA whose transitions from a state on a given input are probabilistic. The PFA emptiness problem is to decide for a given PFA A and threshold λ , whether there is a word accepted by A with probability $> \lambda$. It is undecidable in strong ways ([Paz71, CL89, BC03]). Our reduction constructs from a PFA A a 1r-RMDP whose termination probability under the optimal strategy is precisely the supremum probability of acceptance of any word by A . Please see the full paper for details. With a modified construction we show:

Theorem 7. *Qualitative & quantitative LTL model checking for 1-exit 1r-RMDPs is undecidable; this holds even for a fixed property; moreover, the optimum probability of the property can't be approximated within any constant factor.*

Acknowledgement. Thanks to Amir Pnueli for asking us about 1r-RMCs.

Decidability in Syntactic Control of Interference

J. Laird

Dept. of Informatics, University of Sussex, UK
jim1@sussex.ac.uk

Abstract. We investigate the decidability of observational equivalence and approximation in “Syntactic Control of Interference” (SCI). By associating denotations of terms in an inequationally fully abstract model of finitary basic SCI with multitape finite state automata, we show that observational approximation is not decidable (even at first order), but that observational equivalence is decidable for all terms. We then consider the same problems for basic SCI extended with non-local control in the form of backwards jumps. We show that both observational approximation and observational equivalence are decidable in this language by describing a fully abstract games model in which strategies are regular languages.

1 Introduction

Reynolds’ *Syntactic Control of Interference* [18] is a prototypical functional-imperative language in which covert *interference* between functions and their arguments is prevented by the use of an affine typing discipline. By eliminating phenomena such as aliasing, interference control should make it easier to predict program behaviour. Here, we shall investigate decidability of properties of observational approximation and equivalence for terms over finite datatypes.

The full SCI system contains a notion of passive type (as do related languages with interference control such as SCIR [15]); the programs (and contexts) typable at purely passive types are essentially those of PCF, and equivalence at such types is therefore not decidable [9]. Consequently, we restrict attention to the active types or *basic* SCI, which may be thought of as a common core for interference controlled languages. Basic SCI is essentially a subsystem of Idealized Algol, for which a hierarchy of decidability results has recently been developed, based on “algorithmic game semantics” [3]: associating the denotation of each term as a strategy in a fully abstract game semantics with a formal language. These techniques have been used to show that observational equivalence and approximation in (finitary) Idealized Algol are decidable at third-order types — by showing that the denoting strategies are recognized by deterministic pushdown automata [14] — but not at fourth order [13]. The latter undecidability result depends crucially on the nesting of function calls, which is not possible in SCI.

These results provide motivation and a methodological basis for investigating observational equivalence in basic SCI, but one obstacle is that game semantics appears to be “too sequential” to capture this directly. (McCusker and Wall

have described a games model [12], but the associated full abstraction result depends on a quotient operation.) However, basic SCI has an appealingly simple semantics based on sets and relations, described by Reddy [17], and investigated further by McCusker, who proved that it is fully abstract [10]. We show that the denotations of first-order terms in this semantics correspond to *multitape* deterministic finite state automata, as introduced by Rabin and Scott in 1959 [16]. It is straightforward to show that containment of 2-tape deterministic FSA is undecidable [7]. By contrast, the problem of decidability of equivalence for all multitape deterministic FSA remained open for thirty years, before being resolved (affirmatively) by Harju and Karhumäki [4]. These results have direct implications for basic SCI: observational equivalence (equivalence of denotations) is decidable at first order but observational approximation (inclusion of denotations) is not (even though all first-order terms of Idealized Algol are typable in SCI (up to β -equivalence) — the point being that the possible *observations* of first-order terms are more restricted in SCI). Although denotations of terms at higher-order types do not correspond directly to multitape automata, we show that there is a “definable monomorphism” from every type to a first-order type, and that equivalence is therefore decidable at *all* types.

The undecidability of observational approximation (and associated results, such as the undecidability of equivalence in a non-deterministic variant of the language) raises the question of whether deciding such properties in the presence of interference control is always difficult. The problem in basic SCI is in some respects analogous to the situation in PCF: whilst it is a sequential language, it is not *observably sequential*; different sequentializations of a program may approximate each other (for example, $\lambda x.\lambda y.x; y$ is equivalent in SCI to $\lambda x.\lambda y.y; x$). In the case of PCF, Cartwright and Felleisen [2] have shown that adding simple non-local control operators results in a language (“observably sequential PCF”) with a finitely presentable fully abstract model, for which equivalence and approximation are therefore decidable. Pursuing the analogy between PCF and SCI, we obtain an observably sequential version of the latter by adding backwards jumps to labelled points. We give a regular game semantics for this language and show that it is inequationally fully abstract (although it contains compact elements which are not definable) and that observational approximation is therefore decidable.

2 Basic SCI

The syntax of basic SCI [18] is, in essence, the same as that of Idealized Algol [19] but the typing rules are more restrictive. In our finitary version of the language we assume a base type \underline{n} (of expressions) for each natural number n , containing the numerals $0, \dots, n - 1$, and generate types using the constructors \rightarrow (affine function-space) and $\&$ (additive product). The depth or order of a type (and the corresponding closed terms) is defined: $o(\underline{n}) = 0$, $o(S\&T) = \max\{o(S), o(T)\}$, $o(S \rightarrow T) = \max\{o(S) + 1, o(T)\}$.

Typing judgements are based on the affine λ -calculus with pairing:

$$\frac{}{x:T, \Gamma \vdash x:T} \qquad \frac{\Gamma, x:S, \Delta \vdash M:T}{\Gamma, \Delta, x:S \vdash M:T}$$

$$\frac{\Gamma \vdash M:S \quad \Gamma \vdash N:T}{\Gamma \vdash \langle M, N \rangle : S \& T} \quad \frac{\Gamma, x:S \vdash M:T}{\Gamma \vdash \lambda x. M : S \rightarrow T} \quad \frac{\Gamma \vdash M : S \rightarrow T \quad \Delta \vdash N : S}{\Gamma, \Delta \vdash M N : T}$$

For the sake of concision, we work with a lean syntax which can be easily sugared up to more closely resemble that of Idealized Algol. We write T^n for the n -fold product of copies of T (setting $T^0 = \underline{1}$). We represent the type $\mathbf{var}[n]$ of imperative variables with values in \underline{n} as the type $\underline{n} \& \underline{1}^n$ (the product of the types of its “methods”, assignment and dereferencing).¹ We extend the term formation rules with the following constants (we omit parallel composition as it is observationally equivalent to sequential composition):

Projections $\pi_l : A \& B \rightarrow A$, $\pi_r : A \& B \rightarrow B$ yielding $\pi_i : A^n \rightarrow A$ for $i < n$.

Numerals $i : \underline{n}$ for $i < n$.

Case statements $\mathbf{case}_{n,m} : \underline{n} \& \underline{m}^n \rightarrow \underline{m}$. from which we derive $\mathbf{case}_{n,T} : \underline{n} \& T^n \rightarrow T$ for arbitrary T .

Loops $\mathbf{while0} : \underline{m+1} \rightarrow \underline{m}$. We write Ω for $\mathbf{while0} 0$.

New variable declaration $\mathbf{new} : (\mathbf{var}[n] \rightarrow \underline{m}) \rightarrow \underline{m}$.

If $M : \underline{1}$, we write $\mathbf{case} \langle M, N \rangle$ as $M; N$, and if $M : \underline{0}$ we write $\mathbf{abort} M$ for $\mathbf{case} \langle M, 0 \rangle$. Given $M : \mathbf{var}[n]$, we may write $!M$ for $\pi_l M$ and $M := N$ for $\mathbf{case} \langle N, \pi_r M \rangle$.

The “small-step” operational semantics is based on the evaluation contexts:

$$E[\cdot] ::= [\cdot] \mid E[\cdot] M \mid \pi_i E[\cdot] \mid \mathbf{case} E[\cdot] \mid \mathbf{case} \langle E[\cdot], M \rangle \mid \mathbf{while0} E[\cdot]$$

and the following reductions for pairs M, \mathcal{E} of a term (of ground type) and a store (a set of pairs $\langle a, v \rangle$ of location names and natural numbers).

$$\begin{aligned} E[(\lambda x. M) N], \mathcal{E} &\longrightarrow E[M[N/x]], \mathcal{E} \\ E[\pi_i \langle M_1, M_2 \rangle] &\longrightarrow M_i, \mathcal{E} \\ E[\mathbf{case} \langle i, M \rangle], \mathcal{E} &\longrightarrow E[\pi_i M] \\ E[\mathbf{while0} M] &\longrightarrow E[\mathbf{case} \langle M, \langle \mathbf{while0} M, 0, \dots, 0 \rangle \rangle] \\ E[\mathbf{new} M], \mathcal{E} &\longrightarrow E[M a], \mathcal{E} \cup \{ \langle a, 0 \rangle \} \quad a \notin \pi_1(\mathcal{E}) \\ E[\pi_l a], \mathcal{E} &\longrightarrow E[v], \mathcal{E} \quad \langle a, v \rangle \in \mathcal{E} \\ E[\pi_i (\pi_l a)], \mathcal{E} &\longrightarrow E[0], \mathcal{E} [a \mapsto i] \end{aligned}$$

We write $M \Downarrow$ if evaluation of M, \emptyset terminates, and so define standard notions of observational approximation and equivalence:

$M \lesssim N$ if $C[M] \Downarrow$ implies $C[N] \Downarrow$, and $M \simeq N$ if $M \lesssim N$ and $N \lesssim M$.

¹ So this version of the language implicitly contains “bad variables”. This does not affect the results given here for basic SCI: approximation is shown to be undecidable for the \mathbf{var} -free types, whilst McCusker has shown that observational equivalence in basic SCI with bad variables is conservative over equivalence in the language without bad variables [11].

2.1 Fully Abstract Semantics of Basic SCI

We briefly describe the fully abstract model of basic SCI, based on sets and relations, which we shall use to prove our results. This is essentially a version of Reddy's semantics [17], simplified and proved to be fully abstract by McCusker [10]. We may present this model as a typed **BCK**-algebra [5] with products:

- A collection of objects and a set $\text{el}(\alpha)$ of elements for each object. In the relational model, objects are sets and $\text{el}(\alpha) = \mathcal{P}(\alpha)$.
- Objects $\alpha \rightarrow \beta$ and $\alpha \& \beta$ for each pair of objects α, β . In the relational model, we define $\alpha \rightarrow \beta$ to be the set $\alpha^* \times \beta$ (where α^* is the set of finite words over α) and $\alpha \& \beta$ to be the disjoint union $\alpha + \beta = \{e^l \mid e \in \alpha\} \cup \{e^r \mid e \in \beta\}$. So in the relational model, elements of $\alpha \rightarrow \beta$ are relations between α^* and β , and elements of $\alpha \& \beta$ correspond to pairs of elements from α and β .
- An application operation — a function $\cdot : \text{el}(\alpha \rightarrow \beta) \times \text{el}(\alpha) \rightarrow \text{el}(\beta)$. In the relational model $X \cdot Y = \{z \in \beta \mid \exists \mathbf{y} \in Y^*. \langle \mathbf{y}, z \rangle \in X\}$.
- For each α, β, γ , elements $\mathbf{B} \in \text{el}((\beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \gamma)$, $\mathbf{C} \in \text{el}((\alpha \rightarrow \beta \rightarrow \gamma) \rightarrow \beta \rightarrow \alpha \rightarrow \gamma)$, $\mathbf{T} \in \text{el}(\alpha \rightarrow \beta \rightarrow \alpha \& \beta)$, $\mathbf{P} \in \text{el}((\alpha \rightarrow \beta) \& (\alpha \rightarrow \gamma) \rightarrow \alpha \rightarrow \beta \& \gamma)$, $\pi_l \in \text{el}(\alpha \& \beta \rightarrow \alpha)$ and $\pi_r \in \text{el}(\alpha \& \beta \rightarrow \beta)$ satisfying the axioms:

$$\mathbf{B} \cdot x \cdot y \cdot z = x \cdot (y \cdot z),$$

$$\mathbf{C} \cdot x \cdot y \cdot z = x \cdot z \cdot y$$

$$\pi_l \cdot (\mathbf{T} \cdot x \cdot y) = x \text{ and } \pi_r \cdot (\mathbf{T} \cdot x \cdot y) = y$$

$$\mathbf{P} \cdot (\mathbf{T} \cdot x \cdot y) \cdot z = \mathbf{T} \cdot (x \cdot z) \cdot (y \cdot z)$$

(note that we may define $\mathbf{K} \in \text{el}(\alpha \rightarrow \beta \rightarrow \alpha)$ to be $\mathbf{B} \cdot (\mathbf{B} \cdot \pi_r) \cdot \mathbf{T}$). In the relational model we define e.g. $\mathbf{B} \in \text{el}((\beta \rightarrow \gamma) \rightarrow (\alpha \rightarrow \beta) \rightarrow \alpha \rightarrow \gamma) =$

$$\{\langle \langle \mathbf{b}, c \rangle, \langle e, \langle \mathbf{a}, c \rangle \rangle \rangle \mid \mathbf{a} \in \alpha^*, \mathbf{b} \in \beta^*, c \in \gamma, e \in (\alpha^* \times \beta)^*. e \downarrow \alpha = \mathbf{a} \wedge e \downarrow \beta = \mathbf{b}\}$$

BCK-algebras yield an interpretation of *derivations* in the affine λ -calculus (as standard combinatory algebras do for the λ -calculus), and the extension with products is straightforward. Thus to interpret basic SCI, we define $\llbracket n \rrbracket = \llbracket n \rrbracket = \{i \mid i < n\}$, and assign meanings to the remaining constants as follows:

- $\llbracket \text{case}_{m,n} \rrbracket = \{\langle i^l j^{ir}, j \rangle \mid i < m \wedge j < n\}$,
- $\llbracket \text{while}0 \rrbracket = \{\langle 0^*(n+1), 0 \rangle \mid s \in \{i < n \mid i \neq 0\}^*\}$,
- $\llbracket \text{new} \rrbracket = \{\langle \langle (0^l)^* s, j \rangle, j \rangle \mid s \in \{(0^i)^l (i^r)^* \mid i < n\}^*\}$

Concretely, this interpretation is equivalent to Reddy's and McCusker's (for closed terms), and therefore fully abstract.

Theorem 1 (McCusker [10]). $M \lesssim N$ if and only if $\llbracket M \rrbracket \subseteq \llbracket N \rrbracket$.

Note that the semantics does not have the “finite definability” property: there are compact elements which are not the denotation of any term. In particular, we may interpret a non-deterministic choice between any two terms of the same type as the union of their denotations.

3 Multitape Automata and SCI Terms

Our definition of deterministic multitape finite state automata is tailored for establishing a correspondence with the relational model. However, it is straightforward to show that it yields the same class of languages as the original [16].

A deterministic n -tape automaton $\alpha = (C_0, C_1, \dots, C_n, F, s_0, \delta)$ over an alphabet $\Sigma = \{0, \dots, k\}$ consists of disjoint sets of states C_0, C_1, \dots, C_n, F , an initial state s_0 and a (partial) transition function $\delta : (\Sigma \cup \{\varepsilon\}) \times S \rightarrow S$, where $S = C_0 \cup \dots \cup C_n \cup F$. C_0 consists of states in which (only) a ε -transition may be performed, C_i of states in which a symbol is read from tape i (for $0 < i \leq n$), and F of final states. We say that α accepts a tuple of tapes if it consumes all of them to reach a final state. Formally, for each final state f , we may say that the set of pairs $A_f \subseteq (\Sigma^*)^n \times S$ of tuples and states accepted in state f is the least set such that $\langle \langle \varepsilon, \dots, \varepsilon \rangle, f \rangle \in A_f$, and if $\langle \langle t_1, \dots, t_n \rangle, s \rangle \in A_f$, $s' \in C_i$ and $\delta(m, s') = s$ then if $i = 0$ then $\langle \langle t_1, \dots, t_n \rangle, s' \rangle \in A_f$ and if $i > 0$ then $\langle \langle t_1, \dots, mt_i, \dots, t_n \rangle, s' \rangle \in A_f$.

We write $\mathcal{L}(\alpha)$ for the set $\{x \mid \exists f \in F. \langle x, s_0 \rangle \in A_f\}$ of tuples accepted by α .

There is a natural connection between multitape FSA and SCI terms at first-order types, based on the fact that the denotations of the latter are sets of tuples of words over a finite alphabet.

Proposition 1. *For any 2-tape deterministic FSA α over the alphabet $\{0, \dots, m - 1\}$ there is a (closed) term $M_\alpha : \underline{m} \rightarrow \underline{m} \rightarrow \underline{1}$ such that $\langle s, t \rangle \in L(\alpha) \Leftrightarrow \langle s, \langle t, 0 \rangle \rangle \in \llbracket M_\alpha \rrbracket$.*

Proof. Every deterministic n -tape FSA is equivalent to one with no ε transitions, so we assume C_0 is empty. We number the states of α as $0, \dots, k - 1$, with 0 being initial. We assume terms $\mathbf{state} : \underline{k} \rightarrow \underline{3}$ such that $\llbracket \mathbf{state} s \rrbracket = 0$ if $s \in F$ and $\llbracket \mathbf{state} s \rrbracket = i$ if $s \in C_i$, and $\mathbf{tr} : \underline{k} \rightarrow \underline{k}^m$ such that $\llbracket \pi_i(\mathbf{tr} j) \rrbracket = \delta(j, i)$. M_α may then be defined as follows:

$$\lambda x. \lambda y. \mathbf{new} \lambda s. \mathbf{while0} (\mathbf{case} \langle \mathbf{state} !s, \langle 1, s := \mathbf{case} \langle x, \mathbf{tr} !s \rangle, s := \mathbf{case} \langle y, \mathbf{tr} !s \rangle \rangle \rangle)$$

So we may show undecidability of inclusion of denotations in the fully abstract model, and hence of observational approximation in SCI via the following result, which may be proved via an encoding of Post's correspondence problem.

Proposition 2. [7] *Inclusion of deterministic 2-tape FSA is undecidable.*

Corollary 1. *Observational approximation in SCI is undecidable at first-order.*

Since $M \lesssim N$ if and only if $M \mathbf{or} N \simeq N$, this entails that observational equivalence (w.r.t. may-testing) in SCI with erratic choice is undecidable at first order. The denotations of first-order terms *without loops* are finite sets, and therefore approximation for such terms is decidable at first-order. However, we can simulate any 2-tape FSA as a term of type $(\underline{1}^n \rightarrow \underline{1}) \rightarrow (\underline{1}^n \rightarrow \underline{1}) \rightarrow \underline{1}$ (as in Proposition 1) without using the $\mathbf{while0}$ constant, and so approximation is undecidable at second order for the loop-free language.

The situation with respect to *equivalence* of multitape automata (and hence, as we shall show, observational equivalence of SCI) is different.

Theorem 2 (Harju and Karhumäki [4]). *Equivalence of n -tape deterministic finite state automata is decidable for all n .*

To use this result to show decidability of SCI equivalence, we prove a converse to Proposition 1: the denotation of every first-order term corresponds to the language accepted by a multitape automaton.

Proposition 3. *For each term $x_1 : T_1, \dots, x_n : T_n \vdash M : \underline{m}$, where each T_i is a product of ground types, there is a deterministic n -tape FSA with final states $F = f_0, \dots, f_{m-1}$ which accepts $\langle s_1, \dots, s_n \rangle$ in final state f_i if and only if $\langle \langle s_1, \dots, s_n \rangle, i \rangle \in \llbracket M \rrbracket$.*

Proof. We may show using a reducibility argument that every first-order term is reducible to a $\beta\pi$ -normal form (i.e. no subterms of the form $(\lambda x.P)Q$ or $\pi_i \langle M, N \rangle$). So we assume that M is $\beta\pi$ -normal, and define an n -tape deterministic automaton $(C_0^M, \dots, C_n^M, F, s_0^M, \delta^M)$ with the additional property that if $T_i = m_1 \& \dots \& m_k$ then for any state $s \in C_i^M$, if $\delta^M(v^i, s)$ and $\delta^M(w^j, s)$ are both defined then $i = j$.

- If $M = i$, then $C_j^M = \emptyset$ for all j , $s_0^M = f_i$ and $\delta^M = \emptyset$.
- If $M = \pi_j(x_i)$, then $C_i^M = \{s\}$, $C_j^M = \emptyset$ for $j \neq i$, $s_0^M = s$,
 $\delta(l^k, s_0) = f_i$ if $k = j$, and $\delta(m, s)$ is undefined otherwise.
- If $M = \mathbf{case} \langle L, N_0, \dots, N_{k-1} \rangle$ then $C_i^M = C_i^L + (C_i^{N_0} + \dots + C_i^{N_{k-1}})$,
 $s_0^M = (s_0^L)^l$ and
 $\delta^M(m, s^l) = (s_0^N)^{ir}$ if $\delta^L(m, s) = f_i$, $\delta^M(m, s^l) = (\delta^L(m, s))^l$ otherwise,
 $\delta^M(m, s^{ir}) = f_j$ if $\delta^N(m, s) = f_j$, $\delta^M(m, s^{ir}) = (\delta^N(m, s))^{ir}$ otherwise.
- If $M = \mathbf{while0} N$ then $C_i^M = C_i^N$ for each i , $s_0^M = s_0^N$,
 $\delta^M(m, s) = s_0^N$ if $\delta^N(m, s) = f_0$ and $\delta^M(m, s) = \delta^N(m, s)$, otherwise.
- If $M = \mathbf{new} \lambda x_j : \mathbf{var}[n].N$, then $C_0^M = (C_0^N \cup C_i^N) \times [n]$ and $C_k^M = C_k^N \times [n]$
for $k \notin \{0, j\}$, $s_0^M = \langle s_0^L, 0 \rangle$ and
 $\delta^M(\varepsilon, \langle s, i \rangle) = \langle s', i \rangle$ if $s \in C_j^N$ and $\delta^N(i^l, s) = s'$,
 $\delta^M(\varepsilon, \langle s, i \rangle) = \langle s', j \rangle$ if $s \in C_j^N$ and $\delta(0^{ir}, s) = s'$,
 $\delta^M(m, \langle s, i \rangle) = \langle \delta^N(m, s), i \rangle$, otherwise.

Corollary 2. *Observational equivalence in basic SCI is decidable at first-order.*

At higher types, denotations no longer consist of tuples of words and so we cannot decide observational equivalence between terms at these types simply by constructing multitape automata which recognize their denotations. However, we will show that we can associate a first-order term (and hence a multitape automaton) to each higher-order term in a way which reflects observational equivalence, which is therefore decidable at all types.

Definition 1. *A definable monomorphism between types S and T is a term $\mathbf{mono} : S \rightarrow T$ such that $\llbracket \mathbf{mono} \rrbracket \cdot e = \llbracket \mathbf{mono} \rrbracket \cdot e'$ implies $e = e'$.*

By full abstraction, for any $M, N : S$ we have $M \simeq N$ iff $\llbracket M \rrbracket = \llbracket N \rrbracket$ iff $\llbracket \text{mono} \rrbracket \cdot \llbracket N \rrbracket = \llbracket \text{mono} \rrbracket \cdot \llbracket N \rrbracket$ iff $\text{mono } N \simeq \text{mono } N$. Thus we can prove that equivalence is decidable for terms of type S by showing that there is a definable monomorphism from S to some first-order type.

First, we observe that we may restrict attention to *functional* types — i.e. types which do not contain any instances of the product construction. A *definable retraction* between types S and T is a pair of terms $\text{in} : S \rightarrow T$ and $\text{out} : T \rightarrow S$ such that $\llbracket \lambda x. \text{in} (\text{out } x) \rrbracket = \llbracket \lambda x. x \rrbracket$. Clearly, in is a monomorphism. We note also that if there is a definable retraction from R to R' and from S to S' then there are definable retractions from $S \rightarrow R$ to $S' \rightarrow R'$ and from $S \& R$ to $S' \& R'$.

Proposition 4. *Given functional types S, T there is a functional type $\text{prod}(S, T)$ (of order $\max\{o(S), o(T), 1\}$) such that $S \& T$ is a definable retract of $\text{prod}(S, T)$.*

Proof. is by induction on $o(S) + o(T)$. For the base case, we have $S = \underline{m}, T = \underline{n}$ for some m, n . We define $\text{prod}(S, T) = \underline{2} \rightarrow \max\{m, n\}$, $\text{in} = \lambda x. \lambda y. \text{case } \langle y, x \rangle$ and $\text{out} = \lambda x. \langle x \ 0, x \ 1 \rangle$. For the inductive case, suppose $T = U \rightarrow V$. Then $S \& T \sqsubseteq (U \rightarrow S) \& (U \rightarrow V) \cong U \rightarrow (S \& V) \sqsubseteq U \rightarrow \text{prod}(S, V) =_{df} \text{prod}(S, T)$.

Corollary 3. *For every type T there exists a functional type \overline{T} of order at most $o(T) + 1$ and a definable retraction from T to \overline{T} .*

We now define monomorphisms from higher-order to lower-order functional types. They are based on the observation that we may uniquely represent a sequence of tuples of sequences $\langle \mathbf{s}_{11}, \dots, \mathbf{s}_{1n} \rangle \dots \langle \mathbf{s}_{k1}, \dots, \mathbf{s}_{kn} \rangle$ as a tuple of sequences $\langle \mathbf{s}_{11} @ \dots @ \mathbf{s}_{k1}, \dots, \mathbf{s}_{1n} @ \dots @ \mathbf{s}_{kn} \rangle$, where $@$ is a symbol not occurring in any of the \mathbf{s}_{ij} .

Lemma 1. *For any types S, T , there is a definable monomorphism from $(\underline{n} \rightarrow S) \rightarrow T$ to $\underline{n+1} \rightarrow S \rightarrow T$.*

Proof. Assuming a term $\text{eq} : \underline{n} \& \underline{n} \rightarrow \underline{2}$ such that $\llbracket \text{eq } \langle \mathbf{n}, \mathbf{n} \rangle \rrbracket = \{0\}$ and $\llbracket \text{eq } \langle \mathbf{n}, \mathbf{m} \rangle \rrbracket = \perp$ if $n \neq m$, we define $\text{mono1} : ((\underline{n} \rightarrow S) \rightarrow T) \rightarrow (\underline{n+1}) \rightarrow S \rightarrow T$:

$$\lambda f. \lambda x. \lambda y. f (\lambda z. (\text{while0 } (\text{case } \langle x, \langle \langle \text{eq } \langle \mathbf{i}, z \rangle \mid i < n \rangle, 1 \rangle \rangle)); y)$$

The denotation of mono1 relates each element $\langle \langle \mathbf{j}_1, s_1 \rangle \dots \langle \mathbf{j}_m, s_m \rangle, t \rangle$ to the unique element $\langle \mathbf{j}_1 n \dots \mathbf{j}_m n, \langle s_1 \dots s_n, t \rangle \rangle$. Clearly this is a 1-1 relation, and therefore a monomorphism.

Lemma 2. *For any type $((S \rightarrow T) \rightarrow U) \rightarrow V$ there is a definable monomorphism into $(S \& \underline{1}) \rightarrow (T \rightarrow U) \rightarrow V$.*

Proof. We define $\text{mono2} : (((S \rightarrow T) \rightarrow U) \rightarrow V) \rightarrow (S \& \underline{1}) \rightarrow (T \rightarrow U) \rightarrow V =$

$$\lambda f. \lambda x. \lambda g. f \lambda y. (g (\pi_2(x); (y \pi_1(x))))$$

The denotation of `mono2` relates each element

$$\langle\langle s_{11}, t_{11} \rangle \dots \langle s_{1m_1}, t_{1m_1} \rangle, u_1 \rangle \dots \langle\langle s_{n1}, t_{n1} \rangle \dots \langle s_{nm}, t_{nm} \rangle, u_n \rangle, v \rangle$$

to the unique element

$$\langle 0^r s^l_{11} \dots 0^r s^l_{1m_1} \dots 0^r s^l_{n1} \dots 0^r s^l_{nm}, \langle\langle t_{11} \dots t_{1m_1}, u_1 \rangle \dots \langle t_{n1} \dots t_{nm}, u_n \rangle, v \rangle \rangle$$

Proposition 5. *For any functional type R of order $n + 2$ there is a functional type \widehat{R} of order $n + 1$ and a definable monomorphism from R to \widehat{R} .*

Proof. By induction on the size of R . For the induction step, if R is of order 2 then it is isomorphic to a type of the form $(\underline{n} \rightarrow S) \rightarrow T$. By Lemma 1 there is a definable isomorphism from R to $\underline{n+1} \rightarrow S \rightarrow T$ and hence — using the induction hypothesis — to $\underline{n+1} \rightarrow \widehat{S \rightarrow T}$.

If $o(R) > 2$ then R is isomorphic to a type of the form $((S \rightarrow T) \rightarrow U) \rightarrow V$. By Lemma 2 there is a definable monomorphism from R to $S\&\underline{1} \rightarrow (T \rightarrow U) \rightarrow V$ and hence — using the induction hypothesis — to $\overline{S\&\underline{1}} \rightarrow (T \rightarrow U) \rightarrow V$.

Theorem 3. *Observational equivalence in finitary basic SCI is decidable.*

Proof. We use Proposition 5 to show there is a definable monomorphism from each type of SCI into a first-order type.

4 Observably Sequential SCI

We will now show that observational approximation is decidable in an “observably sequential” version of SCI containing a simple form of non-local control in the form of backwards jumps to labelled program points.² We extend the syntax of SCI with the constant `label` : $(\underline{0} \rightarrow \underline{0}) \rightarrow \underline{1}$, and the operational semantics with the evaluation contexts `label` $E[-]$ and `label` $\lambda k.E[-]$ and the reduction:

$$E[\text{label } \lambda k.E'_k[k]], \mathcal{E} \longrightarrow E[0], \mathcal{E}$$

(where we write $E_k[-]$ for an evaluation context which does not bind k , and assume that all substitutions are capture-avoiding).

We may use `label` to distinguish SCI-equivalent terms such as $x; y$ and $y; x$. More generally, we can express Cartwright and Felleisen’s `catch` operators [2]. For each n , `catch` $_n$: $(T_0 \rightarrow \dots \rightarrow T_{n-1} \rightarrow \underline{m}) \rightarrow \underline{m+n}$ returns i if its argument is strict in its i th argument, or $n + j$ if it is non-strict with value j . We define `catch` $_0 = \lambda x.x$, and `catch` $_{n+1} = \lambda f.\text{new } \lambda x.(\text{label } \lambda k.(x := ((\text{catch}_n(f(\text{abort } k)))) + 1); k); !x$.

² This breaks the equivalence between parallel and sequential composition.

We will now give a fully abstract games model of observably sequential SCI, and show that denotations may be represented as regular languages. It is similar to Abramsky and McCusker’s semantics of Idealized Algol [1], based on Hyland-Ong dialogue games [6]. Since only one thread of computation relating to each argument may be “open” at a time in SCI programs, we may omit explicit justification pointers from our model. As in McCusker and Wall’s semantics of SCI [12] (and the author’s semantics of linearly used continuations [8]) we add an equivalence relation \sim “interference” to the notion of HO-arena in order to indicate which moves may not occur in the same thread. We allow the interpretation of backwards jumps by abandoning the notion of questions and answers, and hence the “bracketing condition”.

A SCI arena is a directed acyclic graph (M_A, \vdash_A) — in the form of a set of nodes or moves M_A , and a set of directed edges (or *enabling relation*) $\vdash_A \subseteq M_A \times M_A$ — with a labelling function $\lambda_A : M_A \rightarrow \{O, P\}$, partitioning the moves between Player and Opponent, and an equivalence relation $\sim \subseteq M_A \times M_A$ such that:

- Root nodes (the *initial moves* M_A^I) are Opponent moves, and there is no edge between two Opponent moves or two Player moves.
- If $m \vdash n$ and $m' \vdash n$ then $m \sim m'$.

For any sequence s of moves, we define a subsequence $\text{open}(s)$ — the “stack of open moves” — containing at most one move from each \sim equivalence class.

$\text{open}(\varepsilon) = \varepsilon$,
 $\text{open}(sm) = tm$, if $tm' \sqsubseteq \text{open}(s)$ and $m' \sim m$,
 $\text{open}(sm) = \text{open}(s)m$, otherwise.

By definition, the stack of open moves contains at most one enabler for each move — which we may designate its *justifier* — and so we may unambiguously define the *view* $\ulcorner \text{open}(s) \urcorner$ as follows:³

$\ulcorner \varepsilon \urcorner = \varepsilon$ and $\ulcorner m \urcorner = m$
 $\ulcorner smtn \urcorner = \ulcorner s \urcorner mn$ if $m \vdash n$.

The set L_A of *legal* sequences of the arena A consists of finite alternating sequences of moves of A containing at most one initial move (well-openedness), in which every non-initial move is preceded by an enabling move, which occurs in the view of the stack of open moves (visibility), and which satisfy the *non-interference condition*. Essentially this requires that two potentially interfering moves cannot be “called” from non-interfering parts of the game.

Definition 2. A sequence t satisfies the non-interference condition if for any $sb, s'b' \sqsubseteq t$ and moves a, a' occurring (respectively) in $\ulcorner \text{open}(s) \urcorner$ and $\ulcorner \text{open}(s') \urcorner$ and having the same justifier: if $b \sim b'$ and $\lambda(a) = \lambda(b)$ then $a \sim a'$.

We define a **BCK**-algebra with products in which the objects are arenas, with product and function-space given by the following constructions:

³ We do not distinguish Player and Opponent views — the view of any sequence is that of the participant about to move.

- $A \& B = (M_A + M_B, [\lambda_A, \lambda_B], \vdash_A + \vdash_B, (\sim_A + \sim_B) \cup ((M_A^l)^l \times (M_B^r)^r) \cup ((M_B^l)^l \times (M_A^r)^r))$
- $A \rightarrow B = (M_A + M_B, [\lambda_A, \lambda_B], (\vdash_A + \vdash_B) \cup ((M_A^l)^l \times (M_B^r)^r), \sim_A + \sim_B)$.

The elements of A are the deterministic strategies on A (non-empty and even-branching subsets of L_A). Application of $\sigma : A \rightarrow B$ to $\tau : A$ is defined $\sigma \cdot \tau = \{s|B \mid s \in \sigma \wedge s|A \in \tau^*\}$. The combinators $\mathbf{B}, \mathbf{C}, \mathbf{T}, \mathbf{P}$ and π_i are interpreted as *copycat strategies*.

Proposition 6. *The BCK-algebra of SCI-arenas and strategies is well-defined.*

Proof. The key point is to show that application is well-defined — that the set of legal sequences is *compositional*: i.e. if $s \in L_{A \rightarrow B}$ and $s|A \in (L_A)^*$ then $s|B \in L_B$. The proof that $s|B \in L_B$ satisfies the non-interference condition is based on techniques used to prove compositionality of innocence in HO-games.

We obtain a model of SCI by setting the denotation of the ground type \underline{n} to be the arena with a single initial move enabling n different Player moves. Thus $\underline{0} \rightarrow \underline{0}$ is isomorphic to $\underline{1}$, and we define the denotation of `label` to be this isomorphism. The remaining constants of SCI are interpreted as in the game semantics of Idealized Algol [1]. Proof of soundness and adequacy uses standard techniques and follows those of similar results for games models.

Proposition 7. *For any closed term $M : \underline{1}$, $M \Downarrow$ if and only if $\llbracket M \rrbracket \neq \perp$.*

We now observe that denotational equivalence and approximation are decidable because the strategy denoting each term is a *regular language*. The key point is that the set of legal sequences over each SCI type-object is itself regular.

Lemma 3. *For any finitary SCI type T , the set $L_{\llbracket T \rrbracket}$ is regular.*

Proof. We define a FSA in which each state is a pair consisting of a non-repetitive (and hence bounded) legal sequence t and a function from M_A to sets of non-repetitive sequences over M_A . The initial state is the pair of the empty sequence and the constantly \emptyset function, and the transition function is defined so that having read the legal sequence of moves r , the FSA is in the state $\langle \text{open}(r), f \rangle$, where $f(m)$ is the set of views of prefixes of r which contain an occurrence of m which is in $\text{open}(r)$: this information is sufficient to determine the legality of the next move to be read.

Hence the copycat strategies interpreting the $\mathbf{B}, \mathbf{C}, \mathbf{K}, \mathbf{P}$ and π combinators are regular. Following [3], we show that the application of one regular strategy to another is regular, and that the interpretations of `case`, `while0`, `label` and `new` are regular.

Proposition 8. *The denotation of each term of observably sequential SCI is regular.*

4.1 Full Abstraction

We will now prove that our interpretation of observably sequential SCI is (in-equationally) fully abstract. This is the case despite the fact that there are finitary strategies in the model which are not the denotations of terms (and may in fact exhibit interfering behaviour). For example, the strategy on the arena $(\underline{1} \rightarrow \underline{1} \rightarrow \underline{1}) \rightarrow \underline{2}$ — corresponding to the Idealized Algol term $\lambda f.\mathbf{new} \lambda x.((f(x := 1))x := 0);!x$ — which runs its argument once, and returns one if the last argument tested by f was the leftmost one and 0 otherwise.

It is sufficient to establish full abstraction for functional types, since every type is a definable retract of such a type (as in Proposition 4). We further simplify the set of types for which we need to prove full abstraction to the *zero* types: functional types generated from the atomic type $\underline{0}$.

Proposition 9. *Every functional type is definably isomorphic to a zero type.*

Proof. Define the type $\underline{0}_k$ for each $k \geq 0$ by $\underline{0}_0 = \underline{0}$ and $\underline{0}_{k+1} = \underline{0} \rightarrow \underline{0}_k$. The arenas denoting $\underline{0}_k$ and \underline{k} are clearly isomorphic; these isomorphisms are definable as $\mathbf{catch}_k : \underline{0}_k \rightarrow \underline{k}$ and $\lambda x.\lambda y.\mathbf{case} \langle x, \langle y_0, \dots, y_{k-1} \rangle \rangle : \underline{k} \rightarrow \underline{0}_k$.

We now show that sufficient “observations” are definable to prove full abstraction. For any sequence s , let $|s|$ be the *multiset* of moves occurring in s .

Lemma 4. *Let T be a functional type. For any sequence $s \in L_{[T]}$, there exists a term $M(s) : T$ such that $s \in \llbracket M(s) \rrbracket$ and if $t \in \llbracket M(s) \rrbracket$ then $|t| \subseteq |s|$.*

Proof. By Corollary 9 we may assume T is a zero type. We define $M(s)$ by induction on the length of s . For the induction case, suppose $s = m_1 m_2 r$ for some r . First we suppose that the move m_2 does not occur in r , and define $M(s)$ by induction on the *arity* of T .

- For the base case, suppose $T = (\mathbf{S} \rightarrow \underline{0}) \rightarrow \underline{0}$. For each i , $s \upharpoonright \llbracket S_i \rrbracket = t_{i1} t_{i2} \dots t_{in}$, where each t_{ij} is a well-opened legal sequence on $\llbracket S_i \rrbracket$ which is shorter than s . Thus we may define $x_i : \mathbf{var}[n + 2] \vdash N_i : S_i = x_i := x_i + 1; \mathbf{case} \langle !x_i, \langle \Omega, M(t_1), \dots, M(t_n), \Omega \rangle \rangle$ for each i , and

$$M(s) = \lambda f.\mathbf{new} \lambda x_1 \dots \mathbf{new} \lambda x_n.(f N_1 \dots N_n)$$

- If T has arity greater than one, it is (definably) isomorphic to a type of the form $\mathbf{R} \rightarrow S \rightarrow (\mathbf{U} \rightarrow \underline{0}) \rightarrow \underline{0}$, where m_2 is the initial move in $\llbracket \mathbf{U} \rightarrow \underline{0} \rrbracket$, so we assume that it has this form. We may show that if $tb \sqsubseteq s$, where b is the initial move in S , then there exists a unique i such that the initial move in U_i occurs in $\ulcorner \mathbf{open}(tb) \urcorner$. By the non-interference condition, for any two occurrences of b in s , this index i is the same. Hence we may define a legal sequence \widehat{s} on the arena $\llbracket \mathbf{R} \rightarrow (\mathbf{V} \rightarrow \underline{0}) \rightarrow \underline{0} \rrbracket$ — where $V_i = S \rightarrow U_i$, and $V_j = U_j$ if $j \neq i$ — by relabelling each move from S in s as the corresponding move in V_i . We may then define

$$M(s) = \lambda x.\lambda y.\lambda z.(M(\widehat{s}) x) \lambda a.z a_1 \dots a_{i-1}(a_i y)a_{i+1} \dots a_n$$

If m_2 does occur in r — i.e. $s = m_1 m_2 r_1 m_2 r_2$, where m_2 does not occur in r_1 , then the sequence $m_1 m_2 r_1 n$ in $\underline{0} \rightarrow T$ (where n is the move from $\underline{0}$) is no longer than s , whilst $m_1 m_2 r_2$ is shorter than s . Thus we may define

$$M(s) = \lambda x.(\text{label } \lambda k.(M(m_1 m_2 r_1 n) k x)); (M(m_1 m_2 r_2) x)$$

Proposition 10. *For any closed $M, N : T$, $\llbracket M \rrbracket \subseteq \llbracket N \rrbracket$ iff $M \not\prec N$.*

Proof. From left to right (soundness) this is standard. For the converse, suppose $\llbracket M \rrbracket \not\subseteq \llbracket N \rrbracket$ and let smn be a minimal length sequence in $\llbracket M \rrbracket - \llbracket N \rrbracket$. By prefixing an initial move $q \in M_{\underline{1}}$ and postfixing its “answer” a , we obtain a legal sequence $qsmna$ in $\llbracket T \rightarrow \underline{1} \rrbracket$. By Lemma 4, there exists $L : T \rightarrow \underline{1}$ such that $qsmna \in \llbracket L \rrbracket$ (hence $\llbracket L M \rrbracket \neq \perp$) and if $t \in \llbracket L \rrbracket$ then $|t| \subseteq |qsmna|$.

Suppose $\llbracket L N \rrbracket \neq \perp$. Then there exists $qta \in \llbracket L \rrbracket$ such that $t \in \llbracket N \rrbracket$. By minimality of smn , $s \in \llbracket N \rrbracket$, and hence by determinacy of $\llbracket L \rrbracket$ and $\llbracket N \rrbracket$, $qsm \subseteq qt$, and so $|qsm| \subseteq |qta| \subseteq |qsmna|$ by definition of $\llbracket L \rrbracket$. But then $t = smn$, contradicting the assumption that $smn \notin \llbracket N \rrbracket$.

Hence $\llbracket L M \rrbracket \neq \perp$ and $\llbracket L N \rrbracket = \perp$, and $L M \Downarrow, L N \not\Downarrow$ as required

Theorem 4. *Observational equivalence and approximation are decidable in finitary observably sequential SCI.*

Abstract. We prove that observational equivalence of $\text{IA}_3 + \mathbf{Y}_0$ (3rd-order Idealized Algol with 0th-order recursion) is equivalent to the DPDA Equivalence Problem, and hence decidable. This completes the classification of decidable fragments of Idealized Algol. We also prove that observational approximation of $\text{IA}_1 + \mathbf{Y}_0$ is undecidable by reducing the DPDA Containment Problem to it.

1 Introduction

Observational equivalence is an extensional notion of program equivalence. Two program phrases are *observationally equivalent* if one can be replaced by the other in any program without causing any observable difference to the computational outcome. Reynolds's Idealized Algol (IA) is an elegant and compact programming language that combines imperative programming with high-order features, mediated by a simple type theory. Observational equivalence in IA is in general undecidable even when ground types are finite sets. This paper is concerned with the question of decidability of observational equivalence for appropriate fragments of IA.

We begin with a quick review of IA. Ground types of IA, which are ranged over by β , are *exp* (expressions), *com* (commands) and *var* (assignable variables). Types of IA, ranged over by θ, θ' etc., are generated from ground types by the function space constructor $\theta \rightarrow \theta'$. The *order* of a type is defined by $\text{ord}(\beta) = 0$ and $\text{ord}(\theta \rightarrow \theta') = \max(\text{ord}(\theta) + 1, \text{ord}(\theta'))$. *Finitary* Idealized Algol, IA_f , is just recursion-free Idealized Algol over finite ground types. We can extend IA_f with iteration by adding the rule

$$\frac{\Gamma \vdash M : \text{exp} \quad \Gamma \vdash N : \text{com}}{\Gamma \vdash \mathbf{while} \ M \ \mathbf{do} \ N : \text{com}}$$

and with general recursion by adding the rule

$$\frac{\Gamma, x : \theta \vdash M : \theta}{\Gamma \vdash \mu x^\theta. M : \theta}$$

* Work supported by the UK EPSRC (GR/R88861/01), European Research Training Network GAMES and St John's College, Oxford.

We call a term an *ith-order term* provided its typing derivation uses exclusively judgments of the shape $\Gamma \vdash M : \theta$ where the types of the free identifiers in Γ have order less than i and $\text{ord}(\theta) \leq i$. The collection of *ith-order* IA_f (resp. $\text{IA}_f + \mathbf{while}$) terms will be denoted by IA_i (resp. $\text{IA}_i + \mathbf{while}$). We write $\text{IA}_i + \mathbf{Y}_j$ to refer to *ith-order* IA_f terms with recursion that can be typed using the recursion rule in which $\text{ord}(\theta) \leq j$. We tabulate all known results on the complexity of observational equivalence of β -normal terms in IA [1, 2, 3, 4]:

	pure	+ while	+ \mathbf{Y}_0	+ \mathbf{Y}_1
IA_1	CONP	PSPACE	?	$= \text{IA}_1 + \mathbf{Y}_0$
IA_2	PSPACE	PSPACE	?	undecidable
IA_3	EXPTIME	EXPTIME	?	undecidable
IA_4	undecidable	undecidable	undecidable	undecidable

The same results as above also hold for observational approximation.

This paper addresses the cases marked with question marks. In $\text{IA}_i + \mathbf{Y}_0$ only programs of ground type can call themselves recursively. For example, while-loops $\mathbf{while} \ b \ \mathbf{do} \ c$ can then be defined by

$$b : \text{exp}, c : \text{com}, z \vdash \mu z^{com}. \mathbf{ifzero} \ b \ \text{skip} \ (c; z).$$

We show that observational equivalence in $\text{IA}_i + \mathbf{Y}_0$ is decidable for $i = 1, 2, 3$ by giving a reduction to the DPDA Equivalence Problem (recently proved decidable by Sénizergues [8]). This does not tell us much about the complexity, though. At the moment it is only known that the complexity of DPDA Equivalence is bounded by a primitive recursive function [5]. We also show that already for $i = 1$ observational equivalence is at least as hard as DPDA Equivalence. In consequence, no advance on the complexity of the former problem can be made without an advance on the latter. Another result is that observational approximation in $\text{IA}_i + \mathbf{Y}_0$ is undecidable for $i = 1, 2, 3$, because the undecidable DPDA Containment Problem [6] can be reduced to it.

Let us comment on the relationship of our results to a recent paper [4] showing decidability of $\text{IA}_3 + \mathbf{while}$. In that paper a simpler language was considered but it was translated to a weaker form of pushdown automata. This was essential to get a precise complexity bound. In this paper we model a richer language but, for reasons explained above, we do not concern ourselves with complexity, hence our constructions are not designed to optimize the size of the resulting automata. In [4] most constructions relied on parallel composition of automata. This is not possible here as DPDAs are not closed under that operation.

2 Game Semantics: Complete Plays

We assume familiarity with the treatment of game semantics of IA as presented, for example, in [7]. Recall that the *multiplicative composition* $\sigma;_{\text{m}} \tau : A \multimap C$

of two strategies $\sigma : A \multimap B$ and $\tau : B \multimap C$ is defined by parallel composition with hiding by letting the strategies interact in the shared subgame B and subsequently hiding the B -moves.

Let $\sigma : A \Rightarrow B$ and $\tau : B \Rightarrow C$. Recall that $A \Rightarrow B = !A \multimap B$ and $B \Rightarrow C = !B \multimap C$. In order to compose the strategies, one first defines $\sigma^\dagger : !A \multimap !B$ by

$$\sigma^\dagger = \{s \in L_{!A \multimap !B} \mid \text{for all initial } m, s \upharpoonright m \in \sigma\},$$

where $s \upharpoonright m$ stands for the subsequence of s (pointers included) whose moves are hereditarily justified by m . Then $\sigma; \tau : A \Rightarrow C$ is taken to be $\sigma^\dagger;_{\text{m}} \tau$.

Given a set σ of positions on G we write $\mathcal{L}(\sigma)$ for the set of the underlying sequences of moves from M_G . For a given strategy σ , we write $\text{comp } \sigma$ for the set of its non-empty plays in which the number of questions matches the number of answers; such plays are called *complete*.

Remark 1. We will be interested in the \dagger construction when $B = \llbracket \theta \rrbracket$ and $\text{ord}(\theta) \leq 1$. Then σ^\dagger can be characterized explicitly as follows.

- $B = \llbracket \beta \rrbracket$: Then $\sigma^\dagger = (\text{comp } \sigma)^* \sigma$, i.e. σ^\dagger simply iterates σ .
- $B = \llbracket \beta_1 \rightarrow \beta_0 \rrbracket$: Then the switching conditions in the game $!A \multimap !B$ imply that a new copy of σ can be started each time σ is finished (as above) and, additionally, after each question q_1 from β_1 . We can thus capture $K = \{\epsilon\} \cup \text{comp}(\sigma^\dagger)$ by the equation below.

$$K = \{\epsilon\} \cup \bigcup \{q_0 U q_1 K a_1 U \cdots q_1 K a_1 U a_0 K \mid q_0 U q_1 a_1 U \cdots q_1 a_1 U a_0 \in \text{comp } \sigma\},$$

where U 's stand for (possibly empty and possibly different) segments of moves from A .

The operational semantics of IA can be found in [7]. We write $M \Downarrow$ if the closed term M reduces to *skip*. Recall that two terms $\Gamma \vdash M_1, M_2 : \theta$ are *observationally equivalent*, written $\Gamma \vdash M_1 \cong M_2$, if for any context $C[-]$ such that $C[M_1]$ and $C[M_2]$ are closed terms of type *com*, we have $C[M_1] \Downarrow$ iff $C[M_2] \Downarrow$. Similarly, M_1 *observationally approximates* M_2 , written $\Gamma \vdash M_1 \sqsubset M_2$, just if for all contexts satisfying the properties above, $C[M_1] \Downarrow$ implies $C[M_2] \Downarrow$.

Theorem 1 ([7]). $\Gamma \vdash M_1 \sqsubset M_2$ iff $\text{comp} \llbracket \Gamma \vdash M_1 \rrbracket \subseteq \text{comp} \llbracket \Gamma \vdash M_2 \rrbracket$. Consequently, $\Gamma \vdash M_1 \cong M_2$ iff $\text{comp} \llbracket \Gamma \vdash M_1 \rrbracket = \text{comp} \llbracket \Gamma \vdash M_2 \rrbracket$.

3 Simple Terms and Pointer-Free Representation

Suppose $\theta = \theta_1 \rightarrow \cdots \rightarrow \theta_n \rightarrow \beta$. Then we write $\text{tail}(\theta) = \beta$. Given $\Gamma \vdash M : \theta$, depending on whether $\text{tail}(\beta)$ is *com*, *exp* or *var* respectively, we define the *sets of sequences of moves* $\llbracket \Gamma \vdash M : \theta \rrbracket$ by the following decompositions:

$$\mathcal{L}(\text{comp} \llbracket \Gamma \vdash M : \theta \rrbracket) = \text{run} \cdot \llbracket \Gamma \vdash M \rrbracket \cdot \text{done}$$

$$\mathcal{L}(\text{comp} \llbracket \Gamma \vdash M : \theta \rrbracket) = q \cdot \sum_{j=0}^{\max} (\llbracket \Gamma \vdash M \rrbracket_j \cdot j)$$

$$\mathcal{L}(\text{comp } \llbracket \Gamma \vdash M : \theta \rrbracket) = \sum_{j=0}^{\max} \text{write}(j) \cdot (\Gamma \vdash M)_j^w \cdot \text{ok} + \text{read} \cdot \sum_{j=0}^{\max} ((\Gamma \vdash M)_j^r \cdot j).$$

It will turn out convenient to define automata accepting $\langle \cdot \cdot \cdot \rangle$ instead of $\mathcal{L}(\text{comp } \llbracket \cdot \cdot \cdot \rrbracket)$, because then it will not be necessary to interpret hiding in many cases (an operation under which DCFLs are not closed in general). Since $\langle \cdot \cdot \cdot \rangle$ are sets of sequences of moves, they do not always represent $\text{comp } \llbracket \cdot \cdot \cdot \rrbracket$ faithfully because they ignore pointers. Nevertheless, we are going to identify a sufficiently rich class of terms for which $\text{comp } \llbracket \cdot \cdot \cdot \rrbracket$ can be recovered from $\langle \cdot \cdot \cdot \rangle$.

First, we note that to establish decidability it suffices to consider β -normal terms only. This does not solve the pointer problem though. To address it we replace the application rule with its multiplicative version (left) and contraction (right):

$$\frac{\Gamma \vdash M : \theta \rightarrow \theta' \quad \Delta \vdash N : \theta}{\Gamma, \Delta \vdash MN : \theta'} \quad \frac{\Gamma, x_1 : \theta, x_2 : \theta \vdash M : \theta'}{\Gamma, x : \theta \vdash M[x/x_1, x/x_2] : \theta'}$$

All β -normal terms in $\mathbf{IA}_3 + \mathbf{Y}_0$ are typable if we allow the above rules for $\text{ord}(\theta) \leq 2$. We will call a β -normal $\mathbf{IA}_3 + \mathbf{Y}_0$ term *simple* if it can be typed by using the contraction rule only for θ such that $\text{ord}(\theta) < 2$. For instance, $\lambda f.f(\lambda x.f(\lambda y.x))$ is *not* simple. Note that pointer reconstruction is uniquely defined for all moves *except* third-order questions (pointers for answers can be reconstructed uniquely thanks to the bracketing condition; first-order moves must point to the unique initial move; finally, because of Visibility, second-order questions must point to the necessarily unique first-order question in the appropriate O-view). As made precise in the lemma below, for simple terms, we can still recover $\text{comp } \llbracket \cdot \cdot \cdot \rrbracket$ from $\langle \cdot \cdot \cdot \rangle$.

Lemma 1. *Suppose $\Gamma \vdash M : \theta$ is simple. If $sq_3 \in \llbracket \Gamma \vdash M : \theta \rrbracket$, and q_3 is a third-order question then q_3 's justifier in sq_3 is the last unanswered enabler of q_3 in s .*

Proof. By induction on the structure of simple terms. The crucial point is that if $\sigma : A \multimap B$ satisfies the Lemma for $B = \llbracket \theta \rrbracket$ such that $\text{ord}(\theta) \leq 1$, so does σ^\dagger . This follows from the description in Remark 1.

On the other hand, simple terms are good representatives of β -normal terms. Any β -normal term of $\mathbf{IA}_3 + \mathbf{Y}_0$ can be typed by extending a typing derivation of a simple term with a number of applications of the contraction rule for θ of order 2 followed by a number of applications of the λ -abstraction rule.

4 G-Automata

We are going to use a variant of deterministic pushdown automata. Their states will be divided into O-states and P-states and the stack will be modified and inspected only during ϵ -moves.

Fig. 1. Transitions in G -automata

- In O-states the automaton will only be able to read an O-move from the input without inspecting or changing the stack; after the transition the state will always change to a P-state.
- In P-states the automaton will either: read a *single* P-move without modifying the stack and move to an O-state, or perform an ϵ -move and go to a P-state possibly modifying the stack.

The constraints are summarized in Figure 1 and captured formally below.

Definition 1. Let G be a game. A G -automaton \mathcal{A} is a tuple $\langle Q, \Omega, i, F, \delta \rangle$ such that

- $Q = Q^O + Q^P$ is the set of states partitioned into Q^O and Q^P , called the sets of O-states and P-states respectively;
- Ω is the stack alphabet;
- $i \in Q^P$ is the initial state, i does not have any incoming transitions;
- $F \subseteq Q^P$ is the set of final states, final states do not have any outgoing transitions;
- $\delta : [Q^O \rightarrow (M_G^O \rightarrow Q^P)] + [Q^P \rightarrow ((M_G^P \times Q^O) + Q^P + (\Omega \times Q^P) + (\Omega \rightarrow Q^P))]$ is the transition function.

The interpretation of a transition $\delta(q_O) \in M_G^O \rightarrow Q^P$ is that the automaton reads a letter $a \in M_G^O$ from the input and changes the state to $\delta(q_O)(a)$. Similarly for $\delta(q_P) = (b, q_O) \in M_G^P \times Q^O$, the automaton expects to see b as the input and then changes its state to q_O . On a transition $\delta(q_P) = q'_P$ the automaton changes its state but does not consume the input or change the stack. On a transition $\delta(q_P) = (\gamma, q'_P)$ the automaton changes the state and pushes γ on the stack. On a transition $\delta(q_P) \in \Omega \rightarrow Q^P$ the automaton makes a pop move and changes its state depending on the letter that was popped. We will use arrow notation for transitions as in Figure 1. Note that slash and comma denote push and pop operations, respectively.

We write $L(\mathcal{A})$ for the language that \mathcal{A} accepts by final state and the empty stack. It is easy to see that G -automata are DPDAs. They have a particularity that they look at the stack only when doing a pop move. We make this restriction to simplify the definitions that follow. It is not difficult to see that for every deterministic pushdown automaton there is an equivalent one with this property.

By a G -automaton *configuration*, we mean a pair qw , where q is a state and $w \in \Omega^*$ is the content of the stack.

Definition 2. *We say that a G -automaton is productive if every non-initial reachable configuration is productive, i.e. the configuration occurs in some accepting run of the automaton.*

Lemma 2. *For every G -automaton there is an equivalent productive automaton.*

Proof. Let $\mathcal{A} = \langle Q, \Omega, i, F, \delta \rangle$ be a G -automaton. Consider the function $\beta : \Omega^* \rightarrow \mathcal{P}(Q)$ which for all contents of the stack $w \in \Omega^*$ returns the set of states q such that the configuration qw is productive. We will first modify \mathcal{A} so that it keeps the current value of β in its state. Note that it is easy to update β after push-transitions, because $\beta(wa)$ depends only on $\beta(w)$ and a : $q \in \beta(wa)$ iff there exists q' such that $q' \in \beta(w)$ and when \mathcal{A} starts with a on the stack in state q it can end up in q' with empty stack (states q' with this property can be precomputed at the very beginning of the construction). In order to handle pop-transitions, we simply force the automaton to push the old value of β in addition to the pushed stack symbol. Finally, it now suffices to suppress all transitions that are not consistent with β to obtain a productive automaton.

Remark 2. (i) The productiveness of the automaton will play an important role in our constructions for several reasons. One is that when \mathcal{A} is productive we can be sure that when running as a subautomaton of some automaton construction (as in the proof of Theorem 2), it will only use the symbols it pushed (it cannot try to make a pop operation on the empty stack as that would be an unproductive configuration). Another consequence of productiveness is that the automaton cannot enter an accepting state while the stack is not empty. Indeed, since there are no outgoing transitions from an accepting state, the resulting configuration would not be productive. Further, as the automaton stack is necessarily empty whenever it reaches a final state, we also know that when it finishes the stack will be exactly as before it has started.

(ii) From an O-state there are in principle several input letters from M_G^O that can make the automaton advance. However, because of productiveness, in general, not every playable O-move can label an outgoing transition from the O-state. From a P-state there is only one input letter from M_G^P that the automaton is prepared to read. We have this asymmetry because G -automata are designed to accept strategies. Thus, an automaton works in cycles: it reads a letter from M_G^P , then a letter from M_G^O and then does some internal manipulations on the stack.

Definition 3. *We say that an automaton is careful if whenever it reaches a configuration qw after reading the sequence of moves s then the sequence of open second-order questions in s appears in the stack w . More formally, there is a function $\pi_{\mathcal{A}} : \Omega \rightarrow M_G \cup \{\epsilon\}$ such that $\pi_{\mathcal{A}}^*(w)$ is the sequence of open second-order questions in s .*

The final definition of this section makes it precise what kind of automata we want to construct. Below, by $\mathcal{A}(F')$ we will denote the automaton \mathcal{A} with F' as the set of accepting states.

Definition 4. *We say that a tuple of G -automata $\langle \mathcal{A}^1, \dots, \mathcal{A}^n \rangle$, where each $\mathcal{A}^j = \langle Q^j, \Omega^j, i^j, F^j, \delta^j \rangle$, is fully productive for $\Gamma \vdash M : \theta$ just if each \mathcal{A}^j is productive and careful; further*

- suppose $\text{tail}(\theta) = \text{com}$: we have $n = 1$ and $L(\mathcal{A}^1) = \langle \Gamma \vdash M : \theta \rangle$
- suppose $\text{tail}(\theta) = \text{exp}$: we have $n = 1$, $F^1 = \bigoplus_{j=0}^{\text{max}} F_j$ and $L(\mathcal{A}^1(F_j)) = \langle \Gamma \vdash M : \theta \rangle_j$ for any $0 \leq j \leq \text{max}$;
- in case $\text{tail}(\theta) = \text{var}$: we have $n = \text{max} + 2$, $F^1 = \bigoplus_{j=0}^{\text{max}} F_j$ and $L(\mathcal{A}^1(F_j)) = \langle \Gamma \vdash M : \theta \rangle_j^r$ for any $0 \leq j \leq \text{max}$; for each $0 \leq k \leq \text{max}$, we have $L(\mathcal{A}^{k+2}) = \langle \Gamma \vdash M : \theta \rangle_k^w$.

5 Modelling Simple Terms

Here we focus on simple terms. The extension to other β -normal terms is discussed in Section 6.

Theorem 2. *For any simple $\mathbf{IA}_3 + \mathbf{Y}_0$ term $\Gamma \vdash M : \theta$ there exists a fully productive tuple of $\llbracket \Gamma \vdash \theta \rrbracket$ -automata for $\Gamma \vdash M : \theta$.*

Proof. We use structural induction. Whenever our constructions fail to preserve productiveness, we simply appeal to Lemma 2 to obtain an equivalent productive automaton.

Thanks to the equalities below and the fact that productive G -automata compose well (see Remark 2 (i))

$$\begin{aligned}
 \langle \Gamma \vdash \lambda x.M \rangle &= \langle \Gamma, x \vdash M \rangle & \langle \Gamma \vdash M; N \rangle &= \langle \Gamma \vdash M \rangle \cdot \langle \Gamma \vdash N \rangle \\
 \langle \Gamma \vdash !M \rangle_j &= \langle \Gamma \vdash M \rangle_j^r & \langle \Gamma \vdash M := N \rangle &= \sum_{j=0}^{\text{max}} (\langle \Gamma \vdash N \rangle_j \cdot \langle \Gamma \vdash M \rangle_j^w) \\
 \langle \Gamma \vdash \mathbf{if} M \mathbf{then} N_1 \mathbf{else} N_2 \rangle &= \langle \Gamma \vdash M \rangle_0 \cdot \langle \Gamma \vdash N_2 \rangle + \\
 & \quad \left(\sum_{j=1}^{\text{max}} \langle \Gamma \vdash M \rangle_j \right) \cdot \langle \Gamma \vdash N_1 \rangle
 \end{aligned}$$

the corresponding cases are easy. We can simply appeal to the inductive hypothesis and construct the new automata by connecting suitable final states with suitable initial states with ϵ -transitions. Note that this does not violate determinism as final states do not have outgoing transitions. Equivalently, one could “glue” final states with initial ones suitably. If one performs the constructions for reachable final states only, productiveness will be preserved. The remaining cases are treated as follows:

The case of $\Gamma \vdash \mathbf{new} X \mathbf{in} M : \beta$. Suppose $\beta = \text{com}$ and $\langle \mathcal{A} \rangle$ is fully productive for $\Gamma, X : \text{var} \vdash M : \beta$. Let us construct $\text{max} + 1$ copies of \mathcal{A} denoted by $\mathcal{A}^0, \dots, \mathcal{A}^{\text{max}}$. We will use superscripts to refer to their states. The unique automaton \mathcal{B} in the fully productive tuple for $\Gamma \vdash \mathbf{new} X \mathbf{in} M$ will consist of all

these copies, the idea being that the index of the copy corresponds to the interim value stored in the variable X . The new initial state will be i^0 , i.e. the initial state of \mathcal{A}^0 . The set of final states will be $H = \bigcup_{h=0}^{max} F^h$, i.e. the set of final states from all the copies \mathcal{A}^h of \mathcal{A} . We make the following changes to the copies of \mathcal{A} . Because \mathcal{A} is productive, we can assume that each \mathcal{A} -transition using the P-moves $read_X$ or $write(k)_X$ ($0 \leq k \leq max$) originating from the distinguished copy of var is followed by transitions on i^1_X, \dots, i^d_X and ok_X respectively, where $\{i^1, \dots, i^d\} \subseteq \{0, \dots, max\}$. To construct \mathcal{B} we redirect transitions in the various copies of \mathcal{A} as shown below

where $0 \leq h \leq max$. These transformations redirect only the transition from p^h , while the transitions from o^h remain as they were. In the first case the transformation is performed only if $h = i^c$ for some $1 \leq c \leq d$. Otherwise, the transition from p^h is just erased. Note that in the second case the new transition connects \mathcal{A}^h to \mathcal{A}^k . After all the transitions on P-moves are dealt with, we delete the transitions from o^h . It is clear that the \mathcal{B} is careful if \mathcal{A} is. Using Lemma 2 we can make it productive. If $\beta = exp$ the same construction can be performed to give us a fully productive tuple for $\Gamma \vdash \mathbf{new} X \mathbf{in} M$. To define the required partition of states $H = \bigoplus_{j=0}^{max} H_j$ we simply take $H_j = \bigcup_{h=0}^{max} F_j^h$, where $F = \bigoplus_{j=0}^{max} F_j$ is the partition given by the inductive hypothesis. The case of $\beta = var$ combines the previous two cases.

The case of $\Gamma \vdash \mu x^\beta.M : \beta$. Suppose $\beta = com$ and $\langle \mathcal{A} \rangle$ is a fully productive tuple for $\Gamma, x : \beta \vdash M : \beta$, where $\mathcal{A} = \langle Q, \Omega, i, F, \delta \rangle$. The unique automaton \mathcal{B} in the fully productive tuple for $\Gamma \vdash \mu x.M$ will be constructed from two copies $\mathcal{A}^0, \mathcal{A}^1$ of \mathcal{A} . Intuitively, \mathcal{A}^1 will be used to process recursive calls from M , whereas \mathcal{A}^0 will correspond to the base copy of M . Accordingly, the initial state will be i^0 and the final states will be those from F^0 . The stack alphabet of \mathcal{B} will, in addition to the stack alphabet of \mathcal{A} , contain two copies of the set of O-states of \mathcal{A} . By productiveness of \mathcal{A} , we can assume that each transition on run_x is followed by a transition on $done_x$. In order to define \mathcal{B} , for each $h = 0, 1$ and for each block of the shape $p^h \xrightarrow{run} o^h \xrightarrow{done} p_{done}^h$ we erase the transition from p^h and add the transitions: $p^h \xrightarrow{\epsilon/o} i^1$ and $f^1 \xrightarrow{\epsilon/o} p_{done}^h$ for any $f \in F$. The case of $\beta = exp$ is similar but, additionally, we have to pass on the result of the recursive call. The notion of a productive tuple will make that easy. Suppose $F = \bigoplus_{j=0}^{max} F_j$. Then we first create two copies $\mathcal{A}^0, \mathcal{A}^1$ of \mathcal{A} and for $h = 0, 1$ and for each block

we erase the transition from p^h and add the transitions: $p^h \xrightarrow{\epsilon/o} i^1$ and $f_i^1 \xrightarrow{\epsilon,o} p_i^h$ for any $1 \leq c \leq d$ and $f_i \in F_i$. The initial state of the new automaton is i^0 , the final states are those in $F^0 = \bigoplus_{j=0}^{max} F_j^0$. The remaining case of $\beta = var$ is more tedious but completely analogous to the previous two. Given a fully productive tuple $\langle \mathcal{A}^1, \dots, \mathcal{A}^{max+2} \rangle$ for $\Gamma, x \vdash M$, blocks $write(j)_x ok_x$ are replaced with calls to a copy of \mathcal{A}^{j+2} as for com , while blocks $read_x j_x$ are replaced by calls to a copy of \mathcal{A}^1 . It is easy to see that the obtained automaton is careful. After the above constructions we can apply Lemma 2 to make the resulting automaton productive.

The case of $fM_1 \cdots M_k$. For demonstration we assume that $k = 1$, $M_1 = M$ and $fM : com$ and f does not occur in M , i.e. $f : \theta \rightarrow com, \Gamma \vdash fM : com$. Let us write r_f, d_f and r, d for the $\llbracket com \rrbracket$ -moves on the left and right respectively. Observe that because fM is interpreted by interaction of the identity strategy (corresponding to f) with $(\llbracket \Gamma \vdash M \rrbracket)^\dagger$ we have $\text{comp} \llbracket f : \theta \rightarrow com, \Gamma \vdash fM : com \rrbracket = r r_f (\{\epsilon\} \cup L) d_f d$, where $L = \phi(\text{comp} \llbracket \Gamma \vdash M : \theta \rrbracket)^\dagger$ and ϕ is the (injective) renaming map which acts like identity on moves from $\llbracket \Gamma \rrbracket$ and maps $\llbracket \theta \rrbracket$ -moves to their copies in $\llbracket \theta \rightarrow com \rrbracket$. Below we examine two representative examples in detail and give the precise shape of ϕ . We use subscripts to refer to (moves from) various copies of com .

- Suppose $\Gamma \vdash M : com_0$ and $f : com_{f,1} \rightarrow com_f, \Gamma \vdash fM : com$. Then $L = \text{comp} \llbracket \Gamma \vdash M \rrbracket^\dagger [r_0 \mapsto r_{f,1}, d_0 \mapsto d_{f,1}]$.
- Suppose $\Gamma \vdash M : com_1 \rightarrow com_0$ and $f : (com_{f,2} \rightarrow com_{f,1}) \rightarrow com_f, \Gamma \vdash fM : com$. Then $L = \text{comp} \llbracket \Gamma \vdash M \rrbracket^\dagger [r_0 \mapsto r_{f,1}, d_0 \mapsto d_{f,1}, r_1 \mapsto r_{f,2}, d_1 \mapsto d_{f,2}]$.

Consequently, the main difficulty is the construction of an automaton accepting $\text{comp}(\sigma^\dagger) \cup \{\epsilon\}$, where $\sigma = \llbracket \Gamma \vdash M : \theta \rrbracket$ and $\text{ord}(\theta) \leq 1$. What is constructed in the following is not a $\llbracket \Gamma \vdash \theta \rrbracket$ -automaton (the initial state, which is an O-state, will coincide with the final one and it will have both incoming and outgoing transitions), but the crucial fact is that it becomes one when the transitions on r_f and d_f (which will become the new initial and final moves respectively) are added. We consider the case of $\theta = com_1 \rightarrow com_0$ for illustration.

Suppose $\langle \mathcal{A} \rangle$ is fully productive for $\Gamma \vdash M : \theta$, $\mathcal{A} = \langle Q, \Omega, i, F, \delta \rangle$ and $\text{ord}(\theta) \leq 1$. Recall from Remark 1 that in this case \dagger iterates as well as stacks copies of the original strategy and a new copy can start either if the previous one finished or after r_1 . To model that, we create two copies $\mathcal{A}^0, \mathcal{A}^1$ of \mathcal{A} with the aim of delegating the copies started after r_1 to \mathcal{A}^1 . The outermost iterated copies will be processed by \mathcal{A}^0 .

First we define a few new states: i_{new}^0 (which will be the initial and final state of the automaton) and (\circ, q) , (\bullet, q) , where $q \in Q^0 + Q^1 + \{i_{\text{new}}^0\}$. We make the following additions to $\mathcal{A}^0, \mathcal{A}^1$:

- $i_{\text{new}}^0 \xrightarrow{r_0} (\bullet, i_{\text{new}}^0) \xrightarrow{\epsilon/(i_{\text{new}}^0, r_0)} i^0$ and $f^0 \xrightarrow{\epsilon, (i_{\text{new}}^0, r_0)} (\circ, i_{\text{new}}^0) \xrightarrow{d_0} i_{\text{new}}^0$ for any $f \in F$.
- Observe that r_1 is always followed by d_1 in σ . By productiveness of \mathcal{A} , we can assume that each transition $p^h \xrightarrow{r_1} o^h$ ($h = 0, 1$) is followed by $o^h \xrightarrow{d_1} p_0^h$. Then we add $o^h \xrightarrow{r_0} (\bullet, o^h) \xrightarrow{\epsilon/(\circ, r_0)} i^1$. This makes it possible for the automaton to start processing a new copy of σ , the return state is saved on the stack. To process call returns, we add $f^1 \xrightarrow{\epsilon, (\circ, r_0)} (\circ, o^h) \xrightarrow{d_0} o^h$ for any $f \in F$.

Note that in addition to return addresses in the form of O-states we have also arranged for the questions r_0 to be pushed on the stack. They will remain there as long as they are not answered in the corresponding position. These questions are redundant for accepting $\text{comp}(\sigma^\dagger) \cup \{\epsilon\}$, but are necessary for the resulting automaton to be careful. Since r_0 will be substituted by $r_{f,1}$, the questions r_0 are exactly the second-order questions contributed by f . The case of $fM_1 \cdots M_k$ is analogous, except that we need to apply \dagger to $\sum_{i=1}^k \llbracket \Gamma \vdash M_i \rrbracket$.

The contraction rule. The contraction rule for free identifiers of type θ , where $\text{ord}(\theta) = 0, 1$, is interpreted simply by identifying moves from the two copies of $\llbracket \theta \rrbracket$. In general this might lead to nondeterminism, but thanks to the structure of our automata this can never happen in our case. There is no problem with P-moves as from each P-state the automaton can read at most one letter. Suppose that a nondeterminism arises from some O-state reachable from the initial configuration. This means that there exists a position s such that the automaton can read both $s o_1$ and $s o_2$, where o_1 and o_2 are the O-moves from two different copies of θ . However, this contradicts that fact that at most one of $s o_1$ and $s o_2$ can satisfy Visibility (because only one first-order question is O-visible in s). Consequently, contraction can be interpreted without loss of determinacy.

6 Representing Pointers

We are going to introduce a representation of pointers for simple terms by following Lemma 1. Consider a position sq_3 , where q_3 is a third-order question. We define $\pi(s, q_3) = k - j + 2$ where q_2^j is the last enabler of q_3 in the sequence q_2^1, \dots, q_2^k of all second-order unanswered questions in s (written in the order they appear in s).

Definition 5. *Suppose $\sigma = \llbracket \Gamma \vdash M : \theta \rrbracket$, where $\Gamma \vdash M : \theta$ is an $\text{IA}_3 + \text{Y}_0$ term. The language $\mathcal{P}(\sigma)$ over the alphabet $M_{\llbracket \Gamma \vdash \theta \rrbracket} + \{\text{check}\}$ is defined by $\mathcal{P}(\sigma) = \{s \text{ check}^{\pi(s, q_3)} \mid sq_3 s' \in \text{comp } \sigma \text{ for some } s'\}$.*

Lemma 3. *For any simple term $\Gamma \vdash M : \theta$ there exists a DPDA accepting $\mathcal{L}(\text{comp } \sigma) \cup \mathcal{P}(\sigma)$, where $\sigma = \llbracket \Gamma \vdash M : \theta \rrbracket$.*

Proof. By Theorem 2 there is a fully productive tuple for $\Gamma \vdash M : \theta$. By adding transitions on the missing initial and final moves, we can construct an automaton \mathcal{A} accepting $\mathcal{L}(\text{comp } \sigma)$. Though \mathcal{A} is not, strictly speaking, a G -automaton, it is nonetheless a DPDA that is productive and careful. (The definitions of productive and careful do carry over in this case.) Next, we will construct a DPDA accepting $\mathcal{L}(\text{comp } \sigma) \cup \mathcal{P}(\sigma)$. Suppose that the automaton \mathcal{A} reads the sequence sq_3 where q_3 is a third-order question. Note that q_3 is always a P-move, so it is uniquely determined by s and σ . As \mathcal{A} is productive, we know that sq_3 can be extended to a complete position. It remains to take care of *check* letters. As \mathcal{A} is careful, all second-order questions that are open in sq_3 will be stored on the stack. Hence, in order to accept the right number of *check*'s after reading s , the automaton can move to a fresh state (reading the letter *check*) and enter a new mode in which it will repeatedly pop the stack reading *check* whenever the topmost stack symbol contains a second-order question and ϵ otherwise. It accepts exactly after it encounters the first enabler of q_3 .

Now that we can represent the semantics of simple terms with pointers, the semantics of other β -normal terms can be obtained by renaming, because in order to type such terms we only need to perform contraction at order 2 and λ -abstraction. The former is done by relabelling (in the same manner as at order 0 or 1; the previous argument that determinism is preserved remains valid), the latter amounts to identity in the games setting. Consequently, we get:

Theorem 3. *For any $\text{IA}_3 + \text{Y}_0$ term $\Gamma \vdash M : \theta$ in β -normal form there exists a DPDA accepting $\mathcal{L}(\text{comp } \sigma) \cup \mathcal{P}(\sigma)$, where $\sigma = \llbracket \Gamma \vdash M : \theta \rrbracket$. Hence, the theorem also holds for any $\text{IA}_3 + \text{Y}_0$ term.*

By Lemma 1, $\mathcal{L}(\text{comp } \sigma) \cup \mathcal{P}(\sigma)$ is a faithful representation of $\text{comp } \sigma$. Thus, by Theorem 3 and the decidability of DPDA equivalence [8], we get

Theorem 4. *Observational equivalence is decidable for terms in $\text{IA}_3 + \text{Y}_0$.*

7 Hardness

A DPDA [6] is a tuple $\mathcal{B} = \langle Q, \Sigma, \Gamma, \delta, q_0, Z_0 \rangle$, where $\delta : Q \times (\Sigma \cup \{\epsilon\}) \times \Gamma \rightarrow Q \times \Gamma^*$. Additionally, whenever $\delta(q, a, X)$ is defined for some $a \in \Sigma$, $\delta(q, \epsilon, X)$ must be undefined. We consider acceptance by empty stack (initially the stack contains Z_0) and write $N(\mathcal{B})$ for the language accepted by \mathcal{B} . For simplicity, we further assume that \mathcal{B} can either pop the stack or push one symbol onto it, i.e. if $\delta(q, a, X) = (q', \alpha)$ then $\alpha = \epsilon$ or $\alpha = \alpha_0\alpha_1$ ($\alpha_0, \alpha_1 \in \Gamma$) and $\alpha_0 = X$. Any DPDA can be easily converted into this form.

We identify values of type *exp* with Σ . Consider the game $G = \llbracket \text{exp} \rrbracket \Rightarrow \llbracket \text{com} \rrbracket$ so that we have $M_G = \{q\} \cup \Sigma \cup \{r, d\}$. Given $L \subseteq \Sigma^*$ define $\widehat{L} \subseteq M_G^*$ by $\widehat{L} = \{rqx_1 \cdots qx_n d \mid x_1 \cdots x_n \in L\}$. Note that $\widehat{L}_1 = \widehat{L}_2$ iff $L_1 = L_2$.

Lemma 4. *For any DPDA \mathcal{B} there exists a term $x : \text{exp} \vdash M_{\mathcal{B}} : \text{com}$ such that $\mathcal{L}(\text{comp} \llbracket x : \text{exp} \vdash M_{\mathcal{B}} : \text{com} \rrbracket) = \overline{N(\mathcal{B})}$.*

Proof. Push transitions are simulated by recursive calls, pop moves by call returns. Before each call, the symbol to be pushed is stored in the variable TOP which is used to initialize the local copy of X after the call. Take $M_{\mathcal{B}}$ to be

$$\begin{aligned}
 x : \text{exp} \vdash & \text{ new } Q := q_0, TOP := Z_0, CH \text{ in} \\
 & \mu z^{com}. \text{ new } POP := 0, X := !TOP \text{ in} \\
 & \text{ while } (\text{not } !POP) \text{ do} \\
 & \quad (\text{if } \delta(!Q, \epsilon, !X) = (q', \alpha) \text{ then} \\
 & \quad \quad (Q := q'; \\
 & \quad \quad \text{if } \alpha = \epsilon \text{ then } POP := 1 \text{ else } ((TOP := \alpha_1); z)) \\
 & \quad \text{else} \\
 & \quad \quad (CH := x; \\
 & \quad \quad \text{if } \delta(!Q, !CH, !X) = (q', \alpha) \text{ then} \\
 & \quad \quad \quad (Q := q'; \\
 & \quad \quad \quad \text{if } \alpha = \epsilon \text{ then } POP := 1 \text{ else } ((TOP := \alpha_1); z)) \\
 & \quad \quad \text{else } \Omega_{com})) : \text{com}
 \end{aligned}$$

Proposition 1. *For any DPDAs $\mathcal{B}_1, \mathcal{B}_2$ we have $N(\mathcal{B}_1) \subseteq N(\mathcal{B}_2)$ iff $M_{\mathcal{B}_1} \sqsubseteq M_{\mathcal{B}_2}$.*

Observe that the term used in Lemma 4 is from $\mathbf{IA}_1 + \mathbf{Y}_0$. Since the Containment Problem for DPDAs is undecidable [6] we have:

Corollary 1. *Observational approximation is undecidable for $\mathbf{IA}_1 + \mathbf{Y}_0$ terms; observational equivalence is at least as hard as DPDA Equivalence.*

Our results complete the classification of decidable and undecidable fragments of IA. The exact complexity of observational equivalence for β -normal terms is known in most cases, as shown in the table in Section 1. The complexity of $\mathbf{IA}_i + \mathbf{Y}_0$ depends on the complexity of DPDA Equivalence, which is not known at present. Our construction, when suitably optimized, yields DPDAs that are doubly exponentially larger than the given term in β -normal form. It is also not yet understood how the presence of β -redexes affects the complexity.

Abstract. We consider a game-theoretical variant of the Steiner forest problem, in which each of k users i strives to connect his terminal pair (s_i, t_i) of vertices in an undirected, edge-weighted graph G . In [1] a natural primal-dual algorithm was shown which achieved a 2-approximate budget balanced cross-monotonic cost sharing method for this game.

We derive a new linear programming relaxation from the techniques of [1] which allows for a simpler proof of the budget balancedness of the algorithm from [1]. Furthermore we show that this new relaxation is strictly stronger than the well-known *undirected cut relaxation* for the Steiner forest problem.

We conclude the paper with a negative result, arguing that no cross-monotonic cost sharing method can achieve a budget balance factor of less than 2 for the Steiner tree and Steiner forest games. This shows that the results of [1, 2] are essentially tight.

1 Introduction

In the *Steiner forest problem* we are given an undirected graph $G = (V, E)$, with vertex set V and edge set E , a non-negative cost function $c : E \rightarrow \mathbb{R}^+$ on the edges of G , and a set of $k > 0$ terminal pairs $R = \{(s_1, t_1), \dots, (s_k, t_k)\} \subseteq V \times V$. A feasible solution for a Steiner forest instance is a forest $F \subseteq E$ such that vertices s_j and t_j are in the same tree of F for all $1 \leq j \leq k$. The objective is to find a feasible solution F of smallest total cost $c(F) := \sum_{e \in F} c(e)$. The *Steiner tree problem* is a special case of the Steiner forest problem that consists of connecting a set of terminals $R \subseteq V$ to a root vertex $r \in V$ in the cheapest possible way.

Computing minimum-cost Steiner trees and forests is NP-hard [3] and APX-complete [4, 5] and therefore, neither of the two problems admits a polynomial-time approximation scheme unless $P=NP$. The best known algorithm for the Steiner forest problem, due to Agrawal, Klein and Ravi [6] and generalized by Goemans and Williamson [7], uses the primal-dual schema. The algorithms in [6, 7] achieve an approximation ratio of $(2 - 1/k)$.

In this paper we will consider the following natural game-theoretic version of the Steiner forest problem: each terminal pair $(s_j, t_j) \in R$ is associated with a player j that wants to establish a connection between s_j and t_j . Player j derives a (privately known) utility value u_j from an existing connection between its terminals.

A *cost sharing method* ξ is an algorithm that, given a subset $Q \subseteq R$ of the players, computes a Steiner forest of cost $c(Q)$ satisfying the connectivity requirements of all players in Q . Moreover, for each player $j \in Q$ it determines a non-negative cost share $\xi_Q(j)$. We say that a cost sharing method is α -*budget balanced* if

$$\frac{1}{\alpha} \cdot c(Q) \leq \sum_{j \in Q} \xi_Q(j) \leq \text{opt}_Q.$$

The first inequality says that at least a $1/\alpha$ fraction of the total cost of servicing the users in Q is recovered by the sum of the cost shares of the users in Q . The second inequality establishes fairness in that the sum of all cost shares is not allowed to exceed the optimum cost of servicing the users in Q , denoted opt_Q . This second inequality is often referred to as *competitiveness*. In this paper we will be interested in cost sharing methods ξ that are computable in polynomial time. Therefore, the cost $c(Q)$ of servicing a set of players Q will necessarily exceed the cost opt_Q of an optimum solution for some instances. This also means that there is no hope to achieve budget balance, i.e., $\alpha = 1$.

An important class of cost sharing methods are the *cross-monotonic* methods. ξ is cross-monotonic if, for any two sets Q and S such that $Q \subseteq S$, and any player $j \in Q$ we have $\xi_S(j) \leq \xi_Q(j)$. In other words, the cost share of any player under the given cost sharing method does not increase if the player set increases. The importance of cross-monotonic cost sharing methods stems from a result by Moulin and Shenker [8]: any budget balanced cross-monotonic cost sharing method can be turned into a budget balanced group-strategyproof mechanism.

Despite the recent interest in computational game theory, examples for combinatorial optimization problems that possess a cross-monotonic cost sharing method are still few: Moulin and Shenker [8] gave a cross-monotonic cost sharing method for problems whose optimal cost function is a sub-modular function of the set Q . However, this condition does not hold for many important network design problems such as Steiner trees and facility location. Jain and Vazirani [2] showed a 2-budget balanced and cross-monotonic cost sharing method for Steiner trees. Pál and Tardos [9] later obtained a 3-budget balanced and group-strategyproof cost sharing method for facility location and also provided a 15-budget balanced solution to the single sink rent-or-buy problem.

In a recent paper, Immorlica, Mahdian and Mirrokni [10] show that combinatorial problems that are well-behaved with respect to their approximability may prove hard when looking for approximately budget balanced cross-monotonic cost sharing methods. Their lower bounds are achieved by using cross-monotonicity only. The authors left open the issue of finding a lower bound on the budget balance factor for the Steiner tree problem.

Our contribution. Both Jain and Vazirani [2] and Pál and Tardos [9] show that the computed cost shares form a feasible solution for the dual of a linear programming relaxation for the problem. Proving competitiveness of the methods can therefore be reduced to an application of weak duality. The budget balance factor corresponds to the performance guarantee of the underlying primal-dual algorithm.

In a recent paper [1], Könemann, Leonardi and Schäfer depart from this line. The authors present a cost sharing method KLS which is an adaptation of the primal-dual algorithm AKR for Steiner forests due to Agrawal, Klein and Ravi [6]. The cost shares computed by KLS are proven to be 2-budget balanced. They do not, however, correspond to a feasible dual solution for any of the known Steiner forest duals.

The obvious question left open by [1], that we answer affirmatively in this paper, is this: Is there an alternate Steiner forest LP formulation such that the cost shares computed by KLS correspond to a feasible dual solution? If so, how does this new LP relaxation relate to the standard undirected-cut LP relaxation?

Theorem 1. *There is a linear programming relaxation (LC-D) for the Steiner forest problem whose optimum solution value is at most the cost of any feasible Steiner forest for the given instance. (LC-D) is strictly stronger than the well-known undirected-cut relaxation for Steiner forests. The dual solution computed by KLS is feasible for (LC-D).*

The algorithms in [6, 7] are based on the classical undirected cut formulation for Steiner forests [11]. The integrality gap of this relaxation is known to be $(2 - 1/k)$ and the results in [6, 7] are therefore tight. Our lifted-cut dual relaxation is strictly stronger than the classical undirected cut formulation. There are instances in which the dual solution achieved by our relaxation provides a much better approximation of the optimum than the undirected-cut dual relaxation. On the other hand, there are instances in which both relaxations achieve an integrality gap of $(2 - 1/k)$.

Secondly, one naturally wonders whether there is a $(2 - \epsilon)$ -budget balanced and cross-monotonic cost sharing method for Steiner trees and forests. The answer to this question is negative, and holds for *any* cross-monotonic cost sharing method for these games, including those taking exponential time:

Theorem 2. *There is no $(2 - \epsilon)$ -budget balanced, cross-monotonic cost sharing method for Steiner trees for any $\epsilon > 0$.*

This lower bound shows that the results in [1, 2] are essentially best possible. Hence there is no hope to obtain a $(2 - \epsilon)$ -budget-balanced cross-monotonic cost sharing scheme even if a linear programming relaxation with such integrality gap

existed. Prior to our work, the only upper bound known for the budget balance factor of a cross-monotonic cost sharing method for the Steiner tree and forest games was the IP/LP gap of the bidirected cut relaxation [10] which is at most 8/9.

2 A Cost Sharing Method for Steiner Forests

We review the cross-monotonic cost sharing method for Steiner forests as given in [1]. The algorithm is similar to the primal-dual algorithm AKR due to Agrawal, Klein and Ravi [6]. In this section, we first state the standard LP formulation on which AKR is based, then review AKR, and finally describe the cost sharing algorithm KLS from [1].

Let $S \subseteq V$. We define $\delta(S)$ to be the set of all edges that have exactly one endpoint in S and we also let $R(S)$ be the set of terminal pairs in R that are separated by S , i.e., $R(S) := \{(s, t) \in R : |\{s, t\} \cap S| = 1\}$. We use $r(S)$ for the cardinality of $R(S)$. A subset $S \subseteq V$ is a *Steiner cut* if $r(S) \geq 1$. Let \mathcal{S} be the set of all Steiner cuts.

Consider a Steiner cut $S \in \mathcal{S}$. Any feasible solution F for a given Steiner forest instance must *cross* this cut at least once, i.e., $|\delta(S) \cap F| \geq 1$. This gives rise to the following integer programming formulation for the Steiner forest problem: We have a variable x_e for each edge $e \in E$ which has value 1 if e is part of the resulting forest and 0 otherwise.

$$\begin{aligned} \text{opt}_{\text{IP}} := \min \quad & \sum_{e \in E} c(e) \cdot x_e && \text{(IP)} \\ \text{s.t.} \quad & \sum_{e \in \delta(S)} x_e \geq 1 && \forall S \in \mathcal{S} \quad (1) \\ & x_e \in \{0, 1\} && \forall e \in E . \end{aligned}$$

The dual of the linear programming relaxation (LP) of (IP) has a variable y_S for all Steiner cuts $S \in \mathcal{S}$. There is a constraint for each edge $e \in E$ that limits the total dual assigned to sets $S \in \mathcal{S}$ that contain exactly one endpoint of e to be at most the cost $c(e)$ of the edge.

$$\begin{aligned} \text{opt}_{\text{D}} := \max \quad & \sum_{S \in \mathcal{S}} y_S && \text{(D)} \\ \text{s.t.} \quad & \sum_{S \in \mathcal{S}: e \in \delta(S)} y_S \leq c(e) && \forall e \in E \quad (2) \\ & y_S \geq 0 && \forall S \in \mathcal{S} . \end{aligned}$$

AKR is a *primal-dual* algorithm. That is, it constructs both a feasible and integral primal solution for (LP) and a feasible dual solution for (D). The algorithm starts with an infeasible primal solution and reduces the degree of infeasibility as it progresses. At the same time, it creates a dual feasible packing of sets of largest possible total value. The algorithm raises dual variables of certain subsets

of vertices. The final dual solution is maximal in the sense that no single set can be raised without violating a constraint of type (2).

We can think of an execution of AKR as a process over time. Let x^τ and y^τ be the primal incidence vector and feasible dual solution at time τ . We use F^τ to denote the forest corresponding to x^τ . Initially, $x_e^0 = 0$ for all $e \in E$ and $y_S^0 = 0$ for $S \in \mathcal{S}$. In the following we say that an edge $e \in E$ is *tight* if the corresponding constraint (2) holds with equality.

Assume that the forest F^τ at time τ is infeasible. We use \bar{F}^τ to denote the subgraph of G that is induced by the tight edges for dual y^τ . A connected component S of \bar{F}^τ is *active* iff S separates at least one terminal pair, i.e., iff $S \in \mathcal{S}$. Let \mathcal{C}^τ be the set of all active connected components of \bar{F}^τ at time τ . AKR raises the dual variables for all sets in \mathcal{C}^τ uniformly at all times $\tau \geq 0$.

Suppose now that two active connected components S_1 and S_2 *collide* at time τ in the execution of AKR. In other words, there are terminals $u \in S_1$ and $v \in S_2$ such that a path between u and v becomes tight as a consequence of increasing y_{S_1} and y_{S_2} . If this happens, we add the path to F^τ and continue. S_1 and S_2 are part of the same connected component of $\bar{F}^{\tau'}$ for $\tau' > \tau$.

The following is the main result of [6]:

Theorem 3. *Suppose that algorithm AKR outputs a forest F and a feasible dual solution $\{y_S\}_{S \in \mathcal{S}}$. Then $c(F) \leq (2 - 1/k) \cdot \sum_{S \in \mathcal{S}} y_S \leq (2 - 1/k) \cdot \text{opt}_R$, where opt_R is the minimum-cost of a Steiner forest for the given input instance with terminal set R .*

We next describe the modifications that are necessary to turn AKR into a cross-monotonic cost sharing algorithm. We use KLS to refer to this algorithm.

Define the *time of death* $d(s, t)$ for each terminal pair $(s, t) \in R$ as

$$d(s, t) := \frac{1}{2} \cdot c(s, t) \quad , \tag{3}$$

where $c(s, t)$ denotes the cost of the minimum-cost s, t -path in G . We assume for ease of presentation that each vertex $v \in V$ has at most one terminal on it. This assumption is without loss of generality since we can replace each vertex in V by a sufficient number of copies and link these copies by zero-cost edges. We extend the death time notion to individual terminals and define $d(s) = d(t) = d(s, t)$ for terminals $s, t \in R$.

Using the notation introduced above we obtain KLS by modifying the definition of \mathcal{C}^τ . We say that a connected component S of \bar{F}^τ is *active* at time τ if it contains at least one terminal $v \in S$ with death time at least τ , i.e., S is active iff there exists a $v \in S$ with $d(v) \geq \tau$. KLS grows all active connected components in \mathcal{C}^τ uniformly at all times $\tau \geq 0$. Observe that this way KLS also raises dual variables of connected components in \mathcal{C}^τ that do not correspond to Steiner cuts. In what follows we denote by \mathcal{N} the set of *non-Steiner cuts*: $\mathcal{N} := \{S \subseteq V : S \notin \mathcal{S}, S \cap R \neq \emptyset\}$. Furthermore, we let $\mathcal{U} := \mathcal{S} \cup \mathcal{N}$ be the set of all Steiner and non-Steiner cuts.

The intuition behind KLS is that a terminal pair (s, t) is active for the time it would take s and t to connect in the absence of all other terminals. Therefore its

activity time is independent of other terminal pairs and this is crucial to achieve cross-monotonicity.

For a terminal $v \in R$ and for $\tau \leq d(v)$ we let $S^\tau(v)$ be the connected component in \bar{F}^τ that contains v . Also let $a^\tau(v)$ be the number of terminals in $S^\tau(v)$ whose death time is at least τ . The cost share of terminal vertex $v \in R$ is defined as

$$\xi_R(v) := \int_{\tau=0}^{d(v)} \frac{1}{a^\tau(v)} d\tau . \tag{4}$$

Furthermore, we define $\xi_R(s, t) := \xi_R(s) + \xi_R(t)$ for all $(s, t) \in R$.

Theorem 4. *ξ is a cross-monotonic cost sharing method that is 2-budget balanced.*

A proof of this theorem was presented in [1]. There, one of the major difficulties was to show that ξ is *competitive*, i.e., that the sum of the cost shares is at most the optimal cost, opt_R . Since we share the entire dual produced during the execution of KLS among the terminal pairs in R , proving competitiveness is equivalent to showing that the dual solution $\{y_S\}_{S \in \mathcal{U}}$ satisfies $\sum_{S \in \mathcal{U}} y_S \leq \text{opt}_R$. If y were a feasible solution to (D) this would follow immediately from weak duality. Here, however, we cannot apply this argument, since KLS also raises dual variables of non-Steiner cuts. Subsequently, we present an alternative, LP-based proof for the competitiveness of ξ .

3 Lifted-Cut LP Relaxation for Steiner Forests

Recall that we let $R = \{(s_1, t_1), \dots, (s_k, t_k)\}$ be the set of terminal pairs in our instance. Without loss of generality, we assume in the following that $d(s_1, t_1) \leq \dots \leq d(s_k, t_k)$. We define a precedence order \prec on R by letting $(s_i, t_i) \prec (s_j, t_j)$ iff $i \leq j$ and we extend this order to terminal vertices by letting $s_1 \prec t_1 \prec s_2 \prec t_2 \prec \dots \prec s_k \prec t_k$. For ease of notation we assume that $v \prec v$ for all $v \in R$.

Consider a terminal w and let \bar{w} be w 's mate in the Steiner forest instance (i.e., $(w, \bar{w}) \in R$). We let $\mathcal{S}_w \subseteq \mathcal{S}$ be the set of Steiner cuts that separate w and \bar{w} and for which (w, \bar{w}) is the highest ranked such terminal pair:

$$\mathcal{S}_w := \{S \in \mathcal{S} : w \in R(S), v \prec w \text{ for all } v \in R(S)\} .$$

We also let $\mathcal{N}_w \subseteq \mathcal{N}$ be the set of all non-Steiner cuts containing w and \bar{w} where (w, \bar{w}) is the terminal pair of highest rank:

$$\mathcal{N}_w := \{S \in \mathcal{N} : \{w, \bar{w}\} \subseteq S \cap R, (v, \bar{v}) \prec (w, \bar{w}) \text{ for all } (v, \bar{v}) \in S \cap R\} .$$

Recall that we define $\mathcal{U} := \mathcal{S} \cup \mathcal{N}$ as the set of all Steiner and non-Steiner cuts. We then say that a terminal $w \in R$ is *responsible* for a cut $S \in \mathcal{U}$ if $S \in \mathcal{S}_w \cup \mathcal{N}_w$.

The dual of the lifted-cut relaxation for the Steiner forest problem is as follows:

$$\begin{aligned}
 \text{opt}_{\text{LC-D}} &:= \max \sum_{S \in \mathcal{U}} y_S && \text{(LC-D)} \\
 \text{s.t.} & \sum_{S \in \mathcal{U}: e \in \delta(S)} y_S \leq c(e) && \forall e \in E \quad (5) \\
 & \sum_{S \in \mathcal{S}} y_S + \sum_{S \in \mathcal{N}} y_S \leq d(w) && \forall w \in R \quad (6) \\
 & y_S \geq 0 && \forall S \in \mathcal{U} .
 \end{aligned}$$

Notice that a feasible solution to (LC-D) may assign positive values to non-Steiner cuts $S \in \mathcal{N}$. The constraints of type (6) are necessary as the objective function value of (LC-D) would be unbounded in their absence.

The linear programming dual of (LC-D) has variables x_e for every edge $e \in E$ and variables x_w for every terminal $w \in R$:

$$\begin{aligned}
 \text{opt}_{\text{LC-P}} &:= \min \sum_{e \in E} c(e) \cdot x_e + \sum_{w \in R} d(w) \cdot x_w && \text{(LC-P)} \\
 \text{s.t.} & \sum_{e \in \delta(S)} x_e + x_w \geq 1 && \forall S \in \mathcal{S}_w, \forall w \in R \quad (7) \\
 & \sum_{e \in \delta(S)} x_e + x_w + x_{\bar{w}} \geq 1 && \forall S \in \mathcal{N}_w, \forall w \in R \quad (8) \\
 & x_e, x_w \geq 0 && \forall e \in E, \forall w \in R .
 \end{aligned}$$

Let $\{x_e, x_w\}_{e \in E, w \in R}$ be an integral solution that is feasible for (LC-P). We argue that this solution gives rise to a feasible Steiner forest with cost not exceeding the objective function value. Define $F := \{e \in E : x_e = 1\}$. The total cost $c(F)$ of F is $\sum_{e \in E} c(e) \cdot x_e$. F is not necessarily a feasible Steiner forest since there might exist a Steiner cut $S \in \mathcal{S}$ with no crossing edge, i.e., $\delta(S) \cap F = \emptyset$. Let $S \in \mathcal{S}_w$ be such a set and let \bar{w} be the mate of w . Constraint (7) for S and w implies that $x_w = 1$ in this case. Next consider the complement $\bar{S} = V \setminus S$. It can be seen that \bar{w} is responsible for \bar{S} and hence, $\bar{S} \in \mathcal{S}_{\bar{w}}$. As no edge crosses \bar{S} , we must have $x_{\bar{w}} = 1$. Therefore, we can add all edges along the shortest w, \bar{w} -path to F at a cost of $2d(w, \bar{w})$.

The following lemma relates the cost of any feasible solution for the given Steiner forest instance to the objective function value of an optimal solution for (LC-P).

Lemma 1. *Let F be a feasible solution for the underlying Steiner forest instance. We can then construct a solution x that is feasible for (LC-P) and satisfies:*

$$\sum_{e \in E} c(e) \cdot x_e + \sum_{w \in R} d(w) \cdot x_w \leq c(F) .$$

In particular, this implies that $\text{opt}_{LC-D} = \text{opt}_{LC-P} \leq \text{opt}_R$.

Proof. Let T be a tree in F . We use $E(T)$ and $V(T)$ to refer to the edges and vertices of T , respectively. We construct a solution x that is feasible for (LC-P) and show that for each tree $T \in F$

$$\sum_{e \in E(T)} c(e) \cdot x_e + \sum_{w \in R \cap V(T)} d(w) \cdot x_w \leq c(T) .$$

The lemma then follows by summing over all trees in F .

Consider a tree $T \in F$. Let (w, \bar{w}) be the terminal pair that is responsible for the non-Steiner cut $V(T)$. Moreover, let P denote the unique w, \bar{w} -path in T . We set $x_e := \frac{1}{2}$ for each edge $e \in E(P)$ and $x_e := 1$ for each edge $e \in E(T) \setminus E(P)$. Moreover, we assign $x_w = x_{\bar{w}} := \frac{1}{2}$ and $x_r := 0$ for all terminals $r \in (R \cap V(T)) \setminus \{w, \bar{w}\}$. By definition (3) of death time, $d(w, \bar{w}) \leq \frac{1}{2}c(P)$. Thus, the objective value for x on T is $c(T) - c(P)/2 + d(w, \bar{w}) \leq c(T)$.

It remains to be shown that x is feasible for (LC-P). We show for each tree T in F and for all $v \in R \cap V(T)$ that x satisfies the cut-requirements of constraints (7) and (8) for sets $S \in \mathcal{S}_v \cup \mathcal{N}_v$.

Consider a cut $S \in \mathcal{S}_v$ for some $v \in R \cap V(T)$. If $v \in \{w, \bar{w}\}$, constraint (7) holds since S intersects P and $x_v = \frac{1}{2}$. Now let $v \notin \{w, \bar{w}\}$. As $S \in \mathcal{S}_v$ and $v \prec w$, by assumption, it follows that either $\{w, \bar{w}\} \subseteq S$ or $\{w, \bar{w}\} \cap S = \emptyset$. We also have $\bar{v} \notin S$. As T connects v and \bar{v} , it can be seen that S either intersects at least one edge e of T that is not on P (and hence $x_e = 1$) or it intersects at least two edges e_1 and e_2 on P (and therefore $x_{e_1} = x_{e_2} = \frac{1}{2}$). Thus, constraint (7) holds in this case as well.

Next consider a non-Steiner cut $S \in \mathcal{N}_v$ for terminal $v \in R \cap V(T)$. If $v \notin \{w, \bar{w}\}$ then $\{w, \bar{w}\} \cap S = \emptyset$ and S crosses at least one edge of T that is not on P or at least two edges of P . Hence constraint (8) holds. Otherwise, S may cross no edge of T but $x_w + x_{\bar{w}} = 1$ and thus (8) is satisfied. \square

Running algorithm KLS on terminal set R yields a cost-share $\xi_R(s, t)$ for all $(s, t) \in R$. It also returns a dual solution y such that $\sum_{(s,t) \in R} \xi_R(s, t) = \sum_{S \in \mathcal{U}} y_S$. It is easy to verify that y is feasible for (LC-D). Lemma 1 therefore yields an alternate proof of the competitiveness of KLS:

Corollary 1. $\sum_{(s,t) \in R} \xi_R(s, t) = \sum_{S \in \mathcal{U}} y_S \leq \text{opt}_{LC-D} \leq \text{opt}_R$.

The next lemma shows that (LC-D) is at least as strong as the standard LP dual (D).

Lemma 2. Let $\{y_S\}_{S \in \mathcal{S}}$ be a feasible dual solution for (D). Then there is a feasible dual solution $\{y'_S\}_{S \in \mathcal{U}}$ for (LC-D) with $\sum_{S \in \mathcal{S}} y_S \leq \sum_{S \in \mathcal{U}} y'_S$. This implies that $\text{opt}_D \leq \text{opt}_{LC-D}$.

Proof. Let y be a feasible solution for (D). The sets \mathcal{S}_w for terminals $w \in R$ form a partition of \mathcal{S} : $\mathcal{S} = \bigcup_{w \in R} \mathcal{S}_w$. First, we argue that we can assume that y is *symmetric* in the following sense. y is symmetric if for all $(s, t) \in R$:

$$l_s := \sum_{S \in \mathcal{S}} y_S = \sum_{S \in \mathcal{S}} y_S =: l_t .$$

Suppose that this equality does not hold for some $(s, t) \in R$ and, without loss of generality, assume that $l_s > l_t$. Then, let $S \in \mathcal{S}_s$ be a set with $y_S > 0$.

Consider the set $\bar{S} = V \setminus S$ and observe that this set is a Steiner cut as well. Moreover, S and \bar{S} trivially separate the same terminal pairs in R , i.e., $R(S) = R(\bar{S})$. It therefore follows that t must be the responsible terminal for \bar{S} and hence $\bar{S} \in \mathcal{S}_t$. Finally, notice that $\delta(S) = \delta(\bar{S})$ and hence we can increase $y_{\bar{S}}$ and decrease y_S at the same rate without violating any of the constraints of type (2). Continuing this procedure will lead to a symmetric dual y that is feasible for (D).

Now define $y'_S = y_S$ if S is a Steiner cut and let $y'_S = 0$ otherwise. y' clearly satisfies all constraints of type (5). We will now show that y' also satisfies all constraints of type (6) and this will finish the proof of the lemma.

Assume for the sake of contradiction that y' violates constraint (6) for some terminal $w \in R$: $l_w + \sum_{S \in \mathcal{N}} y'_S > d(w)$. Since $y'_S = 0$ for all non-Steiner cuts $S \in \mathcal{N}_w$ we therefore must have $l_w > d(w) = c(P)/2$, where $c(P)$ is the cost of a minimum-cost w, \bar{w} -path in G .

Using the symmetry of y we know that $l_w = l_{\bar{w}}$ and hence we must have $l_w + l_{\bar{w}} > c(P)$. On the other hand, adding the constraints of type (2) for all edges $e \in P$ yields

$$l_w + l_{\bar{w}} \leq \sum_{S \in \mathcal{S}} |\delta(S) \cap P| \cdot y_S = \sum_{e \in P} \sum_{S \in \mathcal{S}: e \in \delta(S)} y_S \leq c(P) ,$$

and this is a contradiction. □

The dual of the lifted-cut relaxation is strictly stronger than the standard LP dual (D). The proof of the following lemma is omitted.

Lemma 3. *There exist instances for which $\text{opt}_D < \text{opt}_{LC-D}$.*

Lemmas 1, 2, and 3 together with Corollary 1 finish the proof of Theorem 1. Unfortunately, as with the undirected cut formulation for Steiner forests, the IP/LP gap of the lifted-cut relaxation is about 2 for certain instances. The proof is omitted.

Lemma 4. *There exist instances for which $\text{opt}_R / \text{opt}_{LC-D} = 2 - 2/(k + 1)$.*

4 A Lower Bound for the Steiner Tree Game

The tools used in this section are adaptations of those used in [10]. In particular we consider any given cross-monotonic cost sharing method ξ for the Steiner

tree game and show that there is an instance of the game where the sum of the cost shares of all players is considerably smaller than the cost of an optimum solution. Instead of using a probabilistic argument similar to the one described in [10], we use a more direct (but ultimately equivalent) proof based on convex combinations.

The family of instances used in our proof resembles the one used for the facility location lower bound in [10]. We construct an undirected graph $G = (V, E)$. In this graph, there are k pairwise disjoint classes A_i , $i = 1, \dots, k$, each of which contains m vertices. Every one of these vertices corresponds to a player who wants to connect this vertex with the root. The set of all players that have a vertex associated with them in A_i is denoted by \mathcal{A}_i . The set of all players is $\mathcal{R} := \bigcup_{i=1}^k \mathcal{A}_i$.

Let \mathcal{B} be a set containing all sets with exactly one element from each of the A_i , i.e., $\mathcal{B} := \{\{a_1, \dots, a_k\} : a_i \in A_i, i = 1, \dots, k\}$. For each set $B \in \mathcal{B}$, we introduce a unique vertex f_B with distance 1 to all vertices in B . The distance to the vertices not in B is, by triangle inequality, equal to 3. Finally, every vertex f_B is connected to the root r , with edges of length 3.

The following lemma argues that we may assume that ξ is *symmetric* in the following sense: Consider a subset $\mathcal{T} \subseteq \mathcal{R}$. We then may assume that $\xi_{\mathcal{T}}(c) = \xi_{\mathcal{T}}(d)$ for any two players $c, d \in \mathcal{A}_i \cap \mathcal{T}$ and for any $1 \leq i \leq k$.

Lemma 5. *Suppose that there is an α -budget balanced cost sharing method for the Steiner tree game. Then, given an arbitrary player subset $\mathcal{T} \subseteq \mathcal{R}$, there also is an α -budget balanced cost sharing method with $\xi_{\mathcal{T}}(c) = \xi_{\mathcal{T}}(d)$ for all $c, d \in \mathcal{T} \cap \mathcal{A}_i$ and for all $1 \leq i \leq k$. Moreover, for all $c \in \mathcal{T} \cap \mathcal{A}_i$ and for all $d \in \mathcal{A}_i \setminus \mathcal{T}$, we may assume that $\xi_{\mathcal{T}}(c) = \xi_{(\mathcal{T} \setminus \{c\}) \cup \{d\}}(d)$.*

Proof. Let $\tilde{\xi}$ be an α -budget balanced cost sharing method for the Steiner tree game. Pick an index i and a set of players $\mathcal{T} \subseteq \mathcal{R}$. For a player $c \in \mathcal{A}_i \cap \mathcal{T}$ we let $a_c \in A_i$ be the (original) terminal associated with c . Now consider a permutation π_i of the players in class \mathcal{A}_i . The terminal of c under permutation π_i is $a_{\pi_i(c)}$.

Define the map π by letting $\pi(c) = \pi_i(c)$ iff $c \in \mathcal{A}_i$. For a set of players \mathcal{T} , we define $\pi(\mathcal{T}) := \{d \in \mathcal{R} : \exists c \in \mathcal{T} : d = \pi(c)\}$. Let Π be the set of all $(m!)^k$ possible maps that arise in this way. The cost sharing method ξ is then given by

$$\xi_{\mathcal{T}}(c) = \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{T})}(\pi(c))$$

for all $c \in \mathcal{R}$.

The important observation here is that the cost sharing method $\tilde{\xi}$ works on vertices. So if we swap the terminals associated with two players in \mathcal{T} , the cost shares for these players will be swapped as well. In other words, for any two permutations the algorithm will be presented with the same set of terminals, but the players associated with these terminals may have changed.

Notice that, for a player $c \notin \mathcal{T}$, the value $\xi_{\mathcal{T}}(c)$ is 0 as $\pi(c) \notin \pi(\mathcal{T})$ for all $\pi \in \Pi$. It is now not difficult to see that, for all $1 \leq i \leq k$ and for any two players

$c, d \in \mathcal{A}_i \cap \mathcal{T}$, we have $\xi_{\mathcal{T}}(c) = \xi_{\mathcal{T}}(d)$ as we average over all player permutations. It remains to show that ξ is cross-monotonic and α -budget balanced.

Consider adding a player d to set \mathcal{T} . We have to argue that the cost share of an individual player cannot increase. For a player $c \in \mathcal{T}$ we see that

$$\xi_{\mathcal{T} \cup \{d\}}(c) = \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{T} \cup \{d\})}(\pi(c)) \leq \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{T})}(\pi(c)) = \xi_{\mathcal{T}}(c) .$$

This follows since $\pi(\mathcal{T} \cup \{d\}) = \pi(\mathcal{T}) \cup \{\pi(d)\}$ and hence the cross-monotonicity of $\tilde{\xi}$ can be applied to each term.

Now we show α -budget balance. To this end we must specify which solution is returned by the algorithm. If we denote with S^π the solution returned by cost sharing method $\tilde{\xi}$ when run on set $\pi(\mathcal{T})$, we return the solution $S \in \{S^\pi : \pi \in \Pi\}$ with cost $c(S) = \min_{\pi \in \Pi} c(S^\pi)$.

Of course this solution is not necessarily feasible for the original player set, but because of the symmetry of the instance there is a graph isomorphism that maps the solution back to a feasible one without changing the cost.

Now we can write

$$\begin{aligned} \sum_{c \in \mathcal{T}} \xi_{\mathcal{T}}(c) &= \sum_{c \in \mathcal{T}} \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \tilde{\xi}_{\pi(\mathcal{T})}(\pi(c)) = \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \sum_{c \in \mathcal{T}} \tilde{\xi}_{\pi(\mathcal{T})}(\pi(c)) \\ &\geq \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \frac{1}{\alpha} \cdot c(S^\pi) \geq \sum_{\pi \in \Pi} \frac{1}{(m!)^k} \frac{1}{\alpha} \cdot c(S) = \frac{1}{\alpha} \cdot c(S) . \end{aligned}$$

Competitiveness can be proven using a similar line of reasoning: the cost of the optimal solution must be the same in any permutation. With that, the proof is complete. \square

Now suppose we are given a symmetric cost sharing method ξ . From this point on we will identify players and vertices to avoid complication of notation. Ask the algorithm for cost shares for a subset of players $\{a_1, \dots, a_k\}$ where $a_i \in A_i$. By construction of the graph, all these terminals can connect to vertex $f_{\{a_1, \dots, a_k\}}$ at cost 1, at which point they are only 3 units away from the root. Hence there is a solution of cost $k + 3$ for this subset. Competitiveness states that

$$\sum_{j=1}^k \xi_{\{a_1, \dots, a_k\}}(a_j) \leq \text{opt}_{\{a_1, \dots, a_k\}} \leq k + 3 .$$

Therefore there must be at least one index i such that $\xi_{\{a_1, \dots, a_k\}}(a_i) \leq (k+3)/k$. By Lemma 5, this holds for every set $\{a_1, \dots, a_{i-1}, c, a_{i+1}, \dots, a_k\}$ where $c \in A_i$ and the other a_j are the same as before.

For this index i we consider the instance with subset $Q := \{a_1, \dots, a_k\} \cup A_i$. We bound the sum of the cost shares for this set as follows:

$$\begin{aligned} \sum_{c \in Q} \xi_Q(c) &= \sum_{c \in A} \xi_Q(c) + \sum_{j \neq i} \xi_Q(a_j) \\ &\leq \sum_{c \in A} \xi_{\{a_1, \dots, a_{-1}, c, a_{+1}, \dots, a\}}(c) + \sum_{j \neq i} \xi_{\{a_1, \dots, a_{-1}, a_{+1}, \dots, a\}}(a_j) \quad (9) \\ &\leq m \cdot \frac{k+3}{k} + k + 2 \quad . \quad (10) \end{aligned}$$

The inequality in (9) is due to cross-monotonicity: the cost share of a player over a subset of Q cannot be smaller than the cost share for that player over Q . We know that a set of players never pays more than the cost of the optimal tree connecting these players. For set $\{a_1, \dots, a_{i-1}, a_{i+1}, \dots, a_k\}$, which has one player from $k-1$ of the sets A_j , there is a solution of $3+k-1 = k+2$. This provides an upper bound on the rightmost term of (9). For the leftmost term, we argued above that $\xi_{\{a_1, \dots, a_{-1}, c, a_{+1}, \dots, a\}}(c) \leq (k+3)/k$.

Due to the large amount of symmetry in the instance, we can in fact describe the optimal solution. The proof of the following lemma is omitted.

Lemma 6. *The optimal solution for connecting the players in a set Q , as defined above, to the root has cost $2m+k+1$.*

Combining Lemma 6 with Inequality (10), we can now prove Theorem 2.

Proof (Theorem 2). The ratio between the cost shares of players in the subset Q as defined above and the cost of the network they use can be bounded as follows:

$$\frac{\sum_{c \in Q} \xi_Q(c)}{c(Q)} \leq \frac{\sum_{c \in Q} \xi_Q(c)}{\text{opt}_Q} \leq \frac{m \frac{k+3}{k} + k + 2}{2m + k + 1} = \frac{k^2 + 4k + 2}{2k^2 + k + 1} \quad ,$$

where the last equality holds if we choose $m = k^2$. This ratio tends to $\frac{1}{2}$ as $k \rightarrow \infty$, which completes the proof. \square

How Well Can Primal-Dual and Local-Ratio Algorithms Perform?

Allan Borodin, David Cashman, and Avner Magen

University of Toronto
{bor, cashman, avner}@cs.toronto.edu

Abstract. We define an algorithmic paradigm, the stack model, that captures most primal-dual and local-ratio algorithms for approximating covering and packing problems. The stack model is defined syntactically and without any complexity limitations. Hence our approximation bounds are independent of the P vs NP question. We provide tools to bound the performance of primal dual and local ratio algorithms and supply a $(\log n + 1)/2$ inapproximability result for set-cover, a $4/3$ inapproximability for min steiner tree, and a 0.913 inapproximability for interval scheduling on two machines.

1 Introduction

The primal dual and local ratio schemas for approximation algorithms are two fundamental algorithm design techniques. The use of the primal dual schema is pervasive, having been applied to give good approximation algorithms for several basic NP-hard combinatorial optimization problems including set cover, vertex cover, numerous network design problems, facility location and k -median, steiner forest, and many others. The origins of the primal dual schema can be found in the Bar Yehuda and Even [7] algorithm for the weighted vertex cover problem. The re-introduction of the enhanced primal dual schema leading to its current importance is due to the works of Agarwal, Klein and Ravi [1] and Goemans and Williamson [15].

The list of problems tackled successfully by primal-dual and local-ratio algorithm is long and impressive. For many of these problems the methods achieve the best known approximation (see [24, 6] and references therein). But just how far can these methods go? The goal of this paper is to shed some light on this question. Our first step in achieving this is to put the two algorithmic schemas under a larger umbrella – a syntactic computational model capturing both, devoid of complexity considerations and that is related to the LP formulation via the input model environment it works over. This model is what we call the *stack model* and will be described in detail in Section 2. We then show hardness of approximation results within this model for a few prominent problems in which the primal-dual schema was applied before, sometimes achieving the best bound.

For the clarity of our exposition we will use the set-cover problem as a specific running example. We shall focus our attention on what is considered to be the

common method of the primal-dual schema for covering problems. Let us be more specific: our abstraction of this method corresponds to what Williamson [24] calls the “primal dual algorithm with reverse delete step”. The more restricted version of the method which was the first to appear is called “basic primal-dual algorithm”, can be simulated by the *priority model* of [11]. In the priority model, an algorithm considers each input item once (according to some ordering) and immediately makes an irrevocable decision (i.e. accept or reject) about each input item. For the simulation to be possible, the input items are in correspondence with the 0/1 variables constituting the problem, and the input items contain information about their cost and about the constraints they appear in. In the set-cover example, the items are the sets and the natural representation of a set is its weight and the list of elements it contains, namely the cost and the constraints of the natural LP relaxation. We elaborate on this somewhat subtle issue when we discuss the specific applications we deal with. Returning to priority algorithms, there is some natural restriction on what orderings are permissible and we shall argue that the primal dual schema always leads to a permissible ordering. Roughly speaking, the permissible orderings are those that are induced by any (not necessarily computable) mapping of all possible input items into \mathbb{R} . Also, the ordering in priority algorithms can be established afresh at every iteration of the algorithm.

A substantial leap forward in terms of the applicability of the primal-dual approach was made at the beginning of the nineties, namely the introduction of the “reverse delete step” [15, 17, 21]. Roughly speaking, this is a phase that guarantees that the output of the algorithm is a *minimal* feasible solution (w.r.t set inclusion). This property is shown to be crucial in the analyses of problems such as minimum Steiner tree, the feedback vertex set problem, generalized steiner forests, and others. As is shown in [24] the analysis may sometime depend not only on the minimality of the produced solution, but also on the exact process that ensures this minimality. The analogous leap in the world of abstract models leads us to the definition of the *stack model*. Here, instead of irrevocably rejecting/accepting an item, the algorithm decides whether to reject or to *push* an item onto a stack. Then the elements in the stack are popped and removed when this is possible.

The *stack model* also captures the local-ratio schema as described in the survey of Bar-Yehuda et al [6]. This should not be taken as a surprise as Bar-Yehuda and Rawitz [9] have demonstrated that there is an equivalence between the primal dual and local-ratio schemas. In fact, in this extended abstract we use their observation to argue that the *stack model* simulates regular local-ratio algorithms, without a concrete description of such a simulation.

In contrast to the extensive use of primal-dual and local-ratio for covering problems, the only (albeit important) use of the primal dual schema for packing problems was the approximation of the *bandwidth allocation problem* in Bar-Noy et al [5]. As was shown in [5], the local ratio technique can *optimally* solve the one machine weighted interval selection problem whereas the negative result in [11] precludes the possibility of any constant approximation to the problem within

the priority model. This provably shows that it is sometimes necessary to have a second “clean-up” stage to obtain good approximation bounds.

It is important to note that, while most of the known applications of primal-dual fall under “primal-dual with reverse delete”, there are several applications that do not fit within the stack model framework. Of these, one of the most prominent examples is Jain and Vazirani’s use of primal dual method for the approximation of metric facility location and k -median problems [16]. Notice that these problems are not covering or packing problems, and therefore inherently in need of a more specialized algorithmic paradigm. A more basic example is the steiner tree algorithm for the special class of quasi-bipartite graphs [18]. Their method provides a $3/2 + \epsilon$ approximation by combining local search with primal dual and using the so called *bidirected* LP relaxation as a starting point. (This method utilizes a non-standard input representation by considering each edge as two directed edges and hence automatically falls outside of our model.) Another example of a primal-dual/local-ratio algorithm that does not fit our model are the so called *fractional* local-ratio/primal-dual algorithms which first solve the LP, and use the solution as a guide to ordering items [8] and [10].

2 The Stack Model and Its Ancestor the Primal-Dual

Consider an integer program for a covering problem, and assume that the variables to the problem are the natural 0/1 variables of the problem, and that the constraint matrix A and the cost vector c are nonnegative. In a nutshell, what a primal dual schema does is to consider an LP relaxation of this IP and the dual maximization problem and (i) starts with the feasible dual solution $y = 0$ (ii) increases y continuously until a dual constraint(s) becomes tight (iii) in this case the corresponding primal variable(s) enter the solution (iv) continues as long as the primal solution generated so far is not feasible (v) goes over the primal variables in the solution in a reverse order and removes them whenever feasibility is maintained. Notice that we haven’t specified exactly how the dual vector y is increased, and we choose to stay at this level of generality. Returning to our set-cover example, the dual variables in the natural LP relaxation are elements of the ground set. We increase all the dual variables that do not occur in a tight equation (uncovered elements) uniformly, until a new set (dual constraint) becomes tight, in which case this set joins the solution. Step (v), the reverse-delete, removes a set if it is not needed, while following the reverse order.

We now get to the critical observation that later leads to the abstraction of the model and to our lower bounds. Notice that the above process induces, at each iteration, an ordering on the primal variables that has not entered the solution yet. If at any point an adversary announces that a primal variable that has not yet become tight *has never existed*, the algorithm has no way to recognize such a change as it has no effect on the algorithm’s history. An adversarial approach can be developed from this limitation of the algorithm and may lead to inapproximability results.

This sets the stage for the stack model. We consider a two-pass algorithm, in which the first pass, the push phase, resembles an adaptive priority algorithm, as defined in [11], and the second pass, the pop phase, is a simple greedy phase that is not under the control of the algorithm. Here is a precise description. The algorithm first orders the items by some valid ordering. This is just a total ordering of all possible input items. In our example, one can imagine ordering by cardinality of sets, or more generally by any function f_1 on the characteristic 0/1 vectors and the weight of the sets. Next, it looks at the first item, and either pushes it onto the stack or rejects it. It then may decide to change the ordering using the information of the first item (defining f_2 after looking at the first set). Again, the first (unseen) item in this ordering is either pushed or rejected. This process continues for at most n iterations,¹ at which point the algorithm enters the “pop phase” in which items are popped from the stack (last in, first out). The solution to be produced is a subset of the items on the stack and is defined as follows. Each popped item will be rejected if the items that were popped and accepted, together with the items still on the stack constitutes a feasible solution; otherwise it is accepted. It is easy to see that if, at the beginning of the pop phase, we have a feasible solution, we will have one at the end, and further, that solution is minimal w.r.t set inclusion.

Having defined the stack model, we are ready to make the central claim of this section : Every primal dual algorithm under the scheme described above can be simulated by a stack algorithm. It is here that we insist that the input representation of an item contains its cost and the objects that correspond to the constraints that include it. Indeed, regardless of the way y is increased, we get a primal variable that matches a dual constraint that was just made tight. The variable(s) made tight is the one (are those) minimizing the expression $f(i) = c_i - \sum_{j:a_{ij} > 0} a_{ij}y_j$. But, since the information about item i includes c_i and the positive a_{ij} , and since the algorithm may keep track of y we conclude that $f : [n] \mapsto \mathbb{R}$ is a valid ordering function as it is a function on the items. The first item is taken² and the stack algorithm pushes it and continues. The pop phase is clearly a reflection of step (v) in the primal dual schema.

If the ordering used during the push phase is determined at the beginning and is not changed during the process, we call this a *fixed order* stack algorithm. Without this restriction we say the ordering is *adaptive*.

We now consider the modifications needed in order to define a stack model for packing problems. Here too, we have a push phase and a pop phase where the push phase proceeds like a fixed or adaptive priority algorithm in determining which items to place on the stack. The pop phase starts with the empty set as its existing solution, and then adds popped items to the existing solution unless the addition of the item renders the current solution infeasible.

¹ As we shall see later, the stack algorithm can end the push phase once a feasible solution exists on the stack, as the items past this point are bound to get deleted.

² If some items become tight simultaneously this is simulated by taking those items one after the other.

We briefly indicate how we can derive negative results for approximation ratios in the (adaptive ordering) stack model. An adversary initially presents a large set of potential input items. As the computation proceeds, the adversary is allowed to delete input items. We note that the adversary is allowed this license since the ordering functions depend only on the item and any previously considered items. Eventually the algorithm will consider all input items that have not been deleted and that will end the push phase. Then since the pop phase is completely determined, we can calculate the cost/profit of the stack algorithm and compare it to an optimal solution for the actual set of items (i.e. the input items not deleted by the adversary and hence considered by the algorithm). For the case of fixed-order stack algorithms, the adversary can often construct the initial set of potential items in such a way that some “difficult structure” exists within a subset of the items no matter how the algorithm chose its order.

The reader may notice that in moving from the primal-dual methodology to the abstraction we describe, the linear structure of the (relaxed) problem disappears. One may also ask what role does the integrality gap play in this discussion? As was observed [24], the ratio guarantee of primal dual algorithms is never better than the integrality gap for *the specific linear program relaxation used by the algorithm*. However, *any* formulation of the problem as an LP with positive coefficients can lead to a primal dual algorithm, which in turn provides an ordering of the elements that gives rise to a stack algorithm. In other words the abstraction helps us to understand the power of primal dual algorithms with respect to every LP relaxation with positive coefficients under the (nontrivial) condition that the variables are the “natural” ones, and that the input representation “knows” the cost of an item and the constraints involving it. Specifically, to show an inapproximability result for a suggested LP relaxation we are required to adjust the input-representation when we give the stack lower bound. In vertex cover, for example, we may look at the LP relaxation that uses the inequalities that require variables of the vertices in an odd cycle of size l to sum up to $(l+1)/2$ (on top of the regular inequalities). Notice that this type of tightening is a result of a lift and project method and was discussed in the context of hardness result in [4]. If we obtain a lower bound for an input representation in which a vertex knows all the edges *and* all the odd cycles containing it, this would imply a lower bound for PD algorithm applied to this relaxation!

3 The Minimum Set Cover Problem

We consider the classical minimum set cover problem. We are given a family of subsets S_1, S_2, \dots, S_m of a ground set U of size n . In addition, each set S_i is associated with a cost c_i . The goal is to minimize the cost of a collection of the S_i that cover every element in U . The unweighted version of the problem seeks to minimize the number of subsets chosen.

The well known natural greedy algorithm for set cover selects sets with minimum cost per size ratio, and continues recursively on the remaining set of uncovered items with the remaining sets. The natural greedy algorithm yields an $H(n)$

approximation. Notice that this algorithm is a priority algorithm, and hence a special case of a stack algorithm.

Raz and Safra [19] showed that if $P \neq NP$, then for some constant $c > 0$, set cover cannot be approximated within a ratio of $c \log n$ in polynomial time. Using a stronger complexity assumption, namely that $NP \not\subseteq DTIME(n^{\log \log n})$, Feige was able to show an almost tight bound $(1 - \epsilon)H(n)$. But these hardness results do not apply to our model as the stack algorithm is not restricted to run in polynomial time. Furthermore, stack algorithms may be nonuniform, in the sense of allowing a different algorithm for each n , the the number of input items.

In [2], a $(\log n + 1)/2$ inapproximability bound for the weaker priority algorithm model is shown. Without restating the proof given there, we note that a stack model could provide an optimal solution to the instance that is used in that paper to demonstrate the priority lower bound. Hence, we will need a somewhat more complex set-up to prove the same lower bound for the stack algorithm. We note that a somewhat similar construction is used [23] to show that the integrality gap of the natural LP relaxation for set cover is $\Omega(\log n)$.

We define the ground set U to be the cube $\{0, 1\}^{\log n}$. The initial input to the algorithm consists of $2(n - 1)$ sets, S_v^b where $v \in \{0, 1\}^{\log n} \setminus \{0\}$, and $b \in \{0, 1\}$. Set S_v^b contains all points x for which $\langle v, x \rangle = b$ where $\langle \cdot, \cdot \rangle$ is the inner product over \mathbb{GF}_2 . The sets can be viewed as the inverse images of 0 (1) of all the nontrivial Fourier characters of the boolean cube. We note that for any v , S_v^0 and S_v^1 are a pair of complementary sets.

We require a simple lemma relating the combinatorial properties of sets in our system to the algebraic properties of the vectors that define them:

Lemma 1. *For any set of linearly independent vectors $\{v_1, \dots, v_k\}$ and any choice of b_1, \dots, b_k , the number of elements of U left uncovered by $\{S_{v_1}^{b_1}, \dots, S_v^{b_v}\}$ are selected is exactly $n/2^k$. In particular, any family of sets whose corresponding vectors are linearly independent does not cover U completely.*

Proof. The elements covered by the above sets are $S_{v_1}^{b_1} \cup \dots \cup S_v^{b_v}$, hence the uncovered ones are $S_{v_1}^{1-b_1} \cap \dots \cap S_v^{1-b_v}$. Therefore, x is uncovered iff it is a solution of the system $\langle v_1, x \rangle = 1 - b_1, \dots, \langle v_k, x \rangle = 1 - b_k$. Since the v_i are linearly independent, the co-dimension of the solution space of uncovered elements is k and so it contains $|F_2|^{l-k}$ elements and the first part of the lemma follows. The second part is obvious.

Using the set-system above, we will show that no stack algorithm can achieve a set cover smaller than $\log(n + 1)$, while the optimal set cover is of size 2. At stage i , the algorithm chooses a set S_v^b to look at next. Recall that the adversary may remove sets from the input as the algorithm proceeds.

At each step i , $i < \log n$, suppose the algorithm accepts S_v^b . Then, the adversary removes all the sets S_v^b with $v \in \text{span}\{v_1, \dots, v_i\}$. Notice that this strategy ensures that as long as $i \leq \log n$, the set of vectors defining the sets in the stack are linearly independent. In particular, for any vector v , S_v^0 and S_v^1 cannot both be on the stack.

In the other case in which the algorithm rejects the set S_v^b , we argue that the algorithm may fail to generate *any* set cover. Indeed, as a response the adversary simply deletes all unseen inputs except for S_v^{1-b} . Note that $v_i \notin \text{span}\{v_1, \dots, v_{i-1}\}$ so this is a valid strategy. But even if the algorithm takes that last set, the stack still contains sets with corresponding linearly independent vectors $\{v_1, \dots, v_i\}$, which by Lemma 1 does not form a cover. But of course one exists as the input contains the two complementary sets $\{S_v^{b_0}, S_v^{b_1}\}$. This argument holds also for $i = \log n$.

Now, assuming that the algorithm continues to accept, after the $(\log n)$ -th step, the algorithm has accepted $\log n$ sets whose defining vectors are linearly independent, leaving exactly $n/2^{\log n} = 1$ uncovered element. The adversary will delete all sets *except* for $S_{v^*}^0$ and $S_{v^*}^1$, where $v^* = \sum_{i=1}^{\log n} v_i$. (these sets were not removed before as $v^* \notin \text{span}\{v_1, \dots, v_{\log n-1}\}$). At this point our the “game” is over, and the input to the algorithm is determined. The stack contains $\log n$ linearly independent sets and there are the two remaining sets that the algorithm must consider. Clearly, the sets $S_{v^*}^0$ and $S_{v^*}^1$ constitute a set cover of size 2. It remains to argue that the algorithm must take $\log n + 1$ sets. Since only one element is left uncovered before the two complementary sets are considered, one of the sets is contained in the union of the sets on the stack. This means that this set will be rejected in the pop phase and we may as well assume the algorithm rejects it. The algorithm now has $\log n + 1$ sets on the stack.

We claim that all of these sets must survive the pop phase. Indeed, by the special choice of v^* the vectors v_1, \dots, v_l, v^* are in general position, that is no $\log n$ of them are linearly dependent. Since, by the independence of $v_1, \dots, v_{\log n}$ there may be only one dependency between the $\log n + 1$ vectors, and since summing *all* of them is a dependency, we know that there are no other dependencies, and so the vectors are indeed in general position. We use the corollary again to deduce that no strict sub-family of sets may cover the ground set, and in particular no set can be removed in the pop phase. We have established:

Theorem 1. *No stack algorithm can achieve an approximation ratio better than $\log(n + 1)/2$ for the unweighted minimum set cover problem, where n is the number of elements in the ground set to be covered.*

4 The Steiner Tree Problem

In the Steiner tree problem we are given a weighted graph and a set of distinguished *terminal* vertices T . The goal is to choose a subset of edges that connect all terminal vertices, so as to minimize the sum of the weights. The primal-dual algorithm that achieves a 2-approximation uses the natural LP relaxation in which the IP constraints dictate that every cut separating T is crossed by an edge. The input representation we consider is with edges as items. The information in an item is its weight and the identity of the vertices of the edge. Also, the names of the vertices is known and whether they are terminals or not. Notice that this allows us to know all the separating sets an edge crosses. We later

mention that a lower bound under a much richer input representation is possible, and will discuss the resulting implication. The reverse delete step ensures that if an edge is not needed it will not be taken. In fact, here this step is easily seen to be essential, and the analysis depends on the fact that the resulting set is minimal w.r.t set inclusion. In this section we show that stack algorithms cannot approximate the problem with better than a $4/3$ factor.

In [22], it is shown that unless $\text{Co-RP} = \text{NP}$, no approximation ratio better than about 1.007 is possible for the Steiner Tree problem. The best known algorithm for Steiner tree, due to Robins and Zelikovsky [20] achieves approximation ratio 1.55 and is not a local-ratio/primal-dual algorithm. For the class of quasi-bipartite graphs (i.e. graphs not containing edges between Steiner nodes), their algorithm achieves a ratio of about 1.28, slightly better than our lower bound of $4/3$ for any stack algorithm. We note that our proof applies to quasi-bipartite graphs. In some sense this shows that the algorithm in [20] is superior to any primal-dual approach. We now turn to our result.

Theorem 2. *No stack algorithm can achieve a worst-case approximation ratio better than $4/3$ for the (unweighted) Steiner tree problem.*

Proof. Our proof is motivated by the priority lower bound of Davis and Impagliazzo [13]. Initially we consider the complete bipartite graph $G = \langle T \cup S, R \times S \rangle$, where $T = \{t_1, t_2, t_3\}$ are the terminals and $S = \{s_1, s_2\}$ are the steiner nodes. The algorithm is given the set of terminals and steiner nodes in advance, but is not provided with a list of edges. After each stage of the algorithm, the adversary has the option of deleting any edges that have not yet been seen.

The main ingredient of the proof is the following lemma.

Lemma 2. *In the push phase, consider the first time t that the algorithm has seen two edges connected to some s_j assuming it has not rejected any edges before time t . Call this event D . Then the solution produced by the algorithm must contain these two edges.*

Proof. The lemma is not vacuous : for the graph to have a steiner tree, at least one of the steiner node must have degree at least 2. These edges must be pushed since at time t there is no way to preclude the possibility that the graph is a path of length 4 (this is still consistent with the input so far) and therefore all edges must be taken, and a reject is impossible.

To show that these two edges must be used in the solution produced by the algorithm, we should show that there is no edge e in this pair that will be not rejected in the pop phase. Assume otherwise, then by the definition of the pop phase, there must be a cycle C containing e , so that e is pushed last among all edges in C . But since the graph is bipartite, C must contain two edges out of the other steiner node. This leads to a contradiction, since the later of these edges to be considered must come after e in the order.

Observe that the stars rooted at s_1 and s_2 both have cost 3, while the other steiner trees must use both steiner nodes, and will have cost 4. Note that if an edge adjacent to either steiner node is missing (i.e. deleted by the adversary)

then the star rooted at the other steiner node will be the only Steiner tree with cost 3. Here then is the lower bound strategy. The adversary lets the algorithm run, and waits until either the algorithm rejects an edge, or event D happens.

Suppose that the algorithm rejects an edge before event D happens, say the one connected to s_1 . Then the adversary simply deletes an unseen edge adjacent to s_2 . Such an edge must exist, since event D has not occurred yet. This makes the star rooted at s_1 the unique optimal solution, but the algorithm has just rejected an edge in that star. Hence, in this case the algorithm can achieve a cost of at best 4, for a ratio of $4/3$.

Now, suppose that event D happens first. The algorithm pushes the two edges connected to, say, s_1 . At this point the adversary deletes the third edge adjacent to s_1 , leaving the star rooted at s_2 as the only optimal solution. But by Lemma 2, the algorithm cannot return this unique optimal solution, since it is bound to take both edges connected to s_1 in the solution. This again leads to an approximation lower bound of $4/3$.

By a somewhat more involved example and analysis we can prove a $7/6$ -approximation lower bound when we allow the algorithm to not only know in advance the nodes of the graph, but also the edges of the graph. The only thing not known in advance is the edge costs. This relates quite nicely to the discussion about what LP relaxations we may consider: when all the information is known but the cost vector, then *any* LP relaxation with the natural variables and with positive constraint coefficients is captured by the model.

5 Packing Problems: Scheduling

As was mentioned in the introduction, Bar Noy et al [5] provide the only use to date of local-ratio/primal dual for packing problems. Several problems are discussed there, the most general one being the *NP*-hard bandwidth allocation problem. Here we concentrate on one (polynomial time solvable) special case, namely weighted interval scheduling on 2 identical machines (*WISP*₂), and show that 0.913 is an upper bound to the approximation of this problem by a fixed order (packing) stack algorithm. This should be contrasted with the optimal local ratio algorithm for one machine interval scheduling (*WISP*₁) and the $2/3$ -approximation supplied in [5] for *WISP*₂. We also note that an optimal algorithm for *WISP* _{m} can be obtained by a time $O(n^m)$ dynamic programming algorithm or a time $O(n^2(n - m))$ min cost max flow based algorithm [3].

For the interval scheduling problem (and the more general bandwidth allocation problem) the natural input representation is that the input items are intervals represented by their start times, finish times and weights (profits). This representation is thus good “against” the natural LP formulation in which the constraints are the bounds on the number of intervals that can be scheduled at any time instance t .

For our packing results, we are thus far only able to provide bounds for fixed order stack algorithms. This, however, does capture the one “meta-algorithm” that Bar Noy et al use to solve various cases of the bandwidth allocation prob-

lem. The fixed order there is determined by non-decreasing finishing times which is also the order used for the optimal greedy algorithm for unweighted interval scheduling, and for the one pass algorithms of Erlebach and Spieksma [14]. Obviously our bound does not require the algorithm to use this ordering.

To provide a bound for a fixed-order model (be it a priority algorithm, backtracking algorithm [12], or stack algorithm), it is often useful to provide an initial input set and claim that regardless of the ordering of elements in that set, some combinatorial property must apply to a subset of the initial set. This is analogous to the Ramsey phenomena in graphs; i.e. in every colouring we can say something about one of the colour classes. Restricted to such a (now ordered) subset, we are able to bound the quality of the algorithm (see [12] Theorem 4.1).

We start by describing *forbidden configurations* of the input with respect to an ordering. The first forbidden configuration consists of intervals I, J, K , $I \cap J \cap K \neq \emptyset$, that appear in that order and with profits x, y, z respectively, such that $y < x, z$. We claim that if there is such a configuration, the best approximation ratio achievable is

$$\max\{x/(x + y), (x + y)/(x + z), (y + z)/(x + z)\}. \tag{1}$$

To see the claim, consider the action of the algorithm on input that contains (at most) only I, J and K . If the algorithm decides to reject an interval, that interval becomes the last interval of the input. This leads to approximation ratios $0, x/(x + y)$ or $(x + y)/(x + z)$ when rejecting the first, second or third items respectively. In the more interesting case, all intervals are accepted to the stack, and in the pop phase I will be rejected as it will be popped when J and K are already in the solution. Therefore the algorithm achieves $y + z$ while $x + z$ is possible, and the bound 1 follows.

Another forbidden configuration we consider is the following. There are four intervals I_1, I_2, J, K of profits x, x, y, z respectively. I_1 and I_2 are disjoint, and $I_i \cap J \cap K \neq \emptyset$ for $i = 1, 2$. Also assume that $y < 2x, z$ and that the order is I_1, I_2, J, K or K, J, I_1, I_2 . By a slightly more careful yet similar analysis, we show that this configuration implies a lower bound of

$$\max\{1/2, 2x/(2x + y), (2x + y)/(2x + z), z/(y + z), (y + z)/(2x + z)\}. \tag{2}$$

We now describe the initial input set for our proof: There are two overlapping intervals, one with profit a and the other with profit b , and three intervals, each with profit c . Each c -interval overlaps the a and b intervals, but does not overlap any other c -interval. Finally, for each c -interval, there are three ‘‘child’’ intervals (for a total of 9), each with profit d . Each d -interval overlaps its parent c -interval, and the a and b intervals, but no other intervals. We will later fix the profit values, but for now we only require that $a > b > c > d$ and $2d > b$.

Now, a d or a c interval appearing between two other intervals of greater profit corresponds to configuration I above. A b -interval appearing between an a -interval and two c -intervals, or a c -interval appearing between a b -interval and two d -intervals corresponds to configuration II above. By appropriately substituting the a, b, c, d values for x, y, z in equations 1 and 2, we obtain the following bound on the approximation factor:

$$\max \{a/(a+d), (a+c)/(a+b), (a+d)/(a+c), \\ (c+d)/(b+c), 2c/(2c+b), (2c+b)/(2c+a), \\ (a+b)/(2c+a), 2d/(2d+c), (2d+c)/(2d+b)\} \quad (3)$$

Lemma 3. *Any ordering selected by a fixed ordering stack algorithm will result in at least one of the forbidden configurations described above.*

The proof of the lemma is omitted from this extended abstract. Setting $(a, b, c, d) = (10, 8, 3\sqrt{30} - 10, 5)$, and substituting into (3) gives:

Theorem 3. *For interval scheduling on two machines, no fixed ordering stack algorithm can achieve a constant approximation factor better than .913.*

We remark that the above can be extended to k machines, leading to a $1 - O(1/k)$ inapproximability result. This is not satisfying, as the upper bound achieved by local ratio [5] is $\frac{1}{2-1/k}$ for $k \geq 2$ which limits to $1/2$ for large k .

6 Discussion and Conclusion

We have presented a syntactic model that captures the standard use of primal dual/local ratio algorithms in the context of covering and packing problems. Our framework exposes limits of these paradigms and hence hopefully suggests new ways that modifications of these algorithmic techniques can be applied so as to obtain better approximation guarantees while still maintaining the syntactic and computational simplicity of the basic methods.

For example, our analysis of the interval scheduling problem does not preclude the possibility of close to optimal and efficient (e.g. $O(n \log n)$ time) algorithms for a large but fixed number of processors. For the more general bandwidth allocation problem, we would like to be able to derive a stack algorithm that can yield a ratio better than $1/2$ for small bandwidths. We have also seen the dependency of these methods on the input representation which corresponds to the constraints used in an LP relaxation of the problem. For the natural representations of set cover, steiner tree and bandwidth allocation/interval allocation we can derive limitations on the approximation ratio of such algorithms. But our bounds suggest that further improvements can be made even assuming we stay within the natural input representation. Our stack framework also suggests some natural extensions to the known primal-dual/local-ratio paradigm; for example, allowing the stack algorithm to make irrevocable acceptances during the push phase. The framework also encourages us to think of other reasonable ways to order input items.

Approximating MAX k CSP - Outperforming a Random Assignment with Almost a Linear Factor

Gustav Hast

Department of Numerical Analysis and Computer Science,
Royal Institute of Technology, 100 44 Stockholm, Sweden
ghast@nada.kth.se

Abstract. An instance of MAX k CSP consists of weighted k -ary constraints acting over a set of Boolean variables. The objective is to find an assignment to the Boolean variables such that the total weight of satisfied constraints is maximized. In this paper we provide a probabilistic polynomial time approximation algorithm that $c_0 k (\log k)^{-1} 2^{-k}$ -approximates MAX k CSP, for a constant $c_0 > 0$.

1 Introduction

An instance of MAX k CSP consists of a set of Boolean variables and a set of weighted constraints, each acting over a k -tuple of the variables. A solution is an assignment of the Boolean variables, and its value is the sum of the weights of the satisfied constraints. The objective is to find a solution with as large value as possible. The MAX k CSP problem is a natural generalization of many well-known combinatorial maximization problems, such as MAX CUT and MAX 3SAT.

It is well-known that it is NP-hard to solve MAX k CSP optimally. Therefore, it is interesting to investigate if an efficient algorithm can find a good approximate solution. In order to measure the quality of an approximation algorithm, we say that an algorithm r -approximates a maximization problem if the ratio of the value of the solution found by the algorithm, and the value of an optimal solution, is at least r for all instances. If the algorithm is probabilistic the value of the solution may be an expected value over the random choices that are made by the algorithm.

Trevisan [10] used a linear relaxation algorithm in order to 2^{1-k} -approximate MAX k CSP. He observed that the hardest instances consist of only conjunctions of literals, where a literal is a variable or a negated variable. The problem MAX k CONJSAT consists of such instances. Trevisan then showed how to 2^{1-k} -approximate MAX k CONJSAT. Note that a random assignment satisfies a single conjunction of length k with probability 2^{-k} . This implies that a random assignment 2^{-k} -approximate MAX k CONJSAT, and thus the Trevisan algorithm outperforms a random assignment with a factor of two. Recently, Hast

[5] produced a $2^{1.54-k}$ -approximation of MAX k CSP by utilizing a semi-definite relaxation approach. Essentially, it combined already known algorithms for MAX 2CONJSAT, MAX 3CONJSAT and MAX 4CONJSAT with a technique to reduce large conjunctions into smaller ones.

If a MAX k CSP instance is known to be satisfiable, then it can be $(k+1)2^{-k}$ -approximated by using an algorithm by Trevisan [11]. The technique by Trevisan reduces constraints, with at most k accepting inputs, into linear constraints. A random assignment is then picked from the set of assignments that adhere to the produced linear constraints. This ensures that each constraint is accepted with probability at least $(k+1)2^{-k}$, and thus the algorithm is a $(k+1)2^{-k}$ -approximation.

In this paper we show that it is possible to $c_0k(\log k)^{-1}2^{-k}$ -approximate general MAX k CSP, for a constant $c_0 > 0$. Our algorithm is the first that outperforms a random assignment with an increasing factor for larger values of k . It is interesting to see that we can match, up to a logarithmic factor, the approximation ratio of Trevisan for satisfiable instances, even though we use very different methods.

The power of a probabilistical checkable proof where the verifier asks k bits is closely connected with the approximability of MAX k CSP. The PCP of Samorodnitsky and Trevisan [9] and the enhancement of Engebretsen and Holmerin [3] shows that it is NP-hard to approximate MAX k CSP within $2^{\sqrt{2k-2}+1/2-k}$. Our algorithm implies the following inclusion:

$$\text{PCP}_{c,s}[\log, k] \subseteq \text{P}, \text{ for any } c/s > \frac{\log k}{c_0k} 2^k,$$

where c is the completeness and s the soundness of a verifier that uses a logarithmic number of random bits and asks k questions.

1.1 Our Method

An instance of MAX k ALLEQUAL consists of a collection of weighted constraints. Each constraint is a k -tuple of literals and a constraint is satisfied if all its literals have the same value, i.e., all are true or all are false. A simple reduction shows that an r -approximation of MAX k ALLEQUAL can be turned into an $r/2$ -approximation of MAX k CONJSAT, and thus also into an $r/2$ -approximation of MAX k CSP. In this paper we approximate MAX k ALLEQUAL in two steps. The first step is to produce an unbalanced solution. For such a solution, constraints tend to either have many literals that are true or many that are false. We find such an unbalanced solution by using semi-definite relaxation techniques [2, 13]. We produce an assignment that is biased towards this solution. This is done by, for some $\alpha \in [0, 1]$, assigning a variable according to the unbalanced solution with probability $(1 + \alpha)/2$, and negating the value with probability $(1 - \alpha)/2$.

It can be shown that as long as α is chosen appropriately such a biased random assignment makes the value of all literals in a constraint equal with much higher probability than if an unbiased random assignment is used. To see why this happens we look at a constraint consisting of eight literals of which the

first seven have the same value but the last one has the opposite value according to the unbalanced solution. A random assignment makes all literals equal with probability $2^{-7} \approx 0.0078$. For a biased random assignment the constraint is satisfied if we assign the first seven literals according to the unbalanced solution but the last literal is negated. This happens with probability $\left(\frac{1+\alpha}{2}\right)^7 \left(\frac{1-\alpha}{2}\right)$. By choosing $\alpha = 3/4$ this probability is larger than 0.049 making it more than six times more probable to satisfy the constraint using a biased random assignment compared with using an unbiased random assignment.

Let us briefly explain from where the approximation ratio of our algorithm for MAX *k*ALLEQUAL comes from. Assume that we have a MAX *k*ALLEQUAL instance and let *W* be the total weight of its constraints and let OPT be the value of an optimal solution to the instance. The expected value of a random assignment is $2^{-k}W$, thus if $\text{OPT} \leq W/k$ then a random assignment achieves an approximation ratio of $k2^{-k}$. If $\text{OPT} > W/k$ then the optimal solution turns out to be unbalanced in our measure. If we pick an assignment that is biased towards this solution we achieve an approximation ratio of $k2^{-k}$. However, we do not know the optimal solution and instead we find an unbalanced solution using the approximation algorithm by Charikar and Wirth [2]. In this process we loose a factor of $\log k$ and thus the approximation ratio gets to be $\Omega(k(\log k)^{-1}2^{-k})$.

1.2 Overview of the Paper

In Section 2 we define problems relevant to this paper. The next section contains the formal description of our MAX *k*ALLEQUAL algorithm along with an analysis of its approximation ratio. In Section 4 we evaluate our algorithm numerically and give approximation ratios for MAX *k*CSP, $k = 5 \dots 100$. In the last section we identify a PCP class as a subset of P.

2 Definitions

An instance of the MAX *k*CSP problem consists of a set $\{C_1, \dots, C_m\}$ of constraints with associated non-negative weights $\{w_1, \dots, w_m\}$ and a set of Boolean variables $X = \{x_1, \dots, x_n\}$. Each clause C_i consists of a Boolean function f_i of arity $h \leq k$ and a size h tuple of Boolean variables $(x_{i_1}, \dots, x_{i_h})$ where $x_{i_j} \in X$. A solution is an assignment to X and the objective value of the solution is the sum of the weights of the satisfied clauses. A clause $C_i = (f_i, (x_{i_1}, \dots, x_{i_h}))$ is satisfied if and only if $f_i(x_{i_1}, \dots, x_{i_h})$ is true.

Let \bar{X} define the set $\{\bar{x} : x \in X\}$. MAX *k*CONJSAT is a special type of MAX *k*CSP where each constraint is a conjunction of at most k literals from $X \cup \bar{X}$.

MAX *k*ALLEQUAL is also a special type of MAX *k*CSP. Each constraint is a tuple of at most k literals from $X \cup \bar{X}$, and it is satisfied if and only if all literals have the same value.

The sum of all weights in an instance, $\sum_{i=1}^m w_i$, is denoted by *W*. We use OPT to refer to the value of an optimal solution to an instance and APP is used

to refer to the value of an approximative solution. We also use the normalized values $\text{app} = \text{APP}/W$ and $\text{opt} = \text{OPT}/W$.

3 An Approximation Algorithm for MAX k ALLEQUAL

In this section we describe and analyze our approximation algorithm for MAX k ALLEQUAL. After the analysis we show some consequences for the approximability of MAX k CONJSAT and MAX k CSP.

3.1 Algorithm Description

If some of the constraints of a MAX k ALLEQUAL are not of size k , then these constraints are padded into size k using auxiliary variables, where each new variable only appears once in the instance. This will not effect the satisfiability of the instance. Thus, we can assume that all constraints are of length k . The algorithm is shown in Figure 1.

Input: A set of Boolean variables $\{x_1, \dots, x_n\}$ and a set of all equal constraints $\{C_1, \dots, C_m\}$ with corresponding weights $\{w_1, \dots, w_m\}$.

1. (**EQ₂-gadget**) Each constraint $C_i = z_{i_1} \equiv z_{i_2} \dots \equiv z_{i_k}$ is transformed into $k(k-1)/2$ equality constraints, $z_{i_1} \equiv z_{i_2}, z_{i_1} \equiv z_{i_3}, \dots, z_{i_1} \equiv z_{i_{k-1}}$. Each constraint is given weight w_i .
2. (**Solve MAX 2ALLEQUAL**) Use the Charikar and Wirth [2] algorithm in order to satisfy as much weight of the equality constraints as possible. Let b_i be the value of variable x_i in the produced solution.
3. (**Biased random assignment**) For $i := 1, \dots, n$: assign x_i according to

$$x_i := \begin{cases} b_i & \text{with probability } (1 + \alpha)/2 \\ \bar{b}_i & \text{with probability } (1 - \alpha)/2 \end{cases},$$
 with $\alpha = 1/\sqrt{k}$.

Fig. 1. Algorithm **ALG**: a MAX k ALLEQUAL algorithm

3.2 Algorithm Analysis

Theorem 1. *For a constant $c > 0$, MAX k ALLEQUAL, for $k \geq 2$, can in probabilistical polynomial time be approximated within a factor of $ck(\log k)^{-1}2^{-k}$.*

The proof of Theorem 1 is based on Lemmas 2 and 4.

Given an assignment to a MAX k ALLEQUAL instance we call a constraint unbalanced if either many literals are true or many literals are false. Given an assignment and a constraint C_i , γ_i is defined such that $k/2 + \gamma_i$ literals are true and $k/2 - \gamma_i$ are false. Thus, γ_i is a function depending on an assignment but due to notational convenience we do not make this dependency explicit. For a

fixed assignment, we let γ_i^2 be a measure of how unbalanced C_i is. The following lemma shows that if there exists a good solution to a MAX k ALLEQUAL instance, then we are able to find an assignment which makes constraints of large weight unbalanced. We do this by first transforming the MAX k ALLEQUAL instance into a MAX 2ALLEQUAL instance, and then solving it using the Charikar-Wirth algorithm.

Lemma 2. *Let I be an instance of MAX k ALLEQUAL with total weight W and assume that the value of an optimal solution is $\text{opt} \cdot W$ where $k \cdot \text{opt} \geq 3$. Let $d = c_{cw}(k \cdot \text{opt} - 1)/(4 \log k)$, where c_{cw} is a positive constant defined by the Charikar-Wirth algorithm. Then a solution can be produced in polynomial time such that*

$$dk \leq \mathbb{E} \left[\frac{1}{W} \sum_{i:|\gamma| > \sqrt{k}/2} w_i \gamma_i^2 \right], \tag{1}$$

where the expectation is taken over the random choices of the Charikar-Wirth algorithm.

Proof. Each constraint of k literals is transformed into $k(k - 1)/2$ equality constraints of arity two. If the original constraint is satisfied, then all new equality constraints are satisfied as well. If $k/2 + \gamma$ literals are true and $k/2 - \gamma$ false, then the number of equality constraints that are not satisfied is $(k/2 + \gamma)(k/2 - \gamma) = k^2/4 - \gamma^2$. Thus, at least $k(k - 1)/2 - k^2/4$ constraints are satisfied for any assignment.

A MAX k ALLEQUAL instance is transformed into a MAX 2ALLEQUAL instance according to the first step of Algorithm **ALG**. An optimal solution that satisfies weight $\text{opt} \cdot W$ in the original MAX k ALLEQUAL instance then satisfies clauses of weight

$$\text{opt} \binom{k}{2} W + (1 - \text{opt}) \left(\binom{k}{2} - \frac{k^2}{4} \right) W = \left(\binom{k}{2} - \frac{k^2}{4} + \text{opt} \frac{k^2}{4} \right) W,$$

in the MAX 2ALLEQUAL instance. We define that a solution of weight $W_{eq}(1/2 + \delta)$ has *gain* δ , where $W_{eq} = Wk(k - 1)/2$ is the total weight of the MAX 2ALLEQUAL instance. The gain is a measure of how much better a solution is compared to a random assignment. We let δ^* denote the optimal gain. From

$$W_{eq} \left(\frac{1}{2} + \delta^* \right) \geq \left(\binom{k}{2} - \frac{k^2}{4} + \text{opt} \frac{k^2}{4} \right) W$$

it is not hard to derive the following lower bound

$$\delta^* \geq \frac{k \cdot \text{opt} - 1}{2(k - 1)}.$$

We have the following Lemma due to Charikar and Wirth.

Lemma 3 (Charikar and Wirth [2]). *If δ^* is the optimum gain of a MAX CUT instance, ApproxMaxQP returns a solution whose expected gain is at least*

$$c_{cw} \left(\frac{\delta^*}{\log(1/\delta^*)} \right) ,$$

for a constant $c_{cw} > 0$.

The proof of Lemma 3 shows that $c_{cw} = 1/64$ is a valid choice. *ApproxMaxQP* is a probabilistical polynomial time algorithm and the above lemma is still valid if we instead of a MAX CUT instance consider the more general case of a MAX 2ALLEQUAL instance.

We analyze the logarithmic factor that is lost when using the Charikar-Wirth algorithm. The assumption from Lemma 2 implies that $k \cdot \text{opt} - 1 \geq 2$, thus

$$\log(1/\delta^*) \leq \log \frac{2(k-1)}{k \cdot \text{opt} - 1} < \log k .$$

We run the algorithm of Charikar and Wirth. Lemma 3 implies that the expected gain δ of the produced solution can be lower bounded

$$\delta \geq c_{cw} \frac{\delta^*}{\log(1/\delta^*)} > c_{cw} \frac{k \cdot \text{opt} - 1}{2(k-1) \log k} . \tag{2}$$

Remember that γ_i is the value such that $k/2 + \gamma_i$ of the literals in constraint C_i are true and $k/2 - \gamma_i$ are false according to the solution produced by the Charikar-Wirth algorithm. The weight of satisfied equality constraints corresponding to constraint C_i is then

$$\left(\binom{k}{2} - \binom{k}{2 + \gamma_i} \binom{k}{2 - \gamma_i} \right) w_i = \left(\frac{k(k-1)}{4} + \left(\gamma_i^2 - \frac{k}{4} \right) \right) w_i .$$

We sum the contribution of each constraint in order to get the total weight of satisfied equality constraints. Thus,

$$W_{eq} \left(\frac{1}{2} + \delta \right) = \mathbb{E} \left[\sum_{i=1}^m w_i \left(\frac{k(k-1)}{4} + \left(\gamma_i^2 - \frac{k}{4} \right) \right) \right]$$

which implies that

$$\binom{k}{2} \delta W = \mathbb{E} \left[\sum_{i=1}^m w_i \left(\gamma_i^2 - \frac{k}{4} \right) \right] . \tag{3}$$

We derive from (2) a lower bound for the weighted sum of γ_i^2 which concludes the proof of the lemma:

$$\begin{aligned} & \mathbb{E} \left[\frac{1}{W} \sum_{i:|\gamma| > \sqrt{k}/2} w_i \gamma_i^2 \right] \geq \mathbb{E} \left[\frac{1}{W} \sum_{i:|\gamma| > \sqrt{k}/2} w_i \left(\gamma_i^2 - \frac{k}{4} \right) \right] \\ & \geq \mathbb{E} \left[\frac{1}{W} \sum_{i=1}^m w_i \left(\gamma_i^2 - \frac{k}{4} \right) \right] = \binom{k}{2} \delta \\ & \geq \frac{k(k-1)}{2} c_{cw} \frac{k \cdot \text{opt} - 1}{2(k-1) \log k} \geq \frac{k c_{cw} (k \cdot \text{opt} - 1)}{4 \log k} , \end{aligned}$$

where the equality follows from (3). □

Lemma 4. *Let I be an instance of MAX k ALLEQUAL with total weight W and $\{b_1, \dots, b_n\}$ is a solution such that*

$$dk \leq \frac{1}{W} \sum_{i:|\gamma| > \sqrt{k}/2} w_i \gamma_i^2 ,$$

for $d \geq 1$. Then the solution defined by

$$x_i := \begin{cases} b_i & \text{with probability } (1 + \alpha)/2 \\ \bar{b}_i & \text{with probability } (1 - \alpha)/2 \end{cases} ,$$

with $\alpha = 1/\sqrt{k}$ has an expected value of at least $e^{2\sqrt{d}-1/2} 2^{-k} W$.

Proof. Consider a constraint C_i that has $|\gamma_i| > \sqrt{k}/2$. Let AE_i be the event that all literals in C_i get the same value after the biased random assignment.

$$\begin{aligned} \Pr [AE_i] &= \Pr [\text{all literals true}] + \Pr [\text{all literals false}] \\ &= \left(\frac{1 + \alpha}{2} \right)^{\bar{z} + \gamma} \left(\frac{1 - \alpha}{2} \right)^{\bar{z} - \gamma} + \left(\frac{1 - \alpha}{2} \right)^{\bar{z} + \gamma} \left(\frac{1 + \alpha}{2} \right)^{\bar{z} - \gamma} \\ &> 2^{-k} \left((1 + \alpha)^{\bar{z} + |\gamma|} (1 - \alpha)^{\bar{z} - |\gamma|} \right) \\ &= 2^{-k} \left((1 + \alpha)^{2|\gamma|} (1 - \alpha^2)^{\bar{z} - |\gamma|} \right) \\ &> 2^{-k} e^{2\alpha|\gamma| - \frac{\alpha^2}{2}} . \end{aligned}$$

The following claim validates the last inequality. The proof of the claim can be found in [6].

Claim. For $1 \geq \alpha > 0$ and $2|\gamma_i| \geq k\alpha$,

$$(1 + \alpha)^{2|\gamma|} (1 - \alpha^2)^{\bar{z} - |\gamma|} > e^{2\alpha|\gamma| - \frac{\alpha^2}{2}} .$$

We calculate a lower bound on the expected weight of constraints that either have all literals true or all literals false.

$$\sum_{i:|\gamma_i|>\sqrt{k}/2} w_i \Pr [AE_i] > 2^{-k} \sum_{i:|\gamma_i|>\sqrt{k}/2} w_i e^{2\alpha|\gamma_i| - \frac{1}{2}\alpha^2} \tag{4}$$

We let $s_i = \gamma_i^2$ and rewrite the above lower bound:

$$2^{-k} e^{-\frac{1}{2}\alpha^2} \sum_{i:\sqrt{s_i}>\sqrt{k}/2} w_i e^{2\alpha\sqrt{s_i}} .$$

We consider the terms $e^{2\alpha\sqrt{s_i}}$ as functions of s_i and calculate their second derivative:

$$\frac{\partial}{\partial^2 s_i} e^{2\alpha\sqrt{s_i}} = \left(\alpha - \frac{1}{2\sqrt{s_i}} \right) \alpha s_i^{-1} e^{2\alpha\sqrt{s_i}} .$$

We see that the second derivative is positive as long as $\alpha > \frac{1}{2\sqrt{s_i}}$, thus $e^{2\alpha\sqrt{s_i}}$ is convex for all terms of the sum because $\sqrt{s_i} > \sqrt{k}/2$ and $\alpha = 1/\sqrt{k}$. The condition in the lemma gives a lower bound to $\sum_{i:\sqrt{s_i}>\sqrt{k}/2} w_i s_i$. Thus, using Jensen's inequality we conclude that (4) is minimized if all values of $|\gamma_i|$ over the threshold are equal.

We let W_+ be the weight of all conjunctions meeting the threshold condition, $W_+ = \sum_{i:|\gamma_i|>\sqrt{k}/2} w_i$. We will see that the worst case happens if $W_+ = W$, but for now we are general and let $W_+ = xW$ where x is a value between 0 and 1. In order to minimize (4), the value of all $|\gamma_i|$ above the threshold should be equal and by the assumption of the lemma at least $\sqrt{dk/x}$. We apply this to (4) and get the expected weight of constraints that either have all literals true or all literals false.

$$2^{-k} \sum_{i:|\gamma_i|>\sqrt{k}/2} w_i e^{\frac{2|\gamma_i|}{\sqrt{k}} - \frac{1}{2}} \geq 2^{-k} xW e^{2\sqrt{d/x} - 1/2} . \tag{5}$$

We calculate the derivative of the above expression

$$\frac{\partial}{\partial x} 2^{-k} xW e^{2\sqrt{d/x} - 1/2} = (1 - \sqrt{d/x}) 2^{-k} e^{2\sqrt{d/x} - 1/2} W .$$

As $d \geq 1$, we see that the derivative is non-positive for $x \in (0, 1]$. Thus, (5) is minimized by setting $x = 1$ and thus the expected weight of satisfied constraints is at least $2^{2\sqrt{2d}-1/2} 2^{-k} W$ which concludes the proof of Lemma 4. \square

We are now ready to prove Theorem 1 by using Lemma 2 and Lemma 4.

Proof (Theorem 1). Let I be an instance of MAX k ALLEQUAL and let opt be the normalized value of an optimal solution. Set $c = (c_1/c_{cw} + 1)^{-1}$, where c_1

is a positive constant yet to be defined. If $\text{opt} \leq \log k/(ck)$, then a random assignment achieves the following approximation ratio:

$$\frac{\text{APP}}{\text{OPT}} \geq \frac{2^{-k}W}{\log k/(ck)W} = \frac{ck}{\log k} 2^{-k} .$$

Thus, we only need to consider if $\text{opt} > \log k/(ck)$. Assume that for some $r > 1$ we have that $\text{opt} = r \log k/(ck)$. We note that $k \cdot \text{opt} \geq \log k/c > 3$ and apply Lemma 2 with

$$d = c_{cw} \frac{k \cdot \text{opt} - 1}{4 \log k} = c_{cw} \frac{r/c - 1}{4} = c_{cw} \frac{r(c_1/c_{cw} + 1) - 1}{4} > rc_1/4 .$$

We can now apply Lemma 4 with an expected value of $d = rc_1/4$. However, if $d < 1$ then Lemma 4 does not give anything and thus the expected value of the solution could be zero. The following function expresses a lower bound for the expected value of the solution

$$\begin{cases} 0 & \text{if } 0 \leq d < 1 \\ e^{2\sqrt{d}-1/2} 2^{-k} W & \text{if } d \geq 1 \end{cases} .$$

It is not convex and thus we cannot apply Jensen’s inequality. However, the following linear function is a lower bound for that function:

$$c_2(d - 1)2^{-k}W , \text{ where } c_2 = \min_{d>1} \frac{e^{2\sqrt{d}-1/2}}{d - 1} \approx 9.5 . \tag{6}$$

By applying the lower bound (6) we get that APP, the expected value of the solution, is at least $c_2(rc_1/4 - 1)2^{-k}W$. By setting $c_1 = 4/c_2 + 4$ we ensure that $\text{APP} \geq r2^{-k}W$ and thus the approximation ratio is

$$\frac{\text{APP}}{\text{OPT}} > \frac{r2^{-k}W}{r \log k/(ck)W} = \frac{ck}{\log k} 2^{-k} ,$$

which concludes the proof of Theorem 1. □

3.3 Consequences for MAX k CONJSAT and MAX k CSP

By using a simple observation we derive from Theorem 1 the following result on the approximability of MAX k CONJSAT. The proof can be found in [6].

Theorem 5. *There exists a constant $c_0 > 0$ such that MAX k CONJSAT, for $k \geq 2$, can in probabilistical polynomial time be approximated within a factor of $c_0 k (\log k)^{-1} 2^{-k}$.*

By using the observation of Trevisan [10], we conclude that an algorithm for MAX k CONJSAT implies an approximation algorithm for MAX k CSP with the same approximation ratio. Thus, as a consequence of Theorem 5 we get our main theorem:

Theorem 6. *There exists a constant $c_0 > 0$ such that MAX k CSP, for $k \geq 2$, can in probabilistical polynomial time be approximated within a factor of $c_0 k (\log k)^{-1} 2^{-k}$.*

4 Numerical Approximation Ratios for Fixed Values of k

In this section we give approximation ratios for MAX k CSP for values of $5 \leq k \leq 100$. The ratios are obtained using numerical methods and are presented in Figure 2. For $k \leq 4$ there are known good approximation algorithms, which outperform our algorithm with a broad margin [4, 7, 12].

In this section we use an algorithm slightly different from Algorithm **ALG** which is presented in Figure 1. First we use Zwick’s outward rotation algorithm [13] in order to approximate the MAX 2ALLEQUAL instance instead of the Charikar-Wirth algorithm. This choice is made because an exact approximation ratio can numerically be calculated from [13], if the optimal gain is known. In the last step of Algorithm **ALG** we use a somewhat different value of the bias α . Given the solution of the MAX 2ALLEQUAL instance, it is possible to calculate the optimal value of the parameter α . However, our calculation show that by setting

$$\alpha = \sqrt{\frac{1}{k} + \left(2 - \frac{2}{k}\right) \delta} ,$$

where δ is the expected gain of the approximate solution, we obtain an approximation ratio very close to the ratio that would be obtained if we used the optimal

Fig. 2. Approximation ratios for MAX k CSP

value of α . We choose this suboptimal value to ensure easier reproducibility of the graph in Figure 2.

We can heuristically show why this value of α is suitable. It seems that the worst case is if the solution makes all constraints equally unbalanced, thus the value of $|\gamma_i|$ is equal for all constraints. In the proof of Lemma 2 we saw that

$$\binom{k}{2} \delta W = \mathbb{E} \left[\sum_{i=1}^m w_i \left(\gamma_i^2 - \frac{k}{4} \right) \right].$$

This implies that the worst case is if $|\gamma_i| = \sqrt{\delta k(k-1)/2 + k/4}$.

In the proof of Lemma 4 we showed that the probability that all literals in a constraint get the same value after a biased random assignment is at least $2^{-k} e^{2\alpha|\gamma| - \frac{1}{2}\alpha^2}$. It is easy to show that this expression is maximized by setting $\alpha = 2|\gamma_i|/k$. Inserting the worst case value for $|\gamma_i|$ in this expression we see that α is equal to the value we use.

For each value of k we calculate the approximation ratio in the following way. For each possible optimal gain, using a suitable discretization, we calculate the expected gain δ of the solution produced by the algorithm of Zwick. We then produce a linear program where the objective value is equal to the expected normalized objective value of the solution produced by the biased random assignment. The linear program has $k+1$ variables y_0, y_1, \dots, y_k , where y_i indicates the total weight of constraints with exactly i literals true. There are also constants d_0, \dots, d_k , where $d_i = \frac{k(k-1)}{2} - i(k-i)$ is the number of pair of literals that are equal in a constraint with exactly i literals true. We let b_i be the probability that a constraint with exactly i literals true will be all equal after the biased random assignment. This value depends on our choice of α .

$$\min \sum_{i=0}^k b_i y_i, \text{ given } \sum_{i=0}^k y_i = 1 \text{ and } \sum_{i=0}^k d_i y_i = \frac{k(k-1)}{2} \left(\frac{1}{2} + \delta \right)$$

By solving the linear program we get a numerical value of the approximation ratio of the MAX k ALLEQUAL algorithm. By dividing this value with two we get the approximation ratio of the MAX k CSP algorithm.

Our algorithm approximates MAX 5CSP within $2.91 \cdot 2^{-5}$. The general $2^{1.54-k} = 2.90 \cdot 2^{-k}$ approximation algorithm in [5] do better for small values of k and actually $3.68 \cdot 2^{-5}$ approximates MAX 5CSP. However, for values of $k \geq 6$ our algorithm achieves the best known approximation ratio for MAX k CSP.

5 Relation with PCP Classes

We use the standard notation and definitions in connection with probabilistical checkable proofs, PCPs. For those unfamiliar with these, we refer to the work of Bellare et al. [1] which also contains the history of PCPs. The complexity class $PCP_{c,s}[\log, q]$ contains all languages that have a verifier with completeness c ,

soundness s , which uses only a logarithmic number of random bits and asks at most q (adaptive) questions.

The power of PCPs asking k questions is closely related to the approximability of MAX k CONJSAT as can be seen by the following theorem:

Theorem 7 (Trevisan [10]). *If, for some $r \leq 1$, MAX k CONJSAT is deterministically r -approximable in polynomial time then $\text{PCP}_{c,s}[\log, k] \subseteq \text{P}$ for any $c/s > 1/r$.*

Our MAX k CONJSAT algorithm is probabilistic, thus it is not immediate that the above theorem can be applied. There are two steps in our algorithm that are probabilistic, the rounding in the Charikar-Wirth algorithm and the biased random assignment. We believe that the Charikar-Wirth algorithm can be derandomized using the method of Mahajan and Ramesh [8], but we have not looked into the details. The biased random assignment can be derandomized using conditional probabilities. However, in Theorem 7 we only need an algorithm that give a lower bound of the optimal value, not an approximate solution. We get such a lower bound directly from the semidefinite program of the Charikar-Wirth algorithm. Thus, we have the following theorem.

Theorem 8. $\text{PCP}_{c,s}[\log, k] \subseteq \text{P}$ for any $c/s > \frac{\log k}{c_0 k} 2^k$, where $c_0 > 0$ is the constant in Theorem 5.

Acknowledgment. I am very grateful for the help that Johan Håstad gave me when analyzing Algorithm **ALG** and in preparing this paper.

On Dynamic Bit-Probe Complexity

Corina E. Pătraşcu¹ and Mihai Pătraşcu²

patrascu@fas.harvard.edu
² MIT
mip@mit.edu

Abstract. This paper presents several advances in the understanding of dynamic data structures in the bit-probe model:

- We improve the lower bound record for dynamic language membership problems to $\Omega((\frac{\lg n}{\lg \lg n})^2)$. Surpassing $\Omega(\lg n)$ was listed as the first open problem in a survey by Miltersen.
- We prove a bound of $\Omega(\frac{\lg n}{\lg \lg n})$ for maintaining partial sums in $\mathbb{Z}/2\mathbb{Z}$. Previously, the known bounds were $\Omega(\frac{\lg n}{\lg \lg n})$ and $O(\lg n)$.
- We prove a surprising and tight upper bound of $O(\frac{\lg n}{\lg \lg n})$ for predecessor problems. We use this to obtain the same upper bound for dynamic word and prefix problems in group-free monoids.

1 Introduction

Bit-probe complexity can be considered a fundamental measure of computation. When analyzing space-bounded algorithms (branching programs), it is usually preferred to cell-probe¹ complexity. In data structures, cell-probe complexity is used more frequently, but the machine independence and overall cleanness of the bit-probe measure have made it a persistent object of study since the dawn of theoretical computer science. Nonetheless, many of the most fundamental questions are not yet understood. In this paper, we address this on several fronts.

Record Lower Bound. We prove a lower bound of $\Omega((\frac{\lg n}{\lg \lg n})^2)$ for dynamic connectivity. This problem asks to maintain an undirected graph, under insertion and deletion of edges, and queries asking whether two nodes are in the same connected component. The best upper bound is $O(\lg^2 n \cdot (\lg \lg n)^3)$ [1], so our lower bound is optimal up to doubly logarithmic factors.

Our lower bound is the highest known bound for an explicit dynamic language membership problem. The previous record was $\Omega(\lg n)$, shown in [2]. A survey on cell probe complexity by Miltersen [3] lists improving this bound as the first open

¹ Of course, the bit-probe model is an instantiation of the cell-probe model with one-bit cells. For conciseness, however, we shall use “cell-probe” in a more restricted sense, to refer to the cell-probe model with cells of $\Theta(\lg n)$ bits.

problem among three major challenges for future research. Our lower bound is based on the recent technique of Pătraşcu and Demaine [4], which proved the first $\Omega(\lg n)$ bounds in the cell-probe model. While our contribution is mostly a series of technical tricks necessary for the bit-probe model, it should be noted that in no way is our $\tilde{\Omega}(\lg^2 n)$ bound a mere echo of an $\Omega(\lg n)$ bound in the cell-probe model. Indeed, $\Omega(\frac{\lg n}{\lg \lg n})$ bounds in the cell-probe model have been known for one and a half decades (including for dynamic connectivity), but the bit-probe record has remained just the trivially higher $\Omega(\lg n)$. To our knowledge, our bound is the first to show a quasi-optimal $\tilde{\Omega}(\lg n)$ separation between the cell-probe and bit-probe complexity, when the cell-probe complexity is superconstant.

Lower Bound for Maintaining Partial Sums. One of the most fundamental data-structure problems is maintaining partial sums. This problem asks to maintain an array $A[1..n]$ under an $\text{UPDATE}(k, x)$ operation, which changes $A[k] \leftarrow x$, and a $\text{SUM}(k)$ operation, which asks for a partial sum $\sum_{i=1}^k A[i]$. Because we are concerned with the bit-probe model, it is most natural to consider the case when all operations are done in $\mathbb{Z}/2\mathbb{Z}$, i.e. we are interested in prefix parity. This can be generalized to any fixed cyclic group $\mathbb{Z}/k\mathbb{Z}$, without any change in the bounds discussed below. The only known upper bound is the classic $O(\lg n)$, based on a balanced binary tree. It is widely believed that this is optimal.

Fredman [5] proved a lower bound of $\Omega(\frac{\lg n}{\lg \lg n})$ by considering the following greater-than problem. First, the algorithm is given a number $a \in [n]$, and can write t_u bits. Then, the algorithm is given another number $b \in [n]$, and it must determine whether $b > a$ through t_q bit probes. Observe that there is a trivial reduction from this problem to the partial sums problem, with one update and one query. It is quite tempting to believe that one cannot improve past the trivial upper bound $t_u = t_q = O(\lg n)$, since, in some sense, this is the complexity of “writing down” a . However, we show below that Fredman’s bound is optimal for the greater-than problem. Therefore, one needs a different strategy to improve the lower bound for maintaining partial sums.

It is natural to approach the problem in the framework of [4], which could prove an $\Omega(\lg n)$ bound in the cell-probe model (of course, the group was $\mathbb{Z}/n\mathbb{Z}$ in that case, matching the cell size). Applying the tricks we developed for dynamic connectivity will only reprove the old $\Omega(\frac{\lg n}{\lg \lg n})$ bound. For reasons discussed below, obtaining $\Omega(\lg n)$ seems quite difficult.

We can, nonetheless, prove an $\Omega(\frac{\lg n}{\lg \lg \lg n})$ bound, which is only a triply-logarithmic factor away from the upper bound! We find the technique of this bound at least as interesting as the result itself. The proof uses a variation of the chronogram technique of Fredman and Saks [6]. However, it is well known that the classic chronogram technique can only prove $\Omega(\frac{\lg n}{\lg \lg n})$. We present a small, yet very important variation, which brings a considerable strengthening of this technique: with this improvement, the chronogram technique can prove lower bounds of $\Omega(\lg n)$ in the cell-probe model. To fully appreciate this development, one must remember that the chronogram technique was virtually the only available technique for proving dynamic lower bounds before the work of [4].

At the same time, obtaining a logarithmic bound in the cell-probe model was viewed as one of the most important problems in data-structure lower bounds. It is now quite surprising to find that the answer has always been this close.

Upper Bound for Predecessor Problems. As mentioned already, we can achieve an $O(\frac{\lg n}{\lg \lg n})$ upper bound for Fredman's greater-than problem. In fact, we can achieve the same bound for several predecessor-type problems. Consider the classic predecessor problem: maintain a dynamic set S , under queries to determine (some information about) the predecessor in S of a given number. Unfortunately, we cannot determine the actual predecessor in $o(\lg n)$, because the output itself has this many bits of entropy. But we can recover some constant amount of information about the predecessor (a stored "color"), which proves to be enough for many purposes. For our classification of dynamic prefix problems, it is important to generalize this slightly to the colored k -predecessor problem: the query asks for the colors of the k predecessors of a given number. Here k is part of the definition of the problem, so it is a constant.

In the interest of dynamic prefix problems, we also study a more unusual stabbing problem. The problem itself is an interesting trick to circumvent finding an exact predecessor in many cases. We have to maintain a dynamic set $S = \{b_1, b_2, \dots\}$ under the following query operation: given $j \in (b_i, b_{i+1})$, the query determines a value in (b_i, b_{i+1}) , which is only a function of b_i and b_{i+1} , but not of j or i . Imagine that the elements of S break $[n]$ into segments. The query must then produce a representative for the segment stabbed by j , which is inside the segment, but is independent of the actual choice of j . Adding or removing an element merges or splits segments. The representatives of these affected segments may change arbitrarily, but those of any other segments must remain the same (because they are only functions of the end-points). The segment representative has $\lg n$ bits, so it is maybe surprising that one can be found in $O(\frac{\lg n}{\lg \lg n})$ time. Of course, the query cannot actually write down the representative, but the representative is determined by the query's input and its bit probes.

A tight tradeoff between t_u and t_q was recently given for the greater-than problem [7]. We can match this tradeoff for the more general predecessor problems that we consider. More details will be given in the full version of this paper.

Dynamic Word and Prefix Problems. Dynamic prefix problems are defined like the partial sums problem, except that all additions take place in an arbitrary finite monoid. The word problem is identical to the prefix problem, except that queries only ask for the sum of the entire array, not an arbitrary prefix. The problem is defined by the monoid, so the monoid is considered fixed (and constants may depend on it). The aim is to understand the complexity of the problem in terms of the structure of the monoid. This line of research was inspired by the intense study of parallel word problems, which eventually led to a complete classification. Both in the parallel and in the dynamic case, it can be seen that many fundamental problems are equivalent to word and prefix problems for certain classes of monoids. Examples include partial sums modulo some value, the predecessor problem, and the priority queue problem. In the full version, we also

show that existential range queries in one dimension are captured by a class of monoids. In general, we would expect any fundamental problem of a certain one-dimensional flavor to be represented, making word problems an interesting avenue for complexity-theoretic research.

The seminal paper of Frandsen, Miltersen and Skyum [8] achieved tight bounds for many classes of monoids, both in the bit-probe and in the cell-probe models, but the classification is incomplete in both cases. In this paper, we further the classification for the bit-probe model in two ways. First, our lower bound for partial sums in $\mathbb{Z}/k\mathbb{Z}$ applies to the prefix problem in any monoid containing groups, and for the word problem in monoids containing a certain kind of externally noncommutative cycles [8–Theorem 2.5.1]. Second, we derive an upper bound of $O(\frac{\lg n}{\lg \lg n})$ for the word and prefix problems in group-free monoids. This uses the same algebraic toolkit as used by [8] in the cell-probe model, but our application needs several interesting algorithmic ideas to handle the idiosyncrasies of the bit-probe model.

2 Lower Bound for Dynamic Connectivity

Theorem 1. *Maintaining dynamic connectivity requires $\Omega((\frac{\lg n}{\lg \lg n})^2)$ bit probes, amortized per operation, in the average case of a certain input distribution.*

We first describe the dynamic graph used in our lower-bound construction; refer to Figure 1. The vertex set is roughly given by an integer grid of size $\sqrt{n} \times \sqrt{n}$. The edge set is given by a series of permutation boxes. A permutation box connects the nodes in a column to the nodes in the next column arbitrarily, according to a given permutation in $S_{\sqrt{n}}$. Notice that the permutations decompose the graph into a collection of \sqrt{n} paths. As the paths evolve horizontally, the y coordinates change arbitrarily at each point due to the permutations. In addition to this, there is a special test vertex to the left. This is connected to a subset of the vertices in the first column.

We now describe the hard sequence of operations. The shape of the graph allows us to implement a partial sums problem over $S_{\sqrt{n}}$. The partial sums macro-operations are implemented as follows:

Fig. 1. Our graphs can be viewed as a sequence of \sqrt{n} permutation boxes

UPDATE(i, π): sets $\pi_i = \pi$. This is done by removing all edges in permutation box i and inserting new edges corresponding to the new permutation π . This uses $O(\sqrt{n})$ elementary operations.

SUM(i): returns $\sigma = \pi_1 \circ \dots \circ \pi_i$. We use $O(\lg n)$ phases, each one guessing a bit of $\sigma(j)$ for all j . Phase k begins by removing all edges incident to the test node. Then, we add edges from the test vertex to all vertices in the first column, whose row number has a one in the k -th bit. Then, we test connectivity of all vertices from the i -th column and the test node, respectively. This determines the k -th bit of $\sigma(j)$ for all j . In total, SUM uses $O(\sqrt{n} \lg n)$ elementary operations.

This construction differs from the one used in the cell-probe model. There, it was possible to prove a lower bound for a VERIFY operation, which verifies a given partial sum, rather than compute one from scratch. This does not seem possible in the bit-probe model. The reason is quite technical: the “separators” used for the cell-probe proof are too large. Unfortunately, known lower bounds show that those separators are actually optimal, so the approach fails altogether. In the bit-probe model, we are forced to revert to the SUM operation. Interestingly, we can still prove a good lower bound even if we blow up the queries by a $\lg n$ factor: the cost is just one of the $\lg \lg n$ factors in the denominator.

To fully specify the hard sequence, we must still say how UPDATES and SUMS are generated. We choose $m = n^\varepsilon$ macro-operations randomly and independently ($\varepsilon > 0$ can be an arbitrary small constant). Because queries are $O(\lg n)$ time more expensive, each operation is chosen to be a query with probability $\frac{1}{\lg n}$. The arguments of each operation (i , possibly π) are picked uniformly at random. Let t be the running time of a connectivity operation. The total expected running for m operations is $O(t\sqrt{n}(1 - \frac{1}{\lg n})m + t\sqrt{n} \lg n \cdot \frac{1}{\lg n}m) = O(mt\sqrt{n})$. We shall prove an $\Omega(m\sqrt{n}(\frac{\lg n}{\lg \lg n})^2)$ lower bound, implying the desired bound on t .

Proof of the Lower Bound. Following [4], we consider a tree whose leaves represent the entire sequence of operations in time order. Any bit probe is characterized by when it occurs and when the bit was last written. These times are given by two leaves in the tree. For every node in the tree, we will lower bound the number of bit probes with the write time in the subtree of the node, and the read time in a subtree of a right sibling of the node. We then add up these lower bounds for all nodes, to obtain the overall bound. The correctness of this strategy follows by two observations. First, we never double count a bit probe: it is only counted for the node immediately under the lowest common ancestor of the read and write times. Second, we can sum the lower bounds because they all hold in the average case, under the same distribution.

We choose the branching factor of the time-tree to be $\Theta(\lg n)$, as suggested by the following intuition. Queries are fewer than updates by a logarithmic factor (because they are expensive). For maximal hardness, we must show that essentially all information in a series of updates is extracted. To do this, we must reuse most queries $\Theta(\lg n)$ times. Most nodes have $\Theta(\lg n)$ right siblings. If the node has L leaves under it, we expect $\Theta(L)$ updates in its subtree, and

$\Theta(\lg n \cdot L \frac{1}{\lg n}) = \Theta(L)$ queries in the subtrees of its right siblings, which allows all information to be extracted. Thus, a query is effectively reused $\Theta(\lg n)$ times on each level – in the lower bound for all left siblings of its ancestor.

Lemma 2. *Consider two adjacent intervals of operations, the left one of size L , and the right one of size $\Theta(L \lg n)$. Let r be the number of bit probes executed in the right interval, and c the number of probes from the right interval, which access a bit whose value after the left interval differs from its value before the left interval. Then $E[\lg \binom{r}{c}] = \Omega(L\sqrt{n} \lg n)$.*

Proof. Assume that we are told the entire sequence of macro-operations, except the ones in the left interval. Given this information, the sequence of answers to the SUM queries from the right interval has entropy $\Omega(L\sqrt{n} \lg n)$; see [4–Lemmas 5.3 and 5.4]. In essence, we expect $\Theta(L)$ updates in the left interval, and $\Theta(L)$ queries in the right interval. Further, we expect these to interleave almost perfectly, causing the answers to $\Omega(L)$ queries to be independent.

We now propose the following encoding for the answers to the queries: encode r , c , and the subset of the r bit probes which touch a bit changed during the left interval, and not yet changed in the right interval. This takes $E[\lg \binom{r}{c}] + O(\lg n)$ bits on average. Note that we only encode a c -subset of $[r]$; this identifies the relevant bit probes, but doesn't, for example, identify the addresses they probe. To decode, we first simulate the data structure's behavior before the left interval (we know everything from the past). We then simulate it for the right interval; implicitly we will recover the answers to the queries. This simulation needs to recover the values of all probed bits. If the bit location was written during the simulation of the right interval, we already know the value. Otherwise, we check whether the bit probe is in the set of c special bit probes. In this is true, the value is the negation of what it was before the left interval began; otherwise, it is the old value from before the left interval. \square

Now consider an arbitrary level of the tree. We apply the lemma by setting the left interval to the subtree of a node, and the right interval to the union of the subtrees of its right siblings. We do this only for nodes which are in the first half of their siblings, so that the right interval is $\Theta(\lg n)$ times bigger. For some node i , we obtain $E[\lg \binom{r}{c}] = \Omega(L_i\sqrt{n} \lg n)$. Let us sum this up for all nodes on a level. Clearly, $\sum L_i = \frac{m}{2} = \Theta(m)$. By linearity of expectation, the left hand side becomes $E[\lg \prod \binom{r}{c}]$. It is well known that $\prod \binom{r}{c} \leq \binom{\sum r}{\sum c}$. Now, $\sum r_i = \Theta(T \lg n)$, where T is the total number of bit probes. This is because each bit probe is counted at most once for every sibling of its ancestor on the current level. Let $\sum c_i = C_\ell$, where ℓ is the current level. We can now obtain $E[\lg \binom{\gamma T \lg n}{C_\ell}] = \Omega(m\sqrt{n} \lg n)$, for an appropriate constant γ . Now let us sum over all levels ℓ . As explained in the beginning, $\sum C_\ell \leq T$. Then, we obtain $E[\lg \binom{\gamma T \lg n \cdot \lg n / \lg \lg n}{T}] = \Omega(m\sqrt{n} \lg n \frac{\lg n}{\lg \lg n})$, which implies $E[T]O(\lg \lg n) = \Omega(m\sqrt{n} \frac{\lg^2 n}{\lg \lg n})$.

This completes the proof of our $\Omega((\frac{\lg n}{\lg \lg n})^2)$ lower bound. As explained already, one of the $\lg \lg n$ factors is lost because we need to increase the complexity of queries by a $\lg n$ factor, which translates into a higher branching factor for

the tree, and a depth of just $O(\frac{\lg n}{\lg \lg n})$. The other $\lg \lg n$ factor is lost from our encoding. Intuitively, Lemma 2 should state that $c = \Omega(L\sqrt{n} \lg n)$. This is because the right interval needs $\Omega(L\sqrt{n} \lg n)$ bits of information, and, intuitively, this can only come from so many bit probes. Unfortunately, the fact that a bit was not modified during the left interval is also information, even if it is not clear how such information could ever be used in an upper bound. The factor of $\lg \binom{r}{c} \approx c \lg \lg n$ seems very hard to avoid.

3 Lower Bound for Partial Sums in Cyclic Groups

Let us review the ideas behind the chronogram method, at an intuitive level. First, we generate a sequence of random updates, ended by one random query. Looking back in time from the query, we partition the updates into exponentially growing epochs: for a certain t , epoch i contains the t^i operations immediately *before* epoch $i - 1$. We then argue that for all i , the query needs to read at least one cell from epoch i with constant probability. This is done as follows. Clearly, information about epoch i cannot be reflected in higher epochs (those occurred back in time). The first $i - 1$ epochs contain $O(t^{i-1})$ updates. Assume the cell-probe complexity of each update is bounded by t_u . Then, during the first $i - 1$ epochs, only $O(t^{i-1}t_u)$ cells are written. If $t = C \cdot t_u$ for a sufficiently large constant C , these cells can only include complete information about a fraction of the t^i updates in epoch i . If a random query forces us to learn information about a random update from epoch i , we are forced to read a cell from epoch i , because this information is not available in any other epoch. This gives $\Omega(1)$ probes in expectation to every epoch, so the lower bound on the query time is given by the number of epochs that we can construct, i.e. $t_q = \Omega(\lg n / \lg t_u)$. A tradeoff of this form was indeed obtained by [9], and is the highest tradeoff obtained by the chronogram method. Of course, these calculations assumed that update inputs and query outputs match the cell size.

We now describe the ideas needed to improve the $\lg t_u$ factor in the denominator. Intuitively, the analysis done by the chronogram technique is overly pessimistic, in that it assumes all cells written in the first $i - 1$ epochs concentrate on epoch i , encoding a maximum amount of information about it. In the setup from above, this may actually be tight, up to constant factors, because the data structure knows the division into epochs, and can build a strategy based on it. However, we can randomize the construction of epochs to foil such strategies. We generate a random number of updates, followed by one query; since the data structure cannot anticipate the number of updates, it cannot base its decisions on a known epoch pattern. Due to this randomization, we intuitively expect each update to write $O(t_u/t_q)$ cells about a random epoch (as before, t_q is roughly the number of epochs). Then, we should take $t = C \frac{t}{t}$, and obtain bounds of the form $t_q \lg \frac{t}{t} = \Omega(\lg n)$, implying $\max\{t_u, t_q\} = \Omega(\lg n)$.

Unfortunately, formalizing the intuition that the information written by updates “splits” between epochs seems to lead to elusive information theoretic

arguments. To circumvent this, we need a second idea: we can look at cell reads, as opposed to cell writes. Reads have more graspable information theoretic properties, dictated by the time when the cell was last written, and the time when the read occurs. We can actually show that in expectation, $O(t_u/t_q)$ of the reads made by each update obtain information about a random epoch. Then, regardless of how many cells are written, subsequent epochs can only encode little information about epoch i , because very little information was read by the updates in the first place.

One case in which the above reasoning works is the partial sums problem in the cell-probe model (with the group $\mathbb{Z}/n\mathbb{Z}$), for which the tradeoff is tight. Our bit-probe lower bound from below contains all ideas needed by this proof. This is the largest cell-probe tradeoff known, and a different proof was described recently in [4]. In the bit-probe model, we achieve a slightly weaker bound, because $O(t_u/t_q)$ bit probes into an epoch give more than this number of bits of information. As for the connectivity bound, we must also account for the choice of the relevant $O(t_u/t_q)$ probes from the total of t_u .

Theorem 3. *For the partial-sums problem in $\mathbb{Z}/2\mathbb{Z}$, let t_u be the amortized bit-probe complexity of an update, and t_q the bit-probe complexity of a query. Then in the average case of a certain input distribution, $t_q(\lg \frac{t}{t} + \lg \lg t_q) = \Omega(\lg n)$. In particular, $\max\{t_u, t_q\} = \Omega(\frac{\lg n}{\lg \lg n})$.*

Let $M = n^\epsilon$, for any small $\epsilon > 0$. We generate $2M$ operations $\text{UPDATE}(i, x)$, each with random $i \in [n], x \in \mathbb{Z}/2\mathbb{Z}$. Now pick m uniformly at random from $\{M, \dots, 2M\}$. After m operations, we insert a query to a random index. Looking back in time from the query, divide that last M operations into epochs. Epoch i has the t^i operations preceding epoch $i - 1$, where t will be specified later ($t \geq 2$). The number of epochs is $\Theta(\lg_t M) = \Theta(\lg_t n)$. Let P_i be the number of bit probes from epochs 1 through $i - 1$, touching bits written during epoch i .

Lemma 4. *If i is chosen uniformly at random, $E[\frac{P}{t^{i-1}}] = O(\frac{t}{\lg n})$.*

Proof. We say that a bit probe has span j if $t^{j-1} \leq w - r < t^j$, where r and w are the read and write times (i.e. the index of the operation during which they occur). Let C_j be the total number of bit probes of span j that the $2M$ updates would execute in the absence of an interleaving query. Fix i to some arbitrary value, and let f be the last operation in epoch i . Observe that f is a random variable depending on m . We are interested in bit probes with $w \in (f - t^i, f], r \in (f, m]$. All such bit probes must have span at most $i + 1$, because $m - f < 2t^{i-1}$. For all j , if $r \geq f + t^{j-1}$, the bit probe must have span at least j . We count all probes which satisfy these necessary conditions, thus upper bounding P_i .

Fix the $2M$ updates arbitrarily. Because m is not known to the data structure, the first m updates behave as if no query ever happened. As m is chosen randomly, we are interested in the probes of span j from a random segment of size t^j .

There are $\Omega(M)$ choices for the position of this segment, and we choose uniformly at random between them. Then, the expected number of span- j operations that are relevant is $O(t^j \frac{C}{M})$. For $j = i$ or $j = i + 1$, we can upper bound the segment size by $m - f = O(t^{i-1})$. Then, $E_m[P_i] = O(t^{i-1} \frac{C+C+1}{M}) + \sum_{j < i} O(t^j \frac{C}{M})$, so $E_m[\frac{P}{t-i}] = O(\frac{C}{M} + \frac{C+1}{M} + \sum_{j < i} \frac{C}{M \cdot t^j})$.

Observe that $\sum_i E_m[\frac{P}{t-i}] \leq \sum_i (2 + \sum_{k=1}^\infty t^{-k}) \cdot O(\frac{C}{M}) = \sum_i O(\frac{C}{M})$. By definition, $\sum_i \frac{C}{M}$ is the amortized running time of an update. When updates are chosen uniformly at random, $E[\sum_i \frac{C}{M}] \leq t_u$. Thus, if i is chosen uniformly at random, $E[\frac{P}{t-i}] = O(\frac{t}{\lg n})$. □

Now pick an epoch i at random. We show that with constant probability, the query needs to probe a bit from epoch i . Then, by linearity of expectation, $t_q = \Omega(\lg_t n)$. By the Markov bound, there is a $1 - \delta$ probability that for the chosen i , $E[\frac{P}{t-i}] = O(\frac{t}{\lg n})$. Here the expectation is over the choice of m , and the random updates, but i is already fixed; $\delta > 0$ is an arbitrarily small constant. If this relation does not hold, we make no claim. Otherwise, let p be the probability that a random query accesses a cell from epoch i . We want to prove that p is bounded away from 0. Then, by the union bound, there is a constant probability that a query needs a bit probe into epoch i .

Pick t^i queries independently at random, and imagine that each is run starting with the state of the data structure after m updates. Given the choice of the queries, and the random updates from all epoch except i , the entropy of the answers to all queries is $\Omega(t^i)$; see [4–Lemmas 5.3 and 5.4]. This is intuitive, since the t^i query indices are expected to interleave with the indices updated in epoch i , so each query recovers one more bit of information about the unknown updates. We now propose an encoding for the answers to these queries.

First, we encode which bit probes executed in epochs $[1, i - 1]$ read bits that were changed in epoch i . Let $R_{<i}$ be the total number of bit probes made by epochs $[1, i - 1]$. Since m is chosen randomly, $E[R_{<i}] = O(t^{i-1} t_u)$. This part of the encoding takes $O(\lg P_i + \lg R_{<i}) + \lg \binom{R}{P} = O(P_i \lg \frac{R}{P})$ bits. Since $(x, y) \mapsto x \lg \frac{y}{x}$ is convex, the expected size is $O(E[P_i] \lg \frac{E[R]}{E[P]}) = O(t^{i-1} \frac{t}{\lg n} \lg \frac{t}{t/\lg n}) = O(t^{i-1} \frac{t}{\lg n} \lg \lg_t n)$.

The second part of the encoding identifies which of the t^i queries reads at least one bit-probe from epoch i . If this number is Q , this part takes $\lg \binom{t}{Q} = O(Q \lg \frac{t}{Q})$ bits. By convexity, the expected size is $O(pt^i \lg \frac{t}{pt}) = O(t^i p \lg \frac{1}{p})$. For the queries which read a bit from epoch i , we explicitly encode their answers; this takes pt^i bits in expectation.

It is easy to see that the encoding actually works. We first simulate the data structure up until the beginning of epoch i . Then, we simulate it after epoch i . This can be done because we know which bit probes read later get a changed bit because of epoch i . At the end, we simulate all queries which do not read bits from epoch i . For the rest of the queries, we know the answers.

The total size of the encoding is $O(t^i p \lg \frac{1}{p}) + O(t^{i-1} \frac{t}{\lg n} \lg \lg_t n)$. This must be $\Omega(t^i)$, from which we obtain $p \lg \frac{1}{p} = \Omega(1) - O(\frac{1}{t} \cdot \frac{t}{\lg n} \lg \lg_t n)$. Now choose t satisfying the equation $t = C \cdot \frac{t}{\lg n} \lg \lg_t n$, for a large enough constant C . For this t , we obtain $p \lg \frac{1}{p} = \Omega(1)$, hence $p = \Omega(1)$. The lower bound is $t_q = \Omega(\lg_t n)$, from which we obtain $t_q = \Omega(\lg n / (\lg \frac{t}{t} + \lg \lg t_q))$.

4 Upper Bounds for Predecessor Problems

We only sketch the solution for the segment representatives problem. The other problems are discussed in the full version of this paper. We construct a trie with branching factor $B = \Theta(\frac{\lg n}{\lg \lg n})$, in which each element is represented by a root-to-leaf path. A node is marked active if any leaf under it is in the current set. Among the children of the node, the minimum and maximum active nodes are specially marked. In the full version of this paper, we describe how to maintain these markings in $O(\frac{\lg n}{\lg \lg n})$ per insertion and deletion. It remains to implement queries. The main idea is to find the lowest common ancestor of the predecessor and the successor of the query point, and the children corresponding to the predecessor and the successor. Once this is known, it is easy to determine a canonical representative. First, take the bits corresponding to the LCA, which are common to the query, the predecessor, and the successor. Then, take the $\lg B$ bits giving the child corresponding to the successor. Finally, pad with zeroes. This computation of the representative takes zero time, since all elements are already known.

To find the lowest common ancestor of the predecessor and successor, we proceed as follows. Traverse the leaf-to-root path from the query until an active node is found. Scan the children of the node. If there is both an active node to the left and one to the right of the query, we have found the answer. Otherwise, assume by symmetry there is an active node to the left, so we have only found the predecessor. We continue searching up the tree, until we find a node which is *not* marked as maximum among its siblings. At that point, we scan the right siblings, finding the next active one, which corresponds to the successor.

5 Group-Free Monoids

Theorem 5. *The dynamic prefix problem in any group-free monoid has bit-probe complexity $\Theta(\frac{\lg n}{\lg \lg n})$.*

We use a corollary of the Krohn-Rhodes decomposition [10], which was also used in the cell-probe case [8]. Unfortunately, our application of it is considerably more involved due to the idiosyncrasies of the bit-probe model: we go through considerable lengths to avoid an exact predecessor query.

Theorem 6 ([10]). *Let M be a finite nontrivial group-free monoid. One of the following holds:*

1. $M \setminus \{1\} = \langle a \rangle = \{a, a^2, \dots, a^k = a^{k+1}\};$
2. M is left simple, i.e. $\forall a, b \in M \setminus \{1\}, ab = a;$
3. $M = V \cup T$, with V, T proper submonoids of M , and $T \setminus \{1\}$ a left ideal of M (i.e. $(\forall a \in M, b \in T : ab \in T)$).

We prove our upper bound by induction on the size of M . However, we need a stronger induction hypothesis, which assumes a solution for a slightly harder problem. We call this the prefix problem with breakpoints. Consider an array $A[1..n]$, in which an element can either be an element of M , or a breakpoint, denoted \textcircled{D} . The update operation can change any position of A to any element from $M \cup \{\textcircled{D}\}$. A query on an arbitrary position i must return the composition of $A[j + 1], \dots, A[i]$, where j is the predecessor of i in the set of breakpoints. For uniformity, we say $A[0] = A[n + 1] = \textcircled{D}$. Also, we assume breakpoints do not appear in consecutive positions. This can easily be arranged by doubling the array, and inserting an identity at every other position.

Assume by induction that the predecessor problem with breakpoints in all group-free monoids of size less than $|M|$ has complexity $O(\frac{\lg n}{\lg \lg n})$. Now apply the decomposition theorem. Due to space constraints, cases 1 and 2 are discussed in the full version of this paper.

Case 3 – $M = T \cup V$. Since $|T|, |V| \leq |M| - 1$, we have, by induction, solutions for the prefix problem with breakpoints, both running in $O(\frac{\lg n}{\lg \lg n})$. To obtain a data structure for M , we use the following components:

- a prefix structure for V , built over the array $A^V[1..n]$. The values of A^V are defined as follows: if $A[i] \in V$, $A^V[i] = A[i]$; otherwise ($A[i] \in T \setminus V$ or $A[i] = \textcircled{D}$), let $A^V[i] = \textcircled{D}$.
- a structure for finding segment representatives with the dynamic set being $B = \{i \mid A^V[i] = \textcircled{D}\}$. Denote the elements $B = \{b_1, b_2, \dots\}$.
- a prefix structure for T , built over the array A^T . If $A[i] = \textcircled{D}$, let $A^T[i] = \textcircled{D}$. The other elements are represented in a less straightforward way. For any segment (b_i, b_{i+1}) , let $A^T[\text{repr}(b_i + 1)] = \bigoplus_{j=b_i+1}^{b_{i+1}} A[j]$. Note that all but $A[b_{i+1}]$ are elements from V , but the composition is in T because of the ideal property. All elements which are not segment representatives are 1_M .
- a simple array C . For any segment (b_i, b_{i+1}) , $C[\text{repr}(b_i + 1)] = A[b_{i+1}]$. Other values of C are ignored.

We claim that we can support the following operation: given any element $j \in (b_i, b_{i+1})$, compute the composition of the entire segment in A^V . Clearly, we can recover the composition of the elements between $b_i + 1$ and $j - 1$, by running a prefix query in A^V . In addition, we can define a monoid W , which is “the reverse” of V : $(\forall a, b : a \oplus_W b = b \oplus_V a$. Since $|W| = |V| \leq m - 1$, we can construct a prefix structure on W by the induction hypothesis. We maintain $A^W[n - i + 1] = A^V[i], (\forall i)$. Now, by running a prefix query in A^W at position $n - j + 1$, we are effectively running a suffix query in A^V . By composing the prefix and the suffix, we obtain the composition of the entire segment.

We can now easily support a prefix query to position i . First, we run a prefix query in A^T up to $\text{repr}(i) - 1$. This will give the desired partial sum up to the predecessor of i in B . To get the last part of the prefix, which consists only of elements from V' , we simply ask for the prefix up to i in A^V . This works because the predecessor from B of i is the most recent breakpoint in A^V .

Updates are done in two steps: first we change the old value to 1_M , and then we change this to the new value. We distinguish the following cases:

- both the old and new values are in V (possibly 1_M). We update $A^V[i]$, and compute the composition of the entire segment containing i . Then, we compose this with $C[\text{repr}(i)]$, and we update $A^T[\text{repr}(i)]$ to this new value.
- an element from $T \setminus V$ is replaced by 1_M . We update A^V and remove i from B , which merges two segments. We remove the old segment representatives from A^T (set $A^T[\text{repr}(i - 1)] = A^T[\text{repr}(i + 1)] = 1_M$). Then, we add the representative for the new segment. The value of $B[\text{repr}(i)]$ is given by the old value $B[\text{repr}(i + 1)]$, corresponding to the right segment; $A^T[\text{repr}(i)]$ is obtained by recomputing the composition of i 's segment, as above.
- 1_M is replaced by an element in $T \setminus V$. We update $A^V[i]$ to \textcircled{D} , and insert i into B , thus splitting a segment. We first remove the old segment's representative, setting $A^T[\text{repr}(i)] = 1_M$, and then we add the two new representatives. The values in B are obvious: $B[\text{repr}(i - 1)]$ gets the new value of $A[i]$, and $B[\text{repr}(i + 1)]$ gets the old $B[\text{repr}(i)]$ from the unsplit segment. The values in A^T are obtained by recomputing the compositions of the two segments.
- \textcircled{D} is replaced by 1_M . We update $A^T[i]$ to 1_M . Changing the other structures is identical to the case when an element from $T \setminus V$ is removed.
- 1_M is replaced by \textcircled{D} . We propagate the change to $A^T[i]$. Changing the other structures is identical to the case when an element from $T \setminus V$ is added.

Acknowledgements. We are grateful to Thore Husfeldt for many helpful suggestions. Some of the results in this paper originate in a project of the first author for a research course at Harvard. She is grateful to Nick Rogers for useful comments made on that occasion.

Time-Space Lower Bounds for the Polynomial-Time Hierarchy on Randomized Machines

Scott Diehl* and Dieter van Melkebeek**

University of Wisconsin-Madison, Madison WI 53706, USA
{sfdiehl, dieter}@cs.wisc.edu

Abstract. We establish the first polynomial-strength time-space lower bounds for problems in the linear-time hierarchy on randomized machines with bounded two-sided error. We show that for any integer $\ell > 1$ and constant $c < \ell$, there exists a positive constant d such that QSAT_ℓ cannot be computed by such machines in time n^c and space n^d , where QSAT_ℓ denotes the problem of deciding the validity of a Boolean first-order formula with at most $\ell - 1$ quantifier alternations. Corresponding to $\ell = 1$, we prove that for any constant $c < \phi \approx 1.618$, there exists a positive constant d such that the set of Boolean tautologies cannot be decided by a randomized machine with one-sided error in time n^c and space n^d .

1 Introduction

Proving lower bounds remains one of the most challenging tasks in computational complexity. Satisfiability, the seminal NP-complete problem, is particularly unyielding in this respect. While we believe that any algorithm for satisfiability takes time linear exponential in the number of variables in the formula, we have been unable to prove super-linear time lower bounds on random access machines despite several decades of effort. Additionally, problems complete for higher levels of the polynomial-time hierarchy, while not receiving as much attention, have also resisted nontrivial time lower bounds.

A few years ago, Fortnow [5] realized that if we restrict the work space that a machine can use to solve satisfiability, then we can establish nontrivial lower bounds. Fortnow's technique has its roots in earlier work by Kannan [6] and has been further developed in recent years [8, 9]. For example, Fortnow and Van Melkebeek derived the following time-space lower bound for nondeterministic linear time, which gives the same lower bound for satisfiability due to the tight connection between satisfiability and nondeterministic linear time.

Theorem 1 (Fortnow-Van Melkebeek [4]). *Let $\phi \doteq (\sqrt{5} + 1)/2 \approx 1.618$ denote the golden ratio. For any constant $c < \phi$ there exists a positive constant*

** Partially supported by NSF Career award CCR-0133693.

d such that nondeterministic linear time cannot be simulated by deterministic random-access machines running in time n^c and space n^d .

Fortnow and Van Melkebeek also considered higher levels of the linear-time hierarchy and managed to prove the following time-space lower bound.

Theorem 2 (Fortnow-Van Melkebeek [4]). *For any integer $\ell \geq 2$ and constant $c < \ell$, there exists a positive constant d such that $\Sigma_\ell\text{TIME}[n]$ cannot be simulated by deterministic random-access machines running in time n^c and space n^d .*

The same tight relationship between nondeterministic linear time and satisfiability also exists between $\Sigma_\ell\text{TIME}[n]$ and QSAT_ℓ , the problem of deciding the validity of a given Boolean first-order formula with at most $\ell - 1$ quantifier alternations. Thus, the time-space lower bound for $\Sigma_\ell\text{TIME}[n]$ of Theorem 2 holds for QSAT_ℓ as well.

In this paper, we establish time-space lower bounds for the same problems on *randomized* machines with two-sided error bounded away from $1/2$.

Theorem 3 (Main Theorem). *For any integer $\ell \geq 2$ and constant $c < \ell$, there exists a positive constant d such that $\Sigma_\ell\text{TIME}[n]$ cannot be simulated by randomized random-access machines with two-sided error bounded away from $1/2$ running in time n^c and space n^d .*

Observe that our bounds essentially match those for the deterministic simulations given in Theorem 2, the only difference being the exact dependence of d on c . As in the deterministic case, Theorem 3 implies the same time-space lower bounds for QSAT_ℓ .

One can also view the instantiation of our Main Result for $\ell = 2$ as an analog of Theorem 1. Note that Theorem 1 relates to the question of P versus NP. We know the trivial inclusion that $\text{P} \subseteq \text{NP}$ and do not believe the converse but fail to prove that conjecture. Thus, research evolved towards time-space lower bounds to achieve partial negative results for the converse, as in [5, 8, 4, 9]. Similarly for BPP, we know that $\text{BPP} \subseteq \Sigma_2^{\text{P}}$ but we do not believe the converse. In this work, we turn to time-space lower bounds to achieve nontrivial negative results about the converse.

We also further strengthen Theorem 3 by showing similar lower bounds for problems that can be decided by Σ_ℓ machines in linear time and space n^a for some constant $a < 1$.

We note that Theorem 3 establishes the first polynomial-strength time-space lower bounds for two-sided error randomized simulations of the polynomial-time hierarchy. By time-space lower bounds of “polynomial strength” we mean time lower bounds of the form $\Omega(n^c)$ for some constant $c > 1$ under nontrivial space upper bounds. Previous works establish randomized time-space lower bounds but they either consider problems believed not to be in the polynomial-time hierarchy, or the time lower bounds involved are only slightly super-linear. Allender et al.’s [1] time-space lower bounds for problems in the counting hierarchy on probabilistic machines with unbounded error fall within the first category. Beame et

al. [2] give a (nonuniform) time-space lower bound for a problem in P based on a binary quadratic form, which falls in the second category.

At first glance, it might seem that the known results about space-bounded derandomization let us derive time-space lower bounds on randomized machines as immediate corollaries to the known time-space lower bounds on deterministic machines. In particular, assuming that we can solve satisfiability on a randomized machine in logarithmic space and time n^c , Nisan's deterministic simulation [11] yields a deterministic algorithm for satisfiability that runs in polylogarithmic space and polynomial time. However, even for $c = 1$, the degree of the latter polynomial is far too large for this simulation to yield a contradiction with Theorem 1 as we would like. Thus, we need a more delicate approach for the randomized setting.

Our proofs follow the paradigm of indirect diagonalization. The technique establishes a desired separation by contradiction – assuming the separation does not hold, we derive a sequence of progressively unlikely inclusions of complexity classes until we reach one that contradicts a known diagonalization result. Kannan [6] used the paradigm *avant la lettre* to investigate the relationship between deterministic linear time and nondeterministic linear time. All of the recent work on time-space lower bounds for satisfiability and problems higher up in the polynomial-time hierarchy [5, 8, 4, 9] follow it as well. Allender et al. [1] employed the technique to establish time-space lower bounds for problems in the counting hierarchy.

The critical ingredient that allows us to apply the paradigm to two-sided error randomized algorithms for problems in the polynomial-time hierarchy is a time and space efficient simulation of randomized computations in the second level of the polynomial-time hierarchy with very few guess bits. The latter follows from a careful combination of Nisan's partial space-bounded derandomization [10] and a version of Lautemann's proof that $BPP \subseteq \Pi_2^P$ [7].

We point out that earlier work implies lower bounds for (the complements of) the above problems on randomized machines with *one-sided error*. This follows because the lower bound arguments for conondeterministic linear time on *deterministic* machines typically also work on *nondeterministic* machines, of which randomized machines with one-sided error are special cases. However, the bounds become weaker. For example, the bound on c in Theorem 1 reduces from the golden ratio to $\sqrt{2}$.

Theorem 4 (Fortnow-Van Melkebeek [4]). *For any constant $c < \sqrt{2}$ there exists a positive constant d such that conondeterministic linear time cannot be simulated by randomized random-access machines with one-sided error running in time n^c and space n^d .*

Using ideas from the proof of our main result, we manage to strengthen Theorem 4 so that the bound matches the one in Theorem 1.

Theorem 5. *For any constant $c < \phi$, there exists a positive constant d such that conondeterministic linear time cannot be simulated by randomized random-access machines with one-sided error running in time n^c and space n^d .*

A similar strengthening holds for the analog of Theorem 2.

2 Preliminaries

Most of the notation we use is standard [3, 12]. For a detailed description of the machine model we use, we refer the reader to [9]. We adopt the convention that time and space functions refer to constructible functions from natural numbers to natural numbers. Our results ultimately apply to computations with polynomial time and space bounds, which certainly meet these conditions.

We introduce some additional terminology to reason about randomized computation. In particular, we use the notation $\text{BPTISP}[t, s]$ to refer to the class of languages recognized by randomized machines using time t and space s with error bounded by $\frac{1}{3}$ on both sides.

Our arguments involve Σ_k^P and Π_k^P computations in which the numbers of bits guessed at each stage are bounded by explicitly given small functions. To this end, we use the following notation to describe such computations:

Definition 1. *Given a complexity class \mathcal{C} and a function f , we define the class $\exists^f \mathcal{C}$ to be the set of languages that can be described as*

$$\{x \mid \exists y \in \{0, 1\}^{O(f(|x|))} P(x, y)\},$$

where P is a predicate accepting a language in the class \mathcal{C} when its complexity is measured in terms of $|x|$ (not $|x| + |y|$). We analogously define $\forall^f \mathcal{C}$.

For example, $\exists^f \text{DTIME}[n]$ and $\forall^f \text{DTIME}[n]$ are subsets of NP and coNP for $f(n) = n^{O(1)}$. The requirement that the complexity of P be measured in terms of $|x|$ allows us to express the running times simply in terms of the original input length, which is a more natural notion for our arguments.

We also make use of the standard divide-and-conquer approach for speeding up space bounded computation by introducing alternations. Namely, by splitting up the computation tableau of a $\text{DTISP}[T, S]$ computation into $b > 0$ equal size blocks, we obtain

$$\text{DTISP}[T, S] \subseteq \exists^{bS} \forall^{\log b} \text{DTISP}[T/b, S] \subseteq \Sigma_2 \text{TIME}[bS + T/b]. \tag{1}$$

If we choose b to optimize the running time of the resulting Σ_2 computation, the result is

$$\text{DTISP}[T, S] \subseteq \exists^{\sqrt{TS}} \exists^{\log T} \subseteq \Sigma_2 \text{TIME}[\sqrt{TS}]. \tag{2}$$

When used within the framework of time-space lower bounds, it is not always desirable to choose the block size to optimize the running time in this way, as exhibited by [4]. Therefore, most of our arguments make use of (1) for some unspecified b , and then set b later to yield the strongest results.

Finally, we need a standard diagonalization result from which we can derive contradictions. The following lemma states that for a fixed number of alternations, if we switch from universal to existential initial states and allow for a little more time, we can compute something we couldn't compute before.

Lemma 1 (Folklore). *Let ℓ be a positive integer and t a time function. Then*

$$\Sigma_\ell \text{TIME}[t] \not\subseteq \Pi_\ell \text{TIME}[o(t)].$$

3 Framework of Earlier Deterministic Results

In this section, we provide an overview of the arguments used to establish Theorem 1 since our approach uses the same general framework. Specifically, both arguments follow the paradigm of indirect diagonalization, which can be divided into the following general steps:

1. Assume the inclusion that we wish to show does not hold. For example, $\Sigma_2\text{TIME}[n] \subseteq \text{BPTISP}[t, s]$.
2. Using the hypothesis, derive inclusions of complexity classes which are increasingly unlikely.
3. Eventually one of these inclusions contradicts a known diagonalization result, proving the desired result.

Let us step through a weaker instantiation of Theorem 1 as an example. Namely, we prove the result of [8] that $\text{NTIME}[n] \not\subseteq \text{DTISP}[n^c, n^{o(1)}]$ for $c < \sqrt{2}$ following the outline described above. Therefore, the first step is to assume that

$$\text{NTIME}[n] \subseteq \text{DTISP}[n^c, n^{o(1)}]. \tag{3}$$

Consider the class $\text{DTISP}[T, T^{o(1)}]$ for some polynomial T , say $T(n) = n^2$. Using (2), we can speed up this computation by introducing alternations, resulting in a $\Sigma_2\text{TIME}[T^{1/2+o(1)}]$ simulation. Now observe that we can use the hypothesis (3) to collapse Σ_2 to NP, eliminating one alternation at the small cost of raising the running time of the simulation to the power of c . Since DTISP is closed under complement, this process gives the inclusion

$$\text{DTISP}[T, T^{o(1)}] \subseteq \text{coNTIME}[T^{c/2+o(1)}, T^{o(1)}]. \tag{4}$$

If the cost of removing an alternation by this technique is less than the speedup we gained by its introduction, then (4) is a more unlikely inclusion than the hypothesis, which could lead to a contradiction with Lemma 1.

To find the values of c which yield a contradiction, consider the hypothesis (3) padded to time T . Combining this with (4), we can conclude

$$\text{NTIME}[T] \subseteq \text{DTISP}[T^c, T^{o(1)}] \subseteq \text{coNTIME}[T^{c^2/2+o(1)}],$$

which contradicts Lemma 1 so long as $c^2/2 < 1$. This proves the desired result.

One can obtain stronger results by applying these arguments recursively. Specifically, once the speedup of (1) is applied, the final stage involved in the resulting Σ_2 simulation is itself a space bounded computation taking less time than what we started with. Therefore, we can obtain a contradiction for larger c if we recursively apply the same arguments to further speed up this computation. Doing so in an economical way (with respect to alternations) and choosing the block numbers optimally at each recursive step yields Theorem 1.

4 Lautemann's Proof and Derandomization

For this paper, we wish to derive a contradiction from the assumption

$$\Sigma_2\text{TIME}[n] \subseteq \text{BPTISP}[t, s]. \quad (5)$$

Taking a cue from the deterministic results, we would like to figure out a way to transfer the hypothesis (5) into a statement giving a strong collapse of the polynomial-time hierarchy, such as $\Sigma_2\text{TIME}[n] \subseteq \Pi_2\text{TIME}[f(n)]$ for some small function $f(n)$. We can then use such a collapse to eliminate alternations introduced by applying the speedup of (1). The focus of this section is the derivation of such a statement.

Lautemann's proof that $\text{BPP} \subseteq \Sigma_2^p \cap \Pi_2^p$ is the first tool which helps us accomplish this task. The proof relies on the large gap in sizes of witness sets for a BPP algorithm which uses R bits to accept a language L with sufficiently small error. When $x \in L$, the witness set is large enough so that for most sets of R shifts, the union of the R shifted witness sets covers the entire universe of possible witnesses; when $x \notin L$, the witness set is so small that no set of R shifts covers the universe. These complementary conditions can be expressed by a Σ_2^p predicate. Since BPP is closed under complement, this shows that $\text{BPP} \subseteq \Sigma_2^p \cap \Pi_2^p$. Specifically, we are interested in the Π_2^p side of the inclusion for our results.

Theorem 6 (Lautemann [7]). *Let L be a language recognized by a randomized machine M with error bounded on both sides by $1/R$ that runs in time T , space S (when provided two-way access to the random bits), and uses R random bits. Then*

$$L \in \forall^{R^2} \exists^R \text{DTISP}[RT, S + \log R]. \quad (6)$$

Theorem 6 is a natural candidate to derive the desired strong collapse of the polynomial-time hierarchy from (5). However, the key question is if the inclusion given by Theorem 6 is efficient enough to allow for a sufficiently strong collapse. To answer this, first note the requirement that the error be $1/R$ does not pose a problem, since this can be achieved by taking the majority vote of $O(\log R) = O(\log T)$ repetitions of a standard BPP algorithm. Thus, we can transform an arbitrary BPP computation into an equivalent one satisfying the conditions of Theorem 6 with only a logarithmic time blowup. This is good news since we would be in trouble if the theorem required error exponentially small in R – in general, the running time of the amplified algorithm would be at least quadratic.

On the other hand, the Π_2 simulation resulting in an application of Theorem 6 must run the randomized machine on R different shifts of a witness so its running time is a factor of R greater than that of the randomized machine. Since, in general, R can be as large as T , this slow-down is too much for our arguments to compensate. Therefore, an additional ingredient is needed.

That ingredient exploits the fact that the hypothesis (5) gives simulations by *space-bounded* BPP computations. In that setting, we know of techniques to

reduce the number of random bits used, which in turn reduces the overhead in the Π_2 simulation given by Theorem 6. The means by which we achieve the needed reduction in randomness is the space-bounded derandomization of Nisan [10].

Theorem 7 (Nisan [10]). *Any randomized algorithm running in time T and space S with error ϵ can be simulated by one running in time $O(T)$ and space $O(S \log T)$, which uses only $O(S \log T)$ random bits and has error $\epsilon + 2^{-S}$. If two-way access to the random bits is allowed, the space requirement is reduced to $O(S)$.*

Note that we do not apply Theorem 7 to deterministically simulate the randomized algorithm. Instead, we use it to reduce the randomness required by a $\text{BPTISP}[T, S]$ algorithm to $O(S \log T)$ with no blowup in time. If we subsequently apply Theorem 6, we only incur a blowup of $O(S \log T)$, which is acceptable for polynomial T and small S . Therefore, we can conclude:

Theorem 8.

$$\text{BPTISP}[T, S] \subseteq \forall^{(S \log T)^2} \exists^{S \log T} \text{DTISP}[TS \log^2 T, S]. \tag{7}$$

Proof. Let A be the randomized time T , space S procedure for recognizing $L \in \text{BPTISP}[T, S]$. We first take the majority of $O(\log T)$ independent repetitions of A to reduce the error to $1/T^2$, increasing the running time to $O(T \log T)$. We then apply the derandomization provided by Theorem 7 to obtain a procedure A' taking time $O(T \log T)$, using $O(S \log T)$ random bits, and using space $O(S)$ when allowed two-way access to the random bits. Additionally, A' has error at most $1/T^2 + 2^{-S}$. Since we can assume without loss of generality that $S \leq T \leq 2^S$ and $S = \omega(1)$, we have that $1/T^2 + 2^{-S} = o(1/(S \log T))$. We now apply Theorem 6 to derive (7). □

This result gives exactly the efficient inclusion of space bounded randomized classes in the polynomial time hierarchy that we need. Combining it with the hypothesis (5), we derive the inclusion

$$\Sigma_2 \text{TIME}[n] \subseteq \forall^{(s \log t)^2} \exists^{s \log t} \text{DTISP}[ts \log^2 t, s], \tag{8}$$

which gives the desired strong collapse for small enough t and s .

5 Main Result

We now use the techniques discussed in the previous sections to complete our indirect diagonalization argument for the proof of Theorem 3. Using (8) as a starting point, we derive a series of inclusions giving stronger and stronger collapses of the polynomial-time hierarchy, towards the end of contradicting Lemma 1. Specifically, we derive inclusions of the form $\Sigma_2 \text{TIME}[n] \subseteq \Pi_2 \text{TIME}[f(n)]$ for smaller and smaller $f(n)$, eventually hoping to find such an inclusion for $f(n) = o(n)$. Given that the hypothesis allows a simulation of $\Sigma_2 \text{TIME}[n]$ by

BPTISP[t, s], we rely on finding a sequence of inclusions for the latter to give these collapses. The following process derives the first such inclusion giving an improvement over (8):

1. First, we use Theorem 8 to derive a Π_2 simulation of a BPTISP[t, s] computation.
2. Since the quantifiers of the Π_2 simulation derived in the previous step are over a small number of bits, the dominant term in the running time comes from the final space bounded deterministic computation. Therefore, we can apply the speedup of (1) to the final deterministic computation to achieve a simulation taking less time, whose quantifiers look like $\forall\exists\exists\forall$, i.e., a Π_3 computation.
3. We now eliminate an alternation from this Π_3 computation in two steps. We first apply the hypothesis to simulate the computation represented by the last two quantifiers (a Σ_2 computation) by a BPTISP computation.
4. Finally, we complete the collapse by applying Theorem 8 to simulate this BPTISP computation by a Π_2 computation. Merging the two initial universal quantifiers gives us a Π_2 TIME[$f(n)$] simulation of BPTISP[t, s] for small $f(n)$, depending on the choice of t and s .

For small enough t and s , we have derived a stronger collapse of Σ_2 to Π_2 than that given by (8). We can achieve even stronger collapses by viewing the above procedure as a process that takes as input a BPTISP computation and returns a Π_2 simulation which possibly takes less time. If we recursively apply this procedure to the BPTISP computation in step 4 instead of Theorem 8, we can complete the collapse to Π_2 while possibly further speeding up the computation, providing a stronger collapse. Running this recursive argument more and more times yields the sequence of collapses we require.

The following lemma formalizes the above idea. Specifically, we consider the hypothesis (5) for polynomial t and s , namely $t = n^c, s = n^d$, and derive the running time of the resulting Π_2 simulation in terms c, d , and k , the number of times the argument is recursively applied.

Lemma 2. *Suppose that*

$$\Sigma_2\text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^d] \tag{9}$$

for some constants $c \geq 1$ and $d > 0$ where $c + 2d \leq 2$. Then for any functions T and S and positive integer k such that $2d \leq f_k$,

$$\text{BPTISP}[T, S] \subseteq \Pi_2\text{TIME} \left[((TS^2)^f + (n + S^2)^{c+2d}) \text{polylog}(T + n) \right],$$

where

$$f_k = \left(\frac{c+2d}{2}\right)^k. \tag{10}$$

Lemma 2 gives the sequence of collapses which, for certain values of c and d , leads to a contradiction with Lemma 1. We now derive the resulting time-space lower bound for $\Sigma_2\text{TIME}[n]$.

Theorem 9. *For any constant $c < 2$, there exists a positive constant d such that $\Sigma_2\text{TIME}[n]$ cannot be simulated by randomized random-access machines with error bounded away from $1/2$ running in time n^c and space n^d .*

Proof. For $c < 1$, the Theorem holds for any d by standard techniques.

We prove the case for $c \geq 1$ via indirect diagonalization. Suppose, by way of contradiction, that

$$\Sigma_2\text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^d], \tag{11}$$

for some constant $d > 0$ to be determined later. Then for any time function $\tau(n) \geq n$, the hypothesis and Lemma 2 give us the inclusions

$$\begin{aligned} \Sigma_2\text{TIME}[\tau] &\subseteq \text{BPTISP}[\tau^c, \tau^d] \\ &\subseteq \Pi_2\text{TIME} [((\tau^{c+2d})^f + (\tau^{2d} + n)^{c+2d}) \text{polylog}(\tau)] \end{aligned}$$

when $c + 2d \leq 2$ and $2d \leq f_k$. In the case that $2d \leq f_k$, the dominant power of τ will be $2f_{k+1}$, allowing us to simplify the running time of the Π_2 machine to big-O of

$$(\tau^{2f_{k+1}} + n^{c+2d})\text{polylog}(\tau).$$

Choosing a sufficiently large polynomial τ , we can further simplify this to

$$\tau^{2f_{k+1}}\text{polylog}(\tau).$$

Therefore, we have shown

$$\Sigma_2\text{TIME}[\tau] \subseteq \Pi_2\text{TIME}[\tau^{2f_{k+1}}\text{polylog}(\tau)]. \tag{12}$$

The inclusion (12) gives a contradiction with Lemma 1 for any k with $f_{k+1} < 1/2$. Note that $f_k \rightarrow 0$ as $k \rightarrow \infty$ if $c + 2d < 2$. Therefore, all that remains is to show that the latter condition is compatible with the other ones, i.e., that we can pick a constant $d > 0$ and an integer $k > 0$ such that

$$c + 2d < 2, \tag{13}$$

$$2d \leq f_k, \text{ and} \tag{14}$$

$$f_{k+1} < 1/2. \tag{15}$$

It remains to show that d and k can be chosen to satisfy these constraints. For any c and d satisfying (13), consider choosing k to be the smallest integer such that (15) is satisfied. For such a choice, we can see that $f_k \geq 1/2$, so $d \leq 1/4$ satisfies (14). Therefore, choosing d such that $d \leq \min(1/4, \frac{2-c}{2})$ and then calculating k as described above yields a d and k satisfying all of the constraints. □

We point out that the dependence of d on c in Theorem 9 differs from the deterministic setting. The proofs of Theorem 1 and Theorem 2 show that as c approaches 1 from above, d approaches 1 from below. In the proof of Theorem 9, however, the strategy described for choosing d yields a value approaching $1/4$

from below as c approaches 1 from above. Although we have not optimized our arguments to obtain the largest value of d possible, a smaller value than in the deterministic case seems inherent to our approach.

The proof of Theorem 9 generalizes to higher levels of the linear-time hierarchy, as stated in our Main Theorem. In this setting, we can use the hypothesis that $\Sigma_\ell\text{TIME}[n] \subseteq \text{BPTISP}[n^c, n^d]$ along with Theorem 8 to eliminate more than one alternation at the same cost of removing one alternation in the setting of Theorem 9. This lets us eliminate the alternations introduced by many recursive applications of (1), achieving a greater speedup and allowing contradictions for values of c less than ℓ .

Through a tight connection to nondeterministic linear time, the results of Theorem 1 extend to satisfiability and many other NP-complete problems. This connection also exists between $\Sigma_\ell\text{TIME}[n]$ and Σ_ℓ -complete problems such as QSAT_ℓ , allowing us to extend our time-space lower bounds to randomized computations of such problems.

Corollary 1. *For any integer $\ell \geq 2$ and constant $c < \ell$, there exists a positive constant d such that QSAT_ℓ cannot be solved by randomized random-access machines with error bounded away from $1/2$ running in time n^c and space n^d .*

Paying close attention to the space used by the simulations in our proofs, we actually obtain time-space lower bounds for $\Sigma_2\text{TIME}[n, n^a]$ for certain values of $a < 1$.

Theorem 10. *For any integer $\ell \geq 2$ and any positive constants c and a with $c < 1 + (\ell - 1)a$, there exists a constant $d > 0$ such that $\Sigma_\ell\text{TISP}[n, n^a] \not\subseteq \text{BPTISP}[n^c, n^d]$.*

6 Other Results

In this section, we show how to extend the golden ratio result of Fortnow and Van Melkebeek for deterministic machines (Theorem 1) to randomized machines with one-sided error, yielding Theorem 5. As we will argue, Theorem 5 follows from the next extension of Theorem 1 to a slightly stronger class of machines.

Theorem 11. *For any constant $c < \phi$ there exist positive constants d and b such that conondeterministic linear time cannot be simulated by nondeterministic random-access machines which run in time n^c , space n^d , and nondeterministically guess only n^b bits.*

Nisan's space-bounded derandomization [10] given in Theorem 7 allows us to reduce the number of random bits used by a randomized machine with one-sided error running in time T and space S to $O(S \log T)$ without significantly increasing the time or space used. Since a randomized machine with one-sided error is also a special type of nondeterministic machine, we can view such a derandomized machine as a space bounded nondeterministic machine which guesses only

$O(S \log T)$ bits. Thus, the time-space lower bounds of Theorem 5 for conondeterministic linear time on randomized machines with one-sided error follow as a corollary to Theorem 11.

In order to generalize Theorem 1 to nondeterministic machines that guess a bounded number of bits, we derive an analog to Lemma 2 which gives an unlikely inclusion of $\exists^B \text{DTISP}[T, S]$ into NTIME . Recall that in Section 5, we observed that if the number of bits guessed in a $\Pi_2 \text{TISP}[T, S]$ computation is much less than the running time T , then the entire computation can be sped up by applying (1) to the final deterministic stage of the computation. The same observation allows us to speed up a $\exists^B \text{DTISP}[T, S]$ computation when T dominates B . We accomplish the latter through an extension of Lemma 3.1 from [4], which gives a speedup of $\text{DTISP}[T, S]$ on nondeterministic machines under the hypothesis that $\text{coNTIME}[n] \subseteq \text{NTIME}[n^c]$.

Lemma 3. *Suppose that*

$$\text{coNTIME}[n] \subseteq \text{NTIME}[n^c]$$

for some constant $c \geq 1$. Then for any functions T, S , and B and any integer $k \geq 0$

$$\exists^B \text{DTISP}[T, S] \subseteq \text{NTIME}[(T \cdot S^k)^f + (n + B + S)^c],$$

where f_k is given by,

$$\begin{aligned} f_0 &= 1 \\ f_{k+1} &= c \cdot f_k / (1 + f_k). \end{aligned} \tag{16}$$

We now describe how to use Lemma 3 to prove Theorem 11. First assume that $\text{coNTIME}[n] \subseteq \exists^n \text{DTISP}[n^c, n^d]$ for b and d to be determined later. Padding this assumption and applying Lemma 3 yields the inclusion

$$\text{coNTIME}[\tau] \subseteq \text{NTIME}[\tau^{(c+kd)f} + (n + \tau^b + \tau^d)^c] \tag{17}$$

for any time function $\tau(n) \geq n$. Letting τ be a large enough polynomial and choosing small enough values for b and d , (17) forms a contradiction to Lemma 1 as long as there is a k such that $cf_k < 1$. Since the sequence $(f_k)_k$ defined by (16) decreases monotonically to $c - 1$ for $c < 2$, this is the case if and only if $c(c - 1) < 1$. Since $c(c - 1) = 1$ defines the golden ratio ϕ , this establishes Theorem 11.

We point out that a similar strengthening as Theorem 5 holds for the analog of Theorem 2.

7 Further Research

The techniques discussed in this work allow us to establish time-space lower bounds for two-sided error randomized simulations of the polynomial-time hierarchy at the second level and higher. They do not seem to extend to the first

level in a straightforward way. This is mainly due to the fact that the assumption $\text{NTIME}[n] \subseteq \text{BPTISP}[t, s]$ doesn't seem to allow the collapsing of alternations in an efficient manner. Thus, establishing time-space lower bounds for satisfiability on randomized machines with two-sided error remains open.

Improving the quantitative results of this paper is another direction needing further work. Very recently, Williams [13] used a bootstrapping argument to improve the lower bounds for $\text{NTIME}[n]$ on deterministic machines. He was able to boost the bound on the exponent c in Theorem 1 from the golden ratio $\phi \approx 1.618$ to 1.732, and we have been able to boost it further to 1.759. Using the same technique, we can improve our lower bound for $\text{coNTIME}[n]$ on randomized machines with one-sided error, boosting the bound on the exponent c in Theorem 5 from the golden ratio to 1.759. However, we have been unable to apply the technique to improve our main result, the lower bounds for $\Sigma_\ell\text{TIME}[n]$ on randomized machines with two-sided error, as given in Theorem 3.

Abstract. We consider constant depth circuits augmented with few modular, or more generally, arbitrary symmetric gates. We prove that circuits augmented with $o(\log^2 n)$ symmetric gates must have size $n^{\Omega(\log n)}$ to compute a certain (complicated) function in \mathbf{ACC}^0 .

This function is also hard on the average for circuits of size $n^{\epsilon \log n}$ augmented with $o(\log n)$ symmetric gates, and as a consequence we can get a pseudorandom generator for circuits of size m containing $o(\sqrt{\log m})$ symmetric gates.

For a composite integer m having r distinct prime factors, we prove that circuits augmented with s MOD_m gates must have size $n^{\Omega(\frac{1}{\log \frac{1}{r-1}} n)}$ to compute MAJORITY or MOD_l , if l has a prime factor not dividing m . For proving the latter result we introduce a new notion of representation of boolean function by polynomials, for which we obtain degree lower bounds that are of independent interest.

1 Introduction

Strong size lower bounds have been obtained for several classes of circuits. In particular *constant depth* circuits (\mathbf{AC}^0 circuits) require exponential size to compute even simple functions such as PARITY [1, 2, 3, 4]. More generally, if we also allow gates computing MOD_q for a prime power q we have exponential lower bounds for computing MAJORITY , and if l has a prime divisor not dividing q also for computing MOD_l [5, 6]. If we however allow gates computing MOD_m for an arbitrary integer m , we have no nontrivial lower bounds. The corresponding circuit class \mathbf{ACC}^0 is the smallest natural circuit class, for which we have no nontrivial lower bounds. Another very interesting class of constant depth circuits (containing \mathbf{ACC}^0) is the class of constant depth threshold circuits (\mathbf{TC}^0 circuits), i.e constant depth circuits built entirely from MAJORITY gates.

Viewing \mathbf{TC}^0 circuits as \mathbf{AC}^0 circuits augmented with MAJORITY gates instead, raises a natural question: Can lower bounds be proved if we limit the amount of MAJORITY gates used. This question was answered affirmatively in a series of papers. Aspnes et al [7] proved that \mathbf{AC}^0 circuits with a MAJORITY

gate on top, i.e $\mathbf{MAJ} \circ \mathbf{AC}^0$ circuits, and in fact even \mathbf{AC}^0 circuits with a single MAJORITY gate anywhere in the circuit, require exponential size to compute the MOD_2 function. Beigel et al [8] improved this lower bound to allow for $o(\log n)$ MAJORITY gates, and Beigel [9] showed that the lower bound also holds for \mathbf{AC}^0 circuits augmented with $n^{o(1)}$ MAJORITY gates. Finally Barrington and Straubing [10] generalized this lower bound, showing that it also holds for circuits computing the MOD_m function for any constant m . In fact, the proofs of these lower bounds show that \mathbf{AC}^0 circuits of size $2^{n^{(1)}}$ augmented with $n^{o(1)}$ MAJORITY gates must differ from the MOD_m function on a constant fraction all inputs of length n .

The analogous question for \mathbf{ACC}^0 is: Can lower bounds be proved if we limit the amount of MOD_m gates used. Note that although these functions *can* be computed by small \mathbf{TC}^0 circuits, the above lower bounds for \mathbf{AC}^0 circuits augmented with few MAJORITY gates are not strong enough to be applied. Indeed, these lower bounds are proved for circuit *computing* the MOD_m functions.

Another way of viewing \mathbf{TC}^0 , is as \mathbf{AC}^0 augmented with gates computing arbitrary symmetric functions, since every such function is computable by a depth 2 threshold circuit and MAJORITY is obviously symmetric. Thus, regarding \mathbf{TC}^0 , we could also ask, if lower bounds can be proved if we limit the amount of symmetric functions used. Also note that since the MOD_m functions are symmetric, an affirmative answer would answer both questions.

Our most powerful lower bound is a superpolynomial lower bound for circuits containing $o(\log^2 n)$ arbitrary symmetric gates. Combining a technique of Beigel [9] for reducing the number of symmetric gates with a lower bound for $\mathbf{MAJ} \circ \mathbf{SYM} \circ \mathbf{AC}^0$ circuits by Hansen and Miltersen [11], one can immediately obtain superpolynomial lower bounds for \mathbf{AC}^0 circuits augmented with up to $o(\log \log n)$ MOD_m gates. Our significantly stronger result, is obtained by instead generalizing the results of Håstad and Goldmann [12], Razborov and Wigderson [13] and Hansen and Miltersen [11]. We now give the definition of the functions we prove the lower bounds for. The so-called Generalized Inner Product [14] is defined as $\text{GIP}_{n,k} = (\text{MOD}_2)_n \circ \text{AND}_k$, i.e. the MOD_2 function of n conjunctions each consisting of k variables. Let further $f_{n,k} = (\text{MOD}_2)_n \circ \text{AND}_k \circ (\text{MOD}_2)_n$, i.e. $\text{GIP}_{n,k}$ with each input replaced by the MOD_2 function of n variables.

Theorem 1. *Any \mathbf{AC}^0 circuit augmented with $o(\log^2 n)$ arbitrary symmetric gates computing $f_{n,\log n}$ must have size $n^{\Omega(\log n)}$.*

It follows as a corollary of the following theorem.

Theorem 2. *Any $\mathbf{MAJ} \circ \mathbf{ANY}_s \circ \mathbf{SYM} \circ \mathbf{ANY}_t$ circuit computing $\text{GIP}_{n,t+1}$ must have size $2^{\Omega(\frac{n}{2})}$. For constants $\delta > 0$ and $\gamma > 0$ such that $\delta + \gamma < 1$, if $t = \delta \log n$ and $s = n^\gamma$, any $\mathbf{MAJ} \circ \mathbf{ANY}_s \circ \mathbf{SYM} \circ \mathbf{AC}^0$ circuit computing $f_{n,t+1}$ must have size $n^{\Omega(\log n)}$.*

For circuits augmented with MOD_m gates we are able to give lower bounds for computing much simpler functions than that used for proving Theorem 1. In

particular are all these functions symmetric, and the results are thus incomparable.

Theorem 3. *Let m be a positive integer with $r \geq 2$ distinct prime factors. Any \mathbf{AC}^0 circuit augmented with s MOD_m gates require size $n^{\Omega(\frac{1}{2} \log^{\frac{1}{r-1}} n)}$ to compute MAJORITY or MOD_l , if l has a prime factor not dividing m .*

This complements the mentioned results about circuits with few MAJORITY gates: We cannot compute MOD_m with few MAJORITY gates and we cannot compute MAJORITY with few MOD_m gates. Note also that the lower bounds are for the same functions and under the same conditions as the mentioned lower bounds for circuits with MOD_q gates for prime powers q .

Previously, Hansen and Miltersen [11] used results on *weak representation* of boolean function by polynomials over \mathbf{Z}_m as introduced and proved by Green [15] to obtain exponential lower bounds for circuits augmented with just one MOD_m gate. Theorem 3 is proved, by greatly generalizing this technique. We introduce a new notion of representation of boolean functions by polynomials over \mathbf{Z}_m for which we prove lower bounds and finally apply these to obtain circuit lower bounds.

Beigel and Maciel [16] showed how to convert a $\mathbf{MAJ} \circ \mathbf{OR} \circ \text{MOD}_m$ circuit into a $\mathbf{MAJ} \circ \mathbf{OR}_{O(1)} \circ \text{MOD}_m$ circuit with only a polynomial increase in size, which they could then apply to results by Krause and Pudlák [17] to obtain lower bounds for $\mathbf{MAJ} \circ \mathbf{OR} \circ \text{MOD}_m$ circuits. Applying their technique to our results we immediately obtain the following as a corollary to Theorem 2.

Theorem 4. *Any $\mathbf{MAJ} \circ \mathbf{OR} \circ \text{MOD}_m \circ \mathbf{ANY}_t$ circuit computing $\text{GIP}_{n,t+1}$ must have size $2^{\Omega(\frac{t}{2})}$. Any $\mathbf{MAJ} \circ \mathbf{OR} \circ \text{MOD}_m \circ \mathbf{AC}^0$ circuit computing $f_{n, \log n}$ must have size $n^{\Omega(\log n)}$.*

Viola [18] showed that by combining and modifying the proofs of [13] and [11] one can obtain a function that is hard on the average for $\mathbf{SYM} \circ \mathbf{AC}^0$ circuits of size $n^{\epsilon \log n}$. Viola used his result for constructing a pseudorandom generator for these circuits, using the construction of Nisan and Wigderson [19], and generalized it to circuits with a *constant* number of symmetric gates using the technique of Beigel [9]. Adding our constructions, one can prove that the same function is hard on the average for $\mathbf{ANY}_n \circ \mathbf{SYM} \circ \mathbf{AC}^0$ circuits of size $n^{\epsilon \log n}$ for $\gamma < 1$, and thus also for \mathbf{AC}^0 circuits of size $n^{\epsilon \log n}$ with $\gamma \log n$ symmetric gates. This gives a pseudorandom generator for circuits of size m with $o(\sqrt{\log m})$ symmetric gates. Subsequently to this result, Viola showed how to improve this to $o(\log m)$ symmetric gates [18].

1.1 Organisation of Paper

In Sect. 2 we introduce the notation and previous results we will use in our proofs. In Sect. 3 we prove Theorem 1 and 2. In Sect. 4 we prove Theorem 3 as well as our degree lower bounds used for this.

2 Preliminaries

2.1 Constant Depth Circuits

We consider circuits built from families of unbounded fanin gates. Inputs are allowed to be boolean variables and their negations as well as the constants 0 and 1. Let x_1, \dots, x_n be boolean inputs. For a positive integer m , the MOD_m function is 1 if and only if $\sum_{i=1}^n x_i \not\equiv 0 \pmod{m}$. Generally, for $A \subset \mathbf{Z}_m$ the MOD_m^A function is 1 if and only if $\sum_{i=1}^n x_i \in A \pmod{m}$. The MAJORITY function is 1 if and only if $\sum_{i=1}^n x_i \geq \frac{n}{2}$. A function is symmetric if and only if it only depends on the sum of its inputs.

Let **AND** and **OR** denote the families of unbounded fanin AND and OR gates. Let **MOD_m**, **MAJ**, **SYM** and **ANY** denote the families of MOD_m , MAJORITY, all symmetric gates and *any* kind of gate, respectively. If G is a family of boolean gates and \mathcal{C} is a family of circuits we let $G \circ \mathcal{C}$ denote the class of circuits consisting of a gate from G taking circuits from \mathcal{C} as inputs. If we need to specify a specific bound on the fanin of some of the gates, this will be specified by a subscript.

AC⁰ is the class of functions computed by constant depth circuits built from AND and OR gates. **ACC⁰** is the the analogous class of functions computed when we also allow unbounded fanin MOD_m gates for constants m , and similarly is **TC⁰** the class of functions computed when we instead allow unbounded fanin MAJORITY gates.

2.2 Multiparty Communication Complexity

We consider the ‘‘Number on the Forehead’’ model of multiparty communication as introduced by Chandra, Furst and Lipton [20]. Here k players wish to evaluate a boolean function $f(x_1, \dots, x_k)$ where $x_i \in \{0, 1\}^n$ and player i knows all input except x_i . They exchange messages according to a fixed protocol by broadcasting, and we are interested in the number of bits that must be exchanged in order to evaluate f . We let $C_\epsilon(f)$ denote the minimal number of bits that must be exchanged in the worst case, for a deterministic protocol that computes f correctly with probability at least $1 - \epsilon$ when x is chosen uniformly at random.

Babai, Nisan and Szegedy [14] studied the k -party communication complexity of the Generalized Inner Product, and proved $C_{\frac{1}{2}-\epsilon}(\text{GIP}_{n,k}) = \Omega(\frac{n}{4} + \log \epsilon)$. We state an improvement due to Chung and Tetali [21].

Theorem 5. $C_{\frac{1}{2}-\epsilon}(\text{GIP}_{n,k}) = \Omega(\frac{n}{2} + \log \epsilon)$.

Håstad and Goldmann [12] observed that depth 2 threshold circuit can be evaluated efficiently by a multiparty protocol if the fanin of the bottom gates is restricted. We observe that essentially the same protocol works for depth 3 circuits if we restrict the fanin of both the top and bottom gates.

Proposition 6. *Let f be a boolean function computed by a **ANY_s** \circ **SYM** \circ **ANY_t** circuit of size S . Then there is a $t + 1$ player protocol computing f with $1 + st \log S$ bits exchanged.*

Proof. Since the bottom fanin of the circuit is less than the number of players, every **ANY**_{*t*} gate can be evaluated by at least one player. In the protocol we fix a partition of these gates to the players, such that every player can evaluate all assigned gates. Now for each of the symmetric gates, the first *t* players compute the sum of the assigned inputs and send the results separately to player *t* + 1. Player *t* + 1 can then compute the output of the circuit and communicate the result with 1 extra bit of communication. □

2.3 The Discriminator Lemma and the Switching Lemma

Let *C* be a circuit taking *n* inputs and *f* a boolean function on *n* variables. We say that *C* is an ϵ -discriminator for *f* if $\Pr[C(x) = 1|f(x) = 1] - \Pr[C(x) = 1|f(x) = 0] \geq \epsilon$. The so-called Discriminator Lemma by Hajnal et al [22], states that if a circuit with a MAJORITY gate at the output computes a boolean function *f*, then one of the inputs to the output gate is an ϵ -discriminator for *f*.

Lemma 7. *Let f be a boolean function computed by a circuit C with a MAJORITY gate as the output gate, and let C_1, \dots, C_s be the subcircuits of C whose output gates are the inputs to the output of C . Then for some i , C_i is an $\frac{1}{s}$ -discriminator for f .*

A restriction on a set *V* of boolean variables is a map $\rho : V \rightarrow \{0, 1, \star\}$. It acts on a boolean function $f : V \rightarrow \{0, 1\}$, creating a new boolean function f_ρ on the set of variables for which $\rho(x) = \star$, obtained by substituting $\rho(x)$ for $x \in V$ whenever $\rho(x) \neq \star$. The variables *x* for which $\rho(x) = \star$ are called *free*; the other variables *set*. Let R_n^l denote the set of all restriction ρ leaving *l* of *n* variables free.

A decision tree is a binary tree, where the internal nodes are labeled by variables and leafs are labeled by either 0 or 1. On a given input *x*, its value is the value of the leaf reached by starting at the root, and at any internal node labeled by x_i proceeding to the left child if $x_i = 0$ and to the right child otherwise. We will use the following version of Håstads Switching Lemma due to Beame [23].

Lemma 8. *Let f be a DNF formula in n variables with terms of length at most r . Let $l = pn$ and pick ρ uniformly at random from R_n^l . Then the probability that f_ρ does not have a decision tree of depth at most d is less than $(7pr)^d$.*

The advantage of using Beame’s switching lemma is that it directly gives us a decision tree. If we convert a decision tree into a DNF, we have that all terms are *mutually contradictory*, i.e. we can view it as a sum of terms, instead as an OR of AND’s. This will allow us to absorb the sum into a symmetric gate.

2.4 Representation by Polynomials

For composite *m* there are several different ways of defining representation by polynomials. To obtain our lower bounds we will define new a notion which we will call *weak generalized* representation. Let *f* be a boolean function in *n* variables, and let *P* be a polynomial in *n* variables over \mathbf{Z}_m .

- P is a *strong* representation of f if $f(x) = P(x)$ for all $x \in \{0, 1\}^n$.
- P is a *one-sided* representation of f if $f(x) = 0 \Leftrightarrow P(x) \equiv 0 \pmod{m}$ for all $x \in \{0, 1\}^n$.
- P is a *weak* representation of f if $P \not\equiv 0$ and $P(x) \not\equiv 0 \pmod{m} \Rightarrow f(x) = 1$ for all $x \in \{0, 1\}^n$.
- P is a *generalized*¹ representation of f if there is a set $S \subset \mathbf{Z}_m$ such that $f(x) = 1 \Leftrightarrow P(x) \in S$.
- P is a *weak generalized* representation of f if there is a set $S \subset \mathbf{Z}_m$ and an $\bar{x} \in \{0, 1\}^n$ such that $P(\bar{x}) \in S$ and that for all $x \in \{0, 1\}^n$ we have $P(x) \in S \Rightarrow f(x) = 1$.

The minimal degree of a polynomial satisfying the above properties will be called the strong, one-sided, weak, generalized and weak generalized MOD_m degree, respectively. Note that a strong representation is also a one-sided representation. A one-sided representation is also a weak representation as well as a generalized representation, and these are both weak generalized representations. For a weak generalized representation we can assume that $|S| = 1$, in fact, if P is a weak generalized representation there exist $a \in \mathbf{Z}_m$ such that $P - a$ is a weak generalized representation with respect to $\{0\}$ of the same boolean function.

For convenience we will also consider a representation of a boolean function by more than one polynomial. Let f be as before and let P_1, \dots, P_s be polynomials in n variables over \mathbf{Z}_m . We say P_1, \dots, P_s is a *simultaneous weak* representation of f if there is an $\bar{x} \in \{0, 1\}^n$ such that $P_i(\bar{x}) \not\equiv 0 \pmod{m}$ for all i , and if it holds that whenever $P_i(x) \not\equiv 0 \pmod{m}$ for all i , we have that $f(x) = 1$. The s -simultaneous weak MOD_m degree of f is the minimum over all choices of polynomials P_1, \dots, P_s over \mathbf{Z}_m representing f of the maximal degree of P_1, \dots, P_s .

We will several times use the following well known lemma. (cf. [24]).

Lemma 9. *Let $q = p^k$ for a prime p , let P be a polynomial of degree d in n variables over \mathbf{Z}_q and let $S \subseteq \mathbf{Z}_q$. Then there exists another polynomial P' of degree at most $(q - 1)d$ in n variables over \mathbf{Z}_p such that $P(x) \in S \Rightarrow P'(x) = 1$ and $P(x) \notin S \Rightarrow P'(x) = 0$ for all $x \in \{0, 1\}$.*

Thus if $q = p^k$ for a prime p , the strong MOD_p degree of f is at most $(q - 1)$ times the generalized MOD_q degree of f , and similarly the weak MOD_p degree of f is at most $(q - 1)$ times the weak generalized MOD_q degree of f .

The following lemma shows, that s -simultaneous weak degree and weak generalized degree are essentially the same, when s is a constant.

Lemma 10. *Let m be a positive integer and let $m = q_1 \cdots q_t$ be the factorization in prime powers $q_i = p_i^{k_i}$, let $m' = p_1 \cdots p_t$ and let f be a boolean function. The weak generalized $\text{MOD}_{m'}$ degree of f is at most $s(q - 1)$ times the s -simultaneous weak MOD_m degree of f , where q is the largest prime power factor of m .*

¹ This notion was actually called *weak* representation in [24], but we prefer to reserve this name for the representation introduced by Green [15], which is analogous to the weak degree of a voting polynomial defined by Aspnes et al [7].

On the other hand, the $(m - 1)$ -simultaneous weak MOD_m degree of f is at most as large as the weak generalized MOD_m degree of f .

3 Circuits with Few Symmetric Gates

Proof (of Theorem 2). Let C be a $\text{MAJ} \circ \text{ANY}_s \circ \text{SYM} \circ \text{ANY}_t$ circuit of size S which computes $f = \text{GIP}_{n,t+1}$. From Lemma 7 we have a $\text{ANY}_s \circ \text{SYM} \circ \text{ANY}_t$ subcircuit C_i that is an $\frac{1}{S}$ -discriminator for f , i.e. $\Pr[C_i(x) = 1 \mid f(x) = 1] - \Pr[C_i(x) = 1 \mid f(x) = 0] \geq \frac{1}{S}$. From the Binomial Theorem we have $\Pr[f(x) = 0] - \Pr[f(x) = 1] = (1 - 2^{-t})^n$ and thus $\Pr[f(x) = 0] = \frac{1}{2} + \frac{(1-2^{-t})^n}{2}$. For $a, b \in \{0, 1\}$ let $P_{ab} = \Pr[C_i(x) = a \mid f(x) = b]$. We thus get $\Pr[C_i(x) = f(x)] = P_{11} \Pr[f(x) = 1] + P_{00} \Pr[f(x) = 0] = \frac{1}{2} + \frac{1}{2}(P_{11} - P_{10}) + \frac{(1-2^{-t})^n}{2}(1 - P_{11} - P_{10}) \geq \frac{1}{2} + \frac{1}{2S} - \frac{(1-2^{-t})^n}{2} \geq \frac{1}{2} + \frac{1}{4S}$, where we assume without loss of generality that $S \leq \frac{1}{2}e^{2^{-t}}$. Combining this with Theorem 5 and Proposition 6 we have $1 + st \log S = \Omega(\frac{n}{2} + \log \frac{1}{4S})$ and we can conclude that $S = 2^{\Omega(\frac{n}{2})}$.

For the second part, let C be a depth $d + 3$ $\text{MAJ} \circ \text{ANY}_s \circ \text{SYM} \circ \text{AC}^0$ circuit of size $n^{\epsilon \log n}$ computing $f_{n,t+1}$. Let $m = n^2(t + 1)$. We choose a random restriction $\rho \in R_m^{\frac{2}{3}}$, and argue that for sufficiently small ϵ , with positive probability, $f_{n,t+1}$ contains $\text{GIP}_{n,t+1}$ as a subfunction and the function computed by C_ρ is also computed by a $\text{MAJ} \circ \text{ANY}_s \circ \text{SYM} \circ \text{AND}_t$ circuit of size $n^{\epsilon \log n} 2^t = n^{\delta + \epsilon \log n}$. The statement then follows from the first part.

The probability that ρ fails the first requirement is at most $n(t + 1)$ times the probability that a random subset of size $m^{\frac{2}{3}}$ does not intersect a fixed subset of size n (corresponding to the inputs of the MOD_2 functions substituted in $\text{GIP}_{n,t+1}$). This happens with probability at most $2^{-n} \binom{m}{n} \approx 2^{-n}$.

For the other part, view ρ as a composition of several restrictions ρ_1, \dots, ρ_d where $\rho_i \in R_{m_{i-1}}^m$ and $m_i = m \left(m^{\frac{1}{3}}\right)^{-i}$. Assume that after having applied the first $i - 1$ restrictions, that all functions computed at level $i - 1$ of C are computed by decision trees of depth at most t , and hence DNFs with terms of size at most t . Assume without loss of generality that the gates at level i are OR gates, and thus also computable by decision trees of depth at most t . By Lemma 8, the probability that the function computed by such an OR gate can not be computed by a decision tree of depth t after applying ρ_i is at most $\left(7 \frac{m}{m_{i-1}} t\right)^t = \left(7 m^{-\frac{1}{3}} \delta \log n\right)^{\delta \log n} = n^{-\Omega(\log n)}$. Thus for ϵ sufficiently small, ρ will convert all gates at level d into decision trees of depth at most t . By rewriting these into DNFs with *mutually contradictory* terms, allows us to simply directly feed these terms into the symmetric gate above, resulting in a $\text{MAJ} \circ \text{ANY}_s \circ \text{SYM} \circ \text{AND}_t$ circuit computing the same function. \square

Proof (of Theorem 1). Let C be a AC^0 circuit of size S augmented with s symmetric gates. Let g_1, \dots, g_s denote the symmetric gates, such that there is no path from the output of g_j to an input of g_i if $i < j$. For $\alpha \in \{0, 1\}^s$, let C_i^α

be the $\mathbf{SYM} \circ \mathbf{AC}^0$ subcircuit of C with g_i as output, where each g_j for $j < i$ is replaced by the constant α_j . Similarly, let C^α be the \mathbf{AC}^0 circuit obtained from C where every g_i is replaced by α_i . Note that since the subcircuit of C with output g_i contain at most $i - 1$ other symmetric gates than g_i , we have at most $\sum_{i=1}^s 2^{i-1} = 2^s - 1$ different $\mathbf{SYM} \circ \mathbf{AC}^0$ subcircuits of C . We can now compute the same function as C by a $\mathbf{OR}_2 \circ \mathbf{AND}_{s+1} \circ \mathbf{SYM} \circ \mathbf{AC}^0$ circuit of size $O(2^s S)$ constructed as follows: The output OR gate is fed by ANDs corresponding to all $\alpha \in \{0, 1\}^s$. The AND gates takes C^α as input, as well as C_i^α if $\alpha_i = 1$ and $\neg C_i^\alpha$ (which is also a $\mathbf{SYM} \circ \mathbf{AC}^0$ circuit) otherwise. If $s = o(\log^2 n)$ Theorem 2 gives that $S = n^{\Omega(\log n)}$. \square

4 Circuits with Few Modular Gates

4.1 Degree Lower Bounds

Barrington and Tardos obtained the following lower bound on the generalized degree of the OR function.

Theorem 11 ([24]). *Let m be a positive integer with $r \geq 2$ distinct prime factors, and let q be the smallest maximal prime power of m . The generalized degree of the OR function on n variables is at least $\left(\left(\frac{1}{q-1} - o(1)\right) \log n\right)^{\frac{1}{r-1}}$.*

As a corollary to this we obtain the same lower bounds for the weak generalized degree of the MAJORITY and \neg MAJORITY functions.

Theorem 12. *Let m be a positive integer with $r \geq 2$ distinct prime factors, and let q be the smallest maximal prime power of m . The weak generalized MOD_m degree of the MAJORITY and \neg MAJORITY functions on n variables is at least $\left(\left(\frac{1}{q-1} - o(1)\right) \log n\right)^{\frac{1}{r-1}}$.*

We will use the following lower bound on the degree of weak representation due to Green [15] in a crucial way for proving Lemma 15.

Theorem 13. *Let m and l be positive relative prime integers. The weak MOD_m degree of the MOD_l and $\neg\text{MOD}_l$ functions on n variables is at least $\lfloor \frac{n}{2(l-1)} \rfloor$.*

Corollary 14. *Let l be a positive integer and let $q = p^a$ for a prime p not dividing l . The weak generalized MOD_q degree of the MOD_l and $\neg\text{MOD}_l$ functions on n variables is at least $\frac{1}{(q-1)} \lfloor \frac{n}{2(l-1)} \rfloor$.*

For a subset $S \subseteq \{1, \dots, n\}$, let $\chi(S) \in \{0, 1\}^n$ denote its characteristic vector. Conversely for $x \in \{0, 1\}^n$, let $\sigma(x) \subseteq \{1, \dots, n\}$ be the set of indices where $x_i = 1$.

Lemma 15. *Let P be a polynomial of degree d in n variables over \mathbf{Z}_q where $q = p^a$ for a prime p , and let l be a positive integer not divisible by p . If $k \geq 1$*

satisfies $n \geq 2(l-1) \left(k + (q-1) \sum_{i=1}^d (d+1-i) \binom{k}{i} \right)$, then there exists pairwise disjoint nonempty sets $S^1, \dots, S^k \subseteq \{1, \dots, n\}$ such that for every $y \in \{0, 1\}^k$ we have $P(\sum_{i=1}^k y_i \chi(S^i)) \equiv P(0) \pmod{q}$ and furthermore we have $|S^i| \not\equiv 0 \pmod{l}$ for all i .

Proof. Assume without loss of generality that $P(0) = 0$. We will find the sets S^i inductively with $|S^i| \leq s_i$, where $s_j = 2(l-1) \left(1 + (q-1) \sum_{i=1}^d \binom{j-1}{i-1} (d+1-i) \right)$. First pick a set S of $s_1 = 2(l-1)(d(q-1) + 1)$ variables. If we consider the polynomial obtained from P by substituting 0 for all variables not in S , we obtain a polynomial which can not be a weak generalized representation of $\neg\text{MOD}_l$ with respect to the set $\{0\}$, by Corollary 14. Thus there is a subset $S^1 \subseteq S$ such that $P(\chi(S^1)) = 0 = P(0)$ and $\neg\text{MOD}_l(\chi(S^1)) = 0$, that is $|S^1| \not\equiv 0 \pmod{l}$.

In the general case, assume for $j < k$, that we have already found sets S^1, \dots, S^j , where $|S^i| \leq s_i$ and $|S^i| \not\equiv 0 \pmod{l}$ for all $i \leq j$ and we have $P(\sum_{i=1}^j y_i \chi(S^i)) = 0 = P(0)$ for all $y \in \{0, 1\}^j$. Pick a set S of size s_{j+1} of the remaining variables.

For any $y \in \{0, 1\}^j$, let P_y be the polynomial obtained from P by substituting y_i for all variables in S^i for all i , and further substituting 0 for all remaining variables not in S . Let P'_y be the polynomial over \mathbf{Z}_p , obtained using Lemma 9, that is a strong representation of the boolean function of which P_y is a generalized representation with respect to $\{0\}$. That is $P'_y(x) \equiv 0 \pmod{p} \Leftrightarrow P_y(x) \not\equiv 0 \pmod{q}$ and $P'_y(x) \equiv 1 \pmod{p} \Leftrightarrow P_y(x) \equiv 0 \pmod{q}$.

Let $R = \prod_{y \in \{0,1\}^j} P'_y$. Observe that R only take the values 0 and 1 modulo p , and that $R(x) \equiv 1 \pmod{p}$ if and only if $P'_y(x) \equiv 1 \pmod{p}$ for all y , that is, if and only if $P_y(x) \equiv 0 \pmod{q}$ for all y . If R is not a weak representation of $\neg\text{MOD}_l$, we could thus find a new set S^{j+1} as before. But since the degree of R is $2^j(q-1)d$, this does not give our desired bound on the number of variables s_{j+1} required for this contradiction. However, exactly as in [24] we can use inclusion-exclusion to construct an equivalent polynomial R' , i.e $R'(x) \not\equiv 0$ if and only if $P_y(x) \equiv 0 \pmod{q}$ for all y , of degree $(q-1) \sum_{i=0}^{d-1} \binom{j}{i} (d-i)$. From Theorem 13 and the choice of s_{j+1} we have that R' is not a weak representation of $\neg\text{MOD}_l$. We can thus find $S^{j+1} \subseteq S$ such that $R'(\chi(S^{j+1})) \not\equiv 0 \pmod{p}$ and $\neg\text{MOD}_l(\chi(S^{j+1})) = 0$. It follows that $P_y(\chi(S^{j+1})) = 0$ for all y and $|S^{j+1}| \not\equiv 0 \pmod{l}$. To allow the induction to go through, we need that $n \geq \sum_{j=1}^k s_j$, which is exactly the requirement stated. \square

Theorem 16. *Let m be a positive integer with $r \geq 2$ distinct prime factors, let q be the smallest maximal prime power factor of m and let p be a prime not dividing m . For all $a \in \mathbf{Z}_p$ the weak generalized MOD_m degree of the $\text{MOD}_p^{\{a\}}$ and $\neg\text{MOD}_p^{\{a\}}$ functions on n variables is at least $\left(\left(\frac{1}{2^{(p-1)^2(q-1)}} - o(1) \right) \log n \right)^{\frac{1}{-1}}$.*

Proof. The idea of the proof is to successively use Lemma 15 to convert a given representation into another representation (on fewer variables) that depend on less prime factors, and finally use Corollary 14.

Let $n = n(m, d)$ denote the maximal number of variables, for which there is a weak generalized representation over \mathbf{Z}_m of degree d , for any of the $\text{MOD}_p^{\{a\}}$ and $\neg\text{MOD}_p^{\{a\}}$ functions. We need to prove that $\log n(m, d) \leq (2(p - 1)^2(q - 1) + o(1))d^{r-1}$. Let $m = q_1 m_1$ where q_1 is a maximal prime power divisor of m different from q .

Assume that P is a polynomial in n variables of degree d over \mathbf{Z}_m which is a weak generalized representation of f with respect to $\{0\}$, where f is either $\text{MOD}_p^{\{a\}}$ or $\neg\text{MOD}_p^{\{a\}}$ for some $a \in \mathbf{Z}_p$. By assumption there exists $\bar{x} \in \{0, 1\}^n$ such that $P(\bar{x}) \equiv 0 \pmod{m}$ and $f(\bar{x}) = 1$. If $|\sigma(\bar{x})| < \frac{n}{2}$ let P' be the polynomial obtained from P by setting the variables indexed by $\sigma(\bar{x})$ to 1. Otherwise, if $|\sigma(\bar{x})| \geq \frac{n}{2}$ we can let P' be the polynomial where variables x_i are substituted with $1 - x_i$ if $i \in \sigma(\bar{x})$ and otherwise set to 0, and modify the following proof accordingly. In either case the number n' of variables in P' is at least $\frac{n}{2}$.

For a given integer k , let $k' = (p - 1)k$ and assume that n' is at least $2(p - 1) \left(k' + (q_1 - 1) \sum_{i=1}^d (d + 1 - i) \binom{k'}{i} \right)$. Then using Lemma 15 we can find pairwise disjoint nonempty sets $S^{i_1}, \dots, S^{i_{k'}} \subseteq \{1, \dots, n'\}$ such that for every $y \in \{0, 1\}^{k'}$ we have $P'(\sum_{i=1}^{k'} y_i \chi(S^{i_i})) \equiv P'(0) \equiv 0 \pmod{q_1}$ and furthermore we have $|S^{i_i}| \not\equiv 0 \pmod{p}$ for all i . Choosing the most occurring residue $b \in \mathbf{Z}_p \setminus \{0\}$ among $|S^{i_i}|$ modulo p and extending the sets to $\{1, \dots, n\}$, we have pairwise disjoint nonempty sets $S^1, \dots, S^k \subseteq \{1, \dots, n\}$ such that $P(\bar{x} + \sum_{i=1}^k y_i \chi(S^i)) \equiv P(\bar{x}) \equiv 0 \pmod{q_1}$ for every $y \in \{0, 1\}^k$, and $|S^i| \equiv b$ for all i .

In case f is $\text{MOD}_p^{\{a\}}$, we have $P(\bar{x} + \sum_{i=1}^k y_i \chi(S^i)) \equiv 0 \pmod{m} \Rightarrow |\sigma(\bar{x})| + \sum_{i=1}^k y_i |S^i| \not\equiv a \pmod{p} \Rightarrow \sum_{i=1}^k y_i \not\equiv b^{-1}(a - |\sigma(\bar{x})|) \pmod{p}$. In case f is $\neg\text{MOD}_p^{\{a\}}$ we have $P(\bar{x} + \sum_{i=1}^k y_i \chi(S^i)) \equiv 0 \pmod{m} \Rightarrow |\sigma(\bar{x})| + \sum_{i=1}^k y_i |S^i| \equiv a \pmod{p} \Rightarrow \sum_{i=1}^k y_i \equiv 0 \pmod{p}$. Since $P(\bar{x} + \sum_{i=1}^k y_i \chi(S^i)) \equiv 0 \pmod{m_1} \Rightarrow P(\bar{x} + \sum_{i=1}^k y_i \chi(S^i)) \equiv 0 \pmod{m}$, we thus have that $P(\bar{x} + \sum_{i=1}^k y_i \chi(S^i))$ is a weak generalized MOD_{m_1} representation of either $\text{MOD}_p^{\{b^{-1}(a - |\sigma(\bar{x})|)\}}$ or $\neg\text{MOD}_p^{\{0\}}$. Thus for $k = n(m_1, d) + 1$ we must have $n' < 2(p - 1) \left(k' + (q_1 - 1) \sum_{i=1}^d (d + 1 - i) \binom{k'}{i} \right)$.

If $r = 2$ then $m_1 = q$ and from Corollary 14 we have that $k \leq 2(p - 1)((q - 1)d + 1)$. Using $n(m, d) \leq O(d2^{k'})$ gives $\log n(m, d) \leq O(\log d) + (p - 1)k \leq (2(p - 1)^2(q - 1) + o(1))d$.

If $r > 2$, we have by induction that $\log k \leq (2(p - 1)^2(q - 1) + o(1))d^{r-2}$. Using $n(m, d) \leq O(k'^d)$ gives $\log n(m, d) \leq O(1) + d(\log(p - 1) + \log k) \leq (2(p - 1)^2(q - 1) + o(1))d^{r-1}$. \square

Corollary 17. *Let m be a positive integer with $r \geq 2$ distinct prime factors, let q be the smallest maximal prime power factor of m and let l be a positive integer having a prime factor p not dividing m .*

Then the weak generalized MOD_m degree of the $\text{MOD}_l^{\{a\}}$ and $\neg\text{MOD}_l^{\{a\}}$ functions on n variables is at least $\left(\left(\frac{1}{2(p-1)^2(q-1)} - o(1) \right) \log n \right)^{\frac{1}{r-1}}$.

4.2 Circuit Lower Bounds

Proof (of Theorem 3). Let C be a depth d \mathbf{AC}^0 circuit of size $n^{-\log^{-\frac{1}{s+1}} n}$ containing s MOD_m gates g_1, \dots, g_s computing a function f . Assume there is no path from the output of g_j to an input of g_i if $i < j$. For $\alpha \in \{0, 1\}^s$ let C_i^α be the $\text{MOD}_m \circ \mathbf{AC}^0$ subcircuit of C with g_i as output, where every g_j for $j < i$ is replaced by the constant α_j . Similarly, let C^α be the \mathbf{AC}^0 circuit obtained from C where every g_i is replaced by α_i . We will choose a random restriction $\rho \in R_n^{\sqrt{n}}$ and show that for every $\delta > 0$ we can choose ϵ sufficiently small such that with high probability we can obtain polynomials p_i^α and q^α , of degree $\frac{\delta}{s} \log^{-\frac{1}{s+1}} n$, such that $C_{i,\rho}^\alpha(x) = 1 \Leftrightarrow p_i^\alpha(x) \not\equiv 0 \pmod{m}$ and $C_\rho^\alpha(x) = q^\alpha(x)$ for all x .

If we obtain this we can construct a simultaneous weak representation, using $s+1$ of the polynomials, of either f_ρ or $\neg f_\rho$ as follows: Pick a *maximal* set G of the MOD_m gates that are 1 at the same time for some input x in C_ρ and define α such that $\alpha_i = 1 \Leftrightarrow g_i \in G$. If there exist x such that all the gates in G evaluate to 1 on x and at the same time $C_\rho(x) = 1$, then $\{p_i^\alpha \mid g_i \in G\} \cup \{q^\alpha\}$ is a simultaneous weak representation of f_ρ . Otherwise $\{p_i^\alpha \mid g_i \in G\}$ is a simultaneous weak representation of $\neg f_\rho$.

Note that if f is MOD_l then f_ρ is $\text{MOD}_l^{\{a\}}$ for some a . If f is MAJORITY and the number of 0 and 1 assigned by ρ differ by at most 1 (which happens with probability $\Omega(n^{-\frac{1}{2}})$), we can fix at most 1 extra variable such that f_ρ will compute MAJORITY. In any case we can pick δ sufficiently small and obtain a contradiction to the degree lower bounds in Theorem 12 and Corollary 17, using Lemma 10.

The polynomials are obtained similarly as in the proof of Theorem 2 by applying a series of restrictions ρ_1, \dots, ρ_d , where ρ_i leaves $n \left(n^{\frac{1}{2}}\right)^{-i}$ variables free, simultaneously on all of the at most $2^{s+1} - 1$ different circuits defined above. Here again the crucial step is to feed the terms of a DNF directly to the MOD_m gates, thus obtaining a polynomial over \mathbf{Z}_m . \square

Discrete Random Variables over Domains^{*}

M.W. Mislove

Tulane University, New Orleans, LA 70118

Abstract. In this paper we explore discrete random variables over domains. We show that these lead to a continuous endofunctor on the categories **RB** (domains that are retracts of bifinite domains), and **FS** (domains where the identity map is the directed supremum of deflations finitely separated from the identity). The significance of this result lies in the fact that there is no known category of continuous domains that is closed under the probabilistic power domain, which forms the standard approach to modeling probabilistic choice over domains. The fact that **RB** and **FS** are cartesian closed and also are closed under the discrete random variables power domain means we can now model, e.g., the untyped lambda calculus extended with a probabilistic choice operator, implemented via random variables.

1 Introduction

Domain theory, perhaps the most widely used method for assigning denotational meanings to programming languages, has recently seen its influence broaden to other areas of computation and mathematics. It provides a wide range of constructors for modeling data types, nondeterminism, functional programming, and several other constructs needed in semantics. It also admits a number of cartesian closed categories, the fundamental objects needed to model the lambda calculus. Even probabilistic computation admits a model in the theory, although truth to tell, this particular constructor has proven to be very difficult to unravel. Of particular interest is the question

*Is there a cartesian closed category of domains
that is closed under the probabilistic power domain?*

There have been many attempts to resolve this, but the most we know to date is contained in [9], where it is shown that the probabilistic power domain of a finite tree is in **RB**, that the probabilistic power domain of a finite reversed tree is in **FS**, and that **RB** is closed under the probabilistic power domain if the probabilistic power domain of every finite poset is in **RB**. But, other than finite trees, the only finite posets whose probabilistic power domain is known to be in **RB** is the class of flat posets, whose probabilistic power domains are bounded complete (the continuous analogs of Scott domains).

^{*} This work supported by the US National Science Foundation and the US Office of Naval Research.

We do not contribute to settling this question here, but we do provide an alternative construction—what we call the *power domain of discrete random variables*, which we show defines a continuous endofunctor on the category \mathbf{RB} , as well as on \mathbf{FS} and on \mathbf{CDOM} , the category of coherent domains.

Objects in \mathbf{RB} are retracts of *bifinite domains*, those that can be expressed as bilimits of finite posets under embedding–projection pairs. This category is cartesian closed, and it also is closed under the various power domains for nondeterminism [4]. With the addition of a mechanism to model probabilistic choice, \mathbf{RB} provides virtually all the tools required to support semantic modeling. Furthermore, playing off results of Varacca [20, 21], we show that the formation of the power domain of discrete random variables over \mathbf{RB} yields a monad that enjoys a distributive law with respect to each of the power domain monads, and this in turn implies that each of these power domain monads lifts to a monad on the category \mathbf{RB} that are also algebras for the discrete random variable power domain monad. In short, we can now form domain-theoretic models of computation that respect the laws of discrete random variables as well as any of the laws we choose for nondeterminism: angelic, demonic or convex choice.

The outline of the rest of the paper is as follows. In the next section we provide some background about domains and about the constructions we need. We then review briefly a construction by Varacca [21] which inspired our work, and that Varacca calls the *Plotkin indexed valuations*. In the following section, we investigate bag domains—domain-theoretic models for multisets, which are at the heart of our reformulation of Varacca’s construction, and we then show how our approach recaptures Varacca’s construction. Next we present the main result of the paper, which is to define that what we call the power domain of discrete random variables, and we show it defines a continuous endofunctor on \mathbf{RB} , \mathbf{FS} and on \mathbf{CDOM} . In the final section, we discuss further work along this line, including how to construct Varacca’s other examples of indexed valuations. We also discuss the relationship between a random variable approach to modeling probabilistic computation and one based directly on probability distributions.

1.1 Background

We begin with some basic results about partial orders, and about domains in particular. A general reference for this material is [1] or [3].

A subset A of a partially ordered set P is *directed* if A has an upper bound for each of its finite subsets. A mapping between partially ordered sets is *Scott continuous* if it preserves the order and the suprema of those directed sets that have a supremum. A *directed complete partial order (dcpo)* is a partially ordered set in which each directed set has a least upper bound. A *cpo* is a dcpo with a least element \perp .

If P is a partial order and $x, y \in P$, then we say x is *way-below* y ($x \ll y$) if whenever $A \subseteq P$ is directed and has a supremum, if $y \sqsubseteq \sqcup A$, then $x \sqsubseteq a$ for some $a \in A$. A poset P is *continuous* if $\downarrow y = \{x \in P \mid x \ll y\}$ is directed and $y = \sqcup \downarrow y$ for each $y \in P$. A *domain* is a continuous dcpo.

An *abstract basis* is a pair (B, \ll) where \ll is a transitive relation on B satisfying the *interpolation property*:

$$F \ll x \ \& \ F \subseteq B \text{ finite} \Rightarrow (\exists y \in B) F \ll y \ll x.$$

By $F \ll x$ we mean $z \ll x \ \forall z \in F$. If (B, \ll) is an abstract basis, then $I \subseteq B$ is a *round ideal* if I is a \ll -lower set, and $x \in I \Rightarrow (\exists y \in I) x \ll y$. The *round-ideal completion* of an abstract basis (B, \ll) is the family of round ideals, ordered by inclusion. This forms a domain, where $I \ll J$ iff $(\exists x \ll y \in B) I \subseteq \downarrow x \subseteq \downarrow y \subseteq J$. In fact, every domain P is isomorphic to the round-ideal completion of an abstract basis, namely P is isomorphic to the round ideal completion of (P, \ll) under the mapping sending a point x to $\downarrow x$, whose inverse is the mapping that sends a round ideal to its supremum.

One of the fundamental results about dcpos is that the family of Scott continuous maps between two dcpos is another dcpo in the pointwise order. Since it's easy to show that the finite product of a family of continuous posets is another such, and the one-point poset is a terminal object, a central question is which categories of dcpos and Scott continuous maps are cartesian closed. This is true of DCPO, but not of DOM, the category of domains. Still, there are several full subcategories of DOM that are cartesian closed. Among the notable such categories are:

- BCD *Bounded complete domains*, in which every non-empty subset has a greatest lower bound.
- RB Domains which are retracts of *bifinite domains*, themselves bilimits of families of finite posets under embedding-projection maps; these are pairs of Scott continuous mappings $e: P \rightarrow Q$ and $p: Q \rightarrow P$ satisfying $p \circ e = 1_P$ and $e \circ p \leq 1_Q$.
- FS Domains D satisfying the property that the identity map is the directed supremum of selfmaps $f: D \rightarrow D$ each *finitely separated* from the identity: i.e., for each f there is a finite subset $M_f \subseteq D$ with the property that, for each $x \in D$, there is some $m \in M_f$ with $f(x) \leq m \leq x$.

Actually, BCD is a full subcategory of RB, which in turn is a full subcategory of FS, and FS is a maximal ccc of domains. An interesting (some might say frustrating) open question is whether RB and FS are equal. The objects in all of these categories are *coherent*,¹ but the category CDOM of coherent domains and Scott continuous maps is not a ccc.

We also recall some facts about categories. A *monad* on a category \mathbf{A} is a *triple* (T, μ, η) where $T: \mathbf{A} \rightarrow \mathbf{A}$ is an endofunctor, and $\mu: T^2 \rightarrow T$ and $\eta: 1_{\mathbf{A}} \rightarrow T$ are natural transformations satisfying the laws:

$$\mu \circ T\mu = \mu \circ \mu_T \quad \text{and} \quad \mu \circ \eta_T = T = \mu \circ T\eta$$

If (T, μ, η) is a monad, then a *T-algebra* is a pair (a, h) , where $a \in \mathbf{A}$ and $h: Ta \rightarrow a$ is an \mathbf{A} -morphism satisfying $h \circ \eta_a = 1_a$ and $h \circ Th = h \circ \mu_a$. For

¹ A domain is *coherent* if its Lawson topology is compact; cf. [1].

example, each of a power domains, $\mathcal{P}_L(P)$, $\mathcal{P}_U(P)$ and $\mathcal{P}_C(P)$ define monads on DCPO (cf. [4]), whose algebras are ordered semilattices; another example is the *probabilistic power domain* $\mathbb{V}(P)$ (cf. [7]), whose algebras satisfy equations that characterize the probability measures over P .

One goal of domain theory is to provide a setting in which all of the constructors needed to model a given programming language can be combined. If the aim is to model both nondeterminism and probabilistic choice, then one needs to combine the appropriate nondeterminism monad with the probabilistic power domain monad, in order that the laws of each constructor be preserved in the resulting model. This is the function of a *distributive law*, which is a natural transformation $d: ST \rightarrow TS$ between monads S and T on \mathbf{A} satisfying several identities—cf. [2]. The significance of distributive laws is a theorem of Beck [2], which says there is a distributive law of S over T if and only if T lifts to a monad on the category of S -algebras. Unfortunately, it was shown by Plotkin and Varacca [20] that there is no distributive law of \mathbb{V} over \mathcal{P}_X , or of \mathcal{P}_X over \mathbb{V} for any of the nondeterminism monads \mathcal{P}_X . This led to the work we report on next.

2 Indexed Valuations

We now recall some of the work of Varacca [21] that was motivated by problems associated with trying to model *both* nondeterminism and probabilistic choice. Once it was shown that there is no distributive law between \mathbb{V} and any of the nondeterminism monads, Varacca realized that weakening one of the laws of probabilistic choice could result in a monad that enjoys a distributive law with respect to a monad for nondeterminism. For $0 < p < 1$ and A a domain element, the law in question is

$$pA + (1 - p)A = A \tag{1}$$

which he weakened in three ways:

$$pA + (1 - p)A \supseteq A \tag{2}$$

$$pA + (1 - p)A \sqsubseteq A \tag{3}$$

$$pA + (1 - p)A \text{ and } A \text{ unrelated by order.} \tag{4}$$

He called the monad he constructed satisfying (2) the *Hoare indexed valuations*, the one satisfying (3) the *Smyth indexed valuations* and the one satisfying (4), a non-relation, the *Plotkin indexed valuations*. We exploit this last construction—the so-called *Plotkin indexed valuations* over a domain—in defining our power domain of discrete random variables.

2.1 Plotkin Indexed Valuations

An *indexed valuation* over the poset P is a tuple $(r_i, p_i)_{i \in I}$ where I is an index set,² each $r_i \geq 0$ is a non-negative real number and $p_i \in P$ for each $i \in I$.

² For our discussion, we can assume I is always finite.

Two indexed valuations satisfy $(r_i, p_i)_I \simeq_1 (s_j, q_j)_J$ if $|I| = |J|$ and there is a permutation $\phi \in S(|I|)^3$ with $r_{\phi(i)} = s_i$ and $p_{\phi(i)} = q_i$ for each i . If we let $I' = \{i \in I \mid r_i \neq 0\}$ and similarly for J , then $(r_i, p_i)_I \simeq_2 (s_j, q_j)_J$ if $(r_i, p_i)_{I'} \simeq_1 (s_j, q_j)_{J'}$, and we let \simeq denote the equivalence relation on indexed valuations generated by \simeq_2 . For an indexed valuation $(r_i, p_i)_I$, we let $\langle r_i, p_i \rangle_I$ denote the equivalence class modulo \simeq .

Next, let $\mathbb{R}_{\geq 0}$ denote the extended non-negative real numbers, with the usual order. Then for a domain P , Varacca defines a relation \ll_P on the family $\{\langle r_i, p_i \rangle_I \mid r_i \in \mathbb{R}_{\geq 0} \ \& \ p_i \in P\}$ of indexed valuations over P by

$$\langle r_i, p_i \rangle_I \ll_P \langle s_j, q_j \rangle_J \quad \text{iff} \quad (|I'| = |J'|) (\exists \phi \in S(|I'|)) \tag{5}$$

$$r_i < s_{\phi(i)} \ \& \ p_i \ll_P q_{\phi(i)} \ (\forall i \in I').^4$$

Note that we can “add” indexed valuations $\langle r_i, p_i \rangle_I$ and $\langle s_j, q_j \rangle_J$ by simply concatenating the tuples and taking the equivalence class of the resulting $I \dot{\cup} J$ -tuple. This forms a continuous operation on indexed valuations that is commutative, by construction. We also can let \mathbb{R}_+ act on $\langle r_i, p_i \rangle_I$ by $r \cdot \langle r_i, p_i \rangle_I = \langle r \cdot r_i, p_i \rangle_I$. Varacca’s main result for the family of Plotkin indexed valuations is:

Theorem 1 (Varacca [20]).

- If P is a continuous poset, then the family of Plotkin indexed valuations ordered by \ll_P as defined in (5) is an abstract basis. The family $IV_P(P)$, the round ideal completion of the Plotkin indexed valuations, satisfies the following family of equations:

$$\begin{array}{ll} (1) \ A \oplus B = B \oplus A & (2) \ A \oplus (B \oplus C) = (A \oplus B) \oplus C \\ (3) \ A \oplus \underline{0} = A & (4) \ 0A = \underline{0} \\ (5) \ 1A = A & (6) \ p(A \oplus B) = pA \oplus pB \\ (7) \ p(qA) = (pq)A & \text{where } p, q \in \mathbb{R}_+ \text{ and } A, B, C \in IV_P(P). \end{array}$$

- The Plotkin indexed valuation defines the object level of a functor which is monadic over DOM , and each of the power domain monads satisfies a distributive law with respect to the Plotkin indexed valuations monad.

A corollary of this result is that the composition $\mathcal{P}_P \circ IV_P$ defines a monad on CDOM , the category of coherent domains, whose algebras satisfy the laws listed in Theorem 1 and the laws of the Plotkin power domain:

$$(i) \ X + Y = Y + X \quad (ii) \ X + X = X \quad (iii) \ X + (Y + Z) = (X + Y) + Z$$

In other words, $\mathcal{P}_P(IV_P(P))$ is the initial domain semilattice algebra over P that also satisfies the laws listed in Theorem 1.

³ $S(n)$ denotes the permutation group on n .

⁴ Note that $r < s$ iff $r \ll s$ for $r, s \in \mathbb{R}$.

3 Bag Domains

In this section we develop some results that are fundamental for our main construction. The details of these results are contained in [15]. The construction of *bag domains*—domains whose elements are *bags* or *multisets* from an underlying domain, originated in the work of Vickers [22], and also have been considered by Johnstone [5, 6]. Those works were inspired by work in database theory, and the goals of their work was to capture the abstract categorical nature of the construction. Here we present results along the same line, but we provide a more direct construction that allows us to analyze the internal structure of the objects more closely. It also allows us to capture the constructions of Varacca [20] more concretely. We begin with a simple result about posets:

Definition 1. *Let P be a poset and let $n \in \mathbb{N}$. For $\phi \in S(n)$, define a mapping $\phi: P^n \rightarrow P^n$ by $\phi(d)_i = d_{\phi^{-1}(i)}$. Then ϕ permutes the components of d according to ϕ 's permutation of the indices $i = 1, \dots, n$. Next, define a preorder \sqsubseteq_n on P^n by*

$$d \sqsubseteq_n e \text{ iff } (\exists \phi \in S(n)) \phi(d) \leq e \text{ iff } d_{\phi^{-1}(i)} \leq e_i \ (\forall i = 1 \dots, n). \tag{6}$$

Finally, we define the equivalence relation \equiv on P^n by

$$\equiv = \sqsubseteq_n \cap \supseteq_n, \tag{7}$$

and we note that $(P^n/\equiv, \sqsubseteq_n)$ ⁵ is a partial order. We denote by $[d]$ the image of $d \in P^n$ in P^n/\equiv .

Lemma 1. *Let P be a poset and let $n \in \mathbb{N}$. Then the following are equivalent:*

1. $d \sqsubseteq_n e$,
2. $(\exists \phi \in S(n))(\forall i = 1, \dots, n) d_i \leq e_{\phi(i)}$, for $i = 1, \dots, n$.
3. $\uparrow\{\phi(d) \mid \phi \in S(n)\} \supseteq \uparrow\{\phi(e) \mid \phi \in S(n)\}$.

Proof. For (i) implies (ii), we note that, if $\phi \in S(n)$ satisfies $d_{\phi^{-1}(i)} \leq e_i$, then $d_i \leq e_{\phi(i)}$, for each $i = 1, \dots, n$, so (ii) holds. Next, (ii) implies $\phi^{-1}(e) \in \uparrow d$, and then $\psi(e) \in \uparrow\{\phi(d) \mid \phi \in S(n)\}$ for each $\psi \in S(n)$ by composing permutations, from which (iii) follows. Finally, (iii) implies (i) is clear.

We also need a classic result due to M.-E. Rudin [10]

Lemma 2 (Rudin). *Let P be a poset and let $\{\uparrow F_i \mid i \in I\}$ be a filter basis of non-empty, finitely-generated upper sets. Then there is a directed subset $A \subseteq \cup_i F_i$ with $A \cap F_i \neq \emptyset$ for all $i \in I$.*

Next, let P be a dcpo and let $n > 0$. We can apply the lemma above to derive the following:

⁵ We use \sqsubseteq_n to denote the \sqsubseteq/\equiv , the partial order on P^n/\equiv induced by the pre-order defined above.

Proposition 1. *Let P be a dcpo, and let $n > 0$.*

- *If $A \subseteq P^n/\equiv$ is directed, then there is a directed subset $B \subseteq \bigcup_{[a] \in A} \{\phi(a) \mid \phi \in S(n)\}$ satisfying*

$$\uparrow\{\phi(\sqcup B) \mid \phi \in S(n)\} = \bigcap_{a \in A} \uparrow\{\phi(a) \mid \phi \in S(n)\} \quad \text{and} \quad [\sqcup B] = \sqcup A. \quad (8)$$

- *In particular, $(P^n/\equiv, \sqsubseteq)$ is a dcpo, and the mapping $x \mapsto [x]: P^n \rightarrow P^n/\equiv$ is Scott continuous.*

Proof. If $A \subseteq P^n/\equiv$ is directed, then Lemma 1 implies that $\{\bigcup_{\phi \in S(n)} \uparrow\phi(a) \mid [a] \in A\}$ is a filter basis of finitely generated upper sets, and so by Lemma 2 there is a directed set $B \subseteq \bigcup_{[a] \in A} \{\phi(a) \mid \phi \in S(n)\}$ with $B \cap \{\phi(a) \mid \phi \in S(n)\} \neq \emptyset$ for each $[a] \in A$. Since $B \subseteq P^n$ is directed, we have $x = \sqcup B$ exists. If $[a] \in A$, then $B \cap \{\phi(a) \mid \phi \in S(n)\} \neq \emptyset$ means there is some $\phi \in S(n)$ with $\phi(a) \in B$, so $\phi(a) \leq x$ by Lemma 1. Hence $a \sqsubseteq x$ for each $[a] \in A$, so $[x]$ is an upper bound for A .

We also note that, since $\sqcup B = x$,

$$\bigcap_{b \in B} \uparrow\{\phi(b) \mid \phi \in S(n)\} = \uparrow\{\phi(x) \mid \phi \in S(n)\}.$$

Indeed, the right hand side is clearly contained in the left hand side since $b \leq x$ for all $b \in B$. On the other hand, if y is in the left hand side, then $b \sqsubseteq y$ for each $b \in B$. Now, since $S(n)$ is finite, there is some $\phi \in S(n)$ and some cofinal subset $B' \subseteq B$ with $\phi(b) \leq y$ for each $b \in B'$. But then $\sqcup B' = \sqcup B$, and so $\sqcup\{\phi(b) \mid b \in B'\} = \phi(x)$, from which we conclude that $\phi(x) \leq y$. Thus y is in the right hand side, so the sets are equal.

Now, if $y \in P^n$ satisfies $a \sqsubseteq y$ for each $[a] \in A$, then since $B \subseteq \bigcup_{[a] \in A} \{\phi(a) \mid \phi \in S(n)\}$, it follows that $b \sqsubseteq y$ for each $b \in B$. Then $y \in \bigcap_{b \in B} \uparrow\{\phi(b) \mid \phi \in S(n)\} = \uparrow\{\phi(x) \mid \phi \in S(n)\}$, and so $x \sqsubseteq y$. Thus $[x] = \sqcup A$ in the order \sqsubseteq_n . This also shows the $\bigcap_{[a] \in A} \uparrow\{\phi(a) \mid \phi \in S(n)\} = \uparrow\{\phi(x) \mid \phi \in S(n)\}$

It is clear now that P^n/\equiv is a dcpo, and the argument we just gave shows that directed sets $B \subseteq P^n$ satisfy $[\sqcup B] = \sqcup_{b \in B} [b]$.

Proposition 2. *Let P be a domain and let $n \in \mathbb{N}$. Then*

1. *$(P^n/\equiv, \sqsubseteq_n)$ is a domain. Moreover, $[d_i]_n \ll [e_i]_n$ iff $(\exists \phi \in S(n)) \phi((d_i)_n) \ll (e_i)_n$.*
2. *If P is RB or FS, then so is P^n/\equiv .*
3. *If P is coherent, then so is P^n/\equiv .*

Proof. **P^n/\equiv is a domain:** Proposition 1 shows that $(P^n/\equiv, \sqsubseteq_n)$ is directed complete and that the quotient map is Scott continuous. To characterize the way-below relation on P^n/\equiv , let $x, y \in P^n$ with $x \ll y$. Then $x_i \ll y_i$ for each $i = 1, \dots, n$, and it follows that $\phi(x) \ll \phi(y)$ for each $\phi \in S(n)$. If $A \subseteq P^n/\equiv$ is directed and $[y] \sqsubseteq_n \sqcup A$, then there is some $\phi \in S(n)$ with $\phi(y) \leq z$, where

$[z] = \sqcup A$. Then Proposition 1 shows there is a directed set $B \subseteq \cup_{[a] \in A} \uparrow \{\phi(a) \mid \phi \in S(n)\}$ with $\sqcup B \equiv z$. Hence, there is some $\psi \in S(n)$ with $\psi(y) \leq \sqcup B$. Since $\psi(x) \ll \psi(y)$, it follows that there is some $b \in B$ with $\psi(x) \leq b$, so $[x] \sqsubseteq_n [b]$. Hence $[x] \ll [y]$ in D^n/\equiv .

We have just shown that $x \ll y$ in P^n implies that $[x] \ll [y]$ in P^n/\equiv . Since D^n is a domain, $\downarrow y$ is directed with $y = \sqcup \downarrow y$, and so the same is true for $\downarrow [y] \in D^n/\equiv$. Thus P^n/\equiv is a domain.

P^n/\equiv is RB if P is: Now suppose the P is in RB. Then, by Theorem 4.1 of [8] there is a directed family $f_k: P \rightarrow P$ of Scott continuous maps with $1_P = \sqcup_k f_k$ and $f_k(P)$ finite for each $k \in K$. Then the mappings $(f_k)^n: P^n \rightarrow P^n$ also form such a family, showing P^n is in RB.

Next, given $k \in K, x \in P^n$ and $\phi \in S(n)$, we have $\phi(f_k^n(x)) = f_k^n(\phi(x))$ since f_k^n is f_k acting on each component of x . It follows that there is an induced map $[f_k^n]: P^n/\equiv \rightarrow P^n/\equiv$ satisfying $[f_k^n]([x]) = [f_k^n(x)]$, and this map is continuous since $[\]$ is a quotient map. Finally, $[f_k^n](P^n/\equiv)$ is finite since $f_k^n(P^n)$ is finite, and that $\sqcup_k [f_k^n] = 1_{P^n/\equiv}$ follows from $\sqcup_k f_k^n = 1_{P^n}$. Thus, P^n/\equiv is RB if P is.

P^n/\equiv is FS if P is: Continuing, the domain P is FS if there is a directed family of selfmaps $f_k: P \rightarrow P$ satisfying $\sqcup_k f_k = 1_P$ and for each $k \in K$, there is some finite $M_k \subseteq P$ with $f_k(x) \leq m_x \leq x$ for some $m_x \in M_k$, for each $x \in P$. The remainder is similar to the case of RB.

P^n/\equiv is coherent if P is: Last, we consider coherent domains. Recall a domain is coherent if the Lawson topology is compact, where the Lawson topology has for a basis the family of sets $\{U \setminus \uparrow F \mid F \subseteq P \text{ finite \& } U \text{ Scott open}\}$. Now, if $x \in P^n$, then $\{\phi(x) \mid \phi \in S(n)\}$ is finite, and so if $F \subseteq P^n/\equiv$ is finite, then $[\uparrow F]^{-1} = \cup_{[x] \in F} \uparrow \{\phi(x) \mid \phi \in S(n)\}$ is finitely generated. It follows that $[\]: P^n \rightarrow P^n/\equiv$ is Lawson continuous, so if P is coherent, then so are P^n and P^n/\equiv .

Definition 2. For a domain P , we let $\mathcal{B}_n(P) = P^n/\equiv$ denote the domain of n -bags over P . We also let $\mathcal{B}(P) = \oplus_n \mathcal{B}_n(P)$ denote the coalesced sum⁶ of the $\mathcal{B}_n(P)$, where we identify $P^0 \equiv \downarrow$.

Theorem 2.

1. \mathcal{B}_n defines a continuous endofunctor on the categories DCPO, DOM, CDOM, RB and FS for each $n \in \mathbb{N}$.
2. \mathcal{B} defines a continuous endofunctor on DCPO and DOM, as well as on $\text{CDOM}_\perp, \text{RB}_\perp$ and FS_\perp .⁷
3. In fact, \mathcal{B} defines the monad of commutative monoids over each of the categories listed in 2.

⁶ The coalesced sum of cpos takes their disjoint union and identifies their least elements.

⁷ If \mathbf{A} is a category of dpos, the \mathbf{A}_\perp denotes the subcategory of cpos in \mathbf{A} and maps that preserve least elements.

Proof. \mathcal{B}_n is defined as a composition of constructors that define continuous endofunctors on each of the categories, so it is continuous.

For \mathcal{B} , we must add the countable coalesced sum operator, which it is easy to show leaves each of the indicated categories invariant.

The fact that $\mathcal{B}(P)$ is a monoid follows by defining $\langle p_i \rangle_m \oplus \langle q_j \rangle_n = \langle r_k \rangle_{m+n}$, where $r_k = p_k$ for $k \leq m$ and $r_k = q_{m+k}$ otherwise, with $P^0 \equiv \underline{0}$ as the identity.

Example 1. If $P = \{\perp, a, b, \top\}$ is the four-element lattice with a and b incomparable, then P^2/\equiv is not in BCD: the pair $[a, \perp], [b, \perp]$ has $[a, b]$ and $[\top, \perp]$ as minimal upper bounds.⁸

3.1 Reconstructing $IV_P(P)$

We now use our results on bag domains to reconstruct Varacca’s Plotkin indexed valuations. The facts we need are contained in the following.

Definition 3. We define the family of real n -bags over a domain P by $\mathcal{B}_n^{\mathbb{R}}(P) = \mathcal{B}_n(\overline{\mathbb{R}_{\geq 0}} \times P) / \{[r_i, d_i]_n \mid (\exists i) r_i = 0\}$. We also define $\mathcal{B}^{\mathbb{R}}(P) = \bigoplus_n \mathcal{B}_n^{\mathbb{R}}(P)$.

Theorem 3. $\mathcal{B}_n^{\mathbb{R}}$ and $\mathcal{B}^{\mathbb{R}}$ define continuous endofunctors on CDOM, RB and on FS. Moreover, $\mathcal{B}^{\mathbb{R}}$ defines a monad on each of these categories whose algebras satisfy the laws (1) – (7) of Theorem 1.

Proof. $\mathcal{B}_n^{\mathbb{R}}(P)$ is the quotient of $\mathcal{B}_n(\overline{\mathbb{R}_{\geq 0}} \times P)$ modulo a Scott-closed subset, which shows $\mathcal{B}_n^{\mathbb{R}}(P)$ is in CDOM, RB or FS if P is. The definition of $\mathcal{B}^{\mathbb{R}}(P)$ implies $\underline{0}$ is the least element, which implies $\mathcal{B}^{\mathbb{R}}$ leaves these categories invariant.

Given $f: P \rightarrow Q$, we define $\mathcal{B}_n^{\mathbb{R}}(f)([r_i, d_i]_n) = [r_i, f(d_i)]_n$, and then $\mathcal{B}^{\mathbb{R}}(f) = \bigoplus_n \mathcal{B}_n^{\mathbb{R}}(f)$. Clearly \mathbb{R}_+ acts on $\mathcal{B}_n^{\mathbb{R}}(P)$, and the last part follows from the fact that these Scott-closed subsets are invariant with respect to this action.

Theorem 4. For a domain P , $IV_P(P) \simeq \mathcal{B}^{\mathbb{R}}(P)$.

Proof. This follows by noting that the mapping $\langle r_i, p_i \rangle_n \mapsto [r_i, p_i]_n$ and $\underline{0} \mapsto \underline{0}$ defines a bijection that takes \ll_P on $IV_P(P)$ to \ll on $\mathcal{B}^{\mathbb{R}}(P)$.

Corollary 1. Each of the power domain monads \mathcal{P}_X lifts to a monad on $\mathcal{B}^{\mathbb{R}}$ -algebras.

Proof. Varacca showed that there is a distributive law of IV_P over \mathcal{P}_X in [20], and this implies that \mathcal{P}_X lifts to a monad on the class of $\mathcal{B}^{\mathbb{R}}$ -algebras by Beck’s Theorem [2] and by Theorem 4. In fact, we can easily recover the distributive law that Varacca obtains in [21]: the distributive law $d: \mathcal{B}^{\mathbb{R}}\mathcal{P}_X \rightarrow \mathcal{P}_X\mathcal{B}^{\mathbb{R}}$ can be defined as $d_P([r_i, X_i]_n) = \langle [r_i, x_i]_n \mid x_i \in X_i \in \mathcal{P}_X(P) \rangle$. The result follows.

⁸ Thanks to one of the anonymous referees for this example.

4 Random Variables over Domains

We now show how to construct the power domain of discrete random variables over a domain. Recall that a *random variable* is a function $f: (X, \mu) \rightarrow (Y, \Sigma)$ where (X, μ) is a probability space, (Y, Σ) is a measure space, and f is a measurable function, which means $f^{-1}(A)$ is measurable in X for every $A \in \Sigma$, the specified σ -algebra of subsets of Y . Most often random variables take their values in \mathbb{R} , equipped with the usual Borel σ -algebra. For us, X will be a countable, discrete space, and Y will be a domain, where Σ will be the Borel σ -algebra generated by the Scott-open subsets.

Given a random variable $f: X \rightarrow Y$, the usual approach is to “push the probability measure μ forward” onto Y by defining $f \cdot \mu(A) = \mu(f^{-1}(A))$ for each measurable subset A of Y . But this defeats one of the attractions of random variables: namely, that there may be several points $x \in X$ which f takes to the same value $y \in Y$. This is ‘attractive’ because it means that the random variable f makes distinctions that the probability measure $f \cdot \mu$ does not, and we would like to exploit this fact. Varacca makes exactly this point in his work [20, 21], a point he justifies by showing how to distinguish the random variable f from the probability measure $f \cdot \mu$ operationally. We return to this point later. For the moment, we define our power domain of random variables.

Definition 4. For a domain P , we define the power domain of discrete random variables over P to be the subdomain

$$\mathbb{RV}(P) = \bigcup_n \{ \{r_i d_i\}_n \mid n \geq 1 \ \& \ \sum_i r_i \leq 1 \} \cup \{ \underline{0} \} \subseteq \mathcal{B}^{\mathbb{R}}(P).$$

Remark 1. We can think of a discrete random variable over P as a formal sum $\sum_{i \leq n} r_i \delta_x$ where some of the x_i can be repeated. But, the order from $\mathcal{B}^{\mathbb{R}}(P)$ distinguishes, for example, $\frac{1}{2} \delta_x \oplus \frac{1}{2} \delta_x$ from δ_x , while these two would be identified as probability measures.

We now come to our main result.

Theorem 5. \mathbb{RV} defines a continuous endofunctor on CDOM, RB and FS.

Proof. \mathbb{RV} is obtained by restricting $\mathcal{B}^{\mathbb{R}}$ in the “real components” to ones whose sum is at most 1, which defines a Scott-closed subset of $\mathcal{B}^{\mathbb{R}}(P)$. Hence $\mathbb{RV}(P)$ is in each of the indicated categories if P is. Since continuous maps $f: P \rightarrow Q$ are extended to $\mathcal{B}^{\mathbb{R}}(P)$ by $\mathcal{B}^{\mathbb{R}}(f)[r_i, p_i] = [r_i, f(p_i)]$ and since the elements in $\mathbb{RV}(P)$ are those in $\mathcal{B}^{\mathbb{R}}(P)$ whose real components sum to at most 1; it follows that $\mathcal{B}^{\mathbb{R}}(f)$ preserves this property in $\mathcal{B}^{\mathbb{R}}(Q)$. The result follows.

Corollary 2. Each of the power domain monads \mathcal{P}_X lifts to a monad on \mathbb{RV} -algebras.

Proof. The distributive law given in the proof of Corollary 1 clearly restricts to one for \mathbb{RV} .

This corollary means we can solve domain equations such as $P \simeq \mathcal{P}_X \circ \mathbb{R}\mathbb{V}(P)$ for each of the power domain monads \mathcal{P}_X . The resulting domain P will be a \mathcal{P}_X -algebra and simultaneously a $\mathbb{R}\mathbb{V}$ -algebra.

One might also ask about the relationship between our construction and the traditional probabilistic power domain over a domain. The following provides the answer.

Theorem 6. *If P is a domain, then there is an epimorphism $Flat: \mathbb{R}\mathbb{V}(P) \rightarrow \mathbb{V}(P)$, the domain of valuations over P .*

Proof. The mapping $Flat$ is defined by $Flat([r_i, d_i]_n) = \sum_{i \leq n} r_i \delta_d$, where in $\mathbb{V}(P)$, summands with the same support are identified. This is easily seen to define a continuous map. It is an epimorphism of domains because the simple valuations are dense [7], and clearly they are the range of $Flat$.

5 Summary and Future Work

We have presented a power domain for discrete random variables, and shown that it enjoys a distributive law with respect to each of the power domain monads. Moreover, our construction defines a continuous endofunctor on the cartesian closed categories \mathbf{RB} and \mathbf{FS} , as well as on the category \mathbf{CDOM} . This is where our results on bag domains have their payoff, since trying to devise these last results using abstract bases would be much more difficult. Varacca actually presents three separate constructions, as indicated in Section 2. Our methods can be adopted to recapture each of them; a discussion of the Hoare indexed valuations from our approach is presented in [15]. Since no similar result is known to hold for the probabilistic power domain, our construction provides an alternative for modeling probabilistic choice on domains.

One issue we haven't discussed is what sort of operational intuition there is for random variables. Again, we rely on Varacca, who showed in [21] that, for a simple state-based language supporting nondeterminism and probabilistic choice, probabilistic schedulers could distinguish distinct programs in his model. This is similar to refusal testing in CSP: one tests a process at each place where a probabilistic choice is made. In the more traditional approach using probabilistic bisimulation, such as in [16], one tests processes at the end of their computation, not at each stage. This provides a viable, albeit more complicated method of assigning behaviors to programs.

Another issue not discussed here is whether one can bring Shannon's information theory into the picture [18]. This is based on bringing entropy into play; there are some very interesting results about domains and entropy in Martin's recent work [12], a line we plan to explore. A particularly appealing issue here is defining an order on random variables over a domain relative to which entropy forms a measurement. If Martin's work is any indication, this will probably be a fairly difficult issue to resolve.

Acknowledgment. We wish to thank the anonymous referees for many valuable suggestions.

An Accessible Approach to Behavioural Pseudometrics

With an Application to Probabilistic Systems

Abstract. Behavioural pseudometrics are a quantitative analogue of behavioural equivalences. They provide robust models for those concurrent systems in which quantitative data plays a crucial role. In this paper, we show how behavioural pseudometrics can be defined coalgebraically. Our results rely on the theory of accessible categories. We apply our results to obtain a robust model for probabilistic systems.

1 Introduction

The study of concurrent systems with *quantitative data*, such as probabilities, time, costs or rewards, has led to various extensions of the classical notion of *transition system* and its associated notions of behavioural equivalences, with emphasis on *bisimilarity*. However, such discrete notions (states are either behaviourally equivalent or they are not) sit uneasily with the presence of quantitative data. For instance, if some of the probabilities associated with the transitions change slightly—the probabilities are often obtained experimentally and, hence, are usually approximations—states that used to be behaviourally equivalent may not be anymore or vice versa. In short, behavioural equivalences like probabilistic bisimilarity are not *robust*.

* Supported by the Natural Sciences and Engineering Research Council of Canada.

** Supported by the US Office of Naval Research.

To address this problem, Giacalone, Jou and Smolka [18] suggested to exploit pseudometrics that assign a distance, a real number between 0 and 1, to each pair of states of a system. Such a pseudometric yields a quantitative notion of behavioural equivalence in that the distances between states express the similarity of the behaviour of those states. The smaller the distance, the more the states behave alike. In particular, the distance between states is 0 if they are behaviourally indistinguishable. Recently, there has been a renewed interest in such *behavioural pseudometrics* (see, for example, [6, 9, 10, 11, 12, 13, 14, 15, 19]).

Three different approaches have been put forward to define behavioural pseudometrics. Desharnais, Gupta, Jagadeesan and Panangaden [13] defined a behavioural pseudometric in terms of a real-valued interpretation of a modal *logic*. Van Breugel and Worrell [6] gave a *coalgebraic* definition of a behavioural pseudometric and showed that it coincides with the logical definition. Desharnais et al. [14] also defined a behavioural pseudometric as the greatest *fixed point* of a monotone function on a complete lattice. Each approach has its advantages and disadvantages. The coalgebraic approach is completely driven by a single functor. This allows for a uniform approach and a general theory, which are two of the advantages of the coalgebraic approach. Having a logical, a coalgebraic and a fixed point characterisation of a behavioural pseudometric allows us to exploit the advantages of all three approaches.

There are two types of behavioural pseudometrics: those that *discount the future* and those that do not. In the discounted setting, differences in behaviour in the farther future have less impact on the distance, whereas in the undiscounted setting, all differences are weighted equally (see, for example, [11] for more details). Pseudometrics that do not discount the future usually provide quantitative information different from those that discount the future (even the induced topologies often differ). Both types of behavioural pseudometrics can be defined by means of the logical approach and the fixed point approach. So far, the coalgebraic approach has only been shown to be applicable to the discounted setting. In this paper, we show that behavioural pseudometrics that do not discount the future can be defined coalgebraically as well. Furthermore, we show that the three approaches give rise to the same behavioural pseudometric for (a generalisation of) probabilistic transition systems.

Let us provide some more details of the coalgebraic approach to define a behavioural pseudometric for a class of systems. This approach is completely driven by a functor $\mathcal{F} : \mathbf{CMet}_1 \rightarrow \mathbf{CMet}_1$ on the category \mathbf{CMet}_1 of 1-bounded complete metric spaces and nonexpansive functions. The functor \mathcal{F} should be such that the \mathcal{F} -coalgebras represent the systems of interest and such that a *terminal \mathcal{F} -coalgebra* exists. An \mathcal{F} -coalgebra consists of a space S , which represents the state space of the system, and a function $t : S \rightarrow \mathcal{F}(S)$, which captures the transitions of the system. The terminal \mathcal{F} -coalgebra can be viewed as a universal system, as it contains all possible behaviours. Let us denote the state space of this universal system by T . Then for every \mathcal{F} -coalgebra with state space S , there exists a unique function $h : S \rightarrow T$ that preserves and reflects behaviour. That is, h only maps states s_1 and s_2 to the same state in T if s_1 and s_2 are

behaviourally equivalent. Since T is a metric space, its distance function can be transferred to the set of states S along the function h . That is, the behavioural distance of states s_1 and s_2 is defined as the distance of $h(s_1)$ and $h(s_2)$ in T . Since h preserves and reflects behaviour, states only have distance 0 if they are behaviourally indistinguishable.

De Vink and Rutten [27] have shown that *probabilistic transition systems* can be represented as coalgebras (see also [6]). To prove the existence of a terminal coalgebra, they exploit the metric terminal coalgebra theorem of Turi and Rutten [26]. This theorem is only applicable to functors that give rise to behavioural pseudometrics that discount the future. More generally, all known techniques to solve *recursive equations* of the form $X = \mathcal{F}(X)$ require the functor \mathcal{F} to discount the future (note that this is indeed more general since a terminal \mathcal{F} -coalgebra solves the equation). Such recursive equations play a key role in semantics (see, for example, [3]). In this paper, we show that for many functors \mathcal{F} that are used in semantics, in particular those that do not discount the future, a terminal \mathcal{F} -coalgebra exists and, hence, the equation $X = \mathcal{F}(X)$ can be solved.

The rest of this paper is organised as follows. In Section 2 we present a terminal coalgebra theorem, which is shown to be applicable to the category $\mathbb{C}\text{Met}_1$ in Section 3. In Section 4 and 5 we study some functors used in semantics that do not discount the future. In Section 6 we apply our results to give a coalgebraic definition of a behavioural pseudometric for probabilistic transition systems that does not discount the future. Furthermore, we show that the coalgebraic definition coincides with a logical and a fixed point definition. We assume that the reader is familiar with category theory, metric topology and measure theory (see, for example, [23, 17, 5]).

2 A Terminal Coalgebra Theorem for Accessible Categories

Numerous terminal coalgebra theorems can be found in the literature. As far as we know, only one of them, due to Turi and Rutten [26], is applicable to metric spaces. In this section, we present a terminal coalgebra theorem for accessible categories. This theorem is implicit in the work of Makkai and Paré [24] (see also [4, Theorem 1.2]). As we will see in Section 3, the theorem is applicable to metric spaces. Before we present the theorem, we introduce the reader to those concepts and results of the theory of coalgebra and the theory of accessible categories that we will use in the rest of this paper.

Definition 1. *Let \mathbb{C} be a category. Let $\mathcal{F} : \mathbb{C} \rightarrow \mathbb{C}$ be a functor. An \mathcal{F} -coalgebra consists of an object C in \mathbb{C} together with a morphism $f : C \rightarrow \mathcal{F}(C)$ in \mathbb{C} . An \mathcal{F} -homomorphism from \mathcal{F} -coalgebra $\langle C, f \rangle$ to \mathcal{F} -coalgebra $\langle D, g \rangle$ is a morphism $h : C \rightarrow D$ in \mathbb{C} such that $\mathcal{F}(h) \circ f = g \circ h$. The \mathcal{F} -coalgebras and \mathcal{F} -homomorphisms form a category. If this category has a terminal object, then this object is called a terminal \mathcal{F} -coalgebra.*

For more details about the theory of coalgebra, we refer the reader to, for example, the tutorial [21] of Jacobs and Rutten.

Next, we turn to accessible categories and accessible functors.

Definition 2. *A category \mathbb{C} is accessible if it is κ -accessible for some infinite regular cardinal κ .*

We will not provide the definition of κ -accessible category since we do not need this definition in our paper. It can be found in, for example, [24, Definition 2.1.3]. To prove that categories are accessible, either we will exploit the “logical” characterisation of accessible categories as proposed by Makkai and Paré in [24, § 3.2] or we will make use of the following result.

Proposition 1. (Theorem 5.1.6 of [24]) *If the categories \mathbb{C} and \mathbb{D} are accessible, then the category $\mathbb{C} \times \mathbb{D}$ is accessible.*

Definition 3. *Let κ be an infinite regular cardinal. A functor $\mathcal{F} : \mathbb{C} \rightarrow \mathbb{D}$ is κ -accessible if \mathbb{C} and \mathbb{D} are κ -accessible and \mathcal{F} preserves κ -filtered colimits. A functor $\mathcal{F} : \mathbb{C} \rightarrow \mathbb{D}$ is accessible if it is κ -accessible for some infinite regular cardinal κ .*

We will also not introduce the definition of κ -filtered colimit because we do not need this definition in our paper either. It can be found in, for example, [24, page 13]. To prove that a functor is accessible, we will either prove that the functor preserves all colimits or we will exploit one of the following results.

Proposition 2. (page 32 of [24]) *If the functors $\mathcal{F} : \mathbb{C} \rightarrow \mathbb{D}$ and $\mathcal{G} : \mathbb{D} \rightarrow \mathbb{E}$ are accessible, then the functor $\mathcal{G} \circ \mathcal{F} : \mathbb{C} \rightarrow \mathbb{E}$ is accessible.*

Proposition 3. (Theorem 5.1.6 of [24]) *If the functors $\mathcal{F} : \mathbb{C}_1 \rightarrow \mathbb{D}_1$ and $\mathcal{G} : \mathbb{C}_2 \rightarrow \mathbb{D}_2$ are accessible, then the functor $\mathcal{F} \times \mathcal{G} : \mathbb{C}_1 \times \mathbb{C}_2 \rightarrow \mathbb{D}_1 \times \mathbb{D}_2$ is accessible.*

Proposition 4. (Proposition 2.4.8 of [24]) *Let \mathbb{C} and \mathbb{D} be accessible categories. Any functor $\mathcal{F} : \mathbb{C} \rightarrow \mathbb{D}$ which has a left or right adjoint is accessible.*

The main point of working with accessible categories in this paper is the existence of a terminal coalgebra for accessible functors.

Theorem 1. *If the category \mathbb{C} is accessible and complete and the functor $\mathcal{F} : \mathbb{C} \rightarrow \mathbb{C}$ is accessible, then a terminal \mathcal{F} -coalgebra exists.*

For more details about theory of accessible categories we refer the reader to the textbook [24] of Makkai and Paré and the textbook [1] of Adámek and Rosický.

3 The Category of Complete Metric Spaces Is Accessible

Since the category *Top* of topological spaces and continuous functions is not accessible as shown, for example, in [1, Example 2.3(1)], it may come as a surprise that the category $\mathbb{C}Met_1$ of 1-bounded complete metric spaces and nonexpansive functions is accessible, as we will show below. However, since the category *Ban* of Banach spaces and contractions is accessible as demonstrated in, for example, [24, § 3.4], the accessibility of the category $\mathbb{C}Met_1$ may not be that surprising after all.

Definition 4. *A metric space is a pair (X, d_X) consisting of a set X and a distance function $d_X : X \times X \rightarrow [0, \infty)$ satisfying*

1. *for all $x, y \in X$, $d_X(x, y) = 0$ if and only if $x = y$,*
2. *for all $x, y \in X$, $d_X(x, y) = d_X(y, x)$,*
3. *for all $x, y, z \in X$, $d_X(x, z) \leq d_X(x, y) + d_X(y, z)$.*

Instead of (X, d_X) we often write X and we denote the distance function of a metric space X by d_X . A metric space X is 1-bounded if

4. *for all $x, y \in X$, $d_X(x, y) \leq 1$.*

A metric space X is complete if

5. *each Cauchy sequence in X is convergent in X .*

A sequence $(x_n)_{n \in \mathbb{N}}$ in X is Cauchy if

$$\forall \epsilon > 0 \exists N \in \mathbb{N} \forall m > N \forall n > N \ d_X(x_m, x_n) < \epsilon.$$

A sequence $(x_n)_{n \in \mathbb{N}}$ in X is convergent in X if

$$\exists x \in X \forall \epsilon > 0 \exists N \in \mathbb{N} \forall n > N \ d_X(x_n, x) < \epsilon.$$

A function $f : X \rightarrow Y$ is nonexpansive if for all $x, y \in X$,

$$d_Y(f(x), f(y)) \leq d_X(x, y).$$

The category $\mathbb{C}Met_1$ has 1-bounded complete metric spaces as objects and nonexpansive functions as morphisms. One can prove that $\mathbb{C}Met_1$ is accessible exploiting the “logical” characterisation of accessible categories of Makkai and Paré [24, § 3.2] (see also [1, Section 5.B]).

Theorem 2. *The category $\mathbb{C}Met_1$ is accessible.*

4 The Kantorovich Functor Is Accessible

As we will see in Section 6, probabilistic nondeterminism can be modelled by means of the set of tight Borel probability measures on a metric space endowed with the Kantorovich metric. Below, we will show that the corresponding Kantorovich functor is accessible.

First, let us review the notion of a tight Borel probability measure on a metric space. Let X be a metric space and let the set of open sets $O(X)$ be the smallest set of subsets of X which contains $\{y \in X \mid d_X(x, y) < r\}$ for each $x \in X$ and $r \in [0, \infty)$, and which is closed under unions. The set $B(X)$ of Borel sets is the smallest set of subsets of X which contains $O(X)$ and which is closed under countable intersections and countable unions. Then $\emptyset \in B(X)$, if $B \in B(X)$ then $X \setminus B \in B(X)$, and for each sequence $(B_n)_n$ in $B(X)$, $\bigcup_n B_n \in B(X)$ (see, for example, [25, Theorem I.1.3]), that is, $B(X)$ is a σ -field. A Borel probability measure on X is a function $\mu : B(X) \rightarrow [0, 1]$ satisfying $\mu(X) = 1$ and for each sequence $(B_n)_n$ of pairwise disjoint sets in $B(X)$, $\mu(\bigcup_n B_n) = \sum_n \mu(B_n)$. A Borel probability measure on X is tight if for each $\epsilon > 0$ there exists a compact subset K_ϵ of X such that $\mu(X \setminus K_\epsilon) < \epsilon$. We write $\mathcal{K}(X)$ for the set of tight Borel probability measures on a metric space X . This set is endowed with the Kantorovich metric.

Definition 5. *The Kantorovich metric $d_{\mathcal{K}(X)} : \mathcal{K}(X) \times \mathcal{K}(X) \rightarrow [0, \infty]$ is defined by*

$$d_{\mathcal{K}(X)}(\mu, \nu) = \sup \left\{ \int f d\mu - \int f d\nu \mid f \in X \rightarrow [0, 1] \text{ is nonexpansive} \right\}.$$

If X is a 1-bounded metric space, then so is $\mathcal{K}(X)$. Furthermore, if X is complete, then also $\mathcal{K}(X)$ is complete (see, for example, [16, Theorem 2.5.25]). Given a 1-bounded complete metric space X , the 1-bounded complete metric space $\mathcal{K}(X)$ together with the binary operation mapping the tight Borel probability measures μ and ν to the tight Borel probability measure $\frac{1}{2} \cdot \mu + \frac{1}{2} \cdot \nu$ form a metric mean-value algebra.

Definition 6. *A metric mean-value algebra is a pair $\langle X, \oplus \rangle$ consisting of a 1-bounded complete metric space X and a choice operation $\oplus : X \times X \rightarrow X$ satisfying*

1. for all $x \in X$, $x \oplus x = x$,
2. for all $x, y \in X$, $x \oplus y = y \oplus x$,
3. for all $v, w, x, y \in X$, $(v \oplus w) \oplus (x \oplus y) = (x \oplus w) \oplus (v \oplus y)$, and
4. for all $v, w, x, y \in X$, $d_X(v \oplus w, x \oplus y) \leq \frac{d(v,x) + d(w,y)}{2}$.

A function $f : X \rightarrow Y$ is choice preserving if $f(x \oplus_X y) = f(x) \oplus_Y f(y)$ for all $x, y \in X$.

The above definition is a metric analogue of the notion of mean-value algebra [20] given by Heckmann.

The category $MV(\mathbf{CMet}_1)$ has metric mean-value algebras as objects and nonexpansive and choice preserving functions as morphisms. The metric mean-value algebras provide a finitary description of the algebras of the Kantorovich monad which will enable us to prove that the category of these algebras is accessible (again exploiting the “logical” characterisation of accessible categories) and, hence, that the Kantorovich functor itself is accessible.

Theorem 3. *The category $MV(\mathbb{C}Met_1)$ is accessible.*

The operation mapping a 1-bounded complete metric space X to the metric mean-value algebra $\langle \mathcal{K}(X), \frac{1}{2} \cdot - + \frac{1}{2} \cdot - \rangle$ can be extended to a functor $\mathcal{K} : \mathbb{C}Met_1 \rightarrow MV(\mathbb{C}Met_1)$ as follows.

Definition 7. *Let $f : X \rightarrow Y$ be a nonexpansive function. The function $\mathcal{K}(f) : \mathcal{K}(X) \rightarrow \mathcal{K}(Y)$ is defined by $\mathcal{K}(f)(\mu)(B) = \mu(f^{-1}(B))$.*

The forgetful functor $\mathcal{U} : MV(\mathbb{C}Met_1) \rightarrow \mathbb{C}Met_1$ maps each metric mean-value algebra to the underlying 1-bounded complete metric space. The functors \mathcal{K} and \mathcal{U} are related as follows.

Theorem 4. *\mathcal{K} is a left adjoint for \mathcal{U} .*

From Theorem 2, 3 and 4 and Proposition 2 and 4 we can derive

Corollary 1. *The functor $\mathcal{U} \circ \mathcal{K} : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$ is accessible.*

Instead of $\mathcal{U} \circ \mathcal{K}$ we will just write \mathcal{K} in the sequel.

Similarly, we can show that the Hausdorff functor $\mathcal{H} : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$ that maps a 1-bounded complete metric space to the set of nonempty and compact subsets of the space endowed with the Hausdorff metric is an accessible functor. This functor is often used to model nondeterminism.

5 Other Accessible Functors

After having shown that the Kantorovich functor is accessible, we introduce some other functors that are often used in semantics and we show that they are accessible as well.

The identity functor $\text{Id}_{\mathbb{C}Met_1} : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$ preserves all colimits and, hence, is accessible. Let X be a 1-bounded complete metric space. We denote the constant functor mapping each 1-bounded complete metric space to the space X by $X : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$. We write 1 for a singleton metric space (which is unique up to isomorphism). The functor $1 : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$ is an example of a constant functor. Obviously, these constant functors preserve all colimits and, hence, are accessible.

The coproduct $X + Y$ of X and Y in $\mathbb{C}Met_1$ consists of the disjoint union of the sets underlying the 1-bounded complete metric spaces X and Y endowed with the following distance function.

Definition 8. *Let X and Y be 1-bounded complete metric spaces. The distance function $d_{X+Y} : (X + Y) \times (X + Y) \rightarrow [0, 1]$ is defined by*

$$d_{X+Y}(u, v) = \begin{cases} d_X(u, v) & \text{if } u, v \in X \\ d_Y(u, v) & \text{if } u, v \in Y \\ 1 & \text{otherwise.} \end{cases}$$

This operation can be extended to a bifunctor $+ : \mathbb{C}Met_1 \times \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$. Since the bifunctor $+$ is left adjoint to the diagonal (see, for example, [23, page 85]), we can conclude from Theorem 2 and Proposition 1 and 4 that the functor $+$ is accessible.

The copower $A \cdot X$ of a set A and a 1-bounded complete metric space X consists of the A -fold disjoint union of the set underlying X endowed with the following distance function.

Definition 9. *Let A be a set and X a 1-bounded complete metric space. The distance function $d_{A \cdot X} : A \cdot X \times A \cdot X \rightarrow [0, 1]$ is defined by*

$$d_{A \cdot X}(x_a, y_b) = \begin{cases} d_X(x, y) & \text{if } a = b \\ 1 & \text{otherwise.} \end{cases}$$

The power X^A of a set A and a 1-bounded complete metric space X consists of the A -indexed Cartesian product of the set underlying X endowed with the following distance function.

Definition 10. *Let A be a set and X a 1-bounded complete metric space. The distance function $d_X : X^A \times X^A \rightarrow [0, 1]$ is defined by*

$$d_X (\langle x_a \rangle_a, \langle y_a \rangle_a) = \sup_{a \in A} d_X(x_a, y_a).$$

Given a set A , the operations $A \cdot -$ and $-^A$ can be extended to functors $A \cdot - : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$ and $-^A : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$. Since the functors $A \cdot -$ and $-^A$ form an adjunction (see, for example, [23, page 88]), we can conclude from Theorem 2 and Proposition 4 that both functors are accessible.

Several other functors, including the product and tensor product functor, are accessible as well. The hom functor is not accessible.

6 A Behavioural Pseudometric for Probabilistic Transition Systems

The results of the foregoing sections are applied in this section to give a coalgebraic definition of a behavioural pseudometric for (a generalisation of) probabilistic transition systems. The behavioural pseudometric does not discount the future. Furthermore, we give a fixed point characterisation and a logical characterisation of the behavioural pseudometric.

Definition 11. *A probabilistic transition system is a triple $\langle S, A, (\pi_a)_{a \in A} \rangle$ consisting of*

- a set S of states,
- a set A of actions, and
- for each $a \in A$, a function $\pi_a : S \times S \rightarrow [0, 1]$ satisfying $\sum_{s' \in S} \pi_a(s, s') \leq 1$ for each $s \in S$.

Next, we introduce a family of functors \mathcal{P}^A , such that each probabilistic transition system $\langle S, A, (\pi_a)_{a \in A} \rangle$ can be represented as a \mathcal{P}^A -coalgebra.

Definition 12. *The functor $\mathcal{P}^A : \mathbb{C}Met_1 \rightarrow \mathbb{C}Met_1$ is defined by*

$$\mathcal{P}^A = -^A \circ \mathcal{K} \circ + \circ \langle 1, \text{Id}_{\mathbb{C}Met_1} \rangle,$$

where A is a set.

Proposition 5. *Each probabilistic transition system $\langle S, A, (\pi_a)_{a \in A} \rangle$ can be represented as a \mathcal{P}^A -coalgebra.*

From the fact that the functors $-^A$, \mathcal{K} , $+$, 1 and $\text{Id}_{\mathbb{C}Met_1}$ are accessible and Proposition 2 and 3, we can conclude that the functor \mathcal{P}^A is accessible. Since the category $\mathbb{C}Met_1$ is accessible (Theorem 2) and complete (see, for example, [2, Chapter 4]), we can deduce from Theorem 1 the following result.

Proposition 6. *For each set A , a terminal \mathcal{P}^A -coalgebra exists.*

For the rest of this section, we fix a \mathcal{P}^A -coalgebra $\langle S, \pi \rangle$. To simplify the presentation, we assume that the space S of states is compact.

Definition 13. *Let $\langle T^A, \iota \rangle$ be a terminal \mathcal{P}^A -coalgebra. The distance function $d_c : S \times S \rightarrow [0, 1]$ is defined by*

$$d_c(s_1, s_2) = d_T(h(s_1), h(s_2)),$$

where h is the unique \mathcal{P}^A -homomorphism from the \mathcal{P}^A -coalgebra $\langle S, \pi \rangle$ to the terminal \mathcal{P}^A -coalgebra $\langle T^A, \iota \rangle$.

Since terminal objects are unique up to isomorphism, the definition of the distance function d_c does not depend on which terminal \mathcal{P}^A -coalgebra is chosen. The distance function d_c satisfies the condition 2–4 of Definition 4 but not condition 1. It does satisfy the following weaker condition: 1'. for all $s \in S$, $d(s, s) = 0$. Therefore, d_c is called a 1-bounded pseudometric. Note that in a pseudometric space, different elements may have distance 0. In the behavioural pseudometric d_c , distance 0 captures the behavioural equivalence probabilistic bisimilarity [22].

Theorem 5. *For all $s_1, s_2 \in S$, $d_c(s_1, s_2) = 0$ iff s_1 and s_2 are probabilistic bisimilar.*

Next, we characterise the behavioural pseudometric as the greatest fixed point of a monotone function on a complete lattice. This approach was first proposed by Desharnais et al. [14]. We consider those distance functions on the set underlying the 1-bounded compact metric space S that satisfy condition 1' and condition 2–4 of Definition 4 and order them as follows.

Definition 14. *The relation \sqsubseteq on 1-bounded pseudometrics on S is defined by*

$$d_1 \sqsubseteq d_2 \text{ if } d_1(s_1, s_2) \geq d_2(s_1, s_2) \text{ for all } s_1, s_2 \in S.$$

The set of 1-bounded pseudometrics on S endowed with the order \sqsubseteq forms a complete lattice (see, for example, [14, Lemma 3.2]).

Definition 15. *Let d be a 1-bounded pseudometric on S . The distance function $\Delta(d) : S \times S \rightarrow [0, 1]$ is defined by*

$$\Delta(d)(s_1, s_2) = \sup_{a \in A} \left(\inf \left\{ \int d \, d\mu \mid \mu \in \pi(s_1)_a \otimes \pi(s_2)_a \right\} \right),$$

where $\pi(s_1)_a \otimes \pi(s_2)_a$ denotes the set of Borel probability measures on the product space $(1 + S)^2$ with marginals $\pi(s_1)_a$ and $\pi(s_2)_a$, that is, those Borel probability measures μ such that for all $B \in B(1 + S)$, $\mu(B \times (1 + S)) = \pi(s_1)_a(B)$ and $\mu((1 + S) \times B) = \pi(s_2)_a(B)$.

Note that $\Delta(d)$ is also a 1-bounded pseudometric on S . Furthermore, Δ is monotone, that is, if $d_1 \sqsubseteq d_2$ then $\Delta(d_1) \sqsubseteq \Delta(d_2)$. According to Tarski's fixed point theorem, a monotone function $f : X \rightarrow X$ on a complete lattice X has a greatest fixed point. Hence, we can conclude that Δ has a greatest fixed point d_f .

Theorem 6. $d_c = d_f$.

We conclude this section with a logical characterisation of the behavioural pseudometric, as first given by Desharnais et al. in [13]. We introduce a logic that shows similarities with the modal logic that characterises probabilistic bisimilarity [22] (see [15] for a detailed discussion).

Definition 16. *The logic \mathcal{L} is defined by*

$$\varphi ::= \text{true} \mid \neg\varphi \mid \langle a \rangle\varphi \mid \varphi \ominus q \mid \varphi \wedge \psi$$

where $a \in A$ and $q \in \mathbb{Q} \cap [0, 1]$.

Next, we provide a real-valued interpretation of the logic. For each formula φ and state s , the real number $\varphi(s)$ provides a quantitative measure of the validity of φ in s . The larger $\varphi(s)$, the more likely it is that φ holds in s .

Definition 17. *For each $\varphi \in \mathcal{L}$, the function $\varphi : S \rightarrow [0, 1]$ is defined by*

$$\begin{aligned} \text{true}(s) &= 1 \\ (\neg\varphi)(s) &= 1 - \varphi(s) \\ (\langle a \rangle\varphi)(s) &= \int \varphi \, d\pi(s)_a \\ (\varphi \ominus q)(s) &= \max\{\varphi(s) - q, 0\} \\ (\varphi \wedge \psi)(s) &= \varphi(s) \min \psi(s) \end{aligned}$$

Given the logic and its real-valued interpretation, we can define a behavioural pseudometric as follows.

Definition 18. *The distance function $d_\ell : S \times S \rightarrow [0, 1]$ is defined by*

$$d_\ell(s_1, s_2) = \sup_{\varphi \in \mathcal{L}} \varphi(s_1) - \varphi(s_2).$$

The above definition of d_ℓ can be seen as a logical characterisation of d_c since the pseudometrics d_ℓ and d_c coincide.

Theorem 7. $d_c = d_\ell$.

The proof of the above theorem shows some similarities with the proof of [8, Theorem 42] in which Van Breugel and Worrell show that a coalgebraic and a logical characterisation of a behavioural pseudometric that discounts the future coincide. However, the proof of the above theorem also includes some new ingredients. These ingredients allow us to remove from [8, Theorem 42] the assumption that the set A of actions is finite.

7 Conclusion

Let us briefly highlight our main contributions, before discussing related and future work. We have shown that an accessible endofunctor on an accessible and complete category has a terminal coalgebra. This terminal coalgebra theorem was implicit in [24] (see also [4]). Furthermore, we have shown that the category \mathbf{CMet}_1 is accessible (it is well-known to be complete) and that many functors used in semantics are accessible. As a consequence, for most functors \mathcal{F} used in semantics, a terminal \mathcal{F} -coalgebra exists and, hence, the equation $X = \mathcal{F}(X)$ can be solved, even if \mathcal{F} does not discount the future. As an application of our developed theory, we have presented a coalgebraic definition of a behavioural pseudometric that does not discount the future for probabilistic transition systems. Furthermore, we have provided a fixed point characterisation and a logical characterisation of the behavioural pseudometric. As far as we know, we are the first to relate a fixed point definition to the corresponding coalgebraic and logical definitions. We have also shown that there is no need to restrict to finite action sets when relating the different approaches.

In this paper we have made fruitful use of the theory of accessible categories [1, 24]. Our coalgebraic definition of the behavioural pseudometric is inspired by the work of De Vink and Rutten [27] and Van Breugel and Worrell [6]. The logical characterisation and the fixed point characterisation are based on work of Desharnais et al. [13, 14].

The theory developed in this paper has already been applied to a large class of timed transition systems. The details will be presented in [7].

We are confident that the results developed in this paper can also be exploited to provide coalgebraic characterisations of the fixed point and logical definitions of behavioural pseudometrics given in [9, 10, 11, 12].

Abstract. Turing machines exposed to a small stochastic noise are considered. An exact characterisation of their ($\approx \Pi_2^0$) computational power (as noise level tends to 0) is obtained. From a probabilistic standpoint this is a theory of large deviations for Turing machines.

1 Introduction

Computers are always subjected to faults and component failures, and even random changes of memory bits caused by to cosmic rays or neutrons flipping memory cells [1]. From the practical viewpoint these phenomena are particularly important for computers operating in hostile environments, such as aboard a spacecraft [2]. In the present paper we adopt a more theoretical and abstract approach to this issue and study how small random perturbations can affect the computational power of popular computational models, in our case Turing machines (TMs).

As far as we know, the pioneering paper considering influence of infinitesimal noise on computational models was Puri's [3], where the author introduces the infinitesimally perturbed semantics and solves the reachability problem for timed automata. Fränzle [4] applies a version of Puri's noise to hybrid systems, and argues that such a noise leads to a sort of "practical decidability". The immediate predecessor of the present paper is [5] where computational power is analysed for infinitesimally perturbed hybrid systems and TMs. The main result of [5] is the Π_1^0 completeness of reachability or acceptance problems for such machines. It is important to notice that all the papers cited above considered a non-deterministic noise of a bounded (and tending to zero) magnitude, with no probabilistic assumptions.

The influence of a small stochastic noise on computational models has been considered in [6] for finite-state models, and in [7] for neural networks. Other related work concerns the behaviour of dynamical systems under a small stochastic noise, known as the theory of large deviations. A good reference is [8].

In the present paper we consider TMs exposed to a small stochastic noise, or in other words large deviations for TMs. We give an exact characterisation of their computational power in terms of classes of arithmetic hierarchy (see [9]).

The rest of the paper is organised as follows. In Sec. 2 we introduce Noisy Turing Machines (NTMs) and several versions of “computability” by such machines. In Sec. 3 we explore NTMs with a noise level $\varepsilon > 0$ and establish some basic properties, such as continuity and computability of acceptance probability, decidability of the halting problem etc. In Sec. 4 we describe several interesting NTMs used in the subsequent sections. This section also gives a flavour of “noisy programming” and reasoning about noisy programs. The main technical results of the paper are established in Sec. 5 and 6 where we explore the computational power of NTMs for a noise level *tending to zero*. Such a “limit computational power” turns out to be stronger than that of a TM; we give its precise characterisation.

2 The Model

We consider a standard multi-tape TM augmented by an additional parameter giving the noise level. Formally, a *Noisy Turing Machine* (NTM) is a tuple

$$\mathcal{M}_\varepsilon = (Q, \Sigma, \Gamma, N, \rho, \varepsilon, q_0, q_\top, q_\perp), \tag{1}$$

where Q is the set of states, Σ is the input alphabet (not containing the special blank symbol \sqcup), $\Gamma \supset \Sigma \cup \{\sqcup\}$ is the tape alphabet, N is the number of tapes, $\rho : Q \times \Gamma^N \rightarrow Q \times \Gamma^N \times \{L, R, S\}^N$ is the transition function, ε is the noise level, q_0 is the initial state, q_\top the accepting state and q_\perp the rejecting state.

Every tape is infinite in both directions. Initially the i th tape contains a word $w_i \in \Sigma^*$ completed by two infinite tails of blank symbols \sqcup , and the i th tape head is pointing to the first symbol of w_i . Every computation step performed by an NTM consists of two stages:

At the *noisy stage* the tapes are exposed to a noisy environment, which changes each symbol on the tape independently with probability $\varepsilon \ll 1$. A changed symbol takes any other value in the tape alphabet with equal probability.

At the *progress stage* the computation proceeds as follows. Starting in state q^- , the machine reads the symbol on each tape, giving an N -tuple $s^- \in \Gamma^N$. If $\rho(q^-, s^-) = (q^+, s^+, m^+)$, the machine changes to state q^+ , writes $(s^+)_i$ on the i th tape, and shifts the i th tape head left if $(m^+)_i = L$, right if $(m^+)_i = R$, and does not move it if $(m^+)_i = S$. Whenever the machine arrives at q_\top or at q_\perp it halts.

We are interested in the probabilities $\mathbb{P}(\mathcal{M}_\varepsilon(w) \downarrow)$, $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ and $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \perp)$ that, for a given noise level ε and a given input word w , the NTM \mathcal{M} halts, accepts or rejects, respectively. We are even more interested in the behaviour of those probabilities as $\varepsilon \rightarrow 0$.

Definition 1. *An NTM \mathcal{M} is*

- *lim-halting if $\forall x \in \Sigma^*, \lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) \downarrow) = 1$, i.e the limit probability to halt is 1;*

- almost sure (a.s.)-halting if for any $x \in \Sigma^*$ and any $\varepsilon > 0$ the probability to halt is 1;
- converging if $\forall x \in \Sigma^*$, $\lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top)$ exists.

Clearly if an NTM is a.s.-halting, then it is lim-halting. The former two properties seem restrictive, but in Sec. 3 it will be shown that any NTM is equivalent to an a.s.-halting one, in the sense that the acceptance probabilities are equal.

The “limit computational power” of an NTM captures the behaviour of a machine operating in an environment which is almost, but not entirely, noise-free.

Definition 2. An NTM \mathcal{M} *lim-generates* a function $p : \Sigma^* \rightarrow [0, 1]$ if it is lim-halting, converging, and for any $x \in \Sigma^*$, the limit probability to accept it is $p(x)$:

$$\forall x \in \Sigma^*, \lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top) = p(x).$$

An NTM \mathcal{M} *lim-decides* a set $S \subset \Sigma^*$ if it lim-generates its characteristic function.

Notice that in order to lim-decide a set S , an NTM should satisfy a 0-1 law:

$$\lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top) = \begin{cases} 1, & \text{if } x \in S; \\ 0, & \text{if } x \notin S. \end{cases}$$

A weaker notion of computability considering lim sup (or lim inf) rather than lim is suitable for non-converging machines.

Definition 3. An NTM \mathcal{M} *lim sup-generates* a function $p : \Sigma^* \rightarrow [0, 1]$ if it is lim-halting and for any $x \in \Sigma^*$, the upper limit probability to accept it is $p(x)$:

$$\forall x \in \Sigma^*, \limsup_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top) = p(x).$$

An NTM \mathcal{M} *lim sup-decides* a set $S \subset \Sigma^*$ if for any $x \in \Sigma^*$ it lim sup-generates its characteristic function.

The question whether this can be really considered as a computation is left to a philosophically-minded reader.

2.1 If It Halts Without Noise

We start the study of noisy machines with the easy case when a machine without noise halts on an input x .

Theorem 1. If $\mathcal{M}(x) = \top$ then $\lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top) = 1$. Symmetrically, if $\mathcal{M}(x) = \perp$ then $\lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \perp) = 1$.

Proof. Consider the first case, $\mathcal{M}(x) = \top$; the other case is similar. Let τ be the computation time of \mathcal{M} on the input x . For any $\delta > 0$ take an $\varepsilon < \delta\tau^{-2}$.

A normal computation (without noise) of \mathcal{M} on x uses at most τ tape cells during τ time units. When noise is added the probability for at least one of

those cells being perturbed during τ time units cannot exceed $\tau \cdot \tau \cdot \varepsilon < \delta$. The computation of \mathcal{M} on x leading to acceptance is then unaffected by the noise, hence the NTM \mathcal{M}_ε accepts x with probability at least $1 - \delta$. Since δ is arbitrary, $\lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top) = 1$. \square

Corollary 1. *If a TM \mathcal{M} decides a set $S \subset \Sigma^*$ then its NTM version \lim -decides the same set S .*

3 General Properties: $\varepsilon > 0$

In this section we explore NTMs and acceptance by NTMs for a positive noise level $\varepsilon > 0$. This paves the way for the characterisation of the limit behaviour of NTMs as $\varepsilon \rightarrow 0$ in subsequent sections.

3.1 Automaton

For an NTM \mathcal{M} described by a tuple (1), we can abstract away the memory tapes to obtain an automaton

$$\mathcal{A} = (Q, \rho', q_0, q_\top, q_\perp),$$

where the transition relation $\rho' \subset Q \times Q$ is obtained from $\rho : Q \times \Gamma^N \rightarrow Q \times \Gamma^N \times \{L, R, S\}^N$ by projection. Any allowable sequence of transitions of \mathcal{A} is a possible sequence of transitions for \mathcal{M} , since it is always possible that the element at the tape head changes just before the step to enable the desired transition.

We say a state q of \mathcal{M} is a *looping state* if for every possible sequence of transitions starting at q , no halting state is reached. In this case, the probability that \mathcal{M} halts given that it reaches q is zero.

Theorem 2. *For any NTM \mathcal{M} , there exists an effectively constructible a.s.-halting NTM \mathcal{M}' with the same acceptance probability for any input $x \in \Sigma^*$ and any $\varepsilon > 0$.*

Proof. We construct \mathcal{M}' by deleting all looping states from \mathcal{M} , and replacing all transitions leading to looping states with a transition leading to q_\perp . Then clearly, $\mathbb{P}(\mathcal{M}'_\varepsilon(x) = \top) = \mathbb{P}(\mathcal{M}_\varepsilon(x) = \top)$.

It remains to show that $\mathbb{P}(\mathcal{M}'_\varepsilon(x) \downarrow) = 1$. Since \mathcal{M}' has no looping states, for any state q of \mathcal{M}' , there is a sequence of transitions leading to a halting state in at most $k = |Q|$ steps. This sequence of transitions occurs for the noisy machine with probability at least $(\varepsilon/|\Sigma|)^k$. Therefore the probability that the machine halts after nk steps is at least $1 - (1 - (\varepsilon/|\Sigma|^k))^n$. Hence \mathcal{M}' halts with probability 1. \square

We can therefore replace any NTM with one that halts with probability 1 for every $\varepsilon > 0$ without changing the acceptance probability. This means that, unlike ordinary TMs, we need only consider NTMs which almost surely halt on any input. In the rest of this paper, we assume that all NTMs have no looping states.

3.2 Continuity

Theorem 3. $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ is continuous with respect to ε for $\varepsilon > 0$.

Proof. Let $p(w, \varepsilon, t)$ be the probability that \mathcal{M} halts in time t in state q_\top , and $q(w, \varepsilon, t)$ be the probability that \mathcal{M} halts in time t in state q_\perp . Then clearly $p(w, \varepsilon, t)$ and $q(w, \varepsilon, t)$ are continuous as functions of $\varepsilon > 0$, since they depend on finite computations. Let $r(w, \varepsilon, t) = 1 - p(w, \varepsilon, t) - q(w, \varepsilon, t)$. Then by our standing assumption of almost-sure halting, $r(w, \varepsilon, t) \rightarrow 0$ as $t \rightarrow \infty$.

It is easy to see that

$$p(w, \varepsilon, t) < \mathbb{P}(\mathcal{M}_\varepsilon(w) = \top) < p(w, \varepsilon, t) + r(w, \varepsilon, t) = 1 - q(w, \varepsilon, t). \quad (2)$$

To prove continuity of $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ at ε , take t such that $r(w, \varepsilon, t) < \delta/3$. For ε' sufficiently close to ε , both $|p(w, \varepsilon', t) - p(w, \varepsilon, t)| < \delta/3$ and $r(w, \varepsilon', t) < 2\delta/3$. Then, using (2), we obtain $|\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top) - \mathbb{P}(\mathcal{M}_{\varepsilon'}(w) = \top)| < \delta$. Hence $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ is continuous. \square

3.3 Computability

We now consider ε -perturbed machines for a fixed rational ε . By computability of a real number x (see [10]), we mean that given an error bound $\delta > 0$, there is a TM which computes an approximation to x with an error of at most δ .

Theorem 4. $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ is computable as a function of \mathcal{M} , rational $\varepsilon > 0$ and w .

Proof. Let $p(w, \varepsilon, t)$, $q(w, \varepsilon, t)$ and $r(w, \varepsilon, t)$ be as in the proof of Theorem 3. By simulating all possible runs of the NTM of length at most t and computing the probability of each, we can compute p , q and r exactly. Since $r(w, \varepsilon, t) \rightarrow 0$ as $t \rightarrow \infty$, we can take t sufficiently large so that $r(t, \varepsilon, t) < \delta$, and so $|\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top) - p(w, \varepsilon, t)| < \delta$. \square

4 Some Gadgets

We now describe some generally useful NTMs and their properties.

4.1 Measuring Time

The first gadget is a **TIMER**. Its construction is very simple: it is just a TM with one tape (initially blank), whose head goes right at every step. If it sees a non-blank cell it stops.

The following lemma establishes that, when subjected to an ε -noise, **TIMER** is capable to measure approximately a lapse of $\varepsilon^{-1/2}$ time units.

Lemma 1. Let τ be the time before the **TIMER** $_\varepsilon$ stops. Then for any a, b with $a < 1/2 < b$, the following estimates hold:

1. $\mathbb{P}(\tau < \varepsilon^{-a}) = O(\varepsilon^{1-2a});$
2. $\mathbb{P}(\tau > \varepsilon^{-b}) = O(\varepsilon^d)$ for any $0 < d < 1/2$.

Proof. First we estimate the probability of the event E_1 that $\tau < \varepsilon^{-a}$. This probability can be majorated by the probability of the event E_2 that during $\lfloor \varepsilon^{-a} \rfloor$ time units at least one of the first $\lfloor \varepsilon^{-a} \rfloor$ cells on the tape has been altered by the noise. For each cell and each step the probability to be altered is ε , which gives an upper bound

$$\mathbb{P}(E_1) \leq \mathbb{P}(E_2) \leq \lfloor \varepsilon^{-a} \rfloor \cdot \lfloor \varepsilon^{-a} \rfloor \cdot \varepsilon = O(\varepsilon^{1-2a}).$$

In the sequel we will omit $\lfloor \cdot \rfloor$ and $\lceil \cdot \rceil$ symbols and make all the computations as if all the powers of ε considered were integer numbers.

The event E_3 that $\tau > \varepsilon^{-b}$, implies either the event E_4 that none of the first ε^{-b} cells have been modified before the timer scans them, or the event E_5 that at least one of the first ε^{-b} cells has been modified at least twice in time ε^{-b} . Hence $\mathbb{P}(E_3) \leq \mathbb{P}(E_4) + \mathbb{P}(E_5)$.

E_4 is a conjunction of $\varepsilon^{-b} \cdot \varepsilon^{-b} / 2$ independent events with probabilities $1 - \varepsilon$; each event means that a cell has not been perturbed at a time instant. Hence

$$\mathbb{P}(E_4) = (1 - \varepsilon)^{\varepsilon^{-2} / 2} = O(\exp(-\varepsilon^{1-2b})).$$

In particular, if $b > 1/2$, $\mathbb{P}(E_4) = o(\varepsilon^n)$ for any $n > 0$.

The event E_5 is a disjunction of independent $n = \varepsilon^{-b}$ events. Each of those events is that a particular cell has been perturbed at least twice during ε^{-b} time units. Hence

$$\mathbb{P}(E_5) \leq n(1 - (1 - \varepsilon)^n - n\varepsilon(1 - \varepsilon)^{n-1}) = O(n^3\varepsilon^2) = O(\varepsilon^{2-3b}).$$

Therefore, $\mathbb{P}(E_3) = O(\varepsilon^{2-3b})$ for $1/2 < b < 2/3$. Since $\mathbb{P}(E_3)$ is a decreasing function of b , we must have $\mathbb{P}(E_3) = O(\varepsilon^d)$ for any $0 < d < 1/2$. □

We say an event E occurs with *high probability* if there exists $d > 0$ such that $\mathbb{P}(E) = 1 - O(\varepsilon^d)$. Similarly, it occurs with *low probability* if $\mathbb{P}(E) = O(\varepsilon^d)$.

We remark that it would be easier to build a timer measuring ε^{-1} lapse of time. Such a timer is an NTM staying in place and observing one cell, until its contents is modified. Unfortunately, such a timer would be rather useless, because during such a long time the contents of all the cells on the tape becomes completely random.

We prefer the $\varepsilon^{-1/2}$ timer described at the beginning of this section because during such time the probability of perturbation on a small zone of tape or of a “double error” in the same position of two tapes is low. In the next subsection we formalise these properties, and explain how they allow for reliable computations of duration $\varepsilon^{-1/2}$ and even more. We will then be able to use these constructions to build $O(\varepsilon^{-c})$ TIMERS for $1/2 < c < 1$.

4.2 Tossing Coins

By letting two TIMERS race each other to find a non-blank symbol, we can generate random bits.

A RANDOMBIT machine has two tapes. Two TIMERS are launched concurrently on both tapes. If the first one stops before the second one, the result is \perp , if the second one stops before the result is \top . In the highly improbable case of a tie, the TIMERS are restarted. The following result is straightforward, but important; it shows that NTMs can produce random bits.

Lemma 2. *The RANDOMBIT $_\epsilon$ terminates almost surely and returns \perp and \top (or 0 and 1) with probabilities $1/2$ each. Its computation time is bounded above by ϵ^{-b} (with $b > 1/2$) with probability $1 - O(\epsilon^d)$ for any $0 < d < 1/2$.*

Notice that the RANDOMBIT $_\epsilon$ gadget can also be started some time T after the beginning, and can be run continuously to generate a succession of random bits.

4.3 Memory

Even on time scales of order $\epsilon^{-1/2}$ generated by a TIMER, the behaviour of a noisy version of a regular TM \mathcal{M} has unacceptably high errors. To obtain correct execution with high probability of a time interval of order ϵ^{-a} , we run all computations of \mathcal{M} on a multi-tape MEMORY with error correction.

For computations taking $O(\epsilon^{-a})$ time with $a < 2/3$ we can guarantee error-freedom with high probability by taking three identical copies of the tape and making the same computation on all of them. If at some moment a disagreement between the three tapes is observed, it is immediately corrected by a majority vote. This procedure allows to correct single errors, while Lemma 3 ensures that double errors are highly improbable.

By using more tapes, we can, in fact, construct MEMORY which is error-free with high probability on time intervals $O(\epsilon^{-c})$ for any $c < 1$.

Lemma 3. *Let \mathcal{M}_ϵ be an NTM running on a three-tape MEMORY for a time period $O(\epsilon^{-a})$ using space $O(\epsilon^{-b})$. Then the probability of incorrect execution of \mathcal{M}_ϵ is of order $O(\epsilon^{2-2a-b})$.*

Proof. Incorrect execution can only occur if two cells with the same coordinate are perturbed in time period $\tau = O(\epsilon^{-a})$. The probability of such a “double error” in a given cell is $O(\epsilon^{2(1-a)})$, hence the probability of a double error in any of b cells is $O(\epsilon^{2-2a-b})$.

4.4 Programming NTMs

Armed with a TIMER, a RANDOMBIT and (fairly) reliable MEMORY, we can start to program NTMs by running ordinary TMs on a MEMORY, using a TIMER to halt the computation before the noise-induced errors become too high.

A simple, but very useful gadget is a COUNTER machine. This machine stores an integer n in binary form in a three-tape MEMORY. The COUNTER spends all its time incrementing its value, which asymptotically grows as $n \sim t/\log t$.

Using a COUNTER, we can construct a DELAY gadget. When this gadget is activated, it copies the time n contained in the counter, and computes some (easy to compute) function $f(n) \sim n^s$. It then waits until the COUNTER reaches $f(n)$, emits a signal, and goes back to sleep.

Using the COUNTER and DELAY gadgets, we can construct an improved version of a TIMER. We run an $\sim \varepsilon^{-1/2}$ timer as usual, but when this stops, we activate a DELAY gadget with $f(n) \sim n^{2c}$. The program continues running until the DELAY gadget deactivates. This new TIMER(c) gadget stops in time $\sim \varepsilon^{-c}$ with high probability.

We can use TIMER(c) and RANDOMBIT to construct a RANDOMNUMBER. By storing successively generated bits in a MEMORY, we generate an increasing sequence of rationals r_i converging to a real number r which is uniformly distributed in $[0, 1]$. By using a TIMER(c), we can generate $\sim \varepsilon^{1/2-c}$ digits of r .

4.5 Oscillators

An OSCILLATOR is a gadget which stores a binary digit in a “register” variable where it is unaffected by the noise. (Formally, we construct a register by taking a set of states $Q \times \{0, 1\}$.) When the OSCILLATOR is halted by a TIMER, it stops in q_\top if the register holds 1, and in q_\perp if the register holds 0.

A simple oscillator which changes register state at every step is not very interesting; the limiting acceptance probability is $1/2$. By using a DELAY, we can hold the value of the register for a period $[m, f(m) \sim m^c]$; long enough for its value to be seen when the TIMER halts.

Lemma 4. *Let \mathcal{M} be an OSCILLATOR which uses a delay to switch state at times $n_i = f(n_{i-1})$ with $f(n) \geq n^c$, and which halts when a TIMER stops. Then \mathcal{M} halts almost surely, but $\mathbb{P}(\mathcal{M}_\varepsilon = \top)$ does not converge as $\varepsilon \rightarrow 0$.*

Proof. Choose a, b such that $a < 1/2 < b < 2/3$, $b/a < c$ and $a + b < 1$, and let $d = 1 - a - b$. For any given n , we can find $\varepsilon < 1$ such that $[\varepsilon^{-a}, \varepsilon^{-b}] \subset [n, n^c]$. If oscillator switches at times n_i , then $n_{i+1} \geq n_i^c$. Hence, there is a sequence ε_i with $\varepsilon_i \rightarrow 0$ as $i \rightarrow \infty$ such that $[\varepsilon_i^{-a}, \varepsilon_i^{-b}] \subset [n_i, n_{i+1}]$.

The TIMER halts at $\tau \in [\varepsilon_n^{-a}, \varepsilon_n^{-b}]$ with high probability. Further, in this time the MEMORY ensures correct execution with high probability. Hence for noise levels ε_{2i} , the probability that the timer halts with the register in state 0 tends to 1 as $n \rightarrow \infty$, and for noise levels ε_{2i+1} timer halts with the register in state 1 with high probability. Thus $\mathbb{P}(\mathcal{M}_\varepsilon = \top)$ oscillates between 0 and 1 as $\varepsilon \rightarrow 0$, and does not converge as $\varepsilon \rightarrow 0$. □

5 Decisional Power of NTMs

In this section we address the capabilities of NTMs for deciding sets $S \subset \Sigma^*$. The main result of this section is

Main Result 1. *A set $S \subset \Sigma^*$ is lim-decidable if and only if it is Δ_2^0 . A set $S \subset \Sigma^*$ is lim-sup-decidable if and only if it is Π_2^0 .*

The upper complexity bounds follow from Theorems 9 and 11 in the next section.

5.1 Deciding Recursively Enumerable Sets

The following result illustrates how converging NTMs can be stronger than ordinary TMs, and solve, for example, the halting problem.

Theorem 5. *For any recursively enumerable (Σ_1^0) set S there exists an NTM \mathcal{N} which lim-decides S .*

Proof. Recall that S is Σ_1^0 if there is a TM \mathcal{M} such that $\mathcal{M}(w)$ halts if, and only if, $w \in S$. Given such a TM, we construct an NTM \mathcal{N}_ε with 4 tapes to lim-decide S . On tapes 1, 2 and 3 we have a MEMORY store on which we run \mathcal{M} , correcting errors by majority vote. On tape 4, we run a TIMER gadget.

The computation terminates in the accepting state if \mathcal{M} runs successfully and reaches its halting state. The computation terminates in the rejecting state if the TIMER stops.

Since the TIMER stops almost surely, and does so with high probability in time $\tau \in [\varepsilon^{-a}, \varepsilon^{-b}]$, the computation performed by \mathcal{M} runs successfully with high probability, terminating in state q_+ if $w \in S$ (as long as ε is small enough, namely such that ε^{-a} exceeds the computation time of $\mathcal{M}(w)$), and halts in state q_\perp if $w \notin S$. \square

5.2 Deciding Δ_2^0 Sets

We now strengthen the result of Theorem 5 to show that NTMs can lim-decide Δ_2^0 sets. Recall that a set S is Δ_2^0 if both S and its complement are Π_2^0 .

A particularly useful characterisation of a Π_2^0 set, similar to Büchi acceptance by ω -automata, can be given in terms of *signalling* TMs. A signalling TM has no halting states, but instead a distinguished set of *signalling states* $Q_s \subset Q$. A set S is Π_2^0 if there is a signalling TM \mathcal{M} which enters states from Q_s infinitely often if, and only if, $w \in S$.

Theorem 6. *For any Δ_2^0 set S there exists an NTM which lim-decides S .*

Proof. Let \mathcal{M}^1 be a TM such that $\mathcal{M}^1(w)$ emits a signal infinitely often iff $w \in S$, and \mathcal{M}^0 a TM such that $\mathcal{M}^0(w)$ emits a signal infinitely often iff $w \notin S$.

We can run \mathcal{M}^1 and \mathcal{M}^0 in parallel with a register variable. Whenever \mathcal{M}^i emits a signal, we store i in the register. If $w \in S$, then eventually \mathcal{M}^0 emits no more signals, but \mathcal{M}^1 continues to do so, and the register sticks to 1. Conversely, if $w \notin S$, then eventually the register contains 0. In both cases, after some time $T(w)$ the register's content never changes and is equal to $\chi_S(w)$.

We lim-decide S by an NTM \mathcal{N} running \mathcal{M}^1 and \mathcal{M}^0 as described above. Computation is terminated when a TIMER stops, the outcome is the register's content. Whenever ε is small enough to ensure that the TIMER stops after time $T(w)$, we can easily see that \mathcal{N}_ε operates correctly with high probability and outputs $\chi_S(w)$. Hence \mathcal{N} lim-decides S . \square

5.3 Deciding Π_2^0 Sets

We now investigate the computational power of NTMs without restriction of convergence.

Theorem 7. *For any Π_2^0 set S there exists an NTM which \limsup -decides S .*

Proof. Let \mathcal{M} be a TM such that $\mathcal{M}(w)$ emits a signal infinitely often iff $w \in S$. To ensure that signals are noticed in the presence of noise, we combine \mathcal{M} with a DELAY which activates when \mathcal{M} emits a signal, setting a register to 1. Whenever DELAY deactivates, it resets the register to 0. As usual, the computation is halted whenever the TIMER stops.

Assuming correct operation of \mathcal{M} and DELAY, which occurs with high probability, the register variable is equal to 1 on time intervals $[\tau_i, \tau_i^c]$ infinitely often if $w \in S$, and is eventually equal to 0 if $w \notin S$. Using the argument from the proof of Lemma 4 we can see that \mathcal{N} \limsup -decides S . □

6 Generating Probability Functions

In this section, we investigate the functions which can be generated as the acceptance probability of an NTM as $\varepsilon \rightarrow 0$. We shall prove the following result:

Main Result 2. *A function $p : \Sigma^* \rightarrow [0; 1]$ can be \lim -generated by a converging NTM if and only if it is $0'$ -computable. A function $p : \Sigma^* \rightarrow [0; 1]$ is \limsup -generated by an NTM if and only if it is upper $0'$ -semicomputable.*

6.1 Generating $0'$ -Computable Probabilities

Recall that a function is called $0'$ -computable if it can be computed by a TM using an oracle for the halting problem. Equivalently, p is $0'$ -computable iff $\{(r, w) \in \mathbb{Q} \times \Sigma^* \mid r < p(w)\}$ and $\{(r, w) \in \mathbb{Q} \times \Sigma^* \mid r > p(w)\}$ are Π_2^0 -sets.

Theorem 8. *Let $p : \Sigma^* \rightarrow [0, 1]$ be a $0'$ -computable function. There exists a converging NTM \mathcal{S} that \lim -generates the function p .*

Proof. Since $\{(r, w) \in \mathbb{Q} \times \Sigma^* \mid r < p(w)\}$ is Π_2^0 , there is a TM $\mathcal{M}_<$ such that $\mathcal{M}_<(r, w)$ emits infinitely many signals if, and only if, $r < p(w)$.

We now aim to extend this computation to real numbers. Suppose we have access to an increasing sequence of rationals r_i converging to a real number r . We run $\mathcal{M}_<$ sequentially on inputs (r_i, w) , starting $\mathcal{M}_<(r_n, w)$ after each computation $\mathcal{M}_<(r_i, w)$ (with $i < n$) has emitted $n - i$ signals.

Suppose $r < p(w)$. Then $r_i < p(w)$ for all i , so $\mathcal{M}_<(r_i, w)$ emits infinitely many signals for all i . Conversely, if $r > p(w)$, then $r_i \geq p(w)$ for some i , and $\mathcal{M}_<(r_i, w)$ emits only finitely many signals before looping indefinitely.

We can therefore construct a TM $\mathcal{M}'_<$ which, given $w \in \Sigma^*$ and n digits of r , emits infinitely many signals if $r < p(w)$, and finitely many signals if $r > p(w)$ and n is sufficiently large. Similarly, we can construct a TM $\mathcal{M}'_>$ which, given n elements of a decreasing sequence converging to r , emits infinitely many signals if $r > p(w)$, and finitely many signals if $r < p(w)$ and n is sufficiently large.

We now construct an NTM \mathcal{N} to \lim -generate the function p . We use a RANDOMNUMBER gadget to generate the binary approximants r_i to a random

variable r uniformly distributed in $[0, 1]$. Notice that the distribution of the r_i is independent of the noise ε . We use $\mathcal{M}'_{<}$ and $\mathcal{M}'_{>}$ to compute $r < p(w)$ and $r > p(w)$. The computation is halted by a `TIMER(c)` with $1/2 < c < 2/3$ to ensure that `RANDOMNUMBER` generates sufficiently many bits, but that the `MEMORY` is still error-free with high probability.

Fix $w \in \Sigma^*$ and n , and suppose $p(w) \notin [r_n, r_n + 1/2^n]$, which occurs with probability $1 - 1/2^n$. We claim that after a fixed time T , independent of r , the value of the register does not change. In the case $r_n + 1/2^n < p(w)$, then $r_i < p(w)$ for all i , so $\mathcal{M}'_{<}$ emits infinitely many signals, whereas $\mathcal{M}'_{>}(r_n, w)$ emits only finitely many signals, so after some time $T(r_n)$, machine $\mathcal{M}'_{>}(r_n, w)$ does not emit further signals. Since there are only finitely many possible values of r_n , we can choose T independently of r_n . The case $r_n > p(w)$ is similar.

Using the same argument as in Theorem 6, we see that with high probability, \mathcal{N}_ε accepts if $r_n < p(w)$ and rejects if $p(w) < r_n + 1/2^n$. Hence $\mathbb{P}(\mathcal{N}_\varepsilon(w) = \top) \in [r_n, r_n + 1/2^n]$, and since n is arbitrary, $\mathbb{P}(\mathcal{N}_\varepsilon(w) = \top) = p(w)$. \square

To prove that Theorem 8 gives a precise characterisation of the computational power of a converging NTM, we analyse the limit as $\varepsilon \rightarrow 0$.

Theorem 9. $\lim_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ is $0'$ -computable for any converging NTM.

Proof. The function $f(\varepsilon, w)$ given by $\mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ is computable when ε is rational, and converges as $\varepsilon \rightarrow 0$ for all $w \in \Sigma^*$. By definition,

$$r < \lim_{\varepsilon \rightarrow 0} f(\varepsilon, w) \iff \exists s > r, \exists q > 0, \forall \varepsilon < q, (\neg(s > f(\varepsilon, w))).$$

The inequality $(s > f(\varepsilon, w))$ belongs to the class Σ_1^0 . We deduce that the relation $(r < \lim_{\varepsilon \rightarrow 0} f(\varepsilon, w))$ belongs to the class Σ_2^0 , and hence is $0'$ -recursively enumerable. Symmetrically, the inequality $(r > \lim_{\varepsilon \rightarrow 0} f(\varepsilon, w))$ is also $0'$ -recursively enumerable. Hence $\lim_{\varepsilon \rightarrow 0} f(\varepsilon, w)$ is $0'$ -computable. \square

6.2 Generating Upper $0'$ -Semicomputable Probabilities

Recall that a function p is upper $0'$ -semicomputable if the set $\{(r, w) \in \mathbb{Q} \times \Sigma^* \mid r > p(w)\}$ is of class Σ_2^0 , so that $\{(r, w) \in \mathbb{Q} \times \Sigma^* \mid r \leq p(w)\}$ is of class Π_2^0 .

Theorem 10. Let $p : \Sigma^* \rightarrow [0, 1]$ be an upper $0'$ -semicomputable function. There exists an NTM \mathcal{S} that \limsup -generates p .

Proof. We use the machine $\mathcal{M}'_{<}(r, w)$ and the `RANDOMNUMBER` from the proof of Theorem 8, and combine this with `DELAY` as in the proof of Theorem 7, and a `TIMER(c)` to halt the computation.

Computation proceeds by running $\mathcal{M}'_{<}$, and starting a `DELAY` whenever $\mathcal{M}'_{<}$ emits a signal. If $\mathcal{M}'_{<}$ emits signals infinitely often, then every $r_n < p(w)$, so $r \leq p(w)$, and if $\mathcal{M}'_{<}(r_n, w)$ loops for some r_n , then $r_n \geq p(w)$, so $r \geq p(w)$.

The rest of the proof follows that of Theorems 7 and 8, and is omitted. \square

Theorem 11. $\limsup_{\varepsilon \rightarrow 0} \mathbb{P}(\mathcal{M}_\varepsilon(w) = \top)$ is upper $0'$ -semicomputable.

Proof. As in the proof of Theorem 9, it is easy to show that $\limsup_{\varepsilon \rightarrow 0} f(\varepsilon, w)$ is upper $0'$ -semicomputable whenever $f : (0, 1) \times \Sigma^* \rightarrow [0; 1]$ is continuous and computable. \square

7 Concluding Remarks

We have described a class of randomly perturbed Turing machines and studied their computational properties. We have shown that in the limit of infinitesimal noise, these machines can be programmed to \lim -decide Δ_2^0 , and \limsup -decide Π_2^0 sets. It is interesting to compare this result with [5], where a small nondeterministic noise led to a Π_1^0 computational power only. We have also given a characterisation of the acceptance probability distributions which can be generated. As a future work we are planning to explore how sensitive are these results to the choice of a computational model (discrete, hybrid or analog) and of a stochastic noise model.

A Better Approximation Ratio for the Vertex Cover Problem*

George Karakostas**

Department of Computing and Software, McMaster University
karakos@mcmaster.ca

Abstract. We reduce the approximation factor for Vertex Cover to $2 - \Theta(\frac{1}{\sqrt{\log n}})$ (instead of the previous $2 - \Theta(\frac{\log \log n}{\log n})$, obtained by Bar-Yehuda and Even [3], and by Monien and Speckenmeyer [11]). The improvement of the vanishing factor comes as an application of the recent results of Arora, Rao, and Vazirani [2] that improved the approximation factor of the sparsest cut and balanced cut problems. In particular, we use the existence of two big and well-separated sets of nodes in the solution of the semidefinite relaxation for balanced cut, proven in [2]. We observe that a solution of the semidefinite relaxation for vertex cover, when strengthened with the triangle inequalities, can be transformed into a solution of a balanced cut problem, and therefore the existence of big well-separated sets in the sense of [2] translates into the existence of a big independent set.

1 Introduction

One of the most well-studied problems in combinatorial optimization is the vertex cover (VC) problem: given a graph $G = (V, E)$, we look for a minimum size subset of vertices such that for every $(u, v) \in E$, at least one of u, v belongs to this subset. In the *weighted* version of VC, each vertex has an integral weight, and we are looking for the minimum total weight subset of vertices with the property above.

Since the complexity of VC has been heavily studied since Karp's original proof of its NP-completeness [9], the related bibliography is vast and cannot be covered, of course, in this introductory note. We mention here that VC is known to be APX-complete [12], and moreover it cannot be approximated within a factor of 1.36 [6], unless $P=NP$. A 2-approximation on the other hand can be trivially obtained by taking all the vertices of a maximal matching in the graph.

Improving this simple 2-approximation algorithm has been a quite non-trivial task. The best approximation algorithms known before this work were published 20 years ago by Bar-Yehuda and Even [3], and by Monien and Speckenmeyer [11].

*A preliminary version of this work appeared as a McMaster University Technical Report CAS-04-05-GK and ECCS Report TR04-084, September/October 2004.

**Research supported by an NSERC Discovery grant.

They achieved an approximation factor of $2 - \frac{\ln \ln n}{2 \ln n}$, where n is the number of vertices. If Δ is the maximum degree of the graph, Halperin [8] showed that a factor of $2 - (1 - o(1)) \frac{2 \ln \ln \Delta}{\ln \Delta}$ can be achieved by using the semidefinite programming (SPD) relaxation of VC.

In this work we use a stronger SDP relaxation to improve the approximation factor achieved in polynomial time to $2 - \Theta(\frac{1}{\sqrt{\log n}})$. We observe that the introduction of all the so-called *triangle inequalities* to the standard SDP relaxation of VC is, in fact, very similar to the balanced cut SDP relaxation used by Arora, Rao, and Vazirani [2]. Then we use one of the main results of [2], which asserts that in the solution of this SDP, there are two big and well-separated vertex subsets. At the same time, we show that edges that were not covered by a trivial initial rounding are too big to have both of their endpoints in either of these two sets. Hence, one of these two big subsets has to be a big independent set, which can be excluded. We show this process first for the unweighted VC, and then we show how it can be extended to the weighted case in a straight-forward manner.

Hence the main idea in this improvement of the approximation factor is the transformation of the ‘classic’ SDP formulation of VC to a formulation that corresponds to a balanced cut problem with the addition of the ‘antipodal’ points of the original points. This appears to be a very general technique that can find application to other problems, and bring the Arora, Rao, Vazirani [2] improved approximation factor for balanced cuts to other contexts as well. Indeed, subsequently to our work, Agarwal, Charikar, Makarychev, and Makarychev [1] used this stronger SDP formulation and the negative symmetric metric that it implies, together with a clever iterative application of the separation algorithm of [2], and several other ideas like volume arguments to improve the approximation factor of several problems (MIN UNCUT, MIN 2CNF DELETION, DIRECTED BALANCED SEPARATOR, DIRECTED SPARSEST CUT) to $O(\sqrt{\log n})$.

2 The Unweighted Case

The following is a semidefinite-programming relaxation of unweighted Vertex Cover (VC) for a graph $G = (V, E)$ with n nodes:

$$\min \sum_{i=1}^n \frac{1 + v_0 v_i}{2} \text{ s.t.} \tag{SDP}$$

$$(v_0 - v_i)(v_0 - v_j) = 0, \quad \forall (i, j) \in E \tag{1}$$

$$(v_i - v_j)(v_i - v_k) \geq 0, \quad \forall i, j, k \in V \cup \{0\} \tag{2}$$

$$v_i^2 = 1, \quad \forall i \in V \cup \{0\} \tag{3}$$

where $v_i \in \mathbb{R}^{n+1}$. Constraints (2) are *triangular inequalities*, which must be satisfied by the vertex cover. In an ‘integral’ solution of (SDP) (which would

correspond to a vertex cover of G), vertices that are picked coincide with v_0 , while vertices that are not picked coincide with $-v_0$. In general though, an optimal solution of (SDP) will not be ‘integral’.

In fact one can strengthen this SDP relaxation for VC by adding all the so called triangle inequalities:

$$\begin{aligned} \min \sum_{i=1}^n \frac{1 + v_0 v_i}{2} \text{ s.t.} \\ (v_0 - v_i)(v_0 - v_j) = 0, & \quad \forall (i, j) \in E \\ (v_i - v_j)(v_i - v_k) \geq 0, & \quad \forall i, j, k \in V \cup \{0\} \\ (v_i + v_j)(v_i - v_k) \geq 0, & \quad \forall i, j, k \in V \cup \{0\} \\ (v_i + v_j)(v_i + v_k) \geq 0, & \quad \forall i, j, k \in V \cup \{0\} \\ v_i^2 = 1, & \quad \forall i \in V \cup \{0\} \end{aligned}$$

This relaxation is in fact equivalent to the following relaxation: We add n more ‘shadow’ points to (SDP) so that for every unit vector $v_i, i = 1, \dots, n$ we add unit vector v'_i which is the antipodal of v_i , i.e., $v_i v'_i = -1, \forall i$. Let V' be the set of shadow points. Note that in an integral solution of (SDP), exactly half (n) of the points in $V \cup V'$ coincide with v_0 and the other half coincide with $-v_0$. Therefore the following must hold

$$\sum_{i, j \in V \cup V'} |v_i - v_j|^2 = 4n^2$$

where every pair (i, j) appears only once in the sum. (Hence the set $V \cup V'$ is 1/2-spread in the terminology of [2]). In addition, the triangular inequalities (2) must also hold when we extend V with V' . Hence we have the following strengthened SDP:

$$\begin{aligned} \min \sum_{i=1}^n \frac{1 + v_0 v_i}{2} \text{ s.t.} & \tag{SDP'} \\ (v_0 - v_i)(v_0 - v_j) = 0, & \quad \forall (i, j) \in E \tag{4} \\ (v_i - v_j)(v_i - v_k) \geq 0, & \quad \forall i, j, k \in V \cup V' \cup \{0\} \tag{5} \\ v_i^2 = 1, & \quad \forall i \in V \cup V' \cup \{0\} \tag{6} \\ v_i v'_i = -1, & \quad \forall i \in V \tag{7} \\ \sum_{i, j \in V \cup V'} |v_i - v_j|^2 = 4n^2 & \tag{8} \end{aligned}$$

where $v_i, v'_i \in \mathbb{R}^d$ for some $d \gg \log n$. Constraint (8) is in fact unnecessary since it is always satisfied by a set of points and their antipodals, but we include it in order to point out that this relaxation defines a *spread metric* as defined in [2]. Now we can use results of [2] to find an approximate VC.

For any $\varepsilon > 0$, we define the following two sets of graph vertices:

$$S_1 := \{v \in V : v_0v > \varepsilon\}$$

$$S_2 := \{v \in V \cup V' : -\varepsilon \leq v_0v \leq \varepsilon\}$$

For now, we concentrate our attention on S_2 . Note that in S_2 we have included also shadow points. In fact, note that if $v_i \in V$ belongs to S_2 then its shadow $v'_i \in V'$ belongs to S_2 as well, and vice-versa. In other words, S_2 contains both original points and their shadows.

Lemma 1.

$$\sum_{i,j \in S_2} |v_i - v_j|^2 = 4|S_2|^2$$

Proof. Note that for a particular pair $i, j \in S_2 \cap V$ we have $v_i v'_j = v'_i v_j = -v_i v_j$. So if we group the summation terms according to pairs of vertices $i, j \in S_2 \cap V$, we get the lemma, due to cancellation of terms.

Let $\Delta, \sigma > 0$ be two parameters to be determined later. Let u be a random unit vector, and let

$$S_u := \{v \in S_2 : uv \geq \frac{\sigma}{\sqrt{d}}\}$$

$$T_u := \{v \in S_2 : uv \leq -\frac{\sigma}{\sqrt{d}}.\}$$

Since $v_i = -v'_i$, it is easy to prove the following

Lemma 2. *If $v_i \in S_u$ for some $v_i \in V$, then $v'_i \in T_u$, and vice-versa, if $v'_i \in T_u$, then $v_i \in S_u$. The same holds with the roles of S_u, T_u interchanged.*

As a result of Lemma 2, $S_u \cup T_u$ contains only pairs of points in V with their shadow points, and each such pair is separated between S_u, T_u , and $|S_u| = |T_u|$. Moreover, the following easy fact also holds:

Lemma 3.

$$\left. \begin{matrix} v_i \in S_u, v_j \in T_u, |v_i - v_j|^2 \leq \Delta \\ v'_i \in S_u, v_j \in T_u, |v'_i - v_j|^2 \leq \Delta \\ v_i \in S_u, v'_j \in T_u, |v_i - v'_j|^2 \leq \Delta \\ v'_i \in S_u, v'_j \in T_u, |v'_i - v'_j|^2 \leq \Delta \end{matrix} \right\} \Rightarrow \left\{ \begin{matrix} v'_j \in S_u, v'_i \in T_u, |v'_i - v'_j|^2 \leq \Delta \\ v'_j \in S_u, v_i \in T_u, |v_i - v'_j|^2 \leq \Delta \\ v_j \in S_u, v'_i \in T_u, |v'_i - v_j|^2 \leq \Delta \\ v_j \in S_u, v_i \in T_u, |v_i - v_j|^2 \leq \Delta \end{matrix} \right.$$

Let $c' > 0$ be another parameter which will be defined later. We modify the procedure SET-FIND of [2] as follows:

- If $|S_u| < 2c'|S_2|$ or $|T_u| < 2c'|S_2|$ then we HALT (just like in [2]).
- Otherwise, pick any $x \in S_u, y \in T_u$ such that $|x - y|^2 \leq \Delta$. Then, because of Lemma 3, the corresponding pair of antipodal points $y' \in S_u, x' \in T_u$ also satisfy $|x' - y'|^2 \leq \Delta$. Delete x, x', y, y' . Repeat until no such x, y can be found.

Note that initially T_u contains the antipodal points of S_u (Lemma 2), and every deletion eliminates two points from each of S_u, T_u , and these four actually form two (a point in V , its shadow point in V') pairs. Therefore, in the end, the remaining points in S_u are *exactly* the antipodal points of T_u (or both S_u, T_u are empty). As in [2], $|x - y|^2 > \Delta, \forall x \in S_u, y \in T_u$. One can define the parameters c', σ so that, initially, S_u, T_u are big with high probability:

Lemma 4. [Lemma 4 in [2]] *For every positive $c < 1/3$, there are $c', \sigma > 0$ such that the probability (over the choice of u) is at least $c/8$ that the initial sets S_u, T_u defined above have size at least $2c'|S_2|$.*

Proof. From Lemma 1 and application of Lemma 4 of [2].

In fact, since S_u initially (and throughout the running of the algorithm) contains the antipodal points of $T_u, |S_u| = |T_u| = |S_2|/2$ before the algorithm starts running no matter which u we choose, therefore $c' = 1/4$.

One of the main results of [2] is to show that, with high probability over u , not many points are deleted before SET-FIND terminates. Note that the points removed form a matching (at every step, x is matched to y , and x' is matched to y'). Theorem 5 in [2] shows that, with $\Delta = O(\log^{-2/3} n)$, the probability that SET-FIND removes a matching of size $c'|S_2|$ is $o(1)$. Hence the final S_u, T_u of SET-FIND have size $\geq c'|S_2|$ with probability $\Omega(1)$, and $|S_u| = |T_u|$. In what follows, we assume that S_u, T_u are the big final sets we get with high probability from SET-FIND.

Lemma 5. *If $\varepsilon \leq \Delta/4$, then there is no edge $(i, j) \in E$ such that $v_i, v_j \in V$ belong both to S_u or both to T_u .*

Proof. W.l.o.g. suppose that there is $(i, j) \in E$ such that $v_i, v_j \in S_u$. Then their shadow (antipodal) points belong to T_u , i.e., $v'_i, v'_j \in T_u$. Since $v_i, v_j \in S_2$ and constraint (4) holds, we have that

$$v_i v_j = v_0 v_i + v_0 v_j - 1 \leq -(1 - 2\varepsilon). \tag{9}$$

Since $v'_i \in T_u$ and $v_j \in S_u$ are not deleted in SET-FIND, $|v'_i - v_j|^2 > \Delta$, or, equivalently, $|v_i + v_j|^2 > \Delta$. This implies that

$$v_i v_j > -1 + \frac{\Delta}{2}. \tag{10}$$

But (9) and (10) together imply that $\varepsilon > \Delta/4$ which contradicts the hypothesis.

From now on we set $\varepsilon := \Delta/4 > 0$. Since $|S_u| = |T_u| \geq c'|S_2|$, and the two sets contain antipodal points, one of them (w.l.o.g. let's assume that this is S_u), contains at least $\frac{c'|S_2|}{2}$ points from V . Let I be this set of points from V . Lemma 5 implies that I is an *independent set* of G of size at least $c_0|S_2|$, where $c_0 := c'/2 > 0$. We return the set $S := S_1 \cup (S_2 \setminus (I \cup V'))$ as our vertex cover.

Lemma 6. *S is a vertex cover of G.*

Proof. If there is $(i, j) \in E$ with $v_i, v_j \in V \setminus (S_1 \cup S_2)$, we have (by the definition of S_1, S_2) that $v_0 v_i < -\varepsilon$ and $v_0 v_j < -\varepsilon$, which implies that $v_0 v_i + v_0 v_j - 1 < -1 - 2\varepsilon$. Then constraint (4) implies that $v_i v_j < -1 - 2\varepsilon$, a contradiction. Also, since I is an independent set, not both of v_i, v_j can belong to it. If $v_i \in I$ and $v_j \in V \setminus (S_1 \cup S_2)$, then $v_0 v_i \leq \varepsilon$ and $v_0 v_j < -\varepsilon$, therefore constraint (4) implies that $v_i v_j < -1$, a contradiction. We conclude that every edge must have at least one of its endpoints in S .

Our main result is the following

Theorem 1. $|S| \leq (2 - \Theta(\frac{1}{\log^{2/3} n}))VC(G)$.

Proof. We follow the analysis of Halperin [8]. From (SDP') and the definition of S_1, S_2 we have that

$$VC(G) \geq |S_1| \frac{1 + \varepsilon}{2} + |S_2 \setminus V'| \frac{1 - \varepsilon}{2}$$

or, equivalently,

$$|S_1| \leq \frac{2 \cdot VC(G)}{1 + \varepsilon} - |S_2 \setminus V'| \frac{1 - \varepsilon}{1 + \varepsilon}. \tag{11}$$

Hence

$$|S| = |S_1| + |S_2 \setminus V'| - |I| \stackrel{(11)}{\leq} \frac{2}{1 + \varepsilon} VC(G) + |S_2 \setminus V'| (\frac{2\varepsilon}{1 + \varepsilon} - c_0).$$

Note that for $\Delta = \Theta(\log^{-2/3} n)$, $\frac{2\varepsilon}{1 + \varepsilon} = \Theta(\log^{-2/3} n) < c_0$, for big enough n . Therefore,

$$|S| \leq \frac{2}{1 + \varepsilon} VC(G) = (2 - \Theta(\log^{-2/3} n)) \cdot VC(G).$$

Very recently, J. Lee proved that the SET-FIND algorithm of [2] can also be used to obtain their stronger result [10], i.e., Δ can be as big as $\Theta(1/\sqrt{\log n})$. Therefore we can get the following strengthening of Theorem 1:

Theorem 2. $|S| \leq (2 - \Theta(\frac{1}{\sqrt{\log n}}))VC(G)$.

Theorem 2 can be somewhat strengthened by noticing that in the proof of Theorem 1 we just need to pick Δ so that $\frac{2\varepsilon}{1 + \varepsilon} < c_0$, and therefore [2] and [10] imply that if $x := 1/\Delta^2$, it is enough for x to be the solution of equation

$$\frac{x}{\log x} = c \log n$$

where $c > 0$ is a constant (cf. [5] for more details on solving this equation through Lambert's W function).

3 The Weighted Case

The following is a semidefinite-programming relaxation of weighted Vertex Cover (VC) for a graph $G = (V, E)$ with n nodes:

$$\begin{aligned} \min \sum_{i=1}^n w_i \cdot \frac{1 + v_0 v_i}{2} \text{ s.t.} & \tag{WSDP} \\ (v_0 - v_i)(v_0 - v_j) = 0, & \quad \forall (i, j) \in E \\ (v_i - v_j)(v_i - v_k) \geq 0, & \quad \forall i, j, k \in V \cup \{0\} \\ v_i^2 = 1, & \quad \forall i \in V \cup \{0\} \end{aligned}$$

where w_i is the *integral* weight of node i . Let $W := \sum_{i=1}^n w_i$.

In order to apply the methods of Section 2, we solve (SDP') with the weights incorporated in the objective function, and replace every v_i by w_i copies of v_i (v'_i is also replaced by w_i copies of v'_i). In fact we don't need to do this replacement in practice, but this mental experiment is helpful in order to see how the unweighted case applies here, too. Note that this new set of vectors still satisfies the triangular inequalities, and Lemmata 4 through 6 in Section 2 apply here as well with $n := W$. Note that SET-FIND can be made to run in polynomial time in this case (recall that we don't really do the replacement of v_i with w_i , all we need to do is to keep track of how much weight remains for each node after each matching). Now Theorem 1 (and hence Theorem 2) can be proven in the same way as before, if we replace the cardinality of sets $|\cdot|$ with their weights $w(\cdot)$.

4 Open Problems

Obviously one of the biggest open problems in theoretical computer science is the exact determination of the approximability of VC. There is a big gap between the hardness and the approximability results. Unfortunately, the SET-FIND procedure of [2] is limited to a gap of at most $\Theta(1/\sqrt{\log n})$ by the embedding of the $\log n$ -dimensional hypercube: in this case any two subsets of linear size are closer than $\Theta(1/\sqrt{\log n})$ (this simple fact was pointed out to us by James R. Lee).

We couldn't extend our techniques to other problems related to VC, for example the maximum independent set problem (IS), and we don't know whether this is possible (Halperin's [8] techniques, on the contrary, can be applied to IS). Another extension of VC is the vertex cover problem in hypergraphs. We don't know how to extend our techniques to this problem as well. Therefore we leave the application of the results above to these and other problems as an open question.

Finally, we point out that we don't know what the integrality gap of the strengthened SDP relaxation (SDP') used above is. A weaker formulation, that doesn't contain all the triangle inequalities but is equivalent to Schrijver's θ' function [7], was proven to have an integrality gap of $2 - \varepsilon$ for any constant $\varepsilon > 0$ by Charikar [4]. It would be interesting to show the same result for the stronger SDP.

Acknowledgements. I am grateful to Sanjeev Arora for reading an earlier draft of this work and for bringing [10] to my attention.

Abstract. This paper considers the Steiner tree problem in the model of *two-stage stochastic optimization with recourse*. This model, the focus of much recent research [11, 16, 8, 18], tries to capture the fact that many infrastructure planning problems have to be solved in the presence of uncertainty, and that we have to make decisions knowing merely market forecasts (and not the precise set of demands); by the time the actual demands arrive, the costs may be higher due to inflation.

In the context of the Stochastic Steiner Tree problem on a graph $G = (V, E)$, the model can be paraphrased thus: on Monday, we are given a probability distribution π on subsets of vertices, and can build some subset E_M of edges. On Tuesday, a set of terminals D materializes (drawn from the same distribution π). We now have to buy edges E_T so that the set $E_M \cup E_T$ forms a Steiner tree on D . The goal is to minimize the expected cost of the solution.

We give the first constant-factor approximation algorithm for this problem. To the best of our knowledge, this is the first $O(1)$ -approximation for the stochastic version of a *non sub-additive problem*. In fact, algorithms for the *unrooted* stochastic Steiner tree problem we consider are powerful enough to solve the Multicommodity Rent-or-Buy problem, itself a topic of recent interest [3, 7, 15].

1 Introduction

Real world planning problems often have a significant component of uncertainty. For instance, when designing networks, the precise demand patterns and future costs of building capacity are often unknown to begin with, and only become clear as time progresses. However, with our increasing ability to collect statistical data, and the development of sophisticated and realistic forecast models, the paradigm of stochastic optimization has gained much traction. Indeed, we can now aim to solve a wider class of problems: given not a single input, but a distribution over inputs, we want to find a solution that is good in expectation (taken with respect to the randomness in the model).

In this paper, we study the problem of connecting a group of terminals by a Steiner tree in a stochastic setting. In the classical Steiner tree problem, we are given an undirected graph $G = (V, E)$ with edge costs c_e , and a group of terminals $g = \{t_1, t_2, \dots\}$,

* Supported by ONR grant N00014-98-1-0589 (at Cornell University) and NSF grant EIA 02-05116 (at DIMACS).

$t_k\}$; the goal is to find a subset E' of edges of minimum cost that connects all these terminals. We consider this problem when the group g is not deterministically given in advance; instead, it is given by a random variable Γ , with $\Pr[\Gamma = g]$ being the probability that we will be required to build a network that connects a particular group $g \subseteq V$ of terminals. As sketched in the abstract, we work the model of two-stage stochastic optimization with recourse.

- In the first stage, we assume to have (some) knowledge of the distribution of the random variable Γ . Armed with this information, we construct a network $F^0 \subseteq E$ of edges bought as the first *anticipatory* part of the solution.
- In the second stage, we learn a group $g \subseteq V$ of terminals that is a realization of the random variable Γ . We have to purchase an additional *augmenting* set $F^1(g)$ of edges to ensure that $F^0 \cup F^1(g)$ connects the terminals of g . The problem is interesting when the edges bought in the second stage have a higher cost (due to inflation, or because the second phase has to be built on short notice). We use $\sigma > 1$ to denote the *inflation factor* by which the edges are more expensive.

Our goal is to minimize the expected cost of the two-stage solution. If we define $c(F) = \sum_{e \in F} c_e$, and denote the first and second stage solutions $F^0 \in E$ and $F^1 : 2^V \mapsto 2^E$ to minimize

$$c(F^0) + \mathbf{E}_\Gamma[\sigma \cdot c(F^1(\Gamma))]. \tag{1.1}$$

Our results. The main quantitative result of this paper is the following:

Theorem 1. *There is a 12.6-approximation algorithm for the two-stage stochastic (unrooted) Steiner tree problem.*

Note that while the stochastic Steiner tree problem has been considered in previous papers [11, 8, 9], their model is subtly but significantly different. All these works make the crucial assumption that there is a *fixed root* r , and the goal is to connect the group g to the root r . This assumption, while a trifling detail in the deterministic case, turns out to make a big difference in the stochastic setting, requiring us to develop new techniques. For example, a fact used in one way or another by all previous results was that the first stage solution F^0 in the rooted case can be assumed to be a connected tree containing the root; this is just not true in the unrooted case: insisting on a connected first stage network may cost arbitrarily more than the optimum solution. Indeed, our result is the first approximation algorithm given for a problem that is not sub-additive, and requires us to interpret and use cost-sharing ideas in a novel way.

Specifying the distribution. The distribution π of the random variable Γ is an object whose size may be exponential in $|V|$. Our algorithm does not need to know π explicitly; it only requires access to a *sampling oracle* that can upon request supply independent samples drawn from the distribution π .

Related work. As already mentioned, several papers studied the *rooted version* of the stochastic Steiner tree problem. Immorlica et al. [11] give a $O(\log n)$ approximation in the independent decisions model, while [8] and [9] give constant approximation algorithms for the oracle and scenario models respectively. Karger and Minkoff [13] and

Hayrapetyan et al. [10] study the *maybecast* problem, where one is to output a single tree T , to minimize the expected size of the smallest subtree of T spanning a random set of terminals. While technically this is also a stochastic problem, the recourse action is fixed, and the randomness is present only in the objective function.

Gupta et al. [8] give a simple boosted sampling framework to convert an algorithm for a deterministic minimization problem to an algorithm for its stochastic counterpart. Their framework relies crucially on two ingredients: the deterministic version of the problem at hand has to be *subadditive*, and have an approximation algorithm that admits a *strict* cost sharing function. Since the unrooted Steiner tree problem is not sub-additive (i.e., if T_1 is a solution for terminal set g_1 , and T_2 for g_2 , then $T_1 \cup T_2$ may not be a solution for $g_1 \cup g_2$), we cannot apply their techniques directly here.

The general area of stochastic optimization is studied heavily in the operations research community, dating back to the seminal works of Dantzig [5] and Beale [2] in the 1950s; the books [4, 12] and monograph [17] could serve as introduction for the interested reader. Much of the work related to combinatorial optimization problems in this area has been concerned with finding and characterizing optimal solutions either for restricted classes of inputs or with algorithms without polynomial running times guarantees. Recently, there has been some work on taking solutions to stochastic linear programs and rounding those to obtain approximation algorithms for the stochastic problems [18]; however, it is not clear how to apply those techniques to the Steiner tree problem.

The Boosted Sampling Framework. Gupta et al. [8] propose the *Boosted Sampling* framework of Figure 1 to solve any two-stage stochastic problem Π where the set Γ of demand points is stochastic.

One would naturally expect that in the case of stochastic Steiner tree, the deterministic algorithm of Step 2 would build a Steiner tree on the set of terminals $g_1 \cup g_2 \cup \dots \cup g_\sigma$. In fact, if the support of Γ was on sets that all contained the fixed root r , [8] shows that this is enough to obtain an 3.55-approximation algorithm for stochastic Steiner tree.

Unfortunately, building a Steiner tree fails in the unrooted case. For an example, consider two groups g_1 and g_2 that are very far apart relative to their diameter; assume that $\Pr[\Gamma = g_i] \cdot \sigma$ is large. In this case, the optimum solution must connect up each group g_i in the first stage to avoid high second stage cost, but it should not build a link between g_1 and g_2 (to make F_0 span $g_1 \cup g_2$) if it wants to avoid a high first stage cost. On the other hand, if the two groups are interspersed in the same region

-
- 1: *Boosted Sampling:* Take $\lfloor \sigma \rfloor$ independent samples $g_1, g_2, \dots, g_{\lfloor \sigma \rfloor}$ from the sampling oracle for Γ .
 - 2: *Building First Stage Solution:* Use an algorithm \mathcal{A} to find a solution to the *deterministic equivalent* of the problem Π on the groups $g_1, g_2, \dots, g_{\lfloor \sigma \rfloor}$. Use this solution as the first stage solution to the stochastic problem.
 - 3: *Building Recourse:* Once the group g of required terminals materializes, use an *augmenting algorithm* $\text{Aug}_{\mathcal{A}}$ to augment the first stage solution to a valid solution that satisfies g .
-

Fig. 1. Algorithm Boost-and-Sample(Π)

of the graph, the optimum solution may benefit from link sharing and hence build a single Steiner tree spanning both groups. Hence it seems natural to suggest that the algorithm \mathcal{A} should build a forest ensuring that each group lies within a single connected component; different groups may or may not be in the same component. As it turns out, building a *Steiner Forest* on the groups g_i is a suitable deterministic equivalent of stochastic unrooted Steiner tree; however, proving this requires a lot more work.

To this end, we have to show that the main theorem of [8] which relates the performance of the boosted sampling framework to the notion of *strictness* (which we define shortly) of certain cost-sharing functions can be proved in our case, even though our problem is not sub-additive. The proof of this is simple, and we will sketch it in Section 2. We then define the cost-shares in Section 3, and prove them to be strict in 4.

2 Notation and Preliminaries

Let $G = (V, E)$ be an undirected weighted graph with weights c_e on the edges. A *network* is simply a subset of the edges. We say that a network F is *feasible* for (or *connects*) a group of terminals $g = \{t_1, t_2, \dots, t_k\}$, if all the terminals of g lie in the same connected component of F . The cost of a network F is simply the sum of costs of its edges; that is $c(F) = \sum_{e \in F} c_e$.

In the *Steiner Forest* problem, given a weighted undirected graph G and a list of groups of terminals $\mathcal{D} = \{g_1, g_2, \dots, g_n\}$ with each $g_i = \{t_{i1}, \dots, t_{ik}\}$, we want to construct a network F of minimum cost that is feasible for each group g_i . For a set \mathcal{D} of terminal groups, let $\text{Sols}(\mathcal{D})$ denote the set of networks that are feasible for each of the groups in \mathcal{D} , and let $\text{OPT}(\mathcal{D})$ be the network in $\text{Sols}(\mathcal{D})$ of minimum cost. An algorithm \mathcal{A} is an α -approximation algorithm for the Steiner Forest problem, if for any set \mathcal{D} of terminal groups, it finds a network $F_{\mathcal{D}} \in \text{Sols}(\mathcal{D})$ of cost at most $\alpha \text{cost}(\text{OPT}(\mathcal{D}))$.

Given a group g of terminals and an existing network $F \subseteq E$, the goal of an *augmenting algorithm* is buy a set of extra edges F' so that $F \cup F'$ is a network that connects the group g . For instance, given a network $F_{\mathcal{D}} \in \text{Sols}(\mathcal{D})$ that connects each of the groups in \mathcal{D} , and a new group $g \notin \mathcal{D}$, the augmenting algorithm $\text{Aug}_{\mathcal{A}}$ seeks to find a set of edges F' of minimum cost so that $F_{\mathcal{D}} \cup F' \in \text{Sols}(\mathcal{D} \cup \{g\})$.

Definition 1. A *cost-sharing function* ξ is a function that, for any instance (G, \mathcal{D}) of the Steiner forest problem, assigns a non-negative real number $\xi(G, \mathcal{D}, g_i)$ to every participating group $g_i \in \mathcal{D}$.

We shall drop a reference to the graph G , if clear from the context. *Note that the cost sharing function assigns shares to groups, and not to the individual terminals.*

Since the above definition is so general, let us specify some properties of these functions that we would like to get. A cost-sharing function ξ is *competitive* if $\sum_{g \in \mathcal{D}} \xi(\mathcal{D}, g) \leq \text{cost}(\text{OPT}(\mathcal{D}))$ holds for any Steiner forest instance (G, \mathcal{D}) . Thus, competitive cost-shares serve as a lower bound on the cost of the optimal solution. The following notion is crucial to the development of the paper, and implicitly places lower bounds on the cost-shares themselves.

Definition 2. A cost sharing function ξ is β -strict with respect to an algorithm \mathcal{A} , if there exists an augmenting algorithm $\text{Aug}_{\mathcal{A}}$, such that for any set of demand groups \mathcal{D} and any group $g \notin \mathcal{D}$,

$$\text{cost}(\text{Aug}_{\mathcal{A}}(\mathcal{A}(\mathcal{D}), g)) \leq \beta \xi(\mathcal{D} + g, g). \tag{2.2}$$

Remark 1. There is a fine distinction between the notion of strictness we use here and strictness as defined in [7, 8]. In [7], strictness was defined only for augmentations with groups of size 2; in this paper, we allow for groups of larger sizes. However, the strictness in [8] is stronger than our notion, and allows for multiple group augmentations; the question of proving strictness by this definition remains open despite much effort.

Given all these definitions, we can now state the the following theorem, which can be derived from the proof of [8–Theorem 3.1]. We defer its proof to a full version of the paper.

Theorem 2. Suppose that \mathcal{A} is an α -approximation algorithm for deterministic Steiner forest. Then, the boosted sampling algorithm of Figure 1 is an $(\alpha + \beta)$ -approximation algorithm for unrooted stochastic Steiner tree whenever there is a cost-sharing function ξ that is β -strict with respect to \mathcal{A} and single group augmentations.

3 The Algorithm \mathcal{A} and the Cost Shares ξ

In this section we review the Steiner forest algorithm of [7], although the algorithm of Becchetti et al. [3] would serve our purpose equally well. Both algorithms are extensions of the algorithm of Agarwal, Klein, and Ravi (AKR) [1], and Goemans and Williamson (GW) [6], and are designed to “build a few extra edges” over and above the AKR-GW algorithms, while keeping the overall cost of the solution within a constant factor of the cost of the optimum. We also describe our cost-sharing method.

Recall that we are given a graph $G = (V, E)$ and a set \mathcal{D} of groups g_1, \dots, g_n of terminals, where each group $g_i = \{t_{i1}, t_{i2}, \dots, t_{ik}\} \subseteq V$. Before defining our algorithm, we review the LP relaxation and the corresponding LP dual of the Steiner forest problem that was used in [6]:

$$\begin{array}{ll} \min \sum_e c_e x_e & \text{(SF-LP)} \\ x(\delta(S)) \geq f(S) \quad \forall S \subseteq V & \\ x_e \geq 0 & \end{array} \qquad \begin{array}{ll} \max \sum_S f(S) y_S & \text{(SF-DP)} \\ \sum_{S \subseteq V: e \in \delta(S)} y_S \leq c_e & \\ y_S \geq 0, & \end{array} \tag{3.3}$$

where $f(S)$ is equal to 1 if S separates g_i for some i (that is, if both $S \cap g_i$ and $(V - S) \cap g_i$ is nonempty), and is 0 otherwise. Note that variables y_S for sets S that do not separate any group are not contributing to the dual objective function, they still play an important role in our algorithm.

We now describe a general way to define primal-dual algorithms for the Steiner forest problem. As is standard for the primal-dual approach, the algorithm will maintain a feasible (fractional) dual, initially the all-zero dual, and a primal integral solution (a

set of edges), initially the empty set. The algorithm will terminate with a feasible Steiner forest, which will be proved approximately optimal with the dual solution (which is a lower bound on the optimal cost by weak LP duality). The algorithms of [1, 6] arise as a particular instantiation of the following algorithm. Our presentation is closer to [1], where the “reverse delete step” of Goemans and Williamson [6] is implicit; this version of the algorithm is more suitable for our analysis.

Our algorithm has a notion of *time*, initially 0 and increasing at a uniform rate. At any point in time, some terminals will be *active* and others *inactive*. All terminals are initially active and eventually become inactive. At any point of time, the vertex set is also partitioned into *clusters*, which can again be either active or inactive. In our algorithm, a cluster will be one or more connected components (w.r.t. the currently built edges). Initially, each vertex is a cluster by itself, and the active clusters are just the terminals. We will consider different rules by which demands and clusters become active or inactive, which we describe shortly. To maintain dual feasibility, whenever the constraint (3.3) for some edge e between two clusters S and S' becomes tight (i.e., first holds with equality), the clusters are *merged* and replaced by the cluster $S \cup S'$. We raise dual variables of active clusters until there are no more such clusters.

We have not yet specified how an edge can get built. Towards this end, let us define a (time-varying) equivalence relation \mathcal{R} on the set of terminals. Initially, all terminals lie in their own equivalence class; these classes will only merge with time. When two active clusters are merged, we merge the equivalence classes of all active terminals in the two clusters. Since inactive terminals cannot become active, this rule ensures that all active terminals in a cluster are in the same equivalence class. (Note that if an active cluster merges with an inactive one, this merging of equivalence classes does not happen.)

We build enough edges to maintain the following invariant: the terminals in the same equivalence class are connected by built edges. This clearly holds at the beginning, since the equivalence classes are all singletons. When two active clusters meet, the invariant ensures that, in each cluster, all active terminals lie in a common connected component. To maintain the invariant, we join these two components by adding a path between them. Building such paths without incurring a large cost is simple but somewhat subtle; Agrawal et al. [1] (and implicitly, Goemans and Williamson [6]) show how to do this. We refer the reader to [1] for details of this procedure, instead of repeating it here. Specifying the rule by which clusters are deemed active or inactive now gives us two different algorithms:

1. **Algorithm** $\text{GW}(G, \mathcal{D})$: A terminal $t_{ij} \in g_i$ is active if the current cluster containing it does not contain the entire group g_i . A cluster is active as long as it contains at least one active demand. This implementation of the algorithm is equivalent to the algorithms of Agrawal et al. [1] and Goemans and Williamson [6].
2. **Algorithm** $\text{Timed}(G, D, T)$: This algorithm takes as an additional input a function $T : V \rightarrow \mathbb{R}_{\geq 0}$ which assigns a *stopping time* to each vertex. (We can also view T as a vector with coordinates indexed by V .) A vertex j is active at time τ if $j \in D$ and $\tau \leq T(j)$. (T is defined for vertices not in D for future convenience, but such values are irrelevant, and can be imagined to be set to 0 for the rest of the paper.) As before, a cluster is said to be active if at least one demand in it is active.

To get a feeling for $\text{Timed}(G, D, T)$, consider the following procedure: run the algorithm $\text{GW}(G, D)$ and set $T_{\mathcal{D}}(j)$ to be the time at which vertex j becomes inactive during this execution. (If $j \notin D$, then $T_{\mathcal{D}}(j)$ is set to zero.) Since a vertex stays active for exactly the same duration of time in the two algorithms $\text{GW}(G, D)$ and $\text{Timed}(G, D, T_{\mathcal{D}})$, the two algorithms clearly have identical outputs. Similarly, if for each $t_{ij} \in g_i$ we set $T(t_{ij}) = \max_{t, t' \in g} d_G(t, t')$, we obtain the algorithm of Könemann et al. [14].

It turns out that the Timed algorithm gives us a nice principled way to force the GW algorithm to build additional edges: run the Timed algorithm with a vector of demand activity times that is larger than what is naturally induced by the GW algorithm.

The Algorithm \mathcal{A} : The algorithm **Algorithm $\mathcal{A}(G, D)$** that we use to build the first stage solution is

- 1: Run $\text{GW}(G, D)$, and let $T_{\mathcal{D}}(v)$ be the time at which v becomes inactive.
- 2: Run $\text{Timed}(G, D, \gamma T_{\mathcal{D}})$ —the timed algorithm with the above time vector $T_{\mathcal{D}}$ scaled up by a parameter $\gamma \geq 1$ —and output the resulting forest $F_{\mathcal{D}}$.

A technical point: when $\gamma > 1$, algorithm \mathcal{A} may raise the dual variables of vertex sets that do not separate any group, and hence do not contribute to the value of the dual objective function. However, this will not hinder our analysis. The fact that $F_{\mathcal{D}}$ is a feasible Steiner network for \mathcal{D} is easily verified, using the fact that the terminals of each group became inactive at the same time $T_{\mathcal{D}}(g_i)$ (equal to $T_{\mathcal{D}}(t_{ij})$ for any $t_{ij} \in g_i$) when g_i became connected, and that $\gamma \geq 1$. We now define the cost shares ξ .

The Cost Shares ξ : We want the cost share of a group g_i of users to account for the growth of components that contain only terminals from g_i . Let $a(g_i, \tau)$ be the number of active clusters in the execution of $\text{GW}(G, D)$ that contain a terminal from g_i but do not contain any active terminals outside g_i . We define the cost share of g_i to be

$$\xi(\mathcal{D}, g_i) = \int a(g_i, \tau) d\tau, \quad (3.4)$$

where the integral is over the entire execution of the algorithm. Note that the cost shares defined by Equation (3.4) do not account for the full cost of the dual solution y , as the cost of growth of clusters with active demands from more than one group more than one active demand is not reflected at all. We could fix this by dividing the cost of growing mixed clusters among participating groups in some way; however, we do not see how to use this to improve our approximation ratio.

Augmentation Algorithm $\text{Aug}_{\mathcal{A}}$: A practical augmenting algorithm $\text{Aug}_{\mathcal{A}}$ would simply contract all edges of $F_{\mathcal{D}}$, and then find an approximate Steiner tree on the terminals of g in this contracted graph $G/F_{\mathcal{D}}$. However, in order to bound the second stage cost, we build a specific Steiner tree on g in $G/F_{\mathcal{D}}$, and argue that the cost of *this* tree can be bounded by $\beta \xi(\mathcal{D} + g, g)$ for some $\beta \in \mathbb{R}$. The construction of this tree is implicit in the proof of Theorem 4, and can be found efficiently in polynomial time if required. In the following, we let $\text{Aug}_{\mathcal{A}}$ be the algorithm that constructs this implicit tree. Our main technical result is thus the following.

Theorem 3. *For any $\gamma > 2$, \mathcal{A} is a $\alpha = (\gamma + 1)$ -approximation for the Steiner network problem, and ξ is a $\beta = (4\gamma/(\gamma - 2))$ -strict cost sharing method with respect to the algorithms \mathcal{A} and $\text{Aug}_{\mathcal{A}}$.*

Proof. The fact that \mathcal{A} is a $(\gamma + 1)$ -approximation can be proved along the lines of [3–Lemma 3.1] (We postpone the details to the full paper). The proof of strictness (Theorem 4) is the analytical heart of this paper, and is given in the following section.

4 Proving Strictness

Our analysis follows a fairly natural line of analysis that was also used in [7]. We start by fixing a set \mathcal{D} of demand groups, and a group $g \notin \mathcal{D}$. To prove strictness of our cost shares, we compare two executions of the GW algorithm: the inflated algorithm $\mathcal{A}(G, \mathcal{D})$ on the set of groups \mathcal{D} that results in the forest $F_{\mathcal{D}}$, and the uninflated algorithm $\text{GW}(G, \mathcal{D} + g)$ which is responsible for computing the cost share $\xi(\mathcal{D} + g, g)$.

Recall that we have to show that g can be connected in $F_{\mathcal{D}}$ with cost at most $O(\xi(\mathcal{D} + g, g))$. We prove this in the following theorem, which also implicitly describes the augmenting algorithm $\text{Aug}_{\mathcal{A}}$. In the rest of the discussion, we will assume that $\gamma > 2$.

Theorem 4. *There is a tree F' in the graph $G/F_{\mathcal{D}}$ that spans all terminals of g and has cost at most $4\gamma/(\gamma - 2) \xi(\mathcal{D} + g, g)$. The tree F' can be constructed in polynomial time.*

The main difficulty in proving Theorem 4 arises from the fact that the two executions $\mathcal{A}(G, \mathcal{D})$ and $\text{GW}(G, \mathcal{D} + g)$ may be very different. Hence it is not immediately clear how to relate the cost of augmenting the forest $F_{\mathcal{D}}$ produced by the former by the cost share $\xi(\mathcal{D} + g, g)$ computed by the latter. To make a direct comparison possible, we work through some transformations that allow us to find a mapping between dual variables in these two executions. In the grand finale, we produce a tree \mathbb{T} that spans terminals of g , and show that a $1/\beta$ fraction of its edges is covered by dual variables corresponding to the cost share of g , which will complete the proof. Let us introduce some time vectors to facilitate this comparison.

- Let $T_{\mathcal{D}}$ be the time vector obtained by running $\text{GW}(G, \mathcal{D})$. Recall that $F_{\mathcal{D}}$ is the forest constructed by $\text{Timed}(G, \mathcal{D}, \gamma T_{\mathcal{D}})$; we also let $\mathcal{R}_{\mathcal{D}}$ be the equivalence relation constructed by the latter algorithm.
- Let $T_{\mathcal{D}+g}$ be the time vector generated by the execution $\text{GW}(G, \mathcal{D} + g)$ and let $\tau = T_{\mathcal{D}+g}(g)$ be the time when the terminals of g got connected in this execution.
- Let T be the vector obtained by truncating $T_{\mathcal{D}+g}$ at time τ . That is, $T(v) = \min(\tau, T_{\mathcal{D}+g}(v))$ for $v \in V$. (The intuition for T is loosely this: we do not care about time after g has been connected, and this truncation captures this fact.)
- Finally, let T_{-g} be the vector T with g “taken out”, that is, $T_{-g}(v) = T(v)$ if $v \notin g$, and $T_{-g}(v) = 0$ if $v \in g$. Let \mathcal{R}_{-g} be the equivalence relation constructed by the execution $\text{Timed}(G, \mathcal{D}, \gamma T_{-g})$.

A side-by-side comparison of the executions $\text{GW}(G, \mathcal{D})$ and $\text{GW}(G, \mathcal{D} + g)$ shows that for all $v \in V$,

$$T_{\mathcal{D}}(v) \geq T_{-g}(v); \quad (4.5)$$

the simple inductive proof is omitted. The forest constructed by $\text{Timed}(G, \mathcal{D}, \gamma T_{-g})$ will serve us as a proxy for the forest $F_{\mathcal{D}}$ created by $\text{Timed}(G, \mathcal{D}, \gamma T_{\mathcal{D}})$; intuitively, since T_{-g} is smaller than $T_{\mathcal{D}}$, it should also produce a forest with fewer edges. We will make this intuition precise in Lemma 1 below.

To state the lemma in a general form that will be useful later, we need some more notation. For two weighted graphs G and G' on the same vertex set V , we write $G' \leq G$ if the shortest path distance between any pair of vertices (u, v) in G' is no more than their distance in G . For a graph $G = (V, E)$ and a set $F \subseteq (V \times V)$, the graph $G' = G/F$ is a *contraction* of G , and is obtained by adding a zero-cost edge in G between every pair $(u, v) \in F$. Since $\mathcal{R} \subseteq V \times V$, we can define G/\mathcal{R} in the same way. It immediately follows that if G' is a contraction of G , then $G' \leq G$. For time vectors, let $T \leq T'$ denote coordinate-wise inequality (and hence we can rewrite (4.5) as $T_{-g} \leq T_{\mathcal{D}}$).

Lemma 1 ([7]). *Let $G \leq G'$ be two weighted graphs and $T \leq T'$ be two time vectors. Then, for the equivalence relations \mathcal{R} and \mathcal{R}' produced by the executions $\text{Timed}(G, \mathcal{D}, T)$ and $\text{Timed}(G', \mathcal{D}, T')$, it holds that $\mathcal{R} \subseteq \mathcal{R}'$.*

A Simpler graph H : We now define a simpler graph $H = G/\mathcal{R}_{-g}$; this graph H will act as a proxy for $G/F_{\mathcal{D}}$ in the following sense. For two vertices u, v connected by a zero-cost path in H , we know that u and v are connected by a path in $F_{\mathcal{D}}$. This is because the inequality $T_{-g} \leq T_{\mathcal{D}}$ used with Lemma 1 implies that $\mathcal{R}_{-g} \subseteq \mathcal{R}_{\mathcal{D}}$; now the invariant maintained by the algorithm Timed implies that there is a path connecting u and v in $F_{\mathcal{D}}$ whenever $(u, v) \in \mathcal{R}_{\mathcal{D}}$.

Thus, to prove Theorem 4, it suffices to exhibit a tree \mathbb{T} in H that spans all terminals of g , and has cost at most $4\gamma/(\gamma - 2)\xi(\mathcal{D} + g, g)$. By the properties of the graph H , it then follows that the network $\mathbb{T} \cup F_{\mathcal{D}}$ is feasible for the group g .

Note that each equivalence class of \mathcal{R}_{-g} can also be thought of as a single (super)-vertex of the graph H ; this view may be more useful in some contexts. To complete the correspondence between the two views, let us extend the definition of a time vector to supernodes in the natural way: if w_C is an equivalence class of the relation \mathcal{R}_{-g} , we let $T(w_C) = \max_{v \in C} T(v_i)$; this allows us to talk about running the Timed algorithm on H with the vector T .

4.1 The Tree \mathbb{T} Spanning Terminals of g

We will obtain the desired Steiner tree on the group g in H by considering the execution of the algorithm $\text{Timed}(H, \mathcal{D} + g, T)$; we denote this execution by \mathcal{E} . Recall that the time vector T was defined to ensure that in the execution $\text{Timed}(G, \mathcal{D} + g, T)$ on the original graph G , the terminals of g eventually merge into a single equivalence class of the respective relation \mathcal{R} . Since the graph H is a contraction of G , it follows from Lemma 1 that the terminals of g must end up in the same equivalence class in \mathcal{E} , and hence in the same connected component of the forest constructed by \mathcal{E} . There is a unique minimal tree that spans the terminals of g in this forest; let \mathbb{T} denote this tree.

Since \mathbb{T} was constructed by the execution \mathcal{E} , all of its edges must be fully tight with the dual grown in \mathcal{E} . Our plan of attack is to show that the dual variables corresponding to the terminals of g account for a significant fraction of this dual, and hence the cost share of g must be large enough to pay for a $1/\beta$ fraction of the tree. To pursue this plan, we introduce the following notion of layers as in [7]; this terminology is just a convenient way of talking about “dual moats”.

In an execution of an algorithm, a *layer* (C, I) corresponds to an active cluster C whose dual variable y_C has been growing during the time interval $I = [\tau_1, \tau_2]$; the *thickness* of this layer is $|I| = \tau_2 - \tau_1$. A *layering* \mathcal{L} of an execution is a set of layers such that, for every time τ and every active cluster C , there is exactly one layer $(C, I) \in \mathcal{L}$ such that $\tau \in I$.

Lonely layers: A layer (C, I) is *lonely*, if it does not contain any active terminals except terminals belonging to g . Thus, the cost share of g can be expressed as the total thickness of lonely layers in any layering of $\text{Timed}(G, \mathcal{D} + g, T)$. Using Lemma 1, we can argue that the total thickness of lonely layers in the execution \mathcal{E} is no more than in $\text{Timed}(G, \mathcal{D} + g, T)$ (see [7] for details). Hence the total thickness of lonely layers in the execution \mathcal{E} is a lower bound on the cost share of g .

We lower bound the thickness of lonely layers by arguing that the thickness of non-lonely layers intersecting \mathbb{T} is significantly smaller than the length of \mathbb{T} : since all of \mathbb{T} has to be covered, this leaves a considerable fraction of the tree to be covered by lonely layers. Hence our overall goal can be reduced to giving an upper bound on the thickness of non-lonely layers that intersect the tree \mathbb{T} .

To get a hold on this quantity, we proceed to compare a layering \mathcal{L} of the execution \mathcal{E} —recall that $\mathcal{E} = \text{Timed}(H, \mathcal{D} + g, T)$ —with a layering \mathcal{L}' of its inflated counterpart $\mathcal{E}' = \text{Timed}(H, \mathcal{D}, \gamma T_{-g})$. We construct a mapping that maps every non-lonely layer $\ell = (C, I) \in \mathcal{L}$ to a distinct layer $\ell' = (C', \gamma I) \in \mathcal{L}'$ that is γ times thicker. (Note that lonely layers do not have a natural counterpart, as the terminals of g do not appear at all in the execution \mathcal{E}' .) To ensure the existence of such a mapping, we align the two layerings to satisfy the following property: if $(C, I) \in \mathcal{L}$ and $(C', I') \in \mathcal{L}'$ with $\gamma I \cap I' \neq \emptyset$, then $I' = \gamma I$. (I.e., $I' = [\gamma\tau_1, \gamma\tau_2]$ and $I = [\tau_1, \tau_2]$.) This condition can easily be imposed by repeatedly *splitting* layers of \mathcal{L} and \mathcal{L}' , that is, replacing an offending layer $(C, [\tau_1, \tau_2])$ by two layers $(C, [\tau_1, \hat{\tau}])$ and $(C, [\hat{\tau}, \tau_2])$ for a suitably chosen $\hat{\tau} \in [\tau_1, \tau_2]$.

Mapping non-lonely layers of \mathcal{L} to layers of \mathcal{L}' : Every non-lonely layer $\ell = (C, [\tau_1, \tau_2])$ must contain a terminal $t \in C$ such that $t \notin g$, that was active in the interval $[\tau_1, \tau_2]$. Since $T_{-g} \leq T_{\mathcal{D}}$, the terminal t must have been active in the interval $[\gamma\tau_1, \gamma\tau_2]$ in the execution \mathcal{E}' , and hence there is a unique layer $\ell' = (C', [\gamma\tau_1, \gamma\tau_2])$ such that $t \in C'$. We thus map ℓ to ℓ' . A layer ℓ may contain multiple active terminals outside g ; in that case, pick one of them arbitrarily.

The following two lemmas supply us with all the ammunition we will need to finish our argument. In the next lemma, let $V(\mathbb{T})$ denote the vertex set of the tree \mathbb{T} . The proofs are omitted due to lack of space.

Lemma 2. *The mapping from non-lonely layers of \mathcal{L} to layers of \mathcal{L}' is one to one; that is, distinct layers of \mathcal{L} map to distinct layers of \mathcal{L}' .*

Lemma 3. *Let $\ell = (C, I) \in \mathcal{L}$ be a non-shared layer, such that $V(\mathbb{T}) \cap C \neq \emptyset$. Then, for its corresponding layer $\ell' = (C', \gamma I)$ we have that $V(\mathbb{T}) \cap C' \neq \emptyset$.*

4.2 The Book Keeping

Let L and N denote the total thickness of lonely and non-lonely layers that intersect the tree \mathbb{T} . Note that we count every layer only once, irrespective of how many edges of \mathbb{T} it cuts. We can express the total length of the tree as

$$|\mathbb{T}| = L + N + X, \tag{4.6}$$

where X represents the “extra” contributions of layers that intersect \mathbb{T} more than once. (If a lonely layer intersects \mathbb{T} in three edges, it is counted once in L and twice in X .)

At any time instant τ , consider all the active clusters in the execution \mathcal{E} that have a non-empty intersection with the tree \mathbb{T} . We claim that any such cluster C “carves out” a connected portion of the tree \mathbb{T} , that is, $C \cap \mathbb{T}$ is a connected graph. Hence if we construct a graph with a node for every cluster intersecting \mathbb{T} and an edge between every pair of clusters connected by a direct path along \mathbb{T} , this graph will also be a tree. The number of layers intersecting \mathbb{T} is equal to the number of nodes in this graph; the number of times each layer intersects \mathbb{T} is equal to the degree of the corresponding vertex in this graph. Since the average vertex degree in a tree is at most 2, the number of intersections is at any time bounded by twice the number of layers intersecting \mathbb{T} . Integrating over the course of the execution \mathcal{E} , we obtain that

$$L + N + X \leq 2(L + N). \tag{4.7}$$

A non-lonely layer ℓ is considered *wasted* if ℓ intersects \mathbb{T} , but its image ℓ' does not. According to Lemma 3, this happens only if \mathbb{T} is fully contained inside ℓ' . Let W denote the total thickness of wasted layers. The total thickness of layers of \mathcal{L}' intersecting \mathbb{T} is a lower bound on the length of \mathbb{T} . Since the image of every non-lonely layer ℓ that intersects \mathbb{T} and is not wasted also intersects \mathbb{T} , and because images of distinct layers do not overlap, we get the following lower bound on the length of \mathbb{T} .

$$\gamma(N - W) \leq |\mathbb{T}|. \tag{4.8}$$

The final piece of our argument is the following claim: for every layer that is wasted, there must be a lonely layer growing at the same time, and hence $W \leq L$. To see this claim, suppose that a non-lonely layer $\ell = (C, I)$ intersects \mathbb{T} but is wasted—hence for its inflated image $\ell' = (C', \gamma I)$, we have $V(\mathbb{T}) \subseteq C'$. Since ℓ intersects \mathbb{T} , there must be a terminal $t \in g$ such that $t \notin C$. We now claim that during the interval I , the terminal t must have been a part of a lonely cluster. Indeed, suppose not; let t be inside a non-lonely layer $\ell_1 = (C_1, I)$ with some other active terminal $t_1 \notin g$. But then, by Lemma 3, the inflated image $\ell'_1 = (C'_1, \gamma I)$ of this layer ℓ_1 must contain some

vertex of \mathbb{T} , and since $V(\mathbb{T}) \subseteq C'$, the layers ℓ' and ℓ'_1 have a nonempty intersection. This is possible only if ℓ' and ℓ'_1 are the same inflated layer, which contradicts Lemma 2, as the clearly distinct layers ℓ and ℓ_1 would then map to the same layer $\ell' = \ell'_1$. Thus,

$$W \leq L. \quad (4.9)$$

Combining the inequalities (4.6–4.9), we obtain $(\gamma - 2)|\mathbb{T}| \leq 4\gamma L$, thus proving Theorem 4.

Approximation Algorithms for the Max-coloring Problem^{*}

Sriram V. Pemmaraju and Rajiv Raman

The University of Iowa, Iowa City, IA 52242, USA
{sriram, rraman}@cs.uiowa.edu

Abstract. Given a graph $G = (V, E)$ and positive integral vertex weights $w : V \rightarrow \mathbf{N}$, the *max-coloring problem* seeks to find a proper vertex coloring of G whose color classes C_1, C_2, \dots, C_k , minimize $\sum_{i=1}^k \max_{v \in C_i} w(v)$. The problem arises in scheduling conflicting jobs in batches and in minimizing buffer size in dedicated memory managers.

In this paper we present three approximation algorithms and one inapproximability result for the max-coloring problem. We show that if for a class of graphs \mathcal{G} , the classical problem of finding a proper vertex coloring with fewest colors has a c -approximation, then for that class \mathcal{G} of graphs, max-coloring has a $4c$ -approximation algorithm. As a consequence, we obtain a 4-approximation algorithm to solve max-coloring on perfect graphs, and well-known subclasses such as chordal graphs, and permutation graphs. We also obtain constant-factor algorithms for max-coloring on classes of graphs such as circle graphs, circular arc graphs, and unit disk graphs, which are not perfect, but do have a constant-factor approximation for the usual coloring problem. As far as we know, these are the first constant-factor algorithms for all of these classes of graphs. For bipartite graphs we present an approximation algorithm and a matching inapproximability result. Our approximation algorithm returns a coloring whose weight is within $\frac{8}{7}$ times the optimal. We then show that for any $\epsilon > 0$, it is impossible to approximate max-coloring on bipartite graphs to within a factor of $(\frac{8}{7} - \epsilon)$ unless $P = NP$. Thus our approximation algorithm yields an optimum approximation factor. Finally, we also present an exact sub-exponential algorithm and a PTAS for max-coloring on trees.

1 Introduction

The *max-coloring problem* takes as input a vertex-weighted graph $G = (V, E)$ with weight function $w : V \rightarrow \mathbf{N}$. The problem requires that we find a proper vertex coloring of G whose color classes C_1, C_2, \dots, C_k , minimize the sum of the weights of the heaviest vertices in the color classes, that is, $\sum_{i=1}^k \max_{v \in C_i} w(v)$. When all the weights are one, this problem reduces to the classical problem of

finding a proper vertex coloring of a graph using fewest possible colors. For any color class C of G , we will use $weight(C)$ to denote $\max\{w(v) \mid v \in C\}$. The *weight* of a coloring C_1, C_2, \dots, C_k is then $\sum_{i=1}^k weight(C_i)$.

The max-coloring problem arises in two distinct applications. In one application the max-coloring problem models the problem of minimizing the total buffer size needed for memory management in wireless protocol stacks like GPRS or 3G [7] and in digital signal processing applications [2]. In general, programs that run with stringent memory or timing constraints use a dedicated memory manager that provides better performance than the general purpose memory management of the operating system. The most commonly used memory manager design for this purpose is the *segregated buffer pool*. The problem of minimizing the total size of the buffer pool corresponds to the max-coloring problem.

A second application of max-coloring arises in the scheduling of jobs with conflicts in a multiprocessor environment. In systems in which jobs require exclusive access to certain resources, a fundamental problem is of scheduling jobs onto processors such that jobs requiring access to the same resource are not scheduled together. The problem of scheduling jobs in conflict to processors can be modeled as a graph coloring problem. When jobs have different processing times, this is modeled as a generalized coloring problem on vertex weighted graphs. One such generalization that models the problem of scheduling conflicting jobs in batches to minimize the *makespan* or the time to complete all the jobs in the system corresponds to the max-coloring problem.

Our Results. Although graph coloring is hopelessly hard to approximate on general graphs, the underlying conflict graphs that arise in applications have more structure, and this structure can be exploited to obtain efficient exact or approximation algorithms for max-coloring. However, the max-coloring problem is hard even on instances where the coloring problem can be solved in polynomial time. In [7], the authors prove that max-coloring is NP-hard on interval graphs, even though there is a simple greedy algorithm for the usual coloring problem [1]. [7] also presents a 2-approximation for the max-coloring problem on interval graphs. For other classes of graphs, very little seems to be known about how to solve the max-coloring problem efficiently, either exactly or approximately. In this paper we present three approximation algorithms and one inapproximability result. We show that for any hereditary¹ class of graphs \mathcal{G} , if the usual vertex coloring problem has a c -approximation, then max-coloring has a $4c$ -approximation on \mathcal{G} . One implication is that there is a 4-approximation algorithm to solve max-coloring on perfect graphs. For bipartite graphs we present an approximation algorithm and a matching inapproximability result. Our approximation algorithm always returns a coloring whose weight is within $\frac{8}{7}$ times the optimal and following this we show that for any $\epsilon > 0$, it is impossible to approximate max-coloring on bipartite graphs to within a factor of $(\frac{8}{7} - \epsilon)$ unless

¹ A class \mathcal{G} of graphs is hereditary, if for any $G \in \mathcal{G}$, every induced subgraph of G is also in \mathcal{G} .

$P = NP$. Thus our approximation algorithm yields an optimum approximation factor. Finally, we also present an exact sub-exponential algorithm and a PTAS for trees. The max-coloring problem on trees was also studied by Guan and Zhu [3] where the authors present a polynomial time algorithm that finds an optimal max-coloring of a given tree, that uses exactly r colors for a fixed constant r .

2 Max-coloring Trees

The max-coloring problem has turned out to be surprisingly difficult even for trees. Though we believe that the problem can be solved in polynomial time, the two best algorithms we have are (i) a sub-exponential exact algorithm and (ii) a PTAS. We present these in this section. Our first observation is on the distribution of weights of color classes in an optimal max-coloring of bipartite graphs.

Lemma 1. *Let G be a bipartite graph. Let $\{C_1, C_2, \dots, C_k\}$ be an optimal max-coloring of G with $w_i = \text{weight}(C_i)$ and $w_1 \geq w_2 \geq \dots \geq w_k$. Then, we have that $w_i \geq \sum_{j=i+1}^k w_j$, $i = 1, \dots, k - 1$.*

Proof. If $w_i < \sum_{j=i+1}^k w_j$, then the subgraph induced by vertices in $\cup_{j=i}^k C_j$ can be colored with two colors with weight at most $2w_i$. This coloring has weight less than the weight of $\{C_1, C_2, \dots, C_k\}$, a contradiction. \square

Corollary 1. *Let G be a bipartite graph. Let $\{C_1, \dots, C_k\}$ be an optimal max-coloring of G with $w_i = \text{weight}(C_i)$ and $w_1 \geq w_2 \geq \dots \geq w_k$, we have that $\frac{w_i}{2} \geq w_{i+2}$, for $i = 1, \dots, k - 2$, and hence, $w_1 \geq 2^{\lfloor (i-1)/2 \rfloor} \cdot w_i$.*

Since the weights of the color classes decrease rapidly, we can expect that the max-color number of a tree may not be too high. Let $\chi_{mc}(G)$ denote the max-color number of a graph G , the minimum number of colors required in a minimum cost max-coloring. We now state three upper bounds on χ_{mc} .

Lemma 2. *Let T be an n -vertex tree with maximum degree Δ . Let W denote the ratio of the weight of the heaviest vertex to the weight of the least heavy vertex. Then, (i) $\chi_{mc}(T) \leq \Delta + 1$, (ii) $\chi_{mc}(T) \leq \lceil \log_2 n \rceil + 1$, and (iii) $\chi_{mc}(T) \leq \lceil \log_2 W \rceil + 1$.*

Proof. Let $k = \chi_{mc}(T)$ and let $\{C_1, \dots, C_k\}$ be the color classes in an optimal max-coloring of T . Let $w_i = \text{weight}(C_i)$ and without loss of generality assume that $w_1 \geq w_2 \geq \dots \geq w_k$.

(i) Suppose $\chi_{mc}(T) > \Delta + 1$. For each vertex v in C_k , we can find a color class C_i , $i < k$ such that v is not adjacent to any vertex in C_i . We can thus move each vertex in C_k to a lower color class thus decreasing the coloring weight, a contradiction. Note that this upper bound holds in general for any graph G .

(ii) For each $i > 1$, we can assume without loss of generality that every vertex $v \in C_i$ has a neighbor in C_j , for every $j < i$.

For each vertex $v \in C_1$, let $T(v)$ denote the rooted tree with one vertex, namely v . For each $v \in C_i$, $i > 1$, define $T(v)$ as the tree rooted at v , such that (i) the children of v in $T(v)$ are exactly the neighbors of v in T belonging to color classes C_1, C_2, \dots, C_{i-1} , and (ii) for each child u of v , the subtree of $T(v)$ rooted at u is simply $T(u)$. For each i , $1 \leq i \leq k$, let $S_i = \min\{|T(v)| \mid v \in C_i\}$. In other words, S_i is the size of a smallest tree $T(v)$ rooted at a vertex v in C_i . Then,

$$S_1 = 1$$

$$S_i \geq \sum_{j=1}^{i-1} S_j + 1, \text{ for each } i > 1$$

This implies that $S_i \geq 2^{i-1}$, $1 \leq i \leq k$. Using the fact that $S_k \leq n$, we get $\chi_{mc} = k \leq \lfloor \log_2 n \rfloor + 1$.

(iii) Let $\ell = \min\{t \in \mathbf{N} \mid \text{for all } v \in V(T), w(v) \geq w_1/2^t\}$. Therefore, $\ell = \lceil \log_2 W \rceil$. Recall that W is the ratio of the weights of the heaviest vertex to the lightest vertex. Consider the collection of disjoint intervals $\mathcal{I} = \{I_0, I_1, \dots, I_{\ell-1}\}$, where $I_i = [\frac{w_1}{2^{i+1}}, \frac{w_1}{2^i})$, for $i = 1, \dots, \ell - 1$ and let $I_0 = [\frac{w_1}{2}, w_1]$. Because of the choice of ℓ , for each vertex $v \in V(T)$, $w(v)$ belongs to exactly one interval I_j . Let $V_j = \{v \in V(T) \mid w(v) \in I_j\}$, $j = 0, 1, \dots, \ell - 1$. We say that a vertex v contributes to a color class C_i if $v \in C_i$, and $w(v) = \max\{w(u) \mid u \in C_i\}$. The contribution of an interval I_j is the maximum number of vertices in V_j that contribute to distinct color classes.

Corollary 1 tells us that $w_i \geq 2 \cdot w_{i+2}$ for $i = 1, \dots, k - 2$. This immediately implies that no interval I_j , $j = 1, 2, \dots, \ell - 1$ has a contribution of more than two. Now suppose that intervals $I_{i_1}, I_{i_2}, \dots, I_{i_t}$, $0 \leq i_1 < i_2 < \dots < i_t \leq \ell - 1$, is the sequence of all intervals in \mathcal{I} , each of whose contribution is two. We now claim that for any pair of consecutive intervals I_p , $p = i_j$ and I_q , $q = i_{j+1}$, where $j < t$, there is an interval in $\{I_{p+1}, I_{p+2}, \dots, I_{q-1}\}$ with contribution zero. If we can show this claim, then we can charge the ‘‘extra’’ contribution of each I_i to an interval between I_i and I_{i+1} , whose contribution is zero. Since there are ℓ intervals and since the contribution of I_i is at most two, there is a total contribution of at most $\ell + 1$, implying that there are at most $\ell + 1$ color classes.

We prove the above claim by contradiction, assuming that the contribution of every interval in $\{I_{p+1}, I_{p+2}, \dots, I_{q-1}\}$ is one. Let $\{x_p, x_{p+1}, \dots, x_q\} \cup \{y_p, y_q\}$ be vertices such that (i) for each $j = p, p + 1, \dots, q$, $x_j \in V_j$ and x_j contributes to some color class and (ii) for each $j \in \{p, q\}$, $y_j \in V_j$ and x_j and y_j contribute to distinct color classes. Since $x_j \in V_j$, $w(x_j) \geq \frac{w_1}{2^{j+1}}$, $j = p, p + 1, \dots, q$. Also, since $y_q \in V_q$, $w(y_q) \geq \frac{w_1}{2^{q+1}}$. Therefore,

$$\begin{aligned} \sum_{j=p}^q w(x_j) + w(y_q) &\geq \sum_{j=p}^q \frac{w_1}{2^{j+1}} + \frac{w_1}{2^{q+1}} \\ &= w_1 \frac{2^{q-p+1} - 1}{2^{q+1}} + \frac{w_1}{2^{q+1}} \\ &= \frac{w_1}{2^p} > w(y_p) \end{aligned}$$

This contradicts Lemma 1 and proves the claim. □

There are simple examples that show that the bounds in Lemma 2 are all tight [6].

Since the number of colors are at most $\lceil \log n \rceil + 1$, this immediately gives a simple sub-exponential time algorithm. Try all $\lceil \log n \rceil + 1$ possible colors for each vertex, and return a feasible coloring of minimum weight. This algorithm runs in $O(n^{\log n + 1})$ time.

Now we show that if the given tree has a constant number of distinct vertex weights, we can find an optimal max-coloring in polynomial time. We deal with the case of constant number of distinct weights via the solution to a problem called FEASIBLE k -COLORING.

FEASIBLE k -COLORING

INPUT: A tree T with weight function $w : V \rightarrow \mathbf{N}$, and a positive integer sequence (W_1, W_2, \dots, W_k) of positive integers, satisfying $W_1 \geq W_2 \geq \dots \geq W_k$.

OUTPUT: Either a coloring of the tree into color classes A_1, \dots, A_k , such that for all $v \in A_i$, $w(v) \leq W_i$ or if such a coloring does not exist, a report that no such feasible coloring exists.

There is a simple dynamic programming algorithm for solving FEASIBLE k -COLORING on trees in $O(nk)$ time [6].

The main idea underlying our PTAS is the reduction of the number of distinct weights of the vertices down to a constant. We then pick candidates for the weights of the color classes and for each such choice, using the algorithm for FEASIBLE k -COLORING, we test if there is a legal coloring of the tree with the chosen weights for the color classes.

We are given a tree T , with weight function $w : V \rightarrow \mathbf{N}$ and an $\epsilon > 0$. Let $c > 0$ be an integer such that $(2 \log c + 3)/c \leq \epsilon$, and let $\alpha = (W - 1)/c$ where W is the maximum weight of any vertex. Let I_1, I_2, \dots, I_c be a partition of the range $[1, W]$, where $I_i = [1 + (i - 1)\alpha, 1 + i \cdot \alpha)$, $1 \leq i \leq c$. Let T' be a tree that is identical to T , except in its vertex weights. The tree T' has vertex weights $w' : V \rightarrow \mathbf{N}$ defined by the rule: for any $v \in V$, if $w(v) \in I_j$ then $w'(v) = 1 + (j - 1) \cdot \alpha$ and if $w(v) = W$, then $w'(v) = W$. In other words, except for vertices with maximum weight W , all other vertices have their weights “rounded” down. As a result T' has $c + 1$ distinct vertex weights. Now let OPT' denote the weight of an optimal max-coloring of T' and let $\mathcal{C}' = C'_1, C'_2, \dots, C'_k$ be the color classes corresponding to OPT' . Since the weights of vertices have fallen in going from T to T' , clearly $OPT' \leq OPT$. If we use the coloring \mathcal{C}' for T , we get a coloring whose weight is at most $OPT' + k\alpha$. Substituting $(W - 1)/c$ for α and noting that $W \leq OPT'$, we obtain that weight of \mathcal{C}' used as a coloring for T is at most $(1 + \frac{k}{c})OPT'$. We now show that given the distribution of vertex weights of T' , $k = O(\log c)$. If $k = 2$ we are done, so assume that $k \geq 3$. To see this first observe that the weights of last three color classes C'_k, C'_{k-1} , and C'_{k-2} cannot all be identical, by Lemma 1. Also, observe that the possible vertex weights of T' are $1, 1 + \alpha, 1 + 2\alpha, \dots$. Therefore, $weight(C'_{k-2}) \geq 1 + \alpha$. From Corollary 1, we obtain

$$1 + \alpha \leq weight(C'_{k-2}) \leq \frac{W}{2^{\lfloor (k-3)/2 \rfloor}}.$$

Solving this for k yields $k \leq 2 \log_2(c) + 3$. Therefore, by our choice of c , we have

$$\frac{k}{c} \leq \frac{2 \log_2(c) + 3}{c} \leq \epsilon.$$

Thus $(1 + \epsilon)OPT'$ is an upper bound on the weight of C' used as a coloring for T . Since $OPT' \leq OPT$, we see that the weight of C' used as a coloring for T is at most $(1 + \epsilon)OPT$.

To construct OPT' in polynomial time, for each $k = 1, \dots, 2 \lceil \log_2 c \rceil + 3$, we generate all $O(c^k)$ possible sequences of weights and call algorithm **FEASIBLE k -COLORING** for each subsequence and pick the coloring with the minimum weight. This gives OPT' . Each solution to **FEASIBLE k -COLORING** takes $O(nk)$ time, and we have $O(c^k)$ sequences, for $k = 1, \dots, 2 \lceil \log_2 c \rceil + 3$. Using the fact that $(2 \log_2 c + 3)/c \leq \epsilon$, a little bit of algebra yields a running time that is linear in n and exponential in $1/\epsilon$.

3 Max-coloring Bipartite Graphs

This section presents an $\frac{8}{7}$ -approximation algorithm for the max-coloring problem on bipartite graphs, followed by a hardness of approximation result that shows that for any $\epsilon > 0$, there is no $(\frac{8}{7} - \epsilon)$ -approximation algorithm unless $P = NP$. Thus our approximation algorithm produces an optimal approximation ratio.

One feature of our approximation algorithm is that it uses at most 4 colors, even though an optimal max-coloring of an n -vertex bipartite graph may need a $\Omega(n)$ colors [6]. Our PTAS for the max-coloring problem on trees relied on the fact that the **FEASIBLE k -COLORING** problem on trees can be solved in polynomial time for any k . However, **FEASIBLE k -COLORING** is NP-complete for bipartite graphs for $k \geq 3$ [5]. This has forced us to use a different approach for bipartite graphs. Another difference between max-coloring on trees and max-coloring on bipartite graphs is that in contrast to the $O(\log n)$ upper bound on the number of colors used by an optimal max-coloring for an n -vertex tree, there are simple examples of n -vertex bipartite graphs G with $\chi_{mc}(G) \geq n/2$ [6].

Our $(\frac{8}{7} - \epsilon)$ -hardness result for max-coloring bipartite graphs is via a gap introducing reduction from the **PRE-COLORING EXTENSION** problem [5].

3.1 An $\frac{8}{7}$ -Approximation Algorithm

First note that since bipartite graphs are 2-colorable, Lemma 1 holds and hence if an optimal max-coloring of a bipartite graph uses a large number of colors, the contribution of all but the first few color classes must be quite small. We can use this to our advantage and develop an algorithm that tries to find a *good* approximation to the weights of the first few color classes. We run three algorithms, A_2 , A_3 , and A_4 , that use 2, 3 and 4 colors respectively. The color classes produced by algorithm A_i , $2 \leq i \leq 4$, are denoted $\{A_1^i, A_2^i, \dots\}$, and the weights of the corresponding color classes are denoted $\{a_1^i, a_2^i, \dots\}$. We start with a description of algorithm A_2 .

Algorithm $A_2(G, w)$

1. For each connected component G_i of G do
2. Color G_i with colors 1 and 2, such that a vertex with maximum weight is colored 1.

The fact that A_2 is a 2-approximation immediately follows from the fact that $weight(A_2) \leq 2w_1$, and $w_1 \leq OPT$. We encode this result in the following lemma.

Lemma 3. $weight(A_2) \leq 2w_1$

In an optimum coloring, the weight of the first color class, w_1 is fixed. By using more colors, OPT may gain an advantage because it can then push *heavy* vertices into *lower* color classes. We now introduce algorithm A_3 which constructs a 3-coloring of G such that the weight of the second color class is minimized.

Algorithm $A_3(G, w)$

1. Let S be a *maximal* independent set of G picked by examining vertices in non-increasing weight order.
2. Use Algorithm A_2 to color $G \setminus S$.
3. Rename colors 1 and 2, as colors 2 and 3 respectively.
4. Color S with color 1.

Lemma 4. $weight(A_3) \leq w_1 + 2w_2$.

Proof. In algorithm A_3 , $a_1^3 = w_1$. Since S is a maximal independent set selected in non-increasing weight order, the weight of the second color class of OPT , w_2 cannot be smaller than the weight of any vertex in $G \setminus S$. Hence, $w_2 \geq a_2^3$. Since $a_3^3 \leq a_2^3$, it follows that $weight(A_3) = a_1^3 + a_2^3 + a_3^3 \leq w_1 + w_2 + w_2 = w_1 + 2w_2$. \square

The greedy strategy employed by algorithm A_3 in selecting the first color class causes a_2^3 to be no larger than w_2 . However, it might cause a_3^3 to be significantly larger than w_3 . We rectify this situation by introducing algorithm A_4 that uses four colors to color G .

Algorithm $A_4(G, w)$

1. For all w^* such that there is a $u \in V$, with $w(u) = w^*$ do
2. Partition the vertices of G into two parts

$$P_1 = \{v \in V \mid w(v) > w^*\}, \text{ and}$$

$$P_2 = \{v \in V \mid w(v) \leq w^*\}.$$
3. Use algorithm A_2 to color P_2 .
4. Rename colors 1 and 2 as 3 and 4 respectively.
5. Use algorithm A_2 to color P_1 .
6. Return the coloring with minimum weight, over all choices of w^* .

Lemma 5. $weight(A_4) < w_1 + w_2 + 2w_3$

Proof. Since the weight of every vertex in G is used for the threshold w^* , in some iteration of A_4 , $w^* = w_3$. At this point, A_4 partitions the vertex set such that $P_1 = \{v \mid w(v) > w_3\}$ and $P_2 = \{v \mid w(v) \leq w_3\}$. In this iteration, A_4 colors P_1 with weight at most $w_1 + w_2$, and colors P_2 with weight at most $2w_3$. Since A_4 returns the coloring with minimum weight, over all choices of w^* , it follows that $weight(A_4) \leq w_1 + w_2 + 2w_3$. \square

The final algorithm, which we call **Bipartite Max-Color** runs A_2, A_3, A_4 , and returns the minimum weight coloring.

Theorem 1. *Algorithm Bipartite Max-Color is a $\frac{8}{7}$ -approximation for the max-coloring problem on bipartite graphs.*

Proof. Let $w(B)$ denote the weight of the coloring produced by algorithm **Bipartite Max-Color**. From Lemmas 3, 4, and 5, we know that $w(B) \leq 2w_1$, $w(B) \leq w_1 + 2w_2$, $w(B) \leq w_1 + w_2 + 2w_3$. Now, multiplying the first inequality by 1, the second inequality by 2, the third inequality by 4 and adding, we get

$$7 \cdot w(B) \leq 8 \cdot (w_1 + w_2 + w_3) \leq 8 \cdot OPT \quad \square$$

3.2 An $(\frac{8}{7} - \epsilon)$ -Hardness Reduction

We now show that the $8/7$ -approximation produced by the above algorithm is optimal. We do this by showing a matching hardness result via a reduction from the **PRE-COLORING EXTENSION** problem on bipartite graphs. The **PRE-COLORING EXTENSION** problem for general graphs is defined below.

PRE-COLORING EXTENSION

INPUT: A graph $G = (V, E)$, with $r \geq \chi(G)$, a subset $P \subseteq V$, and a proper assignment $c : P \rightarrow \{1, \dots, r\}$ of colors to vertices in P .

QUESTION: Is there an extension of the proper vertex coloring of P to a proper vertex coloring of G , using colors from $\{1, \dots, r\}$?

In [5], Kratochvil proved that **PRE-COLORING EXTENSION** is NP-complete for planar bipartite graphs even when the color bound $r = 3$. We now show a simple gap introducing reduction from **PRE-COLORING EXTENSION** on bipartite graphs with $r = 3$ to max-coloring on bipartite graphs.

Theorem 2. *For any $\epsilon > 0$, there is no $(8/7 - \epsilon)$ -approximation algorithm for max-coloring on bipartite graphs, unless $P=NP$.*

Proof. The reduction is from **PRE-COLORING EXTENSION**. Let the given instance of **PRE-COLORING EXTENSION** consist of a bipartite graph $G = (V_1, V_2, E)$, a subset $P \subseteq V_1 \cup V_2$, and a proper assignment $c : P \rightarrow \{1, 2, 3\}$ of colors to vertices in P . We transform G into a vertex-weighted bipartite graph $G' = (V'_1, V'_2, E')$ as follows. Add four new vertices, x_1, x_2, y_1 , and y_2 to G . Let $X = \{x_1, x_2\}$,

$Y = \{y_1, y_2\}$, $V'_1 = V_1 \cup X$, and $V'_2 = V_2 \cup Y$. To each vertex $v \in P$, assign a weight $w(v)$ using the rule: $w(v) = 2^{3-i}$ if $c(v) = i$, for each $i \in \{1, 2, 3\}$. If $v \in (V_1 \cup V_2) - P$, set $w(v) = 1$. The new vertices are assigned weights as follows: $w(x_1) = w(y_1) = 4$ and $w(x_2) = w(y_2) = 2$. The edge set E' of G' contains some additional edges between the new vertices and the old.

$$E' = E \cup \{\{x_i, y\} | y \in P \cap V'_2, \text{ and } w(y) < w(x_i)\} \cup \{\{y_i, x\} | x \in P \cap V'_1 \text{ and } w(x) < w(y_i)\} \cup \{\{x_1, y_2\}\} \cup \{\{x_2, y_1\}\}.$$

This completes the description of G' .

Now suppose that the coloring of P can be extended to a proper 3-coloring $c : V_1 \cup V_2 \rightarrow \{1, 2, 3\}$ of G . Start with the coloring c and extend this to a proper vertex coloring of G' by assigning colors to the new vertices as follows: $c(x_1) = c(y_1) = 1$ and $c(x_2) = c(y_2) = 2$. Observe that this indeed produces a proper coloring of G' . To see that the weight of this coloring on G' has weight at most 7, note that the weight of the coloring in G' restricted to the vertices of G is at most 7, and since the coloring above of the vertices $\{x_1, x_2, y_1, y_2\}$ does not increase this cost, we are done.

Now suppose that G does not have a pre-coloring extension. We show by contradiction that in this case G' does not have a proper vertex coloring of weight less than 8. So suppose that there is a proper vertex coloring $c' : V'_1 \cup V'_2 \rightarrow \{1, 2, \dots\}$ of weight less than 8. Without loss of generality, assume that in this coloring, the color classes are labeled in non-increasing order of their weight. Therefore, all vertices of weight 4 are in color class 1. This includes vertices x_1 and y_1 and this forces all vertices of weight 2 to be excluded from color class 1. Since color class 1 has weight 4, to prevent the total weight of the coloring from reaching 8, all vertices of weight 2 have to be included in color class 2. This includes vertices x_2 and y_2 , and so this color class is also non-empty. Therefore the total weight of color classes 1 and 2 is 6. Since c' is a coloring of G' of weight less than 8, it must be the case that color class k , for each $k \geq 4$, is empty. This means that c' is a 3-coloring of G' . Furthermore, it is a 3-coloring of G that respects the pre-coloring of P . This contradicts the assumption that G has no pre-coloring extension and therefore we have that any proper vertex coloring of G' has weight at least 8.

If for some $\epsilon > 0$, there were an $(\frac{8}{7} - \epsilon)$ -approximation algorithm for max-coloring bipartite graphs, then using the above polynomial time transformation from G to G' , we could distinguish between positive and negative instances of PRE-COLORING EXTENSION on bipartite graphs with $r = 3$. This is not possible unless $P = NP$. □

4 Max-coloring on Arbitrary Graphs

Let \mathcal{G} be a hereditary class of graphs for which the minimum vertex coloring problem has a c -approximation. In other words, there is a polynomial time algorithm A that takes a graph $G \in \mathcal{G}$ as input and returns a proper vertex coloring

of G using at most $c \cdot \chi(G)$ colors. In this section, we present an $4c$ -approximation algorithm, that we call **GeomFit**, for the max-coloring problem on the class of graphs \mathcal{G} . The algorithm is inspired by the algorithm of Halldórsson, et. al. [4] for sum-coloring interval and comparability graphs. **GeomFit** will repeatedly use A as a black box to obtain “good” vertex colorings of portions of the input graph. For ease of exposition, below we describe **GeomFit** assuming that $c = 1$.

GeomFit(G, w)

1. Let $i = 0, l_i = 0$
2. While $G \neq \emptyset$ do
 3. Set $c_i = 2^i$
 4. Let $G_i = \text{mkc}(G, c_i)$
 5. Color G_i optimally using colors $l_i + 1, \dots, l_i + c_i$
 6. Set $l_{i+1} = l_i + c_i, i = i + 1$.
 7. Set $G = G \setminus G_i$.
8. End While

A round of the algorithm corresponds to an iteration of the while loop. Suppose that each round is labeled with the value of i at the beginning of that round. For some integer $t > 0$, suppose that the algorithm executes rounds $0, 1, \dots, t - 1$, after which the graph is entirely colored. In each round $i, 0 \leq i < t$, the algorithm calls the subroutine $\text{mkc}(G, c_i)$, that returns a maximal c_i -colorable subgraph of G , obtained by examining vertices in non-increasing order of weight. Here G is the subgraph of the input graph induced by the not yet colored vertices and $c_i = 2^i$. When called, the subroutine $\text{mkc}(G, c_i)$ starts with an empty set S and processes each vertex v of G , in non-increasing order of weight. The subroutine tests if $G[S \cup \{v\}]$ is c_i -colorable or not and if it is, it adds v to S , and proceeds to the next vertex in G . To perform this test, $\text{mkc}(G, c_i)$ calls the algorithm A that returns a minimum vertex coloring of G .

Lemma 6. *If **GeomFit** uses t rounds to color G , then $\chi(G) > c_{t-2}$.*

Proof. In round $t - 2$, the algorithm picks a maximal c_{t-2} colorable subgraph of G . If G were c_{t-2} -colorable, then all of it would have been picked up in round $t - 2$ or earlier. Since we used one more round to color G , it must mean that $\chi(G) > c_{t-2}$. □

Without loss of generality, suppose that OPT uses numbers $1, 2, \dots$ for colors such that color classes are numbered in non-increasing order of weight. Now observe that color classes created in round i by **GeomFit** are all heavier than color classes created in round $i + 1$. Without loss of generality, assume that the color classes created in each round of **GeomFit** are numbered in non-increasing order of weight. Let $color_{OPT}(v)$ denote the color assigned to vertex v in OPT . Now using the color classes of OPT we define a pairwise disjoint collection of vertex subsets of $G, \{V_0, \dots, V_{t-1}\}$, where $V_i = \{v \in G | c_{i-1} < color_{OPT}(v) \leq c_i\}$, $i = 0, \dots, t - 1$. For the definition to make sense, we assume that $c_{-1} = 0$. Since V_{t-1} contains vertices colored $c_{t-2} + 1, c_{t-2} + 2, \dots, c_{t-1}$ by OPT , from Lemma

6, it follows that $V_{t-1} \neq \emptyset$. Now we state and prove a critical inequality that follows from the greedy choice of a subgraph in each round of **GeomFit**. Let W_i denote the weight of color class $c_{i-1} + 1$ in OPT . Note that color class $c_{i-1} + 1$ is a subset of V_i and by our labeling convention, it is a heaviest color class in V_i . Similarly, let R_i denote the weight of color class $l_i + 1$ created by **GeomFit**. Note that this is a heaviest color class created in round i by **GeomFit**. Also note that $l_i = \sum_{j=0}^{i-1} c_j = c_i - 1$ and therefore color class $l_i + 1$ is simply color class c_i .

Lemma 7. $R_i \leq W_i$, for $i = 0, 1, \dots, t - 1$.

Proof. Since R_0 and W_0 are equal to the maximum weight vertex in G , the lemma holds for $i = 0$. By the greedy choice employed in selecting G_0 , we ensure that for any other independent set S of G , the maximum weight of a vertex in $G \setminus S$ is at least as large as the maximum weight vertex in $G \setminus G_0$. This ensures that $R_1 \leq W_1$. By the same reasoning, since in round $i - 1$, we greedily select a maximal c_{i-1} colorable subgraph of OPT , and $V_1 \cup V_2 \cup \dots \cup V_{i-1}$ is c_{i-1} colorable, it follows that $R_i \leq W_i$. □

Theorem 3. Let \mathcal{G} be a hereditary class of graphs on which the minimum vertex coloring problem can be solved in polynomial time. Algorithm **GeomFit** is a 4-approximation algorithm for the max-coloring problem on \mathcal{G} .

Proof. The weight of the max-coloring produced by **GeomFit** is bounded above by

$$weight(\mathbf{GeomFit}) \leq \sum_{i=0}^{t-1} c_i \cdot R_i \leq \sum_{i=0}^{t-1} c_i \cdot W_i$$

The first inequality follows from the fact that in each round i , **GeomFit** uses at most c_i colors and a heaviest color class in round i has weight R_i . The second inequality follows from Lemma 7.

We obtain a lower bound on OPT as follows. The set V_0 contains one color class and this has weight W_0 . Now consider a set V_i , $1 \leq i \leq t - 2$. It contains one color class of weight W_i and the remaining color classes have weight at least W_{i+1} . Recall that V_i has color classes labeled $c_{i-1} + 1, c_{i-1} + 2, \dots, c_i$ and therefore $weight(V_i) \geq W_i + (c_{i-1} - 1)W_{i+1}$.

$$\begin{aligned} OPT &\geq \sum_{i=0}^{t-1} weight(V_i) \geq W_0 + \sum_{i=1}^{t-2} (W_i + (c_{i-1} - 1)W_{i+1}) + W_{t-1} \\ &= W_0 + W_1 + \sum_{i=0}^{t-3} c_i W_{i+2}. \end{aligned}$$

Therefore, $4 \cdot OPT \geq 4W_0 + 4W_1 + \sum_{i=0}^{t-3} 4c_i W_{i+2} = 4W_0 + 4W_1 + \sum_{i=2}^{t-1} c_i W_i$. This lower bound on $4 \cdot OPT$ is larger than the upper bound on $weight(\mathbf{GeomFit})$ above. Therefore, $weight(\mathbf{GeomFit}) \leq 4 \cdot OPT$. □

Now suppose that \mathcal{G} is a hereditary class of graphs that has a c -approximation algorithm A for the minimum vertex coloring problem. A $4c$ -approximation algorithm for max-coloring on graphs in \mathcal{G} is obtained by modifying `GeomFit` slightly. In Step (4), the algorithm computes a maximal $\lfloor c \cdot c_i \rfloor$ -colorable subgraph. Correspondingly, in Step (5), G_i is colored using colors $l_i + 1, \dots, l_i + \lfloor c \cdot c_i \rfloor$. The analysis of this modified `GeomFit` proceeds in a manner similar to the $c = 1$ case. For details, see [6].

Theorem 4. *Let \mathcal{G} be a hereditary class of graphs on which the minimum vertex coloring problem has a c -approximation algorithm. Algorithm `GeomFit` is a $4c$ -approximation algorithm for the max-coloring problem on \mathcal{G} .*

The choice of $c_i = 2^i$ in `GeomFit` gave us an approximation factor of $4c$. This approximation factor can be improved to $3.5c$ by running `GeomFit` twice, once by setting $c_i = 2^i$, and once by setting $c_i = \lfloor 1.5 \times 2^i \rfloor$ and returning the coloring with smaller weight. More generally, setting $c_i = \lfloor \alpha q^i \rfloor$, where α is chosen uniformly at random from a certain range and q is an appropriately chosen constant, may yield a further improvement in the approximation ratio.

Acknowledgments. We would like to thank the anonymous referees for suggestions that led to a simplified proof of Theorem 1, and also for pointing out the work done in [3].

Tight Lower Bounds for Query Processing on Streaming and External Memory Data

Martin Grohe¹, Christoph Koch², and Nicole Schweikardt¹

koch@cs.uni-sb.de

Abstract. We study a clean machine model for external memory and stream processing. We show that the number of scans of the external data induces a strict hierarchy (as long as work space is sufficiently small, e.g., polylogarithmic in the size of the input). We also show that neither joins nor sorting are feasible if the product of the number $r(n)$ of scans of the external memory and the size $s(n)$ of the internal memory buffers is sufficiently small, e.g., of size $o(\sqrt[5]{n})$. We also establish tight bounds for the complexity of XPath evaluation and filtering.

1 Introduction

It is generally assumed that databases have to reside in external, inexpensive storage because of their sheer size. Current technology for external storage systems (disks and tapes) presents us with a reality that performance-wise, a small number of *sequential scans* of the data is strictly preferable over random data accesses. Indeed, the combined latencies and access times of moving to a certain position in external storage are by orders of magnitude greater than actually reading a small amount of data once the read head has been placed on its starting position.

Database engines rely on main memory buffers for assuring acceptable performance. These are usually small compared to the size of the externally stored data. Database technology – in particular query processing technology – has developed around this notion of memory hierarchies with layers of greatly varying sizes and access times. There has been a wealth of research on query processing and optimization along these lines (cf. e.g. [27, 14, 32, 22]). It seems that the current technologies scale up to current user expectations, but on closer investigation it may appear that our theoretical understanding of the problems involved – and of optimal algorithms for these problems – is not quite as developed.

Recently, data stream processing has become an object of study by the data management community (e.g. [15]) but from the viewpoint of database theory, this is, in fact, a special case of the query processing problem on data in external storage where we are limited to a single scan of the input data.

In summary, it appears that there are a variety of data management and query processing problems in which a comparably small but efficiently accessible main memory buffer is available and where accessing external data is costly and is best performed by sequential read/write scans. This calls for an appropriate formal

model that captures the essence of external memory and stream processing. In this paper, we study such a model, which employs a Turing machine with one *external memory tape* (external tape for short) and a number *internal memory tapes* (internal tapes for short). The external tape initially holds the input; the internal tapes correspond to the main memory buffers of a database management system and are thus usually small compared to the input.

As computational resources for inputs of size n , we study the space $s(n)$ available on the internal tapes and the number $r(n)$ of scans of (or, random accesses to) the external tape, and we write $ST(r, s)$ to denote the class of all problems solvable by (r, s) -bounded Turing machines, i.e., Turing machines which comply to the resource bounds $r(n)$ and $s(n)$ on inputs of size n .

Formally, we model the number of scans, respectively the number of random accesses, by the number of reversals of the Turing machine's read/write head on the external tape. The number of reversals of the read/write head on the internal tapes remains unbounded. The reversals done by a read/write head are a clean and fundamental notion [8], but of course real external storage technology based on disks does not allow to reverse their direction of rotation. On the other hand, we can of course simulate k forward scans by $2k$ reversals in our machine model — and allowing for forward as well as backward scans makes our *lower* bound results even stronger.

As we allow the external tape to be both read and written to, the external tape can be viewed, for example, as modeling a hard disk. By closely watching reversals of the external tape head, anything close to random I/O will result in a very considerable number of reversals, while a full sequential scan of the external data can be effected cheaply. We will obtain strong lower bounds in this paper that show that even if the external tape (whose size we do not put a bound on) may be written to and re-read, certain bounds cannot be improved upon. For our matching upper bounds, we will usually not write to the external tape. Whenever one of our results requires writing to the external tape, we will explicitly indicate this.

The model is similar in spirit to the frameworks used in [18, 19], but differs from the previously considered *reversal complexity* framework [8]. Reversal complexity is based on Turing machines with a single read/write tape and the overall number of reversals of the read/write head the main computational resource. In our notion, only the number of reversals on the external tape is bounded, while reversals on the internal tapes are free; however, the space on the internal tapes is considered to be a limited resource.¹

¹ The justification for this assumption is simply that accessing data on disks is currently about five to six orders of magnitude slower than accessing main memory. For that reason, processor cycles and main memory access times are often neglected when estimating query cost in relational query optimizers, where cost measures are often exclusively based on the amount of expected page I/O as well as disk latency and access times. Moreover, by taking buffer space rather than running time as a parameter, we obtain more robust complexity classes that rely less on details of the machine model (see also [31]).

Apart from formalizing the $ST(r, s)$ model, we study its properties and locate a number of data management problems in the hierarchy of $ST(\cdot, \cdot)$ classes. Our technical contributions are as follows:

- We prove a reduction lemma (Lemma 4.1) which allows easy lower bound proofs for certain problems.
- We prove a hierarchy (Corollary 4.11 and Theorem 4.10), stating for each fixed number k that $k + 1$ scans of the external memory tape are strictly more powerful than k scans of the external memory tape.
- We consider machines where the product of the number of scans of the external memory tape, $r(n)$, and internal memory tape size, $s(n)$, is of size $o(\frac{n}{\log n})$, where n is the input size, and show that *joins* cannot be computed by (r, s) -bounded Turing machines (cf., Lemma 4.4).
- We show that the *sorting* problem cannot be solved with $(o(\sqrt[5]{n}), O(\sqrt[5]{n}))$ -bounded Turing machines that are not allowed to write intermediate results to the external memory tape (cf., Corollary 4.9).
- We show (cf., Theorem 4.5) that for some *XQuery* queries, filtering is impossible for machines with $r(T) \cdot s(T) \in o(\frac{n}{\log n})$, where n is the size of the input XML document T .
- We show (cf., Corollary 5.5) that for some *Core XPath* [12] queries, filtering is impossible for machines with $r(T) \cdot s(T) \in o(d)$, where d denotes the *depth* of the input XML document T . Furthermore, we show that the lower bound on *Core XPath* is *tight* in that we give an algorithm that solves the Core XPath filtering problem with a single scan of the external data (zero reversals) and $O(d)$ buffer space.

The primary technical machinery that we use for obtaining lower bounds is that of *communication complexity* (cf. [21]). Techniques from communication complexity have been used previously to study queries on streams [4, 6, 2, 3, 5, 23, 24, 18]. The work reported on in [4] addresses the problem of determining whether a given relational query can be evaluated scalably on a data stream or not at all. In comparison, we ask for tight bounds on query evaluation problems, i.e. we give algorithms for query evaluation that are in a sense worst-case optimal. As we do, the authors of [6] study XPath evaluation; however, they focus on *instance data complexity* while we study worst-case bounds. This allows us to find strong and tight bounds for a greater variety of query evaluation problems. Many of our results apply beyond stream processing in a narrow sense to a more general framework of queries on data in external storage. Also, our worst-case bounds apply for *any* evaluation algorithm possible, that is, our bounds are not in terms of complexity classes closed under reductions that allow for nonlinear expansions of the input (such as LOGSPACE) as is the case for the work on the complexity of XPath in [12, 13, 28].

Lower bound results for a machine model with *multiple* external memory tapes (or harddisks) are presented in [17]. In the present paper, we only consider a single external memory tape, and are consequently able to show (sometimes exponentially) stronger lower bounds.

Due to space limitations we had to defer detailed proofs of our results to the full version of this paper [16] which extends the present paper by an appendix that contains proofs of all results presented here.

2 Preliminaries

In this section we fix some basic notation concerning trees, streams, and query languages. We write \mathbb{N} for the set of non-negative integers. If M is a set, then 2^M denotes the set of all subsets of M . Throughout this paper we make the following convention: Whenever the letters r and s denote functions from \mathbb{N} to \mathbb{N} , then these functions are *monotone*, i.e., we have $r(x) \leq r(y)$ and $s(x) \leq s(y)$ for all $x, y \in \mathbb{N}$ with $x \leq y$.

Trees and Streams. We use standard notation for trees and streamed trees (i.e. *documents*). In particular, we write $Doc(T)$ to denote the XML document associated with an XML document tree T . An example is given in Figure 1.

Query Languages. By $Eval(\cdot, \cdot)$ we denote the evaluation function that maps each tuple (Q, T) , consisting of a query Q and a tree T to the corresponding query result. Let \mathcal{Q} be a query language and let $\mathcal{T}_1 \subseteq Trees_\tau$ and $\mathcal{T}_2 \subseteq \mathcal{T}_1$. We say that \mathcal{T}_2 can be filtered from \mathcal{T}_1 by a \mathcal{Q} -query if, and only if, there is a query $Q \in \mathcal{Q}$ such that the following is true for all $T \in \mathcal{T}_1$: $T \in \mathcal{T}_2 \iff Eval(Q, T) \neq \emptyset$.

We assume that the reader is familiar with first-order logic (*FO*) and monadic second-order logic (*MSO*). An *FO*- or *MSO*-sentence (i.e., a formula without any free variable) specifies a Boolean query, whereas a formula with exactly one free first-order variable specifies a unary query, i.e., a query which selects a set of nodes from the underlying input tree.

It is well-known [9, 30] that the *MSO*-definable Boolean queries on binary trees are exactly the (Boolean) queries that can be defined by finite (deterministic or nondeterministic) bottom-up tree automata. An analogous statement is true about *MSO* on unranked trees and unranked tree automata [7].

Theorem 4.5 in section 4 gives a lower bound on the worst case complexity of the language *XQuery*. As we prove a lower bound for *one* particular *XQuery* query, we do not give a formal definition of the language but refer to [33].

Apart from *FO*, *MSO*, and *XQuery*, we also consider a fragment of the *XPath* language, Core *XPath* [12, 13]. As we will prove not only lower, but also upper bounds for Core *XPath*, we give a precise definition of this query language in [16]. An example of a Core *XPath* query is

$$/descendant::*[child::A and child::B]/child::*,$$

which selects all children of descendants of the root node that (i.e., the descendants) have a child node labeled A and a child node labeled B.

Core *XPath* is a strict fragment of *XPath* [12], both syntactically and semantically. It is known that Core *XPath* is in *LOGSPACE* w.r.t. data complexity

and P-complete w.r.t. combined complexity [13]. In [12], it is shown that Core XPath can be evaluated in time $O(|Q| \cdot |D|)$, where $|Q|$ is the size of the query and $|D|$ is the size of the XML data. Furthermore, every Core XPath query is equivalent to a unary MSO query on trees (cf., e.g., [11]).

Communication complexity. To prove basic properties and lower bounds for our machine model, we use some notions and results from *communication complexity*, cf., e.g., [21].

Let A, B, C be sets and let $F : A \times B \rightarrow C$ be a function. In Yao's [34] basic model of communication two players, Alice and Bob, jointly want to evaluate $F(x, y)$, for input values $x \in A$ and $y \in B$, where Alice only knows x and Bob only knows y . The two players can exchange messages according to some fixed protocol \mathcal{P} that depends on F , but not on the particular input values x, y . The exchange of messages starts with Alice sending a message to Bob and ends as soon as one of the players has enough information on x and y to compute $F(x, y)$.

\mathcal{P} is called a *k-round protocol*, for some $k \in \mathbb{N}$, if the exchange of messages consists, for each input $(x, y) \in A \times B$, of at most k rounds. The *cost* of \mathcal{P} on input (x, y) is the number of bits communicated by \mathcal{P} on input (x, y) . The *cost* of \mathcal{P} is the *maximal* cost of \mathcal{P} over all inputs $(x, y) \in A \times B$. The *communication complexity* of F , $\text{comm-compl}(F)$, is defined as the minimum cost of \mathcal{P} , over all protocols \mathcal{P} that compute F . For $k \geq 1$, the *k-round communication complexity* of F , $\text{comm-compl}_k(F)$, is defined as the minimum cost of \mathcal{P} , over all k -round protocols \mathcal{P} that compute F .

Many powerful tools are known for proving lower bounds on communication complexity, cf., e.g., [21]. In the present paper we will use the following basic lower bound for the problem of deciding whether two sets are disjoint.

Definition 2.1. For $n \in \mathbb{N}$ let the function $\text{Disj}_n : 2^{\{1, \dots, n\}} \times 2^{\{1, \dots, n\}} \rightarrow \{0, 1\}$ be given via

$$\text{Disj}_n(X, Y) := \begin{cases} 1, & \text{if } X \cap Y = \emptyset \\ 0, & \text{otherwise.} \end{cases}$$

□

Theorem 2.2 (cf., e.g., [21]). *For every $n \in \mathbb{N}$, $\text{comm-compl}(\text{Disj}_n) \geq n$.*

3 Machine Model

We consider Turing machines with (1) an input tape, which is a read/write tape and will henceforth be called “external memory tape” or “external tape”, for short, (2) an arbitrary number u of work tapes, which will henceforth be called “internal memory tapes” or “internal tapes”, for short, and, if needed, (3) an additional write-only output tape.

Let M be such a Turing machine and let ρ be a run of M . By $\text{rev}(\rho)$ we denote the number of times the external memory tape's head changes its direction in the run ρ . For $i \in \{1, \dots, u\}$ we let $\text{space}(\rho, i)$ be the number of cells of internal memory tape i that are used by ρ .

The class $ST(r, s)$ for strings

Definition 3.1 ($ST(r, s)$ for strings). Let $r : \mathbb{N} \rightarrow \mathbb{N}$ and $s : \mathbb{N} \rightarrow \mathbb{N}$.

- (a) A Turing machine M is (r, s) -bounded, if every run ρ of M on an input of length n satisfies the following conditions:
 - (1) ρ is finite, (2) $1 + \text{rev}(\rho) \leq r(n)$,² and (3) $\sum_{i=1}^u \text{space}(\rho, i) \leq s(n)$, where u is the number of internal tapes of M .
- (b) A string-language $L \subseteq \Sigma^*$ belongs to the class $ST(r, s)$ (resp., $NST(r, s)$), if there is a deterministic (respectively, nondeterministic) (r, s) -bounded Turing machine which accepts exactly those $w \in \Sigma^*$ that belong to L .
- (c) A function $f : \Sigma^* \rightarrow \Sigma^*$ belongs to the class $ST(r, s)$, if there is a deterministic (r, s) -bounded Turing machine which produces, for each input string $w \in \Sigma^*$, the string $f(w)$ on its write-only output tape. \square

For classes R and S of functions, we let $ST(R, S) := \bigcup_{r \in R, s \in S} ST(r, s)$.

If $k \in \mathbb{N}$ is a constant, then we write $ST(k, s)$ instead of $ST(r, s)$, where r is the function with $r(x) = k$ for all $x \in \mathbb{N}$. We freely combine these notations and use them for $NST(\cdot, \cdot)$ instead of $ST(\cdot, \cdot)$, too.

If we think of the external memory tape of an (r, s) -bounded Turing machine as representing the incoming stream, stored on a hard disk, then admitting the external memory tape's head to reverse its direction might not be very realistic. But as we mainly use our model to prove lower bounds, it does not do any harm either, since the reversals can be used to simulate *random access*. Random access can be introduced explicitly into our model as follows: A *random access Turing machine* is a Turing machine M which has a special internal memory tape that is used as *random access address tape*, i.e., on which only binary strings can be written. Such a binary string is interpreted as a positive integer specifying an external memory address, that is, the position index number of a cell on the external tape (we think of the external tape cells being numbered by positive integers). The machine has a special state q_{ra} . If q_{ra} is entered, then in one step the external memory tape head is moved to the cell that is specified by the number on the random access address tape, and the content of the random access address tape is deleted.

Definition 3.2. Let $q, r, s : \mathbb{N} \rightarrow \mathbb{N}$. A random access Turing machine M is (q, r, s) -bounded, if it is (r, s) -bounded (in the sense of an ordinary Turing machine) and, in addition, every run ρ of M on an input of length n involves at most $q(n)$ random accesses. \square

Noting that a random access can be simulated with at most 2 changes of the direction of the external memory tape head, one immediately obtains:

² It is convenient for technical reasons to add 1 to the number $\text{rev}(\rho)$ of changes of the head direction. As defined here, $r(n)$ bounds the number of sequential scans of the external memory tape rather than the number of changes of head directions.

Lemma 3.3. *Let $q, r, s : \mathbb{N} \rightarrow \mathbb{N}$. If a problem can be solved by a (q, r, s) -bounded random access Turing machine, then it can also be solved by an $(r + 2q, O(s))$ -bounded Turing machine.*

In the subsequent parts of this paper, we will concentrate on ordinary Turing machines (without random access). Via Lemma 3.3, all results can be transferred from ordinary Turing machines to random access Turing machines.

The class $ST(r, s)$ for trees. We make an analogous definition to $ST(r, s)$ on strings for trees. This definition is given in detail in [16].

4 Lower Bounds for the ST Model

A reduction lemma. The following lemma provides a convenient tool for showing that a problem L does not belong to $ST(r, s)$. The lemma’s assumption can be viewed as a *reduction* from the problem $Disj_n(\cdot, \cdot)$ to the problem L .

Lemma 4.1. *Let Σ be an alphabet and let $\lambda : \mathbb{N} \rightarrow \mathbb{N}$ such that the following is true: For every $n_0 \in \mathbb{N}$ there is an $n \geq n_0$ and functions $f_n, g_n : 2^{\{1, \dots, n\}} \rightarrow \Sigma^*$ such that for all $X, Y \subseteq \{1, \dots, n\}$ the string $f_n(X)g_n(Y)$ has length $\leq \lambda(n)$.*

Then we have for all $r, s : \mathbb{N} \rightarrow \mathbb{N}$ with $r(\lambda(n)) \cdot s(\lambda(n)) \in o(n)$, that there is no (r, s) -bounded deterministic Turing machine which accepts a string of the form $f_n(X)g_n(Y)$ if, and only if, $X \cap Y = \emptyset$.

Disjointness. Every n -bit string $x = x_1 \dots x_n \in \{0, 1\}^n$ specifies a set $S(x) := \{i : x_i = 1\} \subseteq \{1, \dots, n\}$. Let L_{Disj} consist of those strings $x\#y$ where x and y specify disjoint subsets of $\{1, \dots, n\}$, for some $n \geq 1$. That is,

$$L_{Disj} := \{ x\#y : \text{ex. } n \geq 1 \text{ with } x, y \in \{0, 1\}^n \text{ and } S(x) \cap S(y) = \emptyset \}.$$

From Lemma 4.1 one easily obtains

Proposition 4.2. *Let $r : \mathbb{N} \rightarrow \mathbb{N}$ and $s : \mathbb{N} \rightarrow \mathbb{N}$. If $r(n) \cdot s(n) \in o(n)$, then $L_{Disj} \notin ST(r, s)$.*

The bound given by Proposition 4.2 is tight, as it can be easily seen that $L_{Disj} \in ST(r, s)$ for all $r, s : \mathbb{N} \rightarrow \mathbb{N}$ with $r(n) \cdot s(n) \in \Omega(n)$.

Joins. Let τ be the set of tag names $\{ \text{rels, rel1, rel2, tuple, no1, no2, 0, 1} \}$. We represent a pair (A, B) of finite relations $A, B \subseteq \mathbb{N}^2$ as a τ -tree $T(A, B)$ whose associated XML document $Doc(T(A, B))$ is a Σ_τ -string of the following form: For each number $i \in \mathbb{N}$ let $Bin(i) = b_{\ell i}^{(i)} \dots b_0^{(i)}$ be the binary representation of i . For each tuple $(i, j) \in \{1, \dots, n\}^2$ let $Doc(i, j) :=$

$$\langle \text{tuple} \rangle \langle \text{no1} \rangle \langle b_{\ell}^{(i)} / \rangle \dots \langle b_0^{(i)} / \rangle \langle / \text{no1} \rangle \langle \text{no2} \rangle \langle b_{\ell}^{(j)} / \rangle \dots \langle b_0^{(j)} / \rangle \langle / \text{no2} \rangle \langle / \text{tuple} \rangle.$$

For each finite relation $A \subseteq \mathbb{N}^2$ let $t_1, \dots, t_{|A|}$ be the lexicographically ordered list of all tuples in A . We let $Doc(A) := Doc(t_1) \cdots Doc(t_{|A|})$. Finally, we let

$$Doc(T(A, B)) := \langle \text{rels} \rangle \langle \text{rel1} \rangle Doc(A) \langle /\text{rel1} \rangle \langle \text{rel2} \rangle Doc(B) \langle /\text{rel2} \rangle \langle /\text{rels} \rangle.$$

It is straightforward to see that the string $Doc(T(A, B))$ has length $O((|A| + |B|) \cdot \log n)$, if $A, B \subseteq \{1, \dots, n\}^2$.

We write $A \bowtie_1 B$ to denote the join of A and B on their first component, i.e., $A \bowtie_1 B := \{ (x, y) : \exists z A(z, x) \wedge B(z, y) \}$. We let

$$\begin{aligned} \mathcal{T}_{Rels} &:= \{ T(A, B) : A, B \subseteq \mathbb{N}^2, A, B \text{ finite} \} \\ \mathcal{T}_{EmptyJoin} &:= \{ T(A, B) \in \mathcal{T}_{Rels} : A \bowtie_1 B = \emptyset \} \\ \mathcal{T}_{NonEmptyJoin} &:= \{ T(A, B) \in \mathcal{T}_{Rels} : A \bowtie_1 B \neq \emptyset \}. \end{aligned}$$

Lemma 4.3. $\mathcal{T}_{NonEmptyJoin}$ can be filtered from \mathcal{T}_{Rels} by an XQuery query.

Lemma 4.4. Let $r, s : \text{Trees}_\tau \rightarrow \mathbb{N}$.

If $r(T) \cdot s(T) \in o\left(\frac{\text{size}(T)}{\log(\text{size}(T))}\right)$, then $\mathcal{T}_{EmptyJoin} \notin ST(r, s)$.

From Lemma 4.4 and Lemma 4.3 we immediately obtain a lower bound on the worst-case data complexity for filtering relative to an XQuery query:

Theorem 4.5. The tree-language $\mathcal{T}_{EmptyJoin}$

(a) can be filtered from \mathcal{T}_{Rels} by an XQuery query,

(b) does not belong to the class $ST(r, s)$, whenever $r, s : \text{Trees}_\tau \rightarrow \mathbb{N}$ with

$$r(T) \cdot s(T) \in o\left(\frac{\text{size}(T)}{\log(\text{size}(T))}\right).$$

Remark 4.6. Let us note that the above bound is ‘‘almost tight’’ in the following sense: The problem of deciding whether $A \bowtie_1 B = \emptyset$ and, in general, all FO-definable problems belong to $ST(1, n)$ – in its single scan of the external memory tape, the Turing machine simply copies the entire input on one of its internal memory tapes and then evaluates the FO-sentence by the straightforward LOGSPACE algorithm for FO-model-checking (cf. e.g. [1]). \square

Sorting. By KEYSORT, we denote the problem of sorting a set S of tuples $t = (K, V)$ consisting of a key K and a value V by their keys. Let $ST^-(r, s)$ denote the class of all problems in $ST(r, s)$ that can be solved without writing to the external memory tape. Then,

Theorem 4.7. Let $r, s : \mathbb{N} \rightarrow \mathbb{N}$. If KEYSORT is in $ST^-(r, s)$, then computing the natural join $A \bowtie B$ of two finite relations A, B is in

$$ST^-\left(r(n^2) + 2, s(n^2) + O(\log n) + O(\max_{t \in A \cup B} |t|)\right).$$

Remark 4.8. Given that the size of relations A and B is known (which is usually the case in practical database management systems DBMS), the algorithm given in the previous proof can do a merge-join without additional scans after the sort run and without a need to buffer more than one tuple. This is guaranteed even if both relations may contain many tuples with the same join key – in current implementations of the merge join in DBMS, this may lead to grass-roots swapping. The (substantial) *practical* drawback of the join algorithm of the proof of Theorem 4.7, however, is that much larger relations A', B' need to be sorted: indeed $|A'| = |A| * |B|$. \square

Corollary 4.9.

- (a) Let $r, s : \mathbb{N} \rightarrow \mathbb{N}$ such that $r(n^2) \cdot (s(n^2) + \log n) \in o\left(\frac{n}{\log n}\right)$.
Then, $\text{KEYSORT} \not\subseteq ST^-(r, s)$.
- (b) $\text{KEYSORT} \not\subseteq ST^-(o(\sqrt[5]{n}), O(\sqrt[5]{n}))$.

It is straightforward to see that by using MergeSort, the sorting problem can be solved using $O(\log n)$ scans of external memory provided that *three* external memory tapes are available. (In [17], this logarithmic bound is shown to be tight, for arbitrarily many external tapes.) Corollary 4.9 gives an exponentially stronger lower bound for the case of a single external tape.

A hierarchy based on the number of scans

Theorem 4.10. For every fixed $k \geq 1$,

$$ST(k, O((\log k) + \log n)) \cap NST(1, O(k \cdot \log n)) \not\subseteq ST(k-1, o\left(\frac{\sqrt{n}}{k^5(\log n)^3}\right)).$$

The proof of this theorem is based on a result due to Duris, Galil and Schnitger [10]. Theorem 4.10 directly implies

Corollary 4.11. For every fixed $k \in \mathbb{N}$ and all classes S of functions from \mathbb{N} to \mathbb{N} such that $O(\log n) \subseteq S \subseteq o\left(\frac{\sqrt{N}}{(\lg n)^3}\right)$ we have $ST(k, S) \not\subseteq ST(k+1, S)$.

Remark 4.12. On the other hand, of course, the hierarchy collapses if internal memory space is at least linear in the size of the input: For every $r : \mathbb{N} \rightarrow \mathbb{N}$ and for every $s : \mathbb{N} \rightarrow \mathbb{N}$ with $s(n) \in \Omega(n)$, we have

$$ST(r, s) \subseteq ST(1, n + s(n)) \quad \text{and} \quad ST(r, O(s(n))) = \text{DSPACE}(O(s(n))).$$

5 Tight Bounds for Filtering and Query Evaluation on Trees

Lower Bound. We need the following notation: We fix a set τ of tag names via $\tau := \{ \text{root, left, right, blank} \}$. Let T_1 be the τ -tree from Figure 1. Note that

T_1 has a unique leaf v_1 labeled with the tag name “left”. For any arbitrary τ -tree T we let $T_1(T)$ be the τ -tree rooted at T_1 ’s root and obtained by identifying node v_1 with the root of T and giving the label “left” to this node. Now, for every $n \geq 2$ let T_n be the τ -tree inductively defined via $T_n := T_1(T_{n-1})$. It is straightforward to see that T_n has exactly $2n$ leaves labeled “blank”. Let $x_1, \dots, x_n, y_1, \dots, y_1$ denote these leaves, listed in *document order* (i.e., in the order obtained by a pre-order depth-first left-to-right traversal of T_n). For an illustration see Figure 2.

We let $\tau_{01} := \tau \cup \{0, 1\}$. For all sets $X, Y \subseteq \{1, \dots, n\}$ let $T_n(X, Y)$ be the τ_{01} -tree obtained from T_n by replacing, for each $i \in \{1, \dots, n\}$, (*) the label “blank” of leaf x_i by the label 1 if $i \in X$, and by the label 0 otherwise and (*) the label “blank” of leaf y_i by the label 1 if $i \in Y$, and by the label 0 otherwise.

We let

$$\begin{aligned} \mathcal{T}_{Sets} &:= \{ T_n(X, Y) : n \geq 1, X, Y \subseteq \{1, \dots, n\} \}, \\ \mathcal{T}_{Disj} &:= \{ T_n(X, Y) \in \mathcal{T}_{Sets} : X \cap Y = \emptyset \}, \\ \mathcal{T}_{NonDisj} &:= \{ T_n(X, Y) \in \mathcal{T}_{Sets} : X \cap Y \neq \emptyset \}. \end{aligned}$$

- Lemma 5.1.** (a) *There is a Core XPath query Q such that the following is true for all τ -trees $T \in \mathcal{T}_{Sets}$: $Eval(Q, T) \neq \emptyset \iff T \in \mathcal{T}_{NonDisj}$.*
 (b) *There is a FO-sentence φ such that the following is true for all τ -trees T : $T \models \varphi \iff T \in \mathcal{T}_{NonDisj}$.*

Lemma 5.2. *Let $r, s : Trees_\tau \rightarrow \mathbb{N}$. If $r(T) \cdot s(T) \in o(depth(T))$, then $\mathcal{T}_{NonDisj} \not\subseteq ST(r, s)$.*

From Lemma 5.1 and Lemma 5.2 we directly obtain a lower bound on the worst-case data complexity of Core XPath filtering:

Theorem 5.3. *The tree-language $\mathcal{T}_{NonDisj}$ (a) can be filtered from \mathcal{T}_{Sets} by a Core XPath query,*

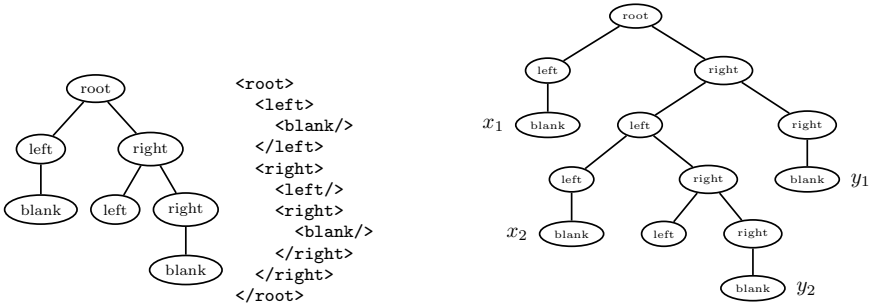

Fig. 1. A τ -tree T_1 and its XML document $Doc(T_1) \in \Sigma_\tau^*$ with tag names $\tau := \{\text{root, left, right, blank}\}$ **Fig. 2.** Tree T_2 and nodes x_1, x_2, y_1, y_2

- (b) is definable by an FO-sentence (and therefore, also definable by a Boolean MSO query and recognizable by a tree automaton), and
- (c) does not belong to the class $ST(r, s)$, whenever $r, s : \text{Trees}_\tau \rightarrow \mathbb{N}$ with $r(T) \cdot s(T) \in o(\text{depth}(T))$.

In the following subsection we match this lower bound with the corresponding upper bound.

Upper bounds. Recall that a tree-language $\mathcal{T} \subseteq \text{Trees}_\tau$ is definable by an MSO-sentence if, and only if, it is recognizable by an unranked tree automaton, respectively, if, and only if, the language $\{\text{BinTree}(T) : T \in \mathcal{T}\}$ of associated binary trees is recognizable by an ordinary (ranked) tree automaton (cf., e.g., [7, 9, 30]).

Theorem 5.4 (implicit in [25, 29]). *Let $\mathcal{T} \subseteq \text{Trees}_\tau$ be a tree-language. If \mathcal{T} is definable by an MSO-sentence (or, equivalently, recognizable by a ranked or an unranked finite tree automaton), then $\mathcal{T} \in ST(1, \text{depth}(\cdot) + 1)$.*

Recall that every Core XPath query is equivalent to a unary MSO query. Thus a Core XPath filter can be phrased as an MSO sentence on trees. From the Theorems 5.4 and 5.3 we therefore immediately obtain a tight bound for Core XPath filtering:

Corollary 5.5. (a) *Filtering from the set of unranked trees with respect to every fixed Core XPath query Q belongs to $ST(1, O(\text{depth}(\cdot)))$.*

(b) *There is a Core XPath query Q such that, for all $r, s : \text{Trees}_\tau \rightarrow \mathbb{N}$ with $r(T) \cdot s(T) \in o(\text{depth}(T))$, filtering w.r.t. Q does not belong to $ST(r, s)$.*

Next, we provide an upper bound for the problem of computing the set $\text{Eval}(Q, T)$ of nodes in an input tree T matching a unary MSO (or Core XPath) query Q . We first need to clarify what this means, because writing the subtree of each matching node onto the output tape requires a very large amount of internal memory (or a large number of head reversals on the external memory tape), and this gives us no appropriate characterization of the difficulty of the problem. We study the problem of computing, for each node matched by Q , its index in the tree, in the order in which they appear in the document $\text{Doc}(T)$. We distinguish between the case where these indexes are to be written to the output tape in ascending order and the case where they are to be output in descending (i.e., reverse) order.

Theorem 5.6 (implicit in [26, 20]). *For every unary MSO or Core XPath query Q , the problem of computing, for input trees T , the nodes in $\text{Eval}(Q, T)$*

(a) *in ascending order belongs to $ST(3, O(\text{depth}(\cdot)))$.*

(b) *in reverse order belongs to $ST(2, O(\text{depth}(\cdot)))$.*

Note that this bound is tight: From Corollary 5.5(c) we know that, for some Core XPath query Q , not even filtering (i.e., checking whether $\text{Eval}(Q, T)$ is empty) is possible in $ST(r, s)$ if $r(T) \cdot s(T) \in o(\text{depth}(T))$.

Abstract. This paper is concerned with the language inclusion problem for timed automata: given timed automata \mathcal{A} and \mathcal{B} , is every word accepted by \mathcal{B} also accepted by \mathcal{A} ? Alur and Dill [3] showed that the language inclusion problem is decidable if \mathcal{A} has no clocks and undecidable if \mathcal{A} has two clocks (with no restriction on \mathcal{B}). However, the status of the problem when \mathcal{A} has one clock is not determined by [3]. In this paper we close this gap for timed automata over infinite words by showing that the one-clock language inclusion problem is undecidable. For timed automata over finite words, building on our earlier paper [20], we show that the one-clock language inclusion problem is decidable with non-primitive recursive complexity. This reveals a surprising divergence between the theory of timed automata over finite words and over infinite words. Finally, we show that if ε -transitions or non-singular post-conditions are allowed, then the one-clock language inclusion problem is undecidable over both finite and infinite words.

1 Introduction

An execution of a real-time system can be modelled as a *timed word* consisting of a sequence of events and their associated timestamps, and properties of such systems can be expressed as languages of timed words. Timed automata were introduced by Alur and Dill [3] to specify languages of timed words, and have since been extensively studied by many researchers. In particular, timed automata have been used as the foundation for several verification algorithms and tools (see [8] for a survey).

One of the most fundamental results about timed automata is the undecidability of the language inclusion problem: ‘Given timed automata \mathcal{A} and \mathcal{B} , is every word accepted by \mathcal{B} also accepted by \mathcal{A} ?’ This problem is undecidable irrespective of whether one considers automata over finite words or automata over infinite words with a Büchi acceptance condition. In this context it is natural to seek subclasses of timed automata, with reduced expressive power, for which

the language inclusion problem is decidable [5, 7, 8, 4, 13, 19, 20]. In this paper we consider subclasses parameterized by the number of clocks an automaton has. In particular, we consider the *n-clock language inclusion problem* in which \mathcal{A} is allowed n clocks but where no restriction is placed on \mathcal{B} .

A close analysis of the proof of the undecidability of language inclusion in [3] reveals that the tightest possible formulation of their result is that the two-clock language inclusion problem is undecidable. On the other hand, from the decidability of language emptiness for timed automata, also proved in [3], it follows that the zero-clock language inclusion problem is (PSPACE-complete) decidable. This leaves an interesting open question about the status of the one-clock language inclusion problem. In fact, many interesting specifications can be expressed by automata with a single clock, or parallel combinations thereof. This is particularly so for *alternating timed automata* [16, 21]. For instance, every formula of *Metric Temporal Logic* [6, 4] can be translated into an alternating timed automaton with a single clock [21]. The model checking problem then corresponds to language inclusion.

Recently, using techniques from the theory of well-quasi-ordered transition systems [11], we showed that over finite words the one-clock language inclusion problem is decidable [20]. However, while finite words are sufficient to capture safety properties, to capture liveness or fairness properties it is most natural to consider automata over infinite words. The main result of this paper is that, for timed automata over infinite words (with Büchi acceptance conditions) the one-clock language inclusion problem is undecidable. This reveals a surprising divergence between the theory of timed automata over finite words and over infinite words. We also show that over finite words the one-clock language inclusion problem has non-primitive recursive complexity. Finally, language inclusion becomes undecidable over both finite and infinite words if ε -transitions are allowed or if reset clocks have nonsingular postconditions (as in [9, 12]).

We use *channel machines* [10] as a convenient middleware between Turing machines and timed automata. This allows us to develop a schematic approach to proving undecidability and complexity results for various classes of timed automata. In each case we show how to encode a certain class of channel computations as a timed language, whose complement can be recognized by a timed automaton of a certain type.

Related Work. The non-primitive recursive complexity of language inclusion over finite words and the undecidability of language inclusion over finite words with ε -transitions have recently and independently been proved by Lasota and Walukiewicz [16]. They have also concurrently discovered the undecidability of universality for one-clock Büchi timed automata [17]. Like us, they make use of channel machines in their work, although via a different encoding of channel histories as timed words.

Alur, La Torre and Madhusudan [7] consider automata with *perturbed clocks* whose rates may vary; they show that for every automaton with a single perturbed clock there is an equivalent deterministic timed automaton. It follows that the language inclusion problem is decidable for this class of automata.

Laroussinie, Markey and Schnoebelen [15] classify the complexity of deciding language emptiness for timed automata with one, two and three clocks respectively.

2 Timed Automata and Timed Words

Let Σ be a finite alphabet and write Σ^ε for $\Sigma \cup \{\varepsilon\}$, where $\varepsilon \notin \Sigma$. Let \mathbb{R}_+ be the set of non-negative reals. A *timed event* is a pair (t, a) , where $t \in \mathbb{R}_+$ is called the *timestamp* of the *event* $a \in \Sigma$. A *timed word* is a finite or infinite sequence $u = (t_0, a_0)(t_1, a_1)(t_2, a_2) \dots$ of timed events whose sequence of timestamps $t_0 t_1 t_2 \dots$ is non-decreasing and is either finite or diverges to infinity. (This last assumption rules out so-called *Zeno words*.) We say that a timed word is *strictly monotonic* if its sequence of timestamps is strictly monotonic increasing. We write $T\Sigma^*$ for the set of finite timed words over alphabet Σ and $T\Sigma^\omega$ for the set of infinite timed words over alphabet Σ .

Let X be a finite set of clocks, denoted x, y, z , etc. We define the set $\Phi(X)$ of clock constraints over X via the following grammar (here $k \in \mathbb{N}$ is a non-negative integer).

$$\phi ::= x < k \mid x \leq k \mid \phi \wedge \phi \mid \neg\phi .$$

Definition 1. A timed automaton is a tuple $\mathcal{A} = (\Sigma, S, S_0, F, X, E)$, where

- Σ is a finite alphabet of events,
- S is a finite set of control states,
- $S_0 \subseteq S$ is a set of initial control states,
- $F \subseteq S$ is a set of accepting control states,
- X is a finite set of clocks, and
- $E \subseteq S \times S \times \Phi(X) \times \Sigma^\varepsilon \times 2^X \times \Phi(X)$ is a finite set of edges. An edge $(s, s', \phi, \alpha, R, \phi')$ allows α -labelled transition from s to s' , provided the precondition ϕ on clocks is met. Afterwards, the clocks in R are nondeterministically reset to values satisfying the postcondition ϕ' , and all other clocks remain unchanged.

A *clock valuation* of \mathcal{A} is a function $\nu : X \rightarrow \mathbb{R}_+$. If $\delta \in \mathbb{R}_+$, we let $\nu + \delta$ be the clock valuation such that $(\nu + \delta)(x) = \nu(x) + \delta$ for all $x \in X$. A *global state* of \mathcal{A} is a pair (s, ν) , where $s \in S$ is a control state and ν is a clock valuation. Write $Q = S \times (\mathbb{R}_+)^X$ for the set of global states.

Automaton \mathcal{A} induces an $(\mathbb{R}_+ \times \Sigma^\varepsilon)$ -labelled transition relation on the set of global states as follows: write $(s, \nu) \xrightarrow{\delta, \alpha} (t, \nu')$ iff there is an edge $(s, t, \phi, \alpha, R, \phi')$ in E such that $\nu + \delta$ satisfies ϕ , ν' satisfies ϕ' and $(\nu + \delta)(x) = \nu'(x)$ for all $x \notin R$.

A *run* of \mathcal{A} is a finite or infinite sequence of transitions

$$(s_0, \nu_0) \xrightarrow{\delta_0, \alpha_0} (s_1, \nu_1) \xrightarrow{\delta_1, \alpha_1} (s_2, \nu_2) \xrightarrow{\delta_2, \alpha_2} \dots \quad (1)$$

where $s_0 \in S_0$ is an initial control state and $\nu_0(x) = 0$ for all $x \in X$. We require that an infinite run contain infinitely many transitions labelled from Σ and that $\sum_{i=0}^\infty \delta_i$ be infinite.

A finite run is *accepting* if the last control state in the run is accepting. An infinite run is accepting if infinitely many control states in the run are accepting. Let $\alpha_{i_0}\alpha_{i_1}\alpha_{i_2}\dots$ be the sequence of non- ε -labels occurring in an accepting run and let $t_j = \sum_{i=0}^j \delta_i$. Then the timed word $(t_{i_0}, \alpha_{i_0})(t_{i_1}, \alpha_{i_1})(t_{i_2}, \alpha_{i_2})\dots$ is said to be *accepted by* \mathcal{A} . We write $L_f(\mathcal{A})$ for the set of finite timed words accepted by \mathcal{A} and $L_\omega(\mathcal{A})$ for the set of infinite timed words accepted by \mathcal{A} .

Remark 1. Definition 1 represents quite a general model of timed automata. We will adopt the convention that, unless otherwise specified, a given timed automaton has no ε -transitions, and has *singular postconditions*, i.e., for each edge $(s, t, \phi, \alpha, R, \phi')$, if clock valuations ν and ν' both satisfy ϕ' , then $\nu(x) = \nu'(x)$ for all $x \in R$.

3 Hardness Results over Finite Words

In [20] we showed that it is decidable whether $L_f(\mathcal{B}) \subseteq L_f(\mathcal{A})$ for an arbitrary timed automaton \mathcal{B} and a one-clock automaton \mathcal{A} . In this section we show that this problem has non-primitive recursive complexity and is undecidable if \mathcal{A} is allowed ε -transitions or non-singular postconditions. We prove these results by reduction from the reachability problem for channel machines.

A *channel machine* [1, 10, 22] consists of a finite-state automaton acting on an unbounded fifo channel (or buffer). More precisely, a channel machine is a tuple $\mathcal{C} = (S, s_0, M, \Delta)$, where S is a finite set of *control states*, $s_0 \in S$ is the *initial control state*, M is a finite set of *messages*, and $\Delta \subseteq S \times L \times S$ is the transition relation over label set $L = \{m!, m? : m \in M\}$.

A *global state* of \mathcal{C} is a pair (s, x) , where $s \in S$ is the control state and $x \in M^*$ is the contents of the channel. The rules in Δ induce an L -labelled transition relation on the set of global states as follows: $(s, m!, t) \in \Delta$ yields a transition $(s, x) \xrightarrow{m!} (t, x \cdot m)$ that writes $m \in M$ to the tail of the channel, and $(s, m?, t) \in \Delta$ yields a transition $(s, m \cdot x) \xrightarrow{m?} (t, x)$ that reads $m \in M$ from the head of the channel. If we only allow the transitions indicated above, then we call \mathcal{C} an *error-free* channel machine.

We also consider channel machines that operate with *insertion errors*. Given $x, y \in M^*$, write $x \sqsubseteq y$ if x can be obtained from y by deleting any number of letters, e.g. sub \sqsubseteq stubborn, as indicated by the underlining. Following [22] we introduce *insertion errors* by extending the transition relation on global states with the following clause: if $(s, x) \xrightarrow{\alpha} (t, y)$, $x' \sqsubseteq x$ and $y \sqsubseteq y'$, then $(s, x') \xrightarrow{\alpha} (t, y')$. Dually, we define *lossy channel machines* by adding by a clause: if $(s, x) \xrightarrow{\alpha} (t, y)$, $x \sqsubseteq x'$ and $y' \sqsubseteq y$, then $(s, x') \xrightarrow{\alpha} (t, y')$.

A *computation* of \mathcal{C} is a finite or infinite sequence of transitions between global states $(s_0, x_0) \xrightarrow{\alpha_0} (s_1, x_1) \xrightarrow{\alpha_1} (s_2, x_2) \xrightarrow{\alpha_2} \dots$.

The *control-state reachability problem* asks, given a channel machine $\mathcal{C} = (S, s_0, M, \Delta)$ and a control state $t \in S$, whether there is a computation of \mathcal{C} starting in global state (s_0, ε) and ending in global state (t, ε) . It is well-known that the control-state reachability problem for error-free channel machines is

undecidable¹. Next we show how to reduce the control-state reachability problem for error-free channel machines to the universality problem (which is a special case of language inclusion) for various classes of timed automata.

Let $\mathcal{C} = (S, s_0, M, \Delta)$ and $t \in S$ be an instance of the control-state reachability problem. Given this data, let $\Sigma = \{m!, m? : m \in M\} \cup \{\checkmark\}$ be a finite alphabet. We encode the finite control of \mathcal{C} as an untimed automaton (i.e., a timed automaton with no clocks) \mathcal{A}_{cont} over alphabet Σ . \mathcal{A}_{cont} is just the underlying control automaton of \mathcal{C} with a \checkmark -labelled self-transition added to every control state, with s_0 as the initial control state and $t \in S$ as the only accepting control state. Let L_{cont} denote the timed language $L_f(\mathcal{A}_{cont})$.

Definition 2. Let $L_{chan} \subseteq T\Sigma^*$ consist of those timed words u such that:

1. u is strictly monotonic.
2. u contains a \checkmark -event at time zero, and thereafter consecutive \checkmark -events are separated by one time unit.
3. Every $m!$ -event in u is followed one time unit later by an $m?$ -event.
4. Every $m?$ -event is preceded one time unit earlier by an $m!$ -event.

Clauses 3 and 4 capture the channel discipline: every message written to the channel is read from the channel one time unit later, and every message that is read from the channel was written to the channel one time unit earlier. The one-to-one unit-time-delayed correspondence between read and write events ensures that messages are read from the channel in the order that they were written to the channel. The requirement that every message written to the channel is eventually read corresponds to the fact that we consider computations that end with an empty channel. The \checkmark -events in L_{chan} have no particular significance other than to facilitate the encoding below.

Proposition 1. \mathcal{C} has an error-free computation from (s_0, ε) to (t, ε) iff $L_{cont} \cap L_{chan} \neq \emptyset$.

Let $\overline{\mathcal{A}_{cont}}$ denote the complement of \mathcal{A}_{cont} as an untimed automaton. It is clear that $\overline{\mathcal{A}_{cont}}$ is also the complement of \mathcal{A}_{cont} with respect to timed languages, i.e., $L_f(\overline{\mathcal{A}_{cont}}) = T\Sigma^* - L_{cont}$. Now suppose that \mathcal{A}_{chan} is a timed automaton such that $L_f(\mathcal{A}_{chan}) = T\Sigma^* - L_{chan}$. From Proposition 1 it holds that $\overline{\mathcal{A}_{cont}} \cup \mathcal{A}_{chan}$ is universal (i.e. accepts every timed word) iff \mathcal{C} has no error-free computation from (s_0, ε) to (t, ε) . Since the control-state reachability problem is undecidable for error-free channel machines, it follows that the universality problem is undecidable for any class of timed automata that is closed under unions and can capture the complement of L_{chan} .

¹ The usual formulation of the problem asks whether there is a computation from (s_0, ε) to (t, x) for some $x \in M^*$. It is straightforward to reduce this problem to the formulation above.

3.1 Two Clocks

We show how to define a timed automaton \mathcal{A}_{chan} with two clocks such that $L_f(\mathcal{A}_{chan}) = T\Sigma^* - L_{chan}$. We define \mathcal{A}_{chan} as the disjunction of several automata, each of which accepts the set of words that fail to satisfy a particular clause in the definition of L_{chan} . The interesting clauses here are 3 and 4.

Automaton \mathcal{A}_1 , below, accepts those timed words in which some $m!$ -event is not followed one time unit later by an $m?$ -event, i.e., those words that fail to satisfy Clause 3 in Definition 2. Automaton \mathcal{A}_2 (both left-hand and right-hand components) accepts those timed words in which some $m?$ -event is not preceded one time unit earlier by *any* event. Note that a strictly monotonic timed word satisfying Clause 2 in Definition 2 fails to satisfy Clause 4 if and only if it is either accepted by \mathcal{A}_2 or contains an α -event followed one time unit later by an $m?$ -event, with $\alpha \neq m!$. It is straightforward to capture this last condition with a one-clock timed automaton. In fact \mathcal{A}_2 is the only component of \mathcal{A}_{chan} that uses two clocks.

Thus we obtain a new proof of Alur and Dill’s classical result [3].

Theorem 1. *The universality problem for timed automata with two clocks is undecidable.*

3.2 ϵ -Transitions

By allowing ϵ -transitions, we can replace the left-hand component of automaton \mathcal{A}_2 , above, with the following automaton which uses only one clock. The ϵ -transition and the $m?$ -transition in \mathcal{A}_3 are separated by exactly one time unit; this prevents any visible event from preceding this occurrence of $m?$ by one time unit.

Theorem 2. *The universality problem for the class of timed automata with one clock and ϵ -transitions is undecidable.*

3.3 Non-singular Postconditions

Instead of ε -transitions we can consider non-singular postconditions for clock resets. In this case we can replace automaton \mathcal{A}_3 with the following one-clock timed automaton, where the \checkmark -labelled edge non-deterministically resets x to a value strictly less than 1.

Theorem 3. *The universality problem for the class of timed automata with one clock and with non-singular postconditions is undecidable.*

3.4 Complexity

The control-state reachability problem for lossy channel machines was shown to be decidable, in contrast to the error-free case, by Abdulla and Jonsson [2]. Later Schnoebelen [22] proved that it has non-primitive recursive complexity.

Proposition 2. *The control-state reachability problem for channel machines with insertion errors has non-primitive recursive complexity.*

Proof. Given a channel machine $\mathcal{C} = (S, s_0, M, \Delta)$, define a new transition relation $\Delta^{op} \subseteq S \times \{m!, m? : m \in M\} \times S$ by

$$\Delta^{op} = \{(s, m!, t) : (t, m?, s) \in \Delta\} \cup \{(s, m?, t) : (t, m!, s) \in \Delta\} .$$

Notice that there is a transition from global state (s, x) to global state (t, y) under Δ iff there is a transition from $(t, rev(y))$ to $(s, rev(x))$ under Δ^{op} , where $rev : M^* \rightarrow M^*$ reverses the order of a finite string. Thus there is computation with lossiness errors from (s, ε) to (t, ε) under Δ iff there is a computation with insertion errors from (t, ε) to (s, ε) under Δ^{op} . This observation allows us to reduce the control-state reachability problem for channel machines with lossiness errors to the control-state reachability problem for channel machines with insertion errors. □

Define the timed language $L_{ins} \subseteq T\Sigma^*$ to consist of those timed words satisfying Clauses 1-3 in Definition 2. Thus for a word in L_{ins} , every $m!$ -event is followed one time unit later by an $m?$ -event, but every $m?$ -event need not be preceded one time unit earlier by an $m!$ -event. This corresponds to a channel with insertion errors.

Proposition 3. *\mathcal{C} has a computation with insertion errors starting in state (s_0, ε) and ending in state (t, ε) iff $L_{cont} \cap L_{ins} \neq \emptyset$.*

Note that we can express $T\Sigma^* - L_{ins}$ as the language of a one-clock timed automaton. This automaton incorporates \mathcal{A}_1 in Section 3.1, but not \mathcal{A}_2 . Thus we obtain

Theorem 4. *The universality problem for the class of timed automata with a single clock has non-primitive recursive complexity.*

4 Universality for One-Clock Büchi Automata

In this section we prove the undecidability of the following universality problem: ‘Given a one-clock timed automaton \mathcal{A} (without ε -transitions and with singular postconditions) does $L_\omega(\mathcal{A}) = T\Sigma^\omega$?’.

As in Section 3 the idea behind the proof is to encode the computations of a certain type of channel machine as a timed language. To this end, say that a non-terminating computation of a channel machine is *space-bounded* if there exists $N \in \mathbb{N}$ such that the number of messages stored on the channel during the computation never exceeds N . We define a timed language $L_{bound} \subseteq T\Sigma^\omega$ encoding space-bounded computations of a channel with insertion errors. We capture the space bound by requiring an upper bound on the number of events per time unit for each word $u \in L_{bound}$. Besides space-boundedness the other key ingredient in our proof is the notion of *alternation*, defined below.

Define a channel machine \mathcal{C} to be *alternating* if we can partition the set of control states into two classes, called *read states* and *write states* respectively, such that each edge is of the form $(s, m?, t)$ with s a read state and t a write state, or of the form $(s, m!, t)$ with s a write state and t a read state. Then any computation of \mathcal{C} consists of an alternating sequence of read transitions and write transitions.

The *recurrent-state problem* for alternating channel machines is as follows. Given an alternating channel machine $\mathcal{C} = (S, s_0, M, \Delta)$, does there exist $x \in M^*$ such that \mathcal{C} has a non-terminating computation starting in global state (s_0, x) and visiting s_0 infinitely often? The following proposition is a relatively straightforward reduction from the halting problem for Turing machines.

Proposition 4. *The recurrent-state problem for error-free alternating channel machines is undecidable.*

The *space-bounded recurrent-state problem* for alternating channel machines with insertion errors asks if a given alternating channel machine has a space-bounded computation, possibly with insertion errors, passing infinitely often through the initial control state. The following proposition, which is reminiscent of a result of Mayr [18] on lossy counter machines, asserts that this problem is undecidable.

Proposition 5. *The space-bounded recurrent-state problem for alternating channel machines with insertion errors is undecidable.*

Proof. Given an alternating channel machine \mathcal{C} , we claim that \mathcal{C} has a space-bounded recurrent computation with insertion errors iff it has an error-free recurrent computation. Then Proposition 5 follows from Proposition 4. Indeed, since \mathcal{C} is alternating, at any point in a computation the total number of insertion errors up to that point is within one of the current size of the channel minus

the size of the channel at the start of the computation. Thus any error-free computation of \mathcal{C} is space-bounded, and any space-bounded computation of \mathcal{C} with insertion errors is eventually error-free (the space bound gives an upper bound on the total number of insertion errors). \square

Definition 3. *Given a strictly monotonic timed word $u = (t_0, a_0)(t_1, a_1) \dots$, define $\text{density}(u) = \sup\{j - i : t_j - t_i \leq 1\}$. The density of a timed word measures the maximum number of events in any time unit along the word.*

Theorem 5. *The universality problem for one-clock Büchi timed automata is undecidable.*

The proof is by reduction from the space-bounded recurrent-state problem for alternating machines with insertion errors. Given an alternating channel machine $\mathcal{C} = (S, s_0, M, \Delta)$, we define a one-clock Büchi timed automaton \mathcal{A} such that \mathcal{C} has a space-bounded recurrent computation with insertion errors iff \mathcal{A} is non-universal.

Let $\Sigma = \{m!, m? : m \in M\} \cup \{\checkmark\}$ be a finite alphabet. We encode the finite control of \mathcal{C} as a Büchi timed automaton \mathcal{A}_{cont} with no clocks over alphabet Σ . \mathcal{A}_{cont} is just the underlying control automaton of \mathcal{C} with a \checkmark -labelled self-transition added to every control state and with s_0 as the initial control state and only accepting control state. Let L_{cont} denote the timed language $L_\omega(\mathcal{A}_{cont})$.

Next we capture the behaviour of a space-bounded channel with insertion errors using a timed language L_{bound} over alphabet Σ .

Definition 4. *L_{bound} consists of those timed words u satisfying:*

1. *u is strictly monotonic and contains infinitely many non- \checkmark -events.*
2. *There is a \checkmark -event at time zero, and thereafter consecutive \checkmark -events are separated by one time unit.*
3. *For every $m!$ -event in u there is an $m?$ -event one time unit later.*
4. *For every $m?$ -event in u there is a $n!$ -event one time unit later, for some $n \in M$.*
5. *$\text{density}(u) < \infty$.*

As with the corresponding clause in Definition 2, Clause 3 captures the channel discipline: every message sent is received. The channel has insertion errors because not every $m?$ -event is necessarily preceded one time unit earlier by an $m!$ -event. On the other hand, Clause 4 has nothing to do with the channel discipline. However its presence, together with Clauses 2 and 3, ensures that for every event of $u \in L_{bound}$ there is an event exactly one time unit later. (This fact will play a significant role later.) Since we are dealing with alternating channel machines, the imposition of Clause 4 will prove to be no restriction when we seek to match words in L_{bound} with channel computations. Finally, Clause 5 corresponds to the space-boundedness of the channel.

Proposition 6. *\mathcal{C} has a space-bounded recurrent computation with insertion errors iff $L_{cont} \cap L_{bound} \neq \emptyset$.*

Proof. (\Leftarrow) Let $u \in L_{cont} \cap L_{bound}$. We show how to recover a space-bounded recurrent computation of \mathcal{C} from u . Since $u \in L_{cont}$, the automaton \mathcal{A}_{cont} , which represents the finite control of \mathcal{C} , has a run

$$(s_0, \nu_0) \xrightarrow{\delta_0, \alpha_0} (s_1, \nu_1) \xrightarrow{\delta_1, \alpha_1} (s_2, \nu_2) \xrightarrow{\delta_2, \alpha_2} \dots \tag{2}$$

on u . Let $\alpha_{i_0} \alpha_{i_1} \alpha_{i_2} \dots$ be the sequence of non- \checkmark -events in u . Then we obtain a recurrent computation of \mathcal{C}

$$(s_{i_0}, x_0) \xrightarrow{\alpha_0} (s_{i_1}, x_1) \xrightarrow{\alpha_1} (s_{i_2}, x_2) \xrightarrow{\alpha_2} \dots$$

where $x_j \in M^*$ is the sequence of messages that occur as read events in the unit time interval $(t_{i_{j-1}}, t_{i_j} + 1]$, where, by convention, $i_{-1} = 0$. Since $u \in L_{bound}$, Clause 3 in Definition 4 ensures that this is a legitimate computation of \mathcal{C} , albeit with insertion errors. Since u has finite density this computation is space-bounded.

(\Rightarrow) We have already observed that if \mathcal{C} has a space-bounded recurrent computation with insertion errors, then it has a space-bounded recurrent error-free computation. The trace of channel events along such an error-free computation can easily be encoded as a word in L_{bound} as we now explain. Since \mathcal{C} is alternating, there is a number $N \in \mathbb{N}$ such that the size of the channel is either N or $N - 1$ at any point in the computation. When any message is written to the channel, the machine performs exactly $2N - 1$ (read and write) operations before that message is read off the channel. We transform the sequence of read and write events along a computation into a timed word u by putting exactly $1/(2N - 1)$ time units between consecutive events. This automatically guarantees that Clauses 3–5 in Definition 4 hold. Finally, adding \checkmark -events at integer times yields a timed word in L_{bound} . \square

Similarly to the development in Section 3, the undecidability of the universality problem will follow from Proposition 6 provided that we can define a one-clock timed automaton \mathcal{A}_{bound} such that $L_\omega(\mathcal{A}_{bound}) = T\Sigma^\omega - L_{bound}$. We define \mathcal{A}_{bound} to be the disjunction of several automata, corresponding to the different clauses in the definition of L_{bound} . It is straightforward, for each clause 1–4, to define an automaton that accepts precisely the timed words that fail to satisfy that clause. Below we define two automata \mathcal{A}_{inc} and \mathcal{A}_{dec} such that, if a timed word u already satisfies 1–4, then it is accepted by \mathcal{A}_{inc} or \mathcal{A}_{dec} precisely if it fails Clause 5, i.e., it has infinite density.

First we recall the following simple proposition about real numbers.

Proposition 7. *If $\mathbf{x} = \langle x_n : n \in \mathbb{N} \rangle$ is a sequence of real numbers in the open interval $(0, 1)$ that takes on infinitely many values, then \mathbf{x} has either a strictly increasing subsequence or a strictly decreasing subsequence.*

Let $u = (t_0, a_0)(t_1, a_1)(t_2, a_2) \dots$ be a timed word satisfying Clauses 1–4 in Definition 4. Then for every event of u there is an event exactly one time unit later. Thus u has infinite density iff $\{frac(t_i) : i \in \mathbb{N}\}$ is infinite. By Proposition 7,

this holds iff the sequence $\langle frac(t_i) : i \in \mathbb{N} \rangle$ has either a strictly increasing subsequence or a strictly decreasing subsequence. We define an automaton \mathcal{A}_{inc} that accepts u iff $\langle frac(t_i) : i \in \mathbb{N} \rangle$ has a strictly increasing subsequence, and an automaton \mathcal{A}_{dec} that accepts u iff $\langle frac(t_i) : i \in \mathbb{N} \rangle$ has a strictly decreasing subsequence.

Consider a run of \mathcal{A}_{inc} (depicted below) on $u = (t_0, a_0)(t_1, a_1)(t_2, a_2) \dots$. Let t_i be the timestamp of the transition that resets clock x for the j -th time. Notice that either $t_{i+1} = t_i + 1$ or $frac(t_{i+1}) > frac(t_i)$. The Büchi condition ensures that the second eventuality holds infinitely often in the run, and so the sequence $frac(t_i)$ has a strictly increasing subsequence. Thus, among those timed words u satisfying Clauses 1–4 in Definition 4, \mathcal{A}_{inc} accepts precisely those for which $\langle frac(t_i) : i \in \mathbb{N} \rangle$ has a strictly increasing subsequence. (Notice the importance of the fact that for each event in u there is an event one time unit later.)

\mathcal{A}_{dec} (depicted below) operates in a similar manner to \mathcal{A}_{inc} except that it accepts those words $u = (t_0, a_0)(t_1, a_1)(t_2, a_2) \dots$ for which $\langle frac(t_i) : i \in \mathbb{N} \rangle$ has a strictly decreasing subsequence.

5 Remarks and Future Work

The main result of this paper is that the universality problem for one-clock Büchi timed automata is undecidable. A closely related problem concerns the decidability of the satisfiability and model checking problems for Metric Temporal Logic (MTL) [6, 4]. This logic is known to be undecidable under an *interval semantics*. However, under a *point-based semantics*—i.e., interpreting the logic over timed words—the satisfiability problem is open, cf. [21].

In [21] we show how to translate an MTL formula into an *alternating timed automaton* with a single clock. In terms of alternating automata, the present paper shows that the emptiness problem for one-clock alternating automata with co-Büchi acceptance conditions is undecidable. However one can express MTL formulas using a particularly simple acceptance condition—the so-called

*weak parity acceptance condition*². It does not seem possible to capture the timed language L_{bound} by an MTL formula, or, more generally, a one-clock alternating automata with weak parity acceptance conditions. So it remains possible that the satisfiability problem for MTL is decidable, and we are currently investigating this question.

Congruences for Visibly Pushdown Languages^{*}

Rajeev Alur¹, Viraj Kumar², P. Madhusudan², and Mahesh Viswanathan²

{kumar, madhu, vmahesh}@cs.uiuc.edu

Abstract. We study congruences on words in order to characterize the class of visibly pushdown languages (VPL), a subclass of context-free languages. For any language L , we define a natural congruence on words that resembles the syntactic congruence for regular languages, such that this congruence is of finite index if, and only if, L is a VPL. We then study the problem of finding canonical minimal deterministic automata for VPLs. Though VPLs in general do not have unique minimal automata, we consider a subclass of VPAs called k -module single-entry VPAs that correspond to programs with recursive procedures without input parameters, and show that the class of well-matched VPLs do indeed have unique minimal k -module single-entry automata. We also give a polynomial time algorithm that minimizes such k -module single-entry VPAs.

1 Introduction

The class of *visibly pushdown languages* (VPL), introduced in [1], is a subclass of context-free languages accepted by pushdown automata in which the input letter determines the type of operation permitted on the stack. Visibly pushdown languages are closed under all boolean operations, and problems such as inclusion, that are undecidable for context-free languages, are decidable for VPL. VPLs are relevant to several applications that use context-free languages such as the model-checking of software programs using their pushdown models [1, 2, 3]. Recent work has shown applications in other contexts: in modeling semantics of effects in processing XML streams [4], in game semantics for programming languages [5], and in identifying larger classes of pushdown specifications that admit decidable problems for infinite games on pushdown graphs [6].

Our main result in this paper is a characterization of the class of VPLs in terms of congruences on strings. It is well known that the *syntactic congruence*, which is defined as $w_1 \approx w_2$ when for every u, v , $uw_1v \in L$ if and only if $uw_2v \in L$, has finite index precisely for languages L that are regular. Our central

thesis is that for VPLs L , when we restrict our attention to *well-matched* words w_1 and w_2 (i.e., words where every push transition has a corresponding pop transition and vice versa), the syntactic congruence has finite index. Moreover, for languages consisting only of well-matched words, if the syntactic congruence on well-matched words has finite index then the language is a VPL. For languages containing strings that are not well-matched, we need some additional conditions only because no congruence on well-matched words can *saturate* such a language. Our characterization of VPLs is a natural generalization of the Myhill-Nerode theorem for regular languages—when restricted to languages that do not require any push or pop operations, our congruence coincides with the right congruence defined by Myhill and Nerode [7, 8].

One important consequence of the congruence based characterization of regular (word) languages and regular tree languages is that for any regular language there is a unique minimum state deterministic automaton recognizing the language, which can also be constructed efficiently [8, 9]. For VPLs, however, we show that in general there is no unique minimum state recognizer. Thus, while our characterization yields the construction of a *canonical* deterministic acceptor for VPLs, it may not in general be minimal. An implicit consequence of the results in [1] is that VPLs have canonical deterministic pushdown automata. It is shown in [1] that with any language L , a language of trees called *stack trees*, can be associated such that L is a VPL exactly when the corresponding set of stack trees form a regular tree language. The unique minimal bottom-up tree automaton accepting the language of stack trees can then be translated to a canonical deterministic visibly pushdown automaton. However, since bottom-up tree automata can only be translated into deterministic pushdown automata with exponentially more states, the implicit construction in [1] does not result in necessarily small deterministic VPAs.

Visibly pushdown automata are a natural model for programs with recursive procedure calls and finite data types. Such programs are called Boolean programs in the literature on software model checking [3]. When modeling a program as a visibly pushdown automaton, the natural structure the model assumes is one where the machine's states are partitioned into k modules, one for each procedure in the program. As one expects, these modules are such that from a state in a module, a sequence of calls and returns to other modules results in a state of the same module. Moreover, if the programs modeled are such that the calls to modules have no input parameters (or if a function is modeled separately for each possible value of its input parameters), then the visibly pushdown automaton assumes additional structure, namely that every call results in going to a unique state in the module corresponding to the call. We call such structured VPAs *k*-module single-entry VPAs (*k*-SEVPAs). They correspond roughly to the model of *recursive state machines* with a single entry per module [10].

Though visibly pushdown languages in general do not have unique minimum-state recognizers, partitioning the calls into the modules they correspond to fixes enough additional structure that there is a minimum-state *k*-SEVPA that respects the partition and accepts the language. More precisely, we show that

for any partition of the call-alphabet into k -sets, there is a unique minimum-state k -SEVPA accepting any well-matched VPL L . If $k = 0$ (that is, there are no calls), the result is equivalent to the Myhill-Nerode theorem for regular languages. The characterization of this unique minimal k -SEVPA is done via a set of $k + 1$ congruences on words. We also present an algorithm which, given any deterministic k -SEVPA accepting a well-matched language, minimizes it in $O(n^3)$ time, where n is the size of the original machine.

The rest of the paper is organized as follows. We first recall the definitions of visibly pushdown languages and visibly pushdown automata in Section 2. Our main result characterizing visibly pushdown languages in terms of language theoretic congruences is presented in Section 3. We also show that VPLs, in general, do not have unique minimum state deterministic recognizers. In Section 4, we define the notion of how partitions on calls define k -module single-entry VPAs and prove that every (well-matched) VPL has a unique minimal k -SEVPA accepting it. We also present an example of a family of languages for which the minimal 1-module machine is super polynomial in the size of the smallest visibly pushdown automaton recognizing it. Conclusions and open problems are presented in Section 5.

2 Preliminaries

In this section, we recall definitions of *visibly pushdown automata* and *visibly pushdown languages*, and introduce some notation that we will use in the rest of the paper.

Pushdown Alphabet. A *pushdown alphabet* is a tuple $\widehat{\Sigma} = (\Sigma_{\text{call}}, \Sigma_{\text{ret}}, \Sigma_{\text{int}})$ that comprises three *disjoint* finite alphabets— Σ_{call} is a finite set of *calls*, Σ_{ret} is a finite set of *returns*, and Σ_{int} is a finite set of *internal actions*. For any such $\widehat{\Sigma}$, let $\Sigma = \Sigma_{\text{call}} \cup \Sigma_{\text{ret}} \cup \Sigma_{\text{int}}$. In the paper we will use u, v, u_1, \dots for strings in Σ^* , c, c_1, c_i, \dots for elements of Σ_{call} , r, r_1, r_i, \dots for elements of Σ_{ret} , and i, i_1, i_j, \dots for elements of Σ_{int} .

Visibly Pushdown Automata. For visibly pushdown automata, unlike the case of pushdown automata, it turns out that deterministic VPAs are as powerful as a non-deterministic VPAs [1]. In light of this, we will only consider deterministic VPAs. A *visibly pushdown automaton* (VPA) on finite strings over $\widehat{\Sigma} = (\Sigma_{\text{call}}, \Sigma_{\text{ret}}, \Sigma_{\text{int}})$ is a tuple $M = (Q, q_0, \Gamma, \delta, Q_F)$ where Q is a finite set of states, $q_0 \in Q$ is the initial state, Γ is a finite stack alphabet that contains a special bottom-of-stack symbol \perp , $\delta = \delta_{\text{call}} \cup \delta_{\text{ret}} \cup \delta_{\text{int}}$ is the transition function, where $\delta_{\text{call}} : Q \times \Sigma_{\text{call}} \rightarrow Q \times (\Gamma \setminus \{\perp\})$, $\delta_{\text{ret}} : Q \times \Sigma_{\text{ret}} \times \Gamma \rightarrow Q$, and $\delta_{\text{int}} : Q \times \Sigma_{\text{int}} \rightarrow Q$, and $Q_F \subseteq Q$ is a set of final states.

If $\delta_{\text{call}}(q, c) = (q', \gamma)$, where $c \in \Sigma_{\text{call}}$ and $\gamma \neq \perp$, there is a *push-transition* from q on input c where on reading c , γ is pushed onto the stack and the control changes from state q to q' ; we denote such a transition by $q \xrightarrow{c/\gamma} q'$. Similarly, if $\delta_{\text{ret}}(q, r, \gamma) = q'$, there is a *pop-transition* from q on input r where γ is read from

the top of the stack and popped (if the top of the stack is \perp , then it is read but not popped), and the control changes from q to q' ; we denote such a transition by $q \xrightarrow{r/\gamma} q'$. If $\delta_{\text{int}}(q, i) = q'$, there is an *internal-transition* from q on input i where on reading i , the state changes from q to q' ; we denote such a transition by $q \xrightarrow{i} q'$. Note that there are no stack operations on internal transitions.

Acceptance. A *stack* is a non-empty finite sequence over Γ ending in the bottom-of-stack symbol \perp . The set of all stacks is denoted as $St = (\Gamma \setminus \{\perp\})^* \cdot \{\perp\}$. A *configuration* is a pair (q, σ) such that q is a state and $\sigma \in St$. The transition function of a VPA can be used to define how the configuration of the machine changes in a single step: we say $\delta((q, \sigma), a) = (q', a')$ ¹ if one of the following holds:

1. If $a \in \Sigma_{\text{call}}$ then there exists $\gamma \in \Gamma$ such that $\delta_{\text{call}}(q, a) = (q', \gamma)$ and $\sigma' = \gamma \cdot \sigma$
2. If $a \in \Sigma_{\text{ret}}$, then there exists $\gamma \in \Gamma$ such that $\delta_{\text{ret}}(q, a, \gamma) = q'$ and either $\gamma \neq \perp$ and $\sigma = \gamma \cdot \sigma'$, or $\gamma = \perp$ and $\sigma = \sigma' = \perp$
3. If $a \in \Sigma_{\text{int}}$ is an internal action, then $\delta_{\text{int}}(q, a) = q'$ and $\sigma' = \sigma$

The transitive closure of the single-step transition function, which we also denote by δ , can be easily defined in the standard inductive manner. For a stack $\sigma \in St$, we define the function $\delta_\sigma : Q \times \Sigma^* \rightarrow Q$ as $\delta_\sigma(q, u) = q'$ whenever $\delta((q, \sigma), u) = (q', \sigma')$ for some $\sigma' \in St$.

A string $u \in \Sigma^*$ is *accepted* by VPA M if $\delta_\perp(q_0, u) \in Q_F$. The *language* of M , $L(M)$, is the set of strings accepted by M .

Visibly Pushdown Languages. A language over finite strings $L \subseteq \Sigma^*$ is a *visibly pushdown language* (VPL) with respect to $\widehat{\Sigma}$ (a $\widehat{\Sigma}$ -VPL) if there is a VPA M over $\widehat{\Sigma}$ such that $L(M) = L$.

Matched calls and returns. Let $MR(\widehat{\Sigma})$ denote the set of all strings where every return has a matched call before it, i.e. $u \in MR(\widehat{\Sigma})$ if for every prefix u' of u , the number of return symbols in u' is at most the number of call symbols in u' . Similarly, let $MC(\widehat{\Sigma})$ denote the set of all strings where every call has a matching return after it, i.e. $u \in MC(\widehat{\Sigma})$ if for every suffix u' of u , the number of call symbols in u' is at most the number of return symbols in u' . The set of *well-matched* strings over $\widehat{\Sigma}$ is $WM(\widehat{\Sigma}) = MR(\widehat{\Sigma}) \cap MC(\widehat{\Sigma})$.

A $\widehat{\Sigma}$ -VPL L is said to be *well-matched* if $L \subseteq WM(\widehat{\Sigma})$.

Remark 1. For every $w \in WM(\widehat{\Sigma})$, there is a unique matching between call and return symbols such that every call-symbol always precedes its matching return-symbol and the substring w' between a matching pair of call and return symbols is a well-matched string.

¹ We abuse notation and use δ for both the transition function of the automaton and the single step transition function on configurations.

3 Congruence Based Characterization of VPLS

In this section we present a congruence based characterization of when a language over $\widehat{\Sigma}$ is a visibly pushdown language. Before presenting the characterization for general VPLs, we first consider the case of VPLs that have only well-matched words.

3.1 Well-Matched Visibly Pushdown Languages

For a language L over the pushdown alphabet $\widehat{\Sigma} = (\Sigma_{\text{call}}, \Sigma_{\text{ret}}, \Sigma_{\text{int}})$, consider the following congruence on well-matched words:

$$w_1 \approx w_2 \text{ iff } \forall u, v \in \Sigma^*, uw_1v \in L \text{ iff } uw_2v \in L$$

Recall that this is the standard syntactic congruence restricted to well-matched words over $\widehat{\Sigma}$. For example, if $\widehat{\Sigma} = (\{c\}, \{r\}, \emptyset)$ and $L = \{c^n.r^n \mid n \geq 0\}$, then there are only two equivalence classes that \approx defines: $\{c^n.r^n \mid n \geq 0\}$ and the complement of this set with respect to $WM(\widehat{\Sigma})$.

Analogous to the case of regular languages, the finiteness of the number of equivalence classes of the syntactic congruence (on well-matched words) provides a precise characterization of *well-matched* VPLs.

Theorem 1. *L is a well-matched $\widehat{\Sigma}$ -VPL iff \approx (as defined above) has finitely many equivalence classes.*

Proof. Suppose L is a $\widehat{\Sigma}$ -VPL and $M = (Q, q_0, \Gamma, \delta, Q_F)$ is a VPA over $\widehat{\Sigma}$ with (unique) initial state q_0 such that $L(M) = L$. Every well-matched string w defines a function $f_w : Q \rightarrow Q$ as follows: $f_w(q) = \delta_{\perp}(q, w)$. Define the following equivalence on well-matched strings:

$$w_1 \approx_M w_2 \text{ iff } f_{w_1} = f_{w_2}$$

Observe that \approx_M has finitely many equivalence classes (bounded by $|Q|^{|Q|}$). We will show that \approx_M is a refinement of \approx , thus establishing that \approx is also of finite index. Consider $w_1 \approx_M w_2$. Then for any $u, v \in \Sigma^*$, we know

$$\begin{aligned} \delta((q_0, \perp), uw_1v) &= \delta(\delta(\delta((q_0, \perp), u), w_1), v) \\ &= \delta(\delta(\delta((q_0, \perp), u), w_2), v) \text{ since } f_{w_1} = f_{w_2} \\ &= \delta((q_0, \perp), uw_2v) \end{aligned}$$

Hence $uw_1v \in L$ iff $uw_2v \in L$, and so $w_1 \approx w_2$. Thus \approx_M is a refinement of \approx . Observe that this proof does not rely on L being a well-matched language.

To prove the converse, consider a language L such that \approx is of finite index. We construct a deterministic (but incomplete²) VPA that recognizes L and whose

² A VPA is incomplete if the transition function δ is not total. An incomplete VPA can be easily modified to yield a VPA with at most one extra “dead” state to which all undefined transitions go.

states are the equivalence classes of \approx . Consider a string with no unmatched returns $u = w_1 c_1 w_2 c_2 \cdots c_k w_{k+1} \in MR(\widehat{\Sigma})$, where c_1, \dots, c_k are the unmatched call symbols in u , and w_1, \dots, w_{k+1} are well-matched strings between the unmatched call symbols. The automaton we construct will maintain the following invariant: after reading the string $u \in MR(\widehat{\Sigma})$, the state of the machine will be $[w_{k+1}]_{\approx}$ and the stack will be $([w_k]_{\approx}, c_k)([w_{k-1}]_{\approx}, c_{k-1}) \cdots ([w_1]_{\approx}, c_1)\perp$.

The formal construction of VPA $M = (Q, q_0, \Gamma, \delta, Q_F)$ is as follows: $Q = \{[w]_{\approx} \mid w \in WM(\widehat{\Sigma})\}$, $q_0 = [\epsilon]_{\approx}$, $\Gamma = \{\perp\} \cup (Q \times \Sigma_{\text{call}})$, and $Q_F = \{[w]_{\approx} \mid w \in L\}$. The transition function δ is defined as follows.

- $[w]_{\approx} \xrightarrow{i} [wi]_{\approx}$ for every $i \in \Sigma_{\text{int}}$
- $[w]_{\approx} \xrightarrow{c/([w]_{\approx}, c)} [\epsilon]_{\approx}$ for every $c \in \Sigma_{\text{call}}$
- $[w]_{\approx} \xrightarrow{r/([w']_{\approx}, c)} [w'cwr]_{\approx}$ for every $r \in \Sigma_{\text{ret}}$

The above machine has no pop transitions when \perp is the only symbol on the stack. Observe that the definitions of Q_F and δ are sound because \approx saturates L ³ and \approx is a congruence with respect to well-matched words. Further, it is easy to verify that the above invariant is maintained. Thus, after reading a *well-matched* word w , the automaton will be in the state $[w]_{\approx}$ and hence $L = L(M) \cap WM(\widehat{\Sigma})$. Since $WM(\widehat{\Sigma})$ is a VPL, and VPLs are closed under intersection, the result follows. \square

3.2 General Visibly Pushdown Languages

For visibly pushdown languages that are not necessarily well-matched, \approx being of finite index is not sufficient. This is because \approx is no longer a congruence that saturates the VPL. We need to define two additional congruences on strings—one that will capture the behavior of a state when the stack only has \perp , and one that will capture the behavior when the stack has more than one element. The reason we need to distinguish the cases of the stack having only \perp and that of the stack having additional elements, is because symbols in Σ_{ret} behave differently. In the first case, elements of Σ_{ret} are like internal actions which leave the stack unchanged, and in the second case they result in the stack being popped.

For a language L over $\widehat{\Sigma}$, define the following congruences.

$$\begin{aligned} &\text{For } u_1, u_2 \in \Sigma^*, u_1 \equiv u_2 \text{ iff } \forall v \in MR(\widehat{\Sigma}). u_1 v \in L \text{ iff } u_2 v \in L \\ &\text{For } u_1, u_2 \in MC(\widehat{\Sigma}), u_1 \sim_0 u_2 \text{ iff } \forall v \in \Sigma^*. u_1 v \in L \text{ iff } u_2 v \in L \end{aligned}$$

Intuitively, the congruence \equiv says that the two strings u_1 and u_2 cannot be distinguished by experiments ($v \in MR(\widehat{\Sigma})$) that do not examine the stacks reached on u_1 and u_2 . The congruence \sim_0 is only defined on strings where every call is matched. Thus, after reading such a word, any VPA will only have \perp on the stack. Starting from such configurations, as was observed earlier, return symbols

³ An equivalence \equiv saturates L iff either $[w]_{\equiv} \cap L = \emptyset$ or $[w]_{\equiv} \subseteq L$, for any equivalence class $[w]_{\equiv}$ of \equiv .

behave like internal actions, and the congruence is the usual Myhill-Nerode right congruence. We now present the main theorem of this paper.

Theorem 2. L is a $\widehat{\Sigma}$ -VPL iff \approx , \equiv and \sim_0 all have finite index.

Proof. For a VPL L , let $M = (Q, q_0, \Gamma, \delta, Q_F)$ be a VPA recognizing L . In the proof of Theorem 1, we already showed that \approx will have finite index. Define the following two equivalences over words in Σ^* :

$$\begin{aligned} u_1 \equiv^M u_2 &\text{ iff } \delta_{\perp}(q_0, u_1) = \delta_{\perp}(q_0, u_2) \\ u_1 \sim_0^M u_2 &\text{ iff } \delta_{\perp}(q_0, u_1) = \delta_{\perp}(q_0, u_2) \end{aligned}$$

It can be shown that \equiv^M refines \equiv , and \sim_0^M refines \sim_0 when restricted to $MC(\widehat{\Sigma})$ (proof skipped in the interests of space). Hence, both \equiv and \sim_0 have finitely many equivalence classes.

For the converse, we show that L is a VPL by once again constructing a VPA M whose states are equivalence classes of the congruences we have defined, but the construction is a bit more involved. The main intuition behind the construction is to ensure that the following invariant is maintained after M has read a string $u \in \Sigma^*$

- If $u \in MC(\widehat{\Sigma})$ then the state of M is $[u]_{\sim_0}$ and the stack is \perp .
- If $u = vc_1w_1 \cdots c_kw_k$, where $v \in MC(\widehat{\Sigma})$, each $w_j \in WM(\widehat{\Sigma})$, and each $c_j \in \Sigma_{\text{call}}$, then M is in state $([u]_{\equiv}, [w_k]_{\approx})$ and the stack is $([w_{k-1}]_{\approx}, c_k) \cdots ([w_1]_{\approx}, c_2)([v]_{\sim_0}, c_1)\perp$.

The formal construction of M is as follows. $M = (Q, q_0, \Gamma, \delta, Q_F)$ where $Q = \{[u]_{\sim_0} \mid u \in MC(\widehat{\Sigma})\} \cup \{([u]_{\equiv}, [w]_{\approx}) \mid u \in \Sigma^*, w \in WM(\widehat{\Sigma})\}$; $q_0 = [\epsilon]_{\sim_0}$; $\Gamma = Q \times \Sigma_{\text{call}} \cup \{\perp\}$; $Q_F = \{[u]_{\sim_0} \mid u \in L\} \cup \{([u]_{\equiv}, [w]_{\approx}) \mid u \in L\}$; and δ is defined as follows:

- $[u]_{\sim_0} \xrightarrow{i} [ui]_{\sim_0}$ for every $i \in \Sigma_{\text{int}}$
- $[u]_{\sim_0} \xrightarrow{c/([u]_{\sim_0}, c)} ([uc]_{\equiv}, [\epsilon]_{\approx})$ for every $c \in \Sigma_{\text{call}}$
- $[u]_{\sim_0} \xrightarrow{r/\perp} [ur]_{\sim_0}$ for every $r \in \Sigma_{\text{ret}}$
- $([u]_{\equiv}, [w]_{\approx}) \xrightarrow{i} ([ui]_{\equiv}, [wi]_{\approx})$ for every $i \in \Sigma_{\text{int}}$
- $([u]_{\equiv}, [w]_{\approx}) \xrightarrow{c/(([u]_{\equiv}, [w]_{\approx}), c)} ([uc]_{\equiv}, [\epsilon]_{\approx})$ for every $c \in \Sigma_{\text{call}}$
- $([u]_{\equiv}, [w]_{\approx}) \xrightarrow{r/([u]_{\sim_0}, c)} [u'cwr]_{\sim_0}$ for every $r \in \Sigma_{\text{ret}}$
- $([u]_{\equiv}, [w]_{\approx}) \xrightarrow{r/(([u]_{\equiv}, [w]_{\approx}), c)} ([u'cwr]_{\equiv}, [w'cwr]_{\approx})$ for every $r \in \Sigma_{\text{ret}}$

The correctness of the construction relies on the intuition outlined earlier and is skipped in the interests of space. \square

Remark 2. Note that in the case where $\Sigma_{\text{call}} = \Sigma_{\text{ret}} = \emptyset$ (i.e. for regular languages), the machine M constructed in Theorem 2 is the unique minimum-state

Fig. 1. Two non-isomorphic minimum-state VPAs

automaton for L because the only reachable states will be of the form $[w]_{\sim_0}$, where $w \in \Sigma^*$.

Despite the above remark, the VPA M constructed in Theorem 2 need not be a *minimum-state* $\widehat{\Sigma}$ -VPA accepting L . Furthermore,

Proposition 1. *There are VPLs that have no unique minimum-state VPA accepting them.*

To illustrate the above proposition, consider the VPAs in Figure 1. Let $\widehat{\Sigma} = (\{c_1, c_2\}, \{r\}, \{a, b\})$. Let $L = c_1L_1r + c_2L_2r$, where L_1 is the regular language over $\{a, b\}$ such that the number of a 's is even, and L_2 is the regular language over $\{a, b\}$ such that the number of b 's is even. The figure shows two *non-isomorphic* minimum-state $\widehat{\Sigma}$ -VPAs accepting L . In both machines, the initial state is q_0 and the following transitions have been omitted in the figure for readability: in both machines, every call-transition not shown is of the form $q \xrightarrow{c/z} q_2$, and every other transition not shown goes to state q_2 .

Notice that the first machine consists of two distinct “modules”, one recognizing L_1 and one recognizing L_2 , and the call symbol c_1 or c_2 determines which module is “invoked”. In contrast, the second machine consists of a single recognizer for both L_1 and L_2 , and this module is invoked regardless of the call symbol. As this example illustrates, it is not clear when splitting the task of recognition into distinct modules reduces the total number of states in the VPA. In the following section, we consider a restricted class of VPAs for which the partition of the VPA into modules has already been provided and the call-symbol determines which module is to be invoked. The task then is to minimize the number of states of the automaton, while preserving the given partition of states into modules.

4 k -Module Single-Entry Visibly Pushdown Automata

In this section we show that the class of well-matched VPLs have *unique* minimum-state k -module single-entry automata (k -SEVPA). As mentioned in the introduction, these automata are motivated by models of programs with finite data-types, and are similar to single-entry recursive state machines [10] (see [11] for a precise comparison).

k-SEVPAs. Let $\{\Sigma_{\text{call}}^j\}_{j=1}^k$ be a partition of Σ_{call} . A VPA $M = (Q, q_0, \Gamma, \delta, Q_F)$ is a k -module single-entry VPA with respect to $\{\Sigma_{\text{call}}^j\}_{j=1}^k$ if there is a partition $\{Q_j\}_{j=0}^k$ of Q and distinguished states $q_j \in Q_j$ for every $j = 1, \dots, k$ such that:

1. $Q_F \subseteq Q_0, q_0 \in Q_0$;
2. $\Gamma = \{\perp\} \cup (Q \times \Sigma_{\text{call}})$;
3. if $q \xrightarrow{i} q'$ for some $i \in \Sigma_{\text{int}}$, then $\exists j. q, q' \in Q_j$;
4. if $q \xrightarrow{c/(q,c)} q'$ for some $c \in \Sigma_{\text{call}}^j$, then $q' = q_j$;
5. if $q' \xrightarrow{r/(q,c)} q''$ for some $c \in \Sigma_{\text{call}}$, then $\exists j. q, q'' \in Q_j$.

Intuitively, Q_0 is the base module (corresponding to the ‘main’ module of a program), and the transition relation is such that a call leads to a unique state in the module corresponding to the call (in models of programs, this state will be the initial control state of the function called), and upon return will return to the calling module. Such automata are no less expressive than VPAs: as Theorem 3 below shows, for any partition of call symbols, any well-matched VPL is accepted by some k -SEVPA.

We use the abbreviation k -SEVPA for such machines and explicitly denote them as $M = ((Q, q_0, \Gamma, \delta, Q_F), \{\Sigma_{\text{call}}^1, \dots, \Sigma_{\text{call}}^k\}, \{Q_0, \dots, Q_k\}, \{q_1, \dots, q_k\})$. For example, for the first VPA in Figure 1, given the partition $\Sigma_{\text{call}} = \{\{c_1\}, \{c_2\}\}$, there is a partition of Q as $\{Q_0, Q_1, Q_2\}$, where $Q_0 = \{q_0, q_5\}$, $Q_1 = \{q_1, q_3\}$, and $Q_2 = \{q_2, q_4\}$ witnessing the fact that this is a 2-SEVPA. Similarly, for the second VPA, given the partition $\Sigma_{\text{call}} = \{\{c_1, c_2\}\}$, there is a partition of Q as $\{Q_0, Q_1\}$, where $Q_0 = \{q_0, q_5\}$ and $Q_1 = \{q_1, q_2, q_3, q_4\}$ establishing that it is a 1-SEVPA.

Remark 3. The automaton constructed in Theorem 1 is a 1-SEVPA. However, in general, this VPA will be much bigger than the smallest 1-SEVPA. The reason for this is similar to the reason why the finite automaton constructed for regular languages from the syntactic congruence is much larger than that obtained from the syntactic right congruence. Thus, in order to characterize the minimal k -SEVPAs, we need a new congruence that partitions words like the Myhill-Nerode right congruence does for regular languages.

In our construction of the minimal k -SEVPA for a language L , we will use $k + 1$ congruences. To model the case when the stack only has \perp , we will use \sim_0 (defined in Section 3.2 on strings with matched calls). For the case when the stack has additional symbols, we need k new congruences that make use of

the fact that the states of the machine are partitioned into k modules identified by the call symbol. Given a k -SEVPA $M = (M', \{\Sigma_{\text{call}}^j\}_{j=1}^k, \{Q_j\}_{j=0}^k, \{q_j\}_{j=1}^k)$ accepting a language L over $\widehat{\Sigma}$, define the following congruences on well-matched strings: for every $j = 1, \dots, k$,

$$w_1 \sim_j w_2 \text{ iff } \forall u, v \in \Sigma^* \forall c \in \Sigma_{\text{call}}^j. ucw_1v \in L \text{ iff } ucw_2v \in L$$

Since \sim_j 's will be used to define states when the stack has more than just \perp , when defining the equivalence we only need to consider contexts where there is an unmatched call. We are ready to present the main theorem of this section.

Theorem 3. *For any well-matched $\widehat{\Sigma}$ -VPL L and any partition $\{\Sigma_{\text{call}}^j\}_{j=1}^k$ of Σ_{call} , there is a unique (upto isomorphism) minimum-state k -SEVPA for L with respect to this partition.*

Proof. We first show that given any partition $\{\Sigma_{\text{call}}^j\}_{j=1}^k$ of Σ_{call} , there is a k -SEVPA M that recognizes L . We construct M using the equivalences $\{\sim_j\}_{j=1}^k$ and \sim_0 (defined in Section 3.2 on strings with matched calls). We then show that this machine M is the unique minimum-state k -SEVPA that recognizes L . The construction of M relies on the observation that \sim_0 and \sim_j 's all have finite index if L is a VPL. From Theorems 1 and 2, we know that when L is a VPL, \sim_0 and \approx are of finite index. Since \approx is a refinement of \sim_j for every j , it follows that all \sim_j 's are also of finite index. For $0 \leq j \leq k$, we use the notation $[u]_j$ to denote the equivalence class of \sim_j containing u .

The formal construction of $M = ((Q, q_0, \Gamma, \delta, Q_F), \{\Sigma_{\text{call}}^j\}_{j=1}^k, \{Q_j\}_{j=0}^k, \{q_j\}_{j=1}^k)$ is: $Q_0 = \{[u]_0 \mid u \in MC(\widehat{\Sigma})\}$, and for every $j = 1, \dots, k$, $Q_j = \{[w]_j \mid w \in WM(\widehat{\Sigma})\}$. For every $j \geq 0$, $q_j = [\epsilon]_j$, and $Q_F = \{[u]_0 \mid u \in L\}$. The transition function δ is given as follows.

- For every $i \in \Sigma_{\text{int}}$ and $j \geq 0$, $[u]_j \xrightarrow{i} [ui]_j$
- For every $c \in \Sigma_{\text{call}}^{j'}$ and $j \geq 0$, $[u]_j \xrightarrow{c/([u], c)} [\epsilon]_{j'}$
- For every $r \in \Sigma_{\text{ret}}$ and $j, j' \geq 0$, $[w]_j \xrightarrow{r/([u], r, c)} [ucwr]_{j'}$
- For every $r \in \Sigma_{\text{ret}}$, $[u]_0 \xrightarrow{r/\perp} [ur]_0$

Q_F is well-defined because \sim_0 is an equivalence that saturates L . The transition function is consistent because $u_1i \sim_j u_2i$ whenever $u_1 \sim_j u_2$ and $i \in \Sigma_{\text{int}}$, and because when $u_1 \sim_{j'} u_2$ and $w_1 \sim_j w_2$, $u_1cw_1r \sim_{j'} u_2cw_2r$ for every $j > 0$, $j' \geq 0$ and $c \in \Sigma_{\text{call}}^j$, $r \in \Sigma_{\text{ret}}$. Thus, the above machine is well defined. Further observe that the following invariant is maintained during the execution: after reading a string u

- If $u \in MC(\widehat{\Sigma})$ then the state of M is $[u]_0$ and the stack is \perp .
- If $u = vc_1w_1 \dots c_lw_l$, where $v \in MC(\widehat{\Sigma})$, each $c_j \in \Sigma_{\text{call}}^m$ and each $w_j \in WM(\widehat{\Sigma})$, then the state of M is $[w_l]_m$ and the stack is $([w_{l-1}]_{m-1}, c_l) \dots ([w_1]_{m_1}, c_2)([v]_0, c_1)\perp$.

Hence, if a string reaches a final state, we are guaranteed that the stack only has \perp , and recognizes L . The formal proof of correctness is skipped.

Consider any k -SEVPA $M' = ((Q', q'_0, \Gamma', \delta', Q'_F), \{\Sigma_{\text{call}}^j\}_{j=1}^k, \{Q'_j\}_{j=0}^k, \{q'_j\}_{j=1}^k)$ recognizing L . We show that M is the unique minimum-state k -SEVPA by demonstrating a homomorphism from M' to M . In other words, we construct an onto function $f : \bigcup_{j \geq 0} Q'_j \rightarrow \bigcup_{j \geq 0} Q_j$ having the following properties.

1. $f(q'_j) = q_j$ for every $j \geq 0$
2. For any $i \in \Sigma_{\text{int}}$, if $p' \xrightarrow{i}_{M'} q'$ then $f(p') \xrightarrow{i}_M f(q')$
3. For any $c \in \Sigma_{\text{call}}$, if $p' \xrightarrow{c/(p',c)}_{M'} q'$ then $f(p') \xrightarrow{c/(f(p'),c)}_M f(q')$
4. For any $r \in \Sigma_{\text{ret}}$, if $p' \xrightarrow{r/(s',c)}_{M'} q'$ then $f(p') \xrightarrow{r/(f(s'),c)}_M f(q')$

Thus, we will be able to conclude that $|\bigcup Q'_j| \geq |\bigcup Q_j|$, and if $|\bigcup Q'_j| = |\bigcup Q_j|$ then f witnesses an isomorphism between M and M' .

The homomorphism f from M' to M is defined as follows:

$$f(q') = \begin{cases} [u]_0 & \text{if } \exists u \in MC(\widehat{\Sigma}). \delta'_\perp(q'_0, u) = q' \\ [w]_j & \text{if } \exists u \in \Sigma^*, c \in \Sigma_{\text{call}}^j, w \in WM(\widehat{\Sigma}). \delta'_\perp(q'_0, ucw) = q' \end{cases}$$

Note that $f(q'_j) = [e]_j$ for every $0 \leq j \leq k$. Observe that f maps states of Q'_j to the equivalence classes of \sim_j for every $0 \leq j \leq k$. We need to show that f is well defined, i.e., f is indeed a function and does not map a state of M' to two different states of M . This follows from the following lemma.

Lemma 1. *If $u_1, u_2 \in MC(\widehat{\Sigma})$ are such that $\delta'_\perp(q'_0, u_1) = \delta'_\perp(q'_0, u_2)$, then $u_1 \sim_0 u_2$. In addition, for well-matched strings w_1 and w_2 and every $j = 1, \dots, k$, if $\delta'_\perp(q'_j, w_1) = \delta'_\perp(q'_j, w_2)$ then $w_1 \sim_j w_2$.*

The proof of the above lemma is similar to the proofs in Theorems 1 and 2 where we show our congruences to have finite index. Thus, f is indeed a function. Further, f is clearly onto. Also, f preserves initial state and distinguished states q_j , by definition. It preserves the transitions of M' because \sim_0 and \sim_j 's are congruences. This completes the proof that there is a unique minimum-state k -SEVPA. □

While the above theorem shows that each (well-matched) VPL has a unique k -SEVPA with respect to a given partition of Σ_{call} , the constructed machine may be much bigger than the smallest VPA recognizing the language because in a k -SEVPA, each module is constrained to have a unique “entry” (an entry is the destination of a push-transition). The presence of multiple entries can greatly reduce the size of the VPA as the following proposition shows.

Proposition 2. *For positive integers m, n , there is a family of well-matched VPLs $L_{m,n}$ such that the smallest VPA recognizing $L_{m,n}$ has at most $O(nm)$ states, while the smallest 1-SEVPA recognizing $L_{m,n}$ has at least n^m states.*

As the following theorem states, there is an efficient algorithm to minimize k -SEVPAs. The algorithm is omitted due to lack of space, but can be found along with the proof of correctness and complexity analysis in [11].

Theorem 4. *Given a k -SEVPA M with respect to a partition $\{\Sigma_{\text{call}}^j\}_{j=1}^k$ of Σ_{call} accepting a well-matched language L , the unique minimum-state k -SEVPA with respect to $\{\Sigma_{\text{call}}^j\}_j$ that accepts L can be computed in time $O(n^3)$, where n is the size M .*

5 Conclusions

We presented a characterization of VPLs in terms of congruences on strings of finite index and gave constructions of canonical automata recognizing visibly pushdown languages. We showed that while VPLs in general do not have unique minimum-state deterministic recognizers, the class of well-matched VPLs do have unique minimal k -module single-entry deterministic visibly pushdown automata (k -SEVPAs) for any fixed partition of the call symbols.

Our constructions of visibly pushdown automata based on congruences can, in general, result in automata with exponentially more states than a smallest deterministic visibly pushdown automaton recognizing the language. A characterization and construction of visibly pushdown automata that are at most polynomial in the size of the smallest automaton recognizing a language is an interesting open problem.

We presented a minimization algorithm for k -SEVPAs that runs in time $O(n^3)$. The computational complexity of the problem of constructing the smallest k -SEVPA given any visibly pushdown automaton (not necessarily k -module) is open, and would be interesting to investigate.

Acknowledgements. We would like to thank a referee for strengthening the lower bound for Proposition 2.

Abstract. In the Euclidean group *Traveling Salesman Problem* (TSP), we are given a set of points P in the plane and a set of m connected regions, each containing at least one point of P . We want to find a tour of minimum length that visits at least one point in each region. This unifies the TSP with Neighborhoods and the Group Steiner Tree problem. We give a $(9.1\alpha + 1)$ -approximation algorithm for the case when the regions are disjoint α -fat objects with possibly varying size. This considerably improves the best results known, in this case, for both the group Steiner tree problem and the TSP with Neighborhoods problem. We also give the first $O(1)$ -approximation algorithm for the problem with intersecting regions.

1 Introduction

A salesman wants to meet a set of potential buyers. Each buyer indicates a set of potential locations where he or she can meet the buyer. The salesman would like to minimize the total length of the tour required to meet all the potential buyers. How to construct such a tour? This problem is a generalization of the classical Traveling Salesman Problem (TSP), and hence is NP-hard. More formally, the problem we study can be stated as follows.

Euclidean Group TSP. Given a set P of points in the Euclidean plane, and m subsets $\{S_1, \dots, S_m\}$ of P , one has to construct a tour on a set $P' \subseteq P$ such that P' contains at least one point from each subset (group) S_i . The objective is to minimize the length of the tour.

This model unifies two important separate bodies of research – the Group Steiner Tree problem, and the Euclidean TSP with Neighborhoods problem, which arise in VLSI design [RW90], and routing-related applications [Mit00]. We describe these problems in more detail.

Group Steiner Tree. Given a graph G on n vertices with non-negative weights on the edges, and m subsets of vertices, the group Steiner tree problem calls for computing a sub-tree of G which contains at least one vertex from each subset (group), and whose total length is minimized.

Slavik [Sla97] presented an $O(k)$ -approximation algorithm for the Group Steiner Tree Problem in the metric case, where k is the maximum group size. Using probabilistic tree embeddings together with randomized rounding, Garg

Fig. 1. a) a tour in Euclidean Group TSP b) a tour in Euclidean TSP with Neighborhoods

et al. [GKR00] obtained a randomized $O(\log^3 n \log m)$ -approximation algorithm for the general case. On the negative side, it was observed (see e.g. [Sla96]) that the problem is a direct generalization of the set covering problem, and hence is NP-hard to approximate within a factor of $\omega(\log m)$.

A natural question is whether the above approximation ratio can be improved, if we consider restricted versions of the problem. For example, when the metric is Euclidean and each group is induced by a geometric object, such as a disk in the plane.

Euclidean TSP with Neighborhoods (TSPN). Given m connected geometric regions S_1, \dots, S_m in the Euclidean plane, find a minimum length tour that hits each region at least once.

The TSPN is a generalization of the classical Euclidean TSP which is known to be NP-hard [GGJ76, Pap77]. A $3/2$ -approximation algorithm, that works for any metric, was given by Christofides [Chr76]. Arora and Mitchell [Aro98, Mit99] independently obtained a $(1 + \epsilon)$ -approximation algorithm.

The TSPN was first studied by Arkin and Hassin [AH94]. They presented constant-factor approximations for the case where the geometric regions are translates of disjoint convex polygons, and for disjoint unit disks. For the general problem, Mata and Mitchell [MM95], and later Gudmundsson and Levcopoulos [GL00], gave an $O(\log m)$ -approximation algorithm. Dumitrescu and Mitchell [DM03] gave an $O(1)$ -approximation algorithm for intersecting unit disks. For disjoint varying-sized convex fat regions de Berg et al. [dBGK⁺02] present a sophisticated algorithm with approximation ratio $12000\alpha^3$, where α is a measure of fatness of the regions. Their algorithm uses Slavik’s algorithm [Sla97] for the Group Steiner tree problem, mentioned above. On the hardness side, Safra and Schwartz [SS03] showed that approximating Euclidean TSPN within $(2 - \epsilon)$ is NP-hard.

By viewing each geometric region S_i as an infinite set of points, the TSPN becomes a special case of the Euclidean Group TSP. In this context, it is natural to study the Euclidean Group TSP in which the point sets are separated by geometric objects, such as disks or more generally fat objects (see Figure 1).

Our Results. As mentioned above, our problem relates to both the Group Steiner Tree and the TSP with neighborhoods problems. Our algorithms improve and give new results in both areas.

In Section 3 we consider the problem with disjoint regions and give a $(9.1\alpha + 1)$ -approximation algorithm for the problem where groups are enclosed by non-intersecting α -fat objects of arbitrary size. This improves the previous best result on the TSP with neighborhoods problem in several ways. First, we dramatically reduce the previous best approximation factor of $12,000\alpha^3$ [dBGK⁺02]. Second, our groups are arbitrary point sets S_1, \dots, S_m , separated by fat objects in the Euclidean plane, whereas previous results only deal with the (continuous) case where each set S_i is the (infinite) set of points belonging to an object. We also do not require the objects to be convex. Furthermore, our algorithm yields an $O(\alpha/\sqrt{d})$ -approximate solution for any dimension d . In contrast, it was shown in [SS03] that TSP with neighborhoods in \mathbb{R}^3 is unlikely to be approximable within $O(\log^{1/2} n)$, and thus, for $d \geq 3$, it is unlikely that there is a approximation factor independent of both n and α .

In Section 4 we consider the variant of the problem in which the instances are defined by m sets of points in the Euclidean plane and a set of m disks. Disks may intersect and each disk defines a group consisting of the enclosed points. Clearly, the intersection between disks admits much more complicated systems of subsets than what we can get from the non-intersecting sets. We present an $O(1)$ -approximation algorithm for this problem.

2 Preliminaries

We consider instances of the Euclidean Group TSP in which the sets S_i are contained in geometric regions in the plane. Formally, we define a *region* as a connected and closed subset of the Euclidean plane \mathbb{R}^2 . An instance of our problem is given by a finite set of points P and m subsets S_1, \dots, S_m of P . The subsets have the property that there exist regions O_1, O_2, \dots, O_m such that $S_i = P \cap O_i$. A solution is given by a tour (spanning tree) on a subset P' of P such that $P' \cap S_i \neq \emptyset$. The objective is to minimize the length of the tour. We denote an optimal tour (spanning tree) by OPT, and its length by $|\text{OPT}|$.

In this paper we restrict to so called *fat* regions. The definition of fatness we use here was introduced by Van der Stappen [Sta94] and used by De Berg et al. [dBGK⁺02] in their paper on the TSP with neighborhoods problem.

Definition 1. An object $O \subseteq \mathbb{R}^2$ is said to be α -fat if for any disk Θ which does not fully contain O and whose center lies in O , the area of the intersection of O and Θ is at least $1/\alpha$ times the area of Θ .

Notice for example that the plane \mathbb{R}^2 has fatness 1, a halfspace has fatness 2 and a disk has fatness 4. We define the *size* of an object as the diameter of its smallest enclosing disk.

Lemma 1 (Packing Lemma). *The length of the shortest path connecting c disjoint α -fat objects in \mathbb{R}^2 is at least $(c/\alpha - 1)\pi S/4$, where S is the size of the smallest object.*

Proof. Consider a path T that connects the c objects and let the center of a disk with diameter S follow this path. At the point where the path touches a certain object, the disk intersects its boundary and hence at least an $1/\alpha$ fraction of the disk at that point intersects the object. The total area covered by the moving disk must be at least c/α times the area $\pi S^2/4$ of the disk. On the other hand, it is easy to see that the total area covered by a disk that follows a continuous path T in \mathbb{R}^2 is at most $\pi S^2/4 + S|T|$. Combining the upper and lower bound on the area we get,

$$c\pi S^2/(4\alpha) \leq \pi S^2/4 + S|T| \Rightarrow |T| \geq (c/\alpha - 1)\pi S/4. \quad \square$$

3 Varying-Sized Objects

In this section, we consider the case where the object O_1, \dots, O_m are pairwise disjoint. Further, we assume that all objects have fatness at most α . However, we do not put any restriction on the size of the objects, i.e., we do not assume that objects have comparable sizes. The problem reduces to geometric TSP when each set S_i consists of a single point.

There exists a simple $(m - 1)$ -approximation algorithm that we denote by GREEDY. We define the *distance* between a point p and a set X as $d(p, X) = \min_{x \in X} d(p, x)$.

Algorithm GREEDY:

- (1) Pick the points $p_i \in S_i$ ($i = 1 \dots m$) that minimize $\sum_{j=2}^m d(p_1, p_j)$.
- (2) For all $j \geq 2$, select twice the edge (p_1, p_j) and construct a tour by short cutting the edges.

Lemma 2. *Algorithm GREEDY gives an $(m - 1)$ -approximate solution for Group TSP.*

Proof. Any TSP-tour contains two edge disjoint paths from S_1 to S_i for all $i \in \{2, \dots, m\}$. Therefore, $(m - 1)|\text{OPT}| \geq 2 \sum_{i=2}^m d(p_1, p_i)$, which is at most the length of the tour constructed by the algorithm. □

By δ_i we denote the *diameter* of the point set S_i , i.e. the largest distance between any two points in S_i . Notice that δ_i is at most the size of its enclosing object. The following is an immediate corollary of Lemma 1.

Corollary 1. *The length of the shortest path connecting c of the given sets is at least $(c/\alpha - 1)\pi\delta/4$, where δ is the minimum of the diameters of the sets.*

Algorithm \mathcal{A} :

- (1) Order the point sets by their diameter $\delta_1 \leq \delta_2 \leq \dots \leq \delta_m$. Pick any p_1 in S_1 . For $i = 2$ up to m pick the point p_i in S_i that minimizes $d(p_i, \{p_1, \dots, p_{i-1}\})$, i.e. pick the point that is closest to the already chosen points.
- (2) Construct a $(1 + \epsilon)$ -approximate TSP tour T on this set of m points.
- (3) Output the minimum of T and the tour constructed by algorithm GREEDY.

The second step can be done efficiently for any $\epsilon > 0$ using techniques from [Aro98] and [Mit99].

Theorem 1. *Algorithm \mathcal{A} gives a $(1 + \epsilon)(9.1\alpha + 1)$ -approximate solution for the group TSP with non-intersecting α -fat neighborhoods.*

Proof. We assume $m - 1 > 9.1\alpha + 1$ since we can use GREEDY for smaller values of m . Denote the set of points chosen by \mathcal{A} as $P' = \{p_1, \dots, p_m\}$. Let $p_i^* \in \{p_1, \dots, p_{i-1}\}$ be the point at minimum distance from p_i and denote the distance by x_i .

Consider some optimal solution OPT and fix an orientation of this tour. We choose some number $c \in \{1, \dots, m\}$ and define T_i as the part of this directed tour that connects exactly c sets and starts from the point in S_i . Let t_i be the length of path T_i .

We choose $c = \lceil \alpha(4/\pi + 1) \rceil$. Notice that $c \in \{1, \dots, m\}$ is satisfied by the assumption in the first line of the proof. (By choosing c a bit smaller we can get a marginal improvement of the approximation ratio. Since this would make the proof more complicated we omit this here.) Consider some $i \in \{1, \dots, m\}$ and let $S_{h(i)}$ be a set with smallest diameter among those from the c sets on the path T_i . Then, by Corollary 1 and the choice of c we have

$$t_i \geq (c/\alpha - 1)\pi\delta_{h(i)}/4 \geq \delta_{h(i)}. \tag{1}$$

Since S_i is on this path T_i and we ordered the sets by their diameter we have $1 \leq h(i) \leq i$. We distinguish two cases.

If $h_i = i$, meaning that S_i has smallest diameter, then by (1) we have

$$t_i \geq \delta_i. \tag{2}$$

Otherwise, if $h(i) < i$, then we argue as follows. Since the algorithm picked point p_i we know that the distance from any point in S_i to the point $p_{h(i)}$ (which is chosen before p_i) is at least x_i . Hence, the distance from any point in S_i to any point in $S_{h(i)}$ is at least $x_i - \delta_{h(i)}$, implying $t_i \geq x_i - \delta_{h(i)}$. Together with (1) this yields

$$t_i \geq \max\{\delta_{h(i)}, x_i - \delta_{h(i)}\} \geq x_i/2. \tag{3}$$

We will construct a tour on the set of points $P' = \{p_1, \dots, p_m\}$ chosen by the algorithm, using the bounds (2) and (3). Let H be the set of indices i for which $t_i \geq \delta_i$ and let OPT $_H$ be the smallest tour through the points $\{p_i | i \in H\}$. Clearly,

$$|\text{OPT}_H| \leq |\text{OPT}| + 2 \sum_{i \in H} \delta_i \leq |\text{OPT}| + 2 \sum_{i \in H} t_i.$$

Let $\bar{H} = \{1, \dots, m\} \setminus H$. Then, by (3) we know that for any $i \in \bar{H}$, the length of the edge (p_i, p_i^*) equals $x_i \leq 2t_i$. We add this edge twice for any $i \in \bar{H}$ to the tour OPT_H . Clearly, the resulting graph is Eulerian. Moreover, it is connected since $p_1 \in H$, and for any i we have $p_i^* = p_j$ for some $j < i$. The total length of the Eulerian graph is

$$|\text{OPT}_H| + 2 \sum_{i \in \bar{H}} d(p_i, p_i^*) \leq |\text{OPT}| + 2 \sum_{i \in H} t_i + 2 \sum_{i \in \bar{H}} 2t_i \leq |\text{OPT}| + 4 \sum_{i=1}^m t_i.$$

When we take the sum over all t_i then every edge is counted $c-1$ times, implying $(c-1)|\text{OPT}| = \sum_{i=1}^m t_i$. Substituting the value of c we conclude that the tour given by our algorithm has length at most

$$(1 + \epsilon)(1 + 4(c-1))|\text{OPT}| < (1 + \epsilon)(9.093\alpha + 1)|\text{OPT}|.$$

□

The algorithm and proof apply directly to the Euclidean TSP with Neighborhoods problem under the weak assumption that, given the points $\{p_1, \dots, p_{i-1}\}$, we can efficiently find the point p_i in the infinite set of points S_i that minimizes $d(p_i, \{p_1, \dots, p_{i-1}\})$.

Corollary 2. *Algorithm \mathcal{A} gives a $(1 + \epsilon)(9.1\alpha + 1)$ -approximate solution for the TSP with neighborhoods problem.*

3.1 Higher Dimensions

The generalization of the definitions and lemma’s of the previous section to higher dimensions is straightforward.

Definition 2. *An object $O \subseteq \mathbb{R}^d$ is said to be α -fat if for any d -dimensional sphere D which does not fully contain O and whose center lies in O , the volume of the intersection of O and D is at least $1/\alpha$ times the volume of D .*

We denote the volume of a d -dimensional sphere with radius r by $V_d(r)$.

Lemma 3. *If the center of a d -dimensional sphere with radius r follows a path T in \mathbb{R}^d , then the volume covered by the sphere is at most $|T|V_{d-1}(r) + V_d(r)$.*

Lemma 4. *The length of the shortest path connecting c disjoint α -fat objects is at least $(c/\alpha - 1)V_d(r)/V_{d-1}(r)$, where r is half the size of the smallest object.*

The volume of a d -dimensional sphere with radius r is

$$V_d(r) = \frac{\pi^{d/2} r^d}{\Gamma(\frac{d+2}{2})},$$

where Γ is the well-known gamma function. For $d \geq 3$ we get

$$\frac{V_d(r)}{V_{d-1}(r)} = r\sqrt{\pi} \frac{\Gamma((d+2)/2)}{\Gamma((d+1)/2)} > r\sqrt{\pi d/2}.$$

For small values of K we can simply get a K -approximation as described in the previous section. If we choose c such that $(c/\alpha - 1)\sqrt{\pi d/2} = 1$, then the proof of Theorem 1 applies here without any adjustment.

Theorem 2. *Algorithm \mathcal{A} is an $O(\alpha/\sqrt{d})$ -approximation algorithm for the TSP in \mathbb{R}^d with non-intersecting α -fat neighborhoods.*

Notice that the approximation factor decreases in the dimension for constant α . However, for bounded objects, α grows exponentially in d . For example, $\alpha = 2^d$ for a d -dimensional sphere.

Safra and Schwartz [SS03] showed that TSP with neighborhoods in \mathbb{R}^3 is unlikely to be approximable within $O(\log^{1/2} n)$. Hence, there is little hope to improve our result for $d \geq 3$ to a ratio independent of the fatness α .

4 Intersecting Objects

In this section, we consider the case when the objects defining the sets S_1, \dots, S_m are intersecting disks of the same radius r . We denote these disks by $\mathcal{D} = \{D_1, \dots, D_m\}$, and their centers by c_i . Then $S_i = P \cap D_i$, and assume that $P = S_1 \cup \dots \cup S_m$.

A subset $P' \subseteq P$ is called a *hitting pointset* for \mathcal{D} if $P' \cap S_i \neq \emptyset$ for $i = 1, \dots, m$ and a *minimal hitting pointset* if for every $x \in P'$ there exists an $i \in [m]$ such that $(P' \setminus \{x\}) \cap S_i = \emptyset$. A minimal hitting set can be found by the natural greedy algorithm: Set $P' = P$, and keep deleting points from P' as long as it is still a hitting set. A (square) box B is called a *covering box* for the set of disks \mathcal{D} if B contains a hitting pointset for \mathcal{D} , and a *minimum covering box* if it has the smallest size amongst all such covering boxes. Since a minimum covering box is determined by two points of P on its boundary, there are only $O(n^2)$ such candidates. By enumerating over all such boxes, and verifying if they contain a hitting set, one can compute a minimum covering box.

Consider the following algorithm for the Group TSP problem on the sets S_1, \dots, S_m . Note that the last step can be done efficiently for any $\epsilon > 0$ using techniques from [Aro98] and [Mit99].

Algorithm \mathcal{B} :

- (1) Compute a minimum covering box B of \mathcal{D} .
- (2) Find a minimal hitting pointset $P' \subseteq P$ for \mathcal{D} inside B .
- (3) Compute a $(1 + \epsilon)$ -approximate TSP tour on P' .

To analyze the performance of the algorithm, we need the following lemma.

Lemma 5. *Let B be a box of diameter L that contains $P = \{p_1, \dots, p_n\}$. Let $\mathcal{D} = \{D_1, \dots, D_n\}$ be a collection of disks of radius r , such that (i) each point $p \in P$ is contained in exactly one disk $D(p) \in \mathcal{D}$ (ii) each disk D contains exactly one point of P . Then there exists a tour T on P with length at most $f(L/r)L$, where $f(L/r)$ is defined in (5). In particular, $f(6) \leq 113$.*

Fig. 2. (a) Partitioning disks into cones. (b) Partitioning B into k strips in direction \hat{a}_2 . The longest path is M (bold) if each angle is at most α

Proof. Fix constants $s, k > 0$. Denote the center of disk D_i by c_i . Set s equally-spaced identical ‘direction’ points on each circle, say a_1, \dots, a_s . Partition each disk D_i into s identical cones A_1, \dots, A_s where $A_j(D_i) = \{q \in D_i : \pi/s \leq \angle c_i q c_i a_j \leq \pi/s\}$. Denote by \hat{a}_j the direction of the tangent to the circles at point a_j . See Figure 2(a).

Now partition P into s subsets P_1, \dots, P_s , where P_j contains all the points $p \in P$ that lie in the cone $A_j(D(p))$ of the disk containing p . We will first construct a path on all the points in each P_j separately, and then connect these paths together.

Fix any set P_j . Partition B into k strips of equal width (each of width at most L/k), in the direction \hat{a}_j . W.l.o.g., assume \hat{a}_j is horizontal (one can always rotate everything to get this). The situation is shown in Figure 2 (b). Let P_j^i be the set of points belonging to the i -th strip. Assume P_j^i is sorted along the x -coordinates. Now construct a path M by connecting all the points in P_j^i in this linear sequence.

Claim. The path M constructed above has length at most $L/\cos \alpha$, where

$$\alpha \leq \max\left\{ \sin^{-1} \frac{L}{rk}, \frac{\pi}{2s} + \frac{\pi}{4} - \frac{1}{2} \sin^{-1} \left(\cos \frac{\pi}{s} - \frac{L}{rk} \right) \right\} \tag{4}$$

Proof. Let $P_j^i = \langle r_1, \dots, r_m \rangle$. We first bound the angle that each $r_l r_{l+1}$ and $r_l r_{l-1}$ makes with the horizontal line passing through r_l . The case of $r_l r_{l-1}$ is symmetric, so we only consider the first case. One can assume that r_{l+1} is below r_l (otherwise, consider the angle made by $r_{l+1} r_l$ with line passing through r_{l+1} ; both angles are the same and now r_l lies below r_{l+1}).

We would like to place points r_l and r_{l+1} such that the angle of the edge $r_l r_{l+1}$ with the horizontal is maximized. By assumption, r_l and r_{l+1} are contained in two disks of radius r containing only their respective points. It is not hard to see that there are two possible worst-case choices, as shown in Figure 3. The first

Fig. 3. The two cases for bounding α

case is when r_l is the center of its enclosing disk $D(r_l)$, and r_{l+1} lies (almost) on the boundary of $D(r_l)$, see Figure 3(a). Clearly, the required angle $\alpha \leq \sin^{-1} \frac{L}{rk}$. The second case is shown in Figure 3(b). By elementary geometry, we get

$$a = r \cos \frac{\pi}{s}, \quad b = a - \frac{L}{k}, \quad \sin c = \frac{b}{r}$$

from which one can derive that

$$\alpha \leq \frac{\pi}{2s} + \frac{\pi}{4} - \frac{1}{2} \sin^{-1} \frac{b}{r}.$$

Therefore, the maximum angle that any edge $r_l r_{l+1}$ makes with the horizontal is given by Equation 4. Finally, the weight of M is maximized if each edge makes the maximum angle (at most α) with the horizontal, as shown in Figure 2 (b). Then $M \leq L / \cos \alpha$, as required. \square

The above claim bounds the weight of the spanning path (constructed by simply sorting the points by x -coordinates and connecting them in this order) of points lying in cone A_j and the i -th strip. There are at most sk such paths, and they can be connected together into a tour T at the cost of additional total length of $sk \cdot L$. Therefore the constructed tour has a total length of at most $L \cdot f(L/r)$, where

$$f\left(\frac{L}{r}\right) = \min_{s,k} \{sk(1 + \sec \alpha(s, k, L/r))\}, \tag{5}$$

and where $\alpha(s, k, L/r) = \max\{\sin^{-1} \frac{L}{rk}, \frac{\pi}{2s} + \frac{\pi}{4} - \frac{1}{2} \sin^{-1}(\cos \frac{\pi}{s} - \frac{L}{rk})\}$. In particular, with $L/r = 6$, and setting $k = 6.5$ and $s = 4.5$, the tour has length at most $113L$. \square

Theorem 3. *Algorithm B is a $O(1)$ -approximation algorithm for the Group TSP problem.*

Proof. Since P' is a hitting set for \mathcal{D} , it is enough to show that there exists a tour T on the set P' whose total cost is within $O(1)$ of the optimum for \mathcal{D} ¹. To P' we can associate a subset of the disks $\mathcal{D}' \subseteq \mathcal{D}$ with the property that $|P' \cap D| = 1$ for all $D \in \mathcal{D}'$ and $|\{D \in \mathcal{D}' : x \in D\}| = 1$ for all $x \in P'$. The set \mathcal{D}' can be found as follows. By the minimality of P' , for every point $x \in P'$ there exists a disk $D(x) \in \mathcal{D}$ such that $D \cap P' = \{x\}$. Let $\mathcal{D}' = \{D(x) : x \in P'\}$.

For a disk $D \in \mathcal{D}'$, let us denote by $x(D)$ the (unique) point of P' contained inside D . Let $\mathcal{I} \subseteq \mathcal{D}'$ be a *maximal independent set* of disks in \mathcal{D}' , i.e. a maximal collection of pairwise disjoint disks. If every maximal independent set in \mathcal{D}' has size at most 2, we assume that \mathcal{I} consists of two disks in \mathcal{D}' , the distance δ between which is the largest. Let $\text{OPT}_{\mathcal{I}}$ be an optimal Group TSP tour on \mathcal{I} , when we are allowed to use any of the points lying inside the disks of \mathcal{I} , and let $\text{OPT}'_{\mathcal{I}}$ an optimal TSP tour on the set of points $\{x(I) : I \in \mathcal{I}\}$. Clearly, $|\text{OPT}_{\mathcal{I}}| \leq |\text{OPT}|$. We consider three cases:

Case 1: $|\mathcal{I}| \geq 3$: By the maximality of \mathcal{I} , every disk in $\mathcal{D}' \setminus \mathcal{I}$ must intersect some disk in \mathcal{I} . Let $\{\mathcal{D}_I \subseteq \mathcal{D}' \setminus \mathcal{I} : I \in \mathcal{I}\}$ be a partition of $\mathcal{D}' \setminus \mathcal{I}$, such that, for $I \in \mathcal{I}$, \mathcal{D}_I contains only disks intersecting I . For $I \in \mathcal{I}$, let OPT_I be an optimal TSP tour on the pointset $S_I = \{x(D) : D \in \mathcal{D}_I\} \cup \{x(I)\}$ contained in the partition of disks intersecting I . To define the tour T , take the union T' of $\text{OPT}_{\mathcal{I}}$ and $\bigcup_{I \in \mathcal{I}} \text{OPT}_I$ to obtain an Eulerian connected graph T' on the pointset P' . Finally, we use short-cutting on an Eulerian tour in T' to get a TSP tour T on P' (see Figure 4).

Fig. 4. Constructing an approximate tour as in the proof of Theorem 3

¹ The constants in the approximation factor can be improved by a more complicated analysis, which we omit from this extended abstract.

Claim. $|T| \leq (1 + (4 + 6f(6))/0.14)|\text{OPT}|$, where $f(\cdot)$ is defined by (5).

Proof. Note that, for $I \in \mathcal{I}$, all the points of S_I lie inside a box of diameter at most $6r$. Thus applying Lemma 5, we conclude that there is a tour on S_I of size at most $f(6) \cdot 6r$. In particular, $|\text{OPT}_I| \leq 6f(6) \cdot r$. On the other hand, by Lemma 1, and using $\alpha = 4$ for disks, one can derive that $|\text{OPT}_{\mathcal{I}}| \geq 0.14r|\mathcal{I}|$. Furthermore, by connecting by a double edge, for each disk $I \in \mathcal{I}$, the point picked by the optimal solution $\text{OPT}_{\mathcal{I}}$ to the point $x(I)$, we can construct a TSP tour on the set $\{x(I) ; I \in \mathcal{I}\}$ of total length at most $|\text{OPT}_{\mathcal{I}}| + 4r|\mathcal{I}|$. Thus it follows that $|\text{OPT}'_{\mathcal{I}}| \leq |\text{OPT}_{\mathcal{I}}| + 4r|\mathcal{I}|$. Combining these together, we get

$$\begin{aligned} |T| &\leq |\text{OPT}'_{\mathcal{I}}| + \sum_{I \in \mathcal{I}} |\text{OPT}_I| \leq |\text{OPT}_{\mathcal{I}}| + (4 + 6f(6))r|\mathcal{I}| \\ &\leq \left(1 + \frac{4 + 6f(6)}{0.14}\right)|\text{OPT}_{\mathcal{I}}| \leq \left(1 + \frac{4 + 6f(6)}{0.14}\right)|\text{OPT}|, \end{aligned}$$

and our claim follows. \square

Case 2: $|\mathcal{I}| = 2$ and $\delta > 2r$: Note that δ is a lower bound on $|\text{OPT}_{\mathcal{I}}|$. Then $r|\mathcal{I}| \leq |\text{OPT}_{\mathcal{I}}|$ and, similar to Case 1, we can construct a tour T of length at most $(1 + (4 + 6f(6))/0.14)|\text{OPT}|$.

Case 3: $|\mathcal{I}| = 2$ and $\delta \leq 2r$, or $|I| = 1$: Let L be the size of the minimum covering box B . Note that $\text{OPT} \geq L$ because (i) any box containing OPT is a covering box, and (ii) the smallest such box has width or height at most $|\text{OPT}|$. It is easy to see, in this case, that all the points of P' lie inside a box of size at most $6r$. In particular, this implies that $L \leq 6r$. By Lemma 5, we can construct a tour T on the pointset P' whose total length does not exceed $f(6) \cdot L \leq f(6)|\text{OPT}|$. \square

Influential Nodes in a Diffusion Model for Social Networks

Abstract. We study the problem of maximizing the expected spread of an innovation or behavior within a social network, in the presence of “word-of-mouth” referral. Our work builds on the observation that individuals’ decisions to purchase a product or adopt an innovation are strongly influenced by recommendations from their friends and acquaintances. Understanding and leveraging this influence may thus lead to a much larger spread of the innovation than the traditional view of marketing to individuals in isolation.

In this paper, we define a natural and general model of influence propagation that we term the *decreasing cascade model*, generalizing models used in the sociology and economics communities. In this model, as in related ones, a behavior spreads in a cascading fashion according to a probabilistic rule, beginning with a set of initially “active” nodes. We study the *target set selection* problem: we wish to choose a set of individuals to target for initial activation, such that the cascade beginning with this active set is as large as possible in expectation. We show that in the decreasing cascade model, a natural greedy algorithm is a $1 - 1/e - \varepsilon$ approximation for selecting a target set of size k .

1 Introduction

Suppose that we are trying to market a product, or promote an idea, innovation or behavior, within a population of individuals. In order to do so, we can “target” individuals; for instance, this “targeting” could take the form of offering free samples of the product, demonstrating an innovation, or explaining an idea (such as the consequences of drug use to teenagers). An important question is

then whom we should target. Clearly, if there were no interaction between the individuals, this would be straightforward: the effect on each targeted individual could be determined in isolation, and we could choose the set of individuals with largest (expected) revenue or reach. However, individuals do not exist in a vacuum; rather, they form complex social networks based on a multitude of different relations and interactions. By virtue of these interactions, they influence each other's decisions in adopting a product or behavior.

Research in the area of *viral marketing* [1, 2, 3, 4, 5] takes advantage of these social network effects, based on the premise that targeting a few key individuals may lead to strong “word-of-mouth” effects, wherein friends recommend a product to their friends, who in turn recommend it to others, and so forth, creating a cascade of recommendations. In this way, decisions can spread through the network from a small set of initial adopters to a potentially much larger group. Given a probabilistic model for the way in which individuals influence one another, the *influence maximization problem* consists in determining a set A of k individuals yielding the largest expected cascade.

The influence maximization problem has been proposed and studied by Domingos and Richardson [2, 5], who gave heuristics for the problem in a very general descriptive model of influence propagation. In recent work [6], we obtained provable performance guarantees for approximation algorithms in several simple, concrete, but extensively studied models from mathematical sociology (see, e.g., [7, 8, 9] for comprehensive introductions to this area).

In this paper, we show that the influence maximization problem can be approximated in a very general model that we term the *decreasing cascade model*. The analysis techniques from our earlier work [6] rely on the concrete forms of influence used in that paper, and we show that they cannot be applied to the general model considered here. We therefore develop a more general framework, which we believe will be of interest in its own right, for reasoning about dynamic processes in network models such as these.

1.1 The Decreasing Cascade Model

Throughout this paper, we call individuals (nodes) *active* if they have adopted the product, and *inactive* otherwise. We assume that once a node becomes active, it will remain so forever (see [6] for a discussion on how this assumption can be lifted). We focus on *cascade models* that capture the dynamics of recommendations in a step-by-step fashion: when a node u first becomes active, say at time t , it is considered *contagious*. It has one chance of influencing each previously inactive neighbor v . A successful attempt will cause v to become active in the next time step $t + 1$. If multiple neighbors of v become active at time t , then their activation attempts are sequenced in an arbitrary order, but we assume that they all happen within time step t . After a node u has made all its attempts at influencing other nodes, it remains active, but is now *non-contagious*. The process terminates when there are no more contagious nodes.

In order to fully describe the model, we need to specify the probability of success for node u 's attempt at activating v . In the simplest *independent cascade*

model [3], this probability is a constant $p_v(u)$, independent of the history of the process. In general, however, v 's propensity for being activated may change as a function of which of its neighbors have already attempted (and failed) to influence it; if S denotes the set of v 's neighbors that have already attempted to influence v , then u 's *success probability* is denoted by $p_v(u, S)$. For this model to be well-defined, we also need to assume *order-independence*: if all nodes from a set T try to influence v , then the order in which their attempts are made does not affect the probability of v being active in the end. Formally, if u_1, \dots, u_r , and u'_1, \dots, u'_r are two permutations of T , and $T_i = \{u_1, \dots, u_{i-1}\}$ as well as $T'_i = \{u'_1, \dots, u'_{i-1}\}$, then order-independence means that

$$\prod_{i=1}^r (1 - p_v(u_i, S \cup T_i)) = \prod_{i=1}^r (1 - p_v(u'_i, S \cup T'_i))$$

for all sets S disjoint from T .

From the point of view of influence maximization, we start by *targeting* a set A of individuals for activation at time 1, making them contagious. Afterwards, the process unfolds as described above, until there are no more contagious nodes; we say that the process *quiesces*. Note that this happens after at most $n + 1$ rounds. At that point, we have some set $\varphi(A)$ of active nodes, which is a random variable. The goal is to choose A so as to maximize the expected size $\sigma(A) := \mathbb{E}[|\varphi(A)|]$ of this final set of active nodes. Due to the computational difficulty of this goal (see the discussion below), we will consider approximation algorithms: for a constant c , we wish to choose a set A for which $\sigma(A)$ is at least $\frac{1}{c}$ times as large as $\sigma(A^*)$ for *any* set A^* of k nodes. The quantity c is thus the approximation guarantee of the algorithm.

The *order-independent cascade model* is very general — it specifies how each node influences each other node, and how the influence is “attenuated” by previous interactions a node has had. It is also equivalent in a precise sense to a generalization of Granovetter’s threshold model [10] for social networks (see Section 3).

In general, it is NP-hard to approximately maximize the size $\sigma(A)$ of the final active set to within $n^{1-\varepsilon}$, for any $\varepsilon > 0$. The inapproximability follows from a straightforward reduction, e.g., from VERTEXCOVER, and can already be shown in the case of a *hard threshold* model [11, 12, 13], where a node v is activated if at least a fixed fraction (say, 1/2) of its neighbors are active; this corresponds to $p_v(u, S)$ being 0 if S contains fewer than half of v 's neighbors, and 1 otherwise.

Thus, we study here a natural restriction that we term the *decreasing cascade model*. In the decreasing cascade model, the functions $p_v(u, S)$ are non-increasing in S , i.e., $p_v(u, S) \geq p_v(u, T)$ whenever $S \subseteq T$. Intuitively, this restriction states that a contagious node’s probability of activating some $v \in V$ decreases if more nodes have already attempted to activate v , and v is hence more “marketing-saturated”. The decreasing cascade model contains the *independent cascade model* [3] as a special case, and even for the independent cascade model, maximizing $\sigma(A)$ is NP-hard [6]; in fact, the proof in [6] shows that it is NP-hard to approximate within $1 - 1/e + \varepsilon$ for any $\varepsilon > 0$.

2 An Approximation Algorithm

In this paper, we analyze the following simple greedy algorithm (Algorithm 1.) for influence maximization. The approximation guarantee for this algorithm is the main theorem of this paper:

Algorithm 1. Greedy Approximation Algorithm

- 1: Start with $A = \emptyset$
 - 2: **for** $i = 1$ to k **do**
 - 3: Let v_i be a node (approximately) maximizing the *marginal gain* $\sigma(A \cup \{v\}) - \sigma(A)$.
 - 4: Set $A \leftarrow A \cup \{v_i\}$.
 - 5: **end for**
-

Theorem 1. *Let A^* be the the set maximizing $\sigma(\cdot)$ among all sets of k nodes.*

1. *If the optimal v_i is chosen in each iteration, then the greedy algorithm is a $(1 - 1/e)$ -approximation, i.e., the set A found by the algorithm satisfies $\sigma(A) \geq (1 - 1/e) \cdot \sigma(A^*)$.*
2. *If the node v_i is a $1 - \varepsilon$ approximate best node in each iteration, then the greedy algorithm is a $(1 - 1/e - \varepsilon')$ -approximation, where ε' depends on ε polynomially.*

Before proceeding with the proof of Theorem 1, a few words are in order about determining the node v_i in the **for** loop of the algorithm. Even in the simple independent cascade model, it is not clear how to evaluate $\sigma(A)$ exactly, or whether this can be done in polynomial time; in fact, we consider the question of evaluating $\sigma(A)$ an interesting direction for further research. However, the cascade process has the property that it can be efficiently simulated, simply by running the probabilistic rule for influence propagation until quiescence (which, as noted above, will occur within at most $n + 1$ rounds). By repeatedly simulating the cascade process and sampling $\varphi(A)$, we can compute arbitrarily close approximations to $\sigma(A)$. A straightforward calculation shows that with a number of simulations polynomial in ε, δ , and n , one can obtain a $1 \pm \varepsilon$ approximation to $\sigma(A)$, with probability at least $1 - \delta$. This approximate evaluation of $\sigma(A)$ in turn is enough to find an element v whose marginal gain $\sigma(A \cup \{v\}) - \sigma(A)$ is within a factor of $1 - \varepsilon'$ of maximal.

The idea for the proof of Theorem 1 is to show that $\sigma(A)$ is a monotone and submodular function of A . The property of submodularity formally means that $\sigma(S \cup \{w\}) - \sigma(S) \geq \sigma(T \cup \{w\}) - \sigma(T)$ whenever $S \subseteq T$. Informally, this is known as the “diminishing returns condition”: the return derived from investing in node w diminishes as the size of the total investment (set) increases.

These properties of $\sigma(A)$ are sufficient to prove the desired approximation guarantee, for we can apply a well-known theorem of Nemhauser, Wolsey and Fischer. The first part of the theorem below is due to Nemhauser, Wolsey and Fischer [14, 15]; the generalization can be obtained by straightforward modifications to the proof.

Theorem 2. *Let f be a non-negative, monotone, submodular function on sets.*

1. *The greedy algorithm, which always picks the element v with largest marginal gain $f(S \cup \{v\}) - f(S)$, is a $(1 - 1/e)$ -approximation algorithm for maximizing f on k -element sets S .*
2. *A greedy algorithm which always picks an element v within $1 - \varepsilon$ of the largest marginal gain results in a $1 - 1/e - \varepsilon'$ approximation, for some ε' depending polynomially on ε .*

Given Theorem 2, in order to prove Theorem 1 (or its approximate version), it is sufficient to establish the following result:

Theorem 3. *For the decreasing cascade model, $\sigma(A)$ is a monotone and submodular function of A .*

Remark. The proof of the $(1 - 1/e)$ approximation guarantee in [6] was based on the same outline. In order to establish submodularity for the independent cascade and linear threshold models of [6], it was shown that for both models, it is possible to define distributions over directed graphs with the following property: for any set S of nodes, the probability that $\varphi(A) = S$ under the influence model is equal to the probability that the nodes of S are exactly the ones reachable from A in a graph chosen according to the corresponding distribution. Submodularity then follows readily from the fact that the number of reachable nodes in a fixed graph is a submodular function of the set of source nodes.

The decreasing cascade model is more general than the models considered in [6]. In Section 5, we give an instance which provably has no corresponding distribution on graphs. Therefore, the proof for submodularity becomes more intricate, and we have to consider the dynamics of the process in a more detailed way.

Most of the rest of this paper will be concerned with the proof of Theorem 3. We first introduce a generalized version of Granovetter’s threshold model [10] in Section 3, as a useful reparametrization of the probability space. Using this threshold model, we then give the proof of Theorem 3 in Section 4.

3 The General Threshold Model

Recall that the notion of order-independence, as defined in Section 1.1, postulates that for a given set S of nodes trying to influence node v , the order in which these attempts are made does not affect the probability that v will be active once all the nodes in S have made their attempts. For the proof of Theorem 3, we require a stronger version of this statement: namely that even if the activation of nodes, or some activation attempts, are deferred for many time steps, the ultimate distribution over active sets remains the same.

It is not clear how to argue this fact directly from the definition of the cascade model, and we therefore introduce the general threshold model, a natural

generalization of Granovetter’s linear threshold model [10]. The linear threshold model has been the foundation for a large body of work in sociology; see, e.g., [8, 16, 17, 18, 19, 20, 21]; its generalization was introduced in [6]. While the General threshold model is a natural model in its own right, in this work, we are most interested in it as a reparametrization of the cascade model. Indeed, Lemma 1 proves that the two models are equivalent.

In the *general threshold model* [6], each node v has a monotone *activation function* $f_v : 2^V \rightarrow [0, 1]$, and a threshold θ_v , chosen independently and uniformly at random from the interval $(0, 1]$. A node v becomes active at time $t + 1$ if $f_v(S) \geq \theta_v$, where S is the set of nodes active at time t . Again, the process starts with the activation of a select set A at time 1.

The threshold model focuses more on the “cumulative effect” of a node set S ’s influence on v , instead of the individual attempts of nodes $u \in S$. The perhaps somewhat surprising fact is that for any activation functions $f_v(\cdot)$, we can define corresponding success probabilities $p_v(\cdot, \cdot)$ such that the distribution over final active sets $\varphi(A)$ is identical under both models, for all sets A .

Specifically, given success probabilities $p_v(u, S)$, we define the activation functions

$$f_v(S) = 1 - \prod_{i=1}^r (1 - p_v(u_i, S_i)), \quad (1)$$

where $S = \{u_1, u_2, \dots, u_r\}$, and $S_i = \{u_1, \dots, u_{i-1}\}$. That f_v is well defined follows from the order-independence assumption on the $p_v(u, S)$. Conversely, given activation functions f_v , we define success probabilities

$$p_v(u, S) = \frac{f_v(S \cup \{u\}) - f_v(S)}{1 - f_v(S)}. \quad (2)$$

It is straightforward to verify that the activation functions defined via Equation (1) satisfy Equation (2), and the success probabilities defined via Equation (2) satisfy Equation (1).

Lemma 1. *Assume that the success probabilities $p_v(u, S)$ and activation functions $f_v(S)$ satisfy Equation (2). Then, for each node set T and each time t , the probability that exactly the nodes of set T are active at time t is the same under the order-independent cascade process with success probabilities $p_v(u, S)$ and the general threshold process with activation functions $f_v(S)$.*

Proof. We show, by induction, a slightly stronger statement: namely that for each time t and any pair (T, T') , the probability that exactly the nodes of T are active at time t , and exactly those of T' are active at time $t + 1$, is the same under both views. By summing over all sets T' , this clearly implies the lemma.

At time $t = 0$, the inductive claim holds trivially, as the probability is 1 for the pair (\emptyset, A) and 0 for all other pairs, for both processes. For the inductive step to time t , we first condition on the event that the nodes of T are active at time $t - 1$, and those of T' at time t .

Consider a node $v \notin T'$. Under the cascade process, v will become active at time $t + 1$ with probability $1 - \prod_{i=1}^r (1 - p_v(u_i, T \cup T'_i))$, where we write $T' \setminus T = \{u_1, \dots, u_r\}$ and $T'_i = \{u_1, \dots, u_{i-1}\}$. Under the threshold process, node v becomes active at time $t + 1$ iff $f_v(T) < \theta_v \leq f_v(T')$. Because node v is not active at time t , and by the Principle of Deferred Decisions, θ_v is uniformly distributed in $(f_v(T), 1]$ at time t , so the probability that v becomes active is $\frac{f_v(T') - f_v(T)}{1 - f_v(T)}$. Substituting Equation (1) for $f_v(T)$ and $f_v(T')$, a simple calculation shows that

$$\frac{f_v(T') - f_v(T)}{1 - f_v(T)} = 1 - \prod_{i=1}^r (1 - p_v(u_i, T \cup T'_i)).$$

Thus, each individual node becomes active with the same probability under both processes. As both the thresholds θ_v and activation attempts are independent for distinct nodes, the probability for any set T'' to be the set of active nodes at time $t + 1$ is the same under both processes. Finally, as the probability distribution over active sets T'' is the same conditioned on any pair (T, T') of previously active sets, the overall distribution over pairs (T', T'') is the same in both the cascade and threshold processes.

Lemma 1, which was stated without proof in [6], shows that the threshold model is a non-trivial reparametrization of the cascade model. In a natural way, it allows us to make all random choices at time 0, before the process starts. An alternate way of attempting to pre-flip all coins, for instance by providing a sequence of random numbers from $[0, 1]$ for use in deciding the success of activation attempts, would not preserve order-independence.

The nice thing about this view is that it makes a strong generalization of the notion of order-independence an almost trivial feature of the model. To formulate this generalization, we allow each node v a finite *waiting time* τ_v , meaning that when v 's criterion for activation has been met at time t (i.e., an influence attempt was successful in the cascade model, or $f_v(S) \geq \theta_v$ in the threshold model), v only becomes active at time $t + \tau_v$. Notice that when $\tau_v = 0$ for all nodes, this is the original threshold/cascade model.

Lemma 2. *Under the general threshold model, the distribution $\varphi(A)$ over active sets at the time of quiescence is the same regardless of the waiting times τ_v . This even holds conditioned upon any random event \mathcal{E} .*

Proof. We prove the stronger statement that for every choice of thresholds θ_v , and every vector τ of waiting times τ_v , the set S_τ of nodes active at the time of quiescence is the same as the set S_0 of nodes active at quiescence when all waiting times are 0. This will clearly imply the claim, by integrating over all thresholds that form the event \mathcal{E} . So from now on, fix the thresholds θ_v .

Let $A_{0,t}$ denote the set of nodes active at time t when all waiting times are 0, and $A_{\tau,t}$ the set of nodes active at time t with waiting times τ . A simple inductive proof using the monotonicity of the activation functions f_v shows that $A_{\tau,t} \subseteq A_{0,t}$ for all times t , which, by setting t to be the time of quiescence of the process with waiting times τ , implies that $S_\tau \subseteq S_0$.

Assume now that $S_\tau \neq S_0$, and let $T = S_0 \setminus S_\tau \neq \emptyset$. Among the nodes in T , let v be one that was activated earliest in the process without waiting times, i.e., $T \cap A_{0,t} = \emptyset$, and $v \in A_{0,t+1}$ for some time t . Because v was activated, we know that $\theta_v \leq f_v(A_{0,t})$, and by definition of v , no previously active nodes are in T , i.e., $A_{0,t} \subseteq S_\tau$. But then, the monotonicity of f_v implies that $\theta_v \leq f_v(S_\tau)$, so v should be active in the process with waiting times τ , a contradiction.

4 Proof of Theorem 3

The monotonicity is an immediate consequence of Lemma 3 below, applied with $V = V'$ and $p'_v(u, S) = p_v(u, S)$ for all S, v, u . So we focus on submodularity for the remainder of the proof. We have to show that, whenever $A \subseteq A'$, we have $\sigma(A \cup \{w\}) - \sigma(A) \geq \sigma(A' \cup \{w\}) - \sigma(A')$, for any node $w \notin A'$.

The basic idea of the proof is to characterize $\sigma(A \cup \{w\}) - \sigma(A)$ in terms of a *residual process* which targets only the node w , and has appropriately modified success probabilities (similarly for $\sigma(A' \cup \{w\}) - \sigma(A')$). To show that these residual processes indeed have the same distributions over final active sets $\varphi(\{w\})$ as the original processes, we use Lemma 2.

Given a node set B , we define the *residual process* on the set $V \setminus B$: the success probabilities are $p_v^{(B)}(u, S) := p_v(u, S \cup B)$, and the only node targeted is w , targeted at time 1. Let $\varphi_B(w)$ denote the set of nodes active at the time of quiescence of the residual process; notice that this is a random variable. We claim that, conditioned on the event that $[\varphi(A) = B]$, the variable $\varphi_B(w)$ has the same distribution as the variable $\varphi(A \cup \{w\}) \setminus \varphi(A)$.

In order to prove this fact, we focus on the threshold interpretation of the process, and assign node w a waiting time of $\tau_w = n + 1$. By Lemma 2, this view does not change the distribution of $\varphi(A \cup \{w\}) \setminus \varphi(A)$. Then, w is the only contagious node at time $n + 1$, and by the conditioning, the other active (but non-contagious) nodes are those from B . This implies that only nodes from $V \setminus B$ will make activation attempts after time $n + 1$. By using the same order of activation attempts, and the same coin flips for each pair $u, v \in V \setminus B$, a simple inductive proof on the time t shows that the set S of nodes is active in the residual process at time t if and only if the set $S \cup B$ is active in the original process at time $n + t$. In particular, this shows that the two random variables have the same distributions.

Having shown this equivalence, we want to compare the expected sizes of $\varphi_B(w)$ and $\varphi_{B'}(w)$, when $B \subseteq B'$. We write $\sigma_B(w) = \mathbb{E}[|\varphi_B(w)|]$, as well as $\sigma_{B'}(w) = \mathbb{E}[|\varphi_{B'}(w)|]$. First off, notice that the node set $V \setminus B$ of the former process is a superset of $V \setminus B'$. Furthermore, for all nodes u, v and node sets S , the decreasing cascade condition implies that

$$p_v^{(B)}(u, S) = p_v(u, S \cup B) \geq p_v(u, S \cup B') = p_v^{(B')}(u, S).$$

Lemma 3 below proves the intuitively obvious fact that the combination of a larger ground set of nodes and larger success probabilities results in a larger set of activated nodes, i.e.,

$$\sigma_w(B) \geq \sigma_w(B') \tag{3}$$

Finally, we can rewrite the expected number of active nodes as

$$\begin{aligned} \sigma(A \cup \{w\}) - \sigma(A) &= \sum_B \sigma_w(B) \cdot \text{Prob}[\varphi(A) = B] \\ &= \sum_B \sum_{B' \supseteq B} \sigma_w(B) \cdot \text{Prob}[\varphi(A) = B, \varphi(A') = B'] \\ &\geq \sum_B \sum_{B' \supseteq B} \sigma_w(B') \cdot \text{Prob}[\varphi(A) = B, \varphi(A') = B'] \\ &= \sum_{B'} \sigma_w(B') \cdot \text{Prob}[\varphi(A') = B'] \\ &= \sigma(A' \cup \{w\}) - \sigma(A'). \end{aligned}$$

The inequality followed by applying Inequality (3) under the sum. In both of the steps surrounding the inequality, we used that $\text{Prob}[\varphi(A) = B, \varphi(A') = B'] = 0$ whenever $B \not\subseteq B'$, by the monotonicity of the cascade process. This completes the proof of submodularity. ■

Lemma 3. *Let $V' \subseteq V$, and assume that $p'_v(u, S) \leq p_v(u, S)$ for all nodes $u, v \in V$ and all sets S . If $A' \subseteq A$ are the targeted sets for cascade processes on V' and V , then the expected size of the active set at the end of the process on V is no smaller than the corresponding expected size for the process on V' .*

Proof. This claim is most easily seen in the threshold view of the process. Equation (1) shows that the activation functions f'_v, f_v corresponding to the success probabilities $p'_v(u, S)$ and $p_v(u, S)$ satisfy $f'_v(S) \leq f_v(S)$, for all nodes v and sets S . Then, for any fixed thresholds θ_v , a simple inductive proof on time steps t shows that the set of active nodes in the former process (with functions f'_v) is always a subset of the set of active nodes in the latter one (with functions f_v). Since the inequality thus holds for every point of the probability space, it holds in expectation.

5 Distributions over Graphs

As mentioned briefly before, the outline of the proof of the $(1 - 1/e)$ approximation guarantee in [6] was the same as here. However, a simpler technique was used to show the submodularity of $\sigma(A)$.

This technique can be most easily understood in the case of the independent cascade model, where each activation attempt of a node u on a node v succeeds independently with probability $p_v(u)$. By the definition of the process, a node v is active in the end if it is reachable from one of the initially targeted nodes by a chain of successful activation attempts. If we consider a graph G that contains a directed arc (u, v) iff u 's activation attempt on v succeeded, then it follows that a node v is active iff it is reachable in G from the targeted set

A. Due to the independence of activation attempts, and by the Principle of Deferred Decisions, the graph G can be generated by including each arc (u, v) independently with probability $p_v(u)$. As the set of nodes reachable from a given set A is a submodular function of A , and the expected size of the activated set is a non-negative linear combination (over all possible graphs G) of these functions, the function $\sigma(A)$ is shown to be submodular.

This technique can be applied whenever the influence model allows for a corresponding distribution on directed graphs G — the fact that we included each arc independently did not matter. In fact, [6] uses this technique to show submodularity in two other, less obvious, cases. In this section, we give an instance of the decreasing cascade model for which there is no distribution over graphs resulting in the same activation probabilities. This example shows that the techniques used to show submodularity of $\sigma(A)$ in [6] cannot be applied for the more general decreasing cascade model.

Our example has five nodes. Node v could potentially be influenced by four nodes u_1, \dots, u_4 . The first two nodes to try activating v have a probability of $\frac{1}{2}$ each to succeed, whereas all subsequent attempts fail. The influences are thus $p_v(u_i, S) = \frac{1}{2}$ whenever $|S| < 2$, and $p_v(u_i, S) = 0$ otherwise. Notice that this is indeed an instance of the decreasing cascade model, and order independent.

Assume, for contradiction, that there is a distribution on graphs such that node v is reachable from a set S with the same probability that S will activate v in the cascade model. For any set $S \subseteq \{1, 2, 3, 4\}$, let q_S denote the probability that in this distribution over graphs, exactly the edges from u_i to v for $i \in S$ are present. Because with probability $\frac{1}{4}$, v does not become active even if all u_i are, we know that $q_\emptyset = \frac{1}{4}$. If u_1, u_2, u_3 are active, then v is also active with probability $\frac{3}{4}$, so the edge (u_4, v) can never be present all by itself (if it were, then the set $\{u_1, u_2, u_3, u_4\}$ together would have higher probability of reaching v than the set $\{u_1, u_2, u_3\}$). Thus, we have that $q_{\{i\}} = 0$ for all i . The same argument shows that $q_{\{i,j\}} = 0$ for all i, j .

Thus, the only non-empty edge sets with non-zero probabilities can be those of size three or four. If node u_1 is the only active node, then v will become active with probability $\frac{1}{2}$, so the edge (u_1, v) is present with probability $\frac{1}{2}$. Hence, $q_{\{1,2,3\}} + q_{\{1,2,4\}} + q_{\{1,3,4\}} + q_{\{1,2,3,4\}} = \frac{1}{2}$, while $q_{\{1,2,3\}} + q_{\{1,2,4\}} + q_{\{1,3,4\}} + q_{\{2,3,4\}} + q_{\{1,2,3,4\}} = 1 - q_\emptyset = \frac{3}{4}$. Therefore, $q_{\{2,3,4\}} = \frac{1}{4}$, and a similar argument for nodes u_2, u_3, u_4 gives that $q_S = \frac{1}{4}$ for each set S of cardinality 3. But then, the total probability mass on edge sets is at least $\frac{5}{4}$, as there are four such sets S , and the empty set also has probability $\frac{1}{4}$. This is a contradiction, so there is no such distribution over graphs.

6 Conclusions

In this paper, we have presented and analyzed a simple greedy algorithm for maximizing the spread of influence in a general model of social influence termed the decreasing cascade model. The proof centered on showing that the expected number of influenced nodes is a monotone and submodular function of the tar-

geted set, which required new techniques beyond those used in previous work, including a non-trivial reparametrization of the probability space.

An interesting direction for future work is to investigate which are the most general influence models for which provable approximation guarantees can be achieved. A conjecture in [6], which is as of yet unresolved, states that whenever the activation functions f_v of the general threshold process of Section 3 are monotone and submodular at each node v , so is $\sigma(A)$.

Another direction for future work concerns the evaluation of the function $\sigma(A)$. At this point, we do not know if the function can be evaluated exactly in polynomial time, even for the simplest influence models.

An Optimal Bound for the MST Algorithm to Compute Energy Efficient Broadcast Trees in Wireless Networks

Christoph Ambühl*

Department of Computer Science,
The University of Liverpool
christoph@csc.liv.ac.uk

Abstract. Computing energy efficient broadcast trees is one of the most prominent operations in wireless networks. For stations embedded in the Euclidean plane, the best analytic result known to date is a 6.33-approximation algorithm based on computing an Euclidean minimum spanning tree. We improve the analysis of this algorithm and show that its approximation ratio is 6, which matches a previously known lower bound for this algorithm.

1 Introduction

Multi-hop wireless networks [14] require neither fixed, wired infrastructure nor predetermined interconnectivity. In particular, ad hoc networks [11, 17] are the most popular type of multi-hop wireless networks. An ad hoc wireless network is built of a bunch of radio stations. The links between them are established in a wireless fashion using the radio transmitters and receivers of the stations.

In order to send a message from a station s to a station t , station s needs to emit the message with enough power such that t can receive it. In the model, the power P_s required by a station s to transmit data to station t must satisfy the inequality

$$\frac{P_s}{\text{dist}(s, t)^\alpha} > \gamma. \quad (1)$$

The term $\text{dist}(s, t)$ denotes the distance between s and t , and $\alpha \geq 1$ is the **distance-power gradient**, and $\gamma \geq 1$ is the **transmission-quality** parameter. In an ideal environment (i.e. in the empty space) it holds that $\alpha = 2$ but it may vary from 1 to more than 6 depending on the environment conditions of the location of the network (see [19]).

In ad hoc networks, a power value is assigned to each station. These values, according to Equation (1), determine the so-called **range** of each station. The range of a station s is the area in which stations can receive all messages sent by s .

* This paper was written while the author worked at the Istituto Dalle Molle di Studi sull' Intelligenza Artificiale in Manno, Switzerland and was supported by the Swiss National Science Foundation project 200021-100539/1, "Approximation Algorithms for Machine Scheduling Through Theory and Experiments". It also contains ideas obtained while the author stayed at Università degli Studi di Roma "Tor Vergata" in Italy and was supported by the European Union under the RTN Project ARACNE.

Using the ranges, one can determine the so-called **transmission graph** $G = (S, A)$. The vertex set S is the set of stations, and the directed edge from s to t is in A if and only if t is within the range of s .

All stations in the range of a station i can receive messages sent by i . The minimal range needed for station i to establish all its out-going connections in G is therefore

$$r_G(i) := \max_{j \in \Gamma^+(i)} \text{dist}(i, j). \tag{2}$$

where $\Gamma^+(i)$ denotes the set of out-neighbors of station i in G . The total power needed to establish all connections in G is therefore

$$\text{power}(G) := \sum_{i \in V} \gamma \cdot r_G(i)^\alpha, \tag{3}$$

Since the value of γ does not influence the relative quality of the solutions, we assume $\gamma = 1$ for the rest of the paper. In this paper we address the following problem:

Problem 1 (Energy Efficient Broadcast Tree Problem (EEBT)). Let S be a set of stations represented by points from the Euclidean plane. That is, the distance function becomes $\text{dist}(s, t) := |st|$, where $|st|$ is the Eulidean distance between s and t . One of the stations is called the source station s . The goal is to find the transmission graph G which minimizes $\text{power}(G)$ and contains a directed spanning tree rooted at s (a branching from s).

The relevance of this problem is due to the fact that any transmission graph satisfying the above property allows the source station to perform a **broadcast** operation. Broadcast is a task initiated by the source station to transmit a message to all stations in the wireless network: This task constitutes a major part of real life multi-hop radio networks [1, 2, 7].

The **EEBT** Problem is known to be \mathcal{NP} -hard [4, 3]. Furthermore, if the dist function is arbitrary, the problem cannot be approximated with a logarithmic factor unless $\mathcal{P} = \mathcal{NP}$ [10]. The currently best approximation algorithm for the **EEBT** Problem is as follows.

Algorithm 1 (MSTALG). *The input of the algorithm is a set of stations S represented by points in the Euclidean plane. One of the stations is designated as the source. The algorithm first computes the Euclidean minimum spanning tree (EMST) of the point set S . Then the EMST is turned into a directed EMST by directing all the edges such that there exists a directed path from the source station to all other stations.*

In [21], Wan, Călinescu, Li, and Frieder claimed that **MSTALG** is a 12-approximation. Unfortunately, there is a small error in their paper. The correct analysis yields an approximation ratio of 12.15, as stated by Klasing, Navarra, Papadopoulos, and Perennes in [13]. Independently, Clementi, Crescenzi, Penna, Rossi, and Vocca showed an approximation ratio of 20 for **MSTALG** [4]. Recently, Flammini, Klasing, Navarra, and Perennes [8] showed that **MSTALG** is a 7.6-approximation algorithm. And even more recently, Navarra proved an approximation ratio of 6.33 [18]. In this paper, we

show that **MSTALG** is a 6-approximation for all $\alpha \geq 2$. This matches the lower bound given in [4] and [21].

Experimental studies reported in [6, 15] show that for most instances, the approximation ratio of **MSTALG** is much better than 6. In [16], exact algorithms for **EEBT** have been studied. The **EEBT** problem falls into the class of so-called **range assignment problems**: Find a transmission range assignment such that the corresponding transmission graph G satisfies a given connectivity property Π , and $\text{power}(G)$ is minimized (see for example [12, 7]). In [5], the reader may find an exhaustive survey on previous results related to range assignment problems.

Theorem 1. *Let S be a set of points from the unit disk around the origin, with the additional property that the origin is in S . Let $e_1, e_2, \dots, e_{|S|-1}$ be the edges of the Euclidean minimum spanning tree of S . Then*

$$\mu(S) := \sum_{i=1}^{|S|-1} |e_i|^2 \leq 6.$$

Theorem 1 is the main theorem of this paper. Together with the next lemma, it proves that **MSTALG** is a 6-approximation algorithm for the **EEBT** problem.

The problem of giving upper bounds for $\mu(S)$ has already been looked at independently of the **EEBT** problem. Already in 1968, Gilbert and Pollack [9] gave an upper bound of $8\pi/\sqrt{3}$, based on a technique very similar to the one used by Wan et al in [21]. In 1989, Steele gave a bound of 16 based on space filling curves [20].

Lemma 1. *A bound on $\mu(S)$ automatically implies the same bound on the approximation ratio of **MSTALG** for $\alpha \geq 2$.*

Up to a few differences concerning the station at the origin of the unit disk, this lemma has already been proven in [21] to obtain the 12.15-approximation. We therefore skip its proof. For the case $\alpha < 2$, Clementi et al have shown that the MST algorithm does not provide a constant approximation ratio [4].

We now sketch the proof of the $\mu(S) \leq 12.15$ bound given in [21]. It works as follows. The cost of each edge e of the MST is represented by a geometric shape called diamonds, shown in Figure 1 on the bottom left. Diamonds consist of two isosceles

Fig. 1. Proof idea of previous bounds

Fig. 2. A worst case example for MSTALG

triangles with an angle of $\frac{2}{3}\pi$. The area of a diamond for an edge e with length $|e|$ is $\lambda \cdot |e|^2$, with $\lambda = \sqrt{3}/6$. Diamonds are considered being open sets. It can be shown that if one puts these diamonds along the edges of an MST as shown in the middle of Figure 1, they do not intersect. It can further be shown that the area of the polygon shown on the right of Figure 1 is an upper bound on the area that can be covered by the diamonds along the MST edges. The area of this polygon is 12.15λ . Therefore one can conclude $\mu(S) \leq 12.15\lambda/\lambda = 12.15$.

Similar bounds can be obtained using diametral disks ($\mu(S) \leq 40$) or half disks ($\mu(S) \leq 20$) [3]. In both cases, one has to give an upper bound on the area generated by these shapes. In the case of diametral disks, this is done using the fact that in any point, at most five diametral disks can intersect. This gives only a very crude bound, which leads to a very crude bound on $\mu(S)$. On the other hand, open half disks do not intersect. But since they are smaller than diamonds, the bound provided by them is worse.

Concerning lower bounds on $\mu(S)$, there is a point set S that attains $\mu(S) = 6$. It is a regular 6-gone with one point in the middle. A lower bound on the approximation ratio of MSTALG is shown in Figure 2 [21, 4]. The length of the edges of the MST shown in Figure 2 are ε and $1 - \varepsilon$, respectively. We have $\text{opt}(S) = 1$ and $\text{power}(G) = \varepsilon^2 + 6 \cdot (1 - \varepsilon)^2$. Hence for $\varepsilon \rightarrow 0$, the ratio between the two becomes 6. This lower bound holds for all values of α . Our analysis will give a matching upper bound for this lower bound for $\alpha \geq 2$. As already stated earlier, MSTALG does not have a constant approximation ratio for the case $\alpha < 2$ [4].

2 The Main Idea of the Proof of Theorem 1

Among the shapes that do not intersect, diamonds seem to be the best possible geometric shape for this kind of analysis. For a better bound, we need to use larger shapes and we need to deal with the intersection of the shapes more accurately. The shapes used for our new bound are pairs of equilateral triangles. As depicted in Figure 3, the equilateral triangles intersect heavily. We will give a quite accurate bound on the area generated by them.

Fig. 3. The total area of the equilateral triangles on the left is bounded by the hatched area in the middle. The point set that maximizes the hatched area is the star shown on the right

A high level description of the proof of our bound is the following. Consider a point set S with n points. Hence, the MST will have $n - 1$ edges and therefore, there will be $2(n - 1)$ equilateral triangles representing the cost of the MST. Let A_{MST} be the total area generated by these triangles.

In order to obtain an upper bound on A_{MST} , let c be the number of edges of the convex hull of S . By triangulating S , we end up with a planar graph G with n vertices, e edges, and f facets. Let t be the number of triangles of the triangulation. Then the following three equations hold.

$$\begin{cases} f &= t + 1 \\ 3t + c &= 2e \\ n + f - e &= 2 \end{cases}$$

The first one simply states that the number of facets is equal to the number of triangles plus the infinite facet. For the second one, we add up the number of edges of all facets. For triangles, this is 3, whereas for the infinite facet, it is c . Since every edge is part of exactly two facets, this sums up to $2e$. The last equation is the Descartes-Euler polyhedral formula [22]. If we solve the system for t , we obtain $t = 2(n - 1) - c$. Hence, if we add c equilateral triangles along the convex hull of S as depicted in the center of Figure 3, the number of triangles becomes equal to the number of triangles generated by the MST, as shown on the left side of the figure. Let A_{TRI} be the total area of the triangles within the convex hull of S plus the c additional triangles along the convex hull.

The main idea of the proof is to show that $A_{\text{MST}} \leq A_{\text{TRI}}$. To get an intuitive understanding of it, consider a point set S obtained from the hexagonal grid for which all edges of the triangulation of its convex hull have the same length. In this case, all triangles that are involved in A_{MST} and A_{TRI} are congruent. Furthermore, since their number is equal, it holds $A_{\text{MST}} = A_{\text{TRI}}$. Intuitively, if the edges of the triangulation have different lengths, A_{MST} will be smaller compared to A_{TRI} since the MST will be composed mainly of small edges.

We then conclude the proof by showing that A_{TRI} is maximized by the star configuration depicted on the right of Figure 3. The area of the star is 6λ . Therefore we get $\mu(S) \leq 6\lambda/\lambda = 6$.

3 A Sketch of the Proof of Theorem 1

First, we introduce some notations. The area of an equilateral triangle with side length s will be denoted by $\Delta(s)$. The area of a triangle with edge lengths a, b , and c is denoted by $\Delta(a, b, c)$. Every edge can be partitioned lengthwise into two **half edges**. Both half edges are incident to the same vertices, but each of them is incident to only one facet. Slightly abusing notations, we call the largest side of an obtuse triangle its **hypotenuse**.

Consider the two triangles incident to an edge e . Let α and β be the two angles opposite e in the two triangles. We will call β the **opposite angle of α** .

Consider the MST of S and the Delaunay triangulation of the convex hull of S . Remember that the MST edges are also edges of the Delaunay triangulation. Now choose any edge e of the triangulation. Consider the unique cycle that is formed by adding e to the MST. This cycle and its (finite) interior is called a **pocket**. The triangles of the Delaunay triangulation within a pocket are called **pocket triangles**. The **area of a pocket** is the total area of all pocket triangles. The edge e is called the **door** of the pocket. All MST edges of the cycle are called **border edges**. Those in the interior are called **interior edges**. If e is an MST edge, the pocket will be called an **empty pocket**. Here, e is a border edge and the door at the same time. Empty pockets have area 0.

Note that the door of a pocket is incident to exactly one pocket triangle. If this triangle is obtuse and the door is its hypotenuse, the pocket is called an **obtuse pocket**, otherwise we call it an **acute pocket**.

The **MST-triangles of a pocket P** is the following set of triangles. Every half edge which is part of the MST and incident to a pocket triangle of P generates an MST-triangle. An MST-triangle of a half edge of length l is an equilateral triangle with side length l .

Obviously, both half edges of an interior edge belong to the pocket. On the other hand, only one half edge of a border edge belongs to the pocket. The **MST-area of a pocket** is the sum of the areas of all the MST-triangles. The MST-area of an empty pocket is $\Delta(e)$.

Figure 4 shows a pocket. The door of the pocket is the dashed line. Its border consists of all the edges of the MST connecting the two end points of the pocket. The largest of these edges is denoted by b_1 . There are four inner edges. Note that the inner edges have two MST-triangles attached, one for each half edge, whereas the border edges have only one. The area of the pocket consists of the interior of the pocket. Because b_1 is part of the MST whereas the door is not, b_1 is never longer than the door.

Lemma 2. *In a acute pocket with largest border edge b , the difference between MST-area and pocket area is bounded by $\Delta(|b|)$.*

The proof of Lemma 2 is quite complicated. We therefore only give a sketch of it towards the end of this section. Using this lemma, one can prove Lemma 3. Due to lack

Fig. 4. A pocket with its MST-triangles on the left and the pocket triangles on the right. Note that there are 22 MST-triangles and 21 pocket triangles

to space, also this proof is omitted here. Lemma 3 in turn leads directly to the proof of Theorem 1.

Lemma 3. *Consider a pocket formed by an edge e . Then its MST-area can be bounded by the area of the pocket plus the area of a set of equilateral triangles whose side lengths are bounded by 1 and add up to $|e|$.*

Proof of Theorem 1. Consider the pockets whose doors are the edges of the convex hull of S . The sum of the MST-areas of all these pockets is equal to the total MST-area generated by S . Using Lemma 3, we can conclude that the total MST-area is bounded by the area of a so-called sun. A sun is defined by a convex set T from the unit disk, with the additional property that all edges of the convex hull are bounded by 1. The **area of a sun** is the convex hull of T plus, for each edge e of the convex hull of T , the area of an equilateral triangle with side length $|e|$.

Observe that the MST-area of S is $\mu(S) \cdot \sqrt{3}/2$. Hence we just need to prove that the area of a sun is bounded by $6\sqrt{3}/2$, which is exactly the area of a sun produced by a regular hexagon.

A point set T maximizing the area of its sun has all points on the unit circle. This holds since by moving a point towards the unit circle, the area of the sun increases. The area of a sun with all points on the unit circle can be partitioned as indicated in Figure 5(a). Each part consists of the triangle formed by the origin and an edge of the convex hull, plus the corresponding equilateral triangle. The area of each part can be expressed in terms of the angle ρ the first triangle forms at the origin. It is

$$f(\rho) := \sin\left(\frac{\rho}{2}\right) \left(\cos\left(\frac{\rho}{2}\right) + 2 \cdot \sin\left(\frac{\rho}{2}\right) \frac{\sqrt{3}}{2} \right) = \frac{1}{2} \sin(\rho) + \sqrt{3} \cdot \sin\left(\frac{\rho}{2}\right)^2.$$

Because we assumed that the edges of the convex hull are bounded by 1, the angle ρ must be between 0 and $\frac{\pi}{3}$. Note that $f(\frac{\pi}{3}) = \sqrt{3}/2$. In order to prove that the sun area is maximized by a regular hexagon, observe from Figure 5(b) that $f(\rho)/\rho$, restricted to the range $0 \leq \rho \leq \frac{\pi}{3}$, is maximized for $\rho = \frac{\pi}{3}$. □

In the remainder of this section, we describe the main ideas of the proof of Lemma 2.

Fig. 5(a). A sun

Fig. 5(b). $f(\rho)/\rho = \frac{\frac{1}{2}\sin(\rho) + \sqrt{3}\sin(\frac{1}{2}\rho)^2}{\rho}$

Lemma 4. *In a pocket, the number of MST-triangles exceeds the number of pocket triangles by one.*

Proof. Let n, e, b, t , be the number of nodes, edges, border edges (not including the door), and pocket triangles of a pocket. Let us first count the MST-triangles. Since the edges of a pocket form a tree, there are $n - 1$ edges of the MST involved in the pocket. Each border edge produces one MST-triangle, whereas each inner edges produces two. Therefore their number is $2n - 2 - b$. Let us now count the pocket triangles. The Descartes-Euler polyhedral formula gives $n + (t + 1) - e = 2$, where the additional 1 is the face outside the pocket. By double counting the half edges, we obtain $2e = 3t + (b + 1)$. Here, the additional 1 stands for the door of the pocket. Solving for t , we get that the number of pocket triangles is $t = 2n - 2 - b - 1$. \square

The **extended pocket area (EP-area)** of a pocket is defined as the area of the pocket triangles plus an additional equilateral triangle with side length b , where b is the longest border edge of the pocket. This additional triangle is called **door triangle**. We call the union of the pocket triangles and the door triangle **EP-triangles**. The **net-area** of the pocket is defined as its EP-area minus its MST-area. Using the above definition, Lemma 2 can be rewritten as

Lemma 2 (reformulated) *The net-area of an acute pocket is non-negative.*

Let $V \subseteq S$ be the set of vertices that are part of the pocket, i.e., all the vertices that are inside or at the border of the pocket. Let $G = (V, E)$ be the weighted graph obtained by adding all the edges of the triangulation of the pocket, including the border edges and the door. The weight of the edge $e = uv, u, v \in S$, is denoted by $w(e)$ and its value is $|uv|$. Observe that the EP-, MST-, and net-area of a pocket are just a sum of triangle areas. Therefore, using Heron’s formula [22]

$$\Delta(a, b, c) = \frac{1}{4} \sqrt{-a^4 - b^4 - c^4 + 2a^2b^2 + 2a^2c^2 + 2b^2c^2}$$

for the area of a triangle with side lengths a, b , and c , their areas can all be expressed in terms of the weighted planar graph G . What is more, defining EP-, MST-, and net-area

in terms of weighted planar graphs allows to define them even if the planar graph does not have an embedding in the plane. The next lemma takes full advantage of this fact.

Lemma 5. *Let G' be a graph obtained from G by setting all weights to the same value. Then the net-area of G' is 0.*

Proof. If all weights of G' are equal, all the triangles involved in the EP-area and the MST-area of G' are equilateral and have the same side length. By Lemma 4, the number of EP-triangles is equal to the number of MST-triangles. Since both the EP-area and the MST-area consist of the same number of congruent triangles, we can conclude that their area is equal. □

We will now define a continuous process that turns G into a graph in which all edges have the same weight. During the process, only the weights of the edges are altered, whereas the combinatorial structure of G remains unchanged. The process is designed in such a way that the net-area of G decreases monotonically. This property, together with Lemma 5, proves that the net-area of G is non-negative.

Let w_{\min} and w_{\max} be the length of the smallest and the largest edge in G . The process will be described by a set of graphs $G(m)$, $m \in \mathbb{R}$, $w_{\min} \leq m \leq w_{\max}$. We start with $G = G(w_{\max})$ and end with $G(w_{\min})$, in which all weights will be w_{\min} .

The complete proof is quite involved and therefore deferred to the full version of this paper. In the remainder of the paper, we sketch the proof for a special case. Namely, we assume that all pocket triangles in G are acute. In this case, the process can be described very easily: Let $w(e)$ and $w_m(e)$ be the weight of edge e in G and $G(m)$ respectively. Then $w_m(e) = \min(m, w(e))$. That is, in every stage of the process, all maximal edges are decreased simultaneously until all edges have the same weight.

During this process only maximal edges are decreased. Hence, the ordering of the edges in terms of length remains unchanged during the process. Therefore the MST of G remains valid in all $G(m)$.

It is easy to see that during the process, the area of the pocket triangles of G decrease monotonically. This holds only because we assumed that the pocket triangles are acute.

We need to show that the net-area decreases. Hence, we have to show that in every $G(m)$, the decrease of the pocket area is at least as large as the decrease of the MST-area. To do this, we will partition $G(m)$ into so-called **chains** for which we will prove that their total net-area decreases monotonically.

Consider a graph $G(m)$ for fixed m . Chains are defined in terms of a graph Q . The vertex set of Q is the set of triangles in $G(m)$ plus the door triangle. Each maximal MST edge e of $G(m)$ creates the following set of edges in Q . If we remove e , the MST is divided into two subtrees. Let $R(e)$ be the ring of triangles that separates the two subtrees. For any pair of adjacent triangles in $R(e)$, we add an edge in Q . Note that if e is a border edge, the door triangle is also part of the ring and it is connected with the triangle incident to e and the pocket triangle incident to the door, as shown on the right of Figure 5. This completes the definition of the graph Q .

The **chains** are defined as the connected components of Q . Let Q' be a chain. We can define the area, the MST-area, and the net-area of Q' as follows. The **area of Q'** is equal to the sum of the areas of all triangles of Q' . Concerning the MST-area, note that every MST half edge h of $G(m)$ and its corresponding MST-triangle can be assigned

Fig. 6. Two chains in a graph G plus the door triangle. During the process, the chain on the left appears when there are two maximal MST edges, whereas the one on the right appears when there are three maximal MST edges. The maximal edges are the thick MST edges

to a unique chain, namely the one that contains the unique triangle h is incident to. The **MST-area** of Q' is equal to the sum of the areas of all MST-triangles belonging to the chain. The **net-area** of Q' is its area minus its MST-area. Since the net-area of a pocket is equal to the sum of the net-areas of all its chains, all we have to do to complete the proof is to show that the net-area of a chain decreases monotonically.

Remember that in $G(m)$, only the maximal MST edge decrease. Therefore only the MST-triangles of maximal MST edges decrease. In what follows, we will show that the decrease of the area of the chain makes up for the decrease of these **maximal MST-triangles**.

Some chains contain only a single triangle and no maximal MST-triangles. For these chains, it is obvious that the net-area decreases. Let us now look at chains that contain maximal MST-triangles. We need to consider two cases.

In case (i), we assume that the door triangle is not part of the chain. The **border** of Q' is the cycle in G with smallest area that contains all the triangles of Q' . The triangles from Q' that are incident to a border edge are called **border triangles**. On the left of Figure 6, the border triangles are shaded.

Let us now change Q' as follows. Let e be a maximal MST edge belonging to Q' . Assume its two incident triangles are q_1 and q_2 . Add two new vertices h_1 and h_2 to Q' . They represent the half edges of e . Then remove the edge q_1q_2 from Q' and add q_1h_1 and q_2h_2 . If we do this for all maximal MST edges e , Q' becomes a tree. Let d_i be the number of vertices of Q' with degree i , let n and e be the number of vertices and edges, respectively. From $e = n - 1$ (since Q' is a tree), $n = d_1 + d_2 + d_3$ and $2e = 3d_3 + 2d_2 + d_1$ (by double counting), we get $d_3 = d_1 - 2$.

The vertices of degree three represent equilateral triangles with side length m in $G(m)$. Let D_3 be the set of these triangles. The vertices of degree one represent the maximal MST half edges in $G(m)$. Let D_1 be the set of their corresponding MST-triangles. The area of the triangles in D_1 and D_3 decreases in the same way. Hence, the decrease of all but two triangles from D_1 is made up by the triangles in D_3 . To complete the proof, one can show that the decrease of the border triangles of the chain makes up

for the decrease of the remaining two maximal MST-triangles. Due to lack of space, we skip this proof here.

For case (ii), assume that the door triangle belongs to Q' . Apply the edge splitting of the previous case to Q' . This time, remove all the leafs adjacent to vertex representing the door triangle. We can do the same analysis as in the previous case to find that if the number of leafs in Q' is d_1 , then the number of degree three vertices is $d_3 = d_1 - 2$. But this time, one of the leafs is the door triangle, which is an equilateral triangle with side length m . Hence there are as many half edges as equilateral triangles. Hence, if m decreases, the MST-area of the chain decreases at least as much as the area of the chain.

Abstract. *Virtual private network design* is the following NP-hard problem. We are given a communication network, represented as a weighted graph with thresholds on the nodes which represent the amount of flow that a node can send to and receive from the network. The task is to reserve capacities at minimum cost and to specify paths between every ordered pair of nodes such that all valid traffic-matrices can be routed along the corresponding paths.

Recently, this network design problem has received considerable attention in the literature. It is motivated by the fact that the exact amount of flow which is exchanged between terminals is not known in advance and prediction is often illusive. The main contributions of this paper are as follows:

- Using Hu’s 2-commodity flow theorem, we provide a new lower bound on the cost of an optimum solution.
- Using this lower bound we reanalyze a simple routing scheme which has been described in the literature many times and provide a considerably stronger upper bound on its approximation ratio.
- We present a new randomized approximation algorithm for which, in contrast to earlier approaches from the literature, the resulting solution does not have tree structure.

* Partially supported by the DFG as part of the Transregional Collaborative Research Center “Automatic Verification and Analysis of Complex Systems” (SFB/TR 14 AVACS).

** Partially supported by the DFG Focus Program 1126, “Algorithmic Aspects of Large and Complex Networks”, grant no. SK 58/4-1.

- Finally we show that a combination of our new algorithm with the simple routing scheme yields a randomized algorithm with expected performance ratio 3.55 for virtual private network design. This is a considerable improvement of the previously best known approximation results (5.55 STOC'03, 4.74 SODA'05).

1 Introduction

Consider a communication network which is represented by an undirected graph $G = (V, E)$ with edge costs $c : E \rightarrow \mathbb{R}_+$. Within this network there is a set of terminals $T \subseteq V$ which want to communicate with each other. However, the exact amount of traffic between pairs of terminals is not known in advance. Instead, each terminal $v \in T$ has an associated input and output threshold $b_{in}(v) \in \mathbb{Z}_{\geq 0}$ and $b_{out}(v) \in \mathbb{Z}_{\geq 0}$. A *traffic matrix* $D \in \mathbb{Q}_{\geq 0}^{T \times T}$ is *valid*, if it respects the lower and upper bounds on the incoming and outgoing traffic of the terminals, i.e., if the following holds for each terminal $i \in T$

$$\sum_{j \in T, j \neq i} D(i, j) \leq b_{out}(i) \quad \text{and} \quad \sum_{j \in T, j \neq i} D(j, i) \leq b_{in}(i).$$

The (*asymmetric*) *Virtual Private Network Design Problem* (VPND) defined by G , c , T and b consists of finding capacities $u(e)$, $e \in E$, and paths P_{ij} for each ordered pair $(i, j) \in T \times T$ such that the following conditions hold:

- All valid traffic matrices can be routed without exceeding the installed capacities where all traffic from terminal i to terminal j is routed along path P_{ij} .
- The total cost of the capacity reservation $\sum_{e \in E} u(e) c(e)$ is minimal.

A reservation of capacities $u : E \rightarrow \mathbb{R}_+$ is a *tree reservation*, if the subgraph of G induced by the edges $e \in E$ with $u(e) > 0$ is a tree. A general reservation is sometimes referred to as a *graph reservation*.

The virtual private network design problem is NP-hard by the following reduction from the Steiner tree problem [9]. Given an instance of the Steiner tree problem, pick a terminal v which has to be connected with the other terminals in a Steiner tree. This terminal is assigned thresholds $b_{in}(v) := 0$ and $b_{out}(v) := 1$. All other terminals of the Steiner tree instance have input threshold one and output threshold zero. It is easy to see that a minimum cost Steiner tree yields an optimum reservation for this VPND-instance.

The virtual private network design problem has independently been defined by Fingerhut et al. [8] in the context of broadband ATM networks, and by Duffield et al. [5] (VPN “hose” model). Since then, it has been studied by various authors in several variations which we discuss next. In the following list, the last variant (*AsymG*) is the one which we refer to as VPND.

(*SymT*) Symmetric thresholds, tree reservation: In this variant, each terminal $i \in T$ has only one threshold $b(i)$, which is an upper bound on the cumulative

amount of traffic that terminal i can send or receive. The task is to find an optimal tree reservation, which supports all valid traffic matrices. Gupta et al. [9] show that $(SymT)$ is polynomially solvable.

- $(SymG)$ Symmetric thresholds, graph reservation: This variant is defined in the same way as $(SymT)$, except that the capacity reservation can be arbitrary and not necessarily a tree. Gupta et al.[9] present a 2-approximation for $(SymG)$. It is not known whether $SymG$ is NP-hard.
- $(BalT)$ Balanced thresholds, tree reservation: The thresholds are *balanced*, which means that $\sum_{v \in T} b_{in}(v) = \sum_{v \in T} b_{out}(v)$. The reservation has to be a tree. Italiano et al. [13] show that this variant can be solved in polynomial time.
- $(AsymT)$ Asymmetric thresholds, tree reservation: This problem is NP-hard [9]. Constant approximation algorithms are presented in [9, 10, 6]. Interestingly, while the algorithm in [9] is deterministic, the other algorithms are randomized and seem difficult to de-randomize.
- $(AsymG)$ Asymmetric thresholds, graph reservation: This is the VPND problem defined above. We have seen that this problem is NP-hard. The randomized approximation results presented in [10, 6] in fact compare the computed tree solution to an optimal graph reservation. The current best approximation algorithm is the one in [6] which achieves an expected performance ratio 4.74.

Simplifying Assumptions and a Lower Bound

Following [10], we make some simplifying assumptions without loss of generality. By duplicating nodes, we can assume that each terminal is either a *sender* s , with $b_{out}(s) = 1$ and $b_{in}(s) = 0$, or a *receiver* r , with $b_{out}(r) = 0$ and $b_{in}(r) = 1$. This simplifying assumption is feasible as long as we make sure that the selected paths in our solution between copies of a terminal v and copies of a terminal u are all equal. Let \mathcal{S} and \mathcal{R} be the set of senders and the set of receivers, respectively. Let $S = |\mathcal{S}|$ and $R = |\mathcal{R}|$ denote the corresponding cardinalities. The algorithms presented in this paper can easily be adapted such as to run in polynomial time even when the thresholds are not polynomially bounded and to satisfy the consistence property described above. Moreover, by symmetry reasons, we always assume $R \geq S$.

We can now interpret VPND as follows. Let $B = (\mathcal{S} \cup \mathcal{R}, E^B)$ be the complete bipartite graph with nodes partitioned into senders and receivers. We have to reserve capacities on the edges of G and we have to specify a set of paths \mathcal{P} in graph G containing one path P_{sr} for each edge $sr \in E^B$ such that each bipartite matching of B can be routed along these paths. In other words, for each edge $e \in E$, the reservation $u(e)$ has to satisfy the following condition:

$$|\{P_{rs} \in \mathcal{P} \mid e \in P_{rs} \text{ and } rs \in M\}| \leq u(e) \quad \text{for each matching } M \text{ in } B. \quad (1)$$

Notice that for a fixed set of paths \mathcal{P} , an optimal reservation of capacity is the component-wise minimal u satisfying (1). (In particular, given \mathcal{P} , the integral capacity $u(e)$ of edge e can be obtained by a maximum bipartite matching computation.) Thus, a solution to VPND can be encoded by only specifying a set of paths \mathcal{P} in G .

The cost of a bipartite matching between senders and receivers in the metric closure of G is obviously a lower bound on OPT , the value of an optimum solution to the VPND-instance. We denote the shortest path distance between nodes u and v of G by $\ell(u, v)$. Thus, if edges (r, s) in B are assigned weights $\ell(r, s)$, then the cost of any matching in B is a lower bound on OPT . This lower bound is used in the analyses of all previous constant factor approximation algorithms for VPND.

Lemma 1 ([10]). *Let $B = (S + \mathcal{R}, E^B)$ be the complete bipartite graph on the senders and receivers with edge weights $\ell : E^B \rightarrow \mathbb{R}_+$ given by the shortest path distances in the graph G . Then, the weight of any matching in B is a lower bound on OPT .*

Contribution of This Paper

The design of good approximation results usually requires two main ingredients: Cleverly constructed algorithms and thoroughly chosen lower bounds on the optimum such that the quality of the computed solutions can be assessed in terms of the lower bounds. We considerably advance the state of the art of approximating VPND by making contributions to both ingredients.

In Section 2 we present a new lower bound which generalizes and thus strengthens the one stated in Lemma 1. We prove that the weight of *any matching* (not necessarily bipartite) on the union of the senders and at most S receivers is at most OPT . The edge-weights in the matching are again the shortest path distances in G . This new lower bound relies on an interesting interrelation between a special case of VPND and 2-commodity flows. Its proof is based on an application of Hu's 2-commodity flow theorem [11].

In Section 3 we employ the new lower bound in order to show that the following simple algorithm achieves performance ratio $1 + R/S$: Find a vertex $v \in V$ whose shortest path tree to the union of senders and receivers is of minimal cost; cumulatively install a capacity of one on each shortest path. One interesting consequence of this result is that ($BalG$), VPND with balanced thresholds and graph reservation, has a 2-approximation. Our result improves upon the 3-approximation of Italiano et al. [13] for this problem and generalizes the 2-approximation for ($SymG$) by Gupta et al. [9].

In Section 4 we present a new randomized algorithm for VPND. The algorithm chooses a random subset of receivers and connects each sender via its own Steiner tree to this subset. The remaining receivers are then connected to the randomly chosen subset of receivers by shortest paths. Due to the Steiner trees for each individual receiver, the resulting solution has in general no tree structure. In contrast to our new approach, the previous algorithm by Gupta et al. [10] and its refinement in [6] construct only one 'high-bandwidth' core which is a Steiner tree with high capacity. In particular, all previous approximation algorithms for VPND produce tree solutions.

Finally, we can show that our new algorithm in combination with the simple algorithm from above yields a 3.55 randomized approximation algorithm. The previously best known algorithm [6] achieves performance ratio 4.74.

Related Work

As discussed above, VPND can be seen as a generalization of the Steiner tree problem. The currently best known approximation ratio for the Steiner tree problem is $\rho < 1.55$ [15]. A related problem is *buy at bulk* network design (see, e.g. [1, 2]). In this problem, there is a fixed demand d_{ij} between each pair of nodes in the graph, specifying the amount of flow which has to be sent from i to j . The costs of the capacities however is a concave function on the amount purchased, which reflects “economies of scale”. Gupta et al. [10] consider the single source buy-at-bulk network design problem and present a constant factor approximation algorithm.

Another important issue in this context is to cope with edge failures [3]. Italiano et al. [14] consider the problem of restoring the network, when at most one edge in a tree-solution to VPND might fail and provide a constant factor approximation algorithm.

Recently, Hurkens, Keijsper and Stougie [12] considered the problem (*SymT*) in the special case when the given network is a ring. It is conjectured that (*SymG*) can be solved in polynomial time. It is in fact conjectured that an optimal solution to (*SymT*) is also an optimal solution to (*SymG*). Hurkens et al. [12] show that this conjecture holds for ring networks. The authors also describe an integer programming formulation for VPND, which proves that a fractional version can be solved in polynomial time. This fractional version allows to specify several paths for each sender-receiver pair and requires the fraction for each of these paths, which describes how the commodity has to be split.

2 A New Lower Bound via Hu’s 2-Commodity Flow Theorem

This section is devoted to proving a new lower bound on the cost of an optimal solution to VPND. Generalizing Lemma 1, we prove that the cost of an arbitrary (not necessarily bipartite) matching between terminals in $S \cup \mathcal{R}'$ is at most OPT , for any subset of receivers $\mathcal{R}' \subseteq \mathcal{R}$ of cardinality $|\mathcal{R}'| = S$. The proof of this result is based on Hu’s classical 2-commodity flow theorem [11].

Theorem 1 (Hu’s 2-commodity flow theorem). *Let $G = (V, E)$ be a graph and let $\{s_1, r_1\}$, $\{s_2, r_2\}$ be pairs of vertices of G ; let $u : E \rightarrow \mathbb{R}_+$ be a capacity function on the edges and let $d_1, d_2 \in \mathbb{R}_+$. Then, there exists a (fractional) 2-commodity flow of value d_1, d_2 if and only if the cut condition is satisfied. Moreover, if all edge capacities are integral, then a half-integral flow exists.*

The cut condition requires that $u(\delta(X)) \geq d_1 \chi_1(X) + d_2 \chi_2(X)$ for each $X \subseteq V$. Here $\delta(X)$ denotes the cut induced by X . Moreover, for $i = 1, 2$, we set $\chi_i(X) = 1$ if the cut $\delta(X)$ separates s_i from r_i and $\chi_i(X) = 0$, otherwise.

Corollary 1. *Let $G = (V, E)$ be an undirected graph with edge capacity function $u : E \rightarrow \mathbb{R}_+$ and $s_1, s_2, r_1, r_2 \in V$. In the following, all demand values*

are equal to 1. If there exists a feasible 2-commodity flow for terminal pairs $\{s_1, r_1\}, \{s_2, r_2\}$ and for terminal pairs $\{s_1, r_2\}, \{s_2, r_1\}$, then there also exists a feasible 2-commodity flow for terminal pairs $\{s_1, s_2\}, \{r_1, r_2\}$.

Proof. In the case of unit demands, the cut condition requires that, for all $X \subseteq V$, the capacity $u(\delta(X))$ of the cut induced by X must be at least the number of terminal pairs which are separated by the cut. It thus remains to prove that the cut condition holds for the terminal pairs $\{s_1, s_2\}, \{r_1, r_2\}$ if it holds for $\{s_1, r_1\}, \{s_2, r_2\}$ and for $\{s_1, r_2\}, \{s_2, r_1\}$.

Consider an arbitrary $X \subseteq V$. If the corresponding cut separates neither $\{s_1, s_2\}$ nor $\{r_1, r_2\}$, nothing needs to be shown. If $\delta(X)$ separates one terminal pair, say $\{s_1, s_2\}$, then it separates either $\{s_1, r_1\}$ or $\{s_2, r_1\}$ since s_1 and s_2 lie on different sides of the cut. In particular, the capacity of the cut is at least 1. Finally, if $\delta(X)$ separates both terminal pairs $\{s_1, s_2\}, \{r_1, r_2\}$, then it either separates $\{s_1, r_1\}$ and $\{s_2, r_2\}$ or it separates $\{s_1, r_2\}$ and $\{s_2, r_1\}$. In both cases it follows that the capacity of the cut is at least 2.

We remark that Corollary 1 is no longer true if we replace “2-commodity flow” by “integral 2-commodity flow”. Even, Itai, and Shamir show that finding an integer 2-commodity flow is NP-hard [7]. On the other hand, Hu’s result states that there always exists a half-integral flow in this case. For a more detailed account of results we refer to Schrijver’s book [16–Chapter 71].

Before we formulate and prove our new lower bound for VPND, we first state a general technique for deriving such lower bounds.

Lemma 2. *Let $\mathcal{S}_1, \dots, \mathcal{S}_k$ be a partition of \mathcal{S} and let $\mathcal{R}_1, \dots, \mathcal{R}_k$ be a partition of \mathcal{R} . We denote the VPND-instance on graph G with senders \mathcal{S}_i and receivers \mathcal{R}_i by I_i . Then,*

$$\sum_{i=1}^k OPT_i \leq OPT ,$$

where OPT_i is the cost of an optimal solution to instance I_i .

We are now ready to prove the main result of this section.

Theorem 2. *Let $\mathcal{R}' \subseteq \mathcal{R}$ be an arbitrary subset of cardinality $|\mathcal{R}'| = S$ and let M be a matching in the complete graph on $\mathcal{S} \cup \mathcal{R}'$. Then,*

$$\sum_{vw \in M} \ell(v, w) \leq OPT.$$

Proof. Let $\mathcal{S} = \{s_1, s_2, \dots, s_S\}$ and $\mathcal{R}' = \{r_1, r_2, \dots, r_S\}$. It suffices to prove the claim for perfect matchings M . Suppose that M consists of edges

$$s_1s_2, s_3s_4, \dots, s_{2k-1}s_{2k}, \text{ and } r_1r_2, r_3r_4, \dots, r_{2k-1}r_{2k},$$

$$\text{and } s_{2k+1}r_{2k+1}, s_{2k+2}r_{2k+2}, \dots, s_Sr_S .$$

Consider the following partition of \mathcal{S} and \mathcal{R}' into $S - k$ subsets \mathcal{S}_i and \mathcal{R}'_i each:

$$\mathcal{S}_i = \{s_{2i-1}, s_{2i}\}, \mathcal{R}'_i = \{r_{2i-1}, r_{2i}\}, \quad \text{for } 1 \leq i \leq k,$$

$$\mathcal{S}_i = \{s_i\}, \mathcal{R}'_i = \{r_i\}, \quad \text{for } 2k + 1 \leq i \leq S.$$

By Lemma 2, the sum of OPT_i for the VPND-instances I_i with senders \mathcal{S}_i and receivers \mathcal{R}'_i is a lower bound on OPT . Thus we only need to prove that

$$\ell(s_{2i-1}, s_{2i}) + \ell(r_{2i-1}, r_{2i}) \leq OPT_i \text{ for each } 1 \leq i \leq k.$$

For $1 \leq i \leq k$, any solution to instance I_i yields a reservation of capacities that supports 2-commodity flows with unit demands for terminal pairs $\{s_{2i-1}, r_{2i-1}\}$, $\{s_{2i}, r_{2i}\}$ and for $\{s_{2i-1}, r_{2i}\}$, $\{s_{2i}, r_{2i-1}\}$. By Corollary 1, it must also support a 2-commodity flow for terminal pairs $\{s_1, s_2\}$, $\{r_1, r_2\}$. Therefore, the cost of this solution is at least $\ell(s_1, s_2) + \ell(r_1, r_2)$. This concludes the proof.

3 The Quality of a Simple Routing Scheme

Consider the following simple VPND algorithm: Select the node with the cheapest shortest path tree to the union of senders and receivers and reserve one unit of capacity along each shortest path. The effect of installing capacities along shortest paths is cumulative. In other words, if k shortest paths share the same edge, the algorithm assigns k units of capacity to that edge. Moreover, the shortest paths can be computed with a consistent tie-breaking rule such that the edges with nonzero capacity form a tree.

This algorithm produces an optimal tree reservation in the symmetric case (*SymT*) [9] and in the balanced case (*BalT*) [13]. In the symmetric case, Gupta et al. [9] show that the tree produced by the algorithm is a 2-approximate solution to the optimum graph reservation. Italiano et al. [13] show that, in the balanced case, the produced tree is a 3-approximate solution to the optimum graph reservation.

In this section, we apply our new lower-bound result to show that this algorithm produces a tree-solution whose cost is within a factor of $1 + R/S$ of the optimum graph reservation cost. As a consequence, also (*BalG*) can be approximated within a factor of two.

In [6] the following inequality is shown which follows from Lemma 1 and which we will use in the proof of the theorem below:

$$\sum_{s \in \mathcal{S}} \sum_{r \in \mathcal{R}} \ell(s, r) \leq R \text{ } OPT. \tag{2}$$

We are now ready to bound the approximation ratio provided by this simple routing scheme.

Theorem 3. *The above described algorithm achieves a performance ratio $1 + R/S$.*

Proof. Let $G^m = (\mathcal{R} \cup \mathcal{S}, E^m)$ be the metric closure of $\mathcal{R} \cup \mathcal{S}$, i.e., the complete graph on $\mathcal{R} \cup \mathcal{S}$ with edge weight $\ell(u, v)$ given by the shortest path distance between u and v in G . We show that there exists a node $u \in \mathcal{R} \cup \mathcal{S}$ such that the cost of its star satisfies

$$\sum_{v \in \mathcal{R} \cup \mathcal{S}} \ell(u, v) \leq (1 + R/S) OPT.$$

If $R = S$, then the edges of E^m can be partitioned into $2S - 1$ perfect matchings. By Theorem 2, the weight of each matching is a lower bound on OPT . Since each edge is contained in exactly two stars of G^m , there must exist one star, whose weight is at most $(2(2S - 1)/(2S)) OPT < 2 OPT$.

Suppose for the remainder of the proof that $R > S$. In the following we denote by \mathcal{M}_S the set of (possibly not perfect) matchings of the senders in G^m and by \mathcal{M}_R the matchings of at most S receivers. Theorem 2 implies the inequality

$$\ell(M_S) + \ell(M_R) \leq OPT \quad \text{for each } M_S \in \mathcal{M}_S, M_R \in \mathcal{M}_R, \tag{3}$$

where $\ell(E') := \sum_{uv \in E'} \ell(u, v)$ for any $E' \subseteq E^m$. In consideration of (3), we distinguish two cases.

First case: $\ell(M_S) \leq OPT/2$ for each $M_S \in \mathcal{M}_S$.

Consider the subgraph G_S^m of G^m which is induced by the senders. The edges of G_S^m can be partitioned into S matchings. On the other hand one has

$$\sum_{s' \in \mathcal{S}} \sum_{s \in \mathcal{S}} \ell(s', s) = 2 \ell(E_S^m) \tag{4}$$

and thus $\sum_{s' \in \mathcal{S}} \sum_{s \in \mathcal{S}} \ell(s', s) \leq S \cdot OPT$. This means that the average weight of a complete star in G_S^m is at most OPT . Let s' be a random sender. Inequality (2) implies that $E[\sum_{r \in \mathcal{R}} \ell(s', r)] \leq (R/S) OPT$. Together with the above discussion this implies for a random sender s'

$$E \left[\sum_{s \in \mathcal{S}} \ell(s', s) + \sum_{r \in \mathcal{R}} \ell(s', r) \right] \leq (1 + R/S) OPT. \tag{5}$$

Second case: $\ell(M_S) > OPT/2$ for some maximum weight matching $M_S \in \mathcal{M}_S$.

Let G_R^m denote the subgraph of G^m which is induced by the receivers. We will show below that the cost of any matching \widetilde{M} in G_R^m is bounded by $(R/S) OPT/2$. Since the edges of G_R^m can be partitioned into R matchings, we can then argue in a similar manner as above that $E[\sum_{r \in \mathcal{R}} \ell(r', r)] \leq (R/S) OPT$ for a random receiver r' . Together with (2) this implies

$$E \left[\sum_{s \in \mathcal{S}} \ell(s, r') + \sum_{r \in \mathcal{R}} \ell(r, r') \right] \leq (1 + R/S) OPT. \tag{6}$$

It remains to bound the cost of any matching \widetilde{M} in G_R^m . First assume that S is even. Theorem 2 implies $\ell(M_R) \leq OPT/2$ for each matching $M_R \in \mathcal{M}_R$ of at most S receivers. As a consequence, the average cost of an edge in a matching \widetilde{M} is at most $(OPT/2)/(S/2) = OPT/S$. Since \widetilde{M} has at most $R/2$ edges, we get $\ell(\widetilde{M}) \leq (R/S) OPT/2$ for any matching \widetilde{M} in G_R^m .

It remains to consider the case that S is odd. Then there is a sender s^* which is missed by the maximum cost matching M_S of G_S^m . Theorem 2 yields

$$\ell(M_{\mathcal{R}}) + \ell(s^*, r_1^*) \leq OPT/2 \tag{7}$$

for each matching $M_{\mathcal{R}} \in \mathcal{M}_{\mathcal{R}}$ and $r_1^* \in \mathcal{R}$ which is not matched by $M_{\mathcal{R}}$. Since $R > S$, there exists another receiver r_2^* which is missed by $M_{\mathcal{R}}$. By the triangle inequality one has $\ell(r_1^*, r_2^*) \leq \ell(s^*, r_1^*) + \ell(s^*, r_2^*)$. As a result we get

$$\ell(M_{\mathcal{R}}) + 1/2 \ell(r_1^*, r_2^*) \leq OPT/2 \tag{8}$$

for each matching $M_{\mathcal{R}} \in \mathcal{M}_{\mathcal{R}}$ and receivers r_1^*, r_2^* which are missed by $M_{\mathcal{R}}$. This implies that the average weight of an edge of \widetilde{M} is bounded by OPT/S and thus $\ell(\widetilde{M}) \leq (R/S)OPT/2$.

4 A New Algorithm for VPND

In Section 3 we described an algorithm which guarantees a good approximation ratio for R close to S . In this section we present a better approximation algorithm for the case that R is sufficiently larger than S . As the algorithm by Gupta et al. [10], this algorithm is based on Steiner-tree computations. However, in contrast to the algorithm in [10], it does not construct a “high bandwidth core”, which is a small Steiner tree with high capacity, which collects and distributes the demands from outside, and routes them along its high capacity paths. Instead, we proceed by constructing Steiner trees for each sender to a previously sampled subset of receivers, and by connecting the other receivers along their shortest paths to the sampled subset.

Algorithm 1.

- (1) Partition \mathcal{R} into S subsets uniformly at random. Among the non-empty subsets in the partition, select one subset \mathcal{R}' uniformly at random.
- (2) For each sender $s \in \mathcal{S}$, compute a ρ -approximate Steiner tree $T(s)$ on $\{s\} \cup \mathcal{R}'$, and add one unit of capacity to each edge of $T(s)$.
- (3) Add one unit of capacity along a shortest path between each receiver $r \in \mathcal{R}$ and \mathcal{R}' .

It is interesting to note here that the thereby produced solution is not a tree solution. Though an optimal tree-solution is a constant-factor approximation to an optimal graph-solution, it is known [9] that an optimal solution to (*AsymT*) is in general not an optimal solution to VPND. All previous constant factor approximation algorithms for VPND produce tree reservations [10, 6].

It remains to specify the path between each sender-receiver pair (s, r) . Assume that the shortest paths are computed in a consistent way. Let r^* be the receiver in \mathcal{R}' which is closest to r . The path P_{sr} between s and r is obtained by concatenating the (simple) path between s and r^* in $T(s)$ with the shortest path between r^* and r .

Before we proceed with the analysis of Algorithm 1, we state a corollary of Lemma 2. Here, given a subset V' of nodes, we denote the cost of an optimum Steiner tree on terminal set V' by $st(V')$.

Corollary 2 ([10]). *Let $\mathcal{R}_1, \dots, \mathcal{R}_s$ be a partition of \mathcal{R} into S (disjoint) subsets. Consider an arbitrary perfect matching between \mathcal{S} and this family of subsets. Let $\mathcal{R}(s)$ be the subset matched with sender s . Then,*

$$\sum_{s \in \mathcal{S}} st(\{s\} \cup \mathcal{R}(s)) \leq OPT.$$

Theorem 4. *Algorithm 1 is a $(2 + \rho)/(1 - e^{-R/S})$ approximation algorithm for VPND.*

Theorem 4 is a straightforward consequence of the following lemmas.

Lemma 3. *For a uniformly chosen random sender s' ,*

$$E[st(\{s'\} \cup \mathcal{R}')] \leq \frac{OPT}{S(1 - e^{-R/S})} .$$

Proof. Consider the following random process. For each receiver r , we assign r to a sender s chosen uniformly at random. Let $\mathcal{R}(s)$ be the subset of receivers assigned to s . Note that the subsets $\mathcal{R}(s)$ partition \mathcal{R} into S (possibly empty) subsets. Thus, by Corollary 2, $\sum_{s \in \mathcal{S}} st(\{s\} \cup \mathcal{R}(s)) \leq OPT$. This means that, for the random sender s' , $E[st(\{s'\} \cup \mathcal{R}(s'))] \leq OPT/S$. Let A denote the event that $\mathcal{R}(s')$ is empty. By elementary probability theory,

$$E[st(\{s'\} \cup \mathcal{R}(s'))] = P(A) E[st(\{s'\} \cup \mathcal{R}(s')) \mid A] + P(\bar{A}) E[st(\{s'\} \cup \mathcal{R}(s')) \mid \bar{A}] .$$

Now observe that $P(\bar{A}) = 1 - (1 - 1/S)^R \geq 1 - e^{-R/S}$. Moreover $E[st(\{s'\} \cup \mathcal{R}(s')) \mid A] = E[st(\{s'\})] = 0$. Thus

$$E[st(\{s'\} \cup \mathcal{R}(s')) \mid \bar{A}] = \frac{E[st(\{s'\} \cup \mathcal{R}(s'))]}{P(\bar{A})} \leq \frac{OPT}{S(1 - e^{-R/S})} .$$

The claim follows by observing that, given \bar{A} , $\mathcal{R}(s')$ and \mathcal{R}' are identically distributed. Thus

$$E[st(\{s'\} \cup \mathcal{R}')] = E[st(\{s'\} \cup \mathcal{R}(s')) \mid \bar{A}] \leq \frac{OPT}{S(1 - e^{-R/S})} .$$

This implies the following upper bound on the expected cost of capacity which is installed in the second step of the algorithm.

Lemma 4. *The expected cost of the capacity installed in the second step of Algorithm 1 is at most*

$$\rho OPT / (1 - e^{-R/S}).$$

The cost of the third step can be bounded as in the following lemma. A proof can be found in the full version of this paper.

Lemma 5. *The expected cost of the capacity installed in the third step of Algorithm 1 is at most*

$$2OPT/(1 - e^{-R/S}).$$

In Section 3 we described a $(1 + R/S)$ approximation algorithm. The factors $1 + R/S$ and $(2 + \rho)/(1 - e^{-R/S})$ are equal for $R/S = 2.78 \dots < 2.79$. Note that $1 + R/S$ is increasing in R/S and $(2 + \rho)/(1 - e^{-R/S})$ is decreasing in R/S . It follows that a combination (taking the minimum cost solution) of the simple routing scheme of section 3 and Algorithm 1 has an expected approximation guarantee of 3.79.

Theorem 5. *The combination (taking the cheaper solution) of the simple routing scheme and Algorithm 1 is an expected 3.79 approximation algorithm for VPND.*

4.1 Computing the Optimum Steiner Tree

The performance ratios of the simple scheme and Algorithm 1 meet roughly at $R/S = 2.78$. In this case, the sampled set \mathcal{R}' of receivers has expected constant size. An optimum Steiner tree on a graph with n nodes and t terminals can be computed in $O(3^t n + 2^t n^2 + n^3)$ time with the Dreyfus-Wagner algorithm [4]. This suggests the following variant of Algorithm 1.

In the second step of Algorithm 1 compute an *optimal* Steiner tree whenever $|\mathcal{R}'| \leq \log n$, where n is the number of nodes in (the original graph) G . A similar technique was already applied in [6].

Clearly, this modification is a polynomial time algorithm whose expected approximation guarantee is not worse than the one of Algorithm 1. In particular, if $R/S \geq \log \log n$, the approximation achieved is

$$(2 + \rho)/(1 - e^{-R/S}) \leq (2 + \rho)/(1 - 1/\log n) = 2 + \rho + o(1) < 3.55.$$

What can be said about the approximation guarantee if $R/S \leq \log \log n$? In that case, the expected size of \mathcal{R}' is $1 + (R - 1)/S < 1 + \log \log n$. The probability that the size of \mathcal{R}' exceeds $\log n$ is, by Markov's inequality, at most $(1 + \log \log n)/\log n$. In this unlikely event however, we can estimate the outcome of the combination of the thereby computed solution with the solution computed by the simple routing scheme described in section 3.

The next theorem is proved in a similar way as the main theorem in [6]. The proof can be found in the full version of this paper.

Theorem 6. *The combination (taking the cheaper solution) of the above described modification of Algorithm 1 and the simple routing scheme described in section 3 is an expected 3.55-approximation algorithm for VPND.*

Hadamard Tensors and Lower Bounds on Multiparty Communication Complexity

Jeff Ford and Anna Gál*

Dept. of Computer Science,
University of Texas at Austin, Austin, TX 78712-1188, USA
{jefford, panni}@cs.utexas.edu

Abstract. We develop a new method for estimating the discrepancy of tensors associated with multiparty communication problems in the “Number on the Forehead” model of Chandra, Furst and Lipton. We define an analogue of the Hadamard property of matrices for tensors in multiple dimensions and show that any k -part communication problem represented by a Hadamard tensor must have $\Omega(n/2^k)$ multipart communication complexity. We also exhibit constructions of Hadamard tensors, giving $\Omega(n/2^k)$ lower bounds on multipart communication complexity for a new class of explicitly defined Boolean functions.

1 Introduction

Communication complexity was introduced by Yao [23] in 1979. Two players wish to compute $f(x, y)$. One player knows x , and the other knows y . Both have unlimited computational power. The communication complexity of f is the number of bits they must exchange on an arbitrary input in order to determine the value of f . This model and many of its variants have been widely studied [14]. Communication complexity arguments have been used to derive results in circuit complexity and in other computational models.

We consider the multiplayer model of Chandra, Furst, and Lipton [7] usually called the “Number on the Forehead” model. With k players, the input is partitioned into k parts: x_1, \dots, x_k . The i -th player has access to every x_j except x_i . The Number on the Forehead model is stronger than the 2-party model, and sometimes the overlap between the players’ inputs can be used to obtain surprising upper bounds (e.g. [18, 17]). This model is harder to analyze than the 2-party model, and very few lower bounds are known. On the other hand, lower bounds in this model have many applications in complexity theory, including constructions of pseudorandom generators for space bounded computation, universal traversal sequences, and time-space tradeoffs [2], as well as circuit complexity lower bounds [13, 16, 18].

The largest known lower bounds for explicit functions are of the form $\Omega(n/2^k)$ where k is the number of players, and n is the number of bits each player misses. The first bounds of this form were given by Babai, Nisan and Szegedy [2] for the “quadratic character of the sum of coordinates” (QCS) function. They also gave an $\Omega(n/4^k)$ lower bound for the “generalized inner product” (GIP) function that was later improved to $\Omega(n/2^k)$ by Chung and Tetali [10]. Chung [9] and Raz [19] generalized the method of [2] to give a sufficient condition for a function to have $\Omega(n/2^k)$ multiparty communication complexity. Raz [19] also obtained $\Omega(\sqrt{n}/2^k)$ lower bounds for a new function based upon matrix multiplication over $\text{GF}(2)$. Babai, Hayes and Kimmel [3] obtained further examples of functions with $\Omega(n/2^k)$ multiparty communication complexity. All of these lower bounds were obtained by estimating discrepancy, and so they also hold in the distributional and randomized communication complexity models.

The known bounds all decrease exponentially as the number of players grows, becoming trivial for $k > \log n$. It is a major open problem, with important implications in circuit complexity, to prove nontrivial lower bounds on multiparty communication problems for a large number of players. The class ACC^0 , defined by Barrington [4], consists of languages recognized by constant depth, unbounded fan-in polynomial size circuit families with AND, OR, NOT and MOD_m gates for a fixed m . By the results of [24, 5, 13], families of functions that belong to ACC^0 can be computed by multiparty protocols with polylogarithmic (in n) communication by a polylogarithmic (in n) number of players (where n is the number of bits each player misses). Separating ACC^0 from other complexity classes (e.g. NP) is a major open problem, and a sufficiently large multiparty communication complexity lower bound would resolve it.

As proved by Chor and Goldreich [8], any Boolean function defined by a Hadamard matrix has $\Omega(n)$ 2-party communication complexity. Their proof uses a lemma by Lindsey (see [11] p. 88) that estimates the largest possible sum of entries in a submatrix of a Hadamard matrix. Lindsey’s lemma implies upper bounds on the discrepancy of functions defined by Hadamard matrices and “nearly” Hadamard matrices. Babai, Nisan and Szegedy [2] generalized the proof of Lindsey’s lemma to obtain upper bounds on the discrepancy of tensors associated with certain multiparty communication problems. The lower bounds that followed (e.g. [9, 10, 19, 3]) all used this approach. These papers did not consider generalizing the Hadamard property to tensors. In fact, [10] mentions that it is not clear how to generalize Hadamard matrices to tensors.

In this paper we propose a generalization of the Hadamard property of matrices to tensors of arbitrary dimension. We show that any k -party communication problem represented by a Hadamard tensor must have $\Omega(n/2^k)$ multiparty communication complexity. We construct families of Hadamard tensors, giving $\Omega(n/2^k)$ lower bounds for a new class of explicitly defined Boolean functions. Our Hadamard property is stronger than the sufficient condition of Chung [9] and Raz [19] for $\Omega(n/2^k)$ bounds, and could yield larger than $\Omega(n/2^k)$ lower bounds. There are no matching upper bounds known for functions represented by Hadamard tensors. We show how the Chung-Raz condition and some pre-

vious lower bounds fit into a “nearly” Hadamard framework. We believe that Hadamard tensors may also be of independent interest.

Our approach is based upon a new general upper bound on the discrepancy of tensors in terms of the largest possible value achievable by multiplying a collection of lines of the tensor by -1 and taking the sum of the entries of the resulting tensor. We refer to this value as the *weight*. This measure has been analyzed for matrices (see e.g. [1, 20]), and the corresponding matrix problem is sometimes called the “switching lights game”. Generalizing the switching lights game to tensors was previously suggested in [10]. As far as we know, the general upper bound we give for the discrepancy of a tensor in terms of its weight is new. We also show that this upper bound is not too much larger than the actual discrepancy. Thus, the weight will give good bounds and may be easier to use than directly computing discrepancy. Since our lower bounds are based on discrepancy, they also hold in the distributional and randomized models.

2 Preliminaries

In the k -party model of Chandra, Furst and Lipton [7], k players with unlimited computational power wish to compute the value of a function $f : X_1 \times \cdots \times X_k \rightarrow \{-1, 1\}$ on input $\mathbf{x} = (x_1, \dots, x_k)$. Usually we assume that $X_1 = \dots = X_k = \{0, 1\}^n$. The function f is known to each player, and player P_i gets all of the input except $x_i \in X_i$. Players communicate by broadcasting messages, so all players receive all messages. If each player misses n bits of input, then $n + 1$ bits of communication is sufficient: Player P_2 broadcasts x_1 , and then player P_1 who now has the entire input broadcasts the answer.

Definition 2.1. *The deterministic k -party communication complexity of f (denoted $C(f)$) is the number of bits communicated by the players on the worst input \mathbf{x} using the best protocol for computing f .*

Definition 2.2. *Let μ be a probability distribution over the input of f . The bias achieved by a protocol P is defined as $|\Pr[P(\mathbf{x}) = f(\mathbf{x})] - \Pr[P(\mathbf{x}) \neq f(\mathbf{x})]|$, where \mathbf{x} is chosen according to the distribution μ .*

The ϵ -distributional communication complexity of f (denoted $C_{\epsilon, \mu}(f)$) is the number of bits communicated by the players on the worst input \mathbf{x} using the best protocol for computing f that achieves bias at least ϵ under the distribution μ . When μ is the uniform distribution we abbreviate to $C_\epsilon(f)$.

Definition 2.3. *[2] A subset $Z_i \subseteq X_1 \times \cdots \times X_k$ is called a cylinder in the i -th dimension, if membership in Z_i does not depend on the i -th coordinate, that is for every $(x_1, \dots, x_i, \dots, x_k) \in Z_i$ and every $x'_i \in X_i$ we have $(x_1, \dots, x'_i, \dots, x_k) \in Z_i$ as well. A subset $Z \subseteq X_1 \times \cdots \times X_k$ is called a cylinder intersection if it can be represented as $Z = \bigcap_{i=1}^k Z_i$, where each Z_i is a cylinder in the i -th dimension.*

A protocol can be thought of as reducing the space of possible inputs at each step until all the remaining possibilities give the same output. A message from

player P_i winnows the input space, but not along the i -th dimension. Thus it causes the space of possible inputs to be intersected with a cylinder in the i -th dimension. After each message the consistent inputs form a cylinder intersection.

Definition 2.4. *The discrepancy of f on the cylinder intersection Z (denoted $\text{Disc}_Z(f)$) is defined by*

$$\text{Disc}_Z(f) = |\text{Pr}[(\mathbf{x} \in Z) \wedge (f(\mathbf{x}) = 1)] - \text{Pr}[(\mathbf{x} \in Z) \wedge (f(\mathbf{x}) \neq 1)]| ,$$

where \mathbf{x} is chosen according to the uniform distribution. The discrepancy of f (denoted $\text{Disc}(f)$) is the maximum of $\text{Disc}_Z(f)$ over all cylinder intersections Z .

Since $\text{Disc}(f)$ is defined with respect to the uniform distribution, and the output of f is from $\{-1, 1\}$, we have the following:

$$\text{Disc}_Z(f) = \left| \sum_{\mathbf{x} \in Z} f(\mathbf{x}) \right| / |X_1 \times \dots \times X_k| .$$

Lemma 2.1. [2] *For any function $f : X_1 \times X_2 \times \dots \times X_k \rightarrow \{-1, 1\}$, $C(f) \geq \log_2(1/\text{Disc}(f))$ and $C_\epsilon(f) \geq \log_2(\epsilon/\text{Disc}(f))$.*

3 A General Upper Bound on Discrepancy

Problems in 2-party communication complexity can be represented as matrices with rows labeled by the possible inputs for player P_1 and columns labeled by the possible inputs for player P_2 . An entry in the matrix at location (x, y) is given by $f(x, y)$.

A multiparty communication complexity problem can be represented by a tensor, the multidimensional analogue of a matrix. Each dimension of the tensor is labeled by the piece of input missed by a player. That is, the i -th dimension of the tensor is indexed by the elements of X_i . We denote by $A(x_1, \dots, x_k)$ the entry of the k -dimensional tensor A at location (x_1, \dots, x_k) . For tensor A_f representing function f we have $A_f(x_1, \dots, x_k) = f(x_1, \dots, x_k)$. If $|X_1| = \dots = |X_k| = N$, we say that the tensor has order N .

Definition 3.1. *Given a tensor A in k dimensions, a line of A is any vector formed by fixing all but one coordinate of A . A face of A is any $(k - 1)$ -dimensional tensor formed by fixing one coordinate of A .*

A tensor of order N has N entries in each line and N^{k-1} entries in each face. It has N^{k-1} lines and N faces along each of the k dimensions.

Definition 3.2. *Let A be a tensor with ± 1 entries. We say that a line of the tensor A is flipped if each entry in that line is multiplied by -1 .*

Definition 3.3. *We say that a tensor is cylindrical in the i -th dimension, if it does not depend on the i -th coordinate x_i .*

If a tensor is cylindrical in the i -th dimension, the entries of any given line along the i -th dimension are identical, and the corresponding N faces are identical. Thus, a k -dimensional cylindrical tensor can be specified by a $(k - 1)$ -dimensional tensor (specifying the face that is repeated N times).

Definition 3.4. We define the excess of a tensor A (denoted $S(A)$) to be the sum of its entries; that is, $S(A) = \sum_{\mathbf{x} \in X_1 \times \dots \times X_k} A(\mathbf{x})$.

Lemma 3.1. (implicit in [10]) $\text{Disc}(f) = \max S(A_f \circ C_1 \circ \dots \circ C_k) / N^k$, where A_f is the ± 1 tensor representing f , and each C_i is a 0/1 tensor which is cylindrical in the i -th dimension. ($A_f \circ C_1 \circ \dots \circ C_k$ denotes the entrywise product of the tensors A, C_1, \dots, C_k .)

Proof. Let $Z_i \subseteq X_1 \times \dots \times X_k$ be a cylinder in the i -th dimension, and let C_i be the 0/1 tensor representing the characteristic function of the cylinder Z_i . Then C_i is cylindrical in the i -th dimension. Conversely, every 0/1 tensor which is cylindrical in the i -th dimension represents the characteristic function of some cylinder in the i -th dimension. The lemma immediately follows from the definitions and our notation. \square

Definition 3.5. We define the weight of a tensor A (denoted $W(A)$) to be the largest possible excess of a tensor A' where A' can be obtained from A by flipping an arbitrary collection of lines (in any direction). Note that the order in which the flips are performed does not matter.

Alternatively, $W(A)$ can be described as $W(A) = \max S(A \circ T_1 \circ \dots \circ T_k)$, where each T_i is a ± 1 tensor which is cylindrical in the i -th dimension. ($A \circ T_1 \circ \dots \circ T_k$ denotes the entrywise product of the tensors A, T_1, \dots, T_k .)

Theorem 3.1. $\text{Disc}(f) \leq W(A_f) / N^k$, where N is the order of the tensor A_f representing f .

Proof. For $i = 1, \dots, k$, let C_i be an arbitrary 0/1 tensor which is cylindrical in the i -th dimension. We inductively define related ± 1 tensors \hat{C}_i and T_i . For each $i = 1, \dots, k$, we define a $(k - 1)$ -dimensional ± 1 tensor \hat{C}_i , where the i -th coordinate is left out. For example, \hat{C}_1 is a $(k - 1)$ -dimensional tensor that depends on the $k - 1$ coordinates x_2, \dots, x_k . To simplify notation, we will denote the entries of these tensors by $\hat{C}_i(\mathbf{x})$, with the understanding that for \hat{C}_i , x_i is not used for indexing. For example, $\hat{C}_1(\mathbf{x})$ stands for $\hat{C}_1(x_2, \dots, x_k)$.

We define \hat{C}_1 as follows: $\hat{C}_1(\mathbf{x}) = \text{sign}(\sum_{x_1} A_f(\mathbf{x}) \cdot C_2(\mathbf{x}) \cdots C_k(\mathbf{x}))$. In other words, to obtain \hat{C}_1 , we collapse the k dimensional tensor $A_f \circ C_2 \circ \dots \circ C_k$ to a $k - 1$ dimensional tensor by summing the entries of each line along the first dimension and taking the sign of each line sum as an entry of \hat{C}_1 . (If a given line sums to a negative number, the corresponding entry in \hat{C}_1 is -1 , otherwise it is 1 .) We use \hat{C}_1 to define the ± 1 tensor T_1 , which is k -dimensional, and cylindrical in the first dimension. T_1 is obtained by taking N copies of \hat{C}_1 and using them as the faces of T_1 (along the first dimension).

Assume that T_1, \dots, T_{i-1} are already defined. We define \hat{C}_i as follows:

$$\hat{C}_i(\mathbf{x}) = \text{sign}\left(\sum_x A_f(\mathbf{x}) \cdot T_1(\mathbf{x}) \cdots T_{i-1}(\mathbf{x}) \cdot C_{i+1}(\mathbf{x}) \cdots C_k(\mathbf{x})\right)$$

Once \hat{C}_i is defined we use it to obtain T_i which is k -dimensional, and cylindrical in the i -th dimension. T_i is obtained by taking N copies of \hat{C}_i and using them as the faces of T_i (along the i -th dimension).

First we show $S(A_f \circ C_1 \circ C_2 \circ \dots \circ C_k) \leq S(A_f \circ T_1 \circ C_2 \circ \dots \circ C_k)$. When we replace C_1 by T_1 , the contribution of each line of the tensor $A_f \circ C_1 \circ C_2 \circ \dots \circ C_k$ (along the first dimension) is replaced by a nonnegative value at least as large as the absolute value of the sum of the entries of the original line. To see this, notice that by definition, \hat{C}_1 and T_1 contain the signs of the sum of the entries of the corresponding lines of $A_f \circ C_2 \circ \dots \circ C_k$. (If the sum is 0, we use 1 for the sign.) Obtaining $A_f \circ T_1 \circ C_2 \circ \dots \circ C_k$ corresponds to multiplying each entry of a given line of $A_f \circ C_2 \circ \dots \circ C_k$ by the sign of the sum of the entries of that line. Recall that each C_i is cylindrical, thus the lines of C_1 along the x_1 coordinate are constants (all 0 or all 1). If all entries of a given line of C_1 are 0 then the corresponding line of $A_f \circ C_1 \circ C_2 \circ \dots \circ C_k$ did not contribute anything to the sum, while after the replacement it contributes a nonnegative value. For the lines of C_1 that are constant 1, the contribution of the corresponding line of $A_f \circ C_1 \circ \dots \circ C_k$ is replaced by its absolute value. Thus, we never decrease the total sum. Similarly, at each inductive step above, we maintain that $S(A_f \circ T_1 \circ \dots \circ T_{i-1} \circ C_i \circ \dots \circ C_k) \leq S(A_f \circ T_1 \circ \dots \circ T_i \circ C_{i+1} \circ \dots \circ C_k)$. It follows that $S(A_f \circ C_1 \circ \dots \circ C_k) \leq S(A_f \circ T_1 \circ \dots \circ T_k)$. By Lemma 3.1 and the definition of $W(A_f)$ the theorem follows. \square

The following simple example shows that the discrepancy $\text{Disc}(f)$ can be strictly smaller than $W(A_f)/N^k$. Let $k = 2$, and f be the parity function, i.e., f is 1 if the number of 1's among the input bits is even, and -1 otherwise. Then the discrepancy $\text{Disc}(f) = 1/4$, while $W(A_f)/N^2 = 1$. To see this, note that in the matrix corresponding to the parity function the sum of entries in any rectangle is at most $N^2/4$. On the other hand, it is possible to flip the lines of the matrix so that we obtain the all 1 matrix. (Theorem 8 in [10] appears to claim that $\text{Disc}(f) = W(A_f)/N^k$. However, this seems to be a mistake in notation, and they in fact prove Lemma 3.1.)

The following theorem shows that the discrepancy can not be too much smaller than the bound given by the weight. Thus, using the weight for bounding discrepancy will give good bounds.

Theorem 3.2.

$$\text{Disc}(f) \geq W(A_f)/(2^k N^k) .$$

Proof. Consider the lines used to generate $W(A_f)$. Partition the entries of A_f into 2^k groups according to whether they were flipped by the lines along each of the k dimensions. Along each dimension the entries flipped by the lines form a cylinder, as do the unflipped entries. Thus the partition splits the entries of A_f

into 2^k cylinder intersections. At least one of these cylinder intersections has entry sum with absolute value at least $W(A_f)/2^k$. Using that cylinder intersection in the discrepancy definition gives discrepancy at least $W(A_f)/(2^k N^k)$. \square

It is known that $W(A) \geq N^{3/2}/\sqrt{2}$ for any N by N matrix A with ± 1 entries (see Theorem 5.1 in [1]; see also [6] (c.f. [15])). We show the following extension of that result:

Theorem 3.3. $W(A) \geq N^{k-\frac{1}{2}}/\sqrt{2}$, for any k dimensional ± 1 tensor A of order N .

Proof. Consider the set of matrices formed by fixing all but the first two dimensions of A . Each of the matrices has weight at least $N^{3/2}/\sqrt{2}$. They do not intersect, so their lines can be flipped independently giving a tensor weight at least $N^{k-2}(N^{3/2}/\sqrt{2})$. \square

A standard probabilistic argument shows that there are tensor with weight $O(\sqrt{k}N^{k-\frac{1}{2}})$. Proving similar upper bounds on the weight of explicitly defined tensors would yield lower bounds of the form $\Omega(n)$ on multiparty communication complexity, for any number of players. Thus, estimating the weight of tensors can potentially give close to optimal bounds on the discrepancy, and on the multiparty communication complexity of the corresponding functions.

4 Hadamard Tensors

An N by N matrix with ± 1 entries is called a *Hadamard matrix* if the inner product of any two of its distinct rows is 0. It is equivalent to state the condition for columns: The product of any two distinct rows is 0 if and only if the product of any two distinct columns is 0.

The Hadamard property is invariant under the arbitrary flipping of lines. Thus, Lindsey’s lemma (see [11] p. 88) gives the following well known statement:

Lemma 4.1. For any Hadamard matrix A of order N , $W(A) \leq N^{3/2}$.

We define the *product of t lines* (along the same dimension) of a tensor as the sum of entries in their entrywise product. For example, if l_1, \dots, l_t are lines along the first dimension, then their product is $\sum_{x_1} l_1(x_1) \cdots l_t(x_1)$.

Let A be a k -dimensional tensor of order N with ± 1 entries. For each of the first $k - 1$ dimensions $i = 1, \dots, k - 1$, choose two distinct indices $y_i, z_i \in X_i$. Picking exactly one of y_i or z_i for each $i = 1, \dots, k - 1$ gives a point in $X_1 \times \dots \times X_{k-1}$, and each such point specifies a line of A along the last coordinate x_k . There are 2^{k-1} possible choices for the selection described above, and since for each $i = 1, \dots, k - 1$, $y_i \neq z_i$, we get 2^{k-1} distinct lines this way. We say that the tensor A is Hadamard, if the product of any 2^{k-1} lines chosen in this way is 0. More formally, we define Hadamard tensors as follows:

Definition 4.1. Let A be a k -dimensional tensor of order N with ± 1 entries. We say that A is a Hadamard tensor if for any $y_1, z_1 \in X_1, \dots, y_{k-1}, z_{k-1} \in X_{k-1}$ such that $y_i \neq z_i$ for $i = 1, \dots, k - 1$, the following holds:

$$\sum_{x \in X} \prod_{x_{-1} \in \{y_{-1}, z_{-1}\}} A(x_1, x_2, \dots, x_k) = 0.$$

When $k = 2$ this definition is identical to the definition of Hadamard matrices.

Lemma 4.2. Let A^x denote the face of A obtained by fixing the i -th coordinate to the value x_i . Let $k \geq 3$. A is a k -dimensional Hadamard tensor if and only if for any $i \neq k$ and $y_i \neq z_i$ the entrywise product of two faces $A^y \circ A^z$ is a $(k - 1)$ -dimensional Hadamard tensor.

Proof. Without loss of generality, let $i = k - 1$. We need to show that for any $y_1, z_1 \in X_1, \dots, y_{k-2}, z_{k-2} \in X_{k-2}$ such that $y_i \neq z_i$ for $i = 1, \dots, k - 2$, the following holds:

$$\sum_{x \in X} \prod_{x_{-2} \in \{y_{-2}, z_{-2}\}} A^{y_{-1}} \circ A^{z_{-1}}(x_1, \dots, x_{k-2}, x_k) = 0.$$

But $A^{y_{-1}} \circ A^{z_{-1}}(x_1, \dots, x_{k-2}, x_k) = \prod_{x_{-1} \in \{y_{-1}, z_{-1}\}} A(x_1, x_2, \dots, x_k)$, and the statement directly follows from Definition 4.1. The proof in the reverse direction is similar. □

Since the k -th coordinate plays a special role in the definition of a Hadamard tensor, we can say that the definition is given with respect to the k -th dimension. It is not hard to see (using Lemma 4.2) that, just as for matrices, if a tensor is Hadamard with respect to one dimension, then it is Hadamard with respect to any other dimension. We leave the proof of this statement for the full version of the paper.

Lemma 4.3. Let A' be a tensor obtained from a Hadamard tensor A by flipping a collection of lines. Then A' is a Hadamard tensor.

Proof. This follows by induction from the characterization of Hadamard tensors given by Lemma 4.2. The result holds for matrices since after flipping a row or column any row or column product that was 0 remains 0. Suppose the result holds for tensors of dimension $k - 1$. Consider any face product $A^y \circ A^z$ of a k -dimensional Hadamard tensor A . Flipping a line of A may miss A^y and A^z entirely, intersect both in one entry, or flip an entire line of A^y or A^z . In the first case the face product is unaffected. In the second case the face product is unchanged since the corresponding entry is negated twice. In the third case the face product has a line flipped. By the induction hypothesis this is still a Hadamard tensor. □

4.1 The Discrepancy of Hadamard Tensors

In light of Theorem 3.1, we can prove upper bounds on the discrepancy of any tensor A by proving upper bounds on $W(A)$. Let $W_k(N)$ denote the largest possible value of $W(A)$ if A is a k -dimensional Hadamard tensor of order N .

Lemma 4.4. *Let A be a k -dimensional Hadamard tensor of order N . Then*

$$(W(A))^2 \leq N^{2k-1} + N^{k+1}(W_{k-1}(N)) .$$

Proof. Let A' be the k -dimensional tensor obtained from A by flipping a collection of lines that achieves maximal excess, that is $W(A) = S(A')$. By Lemma 4.3, A' is a Hadamard tensor, and by Lemma 4.2 the entrywise product of any two distinct faces of A' is a Hadamard tensor in $k - 1$ dimensions. Thus, we have the following estimates (using the Cauchy-Schwartz inequality).

$$\begin{aligned} (S(A'))^2 &= \left(\sum_{\mathbf{x} \in X_1 \times \dots \times X_k} A'(\mathbf{x}) \right)^2 \leq N^{k-1} \sum_{x_1, \dots, x_{k-1}} \left(\sum_{\mathbf{x}} A'(\mathbf{x}) \right)^2 \\ &= N^{k-1} \left(N^k + \sum_{i \neq j} \sum_{x_1, \dots, x_{k-1}} A'(x_1, \dots, x_{k-1}, i) A'(x_1, \dots, x_{k-1}, j) \right) \\ &\leq N^{k-1} (N^k + (N^2 - N)(W_{k-1}(N))) \leq N^{2k-1} + N^{k+1}(W_{k-1}(N)) . \square \end{aligned}$$

Theorem 4.1. *Let A be a k -dimensional Hadamard tensor of order N . Then $W(A) \leq \phi N^{k-(1/2)^{k-1}}$ where $\phi = (1 + \sqrt{5})/2$.*

Proof. Follows by induction using Lemma 4.1 and Lemma 4.4. □

Theorem 4.2. *Let $f : (\{0, 1\}^n)^k \rightarrow \{1, -1\}$ be a function represented by a Hadamard tensor. Then $\text{Disc}(f) \leq \phi N^{-1/2^{k-1}}$ where $\phi = (1 + \sqrt{5})/2$.*

Proof. Follows from Theorem 4.1 and Theorem 3.1. □

By the results of [2] (see Lemma 2.1) this yields the following:

Theorem 4.3. *Let $f : (\{0, 1\}^n)^k \rightarrow \{1, -1\}$ be a function represented by a Hadamard tensor. Then $C(f) = \Omega(n/2^k)$, and $C_\epsilon(f) = \Omega((n/2^k) + \log_2 \epsilon)$.*

4.2 Constructions of Hadamard Tensors

Let x_1, \dots, x_k be n -bit strings. Consider each of these strings as an element of the finite field $\text{GF}(2^n)$, representing the field elements as univariate polynomials over $\text{GF}(2)$ modulo a fixed irreducible polynomial of degree n . (In this representation the i -th bit ($0 \leq i \leq n - 1$) of a given n -bit string indicates whether the corresponding polynomial $p(a)$ contains the term a^i .)

Let χ_S stand for the function obtained by raising -1 to the parity of the bits with coordinates in S , such that χ_S is 1 when the parity is even, and -1 when the parity is odd. It is not hard to see that for any $x, y \in \{0, 1\}^n$,

$$\chi_S(x)\chi_S(y) = \chi_S(x + y), \tag{1}$$

where $+$ represents addition in $\text{GF}(2^n)$. (In fact the χ_S are the additive characters of $\text{GF}(2^n)$.) By the definition of χ_S , $\chi_S(x)\chi_S(y) = \chi_S(x \oplus y)$, viewing x and y as strings and taking bitwise XOR, which is the same as $\chi_S(x + y)$ using addition in the field.

Definition 4.2. Given a function $f : \{0, 1\}^n \rightarrow \{1, -1\}$, we define the function $\text{FFM}_f^{n,k} : (\{0, 1\}^n)^k \rightarrow \{1, -1\}$ by

$$\text{FFM}_f^{n,k}(x_1, \dots, x_k) = f(x_1 \cdot x_2 \cdot \dots \cdot x_k),$$

where $x_1 \cdot x_2 \cdot \dots \cdot x_k$ denotes the product of the field elements x_1, \dots, x_k , and f is applied to the n -bit string representing the resulting field element.

For $S \subseteq \{0, 1, \dots, n - 1\}$, we denote by $\text{FFM}_S^{n,k}$ the function $\text{FFM}_\chi^{n,k}$.

“FFM” is an abbreviation for “Finite Field Multiplication”.

Theorem 4.4. For every $\emptyset \neq S \subseteq \{0, 1, \dots, n - 1\}$, the k -dimensional tensor associated with $\text{FFM}_S^{n,k}$ is Hadamard.

We need the following technical lemma:

Lemma 4.5. For any k and for any $y_1, z_1, \dots, y_k, z_k \in \text{GF}(2^n)$ with $y_1 \neq z_1, \dots, y_k \neq z_k$,

$$\sum_{x_1 \in \{y_1, z_1\}, \dots, x_k \in \{y_k, z_k\}} x_1 x_2 \cdots x_k \neq 0$$

Proof. The proof is by induction. For distinct y_1 and z_1 , $y_1 + z_1$ is nonzero since in $\text{GF}(2^n)$ each element is its own additive inverse. Suppose the statement holds for $k - 1$. Let $y_k, z_k \in \text{GF}(2^n)$ with $y_k \neq z_k$.

$$\begin{aligned} & \sum_{x_1 \in \{y_1, z_1\}, \dots, x_k \in \{y_k, z_k\}} x_1 x_2 \cdots x_k \\ &= y_k \sum_{x_1 \in \{y_1, z_1\}, \dots, x_{k-1} \in \{y_{k-1}, z_{k-1}\}} x_1 x_2 \cdots x_{k-1} + \\ & \quad z_k \sum_{x_1 \in \{y_1, z_1\}, \dots, x_{k-1} \in \{y_{k-1}, z_{k-1}\}} x_1 x_2 \cdots x_{k-1} \\ &= (y_k + z_k) \sum_{x_1 \in \{y_1, z_1\}, \dots, x_{k-1} \in \{y_{k-1}, z_{k-1}\}} x_1 x_2 \cdots x_{k-1} \end{aligned}$$

Since $y_k + z_k$ is nonzero (because in $\text{GF}(2^n)$ each element is its own additive inverse), and the sum is nonzero by the induction hypothesis, this is nonzero. \square

Proof. (of Theorem 4.4) Consider the following sum from Definition 4.1:

$$\sum_x \prod_{x_1 \in \{y_1, z_1\}, \dots, x_{-1} \in \{y_{-1}, z_{-1}\}} \chi_S(x_1 x_2 \cdots x_k)$$

By (1) this is the same as

$$\begin{aligned} & \sum_x \chi_S \left(\sum_{x_1 \in \{y_1, z_1\}, \dots, x_{-1} \in \{y_{-1}, z_{-1}\}} x_1 x_2 \cdots x_k \right) \\ &= \sum_x \chi_S \left(x_k \sum_{x_1 \in \{y_1, z_1\}, \dots, x_{-1} \in \{y_{-1}, z_{-1}\}} x_1 x_2 \cdots x_{k-1} \right) \end{aligned}$$

As shown in Lemma 4.5, the inner sum evaluates to a non-zero field element, so for some fixed non-zero w , we obtain $\sum_x \chi_S(x_k w) = \sum_x \chi_S(x_k) = 0 \quad \square$

By Theorem 4.3 we immediately obtain the following:

Theorem 4.5. *For every $\emptyset \neq S \subseteq \{0, 1, \dots, n - 1\}$, $C(\text{FFM}_S^{n,k}) = \Omega(n/2^k)$, and $C_\epsilon(\text{FFM}_S^{n,k}) = \Omega(n/2^k + \log_2 \epsilon)$.*

Although all finite fields of order 2^n are isomorphic, it is necessary to specify exactly which one is being used to obtain explicit constructions of Boolean functions this way. The deterministic algorithm developed by Shoup [21] can be used to construct an irreducible polynomial of degree n for any given n . Thus the family of Boolean functions associated with the tensors FFM_S belongs to the complexity class P . Note also that the polynomial $x^n + x^{n/2} + 1$ is irreducible over $\text{GF}(2)$ when n is of the form $n = 2 \cdot 3^m$ (Theorem 1.1.28 in [22]). Assuming that an irreducible polynomial of degree n is given, we can show that the corresponding Boolean function can be computed by depth $O(\log k)$ ACC circuits. We leave the proof of this for the full version of the paper.

4.3 Relaxations of the Hadamard Property

Raz [19] considered the function defined as follows: each part of the input $x_i \in \{0, 1\}^n$ is interpreted as a \sqrt{n} by \sqrt{n} matrix with 0, 1 entries. The function is defined by the bit in the upper left corner of the matrix obtained by taking the product (over $\text{GF}(2)$) of the k matrices. Raz [19] proved that this function has (probabilistic) k -party communication complexity $\Omega(\sqrt{n}/2^k)$. The tensor associated with this function is not Hadamard, but we can show that it contains a subtensor of order $2\sqrt{n}$ which is Hadamard. Thus, our methods give $\Omega(\sqrt{n}/2^k)$ lower bounds on the k -party communication complexity of the function.

Chung [9] and Raz [19] state a sufficient condition for a function to have $\Omega(n/2^k)$ multipart communication complexity (generalizing the method of [2]). We can show that satisfying the condition of [9] and [19] is equivalent to being nearly Hadamard in the following, relaxed sense: Instead of requiring that all

the products of the 2^{k-1} -tuples of lines selected according to the Hadamard definition are 0, it is enough to require that the products are small on average; e.g. that the sum of the squares of the line products is small. The tensor corresponding to the “generalized inner product” (GIP) function of [2] is nearly Hadamard in this relaxed sense, but it is not Hadamard. For the tensor corresponding to the “quadratic character of the sum of coordinates” (QCS) function of [2] we can show that each (nontrivial) product of the selected 2^{k-1} tuples of lines is small (at most $2^k\sqrt{N}$). We leave the proof for the full version of the paper. Note that the property we prove for QCS is stronger than the condition required in [9, 19], but weaker than the Hadamard property.

Grolmusz [12] proved an $O(kn/2^k)$ upper bound on the multiparty communication complexity of GIP, showing that the $\Omega(n/2^k)$ lower bounds for GIP cannot be significantly improved. There are no similar upper bounds known for any of the functions that we presented as examples of Hadamard tensors. The examples of Hadamard tensors we give and the QCS function are candidates for having $\Omega(n/poly(k))$ multiparty communication complexity.

Abstract. We prove that an $\omega(\log^3 n)$ lower bound for the three-party number-on-the-forehead (NOF) communication complexity of the set-disjointness function implies an $n^{\omega(1)}$ size lower bound for tree-like Lovász-Schrijver systems that refute unsatisfiable CNFs. More generally, we prove that an $n^{\Omega(1)}$ lower bound for the $(k+1)$ -party NOF communication complexity of set-disjointness implies a $2^{n^{\Omega(1)}}$ size lower bound for all tree-like proof systems whose formulas are degree k polynomial inequalities.

1 Introduction

Linear programming, the problem of optimizing a linear objective function over the points of a given polyhedron, was shown to be polynomial-time solvable over the rationals by Khachian [15]. When integrality constraints are added, however, the resulting integer linear programming problem becomes NP-hard. Many algorithms for such problems attempt to apply efficiencies from rational linear programming to the integral case.

One of the most powerful of such approaches is to begin with the polytope defined by the original linear program without integrality constraints and systematically pare down the polytope by repeatedly refining the linear program with “cutting planes” that remove only nonintegral solutions until we are left with the convex hull of the integral solutions. These are local methods in which the initial polytope Q (expressed by the natural cutting planes constraints) is transformed through a sequence of local operations to smaller and smaller polytopes (each contained in the original one), until the integral hull of Q is reached. (At this point, rational linear programming will find the correct solution.) For decision problems, this sequence terminates with the empty polytope if and only if the initial polytope contains no integral points.

^{*} Paul Beame’s research was supported by NSF grants CCR-0098066 and ITR-0219468. Toniann Pitassi’s research was supported by an Ontario Premiere’s Research Excellence Award, an NSERC grant, and the Institute for Advanced Study where this research was done. Nathan Segerlind’s research was supported by NSF Postdoctoral Fellowship DMS-0303258 and done while at the Institute for Advanced Study.

One such method is that of Gomory-Chvátal cuts [6] which derives each new cutting plane as a linear combination and shift of existing facet constraints. There are even more subtle methods available, particularly in the case of 01-programming, which is also NP-complete. In a seminal paper, Lovász and Schrijver [16] introduced a variety of cutting planes methods that derive new cutting planes by first “lifting” the inequalities to higher degree polynomial inequalities (in particular quadratic inequalities) and then “projecting” them down to linear inequalities using polynomial identities and the fact that $x^2 = x$ for $x \in \{0, 1\}$. These systems are now known as *Lovász-Schrijver systems (LS)*.

It may be too costly to apply these techniques to pare all the way down to the integral hull. However, even applying a smaller number of rounds of the procedure can often lead to a smaller polytope that has good approximability ratio, one for which the best nonintegral solution is not too far away from the best integral solution, so that by rounding we can achieve a good approximation to the optimal value.

Two complexity measures are commonly studied for Lovász-Schrijver and related cutting planes proof systems: *size* and *rank*. Intuitively, rank is the number of intermediate polytopes that must be passed through before arriving at the integral hull. In [16] it was shown that for any (relaxed) polytope P , if the rank of P is d , then the optimization and decision problems for P can be solved exactly deterministically in time $n^{O(d)}$. This very nice algorithmic property of Lovász-Schrijver systems makes them especially appealing for solving or approximating NP-hard optimization problems via linear programming. A variety of rank lower bounds for exact solution are known, even for the case of unsatisfiable systems [4, 8, 11, 7, 12]. Moreover, interesting bounds on the ranks required for good approximations to vertex cover [1] and MaxSAT [5] have been obtained. This, in turn, implies inapproximability results for these problems for *any* polynomial-time algorithm based on rank.

While there is a rich and growing body of results concerning rank, very little is known about the size of LS proofs. Informally, the size of an LS procedure with respect to some polytope P is the smallest number of hyperplanes defining all of the polytopes that we need to pass through before arriving at the integral hull. Clearly size lower bounds imply rank lower bounds, and even tree-size lower bounds imply rank lower bounds, but the converse is not known to be true. The one unconditional (tree-like) size lower bound known for LS [12] is for a family of polytopes for which decision and optimization are trivial and for which the integral hull has a trivial derivation in Chvátal’s cutting planes proof system.

Problems in which the facets represent clauses of a CNF formula and a decision algorithm for 01-programming yields a propositional proof system are particularly important to analyze. Proving (tree-like) size lower bounds for such polytopes was given as one of the main open problems in [12]. The only LS size lower bounds known at present for such polytopes formulas are conditional results. First, it is an easy observation that $\text{NP} \neq \text{coNP}$ implies superpolynomial LS size lower bounds for some family of unsatisfiable CNF formulas. It has also been shown by [19, 9, 10] that these lower bounds also hold under other natural complexity assumptions.

In this paper we develop a new method for attacking size lower bounds for LS and for systems that generalize LS. Our main result is a proof that lower bounds on the 3-

party communication complexity of set disjointness (in the number-on-forehead model) imply lower bounds on the size of tree-like LS proofs for a particular family of unsatisfiable CNF formulas. We also generalize this result to a much more powerful family of proof systems known as semantic LS^k , where lines are now degree k polynomial inequalities. All versions of LS are special cases of LS^2 , and Chvátal's Cutting Planes proof system is a special case of LS^1 .

More generally, we show that proving lower bounds on the $(k + 1)$ -party communication complexity of set disjointness implies lower bounds on the size of tree-like semantic LS^k proofs. By a natural extension of the ideas in [2] one can show that the $(k + 1)$ -party set disjointness problem is "complete" for the $(k + 1)$ -party communication complexity class $(k + 1)\text{-NP}^{cc}$ and a lower bound showing that it is not in $(k + 1)\text{-RP}^{cc}$ would already give excellent lower bounds for LS^k proofs. Such a result is already known in the case $k = 1$ [2] (and was used in [13] to derive tree-like size lower bounds for Chvátal's Cutting Planes system) and set disjointness is one of the most well-studied problems in communication complexity.

Our proof can be seen as a generalization of [13] to arbitrary k but the extension requires a number of new ideas and a substantially more complicated argument that includes a detailed analysis of large sets of vertex-disjoint paths in expander graphs.

2 Definitions

2.1 Multipart Communication Complexity and Set Disjointness

The k -party number-on-the-forehead (NOF) model of communication complexity computes functions (or relations) of input vectors $(x_1, \dots, x_k) \in X_1 \times \dots \times X_k$ distributed among k parties, such that party $i \in [k]$ sees all x_j for all $j \in [k]$, $j \neq i$.

The k -party set disjointness problem $\text{DISJ}_{k,n} : (\{0, 1\}^m)^k \rightarrow \{0, 1\}$ is defined by $\text{DISJ}_{k,n}(\vec{x}) = 1$ iff there is some $j \in [n]$ such that $x_{i,j} = 1$ for all $i \in [k]$. (We follow standard terminology although it might be more appropriate to call this set intersection rather than disjointness.)

A $(0, \epsilon)$ -error k -party NOF communication protocol for set disjointness is a protocol that for every disjoint input produces output 0 and for intersecting inputs outputs 1 with probability at least $1 - \epsilon$.

It is conjectured that for any $k \geq 2$ the k -party set disjointness problem requires nearly linear randomized NOF communication complexity. This conjecture is equivalent showing that nondeterministic k -party communication complexity can be almost optimally separated from randomized k -party communication complexity. The conjecture is proven for $k = 2$ [14], but the best known lower bound for $k \geq 3$ is $\Omega(\log n)$ for general models and $\Omega(n^{1/k})$ for more restricted models [3].

2.2 Threshold Logics and the Complexity of a Search Problem

The two most prevalent classes of threshold logics are Gomory-Chvátal cutting planes [6], and matrix cuts, defined by Lovász and Schriber [16]. These proof systems, CP LS, LS_0 , and LS_+ , are special cases of more general *semantic* threshold logic proof systems.

A k -threshold formula over Boolean variables x_1, \dots, x_n is a formula of the form $\sum_j \gamma_j m_j \geq t$, where γ_j, t are integers, and for all j , m_j is a multilinear monomial of degree at most k . The size of a k -threshold formula is the sum of the sizes of γ_j and t , written in binary notation.

Let f_1, f_2, g be k -threshold formulas in the variables \vec{x} . We say that g is *semantically entailed* by f_1 and f_2 if for every 0/1 assignment to \vec{x} that satisfies both f_1 and f_2 , g is also satisfied.

Let f be an unsatisfiable CNF formula over x_1, \dots, x_n , and let t_1, \dots, t_m be the underlying set of clauses of f , written as 1-threshold inequalities. A **Th(k)** refutation of f , \mathcal{P} , is a sequence of k -threshold formulas, L_1, \dots, L_q , where each L_j is one of the inequalities t_i , $i \in [m]$, or is semantically entailed by two formulas L_i and $L_{i'}$ with $i, i' < j$, and the final formula L_q is $0 \geq 1$. The size of \mathcal{P} is the sum of the sizes of all k -threshold formulas occurring in \mathcal{P} . The proof is *tree-like* if the underlying directed acyclic graph, representing the implication structure of the proof, is a tree. (That is, every formula in the proof, except for the formulas from f , is used at most once as an antecedent of an implication.)

CP refutations are a special case of **Th(1)** semantic refutations, and thus lower bounds for tree-like **Th(1)** semantic refutations imply similar lower bounds for tree-like CP. (This was already shown in [13].)

As mentioned earlier, since we can assume that any of the Lovász-Schrijver systems can be assumed to have fan-in two, it follows that any of the systems LS_0, LS and LS^+ can easily be converted into **Th(2)** semantic refutations with at most a polynomial increase in size, and if the original proof is tree-like, so is the semantic refutation. Thus, lower bounds for tree-like **Th(2)** semantic refutations imply similar lower bounds for all tree-like Lovász-Schrijver systems.

Let f be an unsatisfiable CNF formula. We will be interested in the following search problem, $Search_f$ associated with f : given a truth assignment α , find a clause from f which is falsified by α . The model for this computation is a decision tree whose nodes evaluate polynomial threshold functions:

A k -threshold decision tree is a rooted, directed tree whose vertices are labeled with k -threshold functions and edges are labeled with either 0 or 1. The leaves of the tree are labeled with clauses of f . A k -threshold decision tree solves $Search_f$ in the obvious way: start at the root and evaluate the threshold function; follow the edge that is consistent with the value of the threshold function; continue until the computation reaches a leaf and output the associated clause. The size S of a k -threshold decision tree is the sum of the sizes of all threshold formulas in the tree, where the coefficients are written in binary. The depth of a k -threshold decision tree is the depth of the underlying tree.

Theorem 1. *Suppose that f has a tree-like **Th(k)**-semantic refutation of size S . Then there exists a $k + 1$ -party 0-error randomized NOF communication complexity protocol for $Search_f$ (over any partition of the variables into k groups) that communicates $O(\log^3 S)$ bits and produces an answer with probability at least $1 - 1/n$.*

*Further, if all k -threshold formulas in the **Th(k)**-semantic refutation have coefficients bounded by a polynomial in n , then the 0-error randomized communication complexity can be reduced to $O(\log S (\log \log n)^2)$ or the protocol can be made deterministic using $O(\log S \log n)$ bits.*

Proof (Sketch). First, following ideas similar to the degree 1 case in [13], we recursively search the proof tree using the $\frac{1}{3}$ - $\frac{2}{3}$ trick to derive a k -threshold decision tree for $Search_f$ of depth $O(\log S)$ and size $O(S)$. Then, adapting arguments from [18], we show that any relation computed by a shallow k -threshold decision tree can also be efficiently computed by a $k + 1$ player communication complexity protocol (number-on-forehead model), over any partition of the variables.

2.3 k -Fold Tseitin Formulas

Our hard examples are based on the well-known Tseitin graph formulas. Let $G = (V, E)$ be any connected, undirected graph and let $\vec{c} \in \{0, 1\}^V$. The *Tseitin formula for G with respect to charge vector \vec{c}* , $TS(G, \vec{c})$, has variables $\text{Vars}(G) = \{y_e \mid e \in E\}$. The formula states that for every vertex $v \in V$, the parity of the edges incident with v is equal to the charge, c_v , at node v . It is expressed propositionally as the conjunction of the clauses obtained by expanding $\bigoplus_{e \ni v} y_e = c_v$ for each $v \in V$. For a graph with maximum degree d , each clause is of width $\leq d$ and the number of clauses is $\leq |V|2^d$.

$TS(G, \vec{c})$ is satisfiable if and only if $\sum_{v \in V} c_v$ is even. For odd \vec{c} , $Search_{TS(G, \vec{c})}$ takes a 0/1 assignment α to $\text{Vars}(G)$ and outputs a clause of $TS(G, \vec{c})$ that is violated. In particular, a solution to $Search_{TS(G, \vec{c})}$ will produce a vertex v such that the parity equation associated with vertex v is violated by α .

To make the search problem hard for k -party NOF communication protocols (and thus, by Theorem 1, hard for $k - 1$ -threshold decision trees) we modify $TS(G, \vec{c})$ by replacing each variable y_e by the conjunction of k variables, $\bigwedge_{i=1}^k y_e^i$, and expanding the result into clauses. We call the resulting *k -fold Tseitin formula*, $TS^k(G, \vec{c})$, and its variable set, $\text{Vars}^k(G) = \{y_e^i \mid e \in E, i \in [k]\}$.

For a fixed graph G and different odd-charge vectors $\vec{c} \in \{0, 1\}^{V(G)}$, the various problems $Search_{TS(G, \vec{c})}$ are very closely related. Define $\text{ODDCHARGE}^k(G)$ to be the k -party NOF communication search problem which takes as input an odd charge vector $\vec{c} \in \{0, 1\}^{V(G)}$, seen by all players, and an assignment α to $\text{Vars}^k(G)$, in which player i sees all values but the assignment α_e^i to y_e^i for $e \in E(G)$, and requires that the players output a vertex v that is a solution to $Search_{TS(G, \vec{c})}$.

3 Reduction from Set Disjointness to ODDCHARGE

We give a sequence of reductions to show that for a suitably chosen graph G , an efficient k -party NOF communication complexity protocol for $\text{ODDCHARGE}^k(G)$ will imply an efficient 1-sided error randomized k -party NOF protocol for the set disjointness relation.

We apply the Valiant-Vazirani argument to show that, without loss of generality, it suffices to derive a 1-sided error protocol for a version of set disjointness in which the input has intersection size 0 or size 1, and the job of the players is to distinguish between these two cases. We call this promise problem *zero/one set disjointness*.

Our reduction from zero/one set disjointness to $\text{ODDCHARGE}^k(G)$ goes via an intermediate problem, $\text{EVENCHARGE}^k(G)$, which is the exact analog of $\text{ODDCHARGE}^k(G)$ except that the input charge vector \vec{c} is even rather than odd and

the requirement is *either* to find a charge violation or to determine that no charge violation exists.

The reduction from $\text{EVENCHARGE}^k(G)$ to $\text{ODDCHARGE}^k(G)$, which is similar in spirit to a reduction of Raz and Wigderson [20], works by planting a single randomly chosen additional charge violation. This yields a protocol for $\text{EVENCHARGE}^k(G)$ that works well on average for each class of inputs with a given number of charge violations.

The most difficult part of our argument is the reduction from zero/one set disjointness to $\text{EVENCHARGE}^k(G)$ for suitable graphs G . The key idea is that for even \vec{c} , charge violations of $TS^k(G, \vec{c})$ come in pairs: Given an instance $\vec{x} \in (\{0, 1\}^m)^k$ of zero/one set disjointness, using the public coins, the players randomly choose an even charge vector \vec{c} and m vertex-disjoint paths in G , p_1, \dots, p_m , for each $j \in [m]$, the players plant the $x_{1,j}, \dots, x_{k,j}$ as the assignment along each edge of path p_j , in a random solution that otherwise meets the chosen charge constraint. By construction, a charge violation can occur only at the endpoints of a path and only if there is an intersection in the set disjointness problem.

It is tricky to ensure that the resulting problem looks sufficiently like a random instance of $\text{EVENCHARGE}^k(G)$ with either 0 or 2 charge violations so that we can apply the average case properties of the protocol for $\text{EVENCHARGE}^k(G)$. This places major constraints on the graph G and in particular requires that $m \leq n^{1/3}/\log n$ where $|V(G)| = n$. The bulk of the work is in showing that a small number of specific properties: rapid mixing, modest degree, and high girth – properties all met by a family of expanders constructed in [17] – are sufficient.

Distributions on labeled graphs. For the rest of the paper in the Tseitlin tautologies we will use a family of graphs H_n that is the union of two edge-disjoint graphs on the same set of n vertices $[n]$, G_n and T_n . G_n will be a Δ -regular expander graph of the form defined by Lubotzky, Phillips, and Sarnak [17] for $\Delta = \Theta(\log n)$. Since $\overline{G_n}$ has degree $> n/2$, there is a spanning tree T_n of maximum degree 2 (a Hamiltonian path) in $\overline{G_n}$. Clearly H_n also has maximum degree $\Theta(\log n)$ and thus $TS^k(H_n, \vec{c})$ has size $n^{O(k)}$.

Let H_n be such a graph and let \vec{c} be an even charge vector. We define $Sol(H_n, \vec{c})$ to be the set of all 0/1 assignments to the edges of H_n so that for each vertex $v \in [n]$, the parity of edges incident with v is equal to c_v . A uniform random distribution over $Sol(H_n, \vec{c})$ can be obtained by first selecting 0/1 values uniformly at random for all edges in G_n and then choosing the unique assignment to the edges of T_n that fulfill the charge constraints given by \vec{c} .

Given a bit value b associated with an edge $e \in G_n$, we can define a uniform distribution $\mathcal{L}^k = \mathcal{L}_k(b)$ over the corresponding variables $y_e^i, i \in [k]$. Such an assignment is chosen randomly from \mathcal{L}_k on input b by the following experiment. If $b = 1$ then set all variables associated with edge $e, y_e^i, i \in [k]$ to 1. Otherwise if $b = 0$, set the vector $(\vec{y}_e)_{i \in [k]}$ by choosing uniformly at random from the set of $2^k - 1$ not-all-1 vectors.

Definition 1. For any $t \geq 0$ let \mathcal{D}_t be a distribution given by the following experiment on input $H_n = G_n \cup T_n$.

1. Choose an even charge vector $\vec{c} \in \{0, 1\}^n$ uniformly at random.
2. Choose some $\beta \in Sol(H_n, \vec{c})$ uniformly at random.

3. For each $e \in G_n$, select the values for the vector $(y_e)_{i \in [k]}$ from $\mathcal{L}_k(\beta_e)$ and for each $e \in T_n$, set $y_e^i = \beta_e$ for all $i \in [k]$.
4. Select a random subset $U \subseteq [n]$ of $2t$ vertices and produce charge vector \vec{c}^U from \vec{c} by toggling all bits c_v for $v \in U$.
5. Return the pair (α, \vec{c}^U) where α is the boolean assignment to the variables y_e^i , $i \in [k]$, $e \in H_n$.

Reduction from EVENCHARGE to ODDCHARGE

Lemma 1. *Let G be any connected graph on n vertices and let $\Delta(G)$ be the maximum degree in G . Suppose that Π_{odd} is a randomized k -party NOF protocol for $\text{ODDCHARGE}^k(G)$ that produces an answer with probability at least $1 - \epsilon$, is correct whenever it produces an answer, and uses at most s bits of communication. Then there is a randomized k -party NOF protocol Π_{even} for $\text{EVENCHARGE}^k(G)$ that uses $s + \Delta(G)$ bits of communication and has the following performance:*

$$\Pr_{(\alpha, \vec{c}) \in \mathcal{D}_0} [\Pi_{even}(\alpha, \vec{c}) = \text{true}] = 1$$

$$\Pr_{(\alpha, \vec{c}) \in \mathcal{D}} [\Pi_{even}(\alpha, \vec{c}) \in \text{Err}(\alpha, \vec{c})] \geq 2/3 - \epsilon \text{ for } t \geq 1.$$

Proof. Let Π_{odd} be a protocol for $\text{ODDCHARGE}^k(G)$ and assume that $V(G) = [n]$. We give a protocol Π_{even} for $\text{EVENCHARGE}^k(G)$. On input (α, \vec{c}) and random public string r : Using r , choose a random vertex $v \in [n]$. Check whether the parity equation associated with vertex v is satisfied by α using at most $\Delta(G)$ bits of communication. If it is not, return v . Otherwise, create an odd charge vector, $\vec{c}^{\{v\}}$, which is just like \vec{c} except that the value of c_v is toggled. Now run Π_{odd} on input $(\vec{c}^{\{v\}}, \alpha)$. If Π_{odd} returns the planted error v or if Π_{odd} does not return a value then return “true”; if Π_{odd} returns $u \neq v$, output u .

Suppose that $(\alpha, \vec{c}) \in \mathcal{D}_0$. Then α satisfies all charges specified by \vec{c} , so when Π_{odd} returns a vertex the above protocol must output “true” because Π_{odd} has one-sided error—that is, Π_{odd} will only return a vertex u when there is an error on the parity equation associated with u . Now suppose that $(\alpha, \vec{c}) \in \mathcal{D}_t$ so exactly $2t$ parity equations are violated. If the random vertex v does not satisfy its parity constraints, then the algorithm is correct. The remaining case is when v satisfies the parity equation and in this case we call Π_{odd} on a pair $(\alpha, \vec{c}^{\{v\}})$ where exactly $2t + 1$ parity equations are violated.

We show the probability bound separately for each $T \in [n]^{(2t+1)}$. Because the events $\text{Err}(\alpha, \vec{c}^T) = T$ partition the probability space, this proves the claim. By symmetry, for $T \in [n]^{(2t+1)}$ and any function g with codomain T , we have that $\Pr_{\alpha, \vec{c}, v} [g(\alpha, \vec{c}^{\{v\}}) = v \mid \text{Err}(\alpha, \vec{c}^{\{v\}}) = T] = 1/(2t + 1)$ since it is equally likely for $\vec{c}^T = \vec{c}^{\{v\}}$ to be generated as $\vec{c}^{\{u\}}$ for any $u \in T$. Thus we obtain:

$$\Pr_{\alpha, \vec{c}, v} [\Pi_{even}(\alpha, \vec{c}^{\{v\}}) \text{ errs} \mid \text{Err}(\alpha, \vec{c}^{\{v\}}) = T]$$

$$= \Pr_{\alpha, \vec{c}, v} [\Pi_{odd}(\alpha, \vec{c}^{\{v\}}) = v \text{ or } \Pi_{odd}(\alpha, \vec{c}^{\{v\}}) \text{ is not defined} \mid \text{Err}(\alpha, \vec{c}^{\{v\}}) = T]$$

$$\leq 1/(2t + 1) + \epsilon \leq 1/3 + \epsilon \quad \text{for } t \geq 1.$$

Reduction from Zero/One Set Disjointness to EVENCHARGE: We now show how to use a k -party NOF communication complexity protocol Π_{even} for $EVENCHARGE^k(H_n)$ as guaranteed by Lemma 1 to produce a k -party NOF protocol for the zero/one set disjointness problem which uses the following definition.

Definition 2. Let $P_l^{(m)}$ be the set of all sequences of m vertex-disjoint length l paths in G_n .

Lemma 2. Let $m = n^{1/3} / \log n$. For sufficiently large n and for any even charge vector \vec{c} , if there is a probabilistic k -party NOF communication complexity protocol, Π_{even} for $EVENCHARGE^k(H_n)$ using s bits, satisfying the conditions in Lemma 1 for \mathcal{D}_0 and \mathcal{D}_1 , then there is a randomized $(0, 1/3 + \epsilon + o(1))$ error k -party NOF communication complexity protocol Π_{01disj} for zero/one set disjointness on input $\vec{x} \in (\{0, 1\}^m)^k$ that uses s bits of communication.

Proof. Let \vec{x} be an instance of zero/one set disjointness. Protocol Π_{01disj} will call Π_{even} on the graph H_n , on a pair (α, \vec{c}) chosen according to the following distribution/experiment:

1. On input \vec{x} with public coins r :
 - (a) Using public coins r , choose a random even charge vector $\vec{c} \in \{0, 1\}^n$.
 - (b) Using public coins r , choose a sequence of m vertex-disjoint length l paths, p_1, \dots, p_m uniformly at random from $P_l^{(m)}$.
 - (c) Using the public coins r , choose $\beta \in Sol(H_n - \bigcup_{j=1}^m p_j, \vec{c})$
2. For all edges $e \in H_n$, all players other than player i compute α_e^i as follows:
 - (a) If $e \in p_j$ for $j \in [m]$, set $\alpha_e^i = x_{i,j}$
 - (b) If $e \in G_n$ and $e \notin \bigcup_{j=1}^m p_j$, choose the vector $\alpha_e^1 \dots \alpha_e^k$ according to the distribution $\mathcal{L}_k(\beta_e)$.
 - (c) For the remaining edges $e \in T_n$, set all variables α_e^i for $i \in [k]$ equal to β_e .
3. Return (α, \vec{c})

We write $\mathcal{R}(\vec{x})$ to denote the distribution on assignment/charge pairs produced by reduction Π_{01disj} when given an input \vec{x} . The following lemma, proven in section 4, has the main technical argument and shows that for $t = |\cap \vec{x}| \in \{0, 1\}$, although $\mathcal{R}(\vec{x})$ is not the same as \mathcal{D}_t , $\mathcal{R}(\vec{x})$ is close to the distribution \mathcal{D}_t in the ℓ_1 norm.

Lemma 3. Let $\vec{x} \in (\{0, 1\}^m)^k$ and $|\cap \vec{x}| = 1$. Then $\|\mathcal{R}(\vec{x}) - \mathcal{D}_1\|_1$ is $o(1)$.

Protocol Π_{01disj} will output 0 if Π_{even} returns “true” and 1 otherwise. If $\cap \vec{x} = \emptyset$, by the above construction, the support of $\mathcal{R}(\vec{x})$ is contained in that of \mathcal{D}_0 and thus on $\mathcal{R}(\vec{x})$, Π_{even} must answer “true” and the vector \vec{x} is correctly identified as being disjoint. In the case that $\cap \vec{x}$ contains exactly one element, $\Pr[\Pi_{01disj}(\vec{x}) = 0] \geq 2/3 - \epsilon - o(1)$. This completes the proof of the Lemma 2.

Reduction from Set disjointness to Zero/One Set disjointness

Lemma 4. If there is an $(0, \epsilon)$ randomized NOF protocol for the k -party zero-one-promise set-disjointness problem that uses s bits of communication where ϵ is a constant < 1 , then there is a $(0, \frac{1}{3})$ randomized NOF protocol for the k -party set-disjointness problem that uses $O(s \log n)$ bits of communication.

Naturally, our starting point is the well-known result of Valiant and Vazirani [21].

Lemma 5 (Valiant-Vazirani). *Let a be a positive integer. Fix a nonempty $S \subseteq \{0, 1\}^a$, and choose $w_1, \dots, w_a \in \{0, 1\}^a$ independently and uniformly. With probability at least $1/4$, there exists $j \in \{0, \dots, a\}$ so that $|\{x \in S \mid \forall i \leq j, x \cdot w_i = 0\}| = 1$.*

Proof (of Lemma 4). Let Π be the protocol for the promise problem. Set $a = \lceil \log n \rceil$. Using public coins, independently and uniformly choose $w_1, \dots, w_l \in \{0, 1\}^a$. For $j \in \{0, \dots, a\}$, the players run the protocol Π , using the following rule for evaluating the input $x_{i,r}$ for $i \in [k], r \in [m]$: interpret r as a vector in $\{0, 1\}^a$, and replace the value of $x_{i,r}$ by zero if for some $j' \leq j, w_{j'} \cdot r \neq 0$, and use the value $x_{i,r}$ if for all $j' \leq j, w_{j'} \cdot r = 0$. If the protocol Π returns 1, the players halt and output 1, otherwise, the players proceed to round $j + 1$. If no intersection is found after all $a + 1$ rounds, the players announce that the inputs are disjoint.

Clearly, this protocol uses $O(s \log n)$ bits of communication, and by the 0-error property of Π on disjoint inputs, it never outputs 1 when the inputs are disjoint. When the inputs are non-disjoint, the Valiant-Vazirani construction ensures that with probability at least $1/4$, at some round j the protocol Π is used on an input with a unique intersection, and therefore, conditioned on this event, the correct answer is returned with probability at least $1 - \epsilon$. Therefore, the correct answer is returned with probability at least $\frac{1}{4} - \frac{\epsilon}{4}$. Because ϵ is bounded away from 1 and the error is one-sided, a constant number of repetitions decreases the probability of error to $1/3$.

Combining the reductions

Theorem 2. *Let $k \geq 2$ and $m = n^{1/3} / \log n$. For each n there is an odd charge vector $\vec{c} \in \{0, 1\}^n$ such that for any $\epsilon < 1/2$ the size of any tree-like **Th(k-1)** refutation of $TS^k(H_n, \vec{c})$ is at least $2^{\Omega((R(\text{DISJ}_{k,m}) / \log n)^{1/3})}$. Further if the coefficients in the **Th(k-1)** refutations are bounded by a polynomial in n then the refutation size must be at least $2^{\Omega((R(\text{DISJ}_{k,m}) / (\log n (\log \log n)^2)) / \log^2 n)}$ or at least $2^{\Omega(D(\text{DISJ}_{k,m}) / \log^2 n)}$.*

Proof (Sketch). By Theorem 1 and the definition of $\text{ODDCHARGE}^k(H_n)$, if for every $\vec{c} \in \{0, 1\}^n$ there is tree-like **Th(k-1)** refutation of $TS^k(H_n, \vec{c})$ of size at most S , then there is a $1/n$ -error randomized k -party NOF communication complexity protocol for $\text{ODDCHARGE}^k(H_n)$ in which at most $O(\log^3 S)$ bits are communicated. By sending one more bit the players can check that the answer is correct and only output it in this case. Then applying Lemmas 1, 2, and 4 in turn yields an error $1/3$ randomized k -party NOF protocol for $\text{DISJ}_{k,m}$ of complexity $O(\log^3 S \log n + \log^2 n)$ bits in total. Applying a similar reduction using the other parts of Theorem 1 yields the claimed result.

In the full paper we prove that the same lower bounds as Theorem 2 hold for every odd charge vector $\vec{c} \in \{0, 1\}^n$.

4 Proximity of Distributions \mathcal{D}_1 and $\mathcal{R}(\vec{x})$ When $|\cap \vec{x}| = 1$

In this section we prove Lemma 3 that for $|\cap \vec{x}| = 1$ the distributions $\mathcal{R}(\vec{x})$ and \mathcal{D}_1 are close in the ℓ_1 norm. Let $\mu_{\mathcal{D}_1}$ and $\mu_{\mathcal{R}(\vec{x})}$ be their associated probability measures.

We will show that for all but a set of (α, \vec{c}) with $\mu_{\mathcal{D}_1}$ measure $o(1)$, $\mu_{\mathcal{D}_1}(\alpha, \vec{c}) = (1 \pm o(1))\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c})$.

Given an instance of the set disjointness variables, $\vec{x} = (\{0, 1\}^m)^k$, for $j \in [m]$ we say that the *color* of j is the tuple $(x_{1,j}, \dots, x_{k,j}) \in \{0, 1\}^k$. By construction, the assignment $\mathcal{R}(\vec{x})$ produced by R on this instance has color $(x_{1,j}, \dots, x_{k,j})$ on each edge of the path p_j .

Definition 3. Given an ordered sequence of paths $\vec{p} \in P_l^{(m)}$, an $\vec{x} \in (\{0, 1\}^m)^k$, and an assignment α , write $\chi(\alpha_{\vec{p}}) = \vec{x}$ if and only if every edge on path p_j has color $(x_{1,j}, \dots, x_{k,j})$ for every $j \in [m]$.

We first observe that for any (α, \vec{c}) with $|\text{Err}(\alpha, \vec{c})| = 2$ the probability $\mu_{\mathcal{D}}(\alpha, \vec{c})$ depends only on the number of edges $e \in G_n$ having color 1^k in α .

Definition 4. Let $\phi(a, b) = 2^{-a}(2^k - 1)^{-(a-b)}$.

Lemma 6. For any (α, \vec{c}) with $|\text{Err}(\alpha, \vec{c})| = 2t$ and $m_1 = |\{e \in E(G_n) \mid \alpha_e = 1^k\}|$, $\mu_{\mathcal{D}_1}(\alpha, \vec{c}) = \phi(|E(G_n)|, m_1)/(2^{n-1} \binom{n}{2})$.

Proof. Let $U = \text{Err}(\alpha, \vec{c})$. The probability under \mathcal{D}_1 that U is chosen to be flipped is $1/\binom{n}{2t}$ and, given U , all of the 2^{n-1} even charge vectors \vec{c}^U are equally likely. Conditioned on these events, the chance that α labels the edges for the randomly selected element of $\text{Sol}(H_n, \vec{c})$ is $2^{-|E(G)|} (2^k - 1)^{-(|E(G)| - m_1)}$.

Definition 5. For $U \subset V$ with $|U| = 2$ let $P_l^{(m)}(U)$ be the set of all elements of $P_l^{(m)}$ that have a path whose endpoints are U .

Now consider the measure $\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c})$. Let $\{i\} = \cap \vec{x} \subseteq [n]$, $U = \text{Err}(\alpha, \vec{c})$ with $|U| = 2$, and $m_1 = |\{e \in E(G_n) \mid \alpha_e = 1^k\}|$. By the definition of R ,

$$\begin{aligned} \mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c}) &= \Pr_{\vec{p} \in P^{(m)}} [\text{Ends}(p_i) = \text{Err}(\alpha, \vec{c}) \wedge \chi(\alpha_{\vec{p}}) = \vec{x}] \\ &\quad \times \Pr_{\substack{\vec{c}' \in \{0,1\}^k, \\ \alpha' \in \mathcal{L}(\text{Sol}(H_n - \vec{p}, \vec{c}'))}} [\alpha' = \alpha_G -_{\vec{p}} \text{ and } \vec{c}' = \vec{c}] \\ &= \Pr_{\vec{p} \in P^{(m)}} [\text{Ends}(p_i) = \text{Err}(U)] \times \Pr_{\vec{p} \in P^{(m)}(U)} [\chi(\alpha_{\vec{p}}) = \vec{x}] \\ &\quad \times \phi(|E(G_n)| - ml, m_1 - l)/2^{n-1}. \end{aligned}$$

Observe that p_i is a uniformly chosen element of P_l and we can analyze the first term using the following property of random paths on LPS expanders proven in the full paper.

Lemma 7. For $u \neq v \in V(G_n)$ and $l \geq c_1 \log n / \log \log n$, $\Pr_{p \in P} [\text{Ends}(p) = \{u, v\}] = (1 \pm o(1))/\binom{n}{2}$.

$$\begin{aligned} \text{Thus } \mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c}) &= (1 \pm o(1)) \frac{\phi(|E(G_n)| - ml, m_1 - l)}{\binom{n}{2} 2^{n-1}} \cdot \Pr_{\vec{p} \in P^{(\cdot)}(U)} [\chi(\alpha_{\vec{p}}) = \vec{x}] \\ &= (1 \pm o(1)) \frac{\mu_{\mathcal{D}_1}(\alpha, \vec{c})}{\phi(ml, l)} \cdot \Pr_{\vec{p} \in P^{(\cdot)}(U)} [\chi(\alpha_{\vec{p}}) = \vec{x}]. \end{aligned}$$

It follows that we will obtain the desired result if we can show that for all but a $o(1)$ measure of (α, \vec{c}) under $\mu_{\mathcal{D}_1}$,

$$\Pr_{\vec{p} \in P^{(\cdot)}(U)} [\chi(\alpha_{\vec{p}}) = \vec{x}] = (1 \pm o(1))\phi(ml, l) = (1 \pm o(1))2^{-ml}(2^k - 1)^{-(m-1)l}$$

where $U = \text{Err}(\alpha, \vec{c})$. In the case that this happens, we say that (α, \vec{c}) is *well-distributed* for \vec{x} .

Using the second moment method we prove the following lemma which shows that for all but a $o(1)$ measure of (α, \vec{c}) under $\mu_{\mathcal{D}_1}$, (α, \vec{c}) is indeed well-distributed for \vec{x} . The detailed proof is given in the full paper; the proof uses the fact that $\Theta(\log n)$ -degree LPS expanders have $O(\log n / \log \log n)$ mixing time and $\Omega(\log n / \log \log n)$ girth.

Lemma 8. *Let $m \leq n^{1/3} / \log n$ and $l = 2\lceil c_1 \log n / \log \log n \rceil$ and $\vec{x} \in (\{0, 1\}^m)^k$ with $|\cap \vec{x}| = 1$. For almost all $U \subset [n]$ with $|U| = 2$,*

$$\Pr_{(\alpha, \vec{c}) \in \mathcal{D}_1} [(\alpha, \vec{c}) \text{ is well-distributed for } \vec{x} \mid \text{Err}(\alpha, \vec{c}) = U] = 1 - o(1).$$

Lemma 3 follows from this almost immediately.

Proof (of Lemma 3). Let $\vec{x} \in (\{0, 1\}^m)^k$ and $|\cap \vec{x}| = 1$. By Lemma 8 and the preceding argument, for all but a set B of U that forms $o(1)$ fraction of all subsets $[n]$ of size 2, $\Pr_{(\alpha, \vec{c}) \in \mathcal{D}_1} [\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c}) = (1 \pm o(1))\mu_{\mathcal{D}_1}(\alpha, \vec{c}) \mid \text{Err}(\alpha, \vec{c}) = U] = 1 - o(1)$. By Lemma 7, $\Pr_{(\alpha, \vec{c}) \in \mathcal{D}_1} [\text{Err}(\alpha, \vec{c}) \in B] = o(1)$. Therefore by summing over distinct choices of U , we obtain that with probability $1 - o(1)$ over $(\alpha, \vec{c}) \in \mathcal{D}_1$, $\mu_{\mathcal{R}(\vec{x})}(\alpha, \vec{c}) = (1 \pm o(1))\mu_{\mathcal{D}_1}(\alpha, \vec{c})$. This is equivalent to the desired conclusion that $\|\mathcal{D}_1 - \mathcal{R}(\vec{x})\|_1$ is $o(1)$.

5 Discussion

There are a couple of interesting open problems related to our work beyond the natural problem of the communication complexity of DISJ_k . First, does semantic LS^k have a separation oracle, as LS does? This is closely related to whether or not LS^k is automatizable and we conjecture that the answer to both questions is negative. Secondly, is it possible to extend our lower bounds to other tautologies that would imply inapproximability results for polynomial-time LS^k -based algorithms? (For example, if we could prove superpolynomial lower bounds for tree-like LS^k proofs of random 3CNF formulas, this would imply inapproximability results for LS^k -based linear programming algorithms for MaxSAT [5].)

Finally we would like to point out a connection between our main result and the complexity of disjoint NP pairs. An open question in complexity theory is whether or not all pairs of disjoint NP sets can be separated by a set in P. This is known to be false under the assumption $P \neq UP$ and also by the assumption $P \neq NP \cap \text{coNP}$. It is an open question whether or not it is implied by $P \neq NP$. Let us consider the same question with respect to communication complexity rather than polynomial time: can every pair of relations with small nondeterministic k -party communication complexity be separated by a small probabilistic/deterministic protocol? In [20] the answer is shown to be unconditionally false for $k = 2$. In particular, they give a pair of disjoint properties on $3m$ -vertex graphs G , a matching on $2m$ vertices of G and an independent set of $2m + 1$ vertices of G , and show that this pair cannot be separated by any small probabilistic/deterministic protocol. In this paper, we have shown that for any k , the question is still false, under $k\text{-RP}^{cc} \neq k\text{-NP}^{cc}$.

On the l -Ary GCD-Algorithm in Rings of Integers

Douglas Wikström

Royal Institute of Technology (KTH)
KTH, Nada, S-100 44 Stockholm, Sweden

Abstract. We give an l -ary greatest common divisor algorithm in the ring of integers of any number field with class number 1, i.e., factorial rings of integers. The algorithm has a quadratic running time in the bit-size of the input using naive integer arithmetic.

1 Introduction

The greatest common divisor (GCD) of two integers a and b is the largest integer d such that d divides both a and b . The problem of finding the GCD of two integers efficiently is one of the oldest problems studied in number theory. The corresponding problem can be considered for two elements α and β in any factorial ring R . Then $\lambda \in R$ is a GCD of α and β if it divides both elements, and whenever $\lambda' \in R$ divides both α and β it also holds that λ' divides λ . A precise understanding of the complexity of different GCD algorithms gives a better understanding of the arithmetic in the domain under consideration.

1.1 Previous Work

The Euclidean GCD algorithm is well known. The basic idea of Euclid is that if $|a| \geq |b|$, then $|a \bmod b| < |b|$. Since we always have $\gcd(a, b) = \gcd(a \bmod b, b)$, this means that we can replace a with $a \bmod b$ without changing the GCD. Swapping the order of a and b does not change the GCD, so we can repeatedly reduce $|a|$ or $|b|$ until one becomes zero, at which point the other equals the GCD of the original inputs. In a more general setting with α and β in a factorial ring R , Euclid's idea works essentially unchanged if there exists a valuation $v : R \rightarrow \mathbb{R}^+$ with the following properties for $\alpha, \beta \in R$. There exists $\gamma, \delta \in R$ with $\alpha = \gamma\beta + \delta$ and $\delta = 0$ or $v(\delta) < v(\beta)$, if $\alpha\beta \neq 0$ then $v(\alpha) < v(\alpha\beta)$. Rings for which there exists such a valuation are called Euclidean. If in an algebraic ring $v(\alpha) = |N\alpha|$, where $N\alpha$ is the algebraic norm of α , the ring is called norm-Euclidean. Most algebraic rings are not even Euclidean. If we also want the Euclidean algorithm to terminate there must be a constant k such that $\{\alpha \mid v(\alpha) < k\}$ is finite.

All is however not lost. Kaltofen and Rolletschek [5] devise a GCD algorithm with quadratic running time for the ring of integers in any quadratic number field. Their approach is based on the idea to find an integer j such that $N(j\alpha \bmod$

$\beta) < N\beta$. This is always possible with $|j|$ bounded essentially by the square root of the discriminant. We are not aware of any generalization of this approach to more general rings of integers.

Interestingly, there are alternative approaches to compute the GCD. These are generalizations of Stein's binary GCD algorithm [9], which is particularly well suited for implementation on computers. It is based on the following facts.

$$\begin{aligned} \gcd(a, b) &= 2 \gcd(a/2, b/2) && \text{if } a \text{ and } b \text{ are even,} \\ \gcd(a, b) &= \gcd(a/2, b) && \text{if } a \text{ is even and } b \text{ is odd, and} \\ \gcd(a, b) &= \gcd((a-b)/2, b) && \text{if } a \text{ and } b \text{ are odd.} \end{aligned}$$

One may always apply one of the rules to reduce the size of elements, while preserving the GCD. Thus, by simply shifting and subtracting integers, the GCD of two integers can be computed. Weilert [11] generalizes this algorithm to the Gaussian integers. Damgård and Skovbjerg Frandsen [3, 4] independently also generalize the binary algorithm to the Eisenstein and Gaussian integers.

Sorenson [8] give the l -ary algorithm for computing the GCD of integers, which generalizes the binary algorithm. The l -ary algorithm is based on the result by Minkowski that given a and b one can find c and d such that $ca + db = 0 \pmod{l}$ for an integer l , where $|c|$ and $|d|$ essentially are bounded by \sqrt{l} . Thus, in each iteration the larger of a and b is replaced by $(ca + db)/l$. This is an analog to the binary algorithm, in that in each iteration the size of the largest integer is reduced roughly by a factor $2\sqrt{l}/l$. The details of this algorithm is slightly more involved than the binary algorithm, since the linear expression does not preserve the GCD. Sorenson also constructs a parallel version of his algorithm. Weilert [10] generalizes also this algorithm to the Gaussian integers.

Agarwal and Skovbjerg Frandsen [2] introduce an algorithm related to both the binary and the l -ary algorithms for computing GCD in several complex quadratic rings. It is interesting to note that one of the rings they consider is not Euclidean.

Wikström [13] generalizes the l -ary approach to compute the GCD in the ring of integers in the octic cyclotomic field. This is the first l -ary GCD algorithm in a non-quadratic ring, and the main inspiration to the current work.

The binary or l -ary GCD algorithm in the ring of integers $\mathbb{Z}[\zeta_m]$ of the cyclotomic number fields $\mathbb{Q}(\zeta_m)$ for $m = 2, 3, 4, 8$ can be "translated" to compute the corresponding power residue symbol. Shallit and Sorenson [7] give a binary algorithm for computing the Jacobi symbol. Weilert [11] generalizes the idea to compute the quartic residue symbol. Independently, both Damgård and Skovbjerg Frandsen [3, 4] and Wikström [12] generalize the idea to compute the cubic and quartic residue symbols. Wikström [13] also uses the idea to compute octic residue symbols.

1.2 Contribution

We give a GCD algorithm in the ring of integers \mathcal{O}_K of any number field K with class number 1, i.e., rings of integers with unique factorization. Our result is non-uniform in the sense that we, for each ring, assume that we already know

an integral basis, fundamental units, and several constants derived from these. The running time of the algorithm is quadratic in the bit-size of the input.

As far as we know, the only previous generic GCD algorithm with quadratic running time is given by Kaltofen and Rolletschek [5], and this is only applicable to quadratic rings. The algorithm in [5] is in some sense “almost Euclidean”, whereas our algorithm generalizes the l -ary algorithm [8]. As explained in the introduction, l -ary algorithms have appeared in the literature for specific rings, but the present work is the first to give a generic description of this approach.

We are confident that our algorithm can be “translated” to compute the m -th power residue symbol in the ring of integers of the m -th cyclotomic number field $\mathbb{Q}(\zeta_m)$ if it has class number 1.

Proofs of all claims are given in [14], but we try to convey the main ideas used in each proof here.

2 Notation

We denote the number of elements in a finite set A by $\#(A)$. We write \mathbb{Z} , \mathbb{Q} , \mathbb{R} , and \mathbb{C} for the rational integers, the rational numbers, the real numbers, and the complex numbers. The imaginary unit is denoted by $i = \sqrt{-1}$. We denote the complex absolute value by $|\cdot| : \mathbb{C} \rightarrow \mathbb{R}$, where $|a + bi| = \sqrt{a^2 + b^2}$. We write $\bar{\alpha}$ to denote the complex conjugate of an $\alpha \in \mathbb{C}$.

Throughout the paper we use K to denote a number field with class number 1, and we use \mathcal{O}_K to denote its ring of integers. Since \mathbb{Q} is a perfect field K/\mathbb{Q} is a separable extension. The ring \mathcal{O}_K has an integral basis which we denote by $\omega_1, \dots, \omega_g$, since \mathcal{O}_K is the integral closure of \mathbb{Z} which is a principal ideal domain. This means that $\mathcal{O}_K = \mathbb{Z}\omega_1 + \dots + \mathbb{Z}\omega_g$ and $K = \mathbb{Q}\omega_1 + \dots + \mathbb{Q}\omega_g$. We write \mathcal{O}_K^* to denote the units of \mathcal{O}_K , i.e., the invertible elements. The corresponding notation is used also for other domains. We use $\varepsilon_1, \dots, \varepsilon_h$ to denote a maximal set of independent fundamental units in \mathcal{O}_K . We denote the group of roots of unity by $\mu(K)$. We denote by $G = \text{Hom}_{\mathbb{Q}}(K, \mathbb{C})$ the set of \mathbb{Q} -embeddings of K into \mathbb{C} , i.e., isomorphisms of K , which keep \mathbb{Q} fixed. This implies that $g = \#(G)$. We assume throughout that $g \geq 2$. We use multiplicative notation for the action of an element $\sigma \in \text{Hom}_{\mathbb{Q}}(K, \mathbb{C})$, i.e., $\sigma : \alpha \mapsto \alpha^\sigma$. We denote by $N\alpha = \prod_{\sigma \in G} \alpha^\sigma$ the algebraic norm of α . For $\alpha \in \mathcal{O}_K^*$, we have $N\alpha \in \mathbb{Z}$. We use the term irreducible only for non-units. One source for the above facts is Neukirch [6].

The naive complexity model we use in this paper stipulates that addition or subtraction of positive integers x and y takes time $O(\log x + \log y)$, and multiplication, integer division or computing remainders takes time $O(\log x \log y)$.

3 Preliminary Results

Before we describe the algorithm and analyze it we need to generalize the results given in [13].

3.1 Balanced Elements

Consider the absolute value of the algebraic norm, $|N\alpha| = \prod_{\sigma \in G} |\alpha^\sigma|$, of an element $\alpha \in \mathcal{O}_K$. It is given by the product of the absolute values of the conjugates of α . The quotient $|\alpha^\sigma|/|\alpha^{\sigma'}$ of two such absolute values can be arbitrarily large for elements with a fixed absolute norm $|N\alpha|$. However, it follows from Dirichlet’s Unit Theorem that there exists an associate β of α for which the absolute values $|\beta^\sigma|$ are roughly the same size. This is an important observation, since it allows us to establish a weak triangle inequality. Informally, we could say that we can balance the complex absolute values of the algebraic conjugates of α . We use the following definition.

Definition 1 (Δ -Balanced Element) *We say that a non-zero $\alpha \in K$ is Δ -balanced if $|\alpha^\sigma| \leq \Delta|\alpha^{\sigma'}$ for all $\sigma, \sigma' \in \text{Hom}_{\mathbb{Q}}(K, \mathbb{C})$.*

Note that α is Δ -balanced precisely when all of its conjugates are Δ -balanced, and that the requirement is equivalent to $\frac{1}{\Delta}|\alpha^\sigma| \leq |\alpha^{\sigma'}$ for all $\sigma, \sigma' \in G$.

3.2 A Weak Triangle Inequality

It would be nice if given $\alpha, \beta \in K$, we had $|N(\alpha + \beta)| \leq c \max\{|N\alpha|, |N\beta|\}$ for a constant $c \in \mathbb{R}$, i.e., some type of “triangle inequality”. Unfortunately, for almost all K there is no such law. Instead we show that there exists a triangle inequality for balanced elements.

Theorem 1 (Triangle Inequality for Δ -Balanced Elements) *Let α and β be Δ -balanced elements in K , and set $g = \#(\text{Hom}_{\mathbb{Q}}(K, \mathbb{C}))$. Then*

$$|N(\alpha + \beta)| \leq 2^g \Delta^{g-1} \max\{|N\alpha|, |N\beta|\} .$$

The idea of the proof is to expand the product $|N(\alpha + \beta)| = |\prod_{\sigma \in G} (\alpha^\sigma + \beta^\sigma)|$ as a sum, apply the triangle inequality for the complex absolute value, and bound each term using the fact that α and β are balanced.

Remark 1 If the conjugates of α can be organized in pairs of complex conjugates one can give a slightly tighter inequality as is done in [13].

3.3 Linear Combinations

In this section we construct the cofactors of the l -ary approach, but first we exhibit a large set of elements with relatively small norm. Let $l \in \mathbb{Z}$, $l > 0$, denote a constant to be determined later and define the set

$$S_l = \left\{ \sum_{j=1}^g a_j \omega_j \mid 0 \leq a_j \leq \sqrt{l} + 1 \right\} .$$

Each $\sigma \in G$ may be described as a \mathbb{Z} -linear map in the basis $\omega_1, \dots, \omega_g$. We denote the matrix corresponding to this map by $f_\sigma = (f_{k,j}^\sigma)_{1 \leq k, j \leq g}$, and define the constant $c_\omega = \max_{1 \leq k, j \leq g, \sigma \in G} \{|f_{k,j}^\sigma \omega_k|\}$. We have the following result.

Lemma 1 *Let $\gamma, \gamma' \in S_l$. Then for all $\sigma \in G$*

$$|(\gamma - \gamma')^\sigma| \leq g^2 c_\omega(\sqrt{l} + 1) \text{ , and } \#(S_l) > l^{g/2} \text{ .}$$

The first part of the lemma follows by the linearity of σ , application of the triangle inequality, and the fact that elements in S_l have small positive coefficients. The second part follows by counting.

Denote by T_l the set of pairwise differences $T_l = \{\gamma - \gamma' \mid \gamma, \gamma' \in S_l\}$. We show that for any Δ -balanced elements $\alpha, \beta \in \mathcal{O}_K$, we can find elements $\gamma, \delta \in T_l$ such that $l \mid (\gamma\alpha + \delta\beta)$ and still keep $|N(\gamma\alpha + \delta\beta)|$ relatively small. More precisely we define $C_{\text{lin}}(l) = (g^2 c_\omega(\sqrt{l} + 1))^g \Delta^{g-1}$ and have the following theorem.

Theorem 2 *Let α and β be Δ -balanced elements in \mathcal{O}_K . Then there exists $\gamma, \delta \in T_l$, with $(\gamma, \delta) \neq (0, 0)$, such that $l \mid (\gamma\alpha + \delta\beta)$, and*

$$|N(\gamma\alpha + \delta\beta)| \leq C_{\text{lin}}(l) \max\{|N\alpha|, |N\beta|\} \text{ .}$$

The idea of the proof is as follows. The existence of the γ and δ follows by the pigeon-hole principle. The bound follows by an argument similar to that in the proof of Theorem 1, except that we apply Lemma 1 to bound the norm of the cofactors γ and δ .

In the following we need a notation to identify the cofactors guaranteed to exist by the theorem. We write $\gamma_{\alpha, \beta}$ and $\delta_{\alpha, \beta}$ for a pair of cofactors in T_l such that $l \mid (\gamma_{\alpha, \beta}\alpha + \delta_{\alpha, \beta}\beta)$.

3.4 Spurious Factors

Sorenson [8] notes that $\gcd(a, b) = \gcd(ca + db, b)$ may not hold for rational integers $a, b, c, d \in \mathbb{Z}$. A similar problem arises for algebraic integers. Fortunately, the following straightforward lemma explains this completely.

Lemma 2 *Let α, β, γ , and δ lie in \mathcal{O}_K . Then $\gcd(\alpha, \beta) \mid \gcd(\gamma\alpha + \delta\beta, \beta)$ and $(\gcd(\gamma\alpha + \delta\beta, \beta) / \gcd(\alpha, \beta)) \mid \gamma$.*

3.5 Approximating the Norm of a Δ -Balanced Element

The norm of an element gives in some sense the “size” of the element. Unfortunately, the way the norm is defined requires multiplication of integers, which takes time $O(n^2)$ in the naive arithmetic model. This is far too expensive to be done in each iteration of our algorithm, since we are looking for an algorithm that has a total running time of $O(n^2)$. It is natural to try to approximate the norm, but since elements can have small norm but large representation, i.e., be unbalanced, there may be much cancellation during the computation of the norm.

We consider a weaker estimate of the size of an element, which we call $N_+ : K \rightarrow \mathbb{R}$, and prove some useful results about this function. We do not know how to compute this function quickly, but in contrast to the norm it can be approximated within a constant factor in linear time for elements in \mathcal{O}_K .

Definition 2 Define $N_+ : K \rightarrow \mathbb{R}$ by $N_+\alpha = \max_{\sigma \in G} \{|\alpha^\sigma|\}$.

It is not hard to see that N_+ approximates the norm N arbitrarily badly, but it turns out to be useful anyway. The next lemma says that if an element is Δ -balanced, then N_+ is essentially a good approximation of the norm N .

Lemma 3 Let $\alpha \in K$ be Δ -balanced. Then $\sqrt{|N\alpha|} \leq N_+\alpha \leq \Delta\sqrt{|N\alpha|}$.

For the lemma to be useful there must be a way to balance an element α without computing its norm $N\alpha$, but we ignore this issue for now. Instead we introduce a function N'_+ which approximates N_+ within a constant factor.

Definition 3 Define $N'_+ : K \rightarrow \mathbb{R}$ by $N'_+\alpha = \max_{1 \leq j \leq g} \{ |a_j| \}$ for an element $\alpha \in K$ given by $\alpha = \sum_{j=1}^g a_j \omega_j$ with $a_j \in \mathbb{Q}$.

The function N'_+ can obviously be evaluated in linear time in the bit-size of the input when $\alpha \in \mathcal{O}_K$, since then $a_j \in \mathbb{Z}$. Next we show that it approximates N_+ within a constant factor.

Denote by $K_{\mathbb{C}}^*$ the direct product $\prod_{\sigma \in G} \mathbb{C}^*$, and denote by $\psi : K \rightarrow K_{\mathbb{C}}^*$ the map given by $\psi : \alpha \mapsto (\alpha^\sigma)_{\sigma \in G}$. We consider K as a g -dimensional \mathbb{Q} -vector space, where elements are represented in the basis $\omega_1, \dots, \omega_g$. Then the image $\psi(K)$ is an isomorphic \mathbb{Q} -vector space from the \mathbb{Q} -linearity of the homomorphisms. Denote by $(\psi_{\sigma,j})_{\sigma \in G, 1 \leq j \leq g}$ the complex valued matrix which represents the map $\psi : K \rightarrow \psi(K)$ expressed in the basis $\omega_1, \dots, \omega_g$. Denote by $(\psi'_{j,\sigma})_{\sigma \in G, 1 \leq j \leq g}$ the complex valued matrices corresponding to the map $\psi^{-1} : \psi(K) \rightarrow K$ expressed in the canonical orthonormal basis $\{e_\sigma\}_{\sigma \in G}$ for $K_{\mathbb{C}} = \prod_{\sigma \in G} \mathbb{C}$. Define $\Gamma = g \max_{1 \leq j \leq g, \sigma \in G} \{ |\psi_{\sigma,j}|, |\psi'_{j,\sigma}| \}$. The lemma below follows straightforwardly from the linearity of ψ and its inverse.

Lemma 4 Let $\alpha \in K$. Then $\frac{1}{\Gamma} N_+\alpha \leq N'_+\alpha \leq \Gamma N_+\alpha$.

Corollary 1 Let $\alpha \in K$ be Δ -balanced. Then

$$\frac{1}{\Gamma} \sqrt{|N\alpha|} \leq N'_+\alpha \leq \Gamma \Delta \sqrt{|N\alpha|} .$$

3.6 Balancing Elements

In this section we prove a result that allows us to balance elements in \mathcal{O}_K efficiently. Recall the statement of Dirichlet’s Unit Theorem. It considers a number field K which has r real embeddings and s pairs of conjugates of complex embeddings of K in \mathbb{C} , and says that the group of units \mathcal{O}_K^* is the direct product of the group of roots of unity, $\mu(K)$, and a free abelian group of rank $r + s - 1$. The theorem itself is not strong enough for our purposes, but we can extract a useful result from the construction used in its proof. We follow the exposition given in Neukirch [6], but use slightly different notation.

We have already defined the map $\psi : K \rightarrow K_{\mathbb{C}}^*$. Denote by $\text{vlog} : K_{\mathbb{C}}^* \rightarrow \prod_{\sigma \in G} \mathbb{R}$ the map given by $\text{vlog} : (z_\sigma)_{\sigma \in G} \mapsto (\log |z_\sigma|)_{\sigma \in G}$. Conjugation $F : z \mapsto \bar{z}$ in \mathbb{C} induces involutions. In $K_{\mathbb{C}}^*$ it acts by $F(z_\sigma)_{\sigma \in G} = (\bar{z}_\sigma)_{\sigma \in G}$ and in $\prod_{\sigma \in G} \mathbb{R}$

it acts by $F(x_\sigma)_{\sigma \in G} = (x_{\bar{\sigma}})_{\sigma \in G}$. We define $K_{\mathbb{R}}^*$ and $[\prod_{\sigma \in G} \mathbb{R}]^+$ to be the vector spaces consisting of fixed points of F in $K_{\mathbb{C}}^*$ and $\prod_{\sigma \in G} \mathbb{R}$ respectively. If σ is a real embedding, it is clearly fixed by F , and the complex embeddings comes in pairs. Since there are s pairs of complex embeddings we see that $[\prod_{\sigma \in G} \mathbb{R}]^+$ is isomorphic to \mathbb{R}^{r+s} .

Define $N_{\mathbb{C}} : K_{\mathbb{C}} \rightarrow \mathbb{C}$, $N_{\mathbb{C}} : (z_\sigma)_{\sigma \in G} \mapsto \prod_{\sigma \in G} z_\sigma$ and $\text{Tr}_{\mathbb{R}} : \prod_{\sigma \in G} \mathbb{R} \rightarrow \mathbb{R}$, $\text{Tr}_{\mathbb{R}} : (x_\sigma)_{\sigma \in G} \mapsto \sum_{\sigma \in G} x_\sigma$. It is shown in [6] that the following diagram commutes.

$$\begin{array}{ccccc}
 K^* & \xrightarrow{\psi} & K_{\mathbb{R}}^* & \xrightarrow{\text{vlog}} & [\prod_{\sigma \in G} \mathbb{R}]^+ \\
 N \downarrow & & \downarrow N_{\mathbb{C}} & & \downarrow \text{Tr}_{\mathbb{R}} \\
 \mathbb{Q}^* & \longrightarrow & \mathbb{R}^* & \xrightarrow{\text{log}} & \mathbb{R}
 \end{array}$$

Consider the following subgroups.

$$\begin{aligned}
 \mathcal{O}_K^* &= \{\varepsilon \in \mathcal{O}_K \mid N\varepsilon = \pm 1\} && \text{the units,} \\
 S &= \{y \in K_{\mathbb{R}}^* \mid N_{\mathbb{C}}y = \pm 1\} && \text{the norm one surface, and} \\
 H &= \{x \in [\prod_{\sigma \in G} \mathbb{R}]^+ \mid \text{Tr}_{\mathbb{R}}(x) = 0\} && \text{the trace zero hyperplane.}
 \end{aligned}$$

The commutative diagram above induces the homomorphisms

$$\mathcal{O}_K^* \xrightarrow{\psi} S \xrightarrow{\text{vlog}} H .$$

Denote by λ the composed map $\lambda = \text{vlog} \circ \psi$, and let $L = \lambda(\mathcal{O}_K^*)$ be the image of the units in $[\prod_{\sigma \in G} \mathbb{R}]^+$. Recall the definition of a lattice.

Definition 4 *A lattice in an \mathbb{R} -vector space V is a subgroup $L = E_1\mathbb{Z} + \dots + E_h\mathbb{Z}$, where E_1, \dots, E_h are linearly independent vectors in V . It is called complete if E_1, \dots, E_h is a basis for V .*

It is proved in [6] that the group of roots of unity, $\mu(K)$, is isomorphic to the kernel of λ and that L is a complete lattice in the $(r + s - 1)$ -dimensional vector space H . Dirichlet’s theorem follows from this. Let $h = r + s - 1$. To define the fundamental units $\varepsilon_1, \dots, \varepsilon_h$ we pick a basis E_1, \dots, E_h for L , and define $\varepsilon_j = \lambda^{-1}(E_j)$. We also define $E'_j = gE_j$.

Suppose we map an element α into $[\prod_{\sigma \in G} \mathbb{R}]^+$ using λ . Let $x = (x_\sigma) = \lambda(\alpha)$. Then it is not hard to see that α is balanced when all x_σ are of roughly the same size. Another way to phrase this is that the orthogonal projection of x onto H is close to the origin. If we multiply α by ε_j , the image $\lambda(\alpha\varepsilon_j)$ is translated by the vector E_j , i.e., $\lambda(\alpha\varepsilon_j) = \lambda(\alpha) + \lambda(\varepsilon_j) = x + E_j$. To balance an element we want to find some integer combination of the vectors E_1, \dots, E_h that translates x close to the origin, since this corresponds to multiplying α by the fundamental units $\varepsilon_1, \dots, \varepsilon_h$. We can always write $x = \sum_{j=1}^h r_j E_j$, with $r_j \in \mathbb{R}$, since L is a complete lattice, i.e., E_1, \dots, E_h is a \mathbb{R} -basis for H . Then we pick integers close to these real coefficients. Below we prove two lemmas that allow us to give a simple algorithm for balancing elements that is easy to analyze.

Recall that $\{e_\sigma\}_{\sigma \in G}$ denotes the canonical orthonormal basis for the space $\prod_{\sigma \in G} \mathbb{R}$. We define the max-norm $\|\cdot\| : H \rightarrow \mathbb{R}$ in terms of this basis by $\|\sum_{\sigma \in G} x_\sigma e_\sigma\| = \max_{\sigma \in G} |x_\sigma|$. It is intuitively clear that if an element $x \in H$ is sufficiently far from the origin, we may reduce its max-norm $\|x\|$ by an additive term t by translating it by a bounded element in the lattice L . We define a constant $c_E = \max_{r_1, \dots, r \in [-1/2, 1/2]} \|\sum_{j=1}^h r_j E'_j\|$, and turn this into a precise statement as follows. Denote by $A(t)$ the set $\{x \in H \mid x = \sum_{j=1}^h r_j E'_j, r_j \in \mathbb{R}, \|x\| \leq t + c_E\}$, and define

$$w(t) = \frac{1}{2} + \max_{\sum_{j=1}^h r_j E'_j \in A(t)} \{|r_j|\} ,$$

where $r_j \in \mathbb{R}$. We prove the following result.

Lemma 5 *Let $t > 0$ and let $x \in H$ be an element such that $\|x\| > t + c_E$. Then there exists $k_1, \dots, k_h \in \mathbb{Z}$ with $|k_j| \leq w(t)$ such that*

$$\left\| x + \sum_{j=1}^h k_j E'_j \right\| \leq \|x\| - t .$$

Choose t such that $\frac{t^2}{2} < \frac{1}{2}$ and define the constants $\Phi = w(gt)$ and $\Delta = 2^{2(gt+c)}$. We translate the above lemma from the space H back to \mathcal{O}_K and take care of the lack of precision in our approximation of N_+ . This gives the following lemma.

Lemma 6 *If α in \mathcal{O}_K is not Δ -balanced, then there exists $k_1, \dots, k_h \in \mathbb{Z}$ with $|k_j| \leq \Phi$ such that*

$$N'_+ \left(\alpha \prod_{j=1}^h \varepsilon_j^{k_j} \right) < \frac{1}{2} N'_+ \alpha .$$

The idea of the proof is the following. Suppose α is not balanced and consider the element $\beta = \alpha^g / N\alpha$. Note that β is “normalized” in the sense that $x = \lambda(\beta) \in H$ (we may have $\beta \notin \mathcal{O}_K$ though). Up to a constant factor, the element α is balanced if and only if β is balanced. This implies that $x \in H$ is far from the origin. We then apply Lemma 5 to translate x closer to the origin. Since we do this using the basis E'_1, \dots, E'_h this translates to multiplying β by a product of the fundamental units ϵ_j . When this is no longer possible, x is close to the origin, which implies that β , and thus α , are balanced.

4 The Algorithm

In this section we describe the algorithm. We divide it into subroutine calls to improve readability.

4.1 Subroutines

Consider the set of non-unit elements that divide some δ in the set of cofactors T_l . This set is clearly infinite, since each element in \mathcal{O}_K has an infinite number of associates. This makes it natural to consider the following set instead

$$F_l = \{ \pi \in \mathcal{O}_K : \pi \mid l \text{ or } \pi \mid \delta \in T_l, \text{ and } \pi \text{ is } \Delta\text{-balanced and irreducible} \} .$$

The set F_l is bounded and we denote its elements by $F_l = \{ \pi_1, \dots, \pi_s \}$. We write $F_l \nmid \alpha$ to denote the fact that $\pi \nmid \alpha$ for all $\pi \in F_l$. For clarity we state trial division as an algorithm below.

Algorithm 1 (Extract Small Factors)

SMALL(α)
Input : $\alpha \in \mathcal{O}_K$.
Output : $(\alpha', (k_1, \dots, k_s))$, where $\alpha = \alpha' \prod_{j=1}^s \pi_j^{k_j}$ and $F_l \nmid \alpha'$.
 The algorithm is the trivial one. Find α' , and k_j by trial division.

Lemma 7 *Let $\alpha \in \mathcal{O}_K$ and suppose $(\alpha', (k_1, \dots, k_s)) = \text{SMALL}(\alpha)$. Then the running time of the SMALL-algorithm on input α is $O(n(1 + \log \frac{|N\alpha|}{|N\alpha'|}))$.*

Note that $\pi \mid \alpha$ if and only if $N\pi \mid \frac{N\pi}{\pi}\alpha$. Since $\frac{N\pi}{\pi} \in \mathcal{O}_K$ this reduces, in linear time, trial division in \mathcal{O}_K to trial division in \mathbb{Z} .

Next we consider the problem of Δ -balancing elements. The algorithm below repeatedly applies Lemma 6 to find an increasingly balanced associate of the input. When this is no longer possible, we know that the current associate is Δ -balanced.

Algorithm 2 (Balance Element)

BALANCE(α)
Input : $\alpha \in \mathcal{O}_K$.
Output : a Δ -balanced associate β of α .
 $\beta \leftarrow \alpha$
Do
 $\alpha \leftarrow \beta$
 For $(k_1, \dots, k_h) \in [-\Phi, \Phi]^h$ **Do**
 If $N'_+(\beta \prod_{j=1}^h \varepsilon_j^{k_j}) < \frac{1}{2}N'_+\beta$ **Then**
 $\beta \leftarrow \beta \prod_{j=1}^h \varepsilon_j^{k_j}$
 End If
 End For
While $N'_+\beta < N'_+\alpha$
Return α

Lemma 8 *The output of the BALANCE-algorithm is Δ -balanced, and the algorithm runs in time $O(n(1 + \log(\max_{\sigma, \sigma' \in G} \frac{|\alpha|}{|\alpha'|})))$.*

Identify $\mathcal{O}_K/(l)$ with the set of representatives $\sum_{j=1}^g a_j \omega_j$, with $0 \leq a_j < l$. Then let $(\gamma_{\alpha',\beta'}, \delta_{\alpha',\beta'})_{\alpha',\beta' \in \mathcal{O}_K/(l)}$ be the table of elements from T_l guaranteed to exist by Theorem 2, i.e., elements such that $l \mid (\gamma_{\alpha',\beta'} \alpha' + \delta_{\alpha',\beta'} \beta')$. For clarity we state finding the cofactors as an algorithm.

Algorithm 3 (Find γ and δ)

GAMMADELTA(α, β)
 Input : $\alpha, \beta \in \mathcal{O}_K$.
 Output : $(\gamma, \delta) \in T_l^2$, such that $l \mid (\gamma\alpha + \delta\beta)$.
 Compute $\alpha' = \alpha \bmod (l)$ and $\beta' = \beta \bmod (l)$. Then output $(\gamma_{\alpha',\beta'}, \delta_{\alpha',\beta'})$.

Lemma 9 *The algorithm is correct and runs in time $O(n)$.*

4.2 Greatest Common Divisor

Finally, we are ready to give the algorithm for computing a greatest common divisor of two elements α and β in \mathcal{O}_K . The special case where one of the inputs is zero is treated in the first two lines. Then we extract all small factors of both inputs and store these. This allows us to determine all small factors in a GCD. Then we make sure that β is balanced. Consider now the while-loop of the algorithm. In each iteration α is balanced. This ensures that when we compute $N'_+ \alpha$ and $N'_+ \beta$ the results are in fact approximations of $\sqrt{|N\alpha|}$ and $\sqrt{|N\beta|}$. This gives us a good idea of which of the elements is the larger. The if-statement swaps α and β such that the norm of α is larger or at least within a constant factor of the norm of β . Then a linear expression is formed using the special

Algorithm 4 (Greatest Common Divisor)

GCD(α, β)
 Input : $\alpha, \beta \in \mathcal{O}_K$, with either α or β non-zero.
 Output : The greatest common divisor of α and β .
 If $\alpha = 0$ Return β
 If $\beta = 0$ Return α
 $(\alpha, (k_1, \dots, k_s)) \leftarrow \text{SMALL}(\alpha)$
 $(\beta, (k'_1, \dots, k'_s)) \leftarrow \text{SMALL}(\beta)$
 $\beta \leftarrow \text{BALANCE}(\beta)$
 While $\alpha \neq 0$ Do
 $\alpha \leftarrow \text{BALANCE}(\alpha)$
 If $N'_+ \alpha < N'_+ \beta$ Then
 $(\alpha, \beta) \leftarrow (\beta, \alpha)$
 End If
 $(\gamma, \delta) \leftarrow \text{GAMMADELTA}(\alpha, \beta)$
 $(\alpha, \cdot) \leftarrow \text{SMALL}((\gamma\alpha + \delta\beta)/l)$
 Done
 Return $\beta \prod_{j=1}^s \pi_j^{\min\{k_j, k'_j\}}$

cofactors of bounded norm, and the result is divided by l . This reduces the norm of α . During the iterations of the while-loop spurious factors from the set F_l may be introduced into the current β . These are removed in the subroutine call, and the output is formed in the obvious way.

In each iteration, α , perhaps after swapping with β , is replaced by the expression $(\gamma\alpha + \delta\beta)/l$. We must obviously choose l large enough such that $|N((\gamma\alpha + \delta\beta)/l)| < |N\alpha|$. But, we must also take into account the lack of exactness in the approximation N'_+ of the norm used when deciding which of α and β is the larger. For simplicity we choose l such that the norm of α is guaranteed to be reduced by a factor of two in each iteration. More precisely we choose l as the smallest integer that satisfies the inequality $C_{\text{lin}}(l)/l^g < 1/(2\Gamma^{2g}\Delta^g)$. We can choose l to satisfy this inequality since $C_{\text{lin}}(l) = O(l^{g/2})$.

5 Analysis

In this section we prove the correctness of the algorithm and bound its running time. To simplify the exposition we denote by α_j and β_j , and α'_j and β'_j the values of α and β before and after the if-statement in the j th iteration of the while-loop.

Lemma 10 *The j th iteration, $j > 1$, runs in time $O(n(1 + \log \frac{|N\alpha| \cdot |N\beta|}{|N\alpha_{+1}| \cdot |N\beta_{+1}|}))$.*

To see why the lemma is true, note that from the triangle inequality of the complex absolute value follows that in each iteration, $\max\{|\alpha_{j+1}^\sigma|\}$ can only be a constant factor larger than $\max\{|\alpha'_j{}^\sigma|\}$. This means that if α_{j+1} is very unbalanced, then $|N\alpha_{j+1}|$ must also be much smaller than $|N\alpha'_j|$. The lemma then follows from Lemma 7 and Lemma 8.

Theorem 3 *Algorithm 4 computes the greatest common divisor of its inputs in time $O(n^2)$ in the bit-size n of its input using naive arithmetic in \mathbb{Z} .*

The proof of correctness is straightforward except from the handling of spurious factors. Since all small factors are removed from both inputs and stored before the while-loop, any small factors found in the while-loop can safely be discarded. By Lemma 2, replacing α by $(\gamma\alpha + \delta\beta)/l$ preserves the GCD up to small factors. Since all small factors are removed by the call to the SMALL-algorithm the GCD of α and β is preserved and the output of the algorithm is correct. The bound of the running time is explained as follows. We have chosen l such that the absolute norm of one of the elements is reduced at least by a factor $1/2$ in each iteration. Since the norm is an integer and the algorithm halts when $\alpha = 0$, the algorithm executes at most $d = O(n)$ iterations. The subroutine calls made outside of the while-loop can be done in time $O(n^2)$. The running time of each iteration is bounded in Lemma 10. Thus, it remains to argue that the combined execution time $\sum_{j=2}^d O(n \log \frac{|N\alpha| \cdot |N\beta|}{|N\alpha_{+1}| \cdot |N\beta_{+1}|})$ of all subroutine calls sum to $O(n^2)$, but this follows by calculation.

6 On the Existence of Practical Algorithms

In this paper we focus on conceptual simplicity, and not on minimizing the constants in the running time. In particular the three subroutines SMALL, BALANCE, and GAMMADELTA are trivial brute force algorithms. Thus, an interesting line of future research is to devise more efficient specialized versions of these subroutines, e.g., it should be possible to use lattice reduction techniques to balance elements. Another line of research is to exploit specific properties of \mathcal{O}_K when $\#(G)$ is relatively small. In addition to the complex rings mentioned in the introduction, this seems possible for some real quadratic rings [1].

Acknowledgments

I wish to thank my advisor Johan Håstad for excellent advice. Without his help I would still be struggling. I also thank Torsten Ekedahl who essentially played the role of an extra advisor during this work.

A Fully Abstract Encoding of the π -Calculus with Data Terms*

(Extended Abstract)

Michael Baldamus^{1, **}, Joachim Parrow², and Björn Victor²

² Department of Information Technology, Uppsala University, Sweden

Abstract. The π -calculus with data terms ($\pi\mathcal{T}$) extends the pure π -calculus by data constructors and destructors and allows data to be transmitted between agents. It has long been known how to encode such data types in π , but until now it has been open how to make the encoding *fully abstract*, meaning that two encodings (in π) are semantically equivalent precisely when the original $\pi\mathcal{T}$ agents are semantically equivalent. We present a new type of encoding and prove it to be fully abstract with respect to may-testing equivalence. To our knowledge this is the first result of its kind, for any calculus enriched with data terms. It has particular importance when representing security properties since attackers can be regarded as may-test observers. Full abstraction proves that it does not matter whether such observers are formulated in π or $\pi\mathcal{T}$, both are equally expressive in this respect. The technical new idea consists of achieving full abstraction by encoding data as table entries rather than active processes, and using a firewalled central integrity manager to ensure data security.

1 Introduction

The increasingly complicated mechanisms to guarantee secure communications have spurred the development of appropriate formal description techniques. In this paper we study a prototypical such formalism, a π -calculus enriched with data terms ($\pi\mathcal{T}$), and show how it can be encoded in the more fundamental π -calculus [13] while preserving full abstraction. This means that two processes in $\pi\mathcal{T}$ are equivalent precisely when their encodings are equivalent. Although encodings between such calculi has proved a rich field of study this is the first result of its kind. We achieve it by designing the encoding in a different way from what is usually done. The full proof is very technical and we here outline the main ideas, which are quite general and can in principle be applied to many similar calculi.

$\pi\mathcal{T}$ extends the basic π -calculus by including constructors and destructors for data terms. In this the calculus resembles a high level parallel programming language, and specifications of security protocols can be made in a familiar operational style. It

** To whom correspondence should be addressed (<http://www.lcb.uu.se/~michaelb>).

can be seen as a generalisation of the spi-calculus [3] (which extends π with primitives for encryption and decryption) in that arbitrary constructors and destructors are allowed. It can also be seen as a simplification of the applied π -calculus by Abadi and Fournet [1], since it does not admit equations over the data terms.

A key idea when encoding data was expressed already in the first papers on the π -calculus: a data structure is represented in π as a process with the ability to interact along designated ports in order to carry out operations. In such a manner all known kinds of data structures, certainly including those of $\pi\mathbb{T}$, can be encoded.

The problem with this kind of encoding appears when we consider a useful notion of semantic equality between $\pi\mathbb{T}$ processes. We shall here as a prime example look at *testing* equivalence. The main idea is that two processes are behaviourally equivalent precisely when they can satisfy the same *tests*. Tests are arbitrary processes of the calculus, which of course is expressive enough to describe not only security protocols but also the potential attackers on them. So if we know of two processes that they are testing equivalent we know that they will behave similarly in all conceivable environments. In an earlier paper [4] we have proved for the spi calculus that a process satisfies a test if and only if the encoding of the process satisfies the encoding of the test. The same result, as we will show in this paper, holds for an encoding from $\pi\mathbb{T}$ to π .

Unfortunately, with the traditional kind of encoding from $\pi\mathbb{T}$ to π the testing equivalences in $\pi\mathbb{T}$ and π turn out to be different. The reason is, briefly put, that the encodings of two $\pi\mathbb{T}$ processes satisfy the same tests *only if the tests are encodings of $\pi\mathbb{T}$ tests*. But in the π -calculus there are also tests which are not encodings of any $\pi\mathbb{T}$ test, and some of these may be able to discriminate between the encodings of otherwise equivalent processes. Formally *full abstraction*, the result that two $\pi\mathbb{T}$ processes are equivalent precisely when their encodings are equivalent, has proved elusive, not only for $\pi\mathbb{T}$ but for all similar calculi, and for similar operationally defined equivalences.

In this paper we exhibit an encoding from $\pi\mathbb{T}$ to π and prove it to be fully abstract. A key ingredient is that we use a central so called *integrity manager* (\mathbf{M}) which stores all data values generated throughout a computation. All access to data must go through a level of indirection at \mathbf{M} , which only allows accesses that adheres to the protocols for interacting with data. Thus, the previously dangerous π -calculus processes that are not encodings of $\pi\mathbb{T}$ processes are rendered impotent.

The remaining sections of this paper are organised as follows: Section 2 introduces $\pi\mathbb{T}$. Section 3 presents the encoding of $\pi\mathbb{T}$ into the polyadic π -calculus. The reader may refer to [5] for some parts that have to be left out here due to a lack of space. Section 4 states the full-abstraction result. It also gives an idea of its long and complex proof. The full proof can be found in [5]. Section 5 discusses related work. Section 6 concludes the paper with some final remarks, in particular about the lack of compositionality of the encoding due to the global integrity manager.

2 Background: π -Calculus, $\pi\mathbb{T}$ -Calculus

2.1 The $\pi\mathbb{T}$ -Calculus

As always in π -like calculi, an infinite set of *names* is assumed to be given. This set is here typically ranged over by lower-case letters from the middle of the alphabet, such

as n . Sets of names are typically ranged over by upper-case letters from the middle of the alphabet, such as N . As usual in spi-calculus-like extensions of the π -calculus we distinguish names and *variables*. The set of variables is also assumed to be infinite. It is here typically ranged over by lower-case letters from the end of the alphabet, such as x . We designate finite vectors by means of the $\tilde{\cdot}$ -symbol. The length of any finite vector \tilde{X} is denoted by $|\tilde{X}|$.

The $\pi\mathbb{T}$ -calculus is further characterised by assuming a set of function symbols from which data terms can be formed, distinguishing dedicated *constructors* and *deconstructors* (with minor restrictions, see below). Predictably, constructors are used to build data terms and deconstructors to take them apart. Both the set of constructors and the set of deconstructors are assumed to be finite. Constructors are typically ranged over by f , deconstructors by d . Each constructor f is assumed to have a fixed, finite *arity* $\text{ar}[f]$.

Data terms are then given as follows:

$$T, \dots ::= n \mid x \mid f(T_1, \dots, T_{\text{ar}[f]})$$

For the sake of simplicity, no type discipline is assumed for data terms, only the constructor arities must be respected. The set of all names that occur in any given vector \tilde{T} of data terms is denoted by $\text{nm}[\tilde{T}]$. Deconstructors must not occur within data terms. They may only be applied via the **let** construct introduced below. A *value* is a data term without any variables. Values are typically ranged over by V and W .

Agent expressions are then given as follows:

$$P, \dots ::= \mathbf{0} \mid T(x).P \mid \bar{T}\langle U \rangle.P \mid P \mid Q \mid (\nu n)P \mid !P \\ \mid \text{if } T = U \text{ then } P \text{ else } Q \mid \text{let } x = d(\tilde{T}) \text{ in } P$$

The $\mathbf{0}$ constant denotes the inert process. An input prefix $T(x).P$ can be performed in a context where T evaluates to some name n . Then a value, e.g. V , is received over the channel denoted by n and the process continues as P where x is substituted by V . An output prefix $\bar{T}\langle U \rangle.P$ can also be performed in a context where T evaluates to some name n and U to some value V . Then V is sent via the channel denoted by n and the process continues as P . Here n and T are called the *subject*, and x and V the *object* of the input or output. The next three operators are standard in pi-calculus-like calculi: $P \mid Q$ behaves like P and Q acting concurrently; $(\nu n)P$ behaves like P where n is local; $!P$ behaves like infinitely many copies of P put in parallel. The conditional and the **let** have their usual meaning. In $\pi\mathbb{T}$, **let** is the only place where deconstructors may be applied.

Input prefixing, **let**, and restriction are *binders*: $T(x).P$ and **let** $x = d(\tilde{T})$ **in** P bind the variable x in P ; $(\nu n)P$ binds the name n in P . The set of names occurring free (non-bound) in a process expression P is denoted by $\text{fn}[P]$ and similarly for a vector $\tilde{P} = P_1 \dots P_n$ of process expressions $\text{fn}[\tilde{P}]$ means the union of all $\text{fn}[P_i]$.

We do not distinguish between expressions that differ only up to alpha conversion of bound names and variables. Given any data term or process expression H , $H\{\tilde{x} := \tilde{T}\}$ denotes the term after simultaneously substituting each x_i by T_i . Substitution always entails implicit alpha-conversion of bound names in H such that there is no capture of any free names in \tilde{T} . A *process* is an agent expression without free variables.

We often omit trailing $\mathbf{0}$ suffixes, writing $x\langle y \rangle$ for $x\langle y \rangle.\mathbf{0}$. We often also use an “inline” notation for restriction, and e.g. write $\bar{x}\langle \nu y \rangle.P$ as shorthand for $(\nu y)\bar{x}\langle y \rangle.P$. Further, we use the standard notation $\prod_{i \in \{j_1, \dots, j_k\}} P_i = P_{j_1} \mid \dots \mid P_{j_k}$.

Deconstructor Equations. *Deconstructor equations* describe how deconstructors act upon values. To this end, we need to introduce *value patterns*:

$$G ::= x \mid f(G_1, \dots, G_{\text{ar}[f]})$$

A deconstructor equation is then of the form $d(\tilde{G}) \triangleq x$ where x must occur in \tilde{G} . There may be several, but only finitely many equations for each deconstructor. Since there are finitely many deconstructors, there are only finitely many deconstructor equations.

Operational Semantics. Abadi’s and Fournet’s semantics for the applied π -calculus [1] use active substitutions and rely heavily on structural congruence rules. Our semantics, using the **let** construct for deconstruction, is more direct and does not utilise structural congruence. The rules for scope opening are similar to the variant in [1] giving the finest bisimulation equivalence relation; we are dealing with may testing where this finesse does not matter.

Actions are of one of three forms:

$n(V)$: Input of value V on channel n where V is bound to x as shown below.

$(\nu M)\bar{n}\langle V \rangle$: Output of value V on channel n where the names in M are extruded as private names. The SOS clauses ensure that we always have $M \subseteq \text{fn}(V)$.

τ : Silent action.

The individual clauses are as shown below. The treatment of replication follows [17]. The clauses for **if** - **then** - **else** are slightly non-standard since they entail a τ -action, just like in [1]. This is advantageous for our purposes of considering may-testing. The missing symmetric clauses for interleaving and closure are left implicit.

$$\begin{array}{c} \frac{n(x).P \xrightarrow{n(V)} P\{x := V\} \quad P \xrightarrow{n(V)} P' \quad Q \xrightarrow{(\nu M)\bar{n}\langle V \rangle} Q' \quad \text{fn}[P] \cap M = \emptyset}{\bar{n}\langle V \rangle.P \xrightarrow{(\nu \emptyset)\bar{n}\langle V \rangle} P} \quad \frac{P \mid Q \xrightarrow{\tau} (\nu M)(P' \mid Q')}{P \mid Q \xrightarrow{\tau} (\nu M)(P' \mid Q')} \\ \frac{P \xrightarrow{\alpha} P' \quad \text{bn}[\alpha] \cap \text{fn}[Q] = \emptyset}{P \mid Q \xrightarrow{\alpha} P' \mid Q} \quad \frac{P \xrightarrow{(\nu M)\bar{n}\langle V \rangle} P' \quad n \neq m' \quad m' \in \text{nm}[V] \setminus M}{(\nu m')P \xrightarrow{(\nu M + m')\bar{n}\langle V \rangle} P'} \\ \frac{P \xrightarrow{\alpha} P' \quad n \notin \text{nm}[\alpha]}{(\nu n)P \xrightarrow{\alpha} (\nu n)P'} \quad \frac{\text{if } T = T \text{ then } P \text{ else } Q \xrightarrow{\tau} P \quad T \neq U}{\text{if } T = U \text{ then } P \text{ else } Q \xrightarrow{\tau} Q} \quad \frac{P \xrightarrow{\alpha} P' \quad \text{bn}[\alpha] \cap \text{fn}[P] = \emptyset}{!P \xrightarrow{\alpha} P' \mid !P} \\ \frac{P \xrightarrow{n(V)} P'_1 \quad P \xrightarrow{(\nu M)\bar{n}\langle V \rangle} P'_2 \quad \text{fn}[P] \cap M = \emptyset}{!P \xrightarrow{\tau} ((\nu M)(P'_1 \mid P'_2)) \mid !P} \quad \frac{d(\tilde{G}) \triangleq x \quad \tilde{G}\sigma = \tilde{V}}{\text{let } y = d(\tilde{V}) \text{ in } P \xrightarrow{\tau} P\{y := x\sigma\}} \end{array}$$

We denote by $\text{nm}[\alpha]$ the set of names that syntactically occur in any action α ; we denote by $\text{bn}[\alpha]$ the set of bound names of α : $\text{bn}[n(x)] = \emptyset$, $\text{bn}[(\nu M)\bar{n}\langle T \rangle] = M$, $\text{bn}[\tau] = \emptyset$; $(\nu \{n_1, \dots, n_k\})$ stands for $(\nu n_1) \dots (\nu n_k)$, $k \geq 0$. Also, we denote mappings from variables to values by σ , and by $\tilde{T}\sigma$ the vector that results from applying σ to each element of \tilde{T} .

2.2 Polyadic π -Calculus

In the next section we will encode $\pi\mathbb{T}$ into the polyadic π -calculus. The specific dialect that we use is derived from $\pi\mathbb{T}$ via three simple modifications: First, the sets of constructors and deconstructors are assumed to be empty; second, nondeterministic CCS-like choice of the form $P + Q$ and polyadic input and output prefixes of the form $a(\tilde{x}).P$ or $\bar{a}(\tilde{b})$, respectively, are admitted, where a and b range over both names and variables; third, *process constants* are admitted. They are typically ranged over by upper-case letters from the beginning of the alphabet, such as A . *Process constant definitions* are of the form $A(\tilde{x}) \triangleq P$ where the free variables of P must be from \tilde{x} . There must be a unique definition for each process constant. The number of actual parameters in each instantiation of any process constant must be the same as the number of formal parameters in the constant's definition. The necessary modifications of the above SOS clauses and the accompanying notion of action are standard. Here, we just give the semantics of the nondeterministic choice operator:

$$\frac{P \xrightarrow{\alpha} P'}{P + Q \xrightarrow{\alpha} P'} \quad \frac{Q \xrightarrow{\alpha} Q'}{P + Q \xrightarrow{\alpha} Q'}$$

As α ranges over all actions including τ , $+$ is the ordinary CCS-like nondeterministic choice operator.

3 The Encoding of the $\pi\mathbb{T}$ -Calculus

In this section we present the encoding of $\pi\mathbb{T}$ -processes into the polyadic π -calculus. As in previous work [4], the main issue is encoding values.

The idea is to let encoded processes operate on encoded values only via *value identifiers* (IDs). To this end, an *integrity manager* \mathbf{M} is set up, which maintains tables of the existing IDs and the values these correspond to. Whenever an encoded process wants to operate on one or more encoded values, it must send a specific request carrying the value IDs to \mathbf{M} . \mathbf{M} will check whether it already knows the IDs, i.e., whether the IDs correspond to any actual values: if that is the case, then \mathbf{M} will perform the operation; if not, then the request will deadlock. If the operation requires generating a new value, \mathbf{M} will do so, and it will also generate a new ID that it will associate with the value. Completion will be signalled on a dedicated channel that has been supplied when the request was issued. The channel carries an ID which refers to the result of the operation, if there was any.

\mathbf{M} thus shields encoded processes from any malformed complex values that might be sent to them by π -observers which are not encodings of $\pi\mathbb{T}$ processes. Moreover, as $\pi\mathbb{T}$ - and π -processes have the same pure synchronisation capabilities, π -observers are unable to do anything to encoded $\pi\mathbb{T}$ -processes that encoded $\pi\mathbb{T}$ -observers cannot already do. The only requirement is that no encoded $\pi\mathbb{T}$ -process may ever get connected to a “fake” integrity manager. This is assured by (a) restricting the channels that are used for interacting with \mathbf{M} and (b) setting up a uni-directional firewall \mathbf{F} via which \mathbf{M} can receive requests from an external observer via duplicate, non-restricted channels.

The encoding of $\pi\mathbb{T}$ processes is constructed using one encoding function $\langle \cdot \rangle$ for processes as such (section 3.1), and one encoding function $\langle \cdot \rangle_r$ of values occurring in

the processes (section 3.2), parameterised by a location r used to represent the value. \mathbf{M} is presented in section 3.3.

The full encoding of a $\pi\mathbf{T}$ process P is thus $\llbracket P \rrbracket = (\nu K_{\mathbf{M}})(\langle P \rangle \mid \mathbf{M} \mid \mathbf{F})$, and our main theorem

$$P \approx_{\text{may}} Q \text{ iff } \llbracket P \rrbracket \approx_{\text{may}} \llbracket Q \rrbracket.$$

The encoded processes communicate with \mathbf{M} using a simple protocol over the free names of \mathbf{M} , which we denote by $K_{\mathbf{M}}$. Below we describe their use and the parameters passed over them.

input : (i, r) i is the ID of the channel the process wants to input a value over; r is a fresh name over which the process will receive the value (itself an ID).

output : (i, j, r) i is the ID of the channel the process wants to output a value over; j is the ID of the value to be sent; r is a fresh name which will be used for synchronisation when the output has been performed by \mathbf{M} .

apply_E : (\tilde{i}, r) (for each deconstructor equation $E : d(G_1, \dots, G_k) = x$, where $\tilde{i} = k$). \tilde{i} are the IDs of the actual components of the value pattern; r is a fresh name where the ID of the value corresponding to x (if any) can be received by the process.

r : (i) (for each value occurring in the process). Each value used in the process is represented by a fresh name r , where the process can receive the ID of the value, e.g. to pass in the above operations.

The encoded values register with \mathbf{M} by communicating with it over two additional channels:

new : (n, r) n is a $\pi\mathbf{T}$ name occurring in the source process; r is a name where the ID of the name can be received.

new_f : (\tilde{x}, r) (for each constructor f , where $|\tilde{x}| = \text{ar}[f]$). \tilde{x} are the actual components of the constructor f ; r is a name where the ID of the constructed value $f(\tilde{x})$ can be received.

3.1 Encoding Processes

The encoding of processes is homomorphic for $\mathbf{0}$, $|$, (ν) and $!$ operators:

$$\llbracket \mathbf{0} \rrbracket = \mathbf{0} \quad \llbracket P \mid Q \rrbracket = \llbracket P \rrbracket \mid \llbracket Q \rrbracket \quad \llbracket (\nu n) P \rrbracket = (\nu n) \llbracket P \rrbracket \quad \llbracket !P \rrbracket = !(P)$$

Input and output prefixes (below) encode the subject, request its ID, and contacts \mathbf{M} for doing the actual input or output. In the case of input, the response channel s is used for performing the input, binding the object x , while in the case of output, \mathbf{M} performs the output and responds with a pure synchronisation. r, s, t, i and j are fresh.

$$\begin{aligned} \llbracket T(x).P \rrbracket &= (\nu r)(\langle T \rangle_r \mid r(i).\overline{\text{input}}\langle i, \nu s \rangle.s(x).\llbracket P \rrbracket) \\ \llbracket \overline{T}(U).P \rrbracket &= (\nu r, s)(\langle T \rangle_r \mid \langle U \rangle_s \mid r(i).s(j).\overline{\text{output}}\langle i, j, \nu t \rangle.t().\llbracket P \rrbracket) \end{aligned}$$

The conditional retrieves the IDs of the encodings of the compared values and tests them for identity. (\mathbf{M} ensures that identical values have the same ID.) r, s, i and j are fresh.

$$\llbracket (\text{if } T = U \text{ then } P \text{ else } Q) \rrbracket = (\nu r, s)(\langle T \rangle_r \mid \langle U \rangle_s \mid r(i).s(j).\text{if } i = j \text{ then } \llbracket P \rrbracket \text{ else } \llbracket Q \rrbracket)$$

$$\begin{aligned}
\mathbf{M} = & (\nu \textit{lock}, \textit{unlock}, \textit{put}, \textit{getId}, \textit{getAlias}, [\forall f \in \mathbb{F}. \textit{put}_f, \textit{getId}_f, \textit{getArgIds}_f], \textit{lookUp})(\\

\end{aligned}$$

Fig. 1. Defining equation of integrity manager and empty value table

The `let` processes use a deconstructor. Each deconstructor d of arity k has a set of associated deconstructor equations $\mathbb{E}_{d,k}$. Each such equation E has a handler in \mathbf{M} , contacted over \textit{apply}_E . In the encoding of `let` below (left), all such handlers are applied in parallel (line 2), and the first one to complete (line 3) locks the others out (using the one-time lock u on line 1). \tilde{r}, \tilde{i} and u are fresh.

$$\begin{aligned}
(\textit{let } x = d(T_1, \dots, T_k) \textit{ in } P) = & \quad (f(T_1, \dots, T_{\text{ar}[f]}))_r \\
(\nu r_1, \dots, r_k) & \quad = (\nu r_1, \dots, r_{\text{ar}[f]})(\\
& \quad (T_1)_{r_1} \mid \dots \mid (T_k)_r & \quad (T_1)_{r_1} \mid \dots \mid (T_{\text{ar}[f]})_{r_{\text{ar}[f]}} \quad (4) \\
& \quad | r_1(i_1) \dots r_k(i_k). & \quad | r_1(i_1) \dots r_{\text{ar}[f]}(i_{\text{ar}[f]}). \quad (5) \\

& \quad r(x).u().(P) & \quad (3)
\end{aligned}$$

3.2 Encoding Value Terms

Value terms come in three kinds: constructor terms, names, and variables. Their encoding is above (right). Terms using a constructor f encode their component values (line 4), and supply their IDs (line 5) to the \textit{new}_f handler (line 6). Names are encoded by calling the \textit{new} handler of \mathbf{M} , while occurrences of variables will always be substituted at runtime by an ID, which will then be returned.

3.3 Integrity Manager \mathbf{M}

\mathbf{M} is shown in Figure 1. The names \textit{input} , \textit{output} , \textit{new} , \textit{new}_f for all $f \in \mathbb{F}$, and \textit{apply}_E for all $E \in \mathbb{E}$ are free in \mathbf{M} . They may be used by π -calculus observers to interact with any encoded process, but thanks to the firewall, they can not interfere in the communication between the encoded processes and \mathbf{M} .

\mathbf{M} uses an initially empty value table (**EmptyValTbl**) to maintain the correspondence between values and their value IDs. Each name in the table has an *alias*, used for the actual input and output, such that \mathbf{M} can monitor all values passed, making sure they are value IDs. For each constructor in the table, the IDs of its subcomponents are

maintained. The **Mutex** is used as a mutual exclusion lock for the table. (The reader may refer to [5] for parts that have to be left out here due to a lack of space.)

Additional components of **M** insert new values into the tables, if necessary:

NameRegistrar. The first time a name is used in the encoded process, the name registrar adds its corresponding ID and alias to the name table. Later uses of the name only result in a lookup; the ID and alias is maintained.

ConsTermRegistrar_f (for each $f \in \mathbb{F}$). The constructor term registrars perform the corresponding function for values built by constructors f ; the ID of the value and its components is maintained, and together the name and constructor term registrars ensure that identical values have the same ID.

The remaining components of **M** are (1) the handlers for input and output, **InputInterpreter** and **OutputInterpreter**, which ensure that all names used as channels, and values passed over them, have appropriate table entries and (2) the deconstructor equation handlers **EquationInterpreter_E**, used to match a deconstructor application against deconstructor equations.

Value Table. IDs of names and constructors are added to the value table by communication over *put* and *put_f*, respectively; they can be retrieved over *getId* and *getId_f*. The *lookUp* is used to verify that an ID is in the table. Subcomponents of constructors can be retrieved over *getArgIds*.

The table is built by appending table cells to the initial empty table. Such a cell is either a **NameEntry** or a **ConsTermEntry_f** ($f \in \mathbb{F}$). All requests to retrieve information have among their parameters the names r^+ , r^- , which are used for the response. Each cell checks if it should handle the request, and if not, passes it on to the next cell. If no cell handles the request, the **EmptyValTbl** eventually signals on r^- .

Name Registrar. Name records maintain the IDs and *aliases* of names. The latter are the channels used internally for communication, to make sure all objects passed are value IDs. The *name registrar* first checks if the supplied name is a value ID, supplied by a “malicious” observer: this is an error, and the requester gets no reply. If it is not a value ID, it checks if the name is in the name table; in that case it returns its ID, otherwise it adds the name together with its new ID and alias to the name table, adds the ID to the ID table (since all IDs used must be there), and responds with the ID.

Constructor Term Registrars. The constructor registrars for a constructor f is a variation of the name registrar: it checks that each component value is in the ID table (and thus is a valid value in the encoding), and if they are, either returns the ID of the constructed term (if it is already there) or puts in an association between the constructed term and its (new) ID, puts the ID in the ID table, and returns it.

Equation Interpreters. Given an equation $E : d(G_1, \dots, G_{\text{ar}[E]}) \triangleq x$, an interpreter for E is given a vector of $\text{ar}[E]$ actual value IDs, and tries to match each value ID against the corresponding value pattern G_i of the equation. If it succeeds, the value ID corresponding to x of the equation is returned over the result channel r . If it fails, no result is given.

Given $E : d(G_1, \dots, G_{\text{ar}[E]}) \triangleq x$,

$$\begin{aligned} & \mathbf{EquationInterpreter}_E(\text{lock}, \text{unlock}, [\forall f \in \mathbb{F}. \text{getArgIds}_f], \text{lookUp}, \text{apply}_E) \triangleq \\ & ! \text{apply}_E(i_1, \dots, i_{\text{ar}[E]}, r). \text{lock}(). \overline{\text{lookUp}}\langle i_1, \nu s_1^+, \nu s_1^- \rangle \\ & \quad (s_1^-. \text{unlock}\langle \rangle \\ & \quad + s_1^+\langle \rangle). \\ & \quad \vdots \\ & \quad \overline{\text{lookUp}}\langle i_{\text{ar}[E]}, \nu s_{\text{ar}[E]}^+, \nu s_{\text{ar}[E]}^- \rangle. \\ & \quad (s_{\text{ar}[f]}^-. \text{unlock}\langle \rangle \\ & \quad + s_{\text{ar}[f]}^+\langle \rangle. (G_1, i_1, \dots, G_{\text{ar}[E]}, i_{\text{ar}[E]}, \emptyset)) \dots \end{aligned}$$

where the $(H_1, j_1, \dots, H_k, j_k, S)$ -construct, $k \geq 0$, handles the matching of actual component values against components of the equation. Its definition is recursive.

1. If $k = 0$, then $(S) = \overline{\text{unlock}}\langle \rangle. \bar{r}\langle x \rangle$.
2. If $k \geq 1$ and $H_1 = z$ for some variable $z \notin S$,
 $(H_1, j_1, \dots, H_k, j_k, S) = (H_2, j_2, \dots, H_k, j_k, S \cup \{z\})\{z := j_1\}$
3. If $k \geq 1$ and $H_1 = z$ for some variable $z \in S$,
 $(H_1, j_1, \dots, H_k, j_k, S) = \mathbf{if } z = j_1 \mathbf{ then } (H_2, j_2, \dots, H_k, j_k, S)$
 $\mathbf{else } \overline{\text{unlock}}\langle \rangle$
4. If $k \geq 1$ and $H_1 = f(H'_1, \dots, H'_{\text{ar}[f]})$ for some constructor f and arguments $H'_1, \dots, H'_{\text{ar}[f]}$, then:
 $(H_1, j_1, \dots, H_k, j_k, S) = \overline{\text{getArgIds}_f}\langle j_1, \nu t^+, \nu t^- \rangle.$
 $(t^-. \text{unlock}\langle \rangle$
 $+ t^+(j'_1, \dots, j'_{\text{ar}[f]}).$
 $(H'_1, j'_1, \dots, H'_{\text{ar}[f]}, j'_{\text{ar}[f]}, H_2, j_2, \dots, H_k, j_k, S))$

where $j'_1, \dots, j'_{\text{ar}[f]}$ are fresh.

Communication Interpreters. The communication interpreters handle the *input* and *output* requests to \mathbf{M} . Both look up the *alias* of the subject channel in the name table; the input handler returns this so the encoded input prefix can perform the input and bind the object variable in the correct context; the output handler looks up the object ID and performs the output on behalf of the encoded output prefix, and synchronises on the result channel when done.

$$\begin{aligned} & \mathbf{InputInterpreter}(\\ & \quad \text{lock}, \text{unlock}, \text{getAlias}, \text{input} \\ &) \triangleq ! \text{input}\langle i, r \rangle. \text{lock}(). \\ & \quad \overline{\text{getAlias}}\langle i, \nu s^+, \nu s^- \rangle. \\ & \quad (s^-. \text{unlock}\langle \rangle \\ & \quad + s^+(a). \text{unlock}\langle \rangle. a(x). \bar{r}\langle x \rangle) \end{aligned}$$

$$\begin{aligned} & \mathbf{OutputInterpreter}(\\ & \quad \text{lock}, \text{unlock}, \text{getAlias}, \text{lookUp}, \text{output} \\ &) \triangleq ! \overline{\text{output}}\langle i, j, r \rangle. \text{lock}(). \\ & \quad \overline{\text{getAlias}}\langle i, \nu s^+, \nu s^- \rangle. \\ & \quad (s^-. \text{unlock}\langle \rangle \\ & \quad + s^+(a). \overline{\text{lookUp}}\langle j, \nu t^+, \nu t^- \rangle \\ & \quad (t^-. \text{unlock}\langle \rangle \\ & \quad + t^+(\overline{\text{unlock}}\langle \rangle. \bar{a}\langle j \rangle. \bar{r}\langle \rangle)) \end{aligned}$$

3.4 Firewall

For every free name n of \mathbf{M} , we introduce a distinct fresh name n' via which external observers may interact with \mathbf{M} and thus indirectly also with any encoded $\pi\mathbf{T}$ -process. The firewall \mathbf{F} receives requests on the channels named with those fresh names and encodes them to requests on the corresponding internal channels.

4 Full Abstraction

The relevance of may-testing equivalence for analysing security protocols has been stated elsewhere (see e.g. [3]). For this reason, we keep this section relatively technical apart from stating an outline of the long and complex proof of the full abstraction result. Recall the full encoding of a $\pi\mathbf{T}$ process P is $\llbracket P \rrbracket = (\nu K_{\mathbf{M}})((P) \mid \mathbf{M} \mid \mathbf{F})$.

Definition 1. 1. An observer is a process that may use a distinguished name $\$$. An action on channel $\$$ is a success signal.

2. A test is a parallel composition $P \mid O$ of a process P and an observer O .

3. A process P may pass a test $P \mid O$ if some sequence of τ -steps of $P \mid O$ has a state in which O signals success. Formally, we denote this property by $P \text{ may } O$.

4. Any two processes P and Q are may-testing equivalent if $P \text{ may } O$ if and only if $Q \text{ may } O$ for every observer O – in other words, the tests P and Q may pass are the same. We denote this property by $P \approx_{\text{may}} Q$.

Theorem 2. Given any $\pi\mathbf{T}$ -processes P and Q , $P \approx_{\text{may}} Q$ iff $\llbracket P \rrbracket \approx_{\text{may}} \llbracket Q \rrbracket$.

Proof. (Outline) The proof has two main steps:

1. This step consists of proving that may-tests are preserved, that is to say, proving that the encodings of two $\pi\mathbf{T}$ processes satisfy the same tests if the tests are encodings of $\pi\mathbf{T}$ tests. This result is analogous to earlier work [4] but, at the same time, it is by far more difficult. The reason is that, unlike [4], the global context in the form of the integrity manager has to be taken into account. The solution consists of working with a set-theoretical abstraction of the integrity manager that allows us to consider only factions of it as we exploit the syntax-directed way in which the pure encoding $\llbracket _ \rrbracket$ is defined. In this way we are able to re-instantiate the concept of an ancestor relation introduced in [4] to prove both a forward and a backward operational correspondence between unencoded and encoded process-observer couplings. The preservation of may tests is then an easy corollary once we also have an operational correspondence between abstract and concrete integrity management.

2. This step mainly consists of using the result from Step 1 in obtaining a π -calculus trace characterisation of $\pi\mathbf{T}$ -may-testing equivalence. This property is reminiscent of trace characterisations of may-testing equivalence in other settings (see e.g. [10]). All what is left is then to take the firewall into account to obtain the final full-abstraction result.

The full proof can be found in [5].

5 Related Work

Arbitrary equations between data terms are the most crucial feature of the applied π -calculus that is lacking from $\pi\mathsf{T}$. Also, we require that deconstructors are only used in let-expressions. $\pi\mathsf{T}$ is therefore in between the applied π -calculus and the spi calculus in that it resembles Borgström, Briaïs and Nestmann’s parameterised spi calculus [7]. These simplifications entail a loss of expressiveness when describing security protocols. The advantage is that we can still give a straightforward Structural Operational Semantics (SOS) for agents without having to first define a complex evaluation semantics for value terms. This simplifies our proofs to a great extent.

Full abstraction in the kind of encoding considered here is difficult to achieve. Milner’s encoding of the λ -calculus [12] is not fully abstract. Sangiorgi [16] demonstrates full abstraction for an encoding from the higher order (HO) π -calculus. The main difference is that in $\text{HO}\pi$ the language does not contain an equality test for HO values. In $\pi\mathsf{T}$ there is such a test for data terms. This means that in the encoding the interior of a term must, so to speak, be open for inspection, and this makes our encoding and proof very different.

The applied π -calculus, the spi calculus [3], Burrows, Abadi and Needham’s logic of authentication [9], which is nowadays known as BAN logic, and a number of other modelling and analysis techniques for security protocols rest on the Dolev-Yao assumption [11]. This means that the underlying crypto-system is considered unbreakable, so that the protocol logic on top of that is the only concern. A central aspect of all of these lines of work is that an analysis makes it necessary to explicitly represent the knowledge that an observer of a supposedly secure system can accumulate over time. This situation is similar in mobile process approaches: Observer knowledge has there been incorporated in notions of bisimulation and testing within the framework of the spi calculus; Borgström and Nestmann give a good overview of bisimulation for the spi calculus in [8]; Boreale, De Nicola and Pugliese have, besides treating bisimulation, shown how to take account of may-testing for the spi calculus in terms of knowledge-enriched traces [6]. In contrast to all of them our characterisation seems to be unique in that all observer knowledge is internalised. That is to say, it appears on the calculus level, not on the meta-level. In this sense it could be considered much closer to traditional process algebra methodology than the above-mentioned approaches.

6 Conclusion

We have presented a new encoding from the value-enriched mobile process calculus $\pi\mathsf{T}$ into the polyadic π -calculus. The cornerstone of the translation is an integrity manager that acts as a clearing house for all operations that involve translated values. It is protected by a firewall so that it cannot be impersonated by a hostile environment. Similar techniques were used in [2]. This encoding solves the long open full abstraction problem for $\pi\mathsf{T}$ -like calculi.

Our encoding is not compositional since it has the integrity manager and the firewall as a global context. While compositionality has been put forward as a criterion for whether an encoding from one calculus to the other is good [15], it can be argued

(see [14]) that these criteria are too strong for practical purposes, and that by allowing a top-level context (but keeping the inner encoding compositional), many practically or theoretically motivated encodings turn out to be “good”.

One way to interpret our result is that the π -calculus can provide as much “security” in the sense of protected data values as the π T-calculus and its instantiations such as the spi calculus. The means to achieve this are an integrity manager and a firewall. Thus we could claim to have proved that integrity management plus firewalling is a viable security philosophy. Modulo possible terminological differences this belief may actually be common; our contribution is to prove the correctness of a formal statement of it.

Orthogonal Extensions in Structural Operational Semantics (Extended Abstract)

MohammadReza Mousavi and Michel A. Reniers

Department of Computer Science,
Eindhoven University of Technology,
NL-5600MB Eindhoven, The Netherlands

Abstract. In this paper, we give novel and more liberal notions of operational and equational conservativity for language extensions. We motivate these notions by showing their practical application in existing formalisms. Based on our notions, we formulate and prove meta-theorems that establish conservative extensions for languages defined using Structural Operational Semantics (SOS).

Keywords: Formal Semantics, Structural Operational Semantics (SOS), Conservative Extension, Operational Conservativity, Equational Conservativity, Orthogonality.

1 Introduction

Programming languages and process calculi have been subject to constant extensions. It is often crucial to make sure that such extensions do not change the intuition behind the old subset, or said otherwise, the extensions are *conservative*. In the context of languages with Structural Operational Semantics (SOS) [13], this topic has been studied in depth in [1, 3, 5, 10, 15, 17]. This research has resulted in meta-theorems proving sufficient conditions for an extension to be *operationally* and/or *equationally conservative*. In the remainder, we mostly refer to [5] which gives the most detailed account of the problem and subsumes almost all previous results. We do not treat multi-sorted and variable binding signatures, addressed in [5, 10], in this paper.

So far, *operational conservativity* has only allowed for extensions that consistently deny the addition of any new behavior to the old syntax. One can imagine that an extension which grants a new behavior consistently to the old syntax can also be considered safe or “conservative”. This phenomenon occurs quite often in practice. For example, designers of many timed extensions of existing formalisms (e.g., the timed process algebras of [2, 9, 14]) have decided to add timed behavior homogenously to the terms from the old syntax. Unfortunately, it turns out that the existing definitions and their corresponding meta-theorems come short of any formal result about such extensions.

In this paper, we present a more liberal notion of operational conservativity, called *orthogonality*, which caters for both possibilities (i.e., denying some types of behavior from the old syntax while granting some other types). We show that our notion is useful in the aforementioned cases where the old notions cannot be used. We formulate orthogonality meta-theorems for languages with Structural Operational Semantics and prove them correct.

In [15], *equational conservativity* is considered in the setting where a new set of axioms is added to an existing set. Then, the extension is called *equationally conservative* if it induces exactly the same derivable closed equalities on the old syntax as the original equational theory. In this paper, we remove the requirement for including the old set of axioms in the extended equational theory. This relaxation is motivated by the fact that in many extensions, such as those of [2, 14], for some axioms, only all closed derivable equalities on the old syntax are kept and the axioms themselves are removed. Operational conservativity is usually considered as a means for equational conservativity and we show that our notion of orthogonality leads to equational conservativity in the same way as operational conservativity does (no matter which notion of equational conservativity is chosen, the traditional notion or the relaxed one).

The rest of this paper is structured as follows. Section 2 gives the basic definitions about Structural Operational Semantics, Transition System Specification (TSS) and equational theory. Section 3 presents the notions of operational and equational conservativity and gives sufficient conditions for proving operational conservativity. Orthogonality and related notions are defined in Section 4. Subsequently, Section 5 defines sufficient conditions for orthogonality. In the same section, we also present theorems establishing the link between orthogonality and equational conservativity. Finally, Section 6 summarizes the results and presents future directions. In each section, we provide abstract and concrete examples from the area of process algebra to motivate the definitions and illustrate the results. Due to lack of space, we could not present all of the results and the proofs of the theorems in this extended abstract. Interested readers can find these in the full version of this paper [11].

2 Preliminaries

2.1 Structural Operational Semantics

Structural Operational Semantics [13] is a logical way of defining operational semantics which has found lots of applications in different areas of computer science. A semantic specification in the style of SOS, called a *Transition System Specification (TSS)*, consists of a number of deduction rules which specify the possibility of a transition (in the conclusion of the rules) in terms of the (im)possibility of other transition (in the premises). Predicates on states are other possible ingredients of TSS's which can both be defined in the conclusion of the rules and used in the premises. Predicates can always be coded as transitions with dummy right-hand sides (cf. [16]) and thus, we do not complicate

the presentation with their formal treatment. Next, we formalize the rest of the concepts mentioned above.

Definition 1 (Term and Substitution). We assume that the set of *process terms*, denoted by $T(\Sigma)$ with typical members t, t', t_i, \dots , is inductively defined on a given set of *variables* $V = \{x, y, \dots\}$ and a signature Σ . A *signature* contains a number of *function symbols* (composition operators: f, g, \dots) with fixed *arities*. Function symbols with arity 0 are called *constants*. *Closed terms*, denoted by $C(\Sigma)$ with typical members p, q, p_i, \dots , are terms that do not contain variables. The set of variables appearing in term t is denoted by $\text{vars}(t)$.

A (*closed*) *substitution* σ replaces variables in a term with other (closed) terms. *The set of terms generated by a set of terms* S , denoted by $G(S)$, is the set of all terms $t' = \sigma(t)$, for some $t \in S$ and some σ such that $\forall_{x \in V} \sigma(x) \in S$. A set of terms S *covers* Σ -terms, if $C(\Sigma) \subseteq G(S)$.

A transition system specification, defined below, is a logical way of defining a transition relation on (closed) terms.

Definition 2 (Transition System Specification (TSS)). A *transition system specification* is a tuple (Σ, L, D) where Σ is a signature, L is a set of *labels* (with typical members l, l', l_0, \dots) and D is a set of deduction rules. For all $l \in L$, and $t, t' \in T(\Sigma)$ we define that $(t, l, t') \in \rightarrow$ and $(t, l) \notin \rightarrow$ are *formulae* (positive and negative, respectively). To avoid any confusion, note that $\dots \in \rightarrow$ and $\dots \notin \rightarrow$ are used as a syntactic notation and are not intended to denote the set-theoretic membership at this point. The notion of closed is lifted from terms to formulae in the natural way. A *deduction rule* $dr \in D$, is defined as a tuple (H, c) where H is a set of formulae and c is a positive formula. The formula c is called the *conclusion* and the formulae from H are called *premises*. A deduction rule with label l in its conclusion is called an *l -rule*.

Formulae $(t, l, t') \in \rightarrow$ and $(t, l) \notin \rightarrow$ are denoted by the more intuitive notations $t \xrightarrow{l} t'$ and $t \not\xrightarrow{l}$, respectively. We refer to t as the source of both formulae and to t' as the target of the first one. A deduction rule (H, c) is denoted by $\frac{H}{c}$ in the remainder.

Different interpretations of the transition relation (the set of closed positive formulae) induced by a TSS are given in the literature. In [6], an extensive overview of alternative interpretations is provided. We formulate and prove our main results in such a general way that they remain independent from the chosen interpretation and can be adopted for several existing ones. In cases where we need an explicit transition relation, we assume that this transition relation is uniquely defined by the corresponding TSS using one of the interpretations given in [6]. In such cases, we use the notation $tss \models \phi$ to denote that a closed positive formula ϕ is in the transition relation induced by tss .

One criterium that guarantees the existence and uniqueness of a transition relation associated with a TSS is the following concept of (strict) stratification, which we use for other purposes in this paper, as well.

Definition 3 (Stratification [8]). A TSS tss is stratified by a function \mathcal{S} from closed positive formulae to an ordinal if and only if for all deduction rules in tss of the following form:

$$\frac{\{t_i \xrightarrow{l} t'_i \mid i \in I\} \quad \{t_j \xrightarrow{l} t'_j \mid j \in J\}}{t \xrightarrow{l} t'}$$

and for all closed substitutions σ , $\forall_{i \in I} \mathcal{S}(\sigma(t_i \xrightarrow{l} t'_i)) \leq \mathcal{S}(\sigma(t \xrightarrow{l} t'))$ and $\forall_{j \in J} \mathcal{S}(\sigma(t_j \xrightarrow{l} t'_j)) < \mathcal{S}(\sigma(t \xrightarrow{l} t))$, for all terms t'' . If the measure decreases also from the conclusion to the positive premises, then tss is *strictly stratified* by \mathcal{S} .

The following example illustrates the concepts defined in this section.

Example 1 (Minimal Process Algebra (MPA)). Consider the following deduction rules defined on a signature with a constant δ , a family of unary operators $a.$ (for all $a \in A$, where A is a given set of atomic actions) and a binary operator $+$. The labels of transitions are $a \in A$.

$$(a) \frac{}{a.x \xrightarrow{a} x} \quad (a \in A) \quad (c0) \frac{x \xrightarrow{a} x'}{x + y \xrightarrow{a} x'} \quad (c1) \frac{y \xrightarrow{a} y'}{x + y \xrightarrow{a} y'}$$

This TSS (called tss_m in the remainder) is supposed to define a transition relation for the Minimal Process Algebra (MPA) of [2], simplified here by removing the concept of termination, which we use as our running example in the remainder. Deduction rules of MPA are (strictly) stratified using a measure of size on the terms in the source of formulae and it defines a unique transition relation by all possible interpretations. The following transitions are among those: $tss_m \models (a.\delta) + \delta \xrightarrow{a} \delta$ and $tss_m \models a.(\delta + a.\delta) \xrightarrow{a} \delta + a.\delta$.

2.2 Equational Theory

Equational theories play a central role in process algebras. They capture the basic intuition behind the algebra, and the models of the algebra are expected to respect this intuition (e.g., the models induced by operational semantics). To establish a reasonable link between the operational model and the equational theory of the algebra, a notion of behavioral equality is needed. This notion captures when two syntactic terms show the “same behavior” and thus they should belong to the same equivalence class. There is a spectrum of notions of behavioral equality in the literature [7]. We take the notion of strong bisimilarity [12], denoted by \Leftrightarrow , as the notion of behavioral equivalence, but as we show in the extended version of this paper [11], our results are valid for a wide range of notions in this spectrum.

Getting back to the equational side of the algebra, the notion of behavioral equivalence should ideally coincide with the closed derivations of the equational theory. One side of this coincidence is captured by the soundness theorem which states that all closed derivations of the equational theory are indeed valid with

respect to the particular notion of behavioral equality. The other side of the coincidence, called completeness, phrases that all induced behavioral equalities are derivable from the equational theory, as well. These concepts are formalized in the remainder.

Definition 4 (Equational Theory). An *equational theory* or *axiomatization* (Σ, E) is a set of equalities E on a signature Σ of the form $t = t'$, where $t, t' \in T(\Sigma)$. A closed instance $p = p'$, for some $p, p' \in C(\Sigma)$, is derivable from E , denoted by $E \vdash p = p'$ if and only if it is in the smallest congruence relation induced by the equalities of E .

An equational theory (Σ, E) is *sound* with respect to a TSS tss (also on signature Σ) if and only if for all $p, p' \in C(\Sigma)$, if $E \vdash p = p'$, then it holds that $tss \vdash p \Leftrightarrow p'$. It is *complete* if the implication holds in the other direction.

An equational theory E on Σ *eliminates* function symbols from $\Sigma' \subseteq \Sigma$ if and only if for all $p \in C(\Sigma)$ there exists a term $p' \in C(\Sigma \setminus \Sigma')$ such that $E \vdash p = p'$.

The following example illustrates the idea of equational theory.

Example 2 (MPA: Equational Theory). Consider the Minimal Process Algebra of Example 1. The following is an axiomatization of MPA [2].

$$x + y = y + x \quad x + (y + z) = (x + y) + z \quad x + x = x \quad x + \delta = x$$

It is well-known that this axiomatization is sound and complete with respect to tss_m given in Example 1. The following are examples of derivable equalities from the above axiomatization: $(a.\delta) + \delta = a.\delta$ and $(a.\delta) + a.\delta = a.\delta$.

3 Operational and Equational Conservativity

In this section, we define different concepts regarding language extensions. To extend a language defined by a TSS, one may have to combine an existing signature with a new one. However, not all signatures can be combined into one as the arities of the function symbols may clash. To prevent this, we define two signatures to be *consistent* when they agree on the arity of the shared function symbols. Henceforth, we always assume that extended and extending TSS's are consistent. The following definition formalizes the concept of operational extension.

Definition 5 (Extension of a TSS). Consider TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$. The extension of tss_0 with tss_1 , denoted by $tss_0 \cup tss_1$, is defined as $(\Sigma_0 \cup \Sigma_1, L_0 \cup L_1, D_0 \cup D_1)$.

Next, we define when an extension of a TSS is called operationally conservative.

Definition 6 (Operational Conservativity [15]). Consider TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$. If $\forall_{p \in C(\Sigma_0)} \forall_{p' \in C(\Sigma_0 \cup \Sigma_1)} \forall_{l \in L_0 \cup L_1} tss_0 \cup tss_1 \models$

$p \xrightarrow{l} p' \Leftrightarrow tss_0 \vDash p \xrightarrow{l} p'$, then $tss_0 \cup tss_1$ is an *operationally conservative extension* of tss_0 .

Note that in the above definition, the labels and the targets of the transitions are taken from the extended TSS and thus, any new transition of the old syntax, even with a new label or a new target is prohibited. The following example illustrates the idea of extending TSS's and the concept of operational conservativity.

Example 3 (Timed *MPA*: Operational Semantics). Consider the following deduction rules (divided into three parts) which are defined on a signature with two constants δ and $\underline{\delta}$, a unary function symbol $\underline{\sigma}.$, two families of unary function symbols $a.$ and $\underline{a}.$ (for all $a \in A$) and a binary function symbol $._+._$. The set of labels of the TSS is $A \cup \{1\}$ (for $1 \notin A$).

$$\begin{array}{l}
 \text{(ua)} \frac{}{\underline{a}.x \xrightarrow{a} x} \quad \text{(td)} \frac{}{\underline{\sigma}.x \xrightarrow{1} x} \quad (1) \\
 \text{(tc0)} \frac{x \xrightarrow{1} x' \quad y \xrightarrow{1} y'}{x + y \xrightarrow{1} x' + y'} \quad \text{(tc1)} \frac{x \xrightarrow{1} x' \quad y \xrightarrow{1} y'}{x + y \xrightarrow{1} x'} \quad \text{(tc2)} \frac{y \xrightarrow{1} y' \quad x \xrightarrow{1} y'}{x + y \xrightarrow{1} y'} \quad (2) \\
 \text{(ta)} \frac{}{a.x \xrightarrow{1} a.x} \quad \text{(d)} \frac{}{\delta \xrightarrow{1} \delta} \quad (3)
 \end{array}$$

The above TSS, which we call tss_t defines the aspect of timing in terms of new time transitions $\xrightarrow{1}$ and it is added in [2] to tss_m in Example 1 to define a relative-discrete-time extension of *MPA*. The intuition behind the new underlined function symbols ($\underline{a}.$ and $\underline{\sigma}.$) is that they are not delayable in time and should take their (respectively action and time) transitions immediately. Addition of the first and/or the second parts of the above TSS (each or both) to tss_m results in an operationally conservative extension of the latter as the newly added transitions will be restricted to the new syntax. (Note that in the first and second parts, there is no rule about timed transition of constants in the old syntax.) This claim can be checked formally as an instance of a meta-theorem in the rest of this section. However, the addition of part (3) violates the conservativity of the extension as it adds time transitions ($\xrightarrow{1}$) to the behavior of terms from the old syntax. For example, in combination with the first two parts, it allows for transitions such as $tss_m \cup tss_t \vDash a.\delta \xrightarrow{1} a.\delta$ and $tss_m \cup tss_t \vDash (a.\delta) + \delta \xrightarrow{1} (a.\delta) + \delta$, all of which are prohibited by the original TSS and thus are considered harmful from the operational conservativity point of view.

Next, we formulate sufficient conditions to prove operational conservativity. But before that, we need a few auxiliary definitions.

Definition 7 (Source Dependency). All variables appearing in the source of the conclusion of a deduction rule are called *source dependent*. A variable of a deduction rule is *source dependent* if it appears in a target of a premise of which all the variables of the source are source dependent. A premise is *source dependent*

when all the variables appearing in it are source dependent. A deduction rule is *source dependent* when all its variables are. A TSS is *source dependent* when all its rules are.

Definition 8 (Reduced Rules). For a deduction rule $d = (H, c)$, the reduced rule with respect to a signature Σ is defined by $\rho(d, \Sigma) \doteq (H', c)$ where H' is the set of all premises from H which have a Σ -term as a source.

Theorem 1. (*Operational Conservativity Meta-Theorem [5]*) Given two TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$, $tss_0 \cup tss_1$ is an operationally conservative extension of tss_0 if:

1. tss_0 is source dependent;
2. for all $d \in D_1$ at least one of the following holds:
 - (a) the source of the conclusion has a function symbol in $\Sigma_0 \setminus \Sigma_1$, or
 - (b) $\rho(d, \Sigma_0)$ has a source-dependent positive premise $t \xrightarrow{l} t'$ such that $l \notin \Sigma_0$ or $t' \notin T(\Sigma_0)$.

The following definition formalizes the concept of equational conservativity.

Definition 9 (Equational Conservativity). An equational theory E_1 on signature Σ_1 is an equationally conservative extension of E_0 on Σ_0 if and only if $\Sigma_0 \subseteq \Sigma_1$ and for all $p, p' \in C(\Sigma_0)$, $E_0 \vdash p = p' \Leftrightarrow E_1 \vdash p = p'$.

It is worth mentioning that the above definition is more liberal than the similar notion in [15] in that there, it is required that the same axioms are included in the extended equational theory (i.e., $E_0 \subseteq E_1$). In practice, some process algebras do not keep the same axioms when extending the formalism while they make sure that the closed instantiations of the old axioms with old terms indeed remain derivable (see for example, [2, 14] and Example 4 in the remainder). Hence, we believe that the restriction imposed by [15] unnecessarily limits the applicability of the theory. If, for any reason, one chooses the more restricted notion of [15], the theorems concerning equational conservativity in this paper remain valid.

Example 4 (Timed MPA: Equational Theory). Consider the TSS resulting from extending tss_m of Example 1 with (all three parts) of the timed extension defined in Example 3. The following are a set of sound and complete axioms (w.r.t. strong bisimilarity) for this TSS:

$$\begin{aligned}
 x + y &= y + x & x + (y + z) &= (x + y) + z & x + x &= x & \delta &= \underline{\sigma}.\delta \\
 x + \underline{\delta} &= x & (\underline{\sigma}.x) + \underline{\sigma}.y &= \underline{\sigma}.(x + y) & a.x &= (\underline{a}.x) + \underline{\sigma}.a.x & (a.x) + \delta &= a.x
 \end{aligned}$$

The above axiomatization underscores the fact we mentioned before. Namely, the axioms of the old system do not hold in the new system (e.g., $(\underline{a}.x) + \delta \neq \underline{a}.x$ as an instance of $x + \delta = x$) but all closed instantiations of the old axioms by the old syntax are derivable from the new set of axioms.

It can be checked that the above axiomatization of timed *MPA* is indeed an equationally conservative extension of the axiomatization of *MPA* in the sense of Definition 9. Thus, if one considers operational conservativity as a means to equational conservativity, this example already suggests the need for an extension of Definition 6. In other words, we believe that the transitions added by the extension are quite innocent and harmless to the intuition behind the original semantics, for they are added uniformly to the old syntax without changing the old behavior or violating previously valid equalities. In the next section, we formalize our idea of orthogonal extensions which caters for extensions of the above type.

4 Orthogonality

In this section, we define the notion of orthogonality and an instance of this notion, called *granting extensions*, which can be checked syntactically.

Definition 10 (Orthogonal Extension). Consider TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$. The TSS $tss_0 \cup tss_1$ is an *orthogonal* extension of tss_0 when first, $\forall_{p,p' \in C(\Sigma_0)} \forall_{l \in L_0} tss_0 \cup tss_1 \models p \xrightarrow{l} p' \Leftrightarrow tss_0 \models p \xrightarrow{l} p'$ and second, and $\forall_{p,p' \in C(\Sigma_0)} tss_0 \cup tss_1 \models p \Leftrightarrow p' \Leftrightarrow tss_0 \models p \Leftrightarrow p'$.

Note that it immediately follows from the above definition that orthogonality is a preorder, i.e., a reflexive and transitive relation, on TSS's. Besides strong bisimilarity, our results in this paper are valid for orthogonality with respect to most other notions of behavioral equivalence in the literature (cf. [11]). The notion of *operational conservativity up to ϕ -equivalence* of [15, 3] can be seen as a variant of orthogonality which only has the second condition. This and other variants of the notion of orthogonality can also be useful and our results can be used to establish meta-theorems for these notions. To our knowledge, beyond operational conservativity results (e.g., in [15]), no systematic study of these notions (including meta-theorems guaranteeing them) has been carried out.

Corollary 1. An operationally conservative extension is an orthogonal extension.

Corollary 1 addresses operational conservativity as an extreme case of orthogonality which denies all new transitions from the old syntax; the other extreme is an extension which grants all new behavior to the old syntax. However, for such an extension to be orthogonal, these transitions should be made to equivalent terms from the old syntax. In particular, if we allow for self transitions, we are able to prove orthogonality with respect to many notions of behavioral equivalence. The following definitions and the subsequent theorem substantiate these concepts.

Definition 11 (Granting Extension). Consider TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$ with disjoint labels. We call $tss_0 \cup tss_1$ a *granting extension*

of tss_0 when first, $\forall_{p,p' \in C(\Sigma_0)} \forall_{l \in L_0} tss_0 \models p \xrightarrow{l} p' \Leftrightarrow tss_0 \cup tss_1 \models p \xrightarrow{l} p'$ and second, $\forall_{p \in C(\Sigma_0)} \forall_{p' \in C(\Sigma_0 \cup \Sigma_1)} \forall_{l \in L_1 \setminus L_0} tss_0 \cup tss_1 \models p \xrightarrow{l} p' \Leftrightarrow p = p'$.

The above definition states that granting extensions keep the old transitions on the old terms intact and only add self transitions with all of the new labels to old terms. This definition does not make any statement about the transitions on the new terms, i.e., terms from $T(\Sigma_0 \cup \Sigma_1) \setminus T(\Sigma_0)$.

We are doubtful whether any meaningful relaxation of Definition 11 would be at all possible that allows for anything coarser than syntactic equality on the old terms involved in (the left- or the right-hand side of) the new transitions and still can be captured by simple syntactic checks. This suggests that to formulate syntactic criteria for proving orthogonality, we have to resort to one of the two extremes (operational conservativity or granting extensions). We admit that combining these two extremes is interesting. This is partly possible by exploiting the the transitivity of orthogonal extension relation. This way, one can interleave the application of granting and operational conservativity theorems (cf. Example 5). We propose an alternative method of combining operationally conservative and granting extensions in [11]. Next, we show that granting extensions are indeed orthogonal.

Theorem 2. *For TSS's tss_0 and tss_1 , if tss_1 is a granting extension of tss_0 then tss_1 is an orthogonal extension of tss_0 .*

5 Meta-theorems

In this section, we seek sufficient conditions for establishing orthogonality and equational conservativity.

We start with defining sufficient conditions to prove an extension to be granting. Hence, we need to define when a deduction rule proves (only) self transitions. We use unification as a means to this end.

Definition 12 (Unification). A term t is *unifiable* with t' using σ , denoted by $t \approx_\sigma t'$ if and only if $\sigma(t) = \sigma(t')$. The set of unifiers of t and t' is defined by $U(t, t') = \{\sigma \mid t \approx_\sigma t'\}$. The set of unifiers of a set of pairs is defined as the intersection of the sets of unifiers of each pair. The set of unifiers of an empty set is defined to include all substitutions.

The set of unifiers of a positive formula $t \xrightarrow{l} t'$ is defined as the set of unifiers of t and t' . Unification also naturally extends to a set of positive formulae, again, using intersection.

Next, we characterize the set of rules that induce self transitions. This is done by only allowing for unifiable (positive) formulae in the premises and the conclusion of a rule and further, by forcing the unification of the conclusion to follow from that of the premises.

Definition 13 (Source Preserving Rules). A deduction rule $\frac{H}{c}$ without negative premises is *source preserving* if $U(H) \neq \emptyset$ and $U(H) \subseteq U(c)$. A TSS is *source*

preserving if all its deduction rules are. For a source preserving TSS, the set of *unified conclusions* contains conclusions of the deduction rules with their unifiers applied to them.

Source-preserving rules are safe for the purpose of proving self transitions. However, there might be other rules in the extending TSS that can be harmful in that they may prove other types of transition for old terms. This may be prevented by forcing the other (non-source-preserving) rules to have negative or non-unifiable positive premises addressing the old syntax. The following definition gives sufficient conditions for an extension to be granting.

Definition 14 (Granting Criteria). Consider a TSS $tss = (\Sigma, L, D)$ stratified by \mathcal{S} . It *grants* L_0 transitions on Σ_0 -terms, if $tss = tss_0 \cup tss_1$ (with $tss_x = (\Sigma_x, L_x, D_x)$ for $x \in \{0, 1\}$) such that:

1. tss_0 is strictly stratified by \mathcal{S} , it is source preserving and for all $l \in L_0$, the set containing sources of unified conclusions of l -rules covers Σ_0 -terms, and
2. for all deduction rules $d \in D_1$ at least one of the following holds:
 - (a) d has a function symbol from $\Sigma_1 \setminus \Sigma_0$ in the source of its conclusion, or
 - (b) $\rho(d, \Sigma_0)$ has a negative source-dependent premise with a label in L_1 , or
 - (c) $\rho(d, \Sigma_0)$ has a positive source-dependent premise $t \xrightarrow{l} t'$ with $l \in L_1$ and $U(t, t') = \emptyset$.

The first condition in the above definition is dedicated to proving self transitions from the syntax of Σ_0 , and the the second one takes care of preventing Σ_0 -terms from performing other types of transitions while allowing other terms to do so.

Theorem 3. (*Granting Meta-theorem*) Consider source-dependent TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$. If tss_1 grants L_1 transitions on Σ_0 -terms and $L_0 \cap L_1 = \emptyset$ then $tss_0 \cup tss_1$ is a granting extension of tss_0 .

The following example applies our meta-theorem to obtain orthogonality of relative-discrete-time extension of *MPA*.

Example 5 (Timed *MPA*: Orthogonality). Consider the tss_m of *MPA* in Example 1 and tss_t of Example 3. TSS tss_t can be decomposed into the following three parts: $tss_0 \doteq (\{\underline{a}, \underline{\delta}\}, A, \{\mathbf{ua}, \mathbf{td}\})$, $tss_1 \doteq (\{\delta, a, -, +, -\}, \{1\}, \{\mathbf{tc0}, \mathbf{ta}, \mathbf{d}\})$ and $tss_2 \doteq (\{-, +, -\}, \{1\}, \{\mathbf{tc1}, \mathbf{tc2}\})$.

It follows from Definition 13 that tss_1 is source preserving since:

1. the conclusions of \mathbf{ta} and \mathbf{d} are unifiable using any substitution, hence using the unifiers of the empty set of premises,
2. and the conclusion of $\mathbf{tc0}$ is unifiable using the unifiers of the premises, i.e., those that evaluate x and x' to the same term and y and y' to the same term.

It then follows from Definition 14 that $tss_1 \cup tss_2$ grants time transitions over *MPA* terms since

1. tss_1 is strictly stratified using a simple measure of size on terms, it is source preserving as shown before, and by applying unifiers to the source of conclusion of **(tc0)**, **(ta)** and **(d)**, i.e., the set $\{x + y, a.x, \delta\}$, we can cover the syntax of *MPA*,
2. in tss_2 , deduction rules **(tc1)** and **(tc2)** have source-dependent negative premises with label 1 (note that **(tc1)** and **(tc2)** are the same as their reduced versions).

From Theorem 3, it follows that the extension of tss_m with $tss_1 \cup tss_2$ is a granting extension, hence an orthogonal extension. Furthermore, the extension of $tss_m \cup tss_1 \cup tss_2$ with tss_0 is conservative, hence orthogonal, following Theorem 1. Since orthogonality is a preorder, we conclude that $tss_m \cup tss_t$ is an orthogonal extension of tss_m .

The following theorem establishes the link between orthogonality and equational conservativity. It is very similar to the theorem stated in [16, 17] about the relation between operational and equational conservativity. The theorem states that a sound axiomatization of an operationally conservative extension cannot induce new equalities on the old syntax.

Theorem 4. (*Equational Conservativity Theorem*) Consider TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$ where tss_1 is an orthogonal extension of tss_0 . Also let E_0 be a sound and complete axiomatization of tss_0 and E_1 be a sound axiomatization of tss_1 . If $\forall_{p,p' \in C(\Sigma_0)} E_0 \vdash p = p' \Rightarrow E_1 \vdash p = p'$ then E_1 is an equational conservative extension of E_0 .

Finally, the last theorem establishes sufficient conditions for a sound equationally conservative extension to be a complete equational theory for the extended language.

Theorem 5. (*Elimination Theorem*) Consider TSS's $tss_0 = (\Sigma_0, L_0, D_0)$ and $tss_1 = (\Sigma_1, L_1, D_1)$ where tss_1 is an orthogonal extension of tss_0 . Also let E_0 and E_1 be sound axiomatizations of tss_0 and tss_1 , respectively. If E_0 is also complete for tss_0 , E_1 is an equational conservative extension of E_0 and E_1 eliminates terms from $\Sigma_1 \setminus \Sigma_0$, then E_1 is complete for tss_1 .

A typical line of reasoning starts with taking an orthogonal extension and a sound axiomatization thereof, and proving equational conservativity using Theorem 4. Then, by proving an elimination result for the newly introduced operators, one can get completeness of the axiomatization following Theorem 5.

6 Conclusions

In this paper, we defined a more relaxed notion of operational conservativity, called orthogonality which allows for non-destructive extension of the behavior of the old language. We gave a meta-theorem providing sufficient conditions for this notion. Also, we presented a slightly more general notion of equational conservativity and established the link between these two notions.

Extending the theory presented in this paper with the concept of variable binding is an straightforward extension along the lines of [5]. The second enhancement of our work concerns operational extensions that require a translation of labels (using a kind of abstraction function). Finally, investigating the possibility of other realizations of orthogonality is an interesting subject for future research.

Basic Observables for a Calculus for Global Computing

¹ Dipartimento di Sistemi e Informatica, Università di Firenze

² Dipartimento di Informatica, Università di Roma “La Sapienza”

Abstract. We introduce a foundational language for modelling applications over global computers whose interconnection structure can be explicitly manipulated. Together with process distribution, mobility, remote operations and asynchronous communication through distributed data spaces, the language provides constructs for explicitly modelling inter-node connections and for dynamically establishing and removing them. For the proposed language, we define natural notions of extensional observations and study their closure under operational reductions and/or language contexts to obtain *barbed congruence* and *may testing* equivalence. For such equivalences, we provide alternative characterizations in terms of a labelled *bisimulation* and a *trace* equivalence that can be used for actual proofs.

1 Introduction

In the last decade, we have witnessed the birth of many calculi and kernel languages intended to support programming of global systems and to provide formal tools for reasoning over them. These formalisms in general provide constructs and mechanisms, at different abstraction levels, for modelling the execution contexts of the network where applications roam and run, for coordinating and monitoring the use of resources, for expressing process communication and mobility, and for specifying and enforcing security policies. However, much research effort has been devoted to studying the impact of different communication and mobility paradigms, but little attention has been devoted to the modelling of the actual network underlying global computers as such. Usually, the model of the network implicitly originates from other linguistic choices concerning, e.g., the mobility paradigm. All foundational languages proposed in the literature either model the network as an evolving graph of fully connected nodes [17, 9, 26, 1] or model it as an evolving forest of trees [7, 14, 24, 8]. In our view, both approaches do not convincingly model global computers (the Internet is neither a clique nor a forest of trees) and lack of flexibility (‘sharing of resources’ is difficult to control and requires complex modelling).

Here, we want to develop the semantic theory of a new model that takes its origin from two formalisms with opposite objectives, namely the programming language X-KLAIM [2] and the π -calculus [23]. The former one is a full fledged programming language based on KLAIM [9], while the latter one is the generally recognized minimal common denominator of calculi for mobility. The resulting model has been called τ KLAIM (*topological KLAIM*); it retains the main features of KLAIM (distribution, remote operations, process mobility and asynchronous communication through distributed data

spaces), but extends it with new constructs to flexibly model the interconnection structure underlying a net. τKLAIM permits explicit creation of inter-node connections and their destruction. Connections are essential to perform remote operations: these are possible only if the node where they are initiated and the target one are directly connected.

For the proposed formalism, we introduce two abstract semantics, *barbed congruence* and *may testing*, that are obtained as the closure under operational reductions and/or language contexts of the extensional equivalences induced by what we consider basic *observables* for global computers. For deciding the observables to use, we have been struggling with the following ones:

- i.* a specific site is up and running (i.e., it provides a datum of any kind)
- ii.* a specific information is available in (at least) a site,
- iii.* a specific information is present at a specific site.

Other calculi for global computers make use of (barbed) congruences induced by similar observables: for example, Ambient uses barbs that are somehow related to *i.*; the barbs in $D\pi$ -calculus instead, are strongly related to *iii.* Within our framework, it can be proved that, by closing observations under any τKLAIM context, the three observables all yield the same congruence. This is already an indication of the robustness of the resulting semantic theories. Moreover, the observables are powerful enough to yield interesting theories also when considering lower-level features, such as failures [11].

Of course, the step that comes next after defining equivalence as context closure is determining some alternative characterizations that would permit to better appreciate their discriminating power and to devise proof techniques that avoid universal quantification over contexts (that would render equivalence checking very hard).

In this paper, we concentrate on the barbed and may equivalences induced by the first basic observable (*a site is up and running*) and establish their correspondence with a bisimulation-based and a trace-based equivalence. To this aim, we introduce a labelled transition system for τKLAIM (with labels indicating the performed action) and, on top of it, we define alternative characterizations of barbed congruence and may testing in terms of (non-standard) labelled *bisimilarity* and *trace* equivalence, resp.. The actual development of the alternative characterizations, although performed along the lines of similar results for CCS [20, 4] and π -calculus [23] had to face problems raised by process distribution and mobility, by the explicit use of connections and by asynchrony.

2 The Process Language τKLAIM

The syntax of τKLAIM is reported in Table 1. We assume the existence of two countable and disjoint sets: *names*, ranged over by $l, l', \dots, u, \dots, x, y, \dots$, and *process variables*, ranged over by X, Y, \dots . Names provide the abstract counterpart of the set of *communicable* objects and can be used as localities or variables; notationally, we prefer letters l, l', \dots when we want to stress the use of a name as a locality, and x, y, \dots when we want to stress the use of a name as a variable. We will use u for variables and localities.

Nets, ranged over by N, M, \dots , are finite collections of nodes and inter-node connections. A *node* is a pair $l :: C$, where locality l is the address of the node and C is the (parallel) component located at l . *Components*, ranged over by C, D, \dots , can be either

Table 1. τ KLAIM Syntax

NETS: $N ::= \mathbf{0} \mid l :: C \mid \{l_1 \leftrightarrow l_2\} \mid (\nu l)N \mid N_1 \parallel N_2$	
COMPONENTS: $C ::= \langle l \rangle \mid P \mid C_1 \mid C_2$	PROCESSES: $P ::= \mathbf{nil} \mid a.P \mid P_1 \mid P_2 \mid X \mid \mathbf{rec} X.P$
ACTIONS: $a ::= \mathbf{in}(!x)@u \mid \mathbf{in}(u_2)@u_1 \mid \mathbf{out}(u_2)@u_1 \mid \mathbf{eval}(P)@u \mid \mathbf{new}(l) \mid \mathbf{conn}(u) \mid \mathbf{disc}(u)$	

processes or data, denoted by $\langle l \rangle$. *Connections* are pairs of node addresses $\{l_1 \leftrightarrow l_2\}$ stating that the nodes at address l_1 and l_2 are directly and bidirectionally connected. In $(\nu l)N$, name l is private to N ; the intended effect is that, if one considers the term $M \parallel (\nu l)N$, then locality l of N cannot be referred from within M .

Processes, ranged over by P, Q, R, \dots , are the τ KLAIM active computational units and may be executed concurrently either at the same locality or at different localities. They are built from the inert process \mathbf{nil} and from the basic actions by using prefixing, parallel composition and recursion. *Actions* permit removing/adding data from/to node repositories (actions \mathbf{in} and \mathbf{out}), activating new threads of execution (action \mathbf{eval}), creating new nodes (action \mathbf{new}), and establishing and removing connections (actions \mathbf{conn} and \mathbf{disc}). Notice that $\mathbf{in}(l)@l'$ differs from $\mathbf{in}(!x)@l'$ in that the former evolves only if datum $\langle l \rangle$ is present at l' , while the latter accepts any datum. Indeed, $\mathbf{in}(l)@l'$ is a form of *name matching operator* reminiscent of LINDA's [16] pattern-matching.

Names occurring in τ KLAIM processes and nets can be *bound*. More precisely, prefix $\mathbf{in}(!x)@u.P$ binds x in P ; prefix $\mathbf{new}(l).P$ binds l in P , and, similarly, net restriction $(\nu l)N$ binds l in N ; finally, $\mathbf{rec} X.P$ binds X in P . A name that is not bound is called *free*. The sets $fn(\cdot)$ and $bn(\cdot)$ of free and bound names of a term, respectively, are defined accordingly. The set $n(\cdot)$ of names of a term is the union of its free and bound names. As usual, we say that two terms are *alpha-equivalent* if one can be obtained from the other by renaming bound names. We shall say that a name u is fresh for $_$ if $u \notin n(_)$. In the sequel, we shall work with terms whose bound names are all distinct and different from the free ones.

τ KLAIM operational semantics relies on a structural congruence and a reduction relation. The *structural congruence*, \equiv , is formally defined in [10] and identifies nets which intuitively represent the same net. It is inspired to π -calculus's structural congruence (see, e.g., [23]): it states that ' \parallel ' and ' \mid ' are monoidal operators with $\mathbf{0}$ and \mathbf{nil} as identity elements, it equates alpha-equivalent nets, it regulates commutativity of restrictions, and it allows to freely fold/unfold recursive processes. Moreover, the following laws are crucial in our setting:

(CLONE)	(SELF)	(BiDIR)
$l :: C_1 \mid C_2 \equiv l :: C_1 \parallel l :: C_2$	$l :: \mathbf{nil} \equiv \{l \leftrightarrow l\}$	$\{l_1 \leftrightarrow l_2\} \equiv \{l_2 \leftrightarrow l_1\}$
(RNODE)	(EXT)	
$(\nu l)N \equiv (\nu l)(N \parallel l :: \mathbf{nil})$	$N \parallel (\nu l)M \equiv (\nu l)(N \parallel M)$ if $l \notin fn(N)$	

(CLONE) turns the parallel composition of co-located components into a parallel between nodes; (SELF) states that nodes are self-connected; (BiDIR) states that connections are

Table 2. τ KLAIM Operational Semantics

<p>(R-OUT) $l_1 :: \mathbf{out}(l)@l_2.P \parallel \{l_1 \leftrightarrow l_2\} \mapsto l_1 :: P \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: \langle l \rangle$</p>	<p>(R-PAR) $\frac{N_1 \mapsto N'_1}{N_1 \parallel N_2 \mapsto N'_1 \parallel N_2}$</p>
<p>(R-EVAL) $l_1 :: \mathbf{eval}(P_2)@l_2.P_1 \parallel \{l_1 \leftrightarrow l_2\} \mapsto l_1 :: P_1 \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: P_2$</p>	<p>(R-RES) $\frac{N \mapsto N'}{(\nu l)N \mapsto (\nu l)N'}$</p>
<p>(R-IN) $l_1 :: \mathbf{in}(!x)@l_2.P \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: \langle l \rangle \mapsto l_1 :: P[l/x] \parallel \{l_1 \leftrightarrow l_2\}$</p>	<p>(R-STRUCT) $\frac{N \equiv M \mapsto M' \equiv N'}{N \mapsto N'}$</p>
<p>(R-MATCH) $l_1 :: \mathbf{in}(l)@l_2.P \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: \langle l \rangle \mapsto l_1 :: P \parallel \{l_1 \leftrightarrow l_2\}$</p>	<p>(R-CONN) $l_1 :: \mathbf{conn}(l_2).P \parallel l_2 :: \mathbf{nil} \mapsto l_1 :: P \parallel \{l_1 \leftrightarrow l_2\}$</p>
<p>(R-NEW) $l :: \mathbf{new}(l').P \mapsto (\nu l')(l :: P \parallel l' :: \mathbf{nil})$</p>	<p>(R-DISC) $l_1 :: \mathbf{disc}(l_2).P \parallel \{l_1 \leftrightarrow l_2\} \mapsto l_1 :: P \parallel l_2 :: \mathbf{nil}$</p>

bidirectional; (EXT) is the standard π -calculus rule for scope extension. Finally, (RNODE) states that any restricted name can be used as the address of a node; indeed, we consider restricted names as private network addresses, whose corresponding nodes can be activated and deactivated on demand. In the sequel, we shall assume that each restricted name does correspond to an actual node. This assumption is justified by law (RNODE).

The reduction relation is given in Table 2. In (R-OUT) and (R-EVAL), the existence of a connection between the nodes source and target of the action is necessary to place the spawned component. Notice that existence of the connection can only be checked at run-time: an approach like [17] does not fit well in a global computing setting because it relies on a typing mechanism that would require to statically know the whole net. (R-IN) and (R-MATCH) additionally require the existence of a matching datum in the target node. (R-MATCH) states that action $\mathbf{in}(l)@l_2$ consumes exactly the datum $\langle l \rangle$ at l_2 , while (R-IN) states that action $\mathbf{in}(!x)@l_2$ can consume any $\langle l \rangle$ at l_2 ; l will then replace the free occurrences of x in the continuation of the process performing the action. (R-NEW) states that execution of action $\mathbf{new}(l')$ adds a restriction over l' to the net, while creating a node with address l' . Finally, (R-CONN) and (R-DISC) deal with activation/deactivation of connections. In the first case, we need to ensure that the connected nodes do exist; in the second case, we need to check existence of the connection to be removed.

τ KLAIM adopts a LINDA-like [16] communication mechanism: communication is asynchronous and data are anonymous. Indeed, no synchronization takes place between (sending and receiving) processes, because their interactions are mediated by nodes, that act as data repositories. For the sake of simplicity, we only consider monadic data, but the semantic theories we develop could be smoothly extended to deal with tuples of data and with a full-blown LINDA-like *pattern matching* mechanism.

3 Observables, Closures and Equivalences

In this section we present both a linear time and a branching time equivalence that yield sensible semantic theories for τKLAIM . The approach we follow relies on the definition of an *observation* (also called *barb*) that intuitively formalises the possible interactions of a process. We use observables to define equivalence relations that identify those nets that cannot be taken apart by any basic observation along reductions in any execution context. As usual, \Longrightarrow denotes the reflexive and transitive closure of \mapsto and \bar{l} denotes a possibly empty set of names.

Definition 1 (Barbs and Contexts). *Predicate $N \Downarrow l$ holds true if and only if $N \equiv (\nu \bar{l})(N' \parallel l :: \langle l' \rangle)$ for some \bar{l}, N' and l' such that $l \notin \bar{l}$. Predicate $N \Downarrow l$ holds true if and only if $N \Longrightarrow N'$ for some N' such that $N' \Downarrow l$. A context $C[\cdot]$ is a τKLAIM net with an occurrence of a hole $[\cdot]$ to be filled in with any net. Formally,*

$$C[\cdot] ::= [\cdot] \mid N \parallel C[\cdot] \mid (\nu l)C[\cdot]$$

We have chosen the basic observables by taking inspiration from those used for the asynchronous π -calculus [23]. One may wonder if our choice is “correct” and argue that there are other alternative notions of basic observables that seem quite natural, as we have discussed in the Introduction. In the full paper [10], we prove that the congruences induced by these alternative observables do coincide. This means that our results are quite independent from the observable chosen and vindicates our choice. Now, we say that a binary relation \mathfrak{R} between nets is

- *barb preserving*, if $N \mathfrak{R} M$ and $N \Downarrow l$ imply $M \Downarrow l$;
- *reduction closed*, if $N \mathfrak{R} M$ and $N \mapsto N'$ imply $M \Longrightarrow M'$ and $N' \mathfrak{R} M'$, for some M' ;
- *context closed*, if $N \mathfrak{R} M$ implies $C[N] \mathfrak{R} C[M]$, for every context $C[\cdot]$.

Our touchstone equivalences should at the very least relate nets with the same observable behaviour; thus, they must be barb preserving. However, an equivalence defined only in terms of this property would be too weak: indeed, the set of barbs of a net may change during computations or when interacting with an external environment. Moreover, for the sake of compositionality, our touchstone equivalences should also be congruences. These requirements lead us to the following definitions.

Definition 2 (May testing). \simeq is the largest symmetric, barb preserving and context closed relation between nets.

Definition 3 (Barbed congruence). \cong is the largest symmetric, barb preserving, reduction and context closed relation between nets.

We want to remark that the above definition of barbed congruence is the standard one, see [18, 23]. May testing is, instead, usually defined in terms of *observers*, *experiments* and *success of an experiment* [13]. In [10], we prove that, if we let \simeq' denote the equivalence on τKLAIM nets defined in [13], the two definitions do coincide. Moreover, the inclusions between our touchstone equivalences reflect the inclusions that hold in the π -calculus, since also in our setting may testing, differently from barbed congruence, ignores the branching structure of a process. A pair of nets proving that $\cong \subset \simeq$ can

be obtained from the CCS terms $a_1.(a_2 + a_3)$ and $a_1.a_2 + a_1.a_3$, that are may testing equivalent but not barbed congruent, by implementing the non-deterministic choice ('+') through parallel composition.

The problem with the definitions of barbed congruence and may testing is that context closure makes it hard to prove equivalences due to the universal quantification over contexts. In the following section, we shall provide two alternative characterisations of \cong and \simeq , as a *bisimulation-based* and as a *trace-based* equivalence, respectively.

4 Alternative Characterisations

4.1 A Labelled Transition System

In order to provide more tractable characterisations of our touchstone equivalences, we introduce a labelled transition system (LTS) to make apparent the action a net is willing to perform in order to evolve. The *labelled transition relation*, $\xrightarrow{\alpha}$, is defined as the least relation over nets induced by the inference rules in Table 3. Labels take the form

$$\alpha ::= \tau \mid l_1 \curvearrowright l_2 \mid (\widetilde{v\bar{l}})\langle l \rangle @ l_1 : l_2 \mid l_1 : \triangleright l_2 \mid l_1 : (\widetilde{v\bar{l}})l \triangleleft l_2 \mid l_1 : l_2 \mid l_1 : \neg l_2$$

We let $bn(\alpha)$ be \widetilde{l} if $\alpha = (\widetilde{v\bar{l}})\langle l \rangle @ l_1 : l_2$ or $\alpha = l_1 : (\widetilde{v\bar{l}})l \triangleleft l_2$, and be \emptyset otherwise; $fn(\alpha)$ and $n(\alpha)$ are defined accordingly.

Let us now explain the intuition behind the labels of the LTS and some key rules. Label α in $N \xrightarrow{\alpha} N'$ can be

- τ : this means that N may perform a reduction step to become N' (see Proposition 1).
- $l_1 \curvearrowright l_2$: this means that in N there is a direct connection between nodes l_1 and l_2 (see (LTS-LINK)).
- $(\widetilde{v\bar{l}})\langle l \rangle @ l_1 : l_2$: this means that in N there is a datum $\langle l \rangle$ located at l_1 and a connection $\{l_1 \leftrightarrow l_2\}$; the datum is available for processes located at l_2 (see (LTS-DATUM), (LTS-OFFER) and (LTS-LINK)). Moreover, according to whether $\widetilde{l} = \{l\}$ or $\widetilde{l} = \emptyset$, we also know if N restricts l or not (see (LTS-OPEN)).
- $l_1 : \triangleright l_2$: this means that in N there is a process located at l_1 willing to send a component at l_2 (see (LTS-OUT) and (LTS-EVAL)¹). For the sending to take place, a direct connection between such nodes is needed (see (LTS-SEND)).
- $l_1 : (\widetilde{v\bar{l}})l \triangleleft l_2$: this means that in N there is a process located at l_1 willing to retrieve a (possibly fresh) datum $\langle l \rangle$ at l_2 (see (LTS-IN), (LTS-MATCH) and (LTS-BIN)). For the actual retrieval, a direct connection between such nodes and a proper datum at l_2 are needed (see (LTS-COMM)).
- $l_1 : l_2$: this means that in N there is a process located at l_1 willing to activate a connection with l_2 (see (LTS-CONN)). For the actual activation, the net must contain a node with address l_2 , as pointed out by label $l_2 \curvearrowright l_2$ (see (LTS-EST) and (SELF)).

¹ It should not be surprising that actions **out** and **eval** yield the same label. Of course, the two actions should be taken apart for security reasons because accepting processes for execution is more dangerous than accepting data. However, in our setting, an external observer has not enough power to notice any difference: in both cases, it can just observe that a packet is sent.

$l_1 : \neg l_2$: this means that in N there is a process located at l_1 willing to deactivate a connection with l_2 (see (LTS-DISC)). For the actual deactivation, the net must contain the connection $\{l_1 \leftrightarrow l_2\}$ (see (LTS-REM)).

The last four kinds of labels describe ‘intentions’ of a process running in the net. Thus, (LTS-OUT) should be read as: “process **out**(l)@ l_2 . P running at l_1 is willing to send a component at l_2 ; whenever the execution context provides the connection needed, l_1 will host process P for execution and will run in a net where the connection $\{l_1 \leftrightarrow$

Table 3. A Labelled Transition System

(LTS-OUT) $l_1 :: \mathbf{out}(l)@l_2.P \xrightarrow{l_1: \triangleright l_2} l_1 :: P \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: \langle l \rangle$	(LTS-SEND) $\frac{N_1 \xrightarrow{l_1: \triangleright l_2} N'_1 \quad N_2 \xrightarrow{l_1 \curvearrowright l_2} N'_2}{N_1 \parallel N_2 \xrightarrow{\tau} N'_1 \parallel N'_2}$
(LTS-EVAL) $l_1 :: \mathbf{eval}(P_2)@l_2.P_1 \xrightarrow{l_1: \triangleright l_2} l_1 :: P_1 \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: P_2$	(LTS-COMM) $\frac{N_1 \xrightarrow{l_1: l \triangleleft l_2} N'_1 \quad N_2 \xrightarrow{\langle l \rangle @ l_2: l_1} N'_2}{N_1 \parallel N_2 \xrightarrow{\tau} N'_1 \parallel N'_2}$
(LTS-IN) $l_1 :: \mathbf{in}(!x)@l_2.P \xrightarrow{l_1: l \triangleleft l_2} l_1 :: P[l/x] \parallel \{l_1 \leftrightarrow l_2\}$	(LTS-EST) $\frac{N_1 \xrightarrow{l_1: l_2} N'_1 \quad N_2 \xrightarrow{l_2 \curvearrowright l_2} N'_2}{N_1 \parallel N_2 \xrightarrow{\tau} N'_1 \parallel N'_2}$
(LTS-MATCH) $l_1 :: \mathbf{in}(l)@l_2.P \xrightarrow{l_1: l \triangleleft l_2} l_1 :: P \parallel \{l_1 \leftrightarrow l_2\}$	(LTS-REM) $\frac{N_1 \xrightarrow{l_1: \neg l_2} N'_1 \quad N_2 \xrightarrow{l_1 \curvearrowright l_2} N'_2}{N_1 \parallel N_2 \xrightarrow{\tau} N'_1 \parallel N'_2}$
(LTS-NEW) $l :: \mathbf{new}(l').P \xrightarrow{\tau} (\nu l')(l :: P \parallel l' :: \mathbf{nil})$	(LTS-RES) $\frac{N \xrightarrow{\alpha} N' \quad l \notin n(\alpha)}{(\nu l)N \xrightarrow{\alpha} (\nu l)N'}$
(LTS-CONN) $l_1 :: \mathbf{conn}(l_2).P \xrightarrow{l_1: l_2} l_1 :: P \parallel \{l_1 \leftrightarrow l_2\}$	(LTS-OPEN) $\frac{N \xrightarrow{\langle l \rangle @ l_2: l_1} N' \quad l \notin \{l_1, l_2\}}{(\nu l)N \xrightarrow{(\nu l) \langle l \rangle @ l_2: l_1} N'}$
(LTS-DISC) $l_1 :: \mathbf{disc}(l_2).P \xrightarrow{l_1: \neg l_2} l_1 :: P \parallel l_2 :: \mathbf{nil}$	(LTS-STRUCT) $\frac{N \equiv N_1 \quad N_1 \xrightarrow{\alpha} N_2 \quad N_2 \equiv N'}{N \xrightarrow{\alpha} N'}$
(LTS-LINK) $\{l_1 \leftrightarrow l_2\} \xrightarrow{l_1 \curvearrowright l_2} \mathbf{0}$	
(LTS-DATUM) $l_1 :: \langle l \rangle \xrightarrow{\langle l \rangle @ l_1: l_1} \mathbf{0}$	
(LTS-OFFER) $\frac{N_1 \xrightarrow{\langle l \rangle @ l_2: l_2} N'_1 \quad N_2 \xrightarrow{l_1 \curvearrowright l_2} N'_2}{N_1 \parallel N_2 \xrightarrow{\langle l \rangle @ l_2: l_1} N'_1 \parallel N'_2}$	
(LTS-BIN) $\frac{N \xrightarrow{l_1: l \triangleleft l_2} N' \quad l \notin \mathit{fn}(N)}{N \xrightarrow{l_1: (\nu l) l \triangleleft l_2} N' \parallel l :: \mathbf{nil}}$	
(LTS-PAR) $\frac{N_1 \xrightarrow{\alpha} N_2 \quad \mathit{bn}(\alpha) \cap \mathit{fn}(N) = \emptyset}{N_1 \parallel N \xrightarrow{\alpha} N_2 \parallel N}$	

$l_2\}$ does exist and the datum $\langle l \rangle$ is placed at l_2 ". (LTS-EVAL), (LTS-IN), (LTS-MATCH), (LTS-CONN) and (LTS-DISC) should be interpreted similarly.

(LTS-OPEN) signals extrusion of bound names; as in some presentation of the π -calculus, this rule is used to investigate the capability of processes to export bound names, rather than to actually extend the scope of bound names.

Notice that the LTS of Table 3 may appear unnecessarily complicated as a tool to define the operational semantics of τKLAIM : consider, e.g., the right hand side of the rules for **out/in/eval**, or rule (LTS-BIN) (used to signal that a received name is fresh for the receiving net). Nevertheless, it is adequate as a tool to establish alternative, more tractable, characterisations of the touchstone equivalences we are interested in. Indeed, the complications in the operational rules of Table 3 resemble those arisen in [25] when defining an 'equivalent' LTS depending on the reduction semantics of a calculus. However, in [25] only simple calculi are considered and it would be interesting to investigate if the approach can be satisfactory extended to τKLAIM . Finally, the LTS is 'correct' w.r.t. the actual operational semantics of τKLAIM , \mapsto , as stated by the following Proposition.

Proposition 1. $N \mapsto M$ if and only if $N \xrightarrow{\tau} M$.

4.2 Bisimulation Equivalence

We now characterize barbed congruence by using the labels of the LTS instead of the universal quantification over contexts; in this way, we obtain an alternative characterization of \cong in terms of a labelled *bisimilarity*. As a matter of notation, we let

$$\chi ::= \tau \mid l_1 \curvearrowright l_2 \mid (\sqrt{l}) \langle l \rangle @ l_1 : l_2$$

Moreover, \Rightarrow stands for $\xrightarrow{\tau^*}$, $\overset{\alpha}{\Rightarrow}$ stands for $\Rightarrow \xrightarrow{\alpha} \Rightarrow$, and $\hat{\Rightarrow}$ stands for \Rightarrow , if $\alpha = \tau$, and for $\overset{\alpha}{\Rightarrow}$, otherwise.

Definition 4 (Bisimilarity). A symmetric relation \mathfrak{R} between τKLAIM nets is a (weak) bisimulation if, for each $N \mathfrak{R} M$, it holds that:

1. $N \xrightarrow{\chi} N'$ implies that $M \hat{\Rightarrow} M'$ and $N' \mathfrak{R} M'$, for some M' ;
2. $N \xrightarrow{l_1 : \triangleright l_2} N'$ implies that $M \parallel \{l_1 \leftrightarrow l_2\} \Rightarrow M'$ and $N' \mathfrak{R} M'$, for some M' ;
3. $N \xrightarrow{l_1 : l \triangleleft l_2} N'$ implies that $M \parallel \{l_1 \leftrightarrow l_2\} \parallel l_2 :: \langle l \rangle \Rightarrow M'$ and $N' \mathfrak{R} M'$, for some M' ;
4. $N \xrightarrow{l_1 : l_2} N'$ implies that $M \parallel l_2 :: \mathbf{nil} \Rightarrow M'$ and $N' \mathfrak{R} M'$, for some M' ;
5. $N \xrightarrow{l_1 : \neg l_2} N'$ implies that $M \parallel \{l_1 \leftrightarrow l_2\} \Rightarrow M'$ and $N' \mathfrak{R} M'$, for some M' .

Bisimilarity, \approx , is the largest bisimulation.

Bisimilarity requires that labels of the form $(\sqrt{l}) \langle l \rangle @ l_1 : l_2$ or $l_1 \curvearrowright l_2$ must be replied to with the same label (possibly with some additional τ -step). This is necessary since such labels describe the structure of the net (its data and connections) and, to be equivalent, two nets must have at least the same structure. Labels different from χ only express intentions and are handled differently. For example, the intention of sending a component, say $N \xrightarrow{l_1 : \triangleright l_2} N'$, can be simulated by a net M (in a context where l_1 and l_2 are connected) through the execution of some τ -steps that lead to some M' equivalent to N' . Indeed, since we want our bisimulation to be a congruence, a context that provides

a connection between the source and the target nodes of the sending action must not tell apart N and M . Similar considerations also hold for the last three items of Definition 4.

Notice that labels of the form $l_1 : (\nu l)l \triangleleft l_2$ are not necessary for the definition of bisimulation. Indeed, they exactly work like labels $l_1 : l \triangleleft l_2$ with the extra information that l is fresh for the receiving net; for the bisimulation game this information is useless, while it will be of fundamental importance when considering trace-based equivalence.

Remarkably, though in τKLAIM processes can occur as arguments in process actions (**eval**), the LTS and the bisimulation we developed do not use labels containing processes. Thus, the bisimulation relies only on a standard quantification over names (in the input case) and we strongly conjecture that it is decidable, under proper assumptions: techniques similar to those in [21] could be used here. Moreover, the presence of rule (**LTS-STRUCT**) in the LTS does not compromise the tractability of \approx ; obviously, (**LTS-STRUCT**) can be dropped, if one is prepared to have more rules in the LTS.

We can now present our first main result, whose proof is in the full paper [10].

Theorem 1 (Alternative Characterization of Barbed Congruence). $\approx = \cong$.

4.3 Trace Equivalence

In this section, we develop an alternative characterization of may testing. For some well-known process calculi, may testing coincides with trace equivalence [13, 3, 5]; in this section, we show how a similar result is obtained also in the setting of τKLAIM .

The idea behind trace equivalence is that N and M are related if and only if the sets of their traces coincide. Put in another form, if N exhibits a sequence of visible actions σ , then M must exhibit σ as well, and vice versa. In an asynchronous setting [5], this requirement must be properly weakened, since the discriminating power of asynchronous contexts is weaker: in the asynchronous π -calculus, for example, contexts cannot observe input actions.

To carry out proofs, we found it convenient to introduce a *complementation function* $\bar{\cdot}$ over visible labels (i.e. labels different from τ), ranged over by ϕ , such that

$$\begin{aligned} \overline{l_1 \curvearrowright l_2} &\triangleq l_1 : \triangleright l_2 & \overline{l_1 : \triangleright l_2} &\triangleq l_1 \curvearrowright l_2 & \overline{l_1 : (\nu \tilde{l})l \triangleleft l_2} &\triangleq (\nu \tilde{l}) \langle l \rangle @ l_2 : l_1 \\ \overline{l_1 : l_2} &\triangleq l_2 \curvearrowright l_1 & \overline{l_1 : \neg l_2} &\triangleq l_1 \curvearrowright l_2 & \overline{(\nu \tilde{l}) \langle l \rangle @ l_2 : l_1} &\triangleq l_1 : (\nu \tilde{l})l \triangleleft l_2 \end{aligned}$$

Because of the interplay between free and bound names (bound names are always associated to nodes, see rule (**RNODE**)), we need to distinguish reception of a free name from reception of a bound name (that must be fresh for the receiving net). Similarly to the π -calculus [3, 5], this can be done by exploiting *bound input* labels, $l_1 : (\nu l)l \triangleleft l_2$, generated by rule (**LTS-BIN**) (that also adds a node with address l because of law (**RNODE**)). Finally, we let σ to range over (possibly empty) sequences of visible actions, i.e.

$$\sigma ::= \epsilon \mid \phi \cdot \sigma$$

where ϵ denotes the empty sequence of actions and ‘ \cdot ’ represents concatenation. As usual, $N \xrightarrow{\epsilon}$ denotes $N \Rightarrow$ and $N \xrightarrow{\phi \cdot \sigma}$ denotes $N \xrightarrow{\phi} \xrightarrow{\sigma}$.

The naive formulation of trace equivalence such as “ $N \xrightarrow{\sigma}$ if and only if $M \xrightarrow{\sigma}$ ” is too strong in an asynchronous setting: for example, it would distinguish $l ::$

Table 4. The Ordering Relation on Traces

(L1)	$\sigma \cdot (\widetilde{\nu}l)\sigma' \leq \sigma \cdot (\widetilde{\nu}l)(\beta \cdot \sigma')$	if $(\widetilde{\nu}l)\sigma' \neq UNDEF$
(L2)	$\sigma \cdot (\widetilde{\nu}l)(\phi \cdot \gamma \cdot \sigma') \leq \sigma \cdot (\widetilde{\nu}l)(\gamma \cdot \phi \cdot \sigma')$	if $(\widetilde{\nu}l)(\phi \cdot \gamma \cdot \sigma') \neq UNDEF$
(L3)	$\sigma \cdot (\widetilde{\nu}l)\sigma' \leq \sigma \cdot (\widetilde{\nu}l)(\gamma \cdot \bar{\gamma} \cdot \sigma')$	if $(\widetilde{\nu}l)\sigma' \neq UNDEF$
(L4)	$\sigma \cdot l : \triangleright l \cdot \phi \cdot \sigma' \leq \sigma \cdot \phi \cdot \sigma'$	if $l \in \mathcal{Y}(\phi)$
(L5)	$\sigma \cdot l : \triangleright l \cdot \phi \cdot \sigma' \leq \sigma \cdot \phi \cdot l : \triangleright l \cdot \sigma'$	if $l \notin \text{bn}(\phi)$
(L6)	$\sigma \cdot \phi' \cdot \sigma' \leq \sigma \cdot \phi \cdot \sigma'$	if $(\phi, \phi') \in \Psi$
(L7)	$\sigma \cdot l_1 : (\widetilde{\nu}l) l \triangleleft l_1 \cdot \sigma' \leq \sigma \cdot l_2 : (\widetilde{\nu}l) l \triangleleft l_1 \cdot \sigma'$	
(L8)	$\sigma \cdot l_2 : (\widetilde{\nu}l) l \triangleleft l_1 \cdot \sigma' \leq \sigma \cdot l_1 : (\widetilde{\nu}l) l \triangleleft l_1 \cdot l_1 : \triangleright l_2 \cdot \sigma'$	

In law (L1), β stands for either $l_1 : \triangleright l_2$ or $l_1 : l \triangleleft l_2$ or $l_1 : l_2$ or $l_1 : \neg l_2$.

In laws (L2) and (L3), γ stands for either $l_1 : \triangleright l_2$ or $l_1 : l \triangleleft l_2$.

In law (L4), function $\mathcal{Y}(\cdot)$ is defined as follows: $\mathcal{Y}(l_1 : (\widetilde{\nu}l) l \triangleleft l_2) = \mathcal{Y}(l_1 : l_2) = \{l_1, l_2\}$ and

$$\mathcal{Y}(l_1 \curvearrowright l_2) = \{l_1\} \text{ and } \mathcal{Y}(l_1 : \triangleright l_2) = \mathcal{Y}((\widetilde{\nu}l) \langle l \rangle @ l_1 : l_2) = \{l_2\}.$$

In law (L6), relation Ψ is $\{ (l_1 : \neg l_2, l_1 : \triangleright l_2), (l_1 : \triangleright l_2, l_1 : \neg l_2), (l_2 : \triangleright l_2, l_1 : l_2) \}$.

$\mathbf{in}(!x)@l_1.\mathbf{in}(!y)@l_2$ and $l :: \mathbf{in}(!y)@l_2.\mathbf{in}(!x)@l_1$, which are indeed may testing equivalent. Like in [5], a weaker trace-based equivalence can be defined as follows.

Definition 5 (Trace Equivalence). \approx is the largest symmetric relation between TKLAIM nets such that, whenever $N \approx M$, it holds that $N \xrightarrow{\sigma} \implies M \xrightarrow{\sigma'}$, for some $\sigma' \leq \sigma$.

The crux is to identify a proper ordering on the traces such that may testing is exactly captured by \approx . The ordering \leq is the least reflexive and transitive relation induced by the laws in Table 4. The first three laws have been inspired by [5], while the last five ones are strictly related to inter-node connections. The intuition behind $\sigma' \leq \sigma$ is that, if a context can interact with a net that exhibits σ , then the context can interact with any net that exhibits σ' as well. The ordering \leq relies on the function $(\widetilde{\nu}l)\sigma$, that is used in laws (L1), (L2) and (L3) when moving/removing a label of the form $l_1 : (\nu l) l \triangleleft l_2$. In this case, the information that l is a fresh received value must be kept in the remaining trace. The formal definition is

$$\begin{aligned}
 (\widetilde{\nu}l)\sigma &\triangleq \sigma && \text{if } \widetilde{l} \cap \text{fn}(\sigma) = \emptyset \\
 (\nu l)(\phi \cdot \sigma) &\triangleq \begin{cases} l_1 : (\nu l) l \triangleleft l_2 \cdot \sigma & \text{if } \phi = l_1 : l \triangleleft l_2 \text{ and } l \notin \{l_1, l_2\} \\ \phi \cdot (\nu l)\sigma & \text{if } l \notin \text{n}(\phi) \text{ and } (\nu l)\sigma \neq UNDEF \\ UNDEF & \text{otherwise} \end{cases}
 \end{aligned}$$

Further explanations can be found in the full paper [10].

The rules in Table 4 can be explained as follows. (L1) states that labels representing intentions cannot be directly observed; at most, their effect can be somehow observed. (L2) states that the execution of an input/output/migration can be delayed along com-

putations without being noticed by any observer. (L3) states that two adjacent ‘complementary’ actions can be deleted. (L4) states that an action involving l as source or target node always enables sending actions from l to l ; because, in all these cases, a node at address l exists. Function $\mathcal{Y}(\cdot)$ is needed to restrict applicability of (L4) only to the cases needed to prove Theorem 2. (L5) states that, if a sending action from l to l is enabled after an action ϕ , then the action can take place before ϕ , since the node at l was already present; clearly, this is possible only if l is not bound by ϕ . (L6) states that some intentions are interchangeable; indeed, since the complementation function is not injective, the same observer may enable different kinds of process actions. (L7) states that, if a process located at l_2 can retrieve a datum from l_1 , then processes located at l_1 can retrieve such datum as well. Finally, (L8) states that, if a process located at l_1 can retrieve a datum $\langle l \rangle$ locally and then migrate at l_2 , then processes located at l_2 can retrieve $\langle l \rangle$ remotely.

Remarkably, may testing in the (synchronous/asynchronous) π -calculus [3, 5] cannot distinguish bound names from free ones; thus, a bound name can be replaced with any name in a trace. This is *not* the case here: indeed, bound names can always be considered as addresses of nodes, while free names cannot. This makes a difference for an external observer; thus, a law like

$$\sigma \cdot \langle l \rangle @ l_1 : l_2 \cdot (\sigma' [l'/l]) \leq \sigma \cdot (\nu l) \langle l \rangle @ l_1 : l_2 \cdot \sigma'$$

(that, *mutatis mutandis*, holds for the π -calculus [3, 5]) does not hold for τKLAIM .

We can now state our second major result; detailed proofs are in [10].

Theorem 2 (Alternative Characterization of May Testing). $\asymp = \approx$.

5 Conclusions and Related Work

We have introduced τKLAIM , a foundational language that provides constructs to explicitly model and dynamically establish/remove inter-node connections, and some associated semantic theories. In a companion paper [11], we have applied the theory to a few examples that illustrate usability.

We believe that, although τKLAIM can be somehow encoded in the π -calculus, the introduction of the former is justified by at least two reasons. First, τKLAIM clearly enlightens the key features we want to model such as distribution and mobility of processes, and inter-node connections; an encoding of such features in the π -calculus would hide them within complex process structures. Second, a convincing encoding should enjoy ‘reasonable’ properties, like those pointed out in [22]. We believe this is *not* the case. For example, in [12] we developed an intuitive encoding of a τKLAIM ’s sub-calculus into the asynchronous π -calculus that does not preserve convergence. We are now working on proving that this is not incidental and is due to the check of existence of the target of a communication that is performed in τKLAIM and not in the π -calculus. We conjecture that a divergence free encoding does not exist.

Related Work. To our knowledge, no alternative characterization of may testing in terms of a trace-based equivalence has ever been given for a distributed language with process mobility. Bisimulation-based equivalences for calculi relying on a flat net topology are developed in [1, 17]; such equivalences are mainly derived from bisimulation equivalences for the π -calculus and its variants. Bisimulation-based equivalences for calculi

relying on a hierarchical net topology are developed in [19, 6, 8]. Although these bisimulations are inspired by Sangiorgi's *context bisimulation* [23] and, thus, exploit universal quantification over processes, they yield proof techniques that are usable in practice.

Finally, the most closely related work is [15]; there, a distributed version of the π -calculus is presented where nodes are connected through links that can fail during the computation. A bisimulation-based proof technique is used to establish properties of systems. However, differently from our approach, the authors only consider links that can fail and do not model dynamic connections establishment.

Abstract. We investigate the foundations of a constraint-based compositional verification method for infinite-state systems. We first consider an asynchronous process calculus which is an abstract formalization of several existing languages based on the blackboard model. For this calculus we define a constraint-based symbolic representation of finite computations of a compositional model based on traces. The constraint system we use combines formulas of integer arithmetics with equalities over uninterpreted functions in which satisfiability is decidable. The translation is inductively defined via a CLP program. Execution traces of a process can be compositionally obtained from the solutions of the answer constraints of the CLP encoding. This way, the task of compositional verification can be reduced to constraint computing and solving.

1 Introduction

Compositional verification of infinite state systems introduces several problems along two main axis. On one hand, in order to apply verification methods developed for finite state systems we need suitable abstractions to finitely represent infinite sets of states. On the other hand, compositionality is usually quite difficult to achieve already in the case of finite state systems, as it requires semantics structures which are often rather complicated. Nevertheless, when considering some important classes of infinite state systems, for example those arising in distributed computing, compositional verification is almost mandatory as the environment in which software agents operate cannot be fixed in advance.

In this paper we deal with this problem by proposing a new technique which combines classical compositional semantics based on sequences (or traces) with constraint programming. More specifically, we consider an asynchronous process calculus which is an abstract formalization of several existing languages based on the blackboard model like [4, 11, 16], where processes communicates and synchronize by posting and retrieving messages from a global, common store. For this process calculus we define a symbolical representation, in terms of constraints, of

a compositional model based on traces, thus reducing the task of (compositional) verification to constraint solving.

Technically, our approach is based on the following steps. First of all, we define a compositional model based on traces of basic actions on the store which describes correctly the sequences of stores obtained in a *finite computation*. This follows a standard approach to trace based models of concurrent languages (e.g. see [14, 8]), even though our technical treatment is different. We represent the traces arising in the compositional model by using the constraint system C_{E+Z} which combines linear integer arithmetics with uninterpreted function symbols. Arithmetic constraints allow us to describe the addition and deletion of a message to the store at a given time instant. Uninterpreted symbols are used to relate store configurations in different time instants. Indeed, they can be used to represent variables which depend on other variables as in the formula $s_a(i+1) = s_a(i) + 1$ which can be used to represent the addition of a message a to the store at time i . Following from the results on the combination of decision procedures of [15], we know that the quantifier-free satisfiability problem for constraints in C_{E+Z} is decidable. In order to deal with finite computations of recursive process definitions, the above mentioned constraint system is embedded into a Constraint Logic Programming (CLP) language [13]. Then we compositionally translate a process of our algebra into a CLP program P and a goal G so as to extract the traces describing the semantics of the process from the constraints computed by the evaluation of G in P . In this setting a recursive process definition naturally translates into a CLP recursive clause.

The resulting encoding has several benefits. Firstly, we introduce an implicit, compact representation of finite computations, which are described by C_{E+Z} formulas and which can be obtained explicitly by taking the solutions of these constraints. Moreover, we can use logical operators to represent the operators on sequences which are the semantic counterpart of the syntactic operators of the language, thus obtaining a compositional construction. Notably, the interleaving of sequences which models the syntactic parallel composition, can be simply defined in terms of conjunction of constraints, provided that we select the solutions of the resulting constraint with some care. Secondly, we obtain a natural compositional model by translating processes into CLP programs, where we exploit the and-compositionality of the computed answer constraint of CLP programs. Thirdly, we can combine CLP systems with solvers like CVCL [5] and MathSAT [7] to define compositional verification procedures based on our symbolic semantics. Indeed, since C_{E+Z} constraints can also be used to express initial and final conditions on the store, the verification of a property \mathcal{P} for a process P can be reduced to the existence of a satisfiable answer constraint for the CLP translation of P in conjunction with the constraint defining \mathcal{P} .

Related Work The use of sequences (or traces) in the semantics of concurrent languages is not new: compositional models based on traces have been defined for a variety of concurrent languages, ranging from dataflow languages [14] and imperative ones [8] to (timed) concurrent constraint programming [3] and Linda-like languages (expressed in terms of process algebras) [2]. However, all the existing

approaches consider sequences explicitly and do not take into account the issue of defining a suitable language for expressing and manipulating them implicitly. As a consequence, the resulting models cannot be used directly to define automatic verification tools. On the other hand, our approach introduces a constraint system for expressing and manipulating sequences, where the semantic parallel composition operator can be simply seen in terms of conjunction of constraints. This allows us to express symbolically the semantic of a process and to reason on it without the need to generate explicitly all the sequences, thus reducing the task of property verification to constraint solving. Finally, while in other CLP-based verification methods like [9] arithmetic constraints are used to represent infinite sets of states, in our approach we combine them with uninterpreted function symbols to represent set of traces.

Plan of the paper In Section 2 we present a process algebra for asynchronous processes. In Section 3 we present the logic language $\text{CLP}(C_{E+Z})$. In Section 3 we present the encoding from processes to $\text{CLP}(C_{E+Z})$ programs. Finally, in Section 5 we discuss related and future work.

2 An Asynchronous Process Algebra

The calculus that we consider in this paper is an abstract formalization of several existing concurrent languages based on the blackboard model, e.g., [4, 11, 16]. The calculus is equipped with two basic operations $out(a)$ and $in(a)$ for adding and removing a message from a common global store. Then we have the usual parallel composition and (internal) choice operators. We also have a construct which allows to test for presence of a message, allowing different continuations depending on the result of the test. This construct, which cannot be simulated by the basic operations, is needed in order to obtain Turing completeness. Infinite behaviors are expressed by allowing the recursive definition of process constants.

Definition 1 (The language). Given a finite set of messages Msg , with typical elements $a, b \dots$, and a set of process constants K with typical elements p, q, \dots , the syntax of process terms is given by the following grammar:

$$\begin{aligned} P, Q & ::= \alpha.P \mid \beta?P : Q \mid P \parallel Q \mid P + Q \mid p \mid halt \\ \alpha & ::= out(a) \mid in(a) \\ \beta & ::= inp(a) \mid rdp(a) \end{aligned}$$

where we assume that for each process constant p there exists a single definition $p =_{def} P$ where P is a process term and we assume guarded recursion. A *closed process* is a pair $\langle P, D \rangle$ where P is a process term and D is a set of definitions for all the constants in P .

Since the out operation is non blocking the communication is asynchronous: a process that wants to communicate with another one simply adds a message to the global store and then proceeds in its computation. The process that wants to receive a message can retrieve it from the global store by performing an in

Table 1. The transition system (symmetric rules omitted)

R1 $\langle out(a).P, \mathcal{M} \rangle \rightarrow \langle P, \mathcal{M} \oplus \{a\} \rangle$	
R2 $\langle in(a).P, \mathcal{M} \rangle \rightarrow \langle P, \mathcal{M} \ominus \{a\} \rangle$	provided $a \in \mathcal{M}$
R3 $\langle rdp(a)?P : Q, \mathcal{M} \rangle \rightarrow \langle P, \mathcal{M} \rangle$	provided $a \in \mathcal{M}$
$\langle rdp(a)?P : Q, \mathcal{M} \rangle \rightarrow \langle Q, \mathcal{M} \rangle$	provided $a \notin \mathcal{M}$
R4 $\langle inp(a)?P : Q, \mathcal{M} \rangle \rightarrow \langle P, \mathcal{M} \ominus \{a\} \rangle$	provided $a \in \mathcal{M}$
$\langle inp(a)?P : Q, \mathcal{M} \rangle \rightarrow \langle Q, \mathcal{M} \rangle$	provided $a \notin \mathcal{M}$
R5 $\langle P + Q, \mathcal{M} \rangle \rightarrow \langle P, \mathcal{M} \rangle$	
R6 $\frac{\langle P, \mathcal{M} \rangle \rightarrow \langle P', \mathcal{M}' \rangle}{\langle P \parallel Q, \mathcal{M} \rangle \rightarrow \langle P' \parallel Q, \mathcal{M}' \rangle}$	
R7 $\langle p, \mathcal{M} \rangle \rightarrow \langle P, \mathcal{M} \rangle$	provided $(p =_{def} P) \in D$

operation, which is blocking: if (an occurrence of) the required message is not present in the store then the computation suspends, possibly being resumed later when the message is available. The process $inp(a)?P : Q$ tests for the presence of (an occurrence of) message a in the current store: if present, (an occurrence of) a is removed and the process continues as P , otherwise the process continues as Q . The process $rdp(a)?P : Q$ behaves similarly with the exception that rdp only tests for the presence of a without removing it. The parallel operator is modeled in terms of interleaving, as usual. As for the choice, we consider here the internal (or local) choice, where the environment cannot influence the choice. In the following we will work modulo the congruence relation $halt \equiv halt \parallel halt$.

Operational Semantics The *operational semantics* is formally described by a transition system $T = (Conf, \rightarrow)$. Configurations (in $Conf$) are pairs consisting of a process and a *multiset* of messages \mathcal{M} representing the common store. We will use \ominus and \oplus to denote multiset union and difference, respectively. The transition relation \rightarrow is the least relation satisfying the rules R1-R7 in Table 1, where we omit definitions since these do not change during the computation. So $\langle P, \mathcal{M} \rangle \rightarrow \langle Q, \mathcal{M}' \rangle$ means that the process P with the store \mathcal{M} and a given set of declarations D can perform a transition step yielding the process Q and the store \mathcal{M}' . A computation is a sequence of configurations $C_1 C_2 \dots C_k$ such that $C_i \rightarrow C_{i+1}$ for any $i : 1, \dots, k-1$. In the following $Store$ will denote the set of possible stores, i.e. multiset over Msg , while $Store^*$ will indicate the set of finite sequences over $Store$. The observables are obtained by projecting runs over sequences in $Store^*$.

Definition 2. For any program $\langle P, D \rangle$, we define

$$\mathcal{O}(\langle P, D \rangle) = \{ \mathcal{M}_1 \cdot \dots \cdot \mathcal{M}_n \mid \langle P_1, \mathcal{M}_1 \rangle \rightarrow \dots \rightarrow \langle P_n, \mathcal{M}_n \rangle \not\rightarrow, P = P_1 \}$$

Furthermore, we define the observable of *terminating computations* as follows.

Definition 3. For any program $\langle P, D \rangle$, we define

$$\mathcal{O}_h(\langle P, D \rangle) = \{\mathcal{M}_1 \cdot \dots \cdot \mathcal{M}_n \mid \langle P_1, \mathcal{M}_1 \rangle \rightarrow \dots \rightarrow \langle \text{halt}, \mathcal{M}_n \rangle, P = P_1\}$$

For instance, let $P = \text{out}(b).\text{in}(a).\text{halt}$. Then, $\emptyset \cdot \{b\}$ is in $\mathcal{O}(Q)$ but not in $\mathcal{O}_h(Q)$, whereas $\{a\} \cdot \{a, b\} \cdot \{b\} \in \mathcal{O}(Q) \cap \mathcal{O}_h(Q)$.

2.1 Denotational Semantics

We can compositionally characterize the observables using the set \mathcal{A}^* of sequences built on $\mathcal{A} = \{\text{in}(a), \text{out}(a), \text{inp}(a), \text{rdp}(a), \overline{\text{inp}}(a), \overline{\text{rdp}}(a) \mid a \in \text{Msg}\}$. To define the semantics of parallel, we consider the *shuffle operator* of [12]. The shuffling of s and t in \mathcal{A}^* , denoted $s \odot t$, is the set of all sequences of the form

$$s_1 \cdot t_1 \cdot \dots \cdot s_k \cdot t_k$$

where $k > 0$, $s = s_1 \cdot \dots \cdot s_k$, $t = t_1 \cdot \dots \cdot t_k$, and the sequences s_i and t_i , $1 \leq i \leq k$, can be of arbitrary length (including the empty sequence). The operator \odot associates less than concatenation; it can be extended to sets of sequences as follows: $S \odot T = \{s \odot t \mid s \in S, t \in T\}$.

As an example, $\text{in}(a) \cdot \text{in}(b) \odot \text{in}(c) = \{\text{in}(c) \cdot \text{in}(a) \cdot \text{in}(b), \text{in}(a) \cdot \text{in}(c) \cdot \text{in}(b)\}$.

Definition 4. The denotational semantics is the least function \mathcal{D} from programs to $\wp(\mathcal{A}^*)$ which satisfies the equations in Table 2.

As an example, consider the processes $p = \text{inp}(a)?q : r$, $q = \text{out}(b).\text{out}(c).\text{halt}$ and $r = \text{out}(c).\text{out}(b).\text{halt}$. Then, the denotational semantics $\mathcal{D}[p]$ of p contains the sequences $\text{inp}(a) \cdot \text{out}(b) \cdot \text{out}(c)$ and $\overline{\text{inp}}(a) \cdot \text{out}(c) \cdot \text{out}(b)$.

From the denotational semantics we can reconstruct the observables by resorting to the partial map $\text{eval} \in [\mathcal{A}^* \times \text{Store} \rightarrow \text{Store}^*]$ defined in Table 3. Going back to the previous example, $\text{eval}(\text{inp}(a) \cdot \text{out}(b) \cdot \text{out}(c), \emptyset)$ is undefined, since the evaluation of $\text{inp}(a)$ in the empty store does not succeed, whereas

Table 2. Denotational semantics for process terms with definitions in D

E1 $\mathcal{D}[\text{halt}] = \{\epsilon\}$

E2 $\mathcal{D}[\text{out}(a).P] = \{\text{out}(a) \cdot s \mid s \in \mathcal{D}[P]\}$

E3 $\mathcal{D}[\text{in}(a).P] = \{\text{in}(a) \cdot s \mid s \in \mathcal{D}[P]\}$

E4 $\mathcal{D}[\text{rdp}(a)?P : Q] = \{\text{rdp}(a) \cdot s \mid s \in \mathcal{D}[P]\} \cup \{\overline{\text{rdp}}(a) \cdot s \mid s \in \mathcal{D}[Q]\}$

E5 $\mathcal{D}[\text{inp}(a)?P : Q] = \{\text{inp}(a) \cdot s \mid s \in \mathcal{D}[P]\} \cup \{\overline{\text{inp}}(a) \cdot s \mid s \in \mathcal{D}[Q]\}$

E6 $\mathcal{D}[P \parallel Q] = \mathcal{D}[P] \odot \mathcal{D}[Q]$

E7 $\mathcal{D}[P + Q] = \mathcal{D}[P] \cup \mathcal{D}[Q]$.

E8 $\mathcal{D}[p] = \mathcal{D}[B]$ provided $(p =_{\text{def}} B) \in D$

Table 3. The *eval* mapping

$$\begin{aligned}
 eval(\epsilon, \mathcal{M}) &= \mathcal{M} \\
 eval(out(a) \cdot s, \mathcal{M}) &= \mathcal{M} \cdot eval(s, \mathcal{M} \oplus \{a\}) \\
 eval(in(a) \cdot s, \mathcal{M}) &= \begin{cases} \mathcal{M} \cdot eval(s, \mathcal{M} \ominus \{a\}) & \text{if } a \in \mathcal{M} \\ \mathcal{M} & \text{otherwise} \end{cases} \\
 eval(inp(a) \cdot s, \mathcal{M}) &= \mathcal{M} \cdot eval(s, \mathcal{M} \ominus \{a\}) \quad \text{if } a \in \mathcal{M} \\
 eval(rdp(a) \cdot s, \mathcal{M}) &= \mathcal{M} \cdot eval(s, \mathcal{M}) \quad \text{if } a \in \mathcal{M} \\
 eval(\overline{rdp}(a) \cdot s, \mathcal{M}) &= eval(\overline{inp}(a) \cdot s, \mathcal{M}) = \mathcal{M} \cdot eval(s, \mathcal{M}) \quad \text{if } a \notin \mathcal{M}
 \end{aligned}$$

$eval(\overline{inp}(a) \cdot out(c) \cdot out(b), \emptyset) = \emptyset \cdot \{c\} \cdot \{b, c\}$. Notice that in the definition of the *eval* map the treatment of $in(a)$ and $inp(a)$ is different: in fact, in case the message a is not present in the store the evaluation of $in(a)$ suspends, hence the result of the *eval* is simply the store \mathcal{M} , without any further continuation. On the other hand, if the message a is not present in the store the evaluation of $inp(a)$ does not suspend and follows the alternative branch which, in our sequences, is indicated by the $\overline{inp}(a)$ construct (see equation E5 in Table 2). The following result states the correctness of the denotational semantics with respect to the notion of observables of Def. 2.

Theorem 1. *For any P , $\mathcal{O}(P) = \{eval(s, \mathcal{M}) \mid s \in \mathcal{D}[[P]], \mathcal{M} \in Store\}$.*

3 The Logic Language CLP(C_{E+Z})

In this section we introduce the CLP(C_{E+Z}) language, obtained as a specific instance of the CLP scheme [13] by considering constraints defined over the combination of the first order theories of *equality over uninterpreted functions* and of *integer arithmetics*.

The combined constraint system C_{E+Z} is defined as follows. C_{E+Z} constraints are quantifier free formulas built over the signature $\Sigma_E \cup \Sigma_Z$, where Σ_E is a set of functions symbols, and $\Sigma_Z = \{0, 1, \dots, +, -, <, \leq\}$ is the usual signature of integer arithmetics. An example of C_{E+Z} constraint is the formula $x \leq y \wedge f(x) = g(y) + 1 \wedge f(g(x) + 1) \leq 2$. Thus in C_{E+Z} we can represent arithmetics over variables that depend on other variables. The theory of equality is the Σ_E -theory with no axioms, whereas the theory of arithmetics is defined as the set of Σ_Z -sentences that are true in the standard interpretation of constants, function and predicate symbols in Σ_Z . From the general results of Nelson and Oppen [15], quantifier-free satisfiability is decidable in the combined theory \mathcal{T}_{E+Z} . Solvers like CVCL [5] and MathSAT [7] implement decision procedures to check satisfiability of these constraints.

Let Π be a finite set of predicate symbols (program predicates), disjoint from Σ_{E+Z} and let \mathcal{V} be a denumerable set of variables. The language CLP(C_{E+Z}) is defined on top of C_{E+Z} as follows.

Definition 5 (Clauses, Goals, and Programs). A *clause* is an implicitly universally quantified formula of the form

$$A_0 \Leftarrow \varphi \wedge A_1 \wedge \dots \wedge A_n,$$

and a *goal* is an implicitly existentially quantified formula of the form

$$\varphi \wedge A_1 \wedge \dots \wedge A_n,$$

where φ is a C_{E+Z} constraint over \mathcal{V} , $A_i = p_i(x_1^i, \dots, x_n^i)$ is an atom with $p_i \in \Pi$, $0 \leq i \leq n$, and $x_j^k \in \mathcal{V}$ for $j, k \geq 0$. A *program* is a set of clauses.

We use \Rightarrow_P to denote the usual notion of CLP derivation relation (see [13]) for goals and (renamings of) clauses taken from a $\text{CLP}(C_{E+Z})$ program P . A derivation step replaces an atomic formula A in a goal G with the body B of a clause $A' \Leftarrow B$ whose head A' can be unified with A . The constraint resulting from unification in conjunction with those in B and in G must be satisfiable. \Rightarrow_P^* denotes its reflexive and transitive closure. $\text{CLP}(C_{E+Z})$ programs allow to compute *answer constraints* [10]. Formally, we have the following definition.

Definition 6. The *answer constraint semantics* of P and G is defined as

$$\mathcal{A}(P, G) = \{\varphi \mid G \Rightarrow_P^* \varphi, \varphi \text{ is a } C_{E+Z} \text{ constraint}\}.$$

Thus an answer constraint is the conjunction of constraints which are left when all atomic goals have been resolved using program clauses.

4 Encoding Processes in $\text{CLP}(C_{E+Z})$

First of all, given the set of messages $\text{Msg} = \{a_1, \dots, a_k\}$, we build the signature $\Sigma_E = \{s_1, \dots, s_k\}$ (contained in Σ_{E+Z} by definition). The term $s_i(t)$ is used to represent the number of occurrences of message a_i in the store at time t . The effect of an action like $\text{out}(a_i)$ executed at time x can then be described via the clause like that defining the *store atom* $\text{out}(a_i, x)$ of Fig. 4. Thus in the rest of the paper we will focus our attention on the subclass of C_{E+Z} constraints defined as follows.

Definition 7 (Store Constraints). A *store atom* is a formula $\alpha(a_i, x)$ with $\alpha \in \{\text{out}, \text{in}, \text{inp}, \text{rdp}, \overline{\text{inp}}, \overline{\text{rdp}}\}$ defined by the CLP clauses of Table 4. A *store constraint* is a conjunction of store atoms and arithmetic formulas.

The effect of an action like $\text{out}(a_i)$ executed at time x can then be described via the store atom $\text{out}(a_i, x)$. Its definition describes the addition of a new occurrence of message a_i to the store. More in general, store constraints will allow us to express in a logical way the composition operators of our process algebra. In order to formally relate store constraints to the denotational semantics of a process, we need to refine the notion of solutions as follows.

Definition 8 (Solutions). Given a store constraint φ with variables in V ,

Table 4. Definition of store atoms: a_i is a message in Msg

$$\begin{aligned}
 out(a_i, x) &\leftarrow s_i(x+1) = s_i(x) + 1 \wedge \bigwedge_{j=1, j \neq i}^k s_j(x+1) = s_j(x) \\
 in(a_i, x) &\leftarrow s_i(x) \geq 1 \wedge s_i(x+1) = s_i(x) - 1 \wedge \bigwedge_{j=1, j \neq i}^k s_j(x+1) = s_j(x) \\
 inp(a_i, x) &\leftarrow s_i(x) \geq 1 \wedge s_i(x+1) = s_i(x) - 1 \wedge \bigwedge_{j=1, j \neq i}^k s_j(x+1) = s_j(x) \\
 \overline{inp}(a_i, x) &\leftarrow s_i(x) = 0 \wedge \bigwedge_{j=1}^k s_j(x+1) = s_j(x) \\
 rdp(a_i, x) &\leftarrow s_i(x) \geq 1 \wedge \bigwedge_{j=1}^k s_j(x+1) = s_j(x) \\
 \overline{rdp}(a_i, x) &\leftarrow s_i(x) = 0 \wedge \bigwedge_{j=1}^k s_j(x+1) = s_j(x)
 \end{aligned}$$

- a *partial solution* ν of φ is a map from V to \mathbb{Z} such that φ evaluates to true under some \mathcal{T}_{E+Z} -interpretation which extends ν in the natural way;
- a *solution* extends a partial solution with maps from the function symbols s_i to the functions $\overline{s}_i : \mathbb{Z} \rightarrow \mathbb{Z}$ for $i : 1, \dots, k$;
- a (partial) solution ν is *injective* for $U \subseteq V$ if $\nu(x) \neq \nu(y)$ for every $x, y \in U$ such that $x \neq y$;
- given a subset $U \subseteq V$ with cardinality m , a (partial) solution ν is *closed* for U if $\nu(x) \in [1, m]$ for any $x \in U$.

A C_{E+Z} constraint is satisfiable if it has a solution. The *store function* of a solution ν is defined as $s(t) = \langle \overline{s}_1(t), \dots, \overline{s}_k(t) \rangle$. Notice that $s(t)$ represents the content of the store at time t , i.e., the multiset in which a_i has $s_i(t)$ occurrences for $i : 1, \dots, k$. An injective solution associates distinct values to updates represented in a store constraint. A closed solution associates values from a closed interval. With a closed injective solution each variable in $U = \{x_1, \dots, x_k\}$ is assigned a distinct value in $1, \dots, k$. This notion will be used to consider sequences of a closed system in which events occur at time instants with no gaps between them.

Remark 1. It is important to notice that, given a store constraint φ and a subset U of its variables, the injective (closed) solutions of φ for U coincide with the solutions of the constraint $\varphi \wedge \bigwedge_{x,y \in U} x \neq y$ ($\varphi \wedge \bigwedge_{x \in U} 1 \leq x \leq |U|$).

4.1 Formal Definition of the Translation

The translation of a process term P with definitions in D to a CLP(C_{E+Z}) program is inductively defined via the functions \mathcal{T}_p , \mathcal{T}_d and \mathcal{T} . The function \mathcal{T}_p takes as input the process term P and a variable x , representing a time instant, and returns a CLP program $Prog$ and a goal G . The CLP program contains the clauses defining some new process constants that we introduce in order to represent the choice operator and the conditionals. The goal G is the translation of P where we interpret actions in terms of store constraints, parallel in terms of conjunction and process constants as predicate symbols taken from Π (and therefore not in Σ). The function \mathcal{T}_d translates process definitions in D into CLP(C_{E+Z}) clauses. Finally, the function \mathcal{T} , defined on top of \mathcal{T}_d and \mathcal{T}_p , is used to encode the closed process $\langle P, D \rangle$.

Definition 9 (Translation). Let \mathcal{V} be a denumerable set of variables, then the translation functions \mathcal{T}_p , \mathcal{T}_d and \mathcal{T} are formally defined as follows.

Halt: The process halt does not produce any constraint on the store. Thus, for any $x \in \mathcal{V}$ we define $\mathcal{T}_p(\text{halt}, x) = \langle \emptyset, \text{true} \rangle$.

In/Out: The precondition and effect of the action $\text{out}(a)$ performed at time x can be described via the store atom $\text{out}(a, x)$ of Table 4. Since the effect of $\text{out}(a)$ is visible at time $x + 1$, if y is the time starting from which actions in P may occur, we can enforce the sequentiality between the execution of $\text{out}(a)$ and of the actions in P by requiring that $x < y$. Thus, if $\mathcal{T}_p(P, y) = \langle \text{Prog}, G \rangle$ for some variable $y \in \mathcal{V}$, then we define

$$\mathcal{T}_p(\text{out}(a).P, x) = \langle \text{Prog}, \text{out}(a, x) \wedge x < y' \wedge G' \rangle$$

for any variable $x \in \mathcal{V}$, and renamings y', G' of y, G such that $x \notin \text{Var}(G') \cup \{y'\}$. The treatment of the term $\text{in}(a).P$ is analogous (predicate out is replaced by in).

Conditional: The preconditions and effects of the “if” branch of the conditional $\text{rdp}(a)?P_1 : P_2$ performed at time x can be described by using the store atom $\text{rdp}(a, x)$ in conjunction with the formula representing P_1 . Similarly, the store atom $\overline{\text{rdp}}(a, x)$ can be used to model the “else” branch. In order to describe the whole conditional construct we then use a new predicate symbol which models the choice point in terms of two mutually exclusive clauses, corresponding to the two different cases. Formally, if $\mathcal{T}_p(P_1, y_1) = \langle \text{Prog}_1, G_1 \rangle$ and $\mathcal{T}_p(P_2, y_2) = \langle \text{Prog}_2, G_2 \rangle$ for two variables $y_1, y_2 \in \mathcal{V}$, then we define

$$\begin{aligned} \mathcal{T}_p(\text{rdp}(a)?P_1 : P_2, x) &= \langle \text{Prog} \cup \text{Prog}_1 \cup \text{Prog}_2, p(x) \rangle \\ \text{Prog} &= \{p(u) \Leftarrow \text{rdp}(a, u) \wedge u < y'_1 \wedge G'_1, p(u) \Leftarrow \overline{\text{rdp}}(a, u) \wedge u < y'_2 \wedge G'_2\} \end{aligned}$$

for variables $x, u \in \mathcal{V}$, a new predicate symbol p , and renamings y'_1, y'_2, G'_1, G'_2 of y_1, y_2, G_1, G_2 such that $x, u \notin \text{Var}(G'_1) \cup \text{Var}(G'_2) \cup \{y'_1, y'_2\}$.

The treatment for the term $\text{inp}(a)?P_1 : P_2$ is analogous.

Choice: To model internal choice we use the CLP non-determinism in the selection of the clause to apply to a given goal. Thus, also in this case we introduce a new predicate symbol and we define it using two different CLP clauses, which correspond to the two branches of the choice construct. Formally, if $\mathcal{T}_p(P_1, y_1) = \langle \text{Prog}_1, G_1 \rangle$ and $\mathcal{T}_p(P_2, y_2) = \langle \text{Prog}_2, G_2 \rangle$ for $y_1, y_2 \in \mathcal{V}$, then

$$\begin{aligned} \mathcal{T}_p(P_1 + P_2, x) &= \langle \text{Prog} \cup \text{Prog}_1 \cup \text{Prog}_2, p(x) \rangle \\ \text{Prog} &= \{p(y_1) \Leftarrow G_1, p(y_2) \Leftarrow G_2\} \end{aligned}$$

for any $x \in \mathcal{V}$ and a new predicate symbol p . Notice that, differently from the case of the conditionals, here the two clauses in Prog are not mutually exclusive.

Parallel: The translation of parallel composition is more subtle. The only constraint that we can put on the set of events occurring in two distinct processes running in parallel is that they will occur after the whole system started its execution. Now, suppose that y_1 represent the time at which process P_1 starts,

y_2 the time at which process P_2 starts and assume that x is the starting point of $P_1 \parallel P_2$. Then the constraint $x \leq y_1 \wedge x \leq y_2$ must hold. Notice that the encoding that we use does not forbid solutions that map time variables associated to distinct actions to the same value. This might lead to illegal traces, i.e., traces where two different basic actions are performed on the store at the same time instant, which is not acceptable since we use an interleaving model for the parallel operator. Illegal traces can be ruled out by considering solutions that are *injective* (see Def. 8) for the set of variables associated to actions, thus ensuring that different variables assume distinct values (see Theorem 3). Formally, if $\mathcal{T}_p(P_1, y_1) = \langle \text{Prog}_1, G_1 \rangle$ and $\mathcal{T}_p(P_2, y_2) = \langle \text{Prog}_2, G_2 \rangle$ for $y_1, y_2 \in \mathcal{V}$, then

$$\mathcal{T}_p(P_1 \parallel P_2, x) = \langle \text{Prog}_1 \cup \text{Prog}_2, (x \leq y'_1 \wedge x \leq y'_2) \wedge G'_1 \wedge G'_2 \rangle,$$

for any variable $x \in \mathcal{V}$, and renamings y'_1, y'_2, G'_1, G'_2 of y_1, y_2, G_1, G_2 such that $\text{Var}(G'_1) \cap \text{Var}(G'_2) = \emptyset$, and $x \notin \text{Var}(G'_1) \cup \text{Var}(G'_2) \cup \{y'_1, y'_2\}$.

Constant: A process constant p occurring in a term can be viewed as the invocation of a process definition. In our translation this maps naturally to a goal denoting a call to a clause defining p . Formally, for any $x \in \mathcal{V}$ we define

$$\mathcal{T}_p(p, x) = \langle \emptyset, p(x) \rangle.$$

Definition: Given $p =_{\text{def}} P$ and $\mathcal{T}_p(P, x) = \langle \text{Prog}, G \rangle$ for $x \in \mathcal{V}$, we define

$$\mathcal{T}_d(p =_{\text{def}} P) = \text{Prog} \cup \{p(x) \leftarrow G\}.$$

Program: Now let $D = \{d_1, \dots, d_n\}$ be process definitions, $y \in \mathcal{V}$, and P be a process term such that $\mathcal{T}_p(P, x) = \langle \text{Prog}, G \rangle$ for some $x \in \mathcal{V}$. Then we define

$$\mathcal{T}(\langle P, D \rangle) = \langle \{\mathcal{T}_d(d_1, y), \dots, \mathcal{T}_d(d_n, y)\} \cup \text{Prog}, G \rangle.$$

Notice that the function \mathcal{T} introduces an arbitrary initial time variable x .

4.2 Properties of the Encoding

The translation of a process term into a $\text{CLP}(C_{E+Z})$ program allows us to reconstruct the denotational semantics of Def. 4 and the observables of Def. 2, by considering the answer constraint semantics of Def. 6. To make this claim more formal, it will be convenient to use the following terminology.

Given a (possibly instantiated) store constraint φ , we will use $A(\varphi)$ to denote the set of store atoms occurring in φ , and given a store atom $\alpha(t, x)$, we define $T(\alpha(a, t)) = t$ and $E(\alpha(a, t)) = \alpha(a)$. T and E are extended to sets, formulas, and sequences in the natural way. In particular, T applied to a store constraints φ returns the set of variables (time-stamps for an instantiated constraint) associated to the actions $E(\varphi)$. Furthermore, let ν be a partial solution of φ injective for $T(\varphi)$, and let $A(\nu(\varphi)) = \{A_1, \dots, A_n\}$, then

$$S_\nu(\varphi) = \{A_{i_1} \cdot A_{i_2} \cdot \dots \cdot A_{i_k} \mid T(A_{i_k}) \leq T(A_{i_{k+1}}) \text{ for } k : 1, \dots, n-1\}$$

We are now ready to state the adequacy of our encoding. The following theorem shows that the answer constraints of the $\text{CLP}(C_{E+Z})$ program associated with a closed process is an implicit representation of its denotational semantics.

Theorem 2. For any closed process $S = \langle P, D \rangle$ such that $T(S) = \langle \text{Prog}, G \rangle$, we have that $\mathcal{D}\llbracket S \rrbracket = \{E(s) \mid s \in S_\nu(\varphi), \varphi \in \mathcal{A}(\text{Prog}, G), \text{ and } \nu \text{ is a partial solution of } \varphi \text{ injective for } T(\varphi)\}$.

Now, given a solution of φ with store function s (see Section 4) from φ we can extract the history of updates by evaluating s on the time-stamps $T(\nu(\varphi)) = \{t_1 \leq \dots \leq t_k\}$ (recall that $s(t)$ is an alternative representation of a multiset):

$$O_\nu(\varphi) = \{\mathcal{M}_1 \cdot \dots \cdot \mathcal{M}_k \mid \mathcal{M}_i = s(t_i), \text{ for } i : 1, \dots, k\}$$

The following theorem shows that in order to extract the observables of a *terminating* process we need to consider solutions that are both injective and closed (see Def. 8). Indeed a closed solution assigns to time variables values taken from a closed interval whose cardinality corresponds to the number of possible actions of the original process term.

Theorem 3. For any closed process $S = \langle P, D \rangle$ such that $T(S) = \langle \text{Prog}, G \rangle$, we have that $\mathcal{O}_h(S) = \{s \mid s \in O_\nu(\varphi), \varphi \in \mathcal{A}(\text{Prog}, G), \text{ and } \nu \text{ is a solution of } \varphi \text{ injective and closed for } T(\varphi)\}$.

5 Conclusions

In this paper we have shown how to use CLP to obtain a constraint-based symbolic representation of the set of finite computations of asynchronous processes communicating via a common store. Theorem 2 and 3 are at the basis of a possible compositional verification method for this computational model. Indeed CLP enjoys the *and-compositionality* property: an answer constraint for $G_1 \wedge G_2$ can be obtained by conjoining the answer constraints of G_1 and G_2 [10]. And-compositionality can be exploited for a compositional analysis of composed systems as follows. Suppose that the translation of processes P_1 and P_2 returns the goal G_1 and G_2 and a CLP program $\text{Prog} = \text{Prog}_1 \cup \text{Prog}_2$. Since the combination of P_1 and P_2 can be expressed as a constraint $G_1 \wedge G_2 \wedge \psi$ (ψ depends on the composition operator) we can use and-compositionality to separately analyze G_1 and G_2 and then join the results. Indeed, from Theorem 2, we know that answer constraints characterize open traces of processes that can be further combined with other traces. Furthermore, Theorem 3 can be exploited to combine CLP and a C_{E+Z} solver for checking properties of observables. To illustrate, let us consider a process P encoded via the CLP program Prog and goal G and suppose we are interested in checking if a given store can be reached starting from an initial one. We first notice that we can encode a configuration \mathcal{M} of the store at time t using the constraint $s_1(t) = n_1, \dots, s_k(t) = n_k$ where n_i is the number of occurrences of message a_i in \mathcal{M} for $i : 1, \dots, k$. Reachability can be reduced then constraint computing and solving as follows. We first exploit the CLP component to compute an answer constraint φ of G (by exploiting

and-compositionality this can be done separately for the subcomponents). Suppose now that the time-stamps of actions in φ are $T(\varphi) = \{x_1, \dots, x_m\}$, where x_1 is the initial point of the evaluation of G . Furthermore, let ψ_0 be a constraint expressing initial condition on the store at time x_1 , and ψ_1 be a constraint expressing conditions on the final store (i.e. at a time greater or equal than x_1, \dots, x_m). By Theorem 3, the existence of an injective and closed solution for $\psi_0 \wedge \varphi \wedge \psi_1$ can be used as sufficient condition for the original reachability question. (Notice that to obtain a complete test we need to generate all answer constraints.) From remark 1 and from the encoding of store atoms in C_{E+Z} of Fig. 4 the latter problem can be reduced to a satisfiability problem of a C_{E+Z} formula. This kind of reasoning can be viewed as an extension of the bounded model checking paradigm [6] in which the encoding of a bounded execution of a system is constructed in a compositional way. We are currently working on a prototype implementing this verification method for our process algebra.

Abstract. *Filtering* is a standard technique for fast approximate string matching in practice. In filtering, a quick first step is used to rule out almost all positions of a text as possible starting positions for a pattern. Typically this step consists of finding the exact matches of small parts of the pattern. In the followup step, a slow method is used to verify or eliminate each remaining position. The running time of such a method depends largely on the quality of the filtering step, as measured by its false positives rate. The quality of such a method depends on the number of true matches that it misses, that is, on its false negative rate.

A *spaced seed* is a recently introduced type of filter pattern that allows gaps (i.e. don't cares) in the small sub-pattern to be searched for. Spaced seeds promise to yield a much lower false positives rate, and thus have been extensively studied, though heretofore only heuristically or statistically.

In this paper, we show how to optimally design spaced seeds that yield no false negatives.

1 Introduction

Given a pattern string P of length m , a text string T of length ℓ , and an integer k , the *approximate pattern matching problem* is to find all substrings of T whose edit distance or Hamming distance to P is at most k .

The basic idea employed in many approximate pattern matching algorithms [17, 8] and commonly used software tools such as BLAST [1] is *filtering* based on the use of the pigeonhole principle: Let P and S be two strings with edit distance or Hamming distance at most k . Then P and S must have identical substrings (contiguous blocks) whose sizes are at least $(m - k)/(k + 1)$. This simple observation can be used to perform efficient approximate pattern matching through the following approach. (i) *Anchor finding*: consider each substring of P of size $b \leq (m - k)/(k + 1)$ and find all of its exact occurrences in T . (ii) *Anchor verification*: verify whether each initial *exact match* extends to a complete *approximate match*, through the use of (a localized) dynamic program or any other appropriate method.

When T is available off-line, the anchor finding step above can be implemented very efficiently: (i) build a compact trie of all substrings in T of size b and (ii) search each substring in P of size b on the compact trie. By the use of *suffix links*, the compact trie can be built in $O(\ell)$ time and the pattern processing can be completed in $O(m)$ time, both independent of the size of b .

The running time of the anchor verification step depends on the specific method for extending an initial exact match and the value of b : As b increases, the number of *false positives* is expected to decrease, but if $b > (m - k)/(k + 1)$ some actual occurrences of the pattern may be missed, yielding *false negatives*.

In the remainder of this discussion we will focus on filtering processes with no false negatives, except as noted. Under this constraint, much of the literature on pattern matching via filtering focuses on improving the specific method for verifying anchors. The fastest approximate pattern matching algorithms based on filtering have a running time of $O(\ell(1 + \frac{\text{poly } k \cdot \text{polylog } \ell}{m}))$ and thus are especially powerful for “small” values of k [17, 8, 2]. In general, pattern matching under edit distance can be solved in time $O(\ell k)$ [13], whereas pattern matching under Hamming distance can be solved in time $O(\ell\sqrt{k} \log k)$ [2].

1.1 The Performance of the Filtering Approach

Although the filtering approach does not always speed up pattern matching, it is usually quite efficient on high-entropy texts, such as those in which each character is drawn uniformly at random from the input alphabet (of size σ). Given a pattern P , suppose that the text string T is a concatenation of (1) *actual matches of P* : substrings of size m whose Hamming distance to P is at most k ; (2) *high entropy text*: long stretches of characters, determined uniform i.i.d. from the input alphabet. On this T and P we can estimate the performance of the anchor verification step and thus the filtering approach in general as follows. Let the number of actual matches be $\#occ$. each such match will be identified as an anchor due to the pigeonhole principle. The expected number of false positives, which in this case are substrings from the high entropy text that will be identified as anchors, can be calculated as follows. The probability that a substring $T[i : i + m - 1]$ is identified as an anchor, i.e. has a block of size b which exactly matches its corresponding block in P , is $\leq m\sigma^{-b}$. The expected number of anchors from the high entropy text is thus $\leq \ell \cdot m \cdot \sigma^{-b}$. This implies that the running time of the filtering approach is proportional to $\#occ + \ell m\sigma^{-b}$ as well as the time required to verify a given anchor.

The above estimate of the performance of the filtering approach is determined mostly by problem specific parameters, $\#occ, \ell, m$ or the time for verifying a given anchor, none of which can be changed. There is only one variable, b , that can be determined by the filter designer. Unfortunately, in order to avoid false negatives b must be $\leq (m - k)/(k + 1)$.

It is possible to relax the above constraint on b by performing filtering through the use of non-contiguous blocks, namely substrings with a number of *gaps* (i.e. *don't care* symbols). To understand why searching with blocks having *don't care* symbols can help, consider the case when $k = 1$, that is, we allow one mismatch.

When contiguous blocks are used, the maximum value of b is $(m - 1)/2$. Now consider using a block of size $b + 1$ with one don't care symbol in the center position. How large can b be while guaranteeing that each substring of T with a single mismatching character with P will be found? No matter where the mismatch occurs, we are guaranteed that such a substring can be found even when $b = \lfloor (2m - 1)/3 \rfloor$. This is a substantial improvement over ungapped search, where $b \leq (m - 1)/2$, reducing the time spent on false positives by a factor of $\approx \sigma^{m/6}$.

1.2 Previous Work

The idea of using gapped filters (which are called *spaced seeds*) was introduced in [7] and the problem of designing the *best* possible seed was first posed in [6] without providing any theoretical bound on the quality of the seed design. Available literature on designing “optimal” spaced seeds relies on experimental/statistical techniques [16, 6, 15, 4, 5, 3, 12], or assumes that the input is generated by a random data model [10]. More recent work on the use of multiple spaced seeds are also experimental in nature [11, 19, 18].

Some of the above approaches for designing spaced seeds allow false negatives. However, it is desirable to construct seeds that guarantee no false negatives, i.e., that finds *all* matches of a any pattern P of length m under Hamming distance k . Alternatively, one can want to find all matches of any pattern P' of length $m' \geq m$ within error rate k/m . Unfortunately this *combinatorial seed design* problem has remained largely open (see, for example [6]) since the introduction of spaced seeds in early nineties [7]. In fact, it was proven in [14] that for a specific pattern and a set of substrings that are no more than Hamming distance k from the pattern, the combinatorial seed design problem is NP-hard.

1.3 Our Contributions

In this paper we show how to solve the *general* combinatorial seed design problem optimally. That is, we give worst-case bounds for the combinatorial seed design problem for all possible pattern/text pairs, whereas a particular pattern and text may admit a “better” seed.

Our specific results are as follows. The combinatorial seed design problem has four parameters: minimum pattern length m , the number of “solid” symbols in the seed b , the number of “don't care” symbols in the seed g , and the maximum number of allowed errors between the pattern and its match k . We denote by n the seed length, namely $n = g + b$. Our method can optimize any one of the parameters, given the values of the other three parameters. In this paper we focus on two variants of this optimization problem; solutions to the other variants can be derived from these without much difficulty.

1. Given m, n, g , we show how to maximize the number of errors k ; i.e. we show how to compute the *maximum possible number of errors* k and the associated spaced seed (with length n and g don't cares) which guarantees that *all* matches of a pattern of length m within Hamming distance k are

found. This spaced seed also maximizes the error rate k'/m' for the problem of finding all matches of any given pattern P' whose length is $m' \geq m$.

2. More interestingly, given the number of errors k and minimum pattern length m , we show how to compute the largest possible b such that $b + g = n \leq m$, and the associated seed that guarantees no false negatives. Clearly this seed minimizes the time spent on false positives and thus maximizes the performance of the filtering approach for any given pattern of size m with k errors. This spaced seed also provides the maximum possible b for the problem of finding all matches of any pattern P' of length $m' \geq m$ within error rate k/m .

Our final result is on the design of multiple seeds: for any fixed pattern length m and number of errors k (alternatively minimum pattern length $m \leq m'$ and error rate k/m), we show that by the use of $s \geq m^{1/k}$ seeds one can guarantee to improve on the maximum size of b achievable by a single seed.

2 Preliminaries

For the rest of the paper, the letters A and B will be used to denote strings over the alphabet $\{0, 1\}$. For a string A and an integer l , A^l denotes the concatenation of A l times. Let $\text{ONES}(A)$ be the number ones in the string A . $A[i : j]$ denotes the substring of A that starts at the i -th character of A and ends at the j -th character.

For two strings A and B of equal lengths, we write $A \geq B$ if $A[i] \geq B[i]$ for $i = 1, \dots, |A|$. Note that this differs from lexicographic ordering. We say that a string A covers a string B if there is a substring B' of B of length $|A|$ such that $A \geq B'$. In words, A covers B if we can align A against B such that every character 1 in the aligned region of B , is aligned against a character 1 in A . We will say that such an alignment covers B .

The connection between the above definitions and the seed design problem is as follows: a seed of length n will be represented by a string A of length n such that $A[i] = 1$ if the i -th symbol of the seed is a don't care, and $A[i] = 0$ otherwise. Given a pattern string P and a substring T' of some text T of length m , create a string B of length m , where $B[i] = 0$ if $P[i] = T'[i]$, and $B[i] = 1$ otherwise. Then, the filtering algorithm using seed A will find a match between P and T' if and only if A covers B .

We define $k(n, g, m)$ to be the maximum k such that there is a string A of length n containing g ones that covers every string B of length m with at most k ones. In other words, for a seed length of n with g don't cares, $k(n, g, m)$ is the maximum possible number of errors between any P and any substring T' of length m that is guaranteed to be detected by the best possible seed. Also, $b(k, m)$ is the maximum b such that there is a string A with b zeros that covers every string B of length m with at most k ones. In other words, given the maximum number of errors k , $b(k, m)$ is the maximum number of solid symbols one can have in a seed so that a match between any P and T' with k errors could be detected by the best possible seed.

In the next sections we will give upper and lower bounds on $k(n, g, m)$ and $b(k, m)$ for various values of parameters, effectively solving the combinatorial seed design problem.

3 Maximizing k

We first present our results on maximizing the number of errors k when the other parameters n, g and m are fixed. Our results also extend to the problem of maximizing the error rate k'/m' for any pattern P' of length $m' \geq m$ with fixed n and g .

3.1 Constant g

Theorem 1. *For every fixed g , $k(n, g, m) = (2 - \frac{1}{g+1}) \cdot \frac{m}{n} \pm O(\max(1, \frac{m}{n^2}))$.*

Proof. We first show a lower bound on $k(n, g, m)$. The main idea of the proof is that if B contains “few” 1 characters, then using some form of the pigeonhole principle, there will be an “isolated” 1 in B . Thus, we can align A over B such that the isolated one in B is aligned against some one in A , and there are no more ones in the aligned region of B .

Suppose that n is divisible by $2g + 1$. Let A be the string of length n that contains ones in positions $\frac{n}{2g+1}, 2 \cdot \frac{n}{2g+1}, \dots, g \cdot \frac{n}{2g+1}$, and zeros elsewhere. We will show that A covers any string B of length m with at most $(2 - \frac{1}{g+1}) \cdot \frac{m}{n} - 2$ ones. Let B such a string, and denote by y_1, \dots, y_f the indices in which the character 1 appears in B .

If $y_1 > n$, then $A \geq B[1 : n] = 0^n$, and we are done. In the following, we assume that $y_1 \leq n$. Let $L = \frac{g+1}{2g+1}n, x_1 = y_1 - L, x_i = y_i - y_{i-1}$ for $i = 2, \dots, f$, and $x_{f+1} = m + 1 - y_f$. We note that the reason x_1 is defined as above rather than $x_1 = y_1$ is technical, and will be revealed in the proof of Lemma 1. The average of the numbers x_1, \dots, x_{f+1} is

$$\frac{\sum_{i=1}^{f+1} x_i}{f + 1} = \frac{m - \frac{g+1}{2g+1}n + 1}{f + 1} > \frac{m - \frac{g+1}{2g+1}n}{\frac{2g+1}{g+1} \cdot \frac{m}{n} - 1} \geq \frac{g + 1}{2g + 1}n = L.$$

Lemma 1. *There is an index $i > 1$ such that $x_i > L$ and $x_i + x_{i-1} > 2L$.*

Proof. Suppose conversely that for every index $j > 1$ such that $x_j > L$, we have that $x_{j-1} + x_j \leq 2L$. We say in this case that x_{j-1} and x_j are *matched*. We have that $x_1 \leq L$ because otherwise, $y_1 = x_1 + L > 2L > n$, contradicting the assumption that $y_1 \leq n$. Suppose that there are r pairs of matched x_j -s. From the above, we have that the sum of the matched x_j -s is at most $r \cdot 2L$, and the sum of the unmatched x_j -s is at most $(f + 1 - 2r) \cdot L$. Therefore, $\sum_{j=1}^{f+1} x_j \leq (f + 1)L$, a contradiction. \square

By Lemma 1, the string $B' = B[y_i - 2L : y_i - 1]$ has at most one occurrence of the character one, which may appear at position at most L . There are $2L - n + 1 =$

$\frac{1}{2g+1}n + 1$ ways to align A against B' , and at least one of these alignments cover B' . More precisely, if B' does not contain the character 1, then every alignment of A and B' covers B' . Otherwise, let j be the index such that $B'[j] = 1$, and let $s \leq g$ be the integer for which $\frac{s}{2g+1}n < j \leq \frac{s+1}{2g+1}n$. For $s = 0$, the alignment of A and B' in which $A[1]$ is aligned with $B'[j + 1]$ covers B' . For $s > 1$, the alignment of A' and B in which the s -th one in A is aligned against $B'[j]$ covers B' .

For every n which is not divisible by $2g + 1$, let A' be the string constructed above for the length $n' = (2g + 1)\lceil n/(2g + 1)\rceil$, and let A be the prefix of length n of A' (if A contains less than g ones, arbitrarily change some zeros into ones). A covers every string that is covered by A' . Therefore, A covers any string B of length m with at most $(2 - \frac{1}{g+1}) \cdot \frac{m}{n'} - 2$ ones. Thus,

$$\begin{aligned} k(n, g, m) &\geq \left(2 - \frac{1}{g + 1}\right) \cdot \frac{m}{n'} - 2 \geq \left(2 - \frac{1}{g + 1}\right) \cdot \frac{m}{n + 2g} - 2 \\ &= \left(2 - \frac{1}{g + 1}\right) \cdot \frac{m}{n} - \frac{(2 - \frac{1}{2g+1})2g \cdot m}{n(n + 2g)} - 2. \end{aligned}$$

Upper bound. We now give an upper bound on $k(n, g, m)$. Let A be some string of length n with g ones. We will construct strings B_0, \dots, B_g that are not covered by A , such that at least one of these strings has at most $(2 - \frac{1}{g+1}) \cdot \frac{m}{n} + O(\max(1, \frac{m}{n^2}))$ ones.

Let y_1, \dots, y_g be the indices of the ones in A . Let $Y = \{y_j - y_i : 1 \leq i < j \leq g\}$, and let Z be the multi-set $\{\max(y_i - 1, n - y_i) : i = 1, \dots, g\}$. Denote the elements of Z in a non-decreasing order by z_1, \dots, z_g , and denote $z_{g+1} = n$. Define $d_i = \max(\{0, \dots, z_{i+1}\} \setminus Y)$ for $i = 0, \dots, g$, and $d'_i = \max(\{0, \dots, n - 1 - z_i\} \setminus Y)$ for $i = 1, \dots, g$.

The strings B_0, \dots, B_g are constructed as follows: Let B_0 be the prefix of length m of the string $(0^{d_0-1}1)^m$. The string B_i is the prefix of length m of $(0^{d_i-1}10^{d'_i-1}1)^m$. If either $d_i = 0$ or $d'_i = 0$ for some i , we say that B_i is undefined.

We now show that A does not cover the defined strings in B_0, \dots, B_g . To see that A does not cover B_0 (if it is defined), suppose conversely that there is an alignment of A with B_0 that covers B_0 . Since $d_0 < n$, the aligned region of B_0 contains one in some position j , and this one must be aligned with a one in A . Suppose that $B_0[j]$ is aligned with $A[y_i]$. We can break the string A into two parts: the characters to the left of y_i , and the characters to the right of y_i , whose lengths are $y_i - 1$ and $n - y_i$, respectively. By the definition of z_1 , it follows that the size of the larger part is at least z_1 . W.l.o.g. assume that the larger part is the part of the characters to the right of y_i . Since $d_0 \leq z_1$, the aligned region of B_0 contains another one at position $j + d_0$. From the definitions of d_0 and Y , this position must be aligned with a zero in A , contradicting the assumption that the alignment covers B_0 .

Now, suppose that there is an alignment of A with B_i that covers B_i . The aligned region of B_i must contain one in some position j , which is aligned with $A[y_i]$ for some i . We again break the string A into two parts, and we have that

either the larger part is of size at least z_{l+1} , or the smaller part is of size at most $n - 1 - z_l$. From the definition of d_l, d'_l , and Y , it follows that there is a one in the aligned region of B_l that is aligned against a zero in A , a contradiction.

As A doesn't cover the strings B_0, \dots, B_g , we obtain that $k(n, g, m) < \min\{\text{ONES}(B_i) : i = 0, \dots, g\}$. If $z_1 \geq \frac{g+1}{2g+1}n$, then $d_0 \geq \frac{g+1}{2g+1}n - |Y| \geq \frac{g+1}{2g+1}n - \frac{g^2}{2}$. For large enough n , $d_0 > 0$, so B_0 is defined and

$$\text{ONES}(B_0) \leq \frac{m}{d_0} \leq \frac{m}{\frac{g+1}{2g+1}n - \frac{g^2}{2}} = \frac{2g+1}{g+1} \cdot \frac{m}{n} + O\left(\frac{m}{n^2}\right).$$

Otherwise $z_{g+1} - z_1 > \frac{g}{2g+1}n$, so there is an index $i \geq 1$ such that $z_{i+1} - z_i > \frac{1}{2g+1}n$. Thus, $d'_i \geq n - 1 - z_i - |Y| \geq z_{i+1} - z_i - \frac{g^2}{2} > \frac{1}{2g+1}n - \frac{g^2}{2}$, so for large n , $d'_i > 0$ (and also $d_i > 0$). Moreover, $d_i + d'_i \geq n - 1 + z_{i+1} - z_i - 2|Y| \geq n + \frac{1}{2g+1}n - g^2$, and

$$\text{ONES}(B_i) \leq 2 \left\lceil \frac{m}{d_i + d'_i} \right\rceil \leq \frac{2m}{n + \frac{1}{2g+1}n - g^2} + 2 = \frac{2g+1}{g+1} \cdot \frac{m}{n} + O\left(\max\left(1, \frac{m}{n^2}\right)\right). \quad \square$$

3.2 Non-constant g

Theorem 2. *For every fixed integers $r \geq 2$ and $l \geq r$, $k(n, (1+o(1))l \cdot n^{1-1/r}, m) \geq (r+1 - \frac{r}{l-r+2}) \cdot \frac{m}{n} - O(\max(1, \frac{m}{n^{1+1/r}}))$.*

Proof. Recall that in the construction of Theorem 1, we were able to find an alignment of A and B such that the aligned region of B contained the character 1 at most once, and this character was aligned against one of the ones in A . Here, we will find an alignment that contains at most r ones in the aligned region of B , which will be aligned against ones in A .

We first prove the theorem for the case $r = 2$. Suppose that \sqrt{n} is integer, and that \sqrt{n} is divisible by $3l - 2$. Let A be a string that consists of \sqrt{n} blocks of size \sqrt{n} . The blocks numbered $\frac{2i}{3l-2}\sqrt{n}$ for $i = 1, \dots, l - 1$ contain only ones. The other blocks contain $\sqrt{n} - 1$ zeros, and a one at the end.

We will show that A covers any string B of length m with

$$\text{ONES}(B) \leq \left(3 - \frac{2}{l}\right) \cdot \frac{m}{n} - \frac{m\sqrt{n}}{\frac{l}{3l-2}n(\frac{l}{3l-2}n + \sqrt{n})} - 5.$$

Let B such a string, and denote by y_1, \dots, y_f the indices of the ones in B .

If $y_2 \geq n + \sqrt{n}$, then the string $B[1 : n + \sqrt{n} - 1]$ contains at most one occurrence of the character 1, at position y_1 . If $y_1 > n$ we are done. Otherwise, consider the alignment of A against B in which $A[1]$ is aligned against $B[1]$. Let d be the distance from position y_1 to the nearest occurrence of 1 in A to the left of y_1 ($d = 0$ if $A[y_1] = 1$), and $d = y_1$ if there is no such occurrence. From the construction of A , $d < \sqrt{n}$. Therefore, if we move A d positions to the right along B , the 1 at position y_1 will either be aligned with a 1 of B (if $d \neq y_1$), or

will be outside the aligned region of B (if $d = y_1$). Moreover, the aligned region of B will contain no more ones (as $y_2 \geq n + \sqrt{n}$). Therefore, this alignment covers B . For the rest of the proof we assume that $y_2 < n + \sqrt{n}$.

Let $L = \frac{l}{3l-2}n$, $x_1 = y_1 - 2L$, $x_2 = y_2 - y_1 - 2L$, $x_i = y_i - y_{i-1}$ for $i = 3, \dots, f$, and $x_{f+1} = m + 1 - y_f$. We claim that there is an index $i > 2$ such that $x_i > L + \sqrt{n}$ and $x_i + x_{i-1} + x_{i-2} > 3L + 3\sqrt{n}$. The proof of this claim is similar to the proof of Lemma 1.

If $x_i > n$, then A covers B . Otherwise, let $B' = B[y_i - 3L - 3\sqrt{n} : y_i - 1]$. B' contains at most two ones, where the rightmost one is at position at most $2L + 2\sqrt{n}$. W.l.o.g. assume that B' contains two ones, at positions j and j' , with $j' < j$. Suppose that $j > \frac{2}{3l-2}n + 2\sqrt{n}$ (the case $j \leq \frac{2}{3l-2}n + 2\sqrt{n}$ is similar, and we omit its proof). Let $s \leq l - 1$ be the integer such that $\frac{2s}{3l-2}n + 2\sqrt{n} < j \leq \frac{2(s+1)}{3l-2}n + 2\sqrt{n}$.

Consider an alignment of A and B' in which $B'[j]$ is aligned against $A[\frac{2s}{3l-2}n]$. Note that $A[\frac{2s}{3l-2}n]$ is the last character of block number $\frac{2s}{3l-2}\sqrt{n}$ in A . If $B'[j']$ is not in the aligned region, or it is aligned against a 1 in A then we are done. Otherwise, denote by $i = j' + \frac{2s}{3l-2}n - j$ the position in A which is aligned against $B'[j']$. Let d be the distance from position i to the nearest occurrence of 1 in A to the left of i , and $d = i$ if there is no such occurrence. Since $d < \sqrt{n}$, by moving A d positions to the right, we obtain an alignment that covers B' .

The case when \sqrt{n} is not integer, or when \sqrt{n} is not divisible by $3l - 2$, is handled in the same way as in Theorem 1: We build a string A' of length n' as described above, where n' is the minimal integer greater than n such that $\sqrt{n'}$ is an integer divisible by $3l - 2$, and we take A to be the prefix of length n of A' .

We now deal with the case of $r > 2$. If $n^{1/r}$ is an integer divisible by $(r+1)(l-r+1) + 1$, then we build the string A as follows: We begin by taking $A = 0^n$. We then partition A into blocks of different levels. Level i ($i = 0, \dots, r - 1$) consists of $n^{1-i/r}$ blocks of size $n^{i/r}$ each. For every $i = 0, \dots, r - 2$, and every j which is divisible by $n^{1/r}$, we change block number j in level i to consists of all ones. Furthermore, for $j = 1, \dots, l - r + 1$, we change block number $j \cdot \frac{l-r+2}{(r+1)(l-r+1)+1} \cdot n^{1/r}$ in level $r - 1$ to consists of all ones. The blocks that were changed are called the *ones blocks*.

For every string B of length m with

$$\text{ONES}(B) \leq (r + 1 - \frac{r}{l - r + 2}) \cdot \frac{m}{n} - O(\max(1, \frac{m}{n^{1+1/r}})),$$

we have that either there is a substring B' of B of length $(1 + \frac{r}{(r+1)(l-r+1)+1})n + o(n)$ that contains at most r ones, or the prefix of B of length $n + O(n^{1-1/r})$ contains at most $r - 1$ ones. We describe below the proof for the former case (the proof for the latter case is similar). Suppose w.l.o.g. that B' contains exactly r ones. We create an alignment of A and B that covers B as follows: First, we align the rightmost one in B' with the rightmost character of the appropriate ones block of level $r - 1$. Then, for $i = 2, \dots, r$, we move A to the right, until the i -th one from the right in B' is either aligned against the rightmost character of some ones block of level $r - i$, or it is outside the aligned region. By our construction,

the movement of A is no more than $n^{1-(i-1)/r} - 1$ positions. Moreover, during the movements of A the following invariant is kept: For every $j \leq i - 1$, after the i -th movement, the j -th one from the right in B' is aligned against a character of some ones block of level j' , where $r - i - 1 \leq j' \leq r - j$. In particular, at the end, all the ones in B' are aligned against ones in A , and therefore A covers B .

The case when $n^{1/r}$ is not an integer, or when $n^{1/r}$ is not divisible by $(r + 1)(l - r + 1) + 1$, is handled the same as before. □

The following theorem gives an upper bound that matches the lower bound in Theorem 2 (we omit the proof due to lack of space).

Theorem 3. *For every integer r , if $g \leq n^{1-1/r}$ then $k(n, g, m) \leq r \cdot \frac{m}{n} + O(1)$.*

4 Maximizing b

We now focus on the problem of maximizing b , the number of solid symbols in a seed, given the number of errors k and the pattern length m . This result also provides the maximum b for the problem of finding all matches of any pattern P' of size $m' \geq m$ within error rate $k'/m' = k/m$.

Theorem 4. *For every $k < \frac{1}{2} \log m$,*

$$b(k, m) \geq \begin{cases} m - O(km^{1-1/(k+1)}) & \text{if } k < \log \log m \\ m - O(m^{1-1/(k+1)}) & \text{if } k \geq \log \log m \end{cases}$$

and $b(k, m) \leq m - \Omega(m^{1-1/(k+1)})$.

Proof. We begin with showing the lower bound on $b(k, m)$. Let $s = \lfloor m^{1/(k+1)} \rfloor$. We construct a string A of length $n = m - 2 \sum_{i=1}^k s^i$ by dividing it into blocks in k levels, similarly to Theorem 2: The i -th level of blocks ($i = 0, \dots, k - 1$) consists of blocks of size s^i each (the last $m \bmod s^i$ characters of A do not belong to a level i block). For every $i \leq k - 1$ and every j which is divisible by s , we make block number j in level i a ones block.

We need to show that A covers every string B of length m with k ones. Let B be such string, and let y_1, \dots, y_k be the indices in which the character 1 appears in B . Let $y_{k+1} = m + 1$. If $y_{i+1} - y_i \leq 2s^i$ for all $i \leq k$ then we have that $y_1 \geq m + 1 - \sum_{i=1}^k 2s^i = n + 1$. Therefore $B[1 : n] = 0^n$, and A covers B . Otherwise, let j be the maximum index such that $y_{j+1} - y_j > 2s^j$. Note that from the maximality of j , $y_{j+1} = m + 1 - \sum_{i=j+1}^k (y_{i+1} - y_i) \geq m + 1 - \sum_{i=j+1}^k 2s^i$, so $y_{j+1} - n > 2s^j$.

We align A over B such that $A[n]$ is aligned with $B[\max(n, y_j)]$. Then, for $i = j, j - 1, \dots, 1$, we move A to the right until $B[y_i]$ is against the rightmost character of some level $i - 1$ ones block in A . The total movement of A is at most $\sum_{i=1}^j s_j \leq 2s^j < y_{j+1} - \max(n, y_j)$, and therefore at the end of this process the alignment covers B .

We therefore have that $b(k, m) \geq n - g$, where g is the number of ones in B . The lower bound for $k < \log \log m$ follows from the fact that $g = O(km^{1-1/(k+1)})$.

Now, suppose that $k \geq \log \log m$. We randomly construct a string A of length $n = m - \lfloor m^{1-1/(k+1)} \rfloor$: Each character of A is 1 with probability $p = 100/m^{1/(k+1)}$, and 0 otherwise, where all the choices are independent. By Markov's inequality, with probability at least $1/2$, the number of ones in A is at most $2pn = O(m^{1-1/(k+1)})$. We will show that with probability at least $2/3$, A covers every string of length m with k ones. Therefore, there exists a string of length n with $O(m^{1-1/(k+1)})$ ones that covers every string of length m with k ones, and the lower bound follows.

Let B be some string of length m with k ones at positions y_1, \dots, y_k . There is a set $X \subseteq \{0, \dots, m-n\}$ of size at least $(m-n)/k^2$ such that for every $x, x' \in X$, there are no indices i and j such that $y_i + x = y_j + x'$ (Such a set X can be built by starting from $X = \emptyset$ and $X' = \{0, \dots, m-n\}$ and moving elements from X' to X . Each element added to X rules out at most $k(k-1)$ elements in X' , and therefore $|X| \geq (m-n+1)/(k(k-1)+1) > (m-n)/k^2$).

For every $x \in X$, the probability that the alignment that aligns $A[1]$ with $B[1+x]$ does not cover B is at most $1 - p^k$ (the probability is less than $1 - p^k$ if some of the ones of B are outside the aligned region). From the definition of X , the events above are independent, so the probability that A does not cover B is at most $(1 - p^k)^{|X|}$. Using the union bound we obtain that the probability that there is a string B that is not covered by A is at most

$$\binom{m}{k} (1 - p^k)^{(m-n)/k^2} \leq m^k e^{-p m^{1-1/(k+1)}/k^2} < \frac{1}{3}.$$

Upper bound. Denote $M = \lceil \frac{1}{2} m^{1-1/(k+1)} \rceil$. Let A be a string with b zeros and g ones, and suppose that $b \geq m - M + 1$. We will show that there is a string B of length m with k ones that is not covered by A . Clearly, $g \leq m - b \leq M - 1$.

Define $I_i = \{(i-1)M + 1, \dots, iM\}$ for $i = 1, \dots, 2m^{1/(k+1)} - 1$. Let Y be the set of all k -tuples (j, i_1, \dots, i_{k-1}) such that (1) $j \leq 2m^{1/(k+1)} - 1$ and $M + 1 \leq i_1 < \dots < i_{k-1} \leq jM$, and (2) there is an index $x \in I_j$ such that $A[x] = A[x - i_1] = \dots = A[x - i_{k-1}] = 1$. We have that

$$|Y| \leq \binom{g}{k} < \binom{M}{k} < \frac{\binom{m-2M}{k}}{M}.$$

Since the number of k -tuples that satisfy (1) above is at least $\binom{m-2M}{k}/M$, we have that there is a k -tuple (j, i_1, \dots, i_{k-1}) that satisfies (1) but does not satisfy (2). We now construct a string B of length m that contains ones in positions $jM, jM - i_1, \dots, jM - i_{k-1}$ and zeros elsewhere. If A covers B , then consider some alignment of A and B that covers B , and suppose that $A[1]$ is aligned with $B[y]$. Since the length of A is at least $b \geq m - M + 1$, we have that $y \leq M$. Therefore, $B[jM]$ is aligned with $A[x]$ for some $x \in I_j$. It follows that $(j, i_1, \dots, i_{k-1}) \in Y$, a contradiction. Therefore, A does not cover B , and the upper bound follows. \square

Theorem 5. For every $k \geq \frac{1}{2} \log m$, $b(k, m) = \Omega(\frac{m}{k} \log \frac{m}{k})$ and $b(k, m) = O(\frac{m}{k} \log m)$.

Proof. The lower bound is trivial if $k = \Omega(m)$, so assume that $k < \frac{m}{10}$. By Theorem 4, there is a string A of length $n = \frac{1}{2} \cdot \frac{m}{k} \log \frac{m}{k}$ that contains $b = \Theta(n)$ ones and covers every string of length $2n$ with at most $\log n$ ones. If B is a string of length m with at most k ones, then by the pigeon-hole principle, there is a substring B' of B of length $2n$ that has at most $k \cdot \frac{2n}{m} = \log \frac{m}{k} \leq \log n$ ones, and therefore A covers B' . Thus, A covers B .

Upper bound. Suppose that A is a string of length n with $b \geq \frac{m}{k} \log m$ zeros. Let z_1, \dots, z_b be the positions of the zeros in A . Construct a collection of sets S_1, \dots, S_m , where $S_x = \{y \in \{0, \dots, m - n\} : \exists j \text{ s.t. } z_j + y = x\}$. For every $y = 0, \dots, m - n$, there are b sets among S_1, \dots, S_m that contain y . Therefore, there is a set cover of $\{0, \dots, m - n\}$ using $l \leq \log(m - n + 1) / \log(1 / (1 - b/m))$ sets from S_1, \dots, S_m [9], namely, there are indices x_1, \dots, x_l such that $\cup_{i=1}^l S_{x_i} = \{0, \dots, m - n\}$. Now, let B be a string of length m that contains ones in positions x_1, \dots, x_l and zeros elsewhere. If we align A and B , where $A[1]$ is aligned with $B[1 + y]$ for some $0 \leq y \leq m - n$, then there is an index x_i such that $y \in S_{x_i}$, that is, there is an index j such that $z_j + y = x_i$. This implies that the character $A[z_j] = 0$ is aligned against $B[x_i] = 1$. Therefore, A doesn't cover B . The number of ones in B is at most

$$\frac{\log(m - n + 1)}{\log \frac{1}{1 - b/m}} \leq \frac{m}{b} \cdot \log m \leq k,$$

and the upper bound follows. □

4.1 Multiple Seeds

To model multiple seeds, we define that a set of strings $\{A_1, \dots, A_s\}$ covers a string B if at least one string A_i from the set covers B . Let $b(k, m, s)$ be the maximum b such that there is a set of strings $\{A_1, \dots, A_s\}$ that covers every string B of length m with at most k ones, and each string A_i contains at least b zeros. The following theorem shows that using multiple seeds can give better results than one seed, namely, $b(k, m, m^{1/k})$ is slightly larger than $b(k, m)$ (see Theorem 4).

Theorem 6. For every $k < \log \log m$, $b(k, m, m^{1/k}) \geq m - O(km^{1-1/k})$.

Proof. We take $s = \lfloor m^{1/k} \rfloor$, and build a string A of length $n = m - \sum_{l=0}^{k-1} s^l$, that has $k - 1$ levels of blocks as in the proof of Theorem 4. Then, we build strings A_1, \dots, A_{s-1} , where A_i is obtained by taking the string A and adding ones at positions $js - i$ for $j \geq s$. It is easy to verify that $\{A_1, \dots, A_{s-1}\}$ covers every string of length m with at most k ones. □

Fast Neighbor Joining

Isaac Elias and Jens Lagergren

Dept. of Numerical Analysis and Computer Science,
Royal Institute of Technology, Stockholm, Sweden
{isaac, jens1}@nada.kth.se

Abstract. Reconstructing the evolutionary history of a set of species is a fundamental problem in biology and methods for solving this problem are gaged based on two characteristics: accuracy and efficiency. Neighbor Joining (NJ) is a so-called distance-based method that, thanks to its good accuracy and speed, has been embraced by the phylogeny community. It takes the distances between n taxa and produces in $\Theta(n^3)$ time a phylogenetic tree, i.e., a tree which aims to describe the evolutionary history of the taxa. In addition to performing well in practice, the NJ algorithm has optimal reconstruction radius.

The contribution of this paper is twofold: (1) we present an algorithm called Fast Neighbor Joining (FNJ) with optimal reconstruction radius and optimal run time complexity $O(n^2)$ and (2) we present a greatly simplified proof for the correctness of NJ. Initial experiments show that FNJ in practice has almost the same accuracy as NJ, indicating that the property of optimal reconstruction radius has great importance to their good performance. Moreover, we show how improved running time can be achieved for computing the so-called correction formulas.

1 Introduction

The evolutionary history of a set of species is a central concept in biology that is commonly described by a phylogenetic tree. Frequently it is the case that the phylogenetic tree is unknown and the only information available are the genetic sequences from the extant species, i.e., currently living species. It is therefore a fundamental problem to reconstruct the phylogenetic tree given genetic sequences. Several reconstruction methods have been suggested, and it is natural to compare these based on how accurate they are in reconstructing the correct phylogeny. Unfortunately though, of these methods the more accurate are much too slow to be used in studies that involve reconstructing large or many phylogenies. The focus of this paper is to build an algorithm that is accurate and has quadratic running time in the number of species.

As more genetic information is collected it becomes possible to answer more complex questions. An obvious question that involves reconstructing a large phylogeny is to relate all living species in the tree of life. Another very central question is to relate large sets of genes and from such phylogenies draw conclusion about their function and origin. However, reconstruction of large phylogenies is

not the only case in which efficient reconstruction is necessary. There are other cases that involve many reconstructions, e.g., studies where phylogenies are built for each gene shared by a set of species. The common technique of bootstrapping also requires many reconstructions in order to obtain significance values for a single phylogeny.

Throughout the paper, phylogenetic trees are leaf-labeled binary trees with edge lengths. Thus each phylogenetic tree T naturally induces an additive leaf-to-leaf distance function D_T . The reconstruction methods for which most complexity results have been shown are the so-called distance methods. These algorithms take as input an estimated distance function D (normally computed from the genomic sequences) and construct a phylogeny whose additive distance function is close to D . The problem of finding the closest additive distance function under the infinity norm is known to be NP-hard [1].

The Neighbor Joining (NJ) algorithm is a distance method introduced by Saitou and Nei in [15]. As shown in [8], when NJ is given an *additive* distance function D_T , it reconstructs the unique tree T . However, as Atteson [2] proved NJ reconstructs the closest tree for even more cases. A distance function D is *nearly additive* if there is an additive distance function D_T such that

$$|D - D_T|_\infty < \mu(T)/2, \quad (1)$$

where $\mu(T)$ is the minimum edge length in T . All the additive distance functions for which Equation 1 holds have the same topology, i.e., disregarding the edge lengths, T is the unique tree for which the equation holds. The NJ algorithm has *optimal reconstruction radius* in the sense that: (a) given a nearly additive distance function it reconstructs the unique tree T and (b) there can be more than one tree for which $|D - D_T| < \delta$ holds if $\delta \geq \mu(T)/2$. In practice most distances are far from being nearly additive. Thus, although important, optimal reconstruction radius is not sufficient for an algorithm to be useful in practice.

The estimated distances that are given as input to distance methods are normally deduced from genomic sequences and a probabilistic model. There are various Markov models of sequence evolution which describe how sites evolve independently and identically from the root down toward the leafs. Many of these models have an associated closed correction formula for inverting the model and giving an estimated evolutionary distance for a pair of sequences. These formulas are consistent in the sense that the estimated distance approaches the underlying additive distance as the sequence length approaches infinity. As a result, the NJ algorithm is a consistent method for recovering the correct phylogeny, i.e., NJ reconstructs the correct phylogeny given infinitely long sequences.

An interesting line of research is to design fast-converging algorithms, i.e., algorithms that reconstruct the correct phylogeny from sequences whose length is polynomial in the number of sequences [7, 9, 12, 5]. However, except from the Disc-Covering Method (DCM) [9, 12] these algorithms have had little or no practical impact. The only variation of DCM that is fast-converging and of practical interest uses NJ to construct small sub-phylogenies that are later patched together into one larger phylogeny, i.e., NJ is used as a subroutine.

Although the NJ algorithm is not fast-converging, it has in experimental studies been shown to perform very well [13]. Moreover, with $O(n^3)$ as the worst case running time it has become the reconstruction algorithm that is most frequently used in practice. Heuristic implementations of NJ have been given which, without leading to better worst case analysis of the time complexity, in practice show improved running time [3, 17].

There are two major contributions in this paper: (1) we present an algorithm called Fast Neighbor Joining (FNJ) with optimal reconstruction radius and optimal run time complexity $O(n^2)$ and (2) we present a greatly simplified proof for the correctness of the NJ algorithm. Initial experiments show that the FNJ algorithm in practice has almost the same accuracy as the NJ algorithm; this indicates that it is the optimal reconstruction radius and other similarities with NJ that give FNJ its good performance. We also describe how a better running time for computing the correction formulas can be achieved, in theory, through matrix multiplication and, in practice, through table lookups.

The FNJ algorithm is useful in its own right. But it is also important to note that FNJ together with the proof of optimal reconstruction radius presents a good foundation for building reconstruction algorithms that are both practically useful and fast-converging. For example the running time of DCM can be improved by a factor $O(n)$ by simply replacing NJ with FNJ. It will be interesting to see how the running time of extensions of NJ, such as Weighbor and BioNJ, can be improved using our ideas.

The paper is organized as follows. The next section contains some basic definitions and a description of the NJ algorithm. In Section 3, the FNJ algorithm is introduced. Subsequently we give the proof of the FNJ algorithm and also a more economical and intuitively appealing proof of Atteson's theorem. Finally, in Section 7, we approach the practical problem of computing the correction formulas and also show that the FNJ algorithm in practice performs almost exactly as good as the NJ algorithm. Except for Lemma 1 below, which in [2] (Lemma 12) is proved by straightforward algebraic verification, the present paper is self-contained.

2 Definitions and the Neighbor Joining Algorithm

A $n \times n$ distance function D , for a set of taxa $\mathcal{N}(D)$, is a function $\mathcal{N}(D)^2 \rightarrow R^+$, where $|\mathcal{N}(D)| = n$, which is symmetric and satisfies $D(x, x) = 0$ for every $x \in \mathcal{N}(D)$. For two distance functions D_1 and D_2 such that $\mathcal{N}(D_1) = \mathcal{N}(D_2) = \mathcal{N}$, their distance is defined as $\max_{x, y \in \mathcal{N}} |D_1(x, y) - D_2(x, y)|$ and denoted $|D_1 - D_2|_\infty$. By a *phylogenetic tree* we mean a tree T given together with an edge length function $l_T : E(T) \rightarrow R^+$. For a phylogenetic tree T , $\mu(T)$ denotes the minimum edge length of T , i.e., $\min_{e \in E(T)} l(e)$. The unique path in a tree T between two of its vertices u and v is denoted $P_T(u, v)$. Every phylogenetic tree T induces a distance function for the leaves in the tree, i.e., $D_T : L(T)^2 \rightarrow R^+$ where $D_T(a, b) \triangleq \sum_{e \in P_{(a, b)}} l(e)$.

A distance function D is *additive* if there is a phylogenetic tree T such that $D = D_T$; the tree is said to *realize* D , it is unique, and it is denoted $T(D)$. A

distance function D is *nearly additive* if there is a phylogenetic tree T such that $|D - D_T|_\infty < \mu(T)/2$; again, the tree is said to *realize* D , it is unique, and it is denoted $T(D)$ [2]. The *parent* of a leaf a in a tree T is the unique neighbor of a in T . A pair of leaves of a tree T are *siblings* if they have the same parent in T (note only leaf-siblings).

The NJ algorithm builds a tree by iteratively combining pairs of taxa. It takes as input a distance function D for n taxa and attempts to identify two siblings by selecting the pair of taxa (a, b) that minimizes the *NJ function*, defined by

$$S_D(x, y) \triangleq (|\mathcal{N}(D)| - 2) \cdot D(x, y) - \sum_{z \in \mathcal{N}(D)} (D(z, x) + D(z, y)). \tag{2}$$

Thereafter the pair (a, b) is *reduced* to a new node c , representing the parent, which gives a new distance function D' with $\mathcal{N}(D') = (\mathcal{N}(D) \setminus \{a, b\}) \cup \{c\}$ defined by

$$D'(x, y) \triangleq \begin{cases} D(x, y), & \text{if } c \notin \{x, y\} \\ \frac{D(z, a) + D(z, b)}{2}, & \text{otherwise } z \in \{x, y\} \setminus \{c\}. \end{cases} \tag{3}$$

Finally the algorithm is applied iteratively on the new distance function D' . A formal description of the NJ algorithm is given below.

Algorithm NJ(D_1)

1. For each $i \leftarrow 1$ to $n - 3$ do
 - (a) $(a_i, b_i) \leftarrow \operatorname{argmin}_{x \neq y \in \mathcal{N}(D)} S_D(x, y)$
 - (b) Reduce a_i and b_i to a new node c_i and let D_{i+1} be the new distance function given by the reduction in Equation 3.
 - (c) Connect a_i and b_i to c_i by adding edges (a_i, c_i) and (b_i, c_i) .
2. Connect the three nodes of $\mathcal{N}(D_{n-3})$ in a star and return the resulting tree.

Theorem 1 (Atteson’s Theorem). *Given a nearly additive distance function D NJ outputs $T(D)$. Moreover, in each iteration i , D_i is nearly additive and $T(D_i) = T(D_{i-1}) \setminus \{a_{i-1}, b_{i-1}\}$.*

In Section 3, we will show the analogous theorem for the FNJ algorithm, by showing that for nearly additive distance functions it gives exactly the same output as NJ. In Section 5, we give a proof of Atteson’s theorem above.

3 The Fast Neighbor Joining Algorithm

In Step 1a of the NJ algorithm and for $i \leq n/2$, the minimum is taken over $\Omega(n^2)$ pairs which implies a running time of $\Omega(n^3)$. In the FNJ algorithm an $O(n^2)$ running time is obtained by using two ideas. First, the minimum is taken

over a set, called the *visible set*, of cardinality $O(n)$. Second, using the auxiliary function R , introduced below, the updated NJ function can be computed in constant time. It should be noted that the resulting trees of NJ and FNJ are only guaranteed to be the same if the input is nearly additive.

A pair (a, b) is *visible from* a w.r.t. a distance function D if

$$b = \operatorname{argmin}_{x \in \mathcal{N}(D) \setminus \{a\}} S_D(a, x).$$

A pair (a, b) is *visible* w.r.t. D if it is visible from either a or b . Hence the number of visible pairs is $O(n)$. In the next section it is shown that for each nearly additive distance function D , any sibling pair in $T(D)$ is visible w.r.t. D .

To enable an overall $O(n^2)$ running time, the NJ function is computed using an auxiliary function R defined by $R_D(a) \triangleq \sum_{x \in \mathcal{N}(D)} D(a, x)$, i.e., R is the row sums. It is straightforward to verify that for a D' defined as in Equation 3,

$$R_{D'}(x) = R_D(x) - \frac{D(x, a) + D(x, b)}{2}. \quad (4)$$

Hence, given R_D it is possible to compute the updated row sums $R_{D'}$ in time $O(n)$. Moreover, since $S_D(x, y) = (|\mathcal{N}(D)| - 2) \cdot D(x, y) - R_D(x) - R_D(y)$, the NJ function can be computed in constant time, for any given pair (x, y) .

It should be clear, from the formal description below that the FNJ algorithm runs in time $O(n^2)$. Note that the input actually has size $\Omega(n^2)$.

Algorithm FNJ(D_1)

1. The first visible set \mathcal{V}_1 is initialized to the set of pairs visible w.r.t. D_1 .
2. For each $a \in \mathcal{N}(D)$, $R_{D_1}(a)$ is initialized to $\sum_{x \in \mathcal{N}(D_1)} D_1(a, x)$.
3. For each $i \leftarrow 1$ to $n - 3$ do
 - (a) $(a_i, b_i) \leftarrow \operatorname{argmin}_{(x, y) \in \mathcal{V}} S_D(x, y)$
 - (b) Reduce a_i and b_i to a new node c_i and let D_{i+1} be the new distance function given by the reduction in Equation 3.
 - (c) Connect a_i and b_i to c_i by adding edges (a_i, c_i) and (b_i, c_i) .
 - (d) Compute $R_{D_{i+1}}$.
 - (e) $\mathcal{V}_{i+1} \leftarrow (\mathcal{V}_i \setminus \{(x, y) : x = a_i \text{ or } x = b_i\}) \cup \{(c_i, d)\}$ where (c_i, d) is the pair visible from c_i w.r.t. D_{i+1} .
4. Connect the three nodes of $\mathcal{N}(D_{n-3})$ in a star and return the resulting tree.

4 Correctness of FNJ

According to Theorem 1, given a nearly additive distance function D , NJ outputs $T(D)$, i.e., it outputs the unique tree that is close to D . Here we prove that FNJ has the same property. Since NJ constructs the correct tree, we know that in each iteration the minimum pair over the NJ function is a sibling pair in $T(D_i)$.

Hence, to prove the correctness of FNJ, it suffices to show that in each iteration the minimum pair is in the visible set, \mathcal{V}_i . The proof is in two steps; first the Visibility lemma is presented. According to this, if a has a sibling b in $T(D)$, then (a, b) is in the visible set. Second, in Theorem 2, the Visibility lemma together with the correctness of NJ is used to prove the correctness of FNJ.

Before we proceed to prove the Visibility lemma, we state an observation and a lemma which in Atteson [2] are proved through straightforward algebraic verification. For any tree T , edge e of T , and leaf a of T , let $\mathcal{L}_T(a, e)$ denote the set of leaves of T belonging to the same connected component of $T \setminus \{e\}$ as a .

Observation 1 (Atteson). *If D_T is an additive distance function, then,*

$$S_D(a, b) = \sum_{e \in E(T)} w_e(a, b) l(e), \text{ where}$$

$$w_e(a, b) = \begin{cases} -2 & \text{if } e \in E(P_T(a, b)) \\ -2|L(T) \setminus \mathcal{L}_T(a, e)| & \text{otherwise.} \end{cases}$$

Lemma 1 (Atteson, Lemma 12). *Let D_T and D be two n -domain distance functions such that D_T is additive and D is nearly additive w.r.t. D_T . For any $a, b, x, y \in \mathcal{N}(D)$, the value of $S_D(a, b) - S_D(a, x) + S_D(x, y) - S_D(a, y)$ is*

$$> \begin{cases} -3(n-4)\mu(T) & \text{if } \{a, b\} \cap \{x, y\} = \emptyset \\ -2(n-3)\mu(T) & \text{if } |\{a, b\} \cap \{x, y\}| = 1. \end{cases}$$

Lemma 2 (The Visibility Lemma). *Let D_T and D be two n -domain distance functions such that D_T is additive and D is nearly additive w.r.t. D_T . If a has a sibling b in T , then (a, b) is visible from a w.r.t. D , i.e.,*

$$b = \operatorname{argmin}_{x \in \mathcal{N}(D) \setminus \{a\}} S_D(a, x).$$

Proof. As in Figure 1, let $c \in \mathcal{N}(D) \setminus \{a, b\}$ and let e_a, e_b , and e_c be the edges of T incident with a, b , and c , respectively. Moreover, let e be the edge incident with the parent of a and b which is not incident with either a or b . Consider D_T , by definition of the weights in Observation 1 the following is true

- (i) $w_f(a, b) = -2 = w_f(a, c)$ for any $f \in \{e_a, e_b, e_c\}$,
- (ii) $w_f(a, b) \leq -3 < w_f(a, c)$ for any $f \in E(P_T(a, c)) \setminus \{e_a, e_c\}$,
- (iii) $w_f(a, b) = w_f(a, c)$ for any $f \in E(T) \setminus E(P_T(a, c))$.

Moreover, since $w_e(a, b) = -2(n-2)$ and $w_e(a, c) = -2$, it follows that $S_D(a, c) - S_D(a, b) \geq 2(n-3)\mu(T)$. Finally, by Lemma 1,

$$S_D(a, c) - S_D(a, b) =$$

$$\underbrace{S_D(a, c) - S_D(a, c) + S_D(a, b) - S_D(a, b)}_{> -2(n-3)\mu(T)} + \underbrace{S_D(a, c) - S_D(a, b)}_{\geq 2(n-3)\mu(T)} > 0. \quad \square$$

We are now ready to prove that given a nearly additive distance function D , FNJ in each iteration selects the same sibling pair as NJ, i.e., FNJ outputs $T(D)$. By Atteson's theorem NJ outputs $T(D)$ by in each iteration reducing a pair of siblings such that $T(D_i) = T(D_{i-1}) \setminus \{a_{i-1}, b_{i-1}\}$. Since FNJ uses the same reduction as NJ it is sufficient to show that all sibling pairs are in the visible set. In the next section, we give a short and intuitively appealing proof of Atteson's theorem, which together with the Visibility lemma gives a direct proof of the theorem below.

Theorem 2. *Given a nearly additive distance function D , FNJ outputs $T(D)$.*

Proof. We prove by induction that, for each $i = 1, \dots, n - 3$, \mathcal{V}_i contains all sibling pairs of $T(D_i)$ (here $D_1 = D$). By the Visibility lemma it is clear that the statement is true for $i = 1$. Assume that the statement holds for each $i = 1, \dots, j$.

By the correctness of NJ, if (a_j, b_j) is the minimum over the NJ function, then (a_j, b_j) is a sibling pair $T(D_j)$. Therefore, by the induction assumption, (a_j, b_j) is in \mathcal{V}_j . Consequently, since the minimum over the NJ function is a sibling pair, FNJ and NJ select the same sibling pair in iteration j .

After reducing (a_j, b_j) to c_j , by the Visibility lemma, if c_j has a sibling d in $T(D_{j+1})$, then in Step 3e (c_j, d) is added to \mathcal{V}_{j+1} . Moreover, by the assumption, all other sibling pairs of $T(D_{j+1})$ are in \mathcal{V}_j and therefore also in \mathcal{V}_{j+1} . Hence, by induction and the correctness of NJ, FNJ outputs $T(D)$. \square

5 Atteson's Theorem - Correctness of NJ

The proof of Atteson's theorem is in two steps. The first step consists of the key technical lemma below, of which we give a much more concise and direct proof. The central idea in this proof, is to show that for any additive distance function the difference is large between the value of NJ function applied to a sibling pair, and applied to a pair of leaves which are not siblings. In fact, the difference is so large that even when the distance function is nearly additive the NJ function is minimized by a sibling pair. The final step in proving Atteson's theorem consists of showing that the distance function, after a reduction, remains nearly additive.

Lemma 3. *If D is a nearly additive distance function, $a, b \in \mathcal{N}(D)$, and $S_D(a, b) = \min_{x \neq y \in \mathcal{N}(D)} S_D(x, y)$, then (a, b) is a sibling pair in $T = T(D)$.*

Proof. According to the Visibility lemma, if a has a sibling b then $S_D(a, b) < S_D(a, x)$ for any $x \neq b$. Hence, the lemma follows if for any two leaves, x and y , of which none has a sibling in T , there exists a sibling pair (a, b) , such that $S_D(x, y) - S_D(a, b) > 0$. Let D_T be an additive distance function such that $|D - D_T| < \mu(T)/2$. Notice that

$$\begin{aligned} & S_D(x, y) - S_D(a, b) \\ &= S_D(x, y) - S_D(x, y) + S_D(a, b) - S_D(a, b) + S_D(x, y) - S_D(a, b) \end{aligned}$$

Fig. 1. To the left the figure for the Visibility lemma. To the right the figure for Lemma 3

$$> -3(n - 4)\mu(T) + S_D(x, y) - S_D(a, b),$$

where the inequality follows by Lemma 1. We proceed by showing that $S_D(x, y) - S_D(a, b) > 3(n - 4)\mu(T)$.

In T let x' and y' be the unique neighbors of x and y , respectively (see Figure 1). Further, let T^x and T^y be the subtrees of $T \setminus P_T(x', y')$ containing x and y , respectively. W.l.o.g., assume that $|L(T^x)| \leq |L(T^y)|$, and hence that $|L(T^x)| \leq n/2$. Let e be the edge of $P_T(x', y')$ incident to x' . Since neither x nor y has a sibling, both T^x and T^y contain a sibling pair of T . Let a and b be siblings in T^x , and let f be the edge incident with their parent but not a and not b .

First note that $w_g(a, b) \leq w_g(x, y)$ for any $g \in E(T) \setminus \{e, f\}$. The only edges for which the latter inequality is non-trivial are those of $P_T(a, x')$; for those the inequality follows from the assumption that $|L(T^x)| \leq n/2$. Using the definition of weights, it is straightforward to verify that $w_e(a, b) = -2|L(T) \setminus L(T^x)| \geq -n$ while $w_e(x, y) = -2$, and that $w_f(a, b) = -2(n - 2)$ while $w_f(x, y) = -4$. It follows that

$$\begin{aligned} S_D(x, y) - S_D(a, b) &\geq (-2 - 4 + n + 2(n - 2))\mu(T) \\ &= (3n - 10)\mu(T) \\ &> 3(n - 4)\mu(T). \end{aligned} \quad \square$$

(Proof Theorem 1). The proof is by induction. First note that the theorem holds when $|\mathcal{N}(D)| = 3$. Assume that the theorem holds when $|\mathcal{N}(D)| = n - 1$. We now prove that it holds for $|\mathcal{N}(D)| = n$.

Since D is nearly additive, by the lemma above, NJ in the first iteration reduces a pair (a, b) that are siblings in $T = T(D)$ to a new node c , representing their parent. Denote the distance function after the reduction by D' . We need to prove that D' is nearly additive and that $T(D') = T \setminus \{a, b\}$.

Let S be the tree $T \setminus \{a, b\}$ with the edge length function defined as follows:

$$l_S(u, v) \triangleq l_T(u, v)$$

for all $u, v \in V(S) \setminus \{c\}$, and

$$l_S(c, c') \triangleq l_T(c, c') + \frac{l_T(c, a) + l_T(c, b)}{2}$$

for the unique neighbor c' of c in S . It should be clear that $\mu(T) \leq \mu(S)$.

We now show that $|D' - D_S| < \mu(S)/2$, i.e., that $T(D') = S = T \setminus \{a, b\}$. From this, the theorem follows immediately. For $u, v \in L(S) \setminus \{c\}$,

$$|D'(u, v) - D_S(u, v)| = |D(u, v) - D_T(u, v)| < \frac{\mu(T)}{2} \leq \frac{\mu(S)}{2}$$

For all $u \in L(S)$,

$$\begin{aligned} & |D'(u, c) - D_S(u, c)| \\ &= \left| \frac{D(u, a) + D(u, b)}{2} - D_S(u, c') - l_S(c', c) \right| \\ &= \left| \frac{D(u, a) + D(u, b)}{2} - D_T(u, c') - l_T(c', c) - \frac{l_T(c, a) + l_T(c, b)}{2} \right| \\ &\leq \left| \frac{D(u, a) - D_T(u, a)}{2} + \frac{D(u, b) - D_T(u, b)}{2} \right| \\ &\leq \left| \frac{D(u, a) - D_T(u, a)}{2} \right| + \left| \frac{D(u, b) - D_T(u, b)}{2} \right| \\ &< \frac{\mu(T)}{4} + \frac{\mu(T)}{4} = \frac{\mu(T)}{2} \leq \frac{\mu(S)}{2}. \end{aligned} \quad \square$$

6 Improved Computations of Correction Formulas

As was mentioned in the introduction, the real input to a reconstruction problem is usually n sequences of length l . The assumption is that these sequences have evolved from an original ancestor sequence down the branches of the phylogeny, according to a model of sequence evolution. The distance method approach, to the reconstruction problem, is to first use the sequences to estimate the actual distances between every pair of leaves, and thereafter find a phylogeny that fits the estimated distances. That is, from the n sequences of length l , an $n \times n$ distance function is computed through a correction formula. This formula is dependent on the model assumed to have generated the sequences; the most common models are Jukes-Cantor (JC) [10] and Kimura 2-parameter (K2P) [11]. Most correction formulas are in a sense functions of the hamming distance, e.g., the JC correction formula is given by

$$JC(s_1, s_2) \triangleq -\frac{3}{4} \cdot \log \left(1 - \frac{4 \cdot H(s_1, s_2)}{3l} \right),$$

where H is the hamming distance. Clearly, the straightforward way of computing this function takes $O(l)$ time, and as a result the overall running time of computing all estimated distances is $O(ln^2)$. Since l typically is larger than n , the computation of the correction formula is the bottleneck in fast reconstruction algorithms.

Computing all n^2 pairwise hamming distances for n strings is a special case of matrix multiplication, and can therefore be done in $O(ln^{1.376})$ time [4]. The reduction for strings from the alphabet $\{A, C, G, T\}$, is by representing each string by a row in the matrix M , and code each symbol by the unary code, e.g., by letting $A = 1000$. Thereby, the elements in the matrix MM^T are $l - H(s_i, s_j)$. It should be noted that the general belief is that matrix multiplication can be done in $O(ln)$ time, which would imply that the correction formulas can be computed in optimal time. Unfortunately, all existing matrix multiplication algorithms are slow in practice.

Below we present an algorithm that improved the computations of the correction formula by more than a factor of 3, compared to the straightforward approach. The idea is to first represent each symbol by 2 bits, and then use a precomputed table with 2^{2k} entries to look up the distance for k symbols at a time. In our tests, $k = 7$ resulted in the best running time.

1. Code the symbols of the sequences as follows: $A = 00$, $C = 01$, $G = 10$, $T = 11$.
2. For each pair of compacted strings c_i and c_j
 - (a) Compute the xor $X_{ij} = c_i \oplus c_j$.
 - (b) Read $2k$ bits of X_{ij} at a time and use the table to look up the distance for the associated k symbols.

7 Experiments

In this paper it has been shown that both NJ and FNJ have optimal reconstruction radius. However, there are many distance matrices that are not nearly additive and for which both algorithms reconstruct the closest tree. And for yet more matrices the algorithms fail to reconstruct the tree, but they do not fail by much. Therefore, it is of major interest to know how well the two algorithms perform in practice.

Several studies have been made on the accuracy of different reconstruction algorithms, the most notable work being that by Nakhleh *et al.* [13]. In that paper, four different methods are examined: NJ, DCM-NJ+MP, Weighbor, and Greedy Parsimony. And it is noted that the NJ algorithm, because of its speed, is the method of choice when the input data are accurate, i.e., when the sequence length is large and the corrected distances are close to additive. In this section, we replicate some of the experiments and show that although the NJ algorithm perform slightly better than the FNJ algorithm, when the input data are accurate the performance is in fact close to the same.

The test data were produced in the same way as in [13]. First, the model trees were generated through a random birth-death process using the `r8s`[16] software package. These trees were then made non-ultrametric, i.e., root to leaf paths were made to vary in length, by multiplying the edge lengths with a

Fig. 2. Left: Trees with 400 taxa. Right: Comparing the running time for 10 trees of 4000 taxa

random number in different intervals¹. Subsequently, sequence data was generated according to the JC model using the `Seq-Gen`[14] program. The JC correction formula was then applied to get the distances, and for saturated data a fix factor of 1 was used.

To measure the accuracy we used the normalized Robinson-Foulds (RF) distance between the model tree and the tree given by the method. To get statistically robust results we performed 20 runs on each test size, and computed the average RF rate and standard deviation. In Figure 2, to the left, we plot the average RF rate as a function of the sequence length for trees with 400 taxa. Notice that both methods converge to the true tree as the sequence length increases, and that for accurate data the methods perform almost the same. For these experiments the standard deviation varied between 1-4% except for sequences of length 50. Many more experiments have been performed and the same pattern emerges there too but due to space limitations these data have been omitted.

7.1 Comparison with GME

In Desper *et al.* [6], an $O(n^2)$ algorithm called GME is introduced that, although it does not have optimal reconstruction radius, in practice it has acceptable accuracy. However, as is clearly shown in Figure 2, for 10 trees of 4000 taxa each, FNJ outperforms both GME and NJ. When accuracy is concerned the best algorithm is NJ, tightly followed by FNJ. In addition to GME, Desper *et al.* present a clever nearest neighbor interchange (NNI) algorithm, that in many cases improves the accuracy of reconstruction algorithms. It is therefore reasonable to believe that FNJ in conjunction with NNI would be a very fast and accurate combination.

¹ Following [13] we used ultrametric deviation 4 and generated [13] sequences with diameter factors 0.05, 0.10, 0.25, and 0.5. E.g. diameter factor 0.25 yields the interval $[1/16, 1]$

Acknowledgments

We would like to thank Luay Nakhleh and Tandy Warnow for discussions on experimental studies of the NJ algorithm and for helping us replicate their experiments. We are also grateful to Johan Håstad for valuable comments and ideas.

Randomized Fast Design of Short DNA Words*

Ming-Yang Kao, Manan Sanghi, and Robert Schweller

Department of Computer Science,
Northwestern University,
Evanston, IL 60201, USA

{kao, manan, schweller}@cs.northwestern.edu

Abstract. We consider the problem of efficiently designing sets (codes) of equal-length DNA strings (words) that satisfy certain combinatorial constraints. This problem has numerous motivations including DNA computing and DNA self-assembly. Previous work has extended results from coding theory to obtain bounds on code size for new biologically motivated constraints and has applied heuristic local search and genetic algorithm techniques for code design. This paper proposes a natural optimization formulation of the DNA code design problem in which the goal is to design n strings that satisfy a given set of constraints while minimizing the length of the strings. For multiple sets of constraints, we provide high-probability algorithms that run in time polynomial in n and any given constraint parameters, and output strings of length within a constant factor of the optimal. To the best of our knowledge, this work is the first to consider this type of optimization problem in the context of DNA code design.

1 Introduction

In this paper we study the problem of efficiently designing sets (codes) of DNA strings (words) of near optimal length that fulfill certain combinatorial constraints. Many applications have emerged in recent years that depend on the scalable design of such words. One such problem is in DNA computing where inputs to computational problems are encoded into DNA strands for the purpose of computing via DNA complementary binding [1]. Another application involves implementing Wang tile self-assembly systems by encoding glues of Wang tiles into strands of DNA [17]. DNA words can also be used to store information at the molecular level [4], act as molecular bar codes for identifying molecules in complex libraries [5, 4, 13], or implement DNA arrays [3].

For a set of DNA words to be effective for the above applications, they must fulfill a number of combinatorial constraints. Of particular importance is the need for specific hybridization between a given word and its unique Watson-Crick complement. That is, we need to make sure that hybridization does not

Table 1. This table summarizes our results regarding the efficient design of DNA words. Here n is the number of words; k denotes the maximum of the constraint parameters for constraints 1 through 6 (see Section 2); and $\ell = \Theta(k + \log n)$ denotes the optimal achievable word length for the listed word design problems (see Theorems 1, 3, 4 and 6)

Word Length and Time Complexity for DNA Word Design				
	Word Length		Time Complexity	
	Lower Bound	Upper Bound	Lower Bound	Upper Bound
DWD _{1,2,3,4,5,6,7}	$\Theta(\ell)$ (Thm. 1)	$\Theta(\ell)$ (Thm. 3)	$\Theta(n\ell)$ (Thm. 1)	$\Theta(n\ell)$ (Thm. 3)
DWD _{1,2,3,7,8}	$\Theta(\ell)$ (Thm. 1)	$\Theta(\ell)$ (Thm. 4)	$\Theta(n\ell)$ (Thm. 1)	$\Theta(n\ell)$ (Thm. 4)
DWD _{1,2,3,4,5,6,9}	$\Theta(\ell)$ (Thm. 1)	$\Theta(\ell)$ (Thm. 6)	$\Omega(n\ell)$ (Thm. 1)	$O\left(\min\left\{\ell^{1.5} \log^{0.5} \ell + n\ell, n\ell \log \ell\right\}\right)$ (Thm. 6)

occur among a word and the complement of a different word in the set, or even of any word with any other word in the set. For this requirement Marathe et al. [12] have proposed the *basic Hamming constraint*, *reverse complement Hamming constraint*, and *self-complementary constraint*. We further consider the more restricting *shifting Hamming constraint* which requires a large Hamming distance between all alignments of any pair of words [6].

We also consider three constraints not related to Hamming distance. The *consecutive base constraint* limits the length of any run of identical bases in any given word. Long runs of identical bases are considered to cause hybridization errors [14, 6]. The *GC content constraint* requires that a large percentage of the bases in any given word are either G or C. This constraint is meant to give each string similar thermodynamic properties [14, 16, 15]. The *free energy constraint* requires that the difference in free energy of any two words is bounded by a small constant. This helps ensure that each word in the set has a similar melting temperature [6, 12].

In addition to the above constraints, it is desirable for the length ℓ of each word to be as small as possible. The motivation for minimizing ℓ is evident from the fact that it is more difficult to synthesize longer strands. Similarly, longer DNA strands require more DNA to be used for the respective application.

There has been much previous work in the design of DNA words [6, 12, 4, 9, 10, 11, 13, 16, 15]. In particular, Marathe et al. [12] have extended results from coding theory to obtain bounds on code size for various biologically motivated constraints. However, most work in this area has been based on heuristics, genetic algorithms, and stochastic local searches that do not provide provably good words provably fast.

In this work we provide algorithms with analytical guarantees for combinatorial structures and time complexity. In particular, we formulate an optimization problem that takes as input a desired number of strings n and produces n length- ℓ strings that satisfy a specified set of constraints, while at the same time minimizing the length ℓ . We restrict our solution to this problem in two ways. First, we require that our algorithms run in time only polynomial in the number of strings n as well as any given constraint parameters. Second, we require that our algorithms produce sets of words that achieve word length ℓ that is within a constant multiple of the optimal achievable word length, while at the same time fulfilling the respective constraints with high probability. For various subsets of the constraints we propose, we provide algorithms that do this. We thus provide fast algorithms for the creation of sets of short words.

Paper Layout: In Section 2, we describe the different biologically motivated combinatorial constraints we use. In Section 3 we solve the design problem with subsets of constraints including the Hamming constraints, the consecutive bases constraint, and the GC content constraint. In Section 4 we extend our algorithms to deal with the free energy constraint.

2 Preliminaries

2.1 Notations

Let $X = x_1x_2\dots x_\ell$ be a word where x_i belongs to some alphabet Π . In this paper we deal with two alphabets, namely, the binary alphabet $\Pi_B = \{0, 1\}$ and the DNA alphabet $\Pi_D = \{A, C, G, T\}$. The elements of an alphabet are called *characters*. We will use capital letters for words and small letters for characters. Our goal is to design DNA words but some of our algorithms generate binary words in intermediate steps.

The *reverse* of X , denoted by X^R , is the word $x_\ell x_{\ell-1} \dots x_1$. The *complement* of a character x is denoted by x^c . The complements for the binary alphabet are given by $0^c = 1$, $1^c = 0$, and for the DNA alphabet we have $A^c = T$, $C^c = G$, $G^c = C$, $T^c = A$.

The *complement* of a word is obtained by taking the complement of each of the characters in the word, i.e., $X^C = x_1^c x_2^c \dots x_\ell^c$. The *reverse complement* of X is the complement of X^R , $X^{RC} = x_\ell^c x_{\ell-1}^c \dots x_1^c$. The *Hamming distance* $H(X, Y)$ between two words X and Y is the number of positions where X differs from Y .

We are interested in designing a set \mathcal{W} of n words over Π_D each of length ℓ which satisfy the constraints defined in Section 2.2 below.

2.2 Constraints

The constraints we consider can be classified into two categories: *non-interaction* constraints and *stability* constraints. Non-interaction constraints ensure that unwanted hybridizations between two DNA strands are avoided, and stability constraints ensure that the DNA strands are stable in a solution. The first six

constraints below are non-interaction constraints while the remaining three are stability constraints.

$C_1(k_1)$: **Basic Hamming Constraint** (k_1) = for any words $Y, X \in \mathcal{W}$, $H(Y, X) \geq k_1$.

This constraint limits non-specific hybridizations between the Watson-Crick complement of some word Y with a distinct word X .

$C_2(k_2)$: **Reverse Complementary Constraint** (k_2) = for any words $Y, X \in \mathcal{W}$, $H(Y, X^{RC}) \geq k_2$.

This constraint is intended to limit hybridization between a word and the reverse of another word.

$C_3(k_3)$: **Self Complementary Constraint** (k_3) = for any word Y , $H(Y, Y^{RC}) \geq k_3$.

This constraint prevents a word from hybridizing with itself.

$C_4(k_4)$: **Shifting Hamming Constraint** (k_4) = for any two words $Y, X \in \mathcal{W}$,

$$H(Y[1..i], X[(\ell - i + 1)..\ell]) \geq k_4 - (\ell - i) \text{ for all } i.$$

This is a stronger version of the Basic Hamming Constraint.

$C_5(k_5)$: **Shifting Reverse Complementary Constraint** (k_5) = for any two words $Y, X \in \mathcal{W}$,

$$H(Y[1..i], X[1..i]^{RC}) \geq k_5 - (\ell - i) \text{ for all } i; \text{ and}$$

$$H(Y[(\ell - i + 1)..\ell], X[(\ell - i + 1)..\ell]^{RC}) \geq k_5 - (\ell - i) \text{ for all } i.$$

This is a stronger version of the Reverse Complementary Constraint.

$C_6(k_6)$: **Shifting Self Complementary Constraint** (k_6) = for any word $Y \in \mathcal{W}$,

$$H(Y[1..i], Y[1..i]^{RC}) \geq k_6 - (\ell - i) \text{ for all } i; \text{ and}$$

$$H(Y[(\ell - i + 1)..\ell], Y[(\ell - i + 1)..\ell]^{RC}) \geq k_6 - (\ell - i) \text{ for all } i.$$

This is a stronger version of the Self Complementary Constraint.

$C_7(\gamma)$: **GC Content Constraint** (γ) = γ percentage of bases in any word $Y \in \mathcal{W}$ are either G or C.

The GC content affects the thermodynamic properties of a word [14, 16, 15]. Therefore, having the same ratio of GC content for all the words will assure similar thermodynamic characteristics.

$C_8(d)$: **Consecutive Base Constraint** (d) = no word has more than d consecutive bases for $d \geq 2$.

In some applications, consecutive occurrences (also known as runs) of the same base increase the number of annealing errors.

$C_9(\sigma)$: **Free Energy Constraint** (σ) = for any two words $Y, X \in \mathcal{W}$, $\text{FE}(Y) - \text{FE}(X) \leq \sigma$ where $\text{FE}(W)$ denotes the free energy of a word defined in Section 4.

This constraint ensures that all the words in the set have similar melting temperatures which allows hybridization of multiple DNA strands to proceed simultaneously [13].

For each of the given constraints above we assign a shorthand boolean function $C_i(t)$ to denote whether or not a given set of words \mathcal{W} fulfills constraint C_i with respect to parameter t . For a given integer n , the goal of DNA word design is to efficiently create a set of n length- ℓ words such that a given subset of the above constraints are satisfied, while trying to minimize ℓ . That is, for a given subset of constraints $\{C_{\pi_1}, C_{\pi_2}, \dots, C_{\pi_r}\} \subseteq \{C_1, C_2, \dots, C_9\}$, the corresponding DNA word design (DWD) optimization problem is as follows.

Problem 1 (DWD $_{\pi_1, \pi_2, \dots, \pi_r}$).

INPUT: Integers n, t_1, t_2, \dots, t_r .

OUTPUT: A set \mathcal{W} of n DNA strings each of the minimum length such that for all $1 \leq i \leq r$ the constraint $C_{\pi_i}(t_i)$ is satisfied over set \mathcal{W} .

For this problem we have the following trivial lower bounds for time complexity and the word size ℓ when any one of the first six constraints is applied.

Theorem 1. *Consider a set \mathcal{W} of n DNA words each of length ℓ .*

1. *If \mathcal{W} fulfills any one of the constraints $C_1(k), C_2(k), C_3(k), C_4(k), C_5(k)$, and $C_6(k)$, then $\ell = \Omega(k + \log n)$.*
2. *The time complexity of producing a set \mathcal{W} that fulfills any one of the constraints $C_1(k), C_2(k), C_3(k), C_4(k), C_5(k)$, and $C_6(k)$ is $\Omega(nk + n \log n)$.*

The goal of DNA word design is to simultaneously satisfy as many of the above nine constraints as possible while achieving words within a constant factor of the optimal length ℓ for the given set of constraints. In Section 3 we show how to accomplish this goal for various subsets of the constraints.

3 Algorithms for DNA Word Design

In this section we develop randomized algorithms to generate sets of length- ℓ DNA words that satisfy certain sets of constraints while keeping ℓ within a constant of the optimal value. In particular, we first show how simply generating a set of n words at a specific length $\ell = O(k + \log n)$ uniformly at random is sufficient to fulfill constraints 1, 2, 3, 4, 5, and 6 simultaneously with high probability. We then propose three extensions to this algorithm to fulfill different subsets of constraints within a constant factor of the optimal word length. The first extension yields an algorithm for fulfilling the GC content constraint while the second yields one for the consecutive base and GC content constraints at the cost of the shifting constraints. Finally, we extend the basic randomized algorithm to fulfill the free energy constraint. The first is thus an algorithm for simultaneously fulfilling constraints 1, 2, 3, 4, 5, 6, and 7, the second simultaneously fulfills constraints 1, 2, 3, 7, and 8, and the last one fulfills constraints 1, 2, 3, 4, 5, 6 and 9.

Algorithm. *FastDWD*_{1,2,3,4,5,6}($n, k_1, k_2, k_3, k_4, k_5, k_6$)

1. Let $k = \max\{k_1, k_2, k_3, k_4, k_5, k_6\}$.
2. Generate a set \mathcal{W} of n words over Π_D of length $\ell = 9 \cdot \max\{k, \lceil \log_4 n \rceil\}$ uniformly at random.
3. Output \mathcal{W} .

Fig. 1. A randomized algorithm for generating n DNA strings satisfying constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, and $C_6(k_6)$

3.1 A Simple Randomized Algorithm

Problem 2 (*DWD*_{1,2,3,4,5,6}).

INPUT: Integers $n, k_1, k_2, k_3, k_4, k_5, k_6$.

OUTPUT: A set \mathcal{W} of n DNA strings each of the minimum length such that the constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, $C_6(k_6)$ hold.

The next theorem shows that Algorithm *FastDWD*_{1,2,3,4,5,6} ($n, k_1, k_2, k_3, k_4, k_5, k_6$) in Figure 1 yields a polynomial-time solution to the *DWD*_{1,2,3,4,5,6} problem with high probability. We omit the proof in the interest of space.

Theorem 2. *Algorithm* *FastDWD*_{1,2,3,4,5,6} *produces a set* \mathcal{W} *of* n *DNA words of optimal length* $\Theta(k + \log n)$ *in optimal time* $\Theta(n \cdot k + n \cdot \log n)$ *satisfying constraints* $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$ *and* $C_6(k_6)$ *with probability of failure* $o(1/(n + 4^k))$, *where* $k = \max\{k_1, k_2, k_3, k_4, k_5, k_6\}$.

Proof (Sketch). The probability that two random words violate any of the constraints $C_1(k_1)$, $C_2(k_2)$, $C_4(k_4)$, and $C_5(k_5)$, can be bounded using Chernoff type bounds. Similarly, we can bound the probability of a random word violating any of the constraints $C_3(k_3)$ and $C_6(k_6)$.

We can then apply the Boole-Bonferroni Inequalities to yield a bound on the probability that any pair of words in a set of n random words violates constraints $C_1(k_1)$, $C_2(k_2)$, $C_4(k_4)$, or $C_5(k_5)$; or that any single word violates constraints $C_3(k_3)$ or $C_6(k_6)$. \square

3.2 Incorporating the GC Content Constraint into *FastDWD*_{1,2,3,4,5,6}

Now we show how to modify Algorithm *FastDWD*_{1,2,3,4,5,6} so that it produces a set of words that also satisfies the GC content constraint. That is, we will show how to solve the following problem.

Problem 3 (*DWD*_{1,2,3,4,5,6,7}).

INPUT: Integers $n, k_1, k_2, k_3, k_4, k_5, k_6, \gamma$.

OUTPUT: A set \mathcal{W} of n DNA strings each of the minimum length such that the constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, $C_6(k_6)$, $C_7(\gamma)$ hold.

We modify Algorithm *FastDWD*_{1,2,3,4,5,6} to get Algorithm *FastDWD*_{1,2,3,4,5,6,7} shown in Figure 2. The next theorem shows that *FastDWD*_{1,2,3,4,5,6,7} yields a

Algorithm. *FastDWD*_{1,2,3,4,5,6,7}($n, k_1, k_2, k_3, k_4, k_5, k_6, \gamma$)

1. Let $k = \max\{k_1, k_2, k_3, k_4, k_5, k_6\}$.
2. Generate a set \mathcal{W} of n words over the binary alphabet Π_B of length $\ell = 10 \cdot \max\{k, \lceil \log_2 n \rceil\}$ uniformly at random.
3. For each word $W \in \mathcal{W}$, for any $\lceil \gamma \cdot \ell \rceil$ characters in W , replace 0 by G and 1 by C. For the remaining characters replace 0 by A and 1 by T to get W' . Let \mathcal{W}' be the set of all words W' .
4. Output \mathcal{W}' .

Fig. 2. A randomized algorithm for generating n DNA strings satisfying constraints $C_1(k_1), C_2(k_2), C_3(k_3), C_4(k_4), C_5(k_5), C_6(k_6)$, and $C_7(\gamma)$

polynomial-time solution to *DWD*_{1,2,3,4,5,6,7} with high probability. We omit the proof in the interest of space.

Theorem 3. *Algorithm FastDWD*_{1,2,3,4,5,6,7} produces a set \mathcal{W} of n DNA words of optimal length $\Theta(k + \log n)$ in optimal time $\Theta(n \cdot k + n \cdot \log n)$ satisfying constraints $C_1(k_1), C_2(k_2), C_3(k_3), C_4(k_4), C_5(k_5), C_6(k_6)$, and $C_7(\gamma)$ with probability of failure $o(1/(n + 2^k))$, where $k = \max\{k_1, k_2, k_3, k_4, k_5, k_6\}$.

3.3 Incorporating the Consecutive Bases Constraint into *FastDWD*_{1,2,3,4,5,6,7}

Now we modify Algorithm *FastDWD*_{1,2,3,4,5,6,7} so that it produces a set that satisfies both the GC content constraint and the consecutive base constraint at the cost of the shifting constraints. That is, we will show how to solve the following problem.

Problem 4 (*DWD*_{1,2,3,7,8}).

INPUT: Integers $n, k_1, k_2, k_3, \gamma, d$.

OUTPUT: A set \mathcal{W} of n DNA strings each of the minimum length such that the constraints $C_1(k_1), C_2(k_2), C_3(k_3), C_7(\gamma), C_8(d)$ hold.

We use Algorithm *BreakRuns* shown in Figure 3 to break long runs for a binary word so that it satisfies the consecutive bases constraint with parameter d . Intuitively what this algorithm does is for a given word X , it outputs X' by inserting characters at intervals of $d - 1$ from the left and the right in a manner such that there are no consecutive runs of length greater than d . We need to add characters from both ends to ensure that $H(X, Y^{RC}) \leq H(X', Y'^{RC})$ where X' and Y' are the respective outputs for X and Y from *BreakRuns*.

We modify Algorithm *FastDWD*_{1,2,3,4,5,6,7} to get Algorithm *FastDWD*_{1,2,3,7,8} shown in Figure 3. The next theorem shows that *FastDWD*_{1,2,3,7,8} yields a polynomial-time solution to *DWD*_{1,2,3,7,8} with high probability. We omit the proof in the interest of space.

Theorem 4. *Algorithm FastDWD*_{1,2,3,7,8} produces a set \mathcal{W} of n DNA words of optimal length $\Theta(k + \log n)$ in optimal time $\Theta(n \cdot k + n \cdot \log n)$ satisfying constraints

Algorithm. *BreakRuns*(X, d)

1. Let $X = x_1 x_2 \dots x_\ell$. For $0 < i \leq \lceil \frac{\ell}{2(d-1)} \rceil - 1$, let $x'_\ell = x_{i(d-1)}^c$ and $x'_r = x_{\ell-i(d-1)}^c$. Let $x'_{\text{mid}} = x_{\lceil \ell/2 \rceil}^c$.
2. Output $X' = x_1 \dots x_{d-1} x'_{\ell_1} x_d \dots x_{\lceil \ell/2 \rceil} x'_{\text{mid}} x_{\lceil \ell/2 \rceil + 1} \dots x_{\ell-(d-1)-1} x'_{r_1} x_{\ell-(d-1)} \dots x_\ell$.

Algorithm. *FastDWD*_{1,2,3,7,8}($n, k_1, k_2, k_3, \gamma, d$)

1. Let $k = \max\{k_1, k_2, k_3\}$.
2. Generate a set \mathcal{W} of n words over the binary alphabet Π_B of length $\ell = 10 \cdot \max\{k, \lceil \log_2 n \rceil\}$ uniformly at random.
3. For each word $W \in \mathcal{W}$, let $W' = \text{BreakRuns}(W, d)$. Let \mathcal{W}' be the set of all words W' .
4. For each word $W' \in \mathcal{W}'$, for any $\lceil \gamma \cdot \ell \rceil$ characters in W' , replace 0 by G and 1 by C . For the remaining characters replace 0 by A and 1 by T to get W'' . Let \mathcal{W}'' be the set of all words W'' .
5. Output \mathcal{W}'' .

Fig. 3. Algorithms for generating n DNA strings satisfying constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_7(\gamma)$, and $C_8(d)$

$C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_7(\gamma)$, and $C_8(d)$ with probability of failure $o(1/(n+2^k))$, where $k = \max\{k_1, k_2, k_3\}$.

4 Incorporating the Free Energy Constraint into *FastDWD*_{1,2,3,4,5,6}

Now we give an alternate modification of Algorithm *FastDWD*_{1,2,3,4,5,6} such that the free energy constraint is satisfied. The free-energy $\text{FE}(X)$ of a DNA word $X = x_1 x_2 \dots x_\ell$ is approximated by $\text{FE}(X) = \text{correction factor} + \sum_{i=1}^{\ell-1} \Gamma_{x_i, x_{i+1}}$, where $\Gamma_{x,y}$ is the pairwise free energy between base x and base y [7]. For simplicity, we denote the free energy as simply the sum $\sum_{i=1}^{\ell-1} \Gamma_{x_i, x_{i+1}}$ with respect to a given pairwise energy function Γ . Let Γ_{\max} and Γ_{\min} be the maximum and the minimum entries in Γ respectively. Let $D = \Gamma_{\max} - \Gamma_{\min}$.

We now show how to satisfy the free energy constraint $C_9(\sigma)$ for a constant $\sigma = 4D + \Gamma_{\max}$, while simultaneously satisfying constraints 1, 2, 3, 4, 5, and 6. That is, we show how to solve the following problem.

Problem 5 (*DWD*_{1,2,3,4,5,6,9}).

INPUT: Integers $n, k_1, k_2, k_3, k_4, k_5, k_6$.

OUTPUT: A set \mathcal{W} of n DNA strings each of the minimum length such that the constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, $C_6(k_6)$, $C_9(4D + \Gamma_{\max})$ hold.

We modify Algorithm *FastDWD*_{1,2,3,4,5,6} to get Algorithm *FastDWD*_{1,2,3,4,5,6,9} shown in Figure 4 for solving *DWD*_{1,2,3,4,5,6,9}. The following lemmas identify the properties of symbols $\Delta, \mathcal{W}, \mathcal{W}_{\max}, \mathcal{W}_{\min}, S_i, \hat{S}_j, \alpha, \beta$, and W'_i defined in Figure 4 and are used for proving the correctness of Algorithm *FastDWD*_{1,2,3,4,5,6,9}.

Algorithm. *FastDWD*_{1,2,3,4,5,6,9}($n, k_1, k_2, k_3, k_4, k_5, k_6$)

Let $\hat{S}^1, \hat{S}^2, \dots, \hat{S}^4$ be all possible sequences of length $m = 2\ell$ where ℓ is as defined in Step 2 below such that $\text{FE}(\hat{S}^1) \leq \text{FE}(\hat{S}^2) \leq \dots \leq \text{FE}(\hat{S}^4)$. For two strings X and Y of respective lengths ℓ_X and ℓ_Y where ℓ_Y is even, let $X \otimes Y$ be the string $Y[1..(\ell_Y/2)] X[1..\ell_X] Y[(\ell_Y/2 + 1)..\ell_Y]$. Let $\Delta = \max_i \{\text{FE}(\hat{S}^{i+1}) - \text{FE}(\hat{S}^i)\}$.

1. Let $k = \max\{k_1, k_2, k_3, k_4, k_5, k_6\}$.
2. Generate a set \mathcal{W} of n DNA words of length $\ell = 9 \cdot \max\{k, \lceil \log_4 n \rceil\}$ uniformly at random.
3. Let $\mathcal{W}_{\max} = \max_{X \in \mathcal{W}} \{\text{FE}(X)\}$ and $\mathcal{W}_{\min} = \min_{X \in \mathcal{W}} \{\text{FE}(X)\}$.
if $\mathcal{W}_{\max} - \mathcal{W}_{\min} \leq 3D$, **then output** \mathcal{W} .
else
4. Let $\alpha = \mathcal{W}_{\max} + \hat{S}^1$ and $\beta = \alpha + \Delta$. For each $S_i \in \mathcal{W}$, find \hat{S}_j such that $\alpha \leq \text{FE}(S_i) + \text{FE}(\hat{S}_j) \leq \beta$. Let $W'_i = S_i \otimes \hat{S}_j$.
5. **output** $\mathcal{W}' = \{W'_1, \dots, W'_n\}$.

Fig. 4. A randomized algorithm for generating n DNA strings satisfying constraints $C_1(k_1), C_2(k_2), C_3(k_3), C_4(k_4), C_5(k_5), C_6(k_6)$, and $C_9(4D + \Gamma_{\max})$

Lemma 1. $\Delta < 2D$.

Lemma 2. If $\mathcal{W}_{\max} - \mathcal{W}_{\min} > 3D$, then $\mathcal{W}_{\max} - \mathcal{W}_{\min} + 2D \leq \text{FE}(\hat{S}^4) - \text{FE}(\hat{S}^1)$.

Lemma 3. For each $S_i \in \mathcal{W}$, there exists \hat{S}_j such that $\alpha \leq \text{FE}(S_i) + \text{FE}(\hat{S}_j) \leq \beta$.

Lemma 4. For all i , $\alpha - D \leq \text{FE}(W'_i) \leq \beta + D + \Gamma_{\max}$.

Section 4.1 discusses the details for Step 4 of the algorithm. Finally, Section 4.2 establishes its correctness and time complexity.

4.1 Computing Strings with Bounded Energies

In Step 4 of Algorithm *FastDWD*_{1,2,3,4,5,6,9} we need to produce a set of n DNA strings $\hat{S}_1, \hat{S}_2, \dots, \hat{S}_n$, each of a given length $L = m$, such that $A_i \leq \text{FE}(\hat{S}_i) \leq B_i$ for some A_i, B_i such that $B_i - A_i \leq \Delta$. That is, we need to solve the following problem.

Problem 6 (Bounded-Energy Strand Generation).

INPUT:

1. Integers A_i and B_i for $i = 1$ to n such that
 - (a) $A_i \geq \mathcal{W}_{\min}$;
 - (b) $B_i \leq \mathcal{W}_{\max}$;
 - (c) $B_i - A_i \leq \Delta$.
2. Length L .

OUTPUT: Strings $\hat{S}_1, \hat{S}_2, \dots, \hat{S}_n$ each of length L and respective energy E_i such that $A_i \leq E_i \leq B_i$.

Our solution to this problem involves transforming the blunt of the computational task into the problem of polynomial multiplication. Consider the following polynomial.

Definition 1. For any integer $\ell \geq 1$, let $f_{\ell,a,b}(x)$ be the polynomial $\sum_{z=0}^{\ell \cdot m} \zeta_z x^z$ where coefficient ζ_z is the number of length- ℓ strings whose first character is a , last character is b , and free energy is z .

For $f_\ell(x) = \sum_{a,b \in \Pi} f_{\ell,a,b}(x)$ the coefficient of x^i denotes the number of strings of length ℓ and free energy i . As a first step towards our solution, we use a subroutine BUILD(L) which computes Φ , the polynomials $f_{L,a,b}(x), f_{\lfloor L/2 \rfloor, a,b}(x), \dots, f_{1,a,b}(x)$, for all $a, b \in \Pi$ in $O(L \log L)$ time. The efficient computation of these polynomials relies on the following recursive property.

Lemma 5. For any integers $\ell_1, \ell_2 \geq 1$,

$$f_{\ell_1 + \ell_2, a, b}(x) = \sum_{d_1, d_2 \in \Pi} f_{\ell_1, a, d_1}(x) \cdot f_{\ell_2, d_2, b}(x) \cdot x^{\Gamma_{1,2}}$$

The problem of determining the number of strings of length L and free energy E is considered in [12] and a dynamic programming based $O(L^2)$ -time algorithm is provided. However, exploiting the recursive property of Lemma 5 and Fast Fourier Transforms [8] for polynomial multiplication the subroutine BUILD solves this problem in faster $O(L \log L)$ time and may be of independent interest.

Our algorithm for Problem 6 has two phases, the *build* phase and the *extract* phase. The build phase constructs a data structure that permits the extract phase to be executed quickly. In the extract phase, an extraction routine is run n times to output \hat{S}_i for each $i \in [1, n]$. Since the extraction routine is executed n times and the build routine only once, the phase that constitutes the bottleneck for our algorithm for Problem 6 depends on the values of n and L . We thus provide two forks for the algorithm to take, one with a fast build routine and a modestly fast extract routine, and the other with a slower build routine but an optimally fast extract routine. In particular, if n is sufficiently larger than L , our algorithm for Problem 6 calls a routine SlowBuild(L) which improves the runtime of Extract. Otherwise, only a faster BUILD function is called in the first phase, leading to a slower Extract routine. The algorithm for Problem 6 is given in Figure 5.

Algorithm ConstructStrings makes use of three subroutines – Build, SlowBuild and Extract. The procedure Build(L) computes Φ , a data structure containing for all $a, b \in \Pi$ and a given L , the polynomials $f_{\ell,a,b}(x)$ for $\ell = L, \lfloor \frac{L}{2} \rfloor, \lfloor \frac{L}{4} \rfloor, \lfloor \frac{L}{8} \rfloor, \dots, 1$. This

Algorithm. ConstructStrings($\{A_i\}, \{B_i\}, L$)

1. Let $\Phi \leftarrow \text{Build}(L)$.
2. **if** $n \geq \sqrt{\frac{L}{\log L}}$, **then** $\Psi \leftarrow \text{SlowBuild}(L)$, **else** $\Psi \leftarrow \text{NULL}$.
3. For each $i = 1$ to n , find a nonzero coefficient ζ_E of X^E in some polynomial $f_L^{a,b}(x) \in \Phi$ such that $A_i \leq E_i \leq B_i$.
4. For $i = 1$ to n , set $\hat{S}_i = \text{Extract}(E_i, \Phi, \Psi)$.

Fig. 5. This algorithm solves the Bounded Energy Strand Generation Problem (Problem 6)

permits $\text{Extract}(E, \Phi, \Psi)$ to obtain a length L string of energy E in time $O(L \log L)$. A call to $\text{SlowBuild}(L)$ of time complexity $O(L^{1.5} \log^{0.5} L)$ improves the complexity of $\text{Extract}(E, \Phi, \Psi)$ to $O(L)$ by computing Ψ , a data structure containing for every non-zero term x^i in $f_{\lfloor \frac{L}{2} \rfloor, a, b}$ a corresponding pair of non-zero terms x^j and $x^{i-j-\Gamma}$, 2 in $f_{\lfloor \frac{L}{2} \rfloor, a, d_1}$ and $f_{\lfloor \frac{L}{2} \rfloor, d_2, b}$ respectively. This yields the following theorem.

Theorem 5. *Algorithm $\text{ConstructStrings}(\{A_i\}, \{B_i\}, L)$ solves Problem 6 in time $O(\min\{nL \log L, L^{1.5} \log^{0.5} L + nL\})$.*

4.2 Putting It All Together for $\text{DWD}_{1,2,3,4,5,6,9}$

Theorem 6. *Algorithm $\text{FastDWD}_{1,2,3,4,5,6,9}$ produces a set of n DNA words of optimal length $\Theta(k + \log n)$ in time $O(\min\{n\ell \log \ell, \ell^{1.5} \log^{0.5} \ell + n\ell\})$ satisfying the constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, $C_6(k_6)$, and $C_9(4D + \Gamma_{\max})$ with probability of failure $o(1/(n + 4^k))$, where $k = \max\{k_1, k_2, k_3, k_4, k_5, k_6\}$.*

Proof. From Theorem 2 we know that \mathcal{W} satisfies constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, and $C_6(k_6)$ with probability of failure $o(1/(n + 4^k))$. If $\mathcal{W}_{\max} - \mathcal{W}_{\min} \leq 3D$, then $\text{FastDWD}_{1,2,3,4,5,6,9}$ outputs \mathcal{W} which satisfies $C_9(3D)$ and hence also satisfies $C_9(4D + \Gamma_{\max})$. Otherwise, it is easy to verify that since \mathcal{W} satisfies these six constraints, so does \mathcal{W}' . From Lemma 3 we know that there always exists a string \hat{S}_j as required in Step 4 of $\text{FastDWD}_{1,2,3,4,5,6,9}$. Further, Lemma 4 shows that \mathcal{W}' satisfies $C_9(\Delta + 2D + \Gamma_{\max})$. Therefore, \mathcal{W}' satisfies constraints $C_1(k_1)$, $C_2(k_2)$, $C_3(k_3)$, $C_4(k_4)$, $C_5(k_5)$, $C_6(k_6)$, and $C_9(4D + \Gamma_{\max})$ with the stated failure probability.

The length of any word $W' \in \mathcal{W}'$ is at most 3ℓ where $\ell = \Theta(k + \log n)$, which is optimal from Theorem 1.

Generating \mathcal{W} takes $O(n \cdot k + n \cdot \log n)$ time. The bulk of the time complexity for the algorithm comes from Step 4, which is analyzed in Section 4.1 to get $O(\min\{nL \log L, L^{1.5} \log^{0.5} L + nL\})$ (see Theorem 5) where $L = O(\ell)$. \square

5 Future Work

A number of problems related to this work remain open. It is still unknown how to generate words of optimal length that simultaneously satisfy the free energy constraint and the consecutive bases constraint. We also have not provided a method for combining the consecutive bases constraint with any of the shifting constraints.

Another open research area is the verification problem of testing whether or not a set of words satisfy a given set of constraints. This problem is important because our algorithms only provide a high-probability assurance of success. While verification can clearly be done in polynomial time for all of our constraints, the naive method of verification has a longer runtime than our algorithms for constructing the sets. Finding faster, non-trivial verification algorithms is an open problem.

A third direction for future work involves considering a generalized form of the basic Hamming constraint. There are applications in which it is desirable to design sets of words such that some distinct pairs bind with one another, while others do not [2, 14]. In this scenario, we can formulate a word design problem that takes as input a matrix of pairwise requirements for Hamming distances. Determining when such a problem is solvable and how to solve it optimally when it is are open problems.

Abstract. Simon in his FOCS'94 paper was the first to show an exponential gap between classical and quantum computation. The problem he dealt with is now part of a well-studied class of problems, the hidden subgroup problems. We study Simon's problem from the point of view of quantum query complexity and give here a first nontrivial lower bound on the query complexity of a hidden subgroup problem, namely Simon's problem. More generally, we give a lower bound which is optimal up to a constant factor for any Abelian group.

1 Introduction

Given an Abelian group G and a subgroup $H \leq G$, a function $f : G \rightarrow X$ is said to be hiding H if f can be defined in a one-to-one way on G/H . More precisely, f hides H if and only if

$$\forall g, g' \in G \ (f(g) = f(g') \iff \exists h \in H \ g = g' + h)$$

Suppose G is a fixed group and f is computed by an oracle: a quantum black-box. We are interested here in algorithms that find the hidden subgroup H . A large amount of documentation about the hidden subgroup problem can be found in the book of Nielsen and Chuang [13]¹. Among all work already done about such algorithms one can cite Shor's famous factoring algorithm [17]: it uses a period-finding algorithm, which is a special case of a hidden subgroup problem. In recent years, attention has shifted to non-Abelian hidden subgroup problems but we will restrict our attention here to Abelian groups.

In general, two kinds of complexity measures for black-box problems can be distinguished: query complexity, i.e., the number of times the function f is evaluated using the black-box, and computational or time complexity, i.e., the number of elementary operations needed to solve the problem. Typically, a hidden subgroup algorithm is considered efficient if its complexity (in query or in

¹ History of the problem on page 246 and expression of many problems (order-finding, discrete logarithm...) in terms of hidden subgroup problems on page 241.

time, depending on the interest) is polynomial in the logarithm of the cardinality of G . For example, Kuperberg's algorithm [10] for the (non-Abelian) dihedral hidden subgroup problem is subexponential (but superpolynomial) in both time and query complexities.

Our main result is that the query complexity of finding a subgroup hidden in G is of order $r(G)$ for any Abelian group G , where $r(G)$ denotes the *rank* of G , that is, the minimal cardinality of a generating set of G (for instance, $r((\mathbb{Z}/p\mathbb{Z})^n) = n$ if $p \geq 2$ is an arbitrary integer). The proof of this result is naturally divided into an upper bound and a lower bound proof. The upper bound is achieved through a tight analysis of the standard Fourier sampling algorithm. It is a folklore theorem in quantum computation that this algorithm solves the hidden subgroup problem in Abelian groups with polynomial query complexity (see for instance [7], [5], [2] or [8]), but strangely enough no precise analysis seems to be available in the literature.

The greatest part of this paper is devoted to the lower bound proof. Here all the important ideas already appear in the analysis of Simon's problem, to which our preprint [9] is devoted. It is therefore fitting to recall the history of this problem, which is defined as follows. We are given a function f from $G = (\mathbb{Z}/2\mathbb{Z})^n$ to a known set X of size 2^n , and we are guaranteed that the function fulfills Simon's promises, that is either:

- (1) f is one-to-one, or
- (2) $\exists s \neq 0 \forall w, w' f(w) = f(w') \iff (w = w' \vee w = w' + s)$.

The problem is to decide whether (1) or (2) holds. Note that (1) is equivalent to " f hides the trivial subgroup $H = \{(0, \dots, 0)\}$ " and (2) is equivalent to " f hides a subgroup $H = \{(0, \dots, 0), s\}$ of order 2". The original problem [18] was to compute s and the problem considered here is the associated decision problem. Of course, any lower bound on this problem will imply the same one on Simon's original problem. In his article, Simon shows that his problem can be solved by a quantum algorithm which makes $O(n)$ queries in the worst case and has a bounded probability of error. The time complexity of his algorithm is linear in the time required to solve an $n \times n$ system of linear equations over $(\mathbb{Z}/2\mathbb{Z})^n$. He also shows that any classical (probabilistic) algorithm for his problem must have exponential query complexity. As a side remark, note that Simon also gives a Las Vegas version of his algorithm with expected query complexity $O(n)$. Even better, Brassard and Høyer [4] have given an "exact polynomial time" quantum algorithm for Simon's problem (i.e., their algorithm has a polynomial worst case running time and zero probability of error).

The two main methods for proving query complexity lower bounds in quantum computing are the adversary method of Ambainis and the polynomial method (for an excellent review of these methods in French, read [16]). We shall use the polynomial method, which was introduced in quantum complexity theory in [3]. There are recent interesting applications of this method to the collision and element distinctness problem [1, 12]. All previous applications of the polynomial method ultimately rely on approximation theory lemmas of Paturi [15]

or Nisan and Szegedy [14]. Besides the application to a new type of problems (namely, the hidden subgroup problems) we also contribute to the development of the method by applying it in a situation where these lemmas are not applicable. Instead, we use an apparently new (and elementary) approximation theory result: Lemma 3 from section 3.

The remainder of this paper is organized follows. After some preliminaries in section 2 we give in section 3 an $\Omega(n)$ lower bound for groups of the form $(\mathbb{Z}/p\mathbb{Z})^n$, where p is a prime number. The general case of arbitrary Abelian groups (lower and upper bound) is treated in section 4. The longer version of this paper will also contain lower bounds for other query models than the standard model presented in section 2. Obtaining tight bounds for non-Abelian groups is of course a natural open problem.

2 Preliminaries

From now on, p denotes a prime number and the problem of distinguishing the trivial subgroup from a group of order p in $(\mathbb{Z}/p\mathbb{Z})^n$ will be called “Simon’s problem in $(\mathbb{Z}/p\mathbb{Z})^n$ ” (or sometimes just “Simon’s problem”). More precisely, we are given a function f from $G = (\mathbb{Z}/p\mathbb{Z})^n$ to a known set X of size p^n , and we are guaranteed that the function fulfills Simon’s promises, that is, either:

- (1) f is one-to-one, or
- (2) $\exists s \neq 0 \forall w, w' [f(w) = f(w') \iff w - w' \in \langle s \rangle]$, where $\langle s \rangle$ is the group generated by s .

Again, the problem is to decide whether (1) or (2) holds. As pointed out in the introduction, Simon considered only the case $p = 2$.

We assume here that the reader is familiar with the basic notions of quantum computing [13, 6] and we now present the polynomial method. Let A be a quantum algorithm solving Simon’s decision problem. Without loss of generality, we can suppose that for every n the algorithm A acts like a succession of operations

$$U_0, O, U_1, O, \dots, O, U_{T(n)}, M$$

on a m -qubit, for some $m \geq 2n$, starting from state $|0\rangle^{\otimes m}$. The U_i are unitary operations independent of f and O is the call to the black-box function: if x and y are elements of $\{0, 1\}^n$ then $O|x, y, z\rangle = |x, y \oplus f(x), z\rangle$. The operation M is the measure of the last qubit. There are some states of $(m - 1)$ -qubits $|\phi_0(f, n)\rangle$ and $|\phi_1(f, n)\rangle$ (of norm possibly less than 1) such that

$$U_{T(n)}OU_{T(n)-1}O \dots OU_0|0\rangle^{\otimes m} = |\phi_0(n, f)\rangle \otimes |0\rangle + |\phi_1(n, f)\rangle \otimes |1\rangle.$$

After the measure M , the result is 0 (reject) with probability $\|\phi_0(n, f)\|^2$ and 1 (accept) with probability $\|\phi_1(n, f)\|^2$. The algorithm A is said to solve Simon’s problem with bounded error probability ϵ if it accepts any bijection with probability at least $1 - \epsilon$ and rejects every other function fulfilling Simon’s promise with probability at least $1 - \epsilon$. By definition, the query complexity of A is the function T . In section 3 we will prove the following lower bound.

Theorem 1. *If A is an algorithm which solves Simon’s problem in $(\mathbb{Z}/p\mathbb{Z})^n$ with bounded error probability ϵ and query complexity T , then for every large enough integer n we have:*

$$T(n) \geq \frac{\log_2 \left((2 - 4\epsilon) \frac{p^{n+3}}{p-1} \right) - 1}{2 \log_2 \left(\frac{p^3}{p-1} \right) + 2}.$$

Although it might not be self-evident that $T(n) = \Omega(n)$, this bound is indeed in the expected range. Indeed, it can be checked easily that the right-hand side is equivalent, for large values of n , to $A(p) \cdot n$, where $A(p)$ is positive and

$\lim_{p \rightarrow +\infty} A(p) = \frac{1}{4}$. For $p = 2$ we obtain the result presented in our preprint [9]:

$$T(n) \geq \frac{n+2+\log_2(2-4\epsilon)}{8}.$$

As explained in the introduction, our proof of this theorem is based on the polynomial method. Lemma 1 below is the key observation on which this method relies. We state it using the formalism of [1]: if s is a partial function from $(\mathbb{Z}/p\mathbb{Z})^n$ to X and f a function from $(\mathbb{Z}/p\mathbb{Z})^n$ to X , $|\text{dom}(s)|$ denotes the size of the domain of s . Moreover, we define:

$$I_s(f) = \begin{cases} 1 & \text{if } f \text{ extends } s \\ 0 & \text{otherwise.} \end{cases}$$

Lemma 1. [3] *If A is an algorithm of query complexity T , there is a set S of partial functions from $(\mathbb{Z}/p\mathbb{Z})^n \rightarrow E$ such that for all functions $f : (\mathbb{Z}/p\mathbb{Z})^n \rightarrow E$, A accepts f with probability*

$$P_n(f) = \sum_{s \in S} \alpha_s I_s(f)$$

where for every $s \in S$ we have $|\text{dom}(s)| \leq 2T(n)$ and α_s is a real number.

The goal is now to transform $P_n(f)$ into a low-degree polynomial of a single real variable. This is achieved in Proposition 1. We can then prove and apply our lower bound result on real polynomials (Lemma 3).

3 Lower Bound Proof

An algorithm for Simon’s problem is only supposed to distinguish between the trivial subgroup and a hidden subgroup of cardinality p (we recall that p is a prime number). To establish our lower bound, we will nonetheless need to examine its behavior on a black-box hiding a subgroup of arbitrary order (a similar trick is used in [1] and [12]). Note that this “generalized Simon problem” (finding an arbitrary hidden subgroup of $(\mathbb{Z}/p\mathbb{Z})^n$) can still be solved in $O(n)$ queries and bounded probability of error by essentially the same algorithm, see for instance [6].

From now on we suppose that A is an algorithm solving Simon’s problem with probability of error bounded by $\epsilon < \frac{1}{2}$ and query complexity T . Moreover, $P_n(f) = \sum_{s \in S} \alpha_s I_s(f)$ as given by lemma 1.

For $0 \leq d \leq n$ and $D = p^d$, let $Q_n(D)$ be the probability that A accepts f when f is chosen uniformly at random among the functions from $(\mathbb{Z}/p\mathbb{Z})^n$ to X hiding a subgroup of $(\mathbb{Z}/p\mathbb{Z})^n$ of order D . Of course, $Q_n(D)$ is only defined for some integer values of D and it can be extended in many different ways. By abuse of language we will say that Q_n is a polynomial of degree δ if it can be interpolated by a polynomial of degree δ .

The point of this definition is that we have a bound on some values of Q_n , and a gap between two of them. Namely, we have:

1. for any integer $d \in [0; n]$, $0 \leq Q_n(p^d) \leq 1$ (this number is a probability), and
2. $Q_n(1) \geq 1 - \epsilon$ and $Q_n(p) \leq \epsilon$, hence $|Q'_n(x_0)| \geq \frac{1-2\epsilon}{p-1} > 0$ for some $x_0 \in [1; 2]$.

If we denote by X_D the set of functions hiding a subgroup of order D , by

Lemma 1 we have $Q_n(D) = \sum_{s \in S} \left(\frac{\alpha_s}{|X_D|} \sum_{f \in X_D} I_s(f) \right)$. Hence

$$Q_n(D) = \sum_{s \in S} \alpha_s Q_n^s(D), \tag{1}$$

where $Q_n^s(D)$ is the probability that a random function f hiding a subgroup of order D extends s . We now prove that Q_n is a low-degree polynomial. By (1), it suffices to bound the degree of Q_n^s . Let us start by counting subgroups:

Lemma 2. *Let n and k be nonnegative integers.*

The group $(\mathbb{Z}/p\mathbb{Z})^n$ has exactly $\beta_p(n, k) = \prod_{0 \leq i < k} \frac{p^{n-i}-1}{p^{k-i}-1}$ distinct subgroups of order p^k .

Proof. We look at $(\mathbb{Z}/p\mathbb{Z})^n$ as a vector space over the field $\mathbb{Z}/p\mathbb{Z}$: from this point of view the subgroups are the subspaces. We start by counting the number of free k -tuples of vectors. For the first v_0 , we can choose anything but 0, so there are $p^n - 1$ choices. For the second vector v_1 we can choose any element not in the subspace generated by v_0 ; $p^n - p$ possibilities remain. For the third vector, any linear combination of v_0 and v_1 is forbidden: there are p^2 of them. In general, the number of free k -tuples of vectors is $\alpha_p(n, k) = \prod_{0 \leq i < k} (p^n - p^i)$. Each subspace of dimension k can be generated by $\alpha_p(k, k)$ different k -tuples, so the total number of subspaces of dimension k is $\frac{\alpha_p(n, k)}{\alpha_p(k, k)} = \prod_{0 \leq i < k} \frac{p^{n-i}-1}{p^{k-i}-1}$. Note that this formula is correct even if $k > n$, in which case $\alpha_p(n, k) = 0$.

Proposition 1. *The polynomial Q_n is of degree at most $2T(n)$.*

Proof. By (1), it suffices to show that for all partial functions $s : (\mathbb{Z}/p\mathbb{Z})^n \rightarrow E$ such that $|\text{dom}(s)| \leq 2T(n)$, the probability $Q_n^s(D)$ that a random function f hiding a subgroup of order D extends s is a polynomial in D of degree at most $2T(n)$. So, let s be such a partial function. We will proceed in three steps: we first examine the case where s is a constant function, then the case where s is injective and finally the general case.

Let us therefore suppose that s is constant and note $\text{dom}(s) = \{a_i/i = 1 \dots k\}$, with $k \leq 2T(n)$, the a_i 's being of course all different. A function f hiding a subgroup H extends s if and only if $\{a_i - a_1/i = 1 \dots k\} \subseteq H$ and $f(a_1) = s(a_1)$. So $Q_n^s(D) = Q_n^{s'}(D)$ where $s'(x) = s(x - a_1)$. We will thus suppose without loss of generality that $a_1 = 0$. Since E , the possible range for f , is of size p^n , we have $Q_n^s(D) = \frac{\lambda}{p^n}$, where λ is the proportion, among the subgroups of order D , of those containing $\text{dom}(s)$. Let H' be the subgroup generated by $\text{dom}(s)$, and $D' = p^{d'}$ its order, d' being the dimension of H' as a vector space. The number of subgroups of order D containing H' is equal to the number of subgroups of order $\frac{D}{D'}$ of $(\mathbb{Z}/p\mathbb{Z})^n / H'$, which is isomorphic to $(\mathbb{Z}/p\mathbb{Z})^{n-d'}$; so there are $\beta(n - d', d - d')$ of them. We then have $Q_n^s(D) = \frac{1}{p^n} \frac{\beta(n-d', d-d')}{\beta(n, d)} = \frac{1}{p^n} \prod_{0 \leq i < d'} \frac{p^{d-i} - 1}{p^{n-i} - 1}$, which is a polynomial in D of degree $d' < |\text{dom}(s)| \leq 2T(n)$.

Let us now suppose that s is injective. We still note in the same way $\text{dom}(s) = \{a_i/i = 1 \dots k\}$. A function f hiding a subgroup H extends s if and only if the a_i 's lie in distinct cosets of H and f takes appropriate values on these cosets; so $Q_n^s(D) = \nu\lambda$, where λ is the probability for a subgroup H of order D to contain none of the $a_i - a_j (i \neq j)$ and ν is the probability to extend s for a function h hiding a subgroup H of order D that does not contain any of the $a_i - a_j (i \neq j)$. First we compute ν . For each subgroup H of order D that does not contain any of the $a_i - a_j (i \neq j)$ there are $(p^n)(p^n - 1) \dots (p^n - p^n/D + 1)$ possible functions f : choose a different value for each coset of H . Among these functions, the number of them extending s is $(p^n - k)(p^n - k - 1) \dots (p^n - p^n/D + 1)$: choose a value for each coset not containing any a_i . So $\nu = \frac{(p^n - k)!}{(p^n)!}$. The probability λ is equal to $1 - \mu$, where μ is the probability for a subgroup H of order D to contain some $a_i - a_j$ for some $i \neq j$.

By the inclusion-exclusion formula, we can expand λ as follows:

$$\lambda = 1 - \left[\begin{array}{l} \sum_{i \neq j} \Pr(a_i - a_j \in H) \\ - \sum_{\substack{i_1 \neq j_1 \\ i_2 \neq j_2 \\ \{i_1; j_1\} \neq \{i_2; j_2\}}} \Pr(a_{i_1} - a_{j_1} \in H \wedge a_{i_2} - a_{j_2} \in H) \\ + \dots \\ - \dots \\ \vdots \\ + \Pr(\forall i \neq j \ a_i - a_j \in H) \end{array} \right]$$

Our study of the first case above shows that each term in this sum is a polynomial in D of degree less than d' , where the order of the subgroup generated

by the $a_i - a_j$'s is $p^{d'}$. Since $a_i - a_j$ is always in the subgroup generated by $\text{dom}(s)$, $d' \leq |\text{dom}(s)| \leq 2T(n)$.

Finally, in the general case the partial function s is defined by conditions of the form

$$\begin{cases} s(a_1^1) = s(a_2^1) = \dots = s(a_{k_1}^1) = b_1 \\ s(a_1^2) = s(a_2^2) = \dots = s(a_{k_2}^2) = b_2 \\ \vdots \\ s(a_1^l) = s(a_2^l) = \dots = s(a_{k_l}^l) = b_l \end{cases}$$

with b_1, \dots, b_l all different. In the same way as before, we will suppose without loss of generality that $a_1^1 = 0$. Furthermore, since $f(a_i^j) = f(a_1^j)$ is equivalent to $f(a_i^j - a_1^j) = f(0)$ (i.e. a_i^j and a_1^j are in the same coset of H) we can remove each a_i^j , for $i, j > 1$ from $\text{dom}(s)$ and replace them by adding the point $a_i^j - a_1^j$ to $\text{dom}(s)$ associated to the value b_1 . The size of $\text{dom}(s)$ does not increase. It may happen that s was already defined on one of these entries and that our new definition is contradictory. In that case there is simply no subgroup-hiding function f extending s , so Q_n^s is simply the null polynomial and we are done. We will therefore consider only conditions of the form:

$$\begin{cases} s(0) = s(a_2^1) = \dots = s(a_{k_1}^1) = b_1 \\ s(a^2) = b_2 \\ \vdots \\ s(a^l) = b_l \end{cases}$$

The probability $Q_n^s(D)$ that a function f hiding a subgroup of order D extends s is the probability Q_1 that f satisfies $f(0) = f(a_2^1) = \dots = f(a_{k_1}^1) = b_1$ times the probability Q_2 that f extends s given that $f(0) = f(a_2^1) = \dots = f(a_{k_1}^1) = b_1$. We have already computed the first probability: this is the case where s is constant. Let H' be the subgroup generated by the a_i^1 's and $D' = p^{d'}$ its order; then $Q_1 = \frac{1}{p^n} \prod_{0 \leq i < d'} \frac{p^{d-i}-1}{p^{n-i}-1}$. Let us define s' on G/H' as the quotient of s if it exists (if not, this means again that Q_n^s is the null polynomial, and we are done). If f satisfies $f(0) = f(a_2^1) = \dots = f(a_{k_1}^1) = b_1$ then we can define f' on G/H' as the quotient of f ; the condition “ f extends s and hides a subgroup of order D ” is equivalent to “ f' extends s' and hides a subgroup of order D/D' ”. Since s' is defined by the condition $s'(H') = b_1, s'(a^2 + H') = b_2, \dots, s'(a^l + H') = b_l$ and is injective, our study of the second case shows that $Q_2 = Q_n^{s'}(D/D')$ is a polynomial in D of degree less than $|\text{dom}(s')|$. Hence, $Q_n^s(D)$ is a polynomial in D of degree at most $d' + |\text{dom}(s')| \leq |\text{dom}(s)| \leq 2T$.

Now that we have an upper bound on the degree of Q , let us find a lower bound. The following analogue of the lemmas of Paturi [15] and Nisan-Szegedy [14] will help.

Lemma 3. *Let $c > 0$ and $\xi > 1$ be constants and P a polynomial with the following properties:*

1. For any integer $0 \leq i \leq n$ we have $|P(\xi^i)| \leq 1$.
2. For some real number $1 \leq x_0 \leq \xi$ we have $|P'(x_0)| \geq c$.

Then $\deg(P) = \Omega(n)$, and more precisely: $\deg(P) \geq \min\left(\frac{n}{2}, \frac{\log_2(\xi^{n+3}c)-1}{\log_2\left(\frac{\xi^3}{\xi-1}\right)+1}\right)$.

Proof. Let d be the degree of P , and let us write $P'(X) = \lambda \prod_{i=1}^{d-1} (X - \alpha_i)$, where the α_i 's are real or complex numbers. The polynomials P' and P'' are respectively of degree $d - 1$ and $d - 2$, so there exists an integer $a \in [n - 2d + 2; n - 1]$ such that P'' has no real root in $(\xi^a; \xi^{a+1})$, and P' has no root whose real part is in this same interval. If $d \geq n/2$ there is nothing to prove, so we may and we will assume that $d \leq \frac{n}{2}$. This implies in particular that $\xi^a \geq \xi^2$.

The polynomial P' is monotone on $(\xi^a; \xi^{a+1})$, for P'' has no root in it. This means that P is either convex or concave on this interval, so that the graph of P is either over or under its tangent at the middle point of the interval, which is equal to $\frac{\xi^a + \xi^{a+1}}{2} = \frac{1 + \xi}{2} \xi^a$. Suppose that $P'\left(\frac{1 + \xi}{2} \xi^a\right)$ is nonnegative (the case when it is negative is similar). Then P is increasing on $(\xi^a; \xi^{a+1})$, since P' has no root in this interval. Let $y = t(x)$ be the equation of the tangent of P at $\frac{1 + \xi}{2} \xi^a$. If $t(\xi^{a+1}) > 1$, then $P(\xi^{a+1}) < t(\xi^{a+1})$, so P is concave on $(\xi^a; \xi^{a+1})$, hence $-1 \leq P(\xi^a) \leq t(\xi^a)$. But, since P is monotone on $(\xi^a; \xi^{a+1})$, $t\left(\frac{1 + \xi}{2} \xi^a\right) = P\left(\frac{1 + \xi}{2} \xi^a\right) \leq 1$. Since $t(\xi^{a+1}) - t\left(\frac{1 + \xi}{2} \xi^a\right) = t\left(\frac{1 + \xi}{2} \xi^a\right) - t(\xi^a)$, it follows that $t(\xi^{a+1}) \leq 3$ and $t(\xi^{a+1}) - t(\xi^a) \leq 4$. The same inequality can also be derived if we assume $t(\xi^a) < -1$, and it is of course still true if $t(\xi^a) \geq -1$ and $t(\xi^{a+1}) \leq 1$. We conclude that the inequality $t(\xi^{a+1}) - t(\xi^a) \leq 4$ always holds, which implies that $0 \leq P'\left(\frac{1 + \xi}{2} \xi^a\right) \leq \frac{4}{\xi^a(\xi - 1)}$. If we now include the case where P' is negative, we obtain the inequality

$$\left|P'\left(\frac{1 + \xi}{2} \xi^a\right)\right| \leq \frac{4}{\xi^a(\xi - 1)}.$$

We therefore have

$$\left|\frac{P'\left(\frac{1 + \xi}{2} \xi^a\right)}{P'(x_0)}\right| \leq \frac{4}{c \xi^a (\xi - 1)} \leq \frac{4}{c \xi^{n - 2d + 2} (\xi - 1)}. \tag{2}$$

To conclude we need to state a simple geometric fact. Let MBC be a triangle, M' the orthogonal projection of M onto (BC) , and (d) the perpendicular bissector of $[BC]$. Let us suppose that M is “at the right of (d) ”, i.e. $MC \leq MB$.

Since C is closer to the line (MM') than B , $\tan \alpha = MM'/BM' \leq \tan \beta = MM'/CM'$. Hence $\alpha \leq \beta$, and $\cos \alpha \geq \cos \beta$, i.e.:

$$\frac{MC}{MB} \geq \frac{M'C}{M'B}. \tag{3}$$

Let $f : \left(\begin{array}{l} \mathbb{R} \setminus \{x_0\} \rightarrow \mathbb{R} \\ x \mapsto \left| \frac{\frac{1+\xi}{2}\xi^a - x}{x_0 - x} \right| \end{array} \right)$. Since $x_0 < \xi^a < \frac{1+\xi}{2}\xi^a < \xi^{a+1}$, a quick study of this function shows that for all $x \in \mathbb{R} \setminus (\{x_0\} \cup (\xi^a; \xi^{a+1}))$, $f(x) \geq \min(1, f(\xi^a), f(\xi^{a+1})) \geq \frac{\xi-1}{2\xi}$.

We will distinguish two cases for each $i \in \{1; \dots; d-1\}$.

1. If $\Re(\alpha_i) \leq \frac{1}{2} \left(\frac{1+\xi}{2}\xi^a + x_0 \right)$, then $\left| \frac{\frac{1+\xi}{2}\xi^a - \alpha_i}{x_0 - \alpha_i} \right| \geq 1$.
2. If $\Re(\alpha_i) > \frac{1}{2} \left(\frac{1+\xi}{2}\xi^a + x_0 \right)$, let us apply (3) to the points $M = \alpha_i$, $M' = \Re(\alpha_i)$, $B = x_0$ and $C = \frac{1+\xi}{2}\xi^a$. We obtain the inequality

$$\left| \frac{\frac{1+\xi}{2}\xi^a - \alpha_i}{x_0 - \alpha_i} \right| \geq \left| \frac{\frac{1+\xi}{2}\xi^a - \Re(\alpha_i)}{x_0 - \Re(\alpha_i)} \right|.$$

Remember though that no root of P' has its real part in $(\xi^a; \xi^{a+1})$, so that

$$\left| \frac{\frac{1+\xi}{2}\xi^a - \alpha_i}{x_0 - \alpha_i} \right| \geq \frac{\xi-1}{2\xi}.$$

We conclude that $\left| \frac{1+\xi}{2} \frac{\xi^\alpha - \alpha_i}{x_0 - \alpha_i} \right| \geq \frac{\xi-1}{2\xi}$ in both cases. Taking (2) into account, we finally obtain the inequality $\left(\frac{\xi-1}{2\xi} \right)^{d-1} \leq \frac{4}{c\xi^{n-2d+2}(\xi-1)}$, hence $d \geq \frac{\log_2(\xi^{n+3}c)-1}{\log_2\left(\frac{\xi^3}{\xi-1}\right)+1}$.

We can now complete the proof of Theorem 1. Let A be our algorithm solving Simon’s problem with bounded error probability ϵ and query complexity T . As pointed out before Lemma 2, the associated polynomial Q_n satisfies $|Q'_n(x_0)| \geq 1-2\epsilon$ for some $x_0 \in [1, \xi]$ and $Q_n(\xi^i) \in [0, 1]$ for any $i \in \{0, 1, \dots, n\}$. An application of Lemma 3 to the polynomial $P = 2Q_n - 1$ therefore yields the inequality $\deg(Q_n) \geq \min\left(\frac{n}{2}, \frac{\log_2\left((2-4\epsilon)\frac{\xi^{n+3}}{p-1}\right)-1}{\log_2\left(\frac{\xi^3}{p-1}\right)+1}\right)$. Theorem 1 follows since $\deg(Q_n) \leq 2T(n)$ by Proposition 1.

4 Abelian Groups

In this section we give lower and upper bounds for the quantum query complexity of Abelian hidden subgroup problems. As explained in the introduction, our bounds are optimal up to constant factors.

Let G be a finite Abelian group, \hat{G} its dual group, i.e. the group of its characters (see for example [6]). For each subgroup H of G , we note H^\perp the orthogonal of H , which is a subgroup of \hat{G} consisted of those characters χ such that $\chi(h) = 1$ for all $h \in H$. According to basic representation theory, \hat{G} is isomorphic to G and, for all subgroup $H \leq G$, the index of H^\perp in \hat{G} is equal to the order of H .

The well-established method of Fourier sampling allows one, with one query to the black-box function, to pick a uniformly random element of the orthogonal of the hidden subgroup. In order to solve the hidden subgroup problem for G , this routine is run k times so as to generate k random elements $x_1, \dots, x_k \in H^\perp$. The algorithm outputs the orthogonal of the group generated by x_1, \dots, x_k . This output is correct if x_1, \dots, x_k generate all of H^\perp .

We will now show that this algorithm is optimal if we know when to stop, i.e., how many random elements should be picked in H^\perp . The following lemma states that the query complexity of the cyclic subgroup problem is constant. The proof is omitted from this extended abstract (note that this fact is already pointed out in [17]).

Lemma 4. *For any integer $M \geq 1$, two random elements chosen uniformly and independently in $\mathbb{Z}/M\mathbb{Z}$ generate all of this group with probability at least $\frac{1}{2}$.*

We recall that (following for instance [11]) the rank $r(G)$ of a group G is the minimal cardinality of a generating set of G . According to the fundamental theorem of finite Abelian groups, G is isomorphic to $\mathbb{Z}/m_1\mathbb{Z} \times \mathbb{Z}/m_2\mathbb{Z} \times \dots \times \mathbb{Z}/m_{r(G)}\mathbb{Z}$ where m_i divides m_{i-1} for every $i \in \{2, \dots, r(G)\}$, and this decomposition is unique.

Proposition 2. *For any $\epsilon > 0$ there exists an integer k such that for any finite Abelian group G , $k.r(G)$ random elements chosen uniformly and independently in G generate all of this group with probability at least $1 - \epsilon$.*

Proof. Let us denote by \mathcal{E}_n the supremum of the expectations of the number of random elements of G needed to generate G , taken over the groups G such that $r(G) \leq n$. We can assume that $G = \mathbb{Z}/m_1\mathbb{Z} \times \cdots \times \mathbb{Z}/m_{r(G)}\mathbb{Z}$, where $m_{r(G)} | \cdots | m_1$. To generate G we can proceed with the two following steps.

First we pick enough random elements $(x_1^1, \dots, x_1^{r(G)}), \dots, (x_k^1, \dots, x_k^{r(G)})$ in G so that x_1^1, \dots, x_k^1 generate $\mathbb{Z}/m_1\mathbb{Z}$; the expectation of k is at most \mathcal{E}_1 . By Lemma 4, \mathcal{E}_1 is finite; we can very roughly bound it in the following way.

First pick two random elements in $\mathbb{Z}/m_1\mathbb{Z}$. With probability $p_{\leq 2}$ they generate $\mathbb{Z}/m_1\mathbb{Z}$ and with probability $p_{> 2}$ they do not; when they fail to generate, just forget about them and renew the experiment with two new random elements. In the first case the expectation of the number of elements is 2, in the second case it is at most $2 + \mathcal{E}_1$, so we have $\mathcal{E}_1 \leq 2p_{\leq 2} + (2 + \mathcal{E}_1)p_{> 2}$. Clearly $p_{\leq 2} + p_{> 2} = 1$ and according to Lemma 4 we have $p_{\leq 2} \geq \frac{1}{2}$. This shows that $\mathcal{E}_1 \leq 4$.

Then the subgroup generated by these elements contains some element $y = (y^1, \dots, y^{r(G)})$ such that the order of y^1 is m_1 . The rank of $G/\langle y \rangle$ is equal to $r(G) - 1$ since $G/\langle y \rangle$ is isomorphic to $\mathbb{Z}/m_2\mathbb{Z} \times \cdots \times \mathbb{Z}/m_{r(G)}\mathbb{Z}$. This isomorphism follows from the fact the classes of $e_2, \dots, e_{r(G)}$ generate $G/\langle y \rangle$, where e_i denotes the element of G whose i^{th} coordinate is equal to 1 and all other coordinates equal to 0. We now pick enough random elements $x_{k+1}, \dots, x_{k+l} \in G$ so that their images in $G/\langle y \rangle$ generate all of it; the expectation of l is of course at most $\mathcal{E}_{r(G)-1}$. Putting it together, we get $\mathcal{E}_{n+1} \leq \mathcal{E}_1 + \mathcal{E}_n$, so $\mathcal{E}_n \leq 4n$. By Markov's inequality, if we choose $\lceil \frac{4}{\epsilon} \rceil r(G)$ random elements in a group G , we generate all of this group with probability at least $1 - \epsilon$.

We can now prove our main result.

Theorem 2. *The quantum query complexity of the hidden subgroup problem in a finite Abelian group G is $\Theta(r(G))$.*

Proof. The upper bound is achieved with the standard method: one just applies Proposition 2 to the orthogonal of the hidden subgroup, which is isomorphic to a subgroup of G , using the fact that r is a nondecreasing function on finite Abelian groups.

The lower bound of course comes from Theorem 1. Since for every finite Abelian group G there is some prime p such that $(\mathbb{Z}/p\mathbb{Z})^{r(G)}$ is isomorphic to some subgroup of G , we need only to state that the hidden subgroup problem for a subgroup of G reduces correctly to the hidden subgroup problem for G . Indeed, let H be a subgroup of G and let $H + t_0, \dots, H + t_k$ be the cosets of H in G , where $t_0 = 0$. If $\gamma : H \rightarrow X$ hides a subgroup of H , we can define a function $\gamma' : G \rightarrow X \times \{t_i/0 \leq i \leq k\}$ which hides the same subgroup. Namely, we define $\gamma'(x + t_i) = (\gamma(x), t_i)$ for $x \in H$. Moreover, a call to γ' uses just one call to γ , so we are done.

Abstract. The quantum adversary method is one of the most versatile lower-bound methods for quantum algorithms. We show that all known variants of this method are equal: spectral adversary [1], weighted adversary [2], strong weighted adversary [3], and the Kolmogorov complexity adversary [4]. We also present a few new equivalent formulations of the method. This shows that there is essentially *one* quantum adversary method. From our approach, all known limitations of all versions of the quantum adversary method easily follow.

1 Introduction

1.1 Lower-Bound Methods for Quantum Query Complexity

In the query complexity model, the input is accessed using oracle queries and the query complexity of the algorithm is the number of calls to the oracle. The query complexity model is helpful in obtaining time complexity lower bounds, and often this is the only way to obtain time bounds in the random access model.

The first lower-bound method was the hybrid method of Bennett, Bernstein, Brassard, and Vazirani [5] to show an $\Omega(\sqrt{n})$ lower bound on the quantum database search. Their proof is based on the following simple observation: If the value of function f differs on two inputs x, y , then the output quantum states of any bounded-error algorithm for f on x and y must be almost orthogonal. On the other hand, the inner product is 1 at the beginning, because the computation starts in a fixed state. By upper-bounding the change of the inner product after one query, we lower bound the number of queries that need to be made.

The second lower-bound method is the polynomial method of Beals, Buhrman, Cleve, Mosca, and de Wolf [6]. It is based on the observation that the measure-

ment probabilities can be described by low-degree polynomials in the input bits. If t queries have been made, then the degree is at most $2t$. Since the measurement probabilities are always inside $[0, 1]$, one can apply some degree lower bounds for polynomials and thus obtain good lower bounds for quantum query complexity.

The third lower-bound method is the quantum adversary method of Ambainis [7]. It extends the hybrid method. Instead of examining a fixed input pair, Ambainis takes an average over many pairs of inputs. In this paper, we study different variants of the quantum adversary method.

The fourth lower-bound method is the semidefinite programming method of Barnum, Saks, and Szegedy [1]. It exactly characterizes quantum query complexity by a semidefinite program. The dual of this program gives a lower bound that encompasses the quantum adversary bound.

1.2 The Variants of the Quantum Adversary Method

The original quantum adversary method, let us call it unweighted, was invented by Ambainis [7]. It was successfully used to obtain the following tight lower bounds: $\Omega(\sqrt{n})$ for Grover search [8], $\Omega(\sqrt{n})$ for two-level And-Or trees (see [9] for a matching upper bound), and $\Omega(\sqrt{n})$ for inverting a permutation.

Some functions, such as sorting or ordered search, could not be well lower-bounded by the unweighted method. Høyer, Neerbek, and Shi used a weighting argument [10] to obtain tight bounds for these problems. Barnum, Saks, and Szegedy proposed a general method [1] that gives necessary and sufficient conditions for the existence of a quantum query algorithm. They also described a special case, so-called *spectral method*, which gives a lower bound in terms of spectral norms of an adversary matrix. Ambainis also published a *weighted version of his adversary method* [2]. He applied it to get a lower bound for several iterated functions. Zhang observed that Ambainis had generalized his oldest method [7] in two independent ways, so he unified them, and published a *strong weighted adversary method* [3]. Finally, Laplante and Magniez used Kolmogorov complexity in an unusual way and described a *Kolmogorov complexity method* [4].

A few relations between the methods are known. The strong weighted adversary is clearly at least as good as the weighted adversary. Laplante and Magniez showed [4] that the Kolmogorov complexity method is at least as strong as all the following methods: the Ambainis unweighted and weighted method, the strong weighted method, and the spectral method. The method of Høyer et al. [10] is a special case of the weighted adversary method.

In addition it was known that there were some limitations for lower bounds obtained by the adversary method. Szegedy observed [11] that the weighted adversary method is limited by $\min(\sqrt{C_0 n}, \sqrt{C_1 n})$, where C_0 is the zero-certificate complexity of f and C_1 is the one-certificate complexity of f . Laplante and Magniez proved the same limitation for the Kolmogorov complexity method [4], which implies that all other methods are also bounded. Finally, this bound was improved to $\sqrt{C_0 C_1}$ for total f by Zhang [3] and independently by us.

1.3 Our Results

In this paper, we clean up the forest of adversary methods. We show that there is essentially only one quantum adversary method and that all the former methods [1, 2, 3, 4, 10] are just different formulations of the same method. This means that the quantum adversary method is a very robust concept. Furthermore, we also present a new simple proof of the $\min(\sqrt{C_0 n}, \sqrt{C_1 n})$ limitation of the quantum adversary method for partial f , resp. $\sqrt{C_0 C_1}$ for total f .

This paper is an extended abstract with some proofs omitted. The full version can be downloaded from <http://arxiv.org/abs/quant-ph/0409116>.

1.4 Separation Between the Polynomial and Adversary Method

The polynomial method and the adversary method are incomparable. There are examples when the polynomial method gives better bounds and vice versa.

The polynomial method was successfully applied to obtain tight lower bound $\Omega(n^{1/3})$ for the collision problem and $\Omega(n^{2/3})$ for the element distinctness problem [12] (see [13] for a matching upper bound). The adversary method is incapable of proving such lower bounds due to the small certificate complexity of the function. Furthermore, the polynomial method often gives tight lower bounds for the exact and zero-error quantum complexity, such as n for the Or function [6]. The adversary method can only provide bounded-error lower bounds.

On the other hand, Ambainis exhibited some iterated functions [2], for which the adversary method gives better lower bounds than the polynomial method. The biggest proved gap between the two methods is $n^{1.321}$. Furthermore, the polynomial method did not yet succeed in proving several lower bounds that are very simple to prove by the adversary method. A famous example is the two-level And-Or tree. The adversary method gives a tight lower bound $\Omega(\sqrt{n})$ [7], whereas the best bound obtained by the polynomial method is $\Omega(n^{1/3})$ and it follows from the element distinctness lower bound [12].

There are functions for which none of the methods is known to give a tight bound. A long-standing open problem is the binary And-Or tree. The best known quantum algorithm just implements the classical zero-error algorithm by Saks and Wigderson [14] running in expected time $O(n^{0.753})$. Adversary lower bounds are limited by $\sqrt{C_0 C_1} = \sqrt{n}$. Recently, Laplante, Lee, and Szegedy showed [15] that this limitation \sqrt{n} holds for every read-once $\{\wedge, \vee\}$ formula. The best known lower bound obtained by the polynomial method is also $\Omega(\sqrt{n})$ and it follows from embedding the parity function. The polynomial method might prove a stronger lower bound. Another example is triangle finding. The best upper bound is $O(n^{1.3})$ [16] and the best lower bound is $\Omega(n)$. Again, the adversary method cannot give better than a linear bound, but the polynomial method might.

The semidefinite programming method [1] gives an exact characterization of quantum query complexity. However, it is too general to be applied directly. It is an interesting open problem to find a lower bound that cannot be proved by the adversary or polynomial method.

2 Preliminaries

2.1 Quantum Query Algorithms

We assume familiarity with quantum computing [17] and sketch the model of quantum query complexity, referring to [18] for more details, also on the relation between query complexity and certificate complexity. Suppose we want to compute some function f . For input $x \in \{0, 1\}^N$, a *query* gives us access to the input bits. It corresponds to the unitary transformation, which depends on input x in the following way: $O_x : |i, b, z\rangle \mapsto |i, b \oplus x_i, z\rangle$. Here $i \in [N] = \{1, \dots, N\}$ and $b \in \{0, 1\}$; the z -part corresponds to the workspace, which is not affected by the query. We assume the input can be accessed only via such queries. A T -query quantum algorithm has the form $A = U_T O_x U_{T-1} \cdots O_x U_1 O_x U_0$, where the U_k are fixed unitary transformations, independent of x . This A depends on x via the T applications of O_x . The algorithm starts in initial S -qubit state $|0\rangle$. For a Boolean function f , the output of A is obtained by observing the leftmost qubit of the final superposition $A|0\rangle$, and its acceptance probability on input x is its probability of outputting 1.

2.2 Kolmogorov Complexity

An excellent book about Kolmogorov complexity is the book [19] by Li and Vitányi. A deep knowledge of Kolmogorov complexity is not necessary to understand this paper. Some results on the relation between various classical forms of the quantum adversary method and the Kolmogorov complexity method are taken from Laplante and Magniez [4], and the others just use basic techniques.

A set is called *prefix-free* if none of its members is a prefix of another member. Fix a universal Turing machine M and a prefix-free set S . The *prefix-free Kolmogorov complexity* of x given y , denoted by $K(x|y)$, is the length of the shortest program from S that prints x if it gets y on the input. Formally, $K(x|y) = \min\{|P| : P \in S, M(P, y) = x\}$.

2.3 Notation

Let $[n] = \{1, 2, \dots, n\}$. Let Σ^* denote the set of all finite strings over alphabet Σ . All logarithms are binary. Let I denote the *identity* matrix. Let A^T denote the *transpose* of A . Let $\text{diag}(A)$ denote the column vector containing the *main diagonal* of A . Let $\text{tr}(A)$ be the *trace* of A and let $A \cdot B$ be the scalar product of A and B . For a column vector x , let $|x|$ denote the ℓ_2 -norm of x . Let $\lambda(A)$ denote the *spectral norm* of A , formally $\lambda(A) = \max_{x:|x| \neq 0} |Ax|/|x|$. We say that a matrix is *Boolean*, if it contains only zeroes and ones. Let AB denote the usual *matrix product* and let $A \circ B$ denote the *Hadamard (point-wise) product* [20]. Let $A \geq B$ denote the *point-wise comparison* and let $C \succeq D$ denote that $C - D$ is *positive semidefinite*. Let $r_x(M)$ denote the ℓ_2 -norm of the x -th row of M and let $c_y(M)$ denote the ℓ_2 -norm of the y -th column of M . Let $r(M) = \max_x r_x(M)$ and $c(M) = \max_y c_y(M)$.

We call a function $f : S \rightarrow \{0, 1\}$ *total*, if $S = \{0, 1\}^n$, otherwise it is called *partial*. Let f be a partial function. A *certificate* for an input $x \in S$ is a subset $I \subseteq [n]$ such that fixing the input bits $i \in I$ to x_i determines the function value. Formally, $\forall y \in S : y|_I = x|_I \Rightarrow f(y) = f(x)$, where $x|_I$ denotes the substring of x indexed by I . A certificate I for x is called *minimal*, if $|I| \leq |J|$ for every certificate J for x . Let $\mathcal{C}_f(x)$ denote the lexicographically smallest *minimal certificate* for x . Let $C_0(f) = \max_{x:f(x)=0} |\mathcal{C}_f(x)|$ be the *zero-certificate complexity* of f and let $C_1(f) = \max_{x:f(x)=1} |\mathcal{C}_f(x)|$ be the *one-certificate complexity* of f .

3 Main Result

In this section, we present several equivalent quantum adversary methods and a new simple proof of the limitations of these methods. We can categorize these methods into two groups. Some of them solve conditions on the primal of the quantum system [1]: these are the spectral, weighted, strong weighted, and generalized spectral adversary; and some of them solve conditions on the dual: these are the Kolmogorov complexity bound, minimax, and the semidefinite version of minimax. Primal methods are mostly used to give lower bounds on the query complexity, while we can use the duals to give limitations of the method.

Theorem 1. *Let $n \geq 1$ be an integer, let $S \subseteq \{0, 1\}^n$, and let $f : S \rightarrow \{0, 1\}$ be a partial Boolean function. Let $Q_\varepsilon(f)$ be the ε -error quantum query complexity of f . Then $\frac{Q_\varepsilon(f)}{1-2\sqrt{\varepsilon(1-\varepsilon)}} \geq \text{SA}(f) = \text{WA}(f) = \text{SWA}(f) = \text{MM}(f) = \text{SMM}(f) = \text{GSA}(f) = \Theta(\text{KA}(f))$, where SA, WA, SWA, MM, SMM, GSA, and KA are lower bounds given by the following methods:*

- **Spectral adversary [1].** *Let D_i, F be $|S| \times |S|$ Boolean matrices that satisfy $D_i[x, y] = 1$ iff $x_i \neq y_i$ for $i \in [n]$, and $F[x, y] = 1$ iff $f(x) \neq f(y)$. Let Γ denote an $|S| \times |S|$ non-negative symmetric matrix with $\Gamma \circ F = \Gamma$. Then*

$$\text{SA}(f) = \max_{\Gamma} \frac{\lambda(\Gamma)}{\max_i \lambda(\Gamma \circ D_i)}. \quad (1)$$

- **Weighted adversary [2].¹** *Let w, w' denote a weight scheme as follows:*
 - *Every pair $(x, y) \in S^2$ is assigned a non-negative weight $w(x, y) = w(y, x)$ that satisfies $w(x, y) = 0$ whenever $f(x) = f(y)$.*
 - *Every triple $(x, y, i) \in S^2 \times [n]$ is assigned a non-negative weight $w'(x, y, i)$ that satisfies $w'(x, y, i) = 0$ whenever $x_i = y_i$ or $f(x) = f(y)$, and $w'(x, y, i)w'(y, x, i) \geq w^2(x, y)$ for all x, y, i such that $x_i \neq y_i$.*

¹ We use a different formulation [4] than in the original Ambainis papers [7, 2]. In particular, we omit the relation $R \subseteq A \times B$ on which the weights are required to be nonzero, and instead allow zero weights.

For all x, i , let $wt(x) = \sum_y w(x, y)$ and $v(x, i) = \sum_y w'(x, y, i)$. Then

$$WA(f) = \max_{w, w'} \min_{\substack{x, i \\ f(x, i) = 0 \\ v(x, i) > 0}} \sqrt{\frac{wt(x)}{v(x, i)}} \cdot \min_{\substack{y, j \\ f(y, j) = 1 \\ v(y, j) > 0}} \sqrt{\frac{wt(y)}{v(y, j)}}. \tag{2}$$

- **Strong weighted adversary [3].** Let w, w' denote a weight scheme as above. Then

$$SWA(f) = \max_{w, w'} \min_{\substack{x, y, i \\ w(x, y) > 0 \\ x_i \neq y_i}} \sqrt{\frac{wt(x)wt(y)}{v(x, i)v(y, i)}}. \tag{3}$$

- **Kolmogorov complexity [4].²** Let $\sigma \in \{0, 1\}^*$ denote a finite string. Then

$$KA(f) = \min_{\sigma} \max_{\substack{x, y \\ f(x) \neq f(y)}} \frac{1}{\sum_{i: x_i \neq y_i} \sqrt{2^{-K(i|x, \sigma) - K(i|y, \sigma)}}}. \tag{4}$$

- **Minimax over probability distributions [4].** Let $p : S \times [n] \rightarrow \mathbb{R}$ denote a set of probability distributions, that is $p_x(i) \geq 0$ and $\sum_i p_x(i) = 1$ for every x . Then

$$MM(f) = \min_p \max_{\substack{x, y \\ f(x) \neq f(y)}} \frac{1}{\sum_{i: x_i \neq y_i} \sqrt{p_x(i) p_y(i)}} \tag{5}$$

$$= 1 / \max_p \min_{\substack{x, y \\ f(x) \neq f(y)}} \sum_{i: x_i \neq y_i} \sqrt{p_x(i) p_y(i)}. \tag{6}$$

- **Semidefinite version of minimax.** Let D_i, F be Boolean matrices as above. Then $SMM(f) = 1/\mu_{\max}$, where μ_{\max} is the maximal solution of the following semidefinite program:

$$\begin{aligned} & \text{maximize } \mu \\ & \text{subject to } \forall i : R_i \succeq 0, \\ & \qquad \sum_i R_i \circ I = I, \\ & \qquad \sum_i R_i \circ D_i \geq \mu F. \end{aligned} \tag{7}$$

- **Generalized spectral adversary.** Let D_i, F be Boolean matrices as above. Then $GSA(f) = 1/\mu_{\min}$, where μ_{\min} is the minimal solution of the following semidefinite program:

$$\begin{aligned} & \text{minimize } \mu = \text{tr } \Delta \\ & \text{subject to } \Delta \text{ is diagonal} \\ & \qquad Z \geq 0 \\ & \qquad Z \cdot F = 1 \\ & \qquad \forall i : \Delta - Z \circ D_i \succeq 0. \end{aligned} \tag{8}$$

² We use a different formulation than Laplante and Magniez [4]. They minimize over all algorithms A computing f and substitute $\sigma =$ source code of A , whereas we minimize over all finite strings σ .

Before we prove the main theorem in the next sections, let us draw some consequences. We show that there are limits that none of these quantum adversary methods can go beyond.

Theorem 2. *Let $S \subseteq \{0, 1\}^n$ and let $f : S \rightarrow \{0, 1\}$ be a partial Boolean function. The max-min bound (6) is upper-bounded by $\text{MM}(f) \leq \min(\sqrt{C_0(f)n}, \sqrt{C_1(f)n})$. If f is total, then $\text{MM}(f) \leq \sqrt{C_0(f)C_1(f)}$.*

Proof. The following simple argument is due to Ronald de Wolf. We exhibit a set of probability distributions p such that

$$m(p) = \min_{\substack{x, y \\ f(x) \neq f(y)}} \sum_{i: x_i \neq y_i} \sqrt{p_x(i)p_y(i)} \geq \frac{1}{\sqrt{C_0 n}}, \text{ resp. } \frac{1}{\sqrt{C_0 C_1}}.$$

The max-min bound is $\text{MM}(f) = 1/\max_p m(p)$ and the statement follows.

Let f be partial. For every $x \in f^{-1}(0)$, distribute the probability uniformly over any minimal certificate $\mathcal{C}_f(x)$, and for every $y \in f^{-1}(1)$, distribute the probability uniformly over all input bits. Formally, $p_x(i) = 1/|\mathcal{C}_f(x)|$ iff $i \in \mathcal{C}_f(x)$, $p_x(i) = 0$ for $i \notin \mathcal{C}_f(x)$, and $p_y(i) = 1/n$. Take any x, y such that $f(x) = 0$ and $f(y) = 1$, and the zero-certificate $I = \mathcal{C}_f(x)$. Since $y|_I \neq x|_I$, there is a $j \in I$ such that $x_j \neq y_j$. Now we lower-bound the sum of (6):

$$\sum_{i: x_i \neq y_i} \sqrt{p_x(i)p_y(i)} \geq \sqrt{p_x(j)p_y(j)} = \sqrt{\frac{1}{|\mathcal{C}_f(x)|} \cdot \frac{1}{n}} \geq \frac{1}{\sqrt{C_0 n}}.$$

If f is total, then we can do even better. For every $x \in \{0, 1\}^n$, distribute the probability uniformly over any minimal certificate $\mathcal{C}_f(x)$. Formally, $p_x(i) = 1/|\mathcal{C}_f(x)|$ iff $i \in \mathcal{C}_f(x)$, and $p_x(i) = 0$ otherwise. Take any x, y such that $f(x) \neq f(y)$, and let $I = \mathcal{C}_f(x) \cap \mathcal{C}_f(y)$. There must exist a $j \in I$ such that $x_j \neq y_j$, otherwise we could find an input z that is consistent with both certificates. (That would be a contradiction, because f is total and hence $f(z)$ has to be defined and be equal to both 0 and 1.) After we have found a j , we lower-bound the sum of (6) in the same way as above. \square

Some parts of the following statement have already been observed for individual methods by Szegedy [11], Laplante and Magniez [4], and Zhang [3]. This corollary rules out all adversary attempts to prove good lower bounds for problems with small certificate complexity, such as element distinctness [12], binary And-Or trees [14, 21, 9], or triangle finding [16].

Corollary 1. *All quantum adversary lower-bounds are at most $\min(\sqrt{C_0(f)n}, \sqrt{C_1(f)n})$ for partial functions and $\sqrt{C_0(f)C_1(f)}$ for total functions.*

4 Equivalence of Spectral and Strong Weighted Adversary

In this section, we give a linear-algebraic proof that the spectral bound [1] and the strong weighted bound [3] are equal. The proof has three steps. First, we

show that the weighted bound [2] is at least as good as the spectral bound. Second, using a small combinatorial lemma, we show that the spectral bound is at least as good as the strong weighted bound. The third step is trivial, since the strong weighted bound is always at least as good as the weighted bound. The generalization of the weighted adversary method thus does not make the bound stronger, however its formulation is easier to use.

First, let us state two useful statements upper-bounding the spectral norm of a Hadamard product of two non-negative matrices. The first one is due to Mathias [20]. The second one is our generalization and its proof is omitted.

Lemma 1. [20] *Let S be a non-negative symmetric matrix and let M and N be non-negative matrices such that $S \leq M \circ N$. Then $\lambda(S) \leq r(M)c(N) = \max_{x,y} r_x(M)c_y(N)$. Moreover, for every S there exist M, N such that $S = M \circ N$ and $\lambda(S) = r(M)c(N)$.*

Lemma 2. *Let S be a non-negative symmetric matrix and let M and N be non-negative matrices such that $S \leq M \circ N$. Let $B(M, N) = \max_{S[x,y]>0} r_x(M)c_y(N)$. Then $\lambda(S) \leq B(M, N)$.*

Now we reduce the spectral adversary to the weighted adversary.

Theorem 3. $SA(f) \leq WA(f)$.

Proof. Let Γ be any non-negative symmetric matrix with $\Gamma \circ F = \Gamma$ as in equation (1). Assume without loss of generality that $\lambda(\Gamma) = 1$. Let δ be the principal eigenvector of Γ , that is $\Gamma\delta = \delta$. Define the following weight scheme: $w(x, y) = w(y, x) = \Gamma[x, y] \cdot \delta[x]\delta[y]$. Furthermore, for every i , decompose every $\Gamma_i = \Gamma \circ D_i$ into a Hadamard product of two non-negative matrices $\Gamma_i = M_i \circ N_i$ such that $\lambda(\Gamma_i) = r(M_i)c(N_i)$. This is always possible by Lemma 1. We ensure that $r(M_i) = c(N_i) = \sqrt{\lambda(\Gamma_i)}$ by multiplying M_i and dividing N_i by the same constant. Define w' :

$$w'(x, y, i) = \begin{cases} (M_i[x, y] \delta[x])^2 & \text{iff } f(x) = 0, f(y) = 1, \text{ and } x_i \neq y_i, \\ (N_i[y, x] \delta[y])^2 & \text{iff } f(x) = 1, f(y) = 0, \text{ and } x_i \neq y_i, \\ 0 & \text{otherwise.} \end{cases}$$

Let us verify that w, w' is a weight scheme. From the definition, $w(x, y) = w'(x, y, i) = 0$ if $f(x) = f(y)$, and also $w'(x, y, i) = 0$ if $x_i = y_i$. Furthermore, if $f(x) = 0, f(y) = 1$, and $x_i \neq y_i$, then $w'(x, y, i)w'(y, x, i) = (M_i[x, y] \delta[x])^2 (N_i[x, y] \delta[y])^2 = (\Gamma_i[x, y] \delta[x]\delta[y])^2 = w(x, y)^2$. Finally, let us compute the bound (2) given by the weight scheme. Let $v_b = \max_{f(x)=b} \frac{v(x,i)}{wt(x)}$. Then

$$wt(x) = \sum_y w(x, y) = \delta[x] \sum_y \Gamma[x, y] \delta[y] = \delta[x] (\Gamma\delta)[x] = \delta[x]^2,$$

$$v_0 = \max_{\substack{x,i \\ f(x)=0}} \frac{\sum_y w'(x, y, i)}{wt(x)} \leq \max_{\substack{x,i \\ f(x)=0}} \frac{\sum_y (M_i[x, y])^2 \delta[x]^2}{\delta[x]^2} \leq \max_i (r(M_i))^2,$$

and, analogously, $v_1 \leq \max_i (c(N_i))^2$. Since $r(M_i) = c(N_i) = \sqrt{\lambda(\Gamma_i)}$, both $v_0, v_1 \leq \max_i \lambda(\Gamma_i)$. Hence $1/\sqrt{v_0 v_1} \geq 1/\max_i \lambda(\Gamma_i)$, and the weight scheme w, w' gives at least as good bound as the matrix Γ . \square

Now we reduce the strong weighted adversary to the spectral adversary.

Theorem 4. $\text{SWA}(f) \leq \text{SA}(f)$.

Proof. Let w, w' be any weight scheme as in equation (2). Define the following symmetric matrix Γ on $S \times S$: $\Gamma[x, y] = \frac{w(x, y)}{\sqrt{wt(x)wt(y)}}$. We also define column vector δ on S such that $\delta[x] = \sqrt{wt(x)}$. Let $W = \sum_x wt(x)$. Then $\lambda(\Gamma) \geq \delta^T \Gamma \delta / |\delta|^2 = W/W = 1$. Next, we show that, for every i , we have $\lambda(\Gamma_i) \leq \sqrt{u_i}$ for $u_i = \max_{\substack{x, y \\ w(x, y) > 0, x_i \neq y_i}} \frac{v(x, i)v(y, i)}{wt(x)wt(y)}$. Once we prove this, we are done, since the strong weighted bound (3) is $1/\max_i \sqrt{u_i}$. Let $A = f^{-1}(0)$ and $B = f^{-1}(1)$. Fix i and define the following rectangular matrices on the index set $A \times B$:

$$M_i[x, y] = \sqrt{\frac{w'(x, y, i)}{wt(x)}}, \quad N_i[x, y] = \sqrt{\frac{w'(y, x, i)}{wt(y)}}.$$

Every weight scheme satisfies $w'(x, y, i)w'(y, x, i) \geq w^2(x, y)$ for all x, y, i such that $x_i \neq y_i$. It follows that if we reorder Γ_i to put A first and B last, then

$$\Gamma_i = \Gamma \circ D_i \leq \begin{pmatrix} 0 & M_i \circ N_i \\ M_i^T \circ N_i^T & 0 \end{pmatrix} = \begin{pmatrix} 0 & \bar{M}_i \\ \bar{N}_i^T & 0 \end{pmatrix} \circ \begin{pmatrix} 0 & \bar{N}_i \\ \bar{M}_i^T & 0 \end{pmatrix},$$

where $\bar{M}_i = \sqrt{\frac{c(N_i)}{r(M_i)}} M_i$ and $\bar{N}_i = \sqrt{\frac{r(M_i)}{c(N_i)}} N_i$. This is done for balancing the row norm of M_i and column norm of N_i : $r(\bar{M}_i) = c(\bar{N}_i) = \sqrt{r(M_i)c(N_i)}$. Evaluate

$$B(M_i, N_i^T) = \max_{\substack{x, y \\ \Gamma_i[x, y] > 0}} \sqrt{\sum_k \frac{w'(x, k, i)}{wt(x)} \sum_\ell \frac{w'(y, \ell, i)}{wt(y)}} = \max_{\substack{x, y \\ w(x, y) > 0 \\ x_i \neq y_i}} \sqrt{\frac{v(x, i)v(y, i)}{wt(x)wt(y)}}.$$

By Lemma 2, $\lambda(\Gamma_i) \leq B(\bar{M}_i, \bar{N}_i^T) = B(M_i, N_i^T) = \sqrt{u_i}$, as claimed. \square

5 Equivalence of Minimax and Generalized Spectral Adversary

In this section, we prove that the minimax bound is equal to the generalized spectral bound. We first get rid of the reciprocal by taking the max-min bound. Second, we write this bound as a semidefinite program. An application of duality theory of semidefinite programming finishes the proof.

Theorem 5. $MM(f) = SMM(f)$.

Proof. Let p be a set of probability distributions as in equation (6). Define $R_i[x, y] = \sqrt{p_x(i)p_y(i)}$. Since p_x is a probability distribution, we get that $\sum_i R_i$ must have all ones on the diagonal. The condition $\min_{f(x) \neq f(y)} \sum_{i: x_i \neq y_i} R_i[x, y] \geq \mu$ is rewritten into $\forall x, y : f(x) \neq f(y) \implies \sum_{i: x_i \neq y_i} R_i[x, y] \geq \mu$, which is $\sum_i R_i \circ D_i \geq \mu F$. However, the matrices R_i are rank-1 and they have non-negative entries. We have replaced that condition by $R_i \succeq 0$ to get semidefinite program (7). Hence the program (7) is a relaxation of the condition of (6) and $SMM(f) \leq MM(f)$.

Let us show that every solution R_i of the semidefinite program can be changed to an at least as good rank-1 solution R'_i . Take a Cholesky decomposition $R_i = X_i X_i^T$. Define a column-vector $q_i[x] = \sqrt{\sum_j X_i[x, j]^2}$ and a rank-1 matrix $R'_i = q_i q_i^T$. It is not hard to show that all R'_i satisfy the same constraints as R_i . First, R'_i is positive semidefinite. Second, $R'_i[x, x] = \sum_j X_i[x, j]^2 = R_i[x, x]$, hence $\sum_i R_i \circ I = I$. Third, by a Cauchy-Schwarz inequality,

$$R_i[x, y] = \sum_j X_i[x, j] X_i[y, j] \leq \sqrt{\sum_k X_i[x, k]^2} \sqrt{\sum_\ell X_i[y, \ell]^2} = R'_i[x, y],$$

hence $\sum_i R'_i \circ D_i \geq \sum_i R_i \circ D_i \geq \mu F$. We conclude that $MM(f) \leq SMM(f)$. \square

Theorem 6. $SMM(f) = GSA(f)$.

Proof. Omitted; it only uses the duality theory of semidefinite programming.

6 Equivalence of Generalized Spectral and Spectral Adversary

In this section, we prove that the generalized spectral adversary bound is equal to the spectral adversary bound. The main difference between them is that the generalized method uses a positive diagonal matrix Δ as a new variable.

Theorem 7. $GSA(f) = SA(f)$.

Proof. Let Z, Δ be a solution of (8). First, let us prove that $\Delta \succ 0$. Since both $Z \geq 0$ and $D_i \geq 0$, it holds that $\text{diag}(-Z \circ D_i) \leq 0$. We know that $\Delta - Z \circ D_i \succeq 0$, hence $\text{diag}(\Delta - Z \circ D_i) \geq 0$, and $\text{diag}(\Delta) \geq 0$ follows. Moreover, $\text{diag}(\Delta) > 0$ unless Z contains an empty row, in which case we delete it (together with the corresponding column) and continue. Second, $\Delta - Z \circ D_i \succeq 0$ implies that $Z \circ D_i$ is symmetric for every i . It follows that Z must be also symmetric.

Take a column vector $a = \text{diag}(\Delta^{-1/2})$ and a rank-1 matrix $A = aa^T \succ 0$. It is simple to prove that $A \circ X \succeq 0$ for every matrix $X \succeq 0$.

Since $\Delta - Z \circ D_i \succeq 0$, also $A \circ (\Delta - Z \circ D_i) = I - Z \circ D_i \circ A \succeq 0$ and hence $\lambda(Z \circ D_i \circ A) \leq 1$. Now, define the spectral adversary matrix $\Gamma = Z \circ F \circ A$. Since $0 \leq Z \circ F \leq Z$, it follows that

$$\lambda(\Gamma \circ D_i) = \lambda(Z \circ F \circ A \circ D_i) \leq \lambda(Z \circ D_i \circ A) \leq 1.$$

It remains to show that $\lambda(\Gamma) \geq 1/\text{tr } \Delta$. Let $b = \text{diag}(\sqrt{\Delta})$ and $B = bb^T$. Then

$$1 = Z \cdot F = \Gamma \cdot B = b^T \Gamma b \leq \lambda(\Gamma) \cdot |b|^2 = \lambda(\Gamma) \cdot \text{tr } \Delta.$$

Γ is clearly symmetric, $\Gamma \geq 0$, and $\Gamma \circ F = \Gamma$. The bound (1) given by Γ is bigger than or equal to $1/\text{tr } \Delta$, hence $\text{SA}(f) \geq \text{GSA}(f)$.

For the other direction, let Γ be a non-negative symmetric matrix satisfying $\Gamma \circ F = \Gamma$. Let δ be its principal eigenvector with $|\delta| = 1$. Assume without loss of generality that $\lambda(\Gamma) = 1$ and let $\mu = \max_i \lambda(\Gamma_i)$. Take $A = \delta\delta^T$, $Z = \Gamma \circ A$, and $\Delta = \mu I \circ A$. Then $Z \cdot F = \Gamma \cdot A = \delta^T \Gamma \delta = 1$ and $\text{tr } \Delta = \mu$. For every i , $\lambda(\Gamma_i) \leq \mu$, hence $\mu I - \Gamma \circ D_i \succeq 0$. It follows that $0 \preceq A \circ (\mu I - \Gamma \circ D_i) = \Delta - Z \circ D_i$. The semidefinite program (8) is satisfied and hence its optimum is $\mu_{\min} \leq \mu$. We conclude that $\text{GSA}(f) \geq \text{SA}(f)$. \square

7 Proof of the Main Theorem

In this section, we close the circle of reductions. We use the results of Laplante and Magniez, who recently proved [4] that the Kolmogorov complexity bound is asymptotically lower-bounded by the weighted adversary bound and upper-bounded by the minimax bound. The upper bound is implicit in their paper, because they did not state the minimax bound as a separate theorem.

Theorem 8. [4–Theorem 2] $\text{KA}(f) = \Omega(\text{WA}(f))$.

Theorem 9. $\text{KA}(f) = \text{O}(\text{MM}(f))$.

Proof. Take a set of probability distributions p as in equation (5). The query information lemma [4–Lemma 3] says that $K(i|x, p) \leq \log \frac{1}{p_x(i)} + \text{O}(1)$ for every x, i such that $p_x(i) > 0$. This is true, because any i of nonzero probability can be encoded in $\lceil \log \frac{1}{p_x(i)} \rceil$ bits using the Shannon-Fano code of distribution p_x , and the Shannon-Fano code is prefix-free. Rewrite the inequality as $p_x(i) = \text{O}(2^{-K(i|x, p)})$. The statement follows, because the set of all strings σ in (4) includes among others also the descriptions of all probability distributions p . \square

Proof (of Theorem 1). We have to prove that $\frac{Q_\varepsilon(f)}{1-2\sqrt{\varepsilon(1-\varepsilon)}} \geq \text{SA}(f) = \text{WA}(f) = \text{SWA}(f) = \text{MM}(f) = \text{SMM}(f) = \text{GSA}(f) = \Theta(\text{KA}(f))$. Put together all known equalities and inequalities:

- $\text{SA}(f) = \text{WA}(f) = \text{SWA}(f)$ by Theorem 3 and Theorem 4,
- $\text{MM}(f) = \text{SMM}(f)$ by Theorem 5,
- $\text{SMM}(f) = \text{GSA}(f)$ by Theorem 6,
- $\text{GSA}(f) = \text{SA}(f)$ by Theorem 7,
- $\text{KA}(f) = \Theta(\text{WA}(f))$ by Theorem 8 and Theorem 9.

Finally, one has to prove one of the lower bounds. For example, Ambainis proved [2] that $Q_2(f) \geq (1 - 2\sqrt{\varepsilon(1 - \varepsilon)}) \text{WA}(f)$. \square

Acknowledgments

We thank Ronald de Wolf for many fruitful discussions, for his suggestions concerning Theorem 2, and for proofreading, and Troy Lee for discussions.

Quantum Complexity of Testing Group Commutativity*

Frédéric Magniez¹ and Ashwin Nayak²

¹ CNRS–LRI, UMR 8623 Université Paris–Sud, France

² University of Waterloo and Perimeter
Institute for Theoretical Physics, Canada

Abstract. We consider the problem of testing the commutativity of a black-box group specified by its k generators. The complexity (in terms of k) of this problem was first considered by Pak, who gave a randomized algorithm involving $O(k)$ group operations. We construct a quite optimal quantum algorithm for this problem whose complexity is in $\tilde{O}(k^{2/3})$. The algorithm uses and highlights the power of the quantization method of Szegedy. For the lower bound of $\Omega(k^{2/3})$, we introduce a new technique of reduction for quantum query complexity. Along the way, we prove the optimality of the algorithm of Pak for the randomized model.

1 Introduction

A direction of research in quantum computation pioneered by Grover [1] around search problems in unstructured, structured, or partially structured databases has recently seen an extraordinary expansion. In contrast to problems based on Hidden Subgroup Problem (HSP) (see for instance Ref. [2]), the speed up for these search problems is often only polynomial.

Usually in search problems, the access to the input is done via an oracle modeling access to the input. This leads to the notion of query complexity which measures the number of accesses to the oracle. While no significant lower bounds are known for quantum time complexity, the oracle constraint sometimes enables us to prove such bounds in the query model. For promise problems quantum query complexity indeed can be exponentially smaller than the randomized one. A prominent example is the HSP. On the other hand, for total functions, deterministic and quantum query complexities are polynomially related [3].

In the HSP, the group with its all structure is known to the algorithm designer, and the group operations are generally efficiently computable. In the event that the group is not explicitly known, or the group operations are not efficient to implement, it is appropriate to model the group operations by an oracle or a black-box. The notion of *black-box groups* was introduced by Babai and Szemerédi [4]. In this model, the elements of a group are encoded by words

* For their research support, F.M. thanks the EU 5th framework program RESQ and the French Research Ministry, and A.N. thanks Canada's NSERC and CIAR.

over a finite alphabet, and the group operations are performed by an oracle (the black-box). The groups are assumed to be specified by generators, and the encoding of group elements is not necessarily unique: different strings may encode the same group element. Mosca [2] showed that one can learn in quantum polynomial time the structure of any black-box abelian group. Such a task is known to be hard classically. Then Watrous [5] pioneered the study of black-box group properties in the quantum context.

In this context, we study the problem of testing commutativity of a black-box group (GROUP COMMUTATIVITY) given by its generators. The classical complexity of this problem was first considered by Pak [6]. The straightforward algorithm for the problem has complexity $O(k^2)$, where k is the number of generators, since it suffices to check if every pair of generators commute. Pak presented a surprising randomized algorithm whose complexity is linear in k , and also showed that the deterministic lower bound is quadratic. The linear upper bound on complexity may also be obtained by applying quantum search [1] to locate a pair of generators that do not commute. Using the quantization of random walks by Szegedy [7], we instead present a *sublinear* algorithm in $\tilde{O}(k^{2/3})$ (**Theorem 3**), where the \tilde{O} notation means that logarithmic multiplicative factors are omitted.

GROUP COMMUTATIVITY bears a deceptive resemblance to ELEMENT DISTINCTNESS. The aim in the former is to detect the presence of a pair of generators which collide in the sense that they do not commute. However, since the group structure is unknown, whether or not a pair of generators collide can only be determined by invoking the group oracle. Moreover, the group oracle provides access to elements from the entire group spanned by the given generators, which may be used towards establishing commutativity.

These differences necessitate the use of ideas from Pak's algorithm, the theory of rapidly mixing Markov chains, and perhaps most remarkably, the Szegedy quantization of walks. GROUP COMMUTATIVITY appears to be the first natural problem for which the approach of Szegedy has no equivalent using other known techniques for constructing quantum algorithms—Grover search [1], or the type of quantum walk introduced by Ambainis [8]. A recent result of Buhrman and Spalek [9] on matrix product verification is in the same situation for its time complexity but not for the query complexity, since the approach of Ambainis gives an algorithm whose query complexity is the same in the worst case.

We also prove that our algorithm is almost optimal by giving an $\Omega(k^{2/3})$ lower bound for the quantum query complexity of GROUP COMMUTATIVITY (**Theorem 6**). Simultaneously, we give an $\Omega(k)$ lower bound for its randomized query complexity (**Theorem 5**). This lower bound shows that the algorithm of Pak [6] is optimal, and to our knowledge is new. We first state an easier lower bound using a simple reduction from the problem of detecting a unique collision pair of a function, which is a special case of ELEMENT DISTINCTNESS, when one allows non-unique encoding of the black-box group (**Theorem 4**). For the lower bound for uniquely encoded black-box groups, the proof gets more complex. The randomized case relies upon an adversary argument. The quantum case is subtle. We show the said lower bound for the number of accesses to the given

generators. The lower bound also holds for the number of group operations in *generic* quantum algorithms (see Section 4 for a definition). This is shown using a new kind of reduction based on approximation degree of the problem.

2 Preliminaries

2.1 Black-Box Groups

We will suppose that the elements of the group G are encoded by binary strings of length n for some fixed integer n , which we call the *encoding length*. The groups will be given by generators, and therefore the *input size* of a group is the product of the encoding length and the number of generators. For simplicity, we also assume that the identity element of the group is given. Note that the encoding of group elements need not be unique, a single group element may be represented by several strings. If the encoding is not unique, one also needs an oracle for identity tests. Unless otherwise specified, we assume that the encoding is unique in this paper. All of our results apply when the encoding is not unique if one is given an oracle for identity tests.

Since we will deal with black-box groups we shall shortly describe them in the framework of quantum computing (see also [2] or [5]). For a general introduction to quantum computing the reader might consult [10, 11]. We will work in the quantum circuit model. For a group G of encoding length n , the black-box will be given by two oracles O_G and its inverse O_G^{-1} , both operating on $2n$ qubits. For any group elements $g, h \in G$, the effect of the oracles is the following: $O_G|g\rangle|h\rangle = |g\rangle|gh\rangle$, and $O_G^{-1}|g\rangle|h\rangle = |g\rangle|g^{-1}h\rangle$.

In this notation we implicitly use the encoding of a group element. We will do that everywhere in the paper when there is no ambiguity. Also, not every binary string of length n necessarily corresponds to a group element. In this case, the behavior of the black box can be arbitrary.

2.2 Query Model

The quantum query model was explicitly introduced by Beals, Buhrman, Cleve, Mosca, and de Wolf [3]. In this model, as in its classical counterpart, we pay for accessing the oracle, but unlike the classical case, the machine can use the power of quantum parallelism to make queries in superposition.

The state of the computation is represented by three registers, the query register g , the answer register h , and the work register z . The computation takes place in the vector space spanned by all basis states $|g, h, z\rangle$. In the *quantum model* the state of the computation is a complex combination of all basis states which has unit length in the ℓ_2 norm.

For a black-box group the query operator will be O_G together with its inverse O_G^{-1} . For oracle function $F : X \rightarrow Y$ the query operator is $O_F : |g\rangle|h\rangle \mapsto |g\rangle|h \oplus F(g)\rangle$, where \oplus denotes the bitwise xor operation.

Non-query operations are independent of the oracle. A *k-query algorithm* is a sequence of $(k + 1)$ operations (U_0, U_1, \dots, U_k) where each U_i

is unitary. Initially the state of the computation is set to some fixed value $|\bar{0}, \bar{0}, \bar{0}\rangle$. In case of an oracle function, the sequence of operations $U_0, O_F, U_1, O_F, \dots, U_{k-1}, O_F, U_k$ is applied. For black-box groups, the modified sequence of operations $U_0, O_G^{b_1}, U_1, O_G^{b_2}, \dots, U_{k-1}, O_G^{b_k}, U_k$ is applied, where $b_i = \pm 1$. Finally, one or more qubits designated as output bits are measured to get the outcome of the computation. The quantum algorithms we consider might give an erroneous answer, but the probability of making an error is bounded by some fixed constant $\gamma < 1/2$.

In the query model of computation each query adds one to the *query complexity* of an algorithm, but all other computations are free. The *time complexity* of the algorithm is usually measured in terms of the total circuit size for the unitary operations U_i . We will however take a more coarse grained view of time complexity, and assume that operations such as accessing qubits containing group encodings or updating them, take unit time.

2.3 Quantum Walks

We state a simple version of the recent result of Szegedy [7]. Let P be an ergodic and symmetric Markov chain on a graph $G = (V, E)$ on N vertices. We denote by $P[u, v]$ the transition probability from u to v . Let M be a set of marked nodes of V . Assume, one is given a database D that associates some data $D(v)$ to every node $v \in V$. From $D(v)$ we would like to determine if $v \in M$. We expedite this using a quantum procedure Φ . When operating with D three types of cost are incurred. The cost might denote any measure of complexity such as query or time complexities.

Setup cost S: The cost to set up $D(v)$ for a $v \in V$.

Update cost U: The cost to update $D(v)$ for a $v \in V$, i.e. moving from $D(v)$ to $D(v')$, where the transition from v to v' is allowed by the Markov chain P .

Checking cost C: The query complexity of $\Phi(D(v))$ for a $v \in V$.

Concerning the quantization of the walk P , one needs to consider the quantum time complexity of its implementation in terms of the following parameters.

Initialization time I: The time complexity for constructing the superposition $\frac{1}{\sqrt{N}} \sum_{u,v} \sqrt{P[u, v]} |u, v\rangle$.

Transition time T: The time complexity of realizing the transformation $|u, v\rangle \mapsto 2 \sqrt{P[u, v]} \sum_{v'} \sqrt{P[u, v']} |u, v'\rangle - |u, v\rangle$.

In the following theorem, the notation $O(\cdot)$ denotes the existence of a universal constant so that the expression is an upper bound. We now state the main result of [7].

Theorem 1 (Szegedy [7]). *Let δ be the eigenvalue gap of P , and let $\frac{|M|}{|V|} \geq \varepsilon > 0$ whenever M is non-empty. There exists a quantum algorithm that determines if M is non empty with cost $S + O((U + C)/\sqrt{\delta\varepsilon})$, and an additional time complexity of $I + O(T/\sqrt{\delta\varepsilon})$.*

Moreover, if P is state transitive then the cost of finding a marked element of M is the same as above.

Note that in this theorem, when the cost denotes the time complexity, we need to add to it the additional time complexity term given in the theorem.

2.4 The Problems

Here we define the problems we are dealing with. The focus of the paper is on

GROUP COMMUTATIVITY

Oracle: Group operations O_G and O_G^{-1} for an encoding in $\{0, 1\}^n$

Input: The value of n and the encoding of generators g_1, \dots, g_k of G

Output: **Yes** if G is commutative, and **No** otherwise (if there are two indices i, j such that $g_i g_j \neq g_j g_i$)

The next problem is a special instance of a well-studied problem, **ELEMENT DISTINCTNESS**.

UNIQUE COLLISION

Oracle: A function F from $\{1, \dots, k\}$ to $\{1, \dots, k\}$

Input: The value of k

Output: **Yes** if there exists a unique collision pair $x \neq y \in \{1, \dots, k\}$ such that $F(x) = F(y)$, and **No** if the function is a permutation

This is a promise problem (or a relation) since we do not require a definite output for certain valid oracle functions. We will also use a further specialization of the problem when k is even, **UNIQUE SPLIT COLLISION**, where one element of the colliding pair has to come from $\{1, \dots, k/2\}$ and the other from $\{k/2 + 1, \dots, k\}$. We call this a *split* collision. Note that in the positive instances of this problem, the restriction of the function to the two intervals $\{1, \dots, k/2\}$ and $\{k/2 + 1, \dots, k\}$ is injective.

2.5 Approximation Degree

We describe the notion of approximation degree for oracle decision problems. Let \mathcal{S} be the set of functions from $\{1, \dots, k\}$ to $\{1, \dots, k\}$. An *oracle decision problem* is a boolean function on the set \mathcal{S} . For every function $F \in \mathcal{S}$, we define the variables x_{ij} which are 1 if $F(i) = j$ and 0 otherwise.

Definition 1 ([3, 12]). Let $\Phi : \mathcal{S} \rightarrow \{0, 1\}$ be an oracle decision problem. Then the approximation degree of Φ is the lowest degree of real multivariate polynomials P in variables x_{ij} , such that $|P(x) - \Phi(F)| \leq 1/3$, for every $F \in \mathcal{S}$

The following powerful result relates approximation degree to quantum query complexity.

Proposition 1 ([3, 12]). If the quantum query complexity of Φ is T , then the approximation degree of Φ is at most $2T$.

A beautiful application of the polynomial method gives us the optimal query complexity of UNIQUE COLLISION.

Theorem 2 ([12, 13, 14]). *The approximation degree of UNIQUE COLLISION, and hence its quantum query complexity, is $\Omega(k^{2/3})$.*

The original result of the works cited above refer to the more general problem ELEMENT DISTINCTNESS, which requires the detection of one or more colliding pairs. This was proven by a randomized reduction from the problem COLLISION which detects between a bijection and a two-to-one function. However, the reduction is still valid for the special case we consider. As noticed by Ambainis [14], this reduction also implies the lower bound on the approximation degree.

3 A Quantum Algorithm for Group Commutativity

We are given a black-box group G with generators g_1, \dots, g_k . The problem is to decide if G is abelian. For technical reasons (see the proof of Lemma 1), and without loss of generality, we assume that g_1 is the identity element.

We denote by S_l the set of all l -tuples of distinct elements of $\{1, \dots, k\}$. For any $u = (u_1, \dots, u_l) \in S_l$, we denote by g_u the group element $g_{u_1} \dots g_{u_l}$. Our algorithm is based on the quantization of a random walk on S_l^2 . We will also adapt an approach due to [6]. For this we generalize Lemma 1.3 of [6] for random elements from S_l . Then we show how to walk on S_l^2 for finding a non commutative element in G , if there is any. We will conclude using Theorem 1.

In this section, we let $p = \frac{l(l-1)+(k-l)(k-l-1)}{k(k-1)}$. Observe that when $k = 2l$, then $p = \frac{l-1}{2l-1} \leq \frac{1}{2}$. Moreover, when $l = o(k)$, then $1 - p = \Theta(l/k)$.

Lemma 1. *Let $K \neq G$ be a subgroup of G . Then $\Pr_{u \in S_l}[g_u \notin K] \geq \frac{1-p}{2}$.*

Proof. First we fix a total order (equivalently, a permutation) σ of $\{1, \dots, k\}$, and we denote by S_l^σ that subset of l -tuples in S_l which respect the total order σ . In other words, $u = (u_1, \dots, u_l) \in S_l^\sigma$ iff $\sigma^{-1}(u_i) < \sigma^{-1}(u_{i+1})$ for all $1 \leq i < l$. Since $(S_l^\sigma)_\sigma$ is an equitable partition of S_l , picking a random element from S_l is the same as first picking a random permutation σ , and then picking a random element $u \in S_l^\sigma$. Therefore it is enough to prove the theorem for any fixed order σ . The reader may find it helpful to take σ to be the identity permutation to understand the idea behind the proof.

We denote $g'_j = g_{\sigma(j)}$ for every $j = 1, \dots, k$. Let i be the smallest index such that $g'_i \notin K$. Such an i exists since $K \neq G$. Let j be such that $g'_j = g_1$, the identity element.

Fix an ordered l -tuple u such that $g'_i \notin u$ and $g'_j \in u$. We denote by v the ordered l -tuple where g'_j has been deleted from u , and g'_i has been inserted into it at the appropriate position (that respects the total order). Formally, if $u = (u_1, \dots, u_m, u_{m+1}, \dots, u_l)$ such that $\sigma^{-1}(u_m) < i < \sigma^{-1}(u_{m+1})$, then v is obtained by deleting g'_j from the $(l + 1)$ -tuple $(u_1, \dots, u_m, \sigma(i), u_{m+1}, \dots, u_l)$.

Let $a = g_{u_1}g_{u_2} \cdots g_{u_m}$, and $b = g_{u_{m+1}} \cdots g_{u_l}$. Then $g_u = ab$ and $g_v = ag'_i b$. Note that because of the choice of i , $a \in K$. If $g_u = ab \in K$ so that $b \in K$ as well, then $g_v \notin K$. Therefore $\Pr_{u \in S_l^\sigma} [g_u \in K | i \in u \text{ xor } j \in u] \leq \frac{1}{2}$.

Since $\Pr_{u \in S_l^\sigma} [i, j \in u \text{ or } i, j \notin u] = p$, we conclude that $\Pr_{u \in S_l^\sigma} [g_u \in K] \leq (1 - p) \times \frac{1}{2} + p \times 1$. □

With the approach of [6] and from Lemma 1, we can generalize easily Lemma 1.1 of [6].

Lemma 2. *If G is non commutative then $\Pr_{u,v \in S_l} [g_u g_v \neq g_v g_u] \geq \frac{(1-p)^2}{4}$.*

Proof. If G is non-commutative, then the centre $C(G)$ of G is a proper subgroup. With probability at least $(1 - p)/2$, g_u does not belong to $C(G)$ for a random $u \in S_l$ (Lemma 1). Conditioned upon this event, the probability that for a random $v \in S_l$, g_v does not belong to the centralizer of g_u is also at least $(1 - p)/2$. □

Let t_u be the balanced binary tree with l leaves, whose leaves are from left to right the elements g_{u_i} , for $i = 1, \dots, l$, and such that each internal node is the group product of its two successors. If l is not a power of 2, we put the deepest leaves to the left.

The random walk on S_l^2 that forms the basis of our quantum algorithm will consist of two independent simultaneous walks on S_l . For a pair (u, v) of l -tuples, we will maintain the binary trees t_u, t_v as described above as the data.

The random walk on S_l

Suppose the current state is $u \in S_l$.

With probability $1/2$ stay at u ; with probability $1/2$, do the following:

- Pick a uniformly random position $i \in \{1, \dots, l\}$, and a uniformly random index $j \in \{1, \dots, k\}$.
- If $j = u_m$ for some m , then exchange u_i and u_m , else, set $u_i = j$.
- Update the tree t_u (using $O(\log l)$ group operations).

Lemma 3. *The spectral gap of the walk described above is at least $\frac{c}{l \log l}$, for a universal constant $c \geq \frac{1}{8e}$, provided $l \leq k/2$.*

Proof. First, we will show that the random walk mixes rapidly using a “coupling argument”. Then, using a relation between mixing time and the second largest eigenvalue, we will get a bound on the spectral gap.

Note that the walk is ergodic and has the uniform distribution on S_l as its stationary distribution π . Thus $\pi(u) = \frac{(k-l)!}{k!}$ for all u . Moreover, because of the self-loops, all the eigenvalues of the walk are non-negative.

Let P_x^t be the probability distribution on S_l obtained by performing t steps of the walk starting at x . Let $\Delta(t)$ be the maximum over all starting states $x \in S_l$ of the total variation distance $\|P_x^t - \pi\|$. Let τ (the *mixing time*) be the smallest t such that $\Delta(t') \leq \frac{1}{2e}$ for all $t' \geq t$.

A *coupling* for a Markov chain is a stochastic process on pairs of states (U_t, V_t) such that U_t and V_t , viewed marginally, each evolve according to the Markov chain, and if $U_t = V_t$, then $U_{t+1} = V_{t+1}$. The *coupling time* T is the maximum expected time (over all pairs of initial states (u, v)) for the states U_t, V_t to coincide: $T = \max_{u,v} E[\operatorname{argmin}_t \{U_t = V_t, U_0 = u, V_0 = v\}]$.

We will use the following facts about mixing of Markov chains:

1. [15–Proposition 2.2, Chapter 2] For walks with only non-negative eigenvalues, $\lambda^t \leq \Delta(t) \cdot (\min_u \pi(u))^{-1}$, where λ is the second largest eigenvalue. This bounds the second largest eigenvalue in terms of the total variation distance.
2. (see e.g., Ref. [16]) $\Delta(t) \leq 2 \exp(-\lfloor \frac{t}{\tau} \rfloor)$. This relates the total variation distance at any time t to the mixing time τ .
3. [17] $\tau \leq 2eT$. This bounds the mixing time τ in terms of the coupling time T .

Combining all three relations, taking t -th roots, and letting $t \rightarrow \infty$, we see that $\lambda \leq \exp(-\frac{1}{2eT}) \leq 1 - \frac{1}{4eT}$. Thus, the spectral gap is $1 - \lambda \geq \frac{1}{4eT}$.

A coupling for which $T \leq l \log l$ is the obvious one: for any pair $u, v \in S_l$, follow one step of the random walk with the same choice of random position i and index j . This is clearly a valid coupling.

Let d be the hamming distance between the two tuples u, v . This distance never increases during the process described above. Moreover, in one step of the process, the distance goes down by 1 with probability at least $\frac{d}{2l}$. This is because with probability d/l , the position i is one where u and v are different, and with probability at least $(k-l)/k$, the index j is not one from the positions where u and v are the same. Since $l \leq k/2$, the net probability that the distance decreases by 1 is at least $d/2l$.

By a straightforward calculation, the expected time T for the distance to go to zero is at most $2l \log l$ (since $d \leq l$). Using the relation described above between λ and T , we get our bound on the spectral gap. □

Theorem 3. *There is a quantum algorithm that solves GROUP COMMUTATIVITY problem with $O(k^{2/3} \log k)$ queries and time complexity $O(k^{2/3} \log^2 k)$.*

Proof. The walk is the above described walk on S_l^2 . The database associated with a tuple $u \in S_l$ is the binary tree t_u . Using Szegedy’s theorem 1, we need only compute the eigenvalue gap of the random walk and the initial success probability (in the uniform distribution).

The stationary distribution for the walk is the uniform distribution on $S_l \times S_l$. So, from Lemma 2 above, the success probability is at least $(1-p)^2/4$. The spectral gap for the walk is the same as that on S_l , i.e. $c/(l \log l)$, from Lemma 3.

Since we start with a uniform distribution over $|u, t_u\rangle|v, t_v\rangle$, where $u, v \in S_l$. The setup cost is at most $2(l-1)$ and the updating cost of the walk is $O(\log l)$. We will choose $l = o(k)$ so that $1-p = \Theta(l/k)$. The total query cost is then

$$2(l-1) + O\left(\frac{1}{1-p} \sqrt{l \log l} \cdot \log l\right) = 2(l-1) + O\left(\frac{k}{\sqrt{l}} \log^{3/2} l\right).$$

This expression is minimized when $l = k^{2/3} \log k$, and the cost is $O(k^{2/3} \log k)$.

The time complexity overhead comes from the initialization and transition times that are both essentially equal to the time complexity of performing a Grover diffusion operation. For the initialization, we use a diffusion over S_l^2 , whose time complexity is $O(\log(|S_l|^2)) = O(l \log k)$. For the transition, we use a diffusion over a set of size 2 tensor product with a diffusion over a set of size kl , therefore the corresponding time complexity is $O(\log(kl)) = O(\log k)$. \square

4 Reduction from Unique Split Collision

We begin our presentation of the lower bound by considering the complexity of UNIQUE SPLIT COLLISION. This problem is at least as hard as UNIQUE COLLISION in its query complexity since any bounded-error algorithm for the former can be used to detect an arbitrary collision. The proof is omitted due to the lack of space.

Proposition 2. *The approximation degree and the quantum query complexity of UNIQUE SPLIT COLLISION are both $\Omega(k^{2/3})$. The randomized query complexity of this problem is $\Omega(k)$.*

We conclude by proving the same lower bound for GROUP COMMUTATIVITY as well. We thus show that the algorithm described in the previous section is almost optimal.

The group involved in the proof of the lower bound will be a subgroup G of $U(2k)$, the group (under matrix multiplication) of $2k \times 2k$ unitary matrices. The generators of G will be block diagonal, each with k blocks of dimension 2×2 . Each block will be one of the following three (Pauli) matrices:

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The group may also involve the remaining Pauli matrix $Y = XZ = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$.

No pair of matrices amongst X, Y and Z commute. An encoding of the group consists in words $\sigma_1 \dots \sigma_k$ of length k over the alphabet $\{I, X, Y, Z\}$ together with a sign vector $s = (s_1, s_2, \dots, s_k)$ in $\{+1, -1\}^k$. A tuple $(s, \sigma_1, \dots, \sigma_k)$ represents the matrix $\text{diag}(s_1 \sigma_1, \dots, s_k \sigma_k)$. We will call this encoding the *explicit encoding*.

Let a_j and b_j be generators that have the identity matrix in all their blocks except for the j -th. The j -th block is Z in a_j and X in b_j .

We describe a connection between UNIQUE SPLIT COLLISION and GROUP COMMUTATIVITY. Suppose the oracle for the problem UNIQUE SPLIT COLLISION computes the function $F : \{1, \dots, k\} \rightarrow \{1, \dots, k\}$. We associate a generator g_i of the type described above with each element i in the domain. The generator g_i is $a_{F(i)}$ if $i \leq k/2$, and it is $b_{F(i)}$ if $i > k/2$. As long as the function F is injective on the two intervals $\{1, \dots, k/2\}, \{k/2 + 1, \dots, k\}$, the set of generators $\{g_i\}$ consists of k distinct elements. None of these generators is contained in the span of the remaining generators.

It is straightforward to check that there is a collision in F (with one point on either side of $k/2$) iff the group generated by $\{g_i\}$ is non-commutative. We

use this connection for proving our lower bound. While the main result uses a non-standard method, we first prove a weaker result which explains the intuition behind the final proof to the reader.

Theorem 4. *If non-unique encoding of group elements is allowed, the randomized and the quantum query complexity of GROUP COMMUTATIVITY are respectively $\Omega(k)$ and $\Omega(k^{2/3})$.*

Proof. Suppose we allow non unique encoding of the group G . We show that any algorithm A solving GROUP COMMUTATIVITY may be adapted to solve UNIQUE SPLIT COLLISION, with at most four times the query complexity of A . We then conclude our theorem using Proposition 2.

We construct a black-box group which may invoke the oracle for UNIQUE SPLIT COLLISION to implement group operations. The encoding of the group elements will be either the explicit encoding defined above, or an element of $\{1, \dots, k\}$. When the encoding is an integer $i \in \{1, \dots, k\}$, it represents the generator g_i . When an integer i is involved in a group operation, we query the oracle for F at i , and construct g_i as defined above. One more query to F is required to erase the value of the function. Group operations can be performed without incurring any further calls to F . Operations on previously computed products also do not cost any queries. Therefore a group operation involves F at most four times, when both of the elements are encoded by integers. The oracle hides the group G with this non-unique encoding, and the input is the sequence of encodings $1, 2, \dots, k$. \square

In the case of unique encoding of group elements by the black-box, the reduction above is not guaranteed to work. The reason is that non-trivial products of generators may evaluate to the value of a generator. These products are represented in explicit form, and therefore our simulation possibly uses two different representations for the generators. We can nevertheless modify our simulation to work, while maintaining essential properties of the algorithm. In the classical model, our simulation preserves the number of oracle queries. In the quantum model, our simulation will produce a polynomial that approximates UNIQUE SPLIT COLLISION and has degree of the order of the number of queries made by the commutativity algorithm.

In our arguments, we assume that the algorithm never queries the black-box with encodings that did not result from previous queries to the oracle. This family of algorithm are usually called *generic algorithms*. This notion was introduced to cryptography by Nechaev [18] and Shoup [19]. By suitably randomizing the encoding such as in [20], we can ensure that the probability that the algorithm chances upon a valid pair of encoded group elements is $o(1)$, if this input does not result from previous queries. If we choose n , the encoding length, to be $\Omega(\log |G|)$, this probability would be exponentially small in n . We can therefore assume in the black-box group setting that a correct algorithm is always generic, and we make this assumption until the end of this section. These arguments do not generalize easily to the quantum setting; we leave a proof to a more complete version of this paper. We start with the classical simulation.

Theorem 5. *With unique encoding of group elements, the randomized query complexity of GROUP COMMUTATIVITY is $\Omega(k)$.*

Proof. Our reduction from UNIQUE SPLIT COLLISION works essentially because all the generators are distinct, and because no generator is contained in the span of the remaining $k - 1$ generators. We modify the simulation in the proof of Theorem 4 so that we record the value of the function F at any point which is queried. We retain the explicit encoding for all group elements except the generators as the encoding for the black-box group. The generators are represented by integers $1, \dots, k$. A non-trivial product may equal a generator g_i only if the product contains this generator. The value of F at point i would necessarily have been queried for the algorithm to have computed this product. The index i can therefore be located by examining the record of all queries made thus far in the algorithm, and used to encode the generator. \square

For the modified simulation in the quantum case, we introduce another *implicit* encoding of elements of G as tuples $(s, x_1, x_2, \dots, x_k)$, where $s \in \{+1, -1\}^k$, and $x_i \in \{0, 1\}$. A word in this implicit encoding represents the group element $\text{diag}(s_1 I, s_2 I, \dots, s_k I) \cdot g_1^{x_1} g_2^{x_2} \dots g_k^{x_k}$. This is a unique encoding of elements in G .

As in the proof of the classical lower bound, we restrict ourselves to generic algorithms. In a generic quantum black-box group algorithm, along every computational path, the queries to the oracle involve either a generator, or a product that was previously computed along that path.

Theorem 6. *With unique encoding of group elements, any generic quantum algorithm for GROUP COMMUTATIVITY performs $\Omega(k^{2/3})$ group operations (queries to the group oracle).*

Proof. In using a generic algorithm for GROUP COMMUTATIVITY to solve UNIQUE SPLIT COLLISION we now use the implicit encoding of group elements. The generators are specified in this notation, and we will maintain this representation for all the intermediate products that are computed during the algorithm. The query cost of simulating a group operation is no longer $O(1)$. Indeed, we may need up to $O(k)$ queries to F to implement a multiplication of two elements. Nevertheless, we argue that the degree of the polynomial that results from this simulation is of the order of the query cost of the commutativity algorithm.

We refine the proof of Proposition 1 due to [3, 12] to claim that after t queries:

- The amplitude of any basis state is a polynomial of degree at most $O(t)$ in the variables x_{ij} .
- Fix a classical basis state. If a generator g_i occurs in the implicit encoding of group elements stored in the special registers, then a variable x_{ij} (for some j) is a factor of the polynomial that gives the amplitude of that state.

This ensures that in our simulation, the degree of the polynomial corresponding to a basis state does not increase as we query F to implement a group operation

involving a previously computed product. In making this claim, we rely on the fact that $x_{ij} \in \{0, 1\}$ for inputs of interest to us, so $x_{ij}x_{ij'} = \delta_{jj'}x_{ij}$. (The degree goes up by $O(1)$ when at least one of the operands is a fresh generator.)

As a consequence, we derive a polynomial of degree of the order of the number of queries made by the commutativity algorithm, and this approximates UNIQUE SPLIT COLLISION. We can thus conclude the same lower bound as in Proposition 2 for testing commutativity as well. \square

Note that the complications due to the unique encoding requirement do not arise if we are concerned with the number of accesses to the input generators. For arbitrary (possibly non-generic) quantum algorithms, the same reduction also directly gives a bound on this notion of complexity.

Proposition 3. *The lower bound of $\Omega(k^{2/3})$ above also holds for the query complexity of any quantum algorithm, if the generators to a possibly known group are specified by an input oracle.*

Semantic-Based Code Obfuscation by Abstract Interpretation

Mila Dalla Preda and Roberto Giacobazzi

Dipartimento di Informatica, Università di Verona,
Strada Le Grazie 15, 37134 Verona Italy
dallapre@sci.univr.it, roberto.giacobazzi@univr.it

Abstract. In this paper we introduce a semantic-based approach for code obfuscation. The aim of code obfuscation is to prevent malicious users to disclose properties of the original source program. This goal can be precisely modeled by abstract interpretation, where the hiding of properties corresponds to abstract the semantics. We derive a general theory based on abstract interpretation, where the potency of code obfuscation can be measured by comparing hidden properties in the lattice of abstract interpretations. Semantic-based code obfuscation is applied to show that well known program transformation methods, such as constant propagation, can be seen as code obfuscation.

Keywords: Code Obfuscation, Abstract Interpretation, Program Transformation, Semantics.

1 Introduction

Code obfuscation is a program transformation typically intended to prevent reverse engineering [2, 4, 5, 6]. A number of results are known in the literature providing obfuscation algorithms such as: *Layout* transformations, which remove source code formatting and scramble identifiers; *control* transformations, which affect the control flow of the program; and *data* transformations, which operate obfuscating the data structures used in the program [5]. The major negative result on code obfuscation is given in Barak *et al.* [1]. They prove that there is no obfuscation method that works for any program and it is able to transform them in such a way that the only properties which can be disclosed are those which can be derived from the input/output semantics. This result is not as bad as it might seem, in fact even though the “ideal” obfuscator of Barak *et al.* does not exist, software obfuscation would be still useful when employed for hiding specific code properties and working for specific classes of programs [14]. The classical notion of code obfuscation of Collberg *et al.* [4, 5, 6] defines an obfuscator as a potent transformation that preserves the *observable behavior* of programs. In this setting a transformation is *potent* when the obfuscated program is more complex than the original one. Clearly this definition of code obfuscator relies on a fixed metric for measuring program complexity, and finding such metrics is a major challenge in practical code obfuscation algorithms.

The Problem

The major drawback of most software obfuscation techniques is that they do not have a well found theoretical base, and thus it is unclear how effective they are. Even if semantic preservation is implied in code obfuscation [18], the lack of a complete formal setting where these program transformations can be studied defects any possibility of comparing them with respect to their ability to obfuscate program properties. The main problem here is to fix a measure for potency. Usually syntactic (textual) measures are considered, such as code length, nesting-levels, fan-in-out complexity, branching, *etc* [5]. Semantic-based measures are instead less common, even though they may provide a deeper insight in the true potency of code obfuscation. In order to understand this point we need to model attackers, *i.e.*, code de-obfuscation techniques. Static program analysis is the standard method for making reverse-engineering. Recently dynamic attacks have also been considered in [3] for strengthening static ones for de-obfuscation. Both static and dynamic attacks strongly relies upon program semantics: the first corresponds precisely to a decidable semantic abstraction, while the last are based on the concrete semantics, *e.g.*, interpreters. In both cases syntactic measures can be misleading. More significant measures have to be derived from semantics and this, as far as we know, is an open problem.

Main Results

In this paper we consider the lattice of abstract interpretations as the domain for measuring potency. The goal of code obfuscation is to prevent reverse engineering (*e.g.*, by static or dynamic analysis) to grasp sensible properties on program's structure and semantics. It is well known that static analysis can be completely and fully specified as an abstract interpretation [10], *i.e.*, as an approximation of the concrete semantics of programs. Similarly, dynamic analysis can be seen as a possibly non decidable approximation of the concrete semantics. In this sense, code obfuscation can be seen as a way to prevent that some information about program behaviour is disclosed by an abstract interpretation of its semantics. In order to apply abstract interpretation as a model for attackers, we need to replace syntactic code obfuscators with corresponding semantic transformations. Recently, Cousot & Cousot in [12] have introduced a semantic-based formalization of program transformation based on abstract interpretation. In this construction the relation between syntactic and semantic transformations is specified by an abstract interpretation, where syntax is an abstraction of semantics. This allows us to mirror code obfuscators, viewed as syntactic transformations, in the semantics, by considering corresponding semantic obfuscators instead. Therefore the role of abstract interpretation in a semantic-based approach to code obfuscation is crucial: By fixing a formal relation between syntactic and semantic transformations, abstract interpretation provides the most general setting where attackers can be compared by comparing abstractions, leading us to derive a semantic-based metric for the potency of code obfuscation. Traditionally code obfuscation is intended to preserve input/output (denotational) semantics of programs. This is again an unreasonable

restriction: Semantics at different levels of abstraction can be related by abstract interpretation in a hierarchy of semantics [9]. Therefore, any program transformation τ which preserves a given semantics in the hierarchy may act as a code obfuscation for those properties that are not preserved by the transformation. The idea is that the transformed program $\tau[[P]]$ is more complex (obscure) than the original program P , *i.e.*, τ is potent, when there exists a semantic property, *i.e.*, an abstract semantics, which is not preserved by the transformed program $\tau[[P]]$. Potency is therefore strictly related with the rate of abstraction of the most concrete preserved semantics of a code transformation. This corresponds to map code transformations to the lattice of abstract interpretations to measure their obfuscating potency. We introduce a constructive systematic method for deriving the most concrete preserved abstraction of a generic code transformation. Then we generalize Collberg *et al.* definition of code obfuscation [4, 5] by considering as obfuscators those transformations that mask some abstractions in the lattice of abstract interpretations. This means that, in principle, *any program transformation may potentially act as a code obfuscator*. We show how a well known program transformation for solving the constant propagation problem, can be seen as a code obfuscator. In this case the transformation acts as a code obfuscator relatively to the command-line structure.

2 Preliminaries

Abstract Interpretation. The notation $\langle C, \leq, \vee, \wedge, \top, \perp \rangle$ denotes a complete lattice C , with ordering \leq , *lub* \vee , *glb* \wedge , greatest element \top , and least element \perp . $x \in C$ is *meet-irreducible* if $x = a \wedge b$ then $x \in \{a, b\}$. The set of meet-irreducible elements in C is denoted $Mirr(C)$. The downward closure of $S \subseteq C$ is $\downarrow S \stackrel{\text{def}}{=} \{x \in C \mid \exists y \in S. x \leq y\}$, and for $x \in C$, $\downarrow x$ is a shorthand for $\downarrow \{x\}$, while the upward closure \uparrow is dually defined. Abstract domains can be formulated either in terms of Galois connections or upper closures operators [11]. An *upper closure operator* on a ordered set C , $\mu : C \rightarrow C$, is a monotone, idempotent, and extensive ($\forall x \in C. x \leq \mu(x)$) function. With $uco(C)$ we denote the set of all upper closure operators of C . Each closure $\mu \in uco(C)$ is uniquely determined by the set of its fix-points $\mu(C)$ [17]. $X \subseteq C$ is a set of fix-points of an upper closure operator on C iff X is a *Moore family* of C , *i.e.*, $X = \mathcal{M}(X) \stackrel{\text{def}}{=} \{\wedge S \mid S \subseteq X\}$ - where $\wedge \emptyset = \top \in \mathcal{M}(X)$. If C is a complete lattice also $uco(C)$ is a complete lattice denoted by $\langle uco(C), \sqsubseteq, \sqcup, \sqcap, \lambda x. \top, \lambda x. x \rangle$ where, given two closures η and μ , $\eta \sqsubseteq \mu$ iff $\mu(C) \subseteq \eta(C)$. On the other side a concrete domain C and an abstract domain A form a *Galois Connection* (GC), denoted by (C, α, A, γ) , when $\alpha : C \rightarrow A$ and $\gamma : A \rightarrow C$ define an adjunction, namely $\forall x \in C, y \in A : \alpha(x) \leq y \Leftrightarrow x \leq \gamma(y)$. Given a GC (C, α, A, γ) the closure corresponding to the abstract domain A is $\rho = \gamma \circ \alpha$ on C . If ρ is a closure in C and $\iota : \rho(C) \rightarrow A$ is an isomorphism of complete lattices (with inverse ι^{-1}), then $(C, \iota \circ \rho, A, \iota^{-1})$ is a GC. Given a function $f : C \rightarrow C$ and a closure $\alpha \in uco(C)$, then $f^\#$ is a *correct (sound)* approximation of f in α when $f^\# : \alpha(C) \rightarrow \alpha(C)$ and $\alpha \circ f \circ \alpha \leq f^\#$. $f^\alpha \stackrel{\text{def}}{=} \alpha \circ f \circ \alpha$ is the *best correct approximation* of f in α [11]. The abstraction α is *complete*

Table 1. Abstract syntax

Arithmetic expressions	$E \in \mathbb{E} \quad E ::= n \mid X \mid E_1 - E_2$
Boolean expressions	$B \in \mathbb{B} \quad B ::= E_1 < E_2 \mid B_1 \vee B_2 \mid \neg B_1 \mid true \mid false$
Program actions	$A \in \mathbb{A} \quad A ::= X := E \mid X :=? \mid B$
Commands	$C \in \mathbb{C} \quad C ::= L_1 : A \rightarrow L_2 \text{ where } L_1, L_2 \in \mathbb{L} \cup \{ \mathcal{J} \}$ and \mathcal{J} is the undefined label

when $\alpha \circ f = f^\alpha$ [10, 16]. The point-wise ordering on $uco(C)$ corresponds to the standard ordering used to compare abstract domains with regard to their precision: Let $\rho_i \in uco(C)$ and $A_i = \rho_i(C)$, then A_1 is more precise than A_2 (i.e., A_2 is an abstraction of A_1) iff $A_1 \sqsubseteq A_2$ in $uco(C)$. Let $\{A_i\}_{i \in I} \subseteq uco(C)$: $\sqcup_{i \in I} A_i$ is the most concrete among the domains in $uco(C)$ which is abstraction of all the A_i 's, i.e., $\sqcup_{i \in I} A_i$ is the *least* (w.r.t \sqsubseteq) *common abstraction* of all the A_i 's, and $\prod_{i \in I} A_i$ is the well-known *reduced product* of all the A_i 's, namely the most abstract among the domains in $uco(C)$ which is more concrete than every A_i . *Complementation* corresponds to the inverse of reduced product [7], namely an operator that, given two domains $C \sqsubseteq D$, gives as result the most abstract domain $C \ominus D$, whose reduces product with D is exactly C (i.e., $(C \ominus D) \sqcap D = C$). Therefore we have that $C \ominus D \stackrel{\text{def}}{=} \sqcup \{ E \in uco(C) \mid D \sqcap E = C \}$. It has been proved in [15] that $\mathcal{M}(Mirr(C) \setminus Mirr(D)) = C \ominus D$.

Semantics. Given a transition system $\langle \Sigma, \curvearrowright \rangle$, where Σ is a nonempty set of states and $\curvearrowright \subseteq \Sigma \times \Sigma$ is the transition relation over states, we denote by Σ^+ and $\Sigma^\omega \stackrel{\text{def}}{=} \mathbb{N} \rightarrow \Sigma$ respectively the finite nonempty and the infinite sequences of symbols in Σ . Let $\sigma \in \Sigma^\infty \stackrel{\text{def}}{=} \Sigma^+ \cup \Sigma^\omega$ be a generic (finite or infinite) sequence of states then $|\sigma| \in \mathbb{N} \cup \omega$ is its length, σ_i is its i -th element, and σ_f is the final state if $\sigma \in \Sigma^+$. A finite (infinite) sequence of states σ is a program *trace* when for all $i < |\sigma|$: $\langle \sigma_i, \sigma_{i+1} \rangle \in \curvearrowright$, denoted $\sigma = \sigma_1 \widehat{\curvearrowright} \sigma_2 \widehat{\curvearrowright} \dots \widehat{\curvearrowright} \sigma_i \widehat{\curvearrowright} \dots$. In the following $\sigma_i \widehat{\curvearrowright} \sigma$ denotes the concatenation of a state σ_i with a trace σ . In this context μ is a *subtrace* of σ if there exists $i, j \in [0, |\sigma|)$, where $i < j$, and $\mu = \sigma_i \widehat{\curvearrowright} \dots \widehat{\curvearrowright} \sigma_j$. The *maximal trace semantics* of a transition system is $\tau^\infty \stackrel{\text{def}}{=} \tau^+ \cup \tau^\omega$, where τ^+ is the set of finite traces and τ^ω the set of infinite traces [9] of τ . From now on the trace semantics τ^∞ of the program P is considered as the concrete semantics $S[[P]] \subseteq \Sigma^\infty$. In [9] Cousot defines a hierarchy of semantics, where the big-step, termination and nontermination, Plotkin's natural, Smyth's demonic, Hoare's angelic relational and corresponding denotational, Dijkstra's predicate transformer weakest-precondition and weakest-liberal precondition and Hoare's partial and total axiomatic semantics, have all been derived by successive abstractions from the maximal trace semantics of a transition system τ^∞ . In this setting $uco(\wp(\Sigma^\infty))$ is the lattice of abstract semantics, namely each closure in $uco(\wp(\Sigma^\infty))$ represents an abstraction of trace semantics. For example the (natural) denotational semantics $\mathcal{D} \in uco(\wp(\Sigma^\infty))$ can be formalized as an abstract interpretation of τ^∞ : $\mathcal{D}(X) = \{ \sigma \in \Sigma^+ \mid \exists \delta \in X^+. \sigma_0 = \delta_0 \wedge \sigma_f = \delta_f \} \cup \{ \sigma \in \Sigma^\omega \mid \exists \delta \in X^\omega. \sigma_0 = \delta_0 \}$, where $X^+ \stackrel{\text{def}}{=} X \cap \Sigma^+$ and $X^\omega \stackrel{\text{def}}{=} X \cap \Sigma^\omega$. \mathcal{D} ab-

Table 2. Semantics

Boolean expressions	$\mathbf{B}[E_1 < E_2]\rho \stackrel{\text{def}}{=} \mathbf{A}[E_1]\rho < \mathbf{A}[E_2]\rho$
$\mathbf{B} : \mathcal{E}[\mathbb{X}] \rightarrow \{\text{true}, \text{false}, A\}$ and $\text{var}[B] \subseteq \mathbb{X}$	$\mathbf{B}[B_1 \vee B_2]\rho \stackrel{\text{def}}{=} \mathbf{B}[B_1]\rho \vee \mathbf{B}[B_2]\rho$
	$\mathbf{B}[\neg B]\rho = \neg \mathbf{B}[B], \mathbf{B}[\text{true}/\text{false}]\rho \stackrel{\text{def}}{=} \text{true}/\text{false}$
Program actions	$\mathbf{S}[B]\rho \stackrel{\text{def}}{=} \{ \rho' \mid \mathbf{B}[B]\rho' = \text{true} \wedge \rho' = \rho \}$
$\mathbf{S} : A \rightarrow (\mathcal{E}[\mathbb{X}] \rightarrow \wp(\mathcal{E}[\mathbb{X}]))$ and $\text{var}[A] \subseteq \text{dom}(\rho)$	$\mathbf{S}[X := ?]\rho \stackrel{\text{def}}{=} \{ \rho' \mid \exists z \in \mathbb{Z} : \rho' = \rho[X := z] \}$
	$\mathbf{S}[X := E]\rho \stackrel{\text{def}}{=} \{ \rho[X := \mathbf{A}[E]\rho] \}$
	$\mathbf{S}[\text{true}]\rho \stackrel{\text{def}}{=} \mathbf{S}[\text{skip}]\rho \stackrel{\text{def}}{=} \{ \rho \}$

stracts away the history of the computation by observing the input/output relation of finite traces and the input of diverging computations only. In the following we consider the simple imperative language defined in [12] with abstract syntax in Table 1, together with the following basic functions: $\text{lab}[L_1 : A \rightarrow L_2] \stackrel{\text{def}}{=} L_1$, $\text{lab}[P] \stackrel{\text{def}}{=} \{ \text{lab}[C] \mid C \in P \}$, $\text{var}[L_1 : A \rightarrow L_2] \stackrel{\text{def}}{=} \text{var}[A]$, $\text{var}[P] \stackrel{\text{def}}{=} \cup_{C \in P} \text{var}[C]$, $\text{succ}[L_1 : A \rightarrow L_2] \stackrel{\text{def}}{=} L_2$ and $\text{act}[L_1 : A \rightarrow L_2] \stackrel{\text{def}}{=} A$. Each variable $X \in \text{var}[P]$ has values in the semantic domain D , where the undefined value is denoted by Υ and $D_{\mathcal{Y}} \stackrel{\text{def}}{=} D \cup \{ \Upsilon \}$. We define an *environment* $\rho \in \mathcal{E}$ as a map from variables $X \in \text{dom}(\rho)$ to values $\rho(X) \in D_{\mathcal{Y}}$. Let χ be a subset of variables, then $\rho|_{\chi}$ is the restriction of environment ρ to the domain $\text{dom}(\rho) \cap \chi$. The semantics is in Table 2. A *state* $\sigma_i \in \Sigma \stackrel{\text{def}}{=} \mathcal{E} \times \mathbb{C}$ is a pair $\langle \rho, C \rangle$, where C is the next command to be executed in the environment ρ . The *transition relation* between states specifies the set of states that can be reached from a given state: $R_P(\langle \rho, C \rangle) \stackrel{\text{def}}{=} \{ (\rho', C') \mid \rho' \in \mathbf{S}[\text{act}(C)]\rho, \text{succ}[C] = \text{lab}[C'], \rho, \rho' \in \mathcal{E}[P], C' \in P \}$. The *finite traces* of a program $P \in \mathbb{P}$ are obtained by the computation of the $\text{lfp}_{\subseteq} F[P]$, while the *infinite traces* by the computation of the $\text{gfp}_{\subseteq} F[P]$, where $F[P](X) \stackrel{\text{def}}{=} X \cup \{ \sigma_i \frown \sigma'_i \mid \sigma'_i \in R_P(\sigma_i), \sigma'_i \frown \sigma \in X \}$. We denote with $S[P]$ the set of finite and infinite traces of P .

Program Transformation. In [12] the authors define a language-independent methodology for systematically derive syntactic program transformations from semantic ones by mean of abstract interpretation (see Fig. 1). Given a program $P \in \mathbb{P}$ and a *syntactic transformation* $\tau : \mathbb{P} \rightarrow \mathbb{P}$ which returns the transformed program $\tau[P] \in \mathbb{P}$, we have that the corresponding *semantic transformation* t takes the semantics $S[P] \in \wp(\Sigma^{\infty})$ of P , and returns the semantics $S[\tau[P]]$ of the transformed program. We consider programs as an abstraction of their semantics, as formalized by the Galois connection $(\langle \wp(\Sigma^{\infty}); \sqsubseteq \rangle, p, (\mathbb{P}; \leq), S)$, where $p[\mathcal{S}]$ is the simplest program whose semantics upper approximates $\mathcal{S} \in \wp(\Sigma^{\infty})$ [12]. Therefore the *semantic transformation* $t : \wp(\Sigma^{\infty}) \rightarrow \wp(\Sigma^{\infty})$ induced by the syntactic transformation τ is $t(S[P]) = S[\tau[p(S[P])]]$, while the *syntactic transformation* τ induced by the semantic transformation t is $\tau[P] = p(t(S[P]))$. A program transformation is *correct* if at some level of abstraction it is meaning

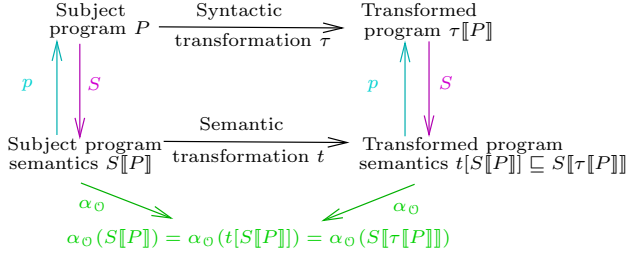

Fig. 1. Syntactic-Semantic Program Transformations

preserving, namely a syntactic transformation τ is correct w.r.t. an observational abstraction $\alpha_{\mathcal{O}}$ if $\alpha_{\mathcal{O}}(S[P]) = \alpha_{\mathcal{O}}(S[\tau[P]])$ [12].

3 Semantic-Based Program Obfuscators

Traditionally a program transformation $\tau : \mathbb{P} \rightarrow \mathbb{P}$ is an obfuscation if: 1) it is a potent transformation and 2) P and $\tau[P]$ have the same observational behavior, *i.e.*, if P fails to terminate or it terminates with an error condition then $\tau[P]$ may or may not terminate; otherwise $\tau[P]$ must terminate and produce the same output as P [4, 5, 6]. This definition requires that given an initial state σ_0 , if $\sigma_0 \widehat{\sigma} \in S[P]^\omega$ or $\sigma_0 \widehat{\sigma} \sigma_e \in S[P]^+$, where $\sigma_e \in Err$ with Err being the set of error states, then $\sigma_0 \widehat{\sigma}' \in S[\tau[P]]^\infty$; otherwise if $\sigma \in S[P]^+$ then $\sigma \in \mathcal{D}(S[\tau[P]]^+)$. We denote by \mathcal{C} the family of these code transformations.

3.1 Abstract Interpretation-Based Code Obfuscation

In this section we specify what is hidden by a syntactic transformation, by introducing a novel definition of code obfuscation based on semantics.

Definition 1. Let $\tau : \mathbb{P} \rightarrow \mathbb{P}$ be a program transformation. τ is potent if there is a property $\alpha \in uco(\wp(\Sigma^\infty))$ such that: $\alpha(S[P]) \neq \alpha(S[\tau[P]])$.

Therefore a transformation τ is potent when there exists a property α and a program P such that the approximation of the concrete trace semantics of P is different from the same approximation for the concrete trace semantics of $\tau[P]$.

Example 1. Let us consider a program P and its transformed version P' :

<p>P:</p> <p>L₁: X := ? → L₂</p> <p>L₂: Y := ? → L₃</p> <p>L₃: out := (X - Y)² → /</p>	<p>P':</p> <p>L₁: X := ? → L₂</p> <p>L₂: Y := ? → L₃</p> <p>L₃: out := X² → L₄</p> <p>L₄: out := out - 2XY → L₅</p> <p>L₅: out := out - Y² → /</p>
--	---

Let us define $\alpha \in uco(\wp(\Sigma^\infty))$ as $\alpha(X) \stackrel{\text{def}}{=} \{ \sigma \in \Sigma^+ \mid \exists \eta \in X : |\sigma| = |\eta| \}$. The property α observes the length of program traces. In this case we have $\alpha(S[P]) = \{ \sigma \in \Sigma^+ \mid |\sigma| = 3 \}$, while $\alpha(S[\tau[P]]) = \{ \sigma \in \Sigma^+ \mid |\sigma| = 5 \}$. It is clear that $\alpha(S[P]) \neq \alpha(S[\tau[P]])$, *i.e.*, the transformation obfuscates α .

In order to factor the observational semantics into preserved and masked properties, we define the most concrete property preserved by a transformation $\tau : \mathbb{P} \rightarrow \mathbb{P}$, as follows $\delta_\tau \stackrel{\text{def}}{=} \sqcap \{ \varphi \in uco(\wp(\Sigma^\infty)) \mid \varphi(S[P]) = \varphi(S[\tau[P]]) \}$.

Lemma 1. *Given a transformation $\tau : \mathbb{P} \rightarrow \mathbb{P}$, $\delta_\tau(S[P]) = \delta_\tau(S[\tau[P]])$.*

Given a program transformation τ we want to characterize the set of properties that are not preserved, *i.e.*, obfuscated, by τ . By considering the transformation τ and the property $\alpha \in uco(\wp(\Sigma^\infty))$ that the attacker wants to observe, we note that $\alpha \ominus (\delta_\tau \sqcup \alpha)$ is precisely what the transformation τ hides of the property α . In fact when $\alpha \ominus (\delta_\tau \sqcup \alpha) \neq \top$ some parts of the property α has been lost in the transformation. In this case we say that the property α is *obfuscated* by the transformation τ , because that property cannot be observed on the semantics of the transformed program.

Definition 2. $O_{\delta_\tau} = \{ \alpha \in uco(\wp(\Sigma^\infty)) \mid \alpha \ominus (\delta_\tau \sqcup \alpha) \neq \top \}$ is the set of properties obfuscated by $\tau : \mathbb{P} \rightarrow \mathbb{P}$.

Given $\delta \in uco(\wp(\Sigma^\infty))$, we define a δ -obfuscator as any potent program transformation $\tau : \mathbb{P} \rightarrow \mathbb{P}$, such that every program is equivalent to its obfuscated version w.r.t. the particular observational semantics δ .

Definition 3. $\tau : \mathbb{P} \rightarrow \mathbb{P}$ is a δ -obfuscator if $\delta = \delta_\tau$ and $O_\delta \neq \emptyset$

Lemma 2. *Given a δ -obfuscator $\tau : \mathbb{P} \rightarrow \mathbb{P}$, then for each $\alpha \in O_\delta$ there exists a program P such that $\alpha(S[P]) \neq \alpha(S[\tau[P]])$.*

The above definition of obfuscator is a generalization of the classical one by Collberg *et al.*, introduced at the beginning of this Section.

Theorem 1. *If τ is a \mathcal{D} -obfuscator then $\tau \in \mathcal{C}$.*

In particular we can define a *partial order* between obfuscating transformations, by considering the set of properties that the transformations hide. Given two program transformations τ and τ' , then τ' is more potent than τ , denoted $\tau \leq_P \tau'$, if $O_{\delta_\tau} \subseteq O_{\delta_{\tau'}}$. We can also compare the potency of τ and τ' w.r.t. a particular property α , namely by measuring the approximation in the knowledge of that property that can be obtained by observing semantics. Let $\alpha \in O_{\delta_\tau} \cap O_{\delta_{\tau'}}$, then τ' is more potent than τ w.r.t. α , denoted $\tau \leq_\alpha \tau'$, if $\alpha \ominus (\delta_{\tau'} \sqcup \alpha) \sqsubseteq \alpha \ominus (\delta_\tau \sqcup \alpha)$. In this case τ' obfuscates the property α more than what τ does. From the structure of the lattice of abstract interpretations $uco(\wp(\Sigma^\infty))$ we can derive the some basic properties of O_δ and therefore of the potency of code obfuscations.

Proposition 1. *Let $\delta, \mu \in uco(\wp(\Sigma^\infty))$ and τ, τ' be program transformations:*
 1) $O_\delta = \{ \alpha \in uco(\wp(\Sigma^\infty)) \mid \alpha \not\leq \delta \}$; 2) *If $\mu \sqsubset \delta$ then $O_\mu \subset O_\delta$, *i.e.*, $\tau_\mu \leq_P \tau_\delta$;*
 3) $O_{\delta \sqcup \mu} = O_\delta \cup O_\mu$; 4) *If $\tau \leq_\delta \tau'$, then for each property $\mu \sqsubseteq \delta$ we have $\tau \leq_\mu \tau'$;*
 5) *If $\tau \leq_{\delta \sqcap \mu} \tau'$, then $\tau \leq_\delta \tau'$ and $\tau \leq_\mu \tau'$.*

3.2 Constructive Characterization of Potency

In this section we define a method for deriving δ_τ for a given syntactic transformation $\tau : \mathbb{P} \rightarrow \mathbb{P}$. By Definition 2, this provides a characterization of the potency of a code transformation. Let $t : \wp(\Sigma^\infty) \rightarrow \wp(\Sigma^\infty)$ be a semantic transformation and $K_{P,t} : uco(\wp(\Sigma^\infty)) \rightarrow uco(\wp(\Sigma^\infty))$ be a domain transformer that, given a property $\mu \in uco(\wp(\Sigma^\infty))$, returns the closest abstraction preserved by t on $P \in \mathbb{P}$: $K_{P,t} \stackrel{\text{def}}{=} \lambda\mu. \sqcap \{ \varphi \in uco(\wp(\Sigma^\infty)) \mid \mu \sqsubseteq \varphi \wedge \varphi(S[P]) = \varphi(t(S[P])) \}$. For a given $\mu \in uco(\wp(\Sigma^\infty))$, $K_{P,t}(\mu)$ is a closure operator on sets of traces. In order to characterize the set of its fix-points, we have to specify the set of traces $X \subseteq \Sigma^\infty$ preserved by the transformation t on a particular program P . The predicate $Pres_{P,t}(X)$, where $X \in \wp(\Sigma^\infty)$, precisely captures this notion, in fact $Pres_{P,t}(X)$ evaluates to *true* if and only if $\forall Y \subseteq S[P] : Y \subseteq X \Rightarrow t(Y) \subseteq X$.

Lemma 3. $\{ X \in \wp(\Sigma^\infty) \mid Pres_{P,t}(X) \}$ is preserved by t on program P .

Theorem 2. $K_{P,t}(id) = \{ X \in \wp(\Sigma^\infty) \mid Pres_{P,t}(X) \}$

$K_{P,t}(id)$ models the most concrete property preserved by the transformation t for the program P . The generalization of this notion for all programs follows straightforwardly.

Corollary 1. Let $\tau : \mathbb{P} \rightarrow \mathbb{P}$, then $\delta_\tau = \bigsqcup_{P \in \mathbb{P}} K_{P, \rho \circ \tau \circ S}(id)$.

4 An Example: Obfuscation by Program Specialization

In this section we consider constant propagation as code obfuscation. This proves that our semantic-based approach to code obfuscation is adequate both to include a wide range of program transformation techniques and to compare them by extracting what is actually masked by the transformation. We follow Cousot & Cousot [12] in the definition of an algorithm for constant propagation.

4.1 Cousot's Constant Propagation

The *residual* $R[E]\rho$ of an arithmetic or boolean expression E in an environment ρ is the expression resulting by the specialization of E in such environment (see Table 3). An expression $E \in \mathbb{E} \cup \mathbb{B}$ is *static* in the environment ρ , denoted $\mathbf{static}[E]\rho$, if it can be fully evaluated in ρ , that is $var[E] \subseteq dom(\rho)$; otherwise E is *dynamic*. With $R[A]\rho$ we denote the specialization of action A in the environment ρ (see Table 3). We consider syntactic and semantic program transformations relative to the constant propagation problem as formalized in [12], where the arguments of the program transformation are the semantics $S[P]$ and the result of a constant detection static analysis $S^C[P]$.

Abstract semantics: It is defined as $S^C = \alpha^C \circ S$, where α^C is given by:

$$\alpha^C(S[P]) = \lambda L. \lambda X. \bigsqcup \{ \rho(X) \mid \sigma \in S[P], C \in \mathbb{C}, \sigma_i = \langle \rho, C \rangle, lab[C] = L \}$$

Table 3. Expression and Action specialization

<u>Expressions</u>	$R \in \mathbb{E} \times \mathcal{E} \rightarrow \mathbb{E}$
$R[[n]]\rho = n$	
$R[[X]]\rho =$	if $X \in \text{dom}(\rho)$ then $\rho(X)$ else X
$R[[E_1 - E_2]]\rho =$	let $E_1^r = R[[E_1]]\rho$ and $E_2^r = R[[E_2]]\rho$ if $E_1^r = \Lambda$ or $E_2^r = \Lambda$ then Λ else if $E_1^r = n_1$ and $E_2^r = n_2$ then $n = n_1 - n_2$ else $E_1^r - E_2^r$
	$R \in \mathbb{B} \times \mathcal{E} \rightarrow \mathbb{B}$
$R[[E_1 < E_2]]\rho =$	let $E_1^r = R[[E_1]]\rho$ and $E_2^r = R[[E_2]]\rho$ if $E_1^r = \Lambda$ or $E_2^r = \Lambda$ then Λ else if $E_1^r = n_1$ and $E_2^r = n_2$ and $b = n_1 < n_2$ then b else $E_1^r < E_2^r$
$R[[B_1 \vee B_2]]\rho =$	let $B_1^r = R[[B_1]]\rho$ and $B_2^r = R[[B_2]]\rho$ if $B_1^r = \Lambda$ or $B_2^r = \Lambda$ then Λ else if $B_1^r = \text{true}$ or $B_2^r = \text{true}$ then true else if $B_1^r = \text{false}$ then B_2^r else if $B_2^r = \text{false}$ then B_1^r else $B_1^r \vee B_2^r$
$R[[\neg B]]\rho =$	let $B^r = R[[B]]\rho$ if $B^r = \Lambda$ then Λ else if $B^r = \text{true}$ then false else if $B^r = \text{false}$ then true else $\neg B^r$
$R[[\text{true}]]\rho =$	true
$R[[\text{false}]]\rho =$	false
<u>Actions</u>	$R \in \mathbb{A} \times \mathcal{E} \rightarrow \mathbb{A}$
$R[[B]]\rho =$	$\langle \rho, R[[B]]\rho \rangle$
$R[[X := ?]]\rho =$	$\langle \rho \setminus X, X := ? \rangle$
$R[[X := E]]\rho =$	if $\text{static}[[E]]\rho$ then $\langle \rho[X := R[[E]]\rho] \rangle$, <i>skip</i> else $\langle \rho \setminus X, X := R[[E]]\rho \rangle$

This function, given a label L and a variable X , returns the least upper bound \sqcup on the flat lattice of program values for X at the program point L .

Semantic transformation: The semantic transformation t^C is defined in [12] where: $t^C[S[[P]], S^C[[P]]] \stackrel{\text{def}}{=} \{t^C[\sigma, S^C[[P]]] \mid \sigma \in S[[P]]\}$ is the transformation of semantics, $t^C[\sigma, S^C[[P]]] \stackrel{\text{def}}{=} \lambda i. t^C[\sigma_i, S^C[[P]]]$ is the transformation of traces, and $t^C[\langle \rho, C \rangle, S^C[[P]]] \stackrel{\text{def}}{=} \langle \rho, t^C[C, \tau^C(\text{lab}[[C]])] \rangle$ is the transformation of states, where $t^C[L_1 : A \rightarrow L_2, \rho^C] \stackrel{\text{def}}{=} L_1 : t^C[A, \rho^C] \rightarrow L_2$ is command specialization and $t^C[A, \rho^C] = \text{let } \langle \rho_r, A_r \rangle \stackrel{\text{def}}{=} R[[A]]\rho \mid_{\{X \in \mathbb{X} \mid \rho^C(X) \in D_T\}} \in A_r$ is action specialization. The syntactic transformation τ^C can be systematically derived as shown in [12].

Observational semantics: Given a partial trace σ , the observational semantics α_0^C returns the sequence of its environments: $\alpha_0^C(S[[P]]) \stackrel{\text{def}}{=} \{\alpha_0^C(\sigma) \mid \sigma \in S[[P]]\}$, $\alpha_0^C(\sigma) \stackrel{\text{def}}{=} \lambda i. \alpha_0^C(\sigma_i)$, and $\alpha_0^C(\langle \rho, C \rangle) \stackrel{\text{def}}{=} \rho$.

Table 4. A simple program from [8]

a:= 1; b:=2; c:=3; d:=3; e:=0;	$L_1 : a:= 1; b:=2; c:=3; d:=3; e:=0; \rightarrow L_2$
while B do	$L_2 : B \rightarrow L_3$
b:=2*a; d:=d+1; e:=e-a;	$L_2 : \neg B \rightarrow L_5$
a:=b-a; c:=e+d;	$L_3 : b:=2*a; d:=d+1; e:=e-a; \rightarrow L_4$
endw	$L_4 : a:=b-a; c:=e+d; \rightarrow L_2$
	$L_5 : \text{stop} \rightarrow I$

4.2 Code Obfuscation by Constant Propagation

In order to specify the properties obfuscated by constant propagation τ^C , we derive δ_{τ^C} . Let us define the property θ as follows: $\theta(S[P]) \stackrel{\text{def}}{=} \{\theta(\sigma) \mid \sigma \in S[P]\}$, $\theta(\sigma) \stackrel{\text{def}}{=} \lambda i. \theta(\sigma_i)$, and $\theta(\langle \rho, C \rangle) \stackrel{\text{def}}{=} \langle \rho, \text{lab}[C], \text{succ}[C] \rangle$.

Theorem 3. $\theta = \delta_{\tau^C}$ and $O_\theta \neq \emptyset$.

It is worth noting that θ is the most concrete property preserved by constant propagation τ^C . Let us consider the property $\vartheta \in \text{uco}(\wp(\Sigma^\infty))$, observing the environment, the labels, and the type of actions: $\vartheta(\tau^\infty) \stackrel{\text{def}}{=} \{\vartheta(\sigma) \mid \sigma \in \tau^\infty\}$, $\vartheta(\sigma) \stackrel{\text{def}}{=} \lambda i. \vartheta(\sigma_i)$, and $\vartheta(\langle \sigma, C \rangle) \stackrel{\text{def}}{=} \langle \rho, \text{lab}[C], \text{succ}[C], \text{type}(\text{act}[C]) \rangle$, where *type* maps actions into the following set of action types $\{\text{assign}, \text{skip}, \text{test}\}$. This property belongs to O_θ , meaning that $O_\theta \neq \emptyset$, as requested by Definition 3 and shown in Example 2 below. This proves that τ^C is actually a program obfuscator, hiding the type of the command actions. This is a consequence of the structure of the masked closure $\vartheta \ominus (\vartheta \sqcup \theta)$, which characterizes what is obfuscated from ϑ by τ^C . Consider the closure η which observes the *type* of actions defined as follows:

$$\eta = \lambda X. \left\{ \sigma \mid \begin{array}{l} \sigma' \in X \text{ and } \forall i. \sigma_i = \langle \rho_i, C_i \rangle, \sigma'_i = \langle \rho'_i, C'_i \rangle \\ \text{type}(C_i) = \text{type}(C'_i) \end{array} \right\}$$

The following theorem specifies that η is masked by the constant propagation, *i.e.*, τ^C obfuscates η .

Theorem 4. $\vartheta \ominus (\vartheta \sqcup \theta) \sqsubseteq \eta$.

Example 2. As observed above, ϑ is not preserved by t^C , namely it could happen that: $\vartheta(S[P]) \neq \vartheta(t^C[S[P], S^C[P]])$. In the following we represent the environment as a tuple $(v_a, v_b, v_c, v_d, v_e)$ of values corresponding to the variables a, b, c, d, e in a certain execution point. Let us run the program in Table 4, and consider the states $\sigma_2 = \langle (1, 2, 3, 3, 0), L_3 : b := 2*a; d := d+1; e := e-a; \rightarrow L_4 \rangle$ and $\sigma_3 = \langle (1, 2, 3, 4, -1), L_4 : a := b-a; c := e+d \rightarrow L_2 \rangle$. Their transformed versions are: $t^C(\sigma_2) = \langle (1, 2, 3, 3, 0), L_3 : d := d+1; e := e-a; \rightarrow L_4 \rangle$ and $t^C(\sigma_3) = \langle (1, 2, 3, 4, -1), L_4 : \text{skip} \rightarrow L_2 \rangle$. In this case $\vartheta(\sigma_2) = \langle (1, 2, 3, 3, 0), L_3, L_4, \text{assign} \rangle$ and $\vartheta(\sigma_3) = \langle (1, 2, 3, 4, -1), L_4, L_2, \text{assign} \rangle$; while $\vartheta(t^C(\sigma_2)) = \langle (1, 2, 3, 3, 0), L_3, L_4, \text{assign} \rangle$ and $\vartheta(t^C(\sigma_3)) = \langle (1, 2, 3, 4, -1), L_4, L_2, \text{skip} \rangle$, showing that the property η is not preserved.

5 Discussion

In this paper we introduce a notion of code obfuscation providing a general enough definition including both most program transformation techniques as obfuscators and the standard definition of Collberg *et al.* [5] as special cases. Moreover, it provides advanced techniques for comparing obfuscating algorithms relatively to their potency in the lattice of abstract interpretations. This definition can be considered as the first step towards a semantic-based theory for code obfuscation. Note however that in Definition 1 we consider abstractions of concrete semantics and not arbitrary sound, possibly incomplete, abstract interpretations. This makes Definition 1 too strong for modeling attackers which can be any decidable sound approximation of semantics, *e.g.*, arbitrary static program analyzers. Consider the following example of program transformation:

$$\begin{array}{ll}
 P: & P': \\
 L_1: X := ? \rightarrow L_2 & L_1: X := ? \rightarrow L_2 \\
 L_2: Y := ? \rightarrow L_3 & L_2: Y := ? \rightarrow L_3 \\
 L_3: \text{out} := (X - Y)^2 \rightarrow \perp & L_3: \text{out} := X^2 - 2XY + Y^2 \rightarrow \perp
 \end{array}$$

Let's consider the property of the sign of a variable, *i.e.*, the abstract domain $Sign \stackrel{\text{def}}{=} \{\mathbb{Z}, \mathbb{Z}^+, \mathbb{Z}^-, \emptyset\}$. By considering the sign of the variable `out`, when `X` is positive and `Y` is negative, we have that: $Sign(S[P]) = Sign(S[\tau[P]]) = \mathbb{Z}^+$, while $S^{Sign}[P] = \mathbb{Z}^+$ and $S^{Sign}[\tau[P]] = \mathbb{Z}$. Therefore the previous transformation obfuscates program P for the sign analysis, because the static sign analysis of the transformed program is unable to get the sign of `out`. This is not captured by Definition 1, because $Sign$ is incomplete for integer addition [16]. Indeed, in Definition 1, the abstraction is applied to the concrete semantics, returning \mathbb{Z}^+ in both cases. It would be important to weaken our notion of potency by considering abstract semantics derived by sound (possibly incomplete) approximations of the concrete semantics. This is crucial in order to include in our model of attackers arbitrary sound program analyzers. Moreover the systematic design of program transformation by abstract interpretation [12] can be applied for the systematic design of code obfuscation algorithms, driven by the abstraction (semantic property) to be masked. We can observe that other program transformations, such as *abstract watermarking* [13], can be seen as a particular code obfuscation. The relation between our notion of code obfuscation and abstract watermarking deserves further investigation.

About Hoare Logics for Higher-Order Store^{*}

Bernhard Reus^{1, **} and Thomas Streicher²

¹ University of Sussex, Brighton BN1 9QH, UK

² TU Darmstadt, 64298 Darmstadt, Germany

Abstract. We present a Hoare logic for a simple imperative while-language with stored commands, ie. stored parameterless procedures. Stores that may contain procedures are called higher-order. Soundness of our logic is established by using denotational rather than operational semantics. The former is employed to elegantly account for an inherent difficulty of higher-order store, namely that assertions necessarily describe recursive predicates on a recursive domain. In order to obtain proof rules for mutually recursive procedures, assertions have to explicitly refer to the code of the procedures.

1 Introduction and Motivation

Hoare logic for imperative languages has been invented in the late 60es [7] and since then extended in many directions (for a survey see e.g. [4]). Procedures are a typical example. For a simple while language with parameterless recursive procedures it is common to apply the following rule (see [4]) for a procedure p declared with body C :

$$(proc) \frac{\{P\} p \{Q\} \vdash \{P\} C \{Q\}}{\{P\} p \{Q\}}$$

In order to verify the effect of a procedure call, one has to show that the procedure body satisfies the very same effect under the assumption that the call already does so. Semantically, this corresponds to a form of fixpoint induction where admissibility of the semantical predicates is guaranteed automatically as store is modeled by a flat domain. Thus, in rule *(proc)* the $\{P\} p \{Q\}$ in the conclusion refers to the fixpoint of the definition $\text{rec } p \Leftarrow C[p]$ whereas on the left hand side in the premise it refers to an arbitrary implementation of p .

The situation changes dramatically if one allows stored procedures, ie. if procedures are kept in the store – in the same way as basic data like numbers – and called by their (variable) name. For example, $\text{run } x$ invokes the procedure

stored in variable x . The semantics of programs, being state transformers, now becomes implicitly higher-order, as they depend on the (code in the) store which contains such transformers itself. For this reason such stores are sometimes called “higher-order” or even recursive.

Landin had already observed¹ that in such situations one is able to tie “knots through the store”. Put differently, recursion through the store becomes available such that additional fixpoint operators are obsolete. Consider e.g. the example $x := C; \text{run } x$ which first stores a command C in x and then runs this command. But C itself may contain a command $\text{run } x$, in which case we obtain a recursive procedure. In traditional semantics (see [9, 14, 6]) the semantics of a procedure is a fixpoint. This is fine as long as newly added code can only call the old procedures and not vice-versa. In object-oriented languages, however, new subclasses can change the semantics of the old classes (that is the whole point of object-orientation) and the traditional semantics cannot cope with that. For languages with higher-order store this is no problem, as recursion is through the store and not by fixpoint.

To the best of our knowledge, there is no Hoare-calculus for partial correctness of (even simple) imperative languages with higher-order store in the literature. However, in [8] a calculus for *total* correctness of programs with higher-order store has been presented recently where soundness is based on induction on a termination measure. The semantics does not make use of domain theory and does not seem to be easily extendible to partial correctness.

Several (fully-abstract) models using games (or abstract versions of games) have been developed but they focus on observational equivalence, e.g. [3, 10, 11].

A Hoare-like calculus for an object-based language, Abadi and Cardelli’s imperative object calculus [1], has been suggested in [2]. In that language, simple field values and method closures are kept together in the same store. Hence, the store is higher-order. In [2], the program logic does not use Hoare-triples but specifications that refer to the state before and after method execution. Consequently, in [2], method specifications can only use static information about other methods and thus cannot cope with callbacks or dynamic loading where specifications may change at runtime. Method update had to be disallowed. Note that in this paper our stored procedures can be updated.

In [16, 17], we have presented a denotational technique to understand and model such object logics. This has been extended to a complete analysis of the entire Abadi-Leino calculus in [15]. Separately, in [5], Calcagno and O’Hearn set out to put ideas of separation logic [12] into a program logics for objects in a traditional Hoare-triple style but had problems with the object introduction rule.

In this paper we present a simple imperative language (Sect. 2) with higher-order store but without objects, and an assertion language (Sect. 3). We present some new proof rules (Sect. 4), give examples (Sect. 5) and prove soundness

¹ As Peter O’Hearn pointed out to the first author.

Table 1. BNF syntax of \mathcal{L}

$x \in \mathbf{Var}$	variable
$e \in \mathbf{Exp} ::= x$	variable expression
k	numbers and other constants
$e \circ_2 e$	binary operators
$\circ_1 e$	unary operators
$'s'$	quote (command as expression)
$s \in \mathbf{Com} ::= \mathbf{nop}$	no op
$x := e$	assignment
$s; s$	sequential composition
$\text{if } e \text{ then } s \text{ else } s$	conditional
$\text{run } x$	unquote (run the command in x)

(Sect. 6). We finish with an outlook where the results of this paper may lead us and how related work could be helpful.

The language in use is arguably the simplest language that uses higher-order store. It is thus an ideal candidate to investigate the problems caused by higher-order store in isolation. Using denotational semantics we will discover where exactly the difficulties of higher-order store are rooted.

2 The Programming Language

Syntax First we define the programming language syntax of our language, called \mathcal{L} . Let \mathbf{Var} be the set of (countable) program variables, \mathbf{Exp} the side effect free expressions, and \mathbf{Com} the statements (commands). A BNF grammar for \mathcal{L} is presented in Table 1.

The simplest non-terminating loop can be written as $x := \text{'run } x\text{'}; \text{run } x$.

Semantics The semantics is developed in a category of cpo-s and partial continuous maps (predomains). For any (pre-)domain there is, as usual, a partial order \sqsubseteq , and for a partial continuous function $f \in A \rightarrow B$ and $a \in A$, we write $f(a) \downarrow$ to state that the application is defined.

Let \mathbf{BVal} be the set of basic first-order values like numbers or booleans ordered discretely. Values and stores are defined by the following system of (pre-)domain equations

$$\mathbf{Val} = \mathbf{BVal} + [\mathbf{St} \rightarrow \mathbf{St}] \qquad \mathbf{St} = \mathbf{Val}^{\mathbf{Var}}$$

Stores in \mathbf{St} map variables into values in \mathbf{Val} . The fact that state transformers can be values reflects the fact that the store is higher-order. Note that for a store σ , a variable x , and a value a we write $\sigma[x \mapsto a]$ for the map σ' defined as

$$\sigma'(y) = \begin{cases} a & \text{if } y \equiv x \\ \sigma(y) & \text{otherwise} \end{cases}$$

Table 2. Semantics of \mathcal{L}

$\llbracket x \rrbracket^e \sigma$	$= \sigma(x)$
$\llbracket s \rrbracket^e \sigma$	$= \llbracket s \rrbracket$
$\llbracket k \rrbracket^e \sigma$	$= k$
$\llbracket e_1 \circ_2 e_2 \rrbracket^e \sigma$	$= \circ_2(\llbracket e_1 \rrbracket^e \sigma, \llbracket e_2 \rrbracket^e \sigma)$
$\llbracket \circ_1 e_1 \rrbracket^e \sigma$	$= \circ_1(\llbracket e_1 \rrbracket^e \sigma)$
$\llbracket \text{nop} \rrbracket \sigma$	$= \sigma$
$\llbracket x := e \rrbracket \sigma$	$= \sigma[x \mapsto \llbracket e \rrbracket^e \sigma]$
$\llbracket s_1; s_2 \rrbracket \sigma$	$= \llbracket s_2 \rrbracket(\llbracket s_1 \rrbracket \sigma)$
$\llbracket \text{if } e \text{ then } s_1 \text{ else } s_2 \rrbracket \sigma$	$= \begin{cases} \llbracket s_1 \rrbracket \sigma & \text{if } \llbracket e \rrbracket^e \sigma = \text{true} \\ \llbracket s_2 \rrbracket \sigma & \text{if } \llbracket e \rrbracket^e \sigma = \text{false} \\ \text{undefined} & \text{otherwise} \end{cases}$
$\llbracket \text{run } x \rrbracket \sigma$	$= \sigma(x)(\sigma)$

The equations for higher-order store can thus be rewritten in one equation as follows:

$$\text{St} = (\text{BVal} + [\text{St} \rightarrow \text{St}])^{\text{Var}}$$

or equivalently, by setting $\text{Cl} = [\text{St} \rightarrow \text{St}]$,

$$\text{Cl} = [(\text{BVal} + \text{Cl})^{\text{Var}} \rightarrow (\text{BVal} + \text{Cl})^{\text{Var}}]$$

The mixed-variant functor for which Cl is the solution is given by its object and morphism part below:

$$F(X, Y) = [(\text{BVal} + X)^{\text{Var}} \rightarrow (\text{BVal} + Y)^{\text{Var}}]$$

If $e : X \rightarrow Y$ then let $\hat{e} = (\text{BVal} + e)^{\text{Var}} : (\text{BVal} + X)^{\text{Var}} \rightarrow (\text{BVal} + Y)^{\text{Var}}$. More precisely, for a store $\sigma \in (\text{BVal} + X)^{\text{Var}}$, $\hat{e}(\sigma)$ is defined as follows:

$$\hat{e}(\sigma)(x) = \begin{cases} \sigma(x) & \text{if } \sigma(x) \in \text{BVal} \\ e(\sigma(x)) & \text{if } \sigma(x) \in X \end{cases}$$

Now we can define the morphism part:

$$F(e, f) = \lambda h : F(X, Y). \hat{f} \circ h \circ \hat{e}.$$

For $e \in [\text{Cl} \rightarrow \text{Cl}]$ let $e^A \in [\text{Cl}^A \rightarrow \text{Cl}^A]$ be defined by $e^A(h)(a) = e(h(a))$. We can interpret \mathcal{L} using an interpretation function for expressions $\llbracket _ \rrbracket^e : \text{Exp} \rightarrow [\text{St} \rightarrow \text{Val}]$ and commands $\llbracket _ \rrbracket : \text{Com} \rightarrow [\text{St} \rightarrow \text{St}]$ as presented in Table 2.

The last equation $\llbracket \text{run } x \rrbracket \sigma = \sigma(x)(\sigma)$ is reminiscent of the self-application semantics of method call in OO-languages.

3 The Assertion Language

The assertion language is based on the assertions of the classic Hoare-calculus with the difference, though, that expressions can also refer to stored procedures.

Table 3. Syntax of Assertions

$n, p \in \text{AuxVar}$		
$\tau \in \text{Type}$::= bool int com	types
$e \in \text{Exp}$::= n p	auxiliary variables in BVal and Cl
	x k $e \circ_2 e$ $\circ_1 e$ $'s'$	
$P \in \text{Asrt}$::= <i>false</i>	falsity
	$P \wedge P$	conjunction
	$\neg P$	negation
	$\forall n. P$	universal quantification
	$\tau? e$	type check
	$e \leq_\tau e$	comparison

Table 4. Semantics of Assertions

$\llbracket \text{false} \rrbracket \eta$	= \emptyset
$\llbracket P \wedge Q \rrbracket \eta$	= $\llbracket P \rrbracket \eta \cap \llbracket Q \rrbracket \eta$
$\llbracket \forall n. P \rrbracket \eta$	= $\bigcap_{v \in \text{Val}} \llbracket P \rrbracket \eta[n \mapsto v]$
$\llbracket \tau? e \rrbracket \eta$	= $\{ \sigma \mid \llbracket e \rrbracket^e \eta \sigma \in \llbracket \tau \rrbracket \}$ where $\llbracket \text{com} \rrbracket = \text{Cl}$, $\llbracket \text{int} \rrbracket = \mathbb{Z}$, $\llbracket \text{bool} \rrbracket = \mathbb{B}$
$\llbracket \neg P \rrbracket \eta$	= $\{ \sigma \mid \sigma \notin \llbracket P \rrbracket \eta \}$
$\llbracket e_1 \leq_\tau e_2 \rrbracket \eta$	= $\{ \sigma \mid \llbracket e_1 \rrbracket^e \eta \sigma \in \llbracket \tau \rrbracket \wedge \llbracket e_2 \rrbracket^e \eta \sigma \in \llbracket \tau \rrbracket \wedge \llbracket e_1 \rrbracket^e \eta \sigma \sqsubseteq \llbracket e_2 \rrbracket^e \eta \sigma \}$

Syntax The syntax of assertions is presented in Table 3. They may contain expressions of \mathcal{L} which have no side effects. Note that $e = e$ and $\phi \vee \phi$ can be expressed using \leq , and \wedge and \neg , respectively.

As already known from classic Hoare-calculus one needs “ghost variables” (also called *auxiliary variables*) to be able to refer to values in the pre-execution state. For example, in the Hoare-triple $\{x = n\} \text{fac} \{x = n!\}$ we have a program variable x , and an auxiliary variable n . The countable set of auxiliary ghost variables is called **AuxVar**. Throughout the paper we use x, y, z to denote instances of program variables in **Var** and n, p, q to denote instances of auxiliary variables in **AuxVar** where n is usually used for auxiliary variables of basic type and p and q for auxiliary variables for commands (procedures). It is important not to confuse those different types of variables.

Semantics The denotational semantics of assertions is standard but we have to take care of auxiliary variables. For those variables an additional environment is in use of type $\text{Env} = \text{Val}^{\text{AuxVar}}$. Correspondingly, an interpretation function for assertions must have type $\llbracket _ \rrbracket : \text{Asrt} \rightarrow \text{Env} \rightarrow \mathcal{P}(\text{St})$ and its equations can be found in Table 4.

Observe that $\llbracket _ \rrbracket^e$ has to be extended to auxiliary variables. Therefore, we stipulate $\llbracket n \rrbracket^e \eta \sigma = \eta(n)$ and assume that the definitional equations for $\llbracket _ \rrbracket^e$ in Table 2 have been changed accordingly.

Table 5. Syntax of pure assertions without undesired comparisons of commands

$$\begin{aligned} \phi, \in \mathbf{BASrt} & ::= \text{false} \mid \phi \wedge \phi \mid \neg\phi \mid \forall n. \phi \mid \tau?e \mid e \leq_{\text{nat}} e \mid e \leq_{\text{bool}} e \\ P \in \mathbf{DCIASrt} & ::= \phi \mid \forall n. P \mid x \leq_{\text{com}} n \mid x \leq_{\text{com}} 's' \mid 's' \leq_{\text{com}} 's' \mid P \wedge P \mid P \vee P \end{aligned}$$

A particular subset of downward-closed assertions Equality between procedures (\leq_{com}) is problematic as it is not a downward-closed predicate which will be important for our semantics. We therefore identify a particular sublanguage of assertions, $\mathbf{DCIASrt}$, which are more restrictive with respect to comparisons of commands, in particular they do not admit equality on procedures. To define $\mathbf{DCIASrt}$, we introduce “basic assertions” \mathbf{BASrt} first, which do not use any comparison between expressions of type com at all. The exact definitions can be found in Table 5.

Assertions like $x =_{\text{com}} 's'$, i.e. $x \leq_{\text{com}} 's' \wedge 's' \leq_{\text{com}} x$, are not in $\mathbf{DCIASrt}$ as $'s' \leq_{\text{com}} x$ is *not* in $\mathbf{DCIASrt}$. The assertions in $\mathbf{DCIASrt}$ all satisfy three conditions explained in Lemma 1 below. These properties will turn out to be crucial to obtain a semantics that validates the proof rules introduced in the next section.

Lemma 1. *For any assertion $P \in \mathbf{DCIASrt}$ its semantics $\langle\!\langle P \rangle\!\rangle \in \text{Env} \rightarrow \mathcal{P}(\text{St})$ has the following properties:*

1. $\langle\!\langle P \rangle\!\rangle \eta$ is a downward closed predicate for all $\eta \in \text{Env}$.
2. $\langle\!\langle P \rangle\!\rangle$ is monotonic in its (procedure environment) argument.
3. $\langle\!\langle P \rangle\!\rangle \eta \sigma$ implies $\langle\!\langle P \rangle\!\rangle \hat{e}(\eta) \hat{e}(\sigma)$ for all $e \in \text{Cl} \rightarrow \text{Cl}$, $\sigma \in \text{St}$, and $\eta \in \text{Env}$ where $\hat{e}(\eta)$ is defined analogously to $\hat{e}(\sigma)$ with the only difference that the variables used in Env are AuxVar whereas those used in St are Var .

Proof. We only have to consider assertions on commands. Assertions on basic types trivially fulfill the requirements since \mathbf{BVal} is ordered discretely. Since \forall , \wedge , and \vee preserve the conditions above we only need to show each of them for the three comparisons on commands (and the type check assertion $\text{com}?e$ which trivially fulfills all conditions). (1) and (2) are immediate by definition of the assertions. For (3) we show the interesting case: $\llbracket x \leq_{\text{com}} n \rrbracket \eta \sigma$ iff $\sigma(x) \sqsubseteq \eta(n)$ (\dagger). Now $\llbracket x \leq_{\text{com}} n \rrbracket \hat{e}(\eta) \hat{e}(\sigma)$ iff $\hat{e}(\sigma)(x) = e(\sigma(x)) \sqsubseteq \hat{e}(\eta)(n) = e(\eta(n))$ which follows from (\dagger) as e is monotonic.

4 Proof Rules

First of all, the standard rules for assignment (A), composition (S), conditional (I), weakening (W), and no operation (ϵ) are in use as presented in Fig. 1.

New rules are needed to deal with stored procedures as outlined in Fig. 2. The run-rule (R) is canonical for non-recursive procedure calls. Rule (H) is like (R) for cases where the code in a variables is not known but described by an auxiliary variable. Finally, the recursion rule (μ) is used for stored procedures that are (mutually) recursive. This is necessary as rule (R) is not able to get rid of the

$$\begin{array}{c}
 (A) \frac{}{\{P[e/x]\} x := e \{P\}} \quad (S) \frac{\{P\} C_1 \{R\} \quad \{R\} C_2 \{Q\}}{\{P\} C_1; C_2 \{Q\}} \\
 (I) \frac{\{b \wedge P\} C_1 \{Q\} \quad \{\neg b \wedge P\} C_2 \{Q\}}{\{P\} \text{if } b \text{ then } C_1 \text{ else } C_2 \{Q\}} \quad (W) \frac{P \Rightarrow P' \quad \{P'\} C \{Q'\} \quad Q' \Rightarrow Q}{\{P\} C \{Q\}} \\
 (\epsilon) \frac{}{\{P\} \text{nop} \{P\}}
 \end{array}$$

Fig. 1. Standard Rules

$$\begin{array}{c}
 (R) \frac{\{P \wedge x \leq 'C'\} C \{Q\}}{\{P \wedge x \leq 'C'\} \text{run } x \{Q\}} \quad Q \in \text{DCIAsr} \\
 (H) \frac{}{\{P \wedge x \leq p\} p \{Q\} \vdash \{P \wedge x \leq p\} \text{run } x \{Q\}} \quad Q \in \text{DCIAsr} \\
 (\mu) \frac{\bigwedge_{1 \leq i \leq n} \{P_1\} p_1 \{Q_1\} \dots \{P_n\} p_n \{Q_n\} \vdash \{P_i\} C_i \{Q_i\}}{\bigwedge_{1 \leq i \leq n} \{P_i[C/p]\} C_i \{Q_i[C/p]\}} \quad \forall 1 \leq i \leq n. P_i, Q_i \in \text{DCIAsr}
 \end{array}$$

Fig. 2. New Rules for Stored Procedures

circular reference to the procedure. Rule (μ) is able to do just that analogously to the standard procedure rule (*proc*) mentioned in the introduction. In fact, by using first (R) and then (μ) , one obtains the derived rule stated below (left). For comparison the standard recursive procedure rule is repeated next to it (right).

$$\frac{\{P \wedge x \leq p\} p \{Q\} \vdash \{P \wedge x \leq p\} C \{Q\}}{\{P \wedge x \leq 'C'\} \text{run } x \{Q\}} \quad (\text{proc}) \frac{\text{rec } p \Leftarrow C[p] \quad \{P\} p \{Q\} \vdash \{P\} C \{Q\}}{\{P\} p \{Q\}}$$

Whereas for (*proc*) the definition of the procedure p is separate, for stored procedure x one needs to use an auxiliary variable p to denote the content of x during execution of its body which may change x .

Note that throughout the rest of the paper we simply write \leq instead of \leq_{com} when one of its arguments is obviously of type *com*. The necessity of the side conditions for (μ) , (R) , and (H) will become clear when we discuss the soundness of these rules.

5 Sample Derivations

We present some sample derivations to demonstrate how the proof rules above are to be used.

Example 1. A derivation for a specification of our introductory example of a non-terminating loop, $\{\text{true}\} x := \text{'run } x\text{'}; \text{run } x \{\text{false}\}$, is outlined in Figure 3.

Example 2. Because of recursion through the store we can simulate a while loop $\text{while } B \text{ do } C \text{ od}$ as $z := \text{'if } B \text{ then } C\text{'}; \text{run } z \text{ else nop'}$; $\text{run } z$. Of course, program

$$\begin{array}{c}
\frac{}{\{\text{'run } x' \sqsubseteq \text{'run } x'\} x := \text{'run } x' \{x \sqsubseteq \text{'run } x'\}} \quad (A) \qquad \frac{}{\{x \sqsubseteq q\} q \{false\} \vdash \{x \sqsubseteq q\} \text{run } x \{false\}} \quad (H) \\
\frac{}{\{true\} x := \text{'run } x' \{x \sqsubseteq \text{'run } x'\}} \quad (W) \qquad \frac{}{\{x \sqsubseteq \text{'run } x'\} \text{run } x \{false\}} \quad (\mu) \\
\hline
\{true\} x := \text{'run } x'; \text{run } x \{false\} \quad (S)
\end{array}$$

Fig. 3. Derivation for Example 1

variable z is not supposed to occur in C . When doing the proof it becomes clear that it is enough that z is not altered by C . The standard rule for while and its derived equivalent for the encoding in \mathcal{L} read as follows:

$$\frac{\{B \wedge I\} C \{I\}}{\{I\} \text{while } B \text{ do } C \text{ od } \{\neg B \wedge I\}} \qquad \frac{\{B \wedge I \wedge z \leq p\} C \{I \wedge z \leq p\}}{\{I\} \text{while } B \text{ do } C \text{ od } \{\neg B \wedge I\}}$$

The encoded form has to state that z is invariant, i.e. that the content of this cell is not changed by the body of the while statement. This is expressed using an auxiliary variable $p \in \text{AuxVar}$.

For the proof assume that $(*) \{B \wedge I \wedge z \leq p\} C \{I \wedge z \leq p\}$ and let IF abbreviate the expression (of command type) ‘if B then C ; run z else nop’. The first part of the derivation is straightforward (see Fig. 4). The remaining open goal $\{I \wedge z \leq IF\} \text{run } z \{\neg B \wedge I\}$ is then derived in (β) in the second proof tree of Fig. 4. The application of the recursion rule (μ) will introduce the hypothesis $(\dagger) \{I \wedge z \leq p\} p \{\neg B \wedge I\}$ to be used at the top of subtree (β) .

$$\begin{array}{c}
\frac{}{\{I \wedge IF \leq IF\} z := IF \{I \wedge z \leq IF\}} \quad (A) \\
\frac{}{\{I\} z := IF \{I \wedge z \leq IF\}} \quad (W) \qquad \frac{}{\{I \wedge z \leq IF\} \text{run } z \{\neg B \wedge I\}} \quad (R) \\
\hline
\{I\} z := IF; \text{run } z \{\neg B \wedge I\} \quad (S)
\end{array}$$

where (β) is the following proof tree

$$\begin{array}{c}
\frac{}{\{I \wedge z \leq p\} p \{\neg B \wedge I\}} \quad (\dagger) \\
\frac{}{\{B \wedge I \wedge z \leq p\} C \{I \wedge z \leq p\}} \quad (*) \qquad \frac{}{\{I \wedge z \leq p\} \text{run } z \{\neg B \wedge I\}} \quad (H) \qquad \frac{}{\{\neg B \wedge I\} \text{nop } \{\neg B \wedge I\}} \quad (N) \\
\frac{}{\{B \wedge I \wedge z \leq p\} C; \text{run } z \{\neg B \wedge I\}} \quad (S) \qquad \frac{}{\{\neg B \wedge I \wedge z \leq p\} \text{nop } \{\neg B \wedge I\}} \quad (W) \\
\hline
\{I \wedge z \leq p\} \text{if } B \text{ then } C; \text{run } z \text{ else nop } \{\neg B \wedge I\} \quad (\mu) \\
\frac{}{\{I \wedge z \leq IF\} \text{ite } BC; \text{run } z \text{nop } \{\neg B \wedge I\}} \quad (\mu) \\
\hline
\{I \wedge z \leq IF\} \text{run } z \{\neg B \wedge I\} \quad (R)
\end{array}$$

Fig. 4. Derivation for Example 2

Table 6. Semantics of Triples

$(\eta, \sigma) \models \{P\} C \{Q\}$	$\Leftrightarrow \forall \sigma' \in \text{St}. (P) \eta \sigma \wedge \llbracket C \rrbracket \sigma = \sigma' \Rightarrow (Q) \eta \sigma'$
$(\eta, \sigma) \models \{P\} p \{Q\}$	$\Leftrightarrow \forall \sigma' \in \text{St}. (P) \eta \sigma \wedge \eta(p)(\sigma) = \sigma' \Rightarrow (Q) \eta \sigma'$
$\models \{P_1\} p_1 \{Q_1\}, \dots, \{P_n\} p_n \{Q_n\}$	$\Leftrightarrow \forall \eta \in \text{Env}. (\forall \sigma \in \text{St}. \bigwedge_{1 \leq i \leq n} (\eta, \sigma) \models \{P_i\} p_i \{Q_i\})$
$\vdash \{P\} C \{Q\}$	$\Rightarrow \forall \sigma \in \text{St}. (\eta, \sigma) \models \{P\} C \{Q\}$

Example 3. This example shows how procedures can modify themselves so that different invocations of x behave differently. Let

$$S \equiv \text{'if } z=0 \text{ then nop else } (y := y + z; z := z - 1; \text{run } x)\text{'}$$

and consider the program $x := \text{'}y := y + 1; x := S\text{'}; \text{run } x; \text{run } x$ for which we can derive the following annotations:

$$\begin{array}{ll}
 \{y = n \wedge z = m\} & \\
 x := \text{'}y := y + 1; x := S\text{'} & \text{(A),(W)} \\
 \{y = n \wedge z = m \wedge x \leq \text{'}y := y + 1; x := S\text{'}\} & \\
 \text{run } x & \text{(R),(A),(S),(W)} \\
 \{y = n + 1 \wedge z = m \wedge x \leq S\} & \\
 \text{run } x & \text{(R),(\mu),(I),(S),(A),(W),(\epsilon)} \\
 \{y = n + 1 + \sum_1^m i \wedge z = 0 \wedge x \leq S\} &
 \end{array}$$

6 Soundness

Pre-condition P and post-condition Q of Hoare triples do not only depend on the store but also on the values for the auxiliary variables in environment Env . We write $(\eta, \sigma) \models \{P\} C \{Q\}$ meaning that $\{P\} C \{Q\}$ is valid in σ and η .

Definition 1. *The semantics of Hoare triples for commands, for closure variables, and for commands in context, resp., is given in Table 6. Note that triples express partial correctness.*

Now we are in a position to formally prove the soundness of the new rules.²

Theorem 1. *The (run-)rules (R) and (H) are sound.*

Proof. Let C be a command. Assume that (1) $\models \{P \wedge x \leq \text{'}C\text{'}\} C \{Q\}$. We have to show $\models \{P \wedge x \leq \text{'}C\text{'}\} \text{run } x \{Q\}$. Therefore, assume that $\eta \in \text{Env}$, and $\sigma \in \text{St}$ such that (2) $(P \wedge x \leq \text{'}C\text{'}) \eta \sigma$ and that (3) $\llbracket \text{run } x \rrbracket \sigma = \sigma'$. It remains to show that $(Q) \eta \sigma'$. Define (4) $\sigma'' := \llbracket C \rrbracket \sigma$. From (1), (2) and (4) we obtain $(Q) \eta \sigma''$. Since (Q) is downward-closed by Lemma 1(2) and $Q \in \text{DCIAsrt}$, it suffices to prove that $\sigma' \sqsubseteq \sigma''$. But

$$\sigma' =_{(3)} \llbracket \text{run } x \rrbracket \sigma = \sigma(x)(\sigma) \sqsubseteq_{(2)} \llbracket C \rrbracket \sigma =_{(4)} \sigma'' \quad .$$

² Soundness of the old rules is standard.

The proof for (H) is carried out analogously.

In the next proof we will make use of a binary operation $+ : \text{Env} \times \text{Cl}^A \rightarrow \text{Env}$ that represents “overwriting of environments” where $A \subseteq \text{AuxVar}$. Accordingly, $(\eta + \delta)(n) = \eta(n)$ if $n \in A$ and $\delta(n)$ otherwise.

Theorem 2. *The rule (μ) is correct.*

Proof. Let $\llbracket P_i \rrbracket, \llbracket Q_i \rrbracket \subseteq \text{Env} \times \text{St}$ for $1 \leq i \leq n$ be the denotations of the predicates in the assertions of (μ) . We basically follow the ideas of [16] where similar arguments were used to prove the correctness of the object introduction rule of [2]. For arbitrary $\eta \in \text{Env}$ let $A_\eta \subseteq \text{Cl}^{\{p_1, \dots, p_n\}} \times \text{Cl}^{\{p_1, \dots, p_n\}}$ be defined as follows:

$$A_\eta(\psi, \phi) \equiv \forall 1 \leq j \leq n. \forall \sigma \in \text{St}. \\ \llbracket P_j \rrbracket(\eta + \psi) \sigma \wedge \phi(p_j)(\sigma) \downarrow \Rightarrow \llbracket Q_j \rrbracket(\eta + \psi) (\phi(p_j)(\sigma))$$

Let $p_i \mapsto \llbracket C_i \rrbracket$ be the environment in $\text{Cl}^{\{p_1, \dots, p_n\}}$ that assigns $\llbracket C_i \rrbracket$ to p_i for $1 \leq i \leq n$. Then verifying rule (μ) amounts to showing that for arbitrary $\eta \in \text{Env}$:

$$(\dagger) \quad \forall \phi \in \text{Cl}^{\{p_1, \dots, p_n\}}. A_\eta(\phi, \phi) \Rightarrow A_\eta(\phi, p_i \mapsto \llbracket C_i \rrbracket) \\ \text{implies} \\ A_\eta(p_i \mapsto \llbracket C_i \rrbracket, p_i \mapsto \llbracket C_i \rrbracket)$$

since in general $\forall \phi \in \text{Env}. R \phi$ is equivalent to $\forall \phi \in \text{Env}. \forall \psi \in \text{Cl}^{\{p_1, \dots, p_n\}}. R(\phi + \psi)$. Let S be a predicate on $\text{Cl}^{\{p_1, \dots, p_n\}}$ such that for all $\phi \in \text{Cl}^{\{p_1, \dots, p_n\}}$

$$(1) \quad S(\phi) \iff \forall \psi \in \text{Cl}^{\{p_1, \dots, p_n\}}. S(\psi) \Rightarrow A_\eta(\psi, \phi)$$

from which it follows that for any ϕ

$$(2) \quad S(\phi) \Rightarrow A_\eta(\phi, \phi).$$

Now from (2) and assumption (\dagger) it follows that

$$(3) \quad S(\phi) \Rightarrow A_\eta(\phi, p_i \mapsto \llbracket C_i \rrbracket)$$

i.e. $S(p_i \mapsto \llbracket C_i \rrbracket)$ due to (1) as ϕ was arbitrary such that by (1) again we obtain $A_\eta(p_i \mapsto \llbracket C_i \rrbracket, p_i \mapsto \llbracket C_i \rrbracket)$ as desired. The existence of an appropriate S in (1) is shown in Lemma 2.

Lemma 2. *There is a $S \subseteq \text{Env}$ such that $S(\phi) \iff \forall \rho \in \text{Env}. S(\rho) \Rightarrow A_\eta(\rho, \phi)$ for any $\eta \in \text{Env}$.*

Proof. Let \mathcal{L} denote the admissible subsets of $\text{Cl}^{\{p_1, \dots, p_n\}}$ ordered by \subseteq and

$$\Phi : \mathcal{L}^{\text{op}} \rightarrow \mathcal{L} : S \mapsto \{ \phi \in \text{Cl}^{\{p_1, \dots, p_n\}} \mid \forall \rho \in \text{Cl}^{\{p_1, \dots, p_n\}}. S(\rho) \Rightarrow A_\eta(\rho, \phi) \}$$

for which it is necessary that $A_\eta(\rho, -)$ specifies an admissible subset of $\text{Cl}^{\{p_1, \dots, p_n\}}$ for all $\rho \in \text{Cl}^{\{p_1, \dots, p_n\}}$ which follows from Lemma 1(1). For guaranteeing existence (and uniqueness) of such an S by Pitts’ Theorem [13] we have to show that $e : S_1 \subseteq S_2$ implies $F(e, e) : \Phi(S_2) \subseteq \Phi(S_1)$ for all (idempotent) $e \sqsubseteq \text{id}_{\text{Cl}}$ where for $X, Y \subseteq \text{Cl}^{\{p_1, \dots, p_n\}}$ one defines $e : X \subseteq Y$ iff $\forall x \in X. \hat{e}(x) \Rightarrow \hat{e}(x) \in Y$. Suppose $e \sqsubseteq \text{id}_{\text{Cl}}$ with $e : S_1 \subseteq S_2$ and $\Phi(S_2)(\phi)$. We have to show $\Phi(S_1)(\widehat{F(e, e)}(\phi))$. For this to be possible we need that $\llbracket P_j \rrbracket$ and $\llbracket Q_j \rrbracket$ satisfy all three properties of Lemma 1.

7 Loose Ends and Related Work

Our programming language \mathcal{L} contains only constant command expressions. Self-modifying programs would also modify commands, in other words, use operations on commands.

Consider, for example, an operation `make_com` that concatenates two commands returning a new one, such that modifications like $x := \text{make_com}(x, y)$ become possible. To allow for such expressions one needs to axiomatise `make_com` algebraically, i.e. the underlying first-order logic on data types needs to be enriched by axioms like $\text{make_com}('s_1', 's_2') = 's_1; s_2'$ and a monotonicity axiom for `make_com` w.r.t. \leq_{com} .

Procedures with parameters have not been discussed here but are certainly an issue. We expect, however, that they are not more difficult to cope with than in ordinary Hoare-calculus with recursive procedures. In particular, if parameters are passed by value.

The logic presented is not modular as all code must be known in advance and must be carried around in assertions. In [5], a calculus for objects was suggested that uses nested Hoare triples in order to state properties of programs in the store rather than referring to their explicit code without a hint on a denotational semantics nor a soundness proof. The meaning of such a “specification” triple in our setting would be a recursively defined predicate:

$$\begin{aligned} (\sigma, \eta) \models \{P\}x\{Q\} &\Leftrightarrow \forall \sigma', \sigma'' \in \text{St}. \\ &(\sigma', \eta) \models \{P\}x\{Q\} \wedge (\{P\}\sigma' \wedge \sigma(x)(\sigma') = \sigma'' \Rightarrow (\{Q\}\sigma'') \end{aligned}$$

Unfortunately, such a recursively defined semantics of triples, \models , does not allow for a separate specification for mutual recursive procedures (there is no “Bekic Lemma”). This suggests that it is highly unlikely that there is a modular logic for \mathcal{L} . On the other hand, in [2, 15] it has been shown that modularity can be achieved for Abadi and Leino’s object logic in a setting where assignments to procedure variables are disallowed. It is unclear yet, to which extent this restriction can be relaxed. In [17] we have discussed an idea for a relaxation but it will have to be tested on a fully-fledged soundness proof where frame properties are to be shown.

Alternative models for higher-order store have been suggested by [3, 10, 11] using games or locally boolean domains. It might be worthwhile to consider the domain equation for `Cl` within such locally boolean domains (or equivalently the category of sequential algorithms). This would already provide us with a fully abstract model for higher-order store in the sense of Idealized Algol.

Another open question is relative completeness of our logic. It is no problem to express weakest liberal preconditions, at least when extending the assertion language such that it can express arbitrary inductively defined predicates. The hard problem is to show, by induction on S , that $\{\text{wlp}(C, P)\}C\{P\}$ is derivable for all post-conditions P .

The results of this paper, however, are the first step to get a grip on higher-order store from a programming logic point of view.

Abstract. Although every terminating loop has a ranking function, not every loop has a ranking function of a restricted form, such as a lexicographic tuple of polynomials over program variables. The *polyranking principle* is proposed as a generalization of polynomial ranking for analyzing termination of loops. We define *lexicographic polyranking functions* in the context of loops with parallel transitions consisting of polynomial assertions, including inequalities, over primed and unprimed variables. Next, we address *synthesis* of these functions with a complete and automatic method for synthesizing *lexicographic linear polyranking functions* with supporting linear invariants over linear loops.

1 Introduction

Guaranteed termination of program loops is necessary in many settings, such as embedded systems and safety critical software. Additionally, proving general temporal properties of infinite state programs requires termination proofs, for which automatic methods are welcome [13, 9, 11]. We propose a termination analysis based on lexicographic polynomial *polyranking* functions, which subsume lexicographic polynomial *ranking* functions.

Although every terminating loop has a ranking function, not every terminating loop has a ranking function of a restricted form, such as a lexicographic tuple of polynomials over program variables. In [2], we present a method for identifying bounded expressions that are eventually negative over loops with parallel transitions expressed as simultaneous assignments of polynomial expressions to variables. For showing termination, a function that *eventually* ranks is as good as a function that always ranks. That transitions are only assignments allows an efficient analysis based on *finite difference expressions* with respect to transitions. In this paper, we generalize our approach to loops with assertional transition relations, rather than just assignments. Including assertional transition relations in a loop abstraction language makes it more widely applicable for

modeling infinite state systems. The main idea for analyzing these loops is to identify eventually decreasing expressions that upper bound differences.

In [1], we show how to synthesize lexicographic linear ranking functions with supporting linear invariants over loops with linear assertional transition relations. We extend the machinery in this paper to synthesize lexicographic linear polyranking functions with supporting linear invariants over linear loops. This extension requires solving complex structural constraints induced by the recursive definition of polyranking functions. The synthesis method solves efficiently a combination of structural and numerical constraints. It searches a space of *partial* structures, solving induced constraint systems to guide the search. These partial structures represent sets of complete structures so that an infeasible induced constraint system excludes entire sets. For our application, the induced constraint systems are numerical. We believe that the general strategy is applicable to other problem domains.

Termination of loops has received a fair amount of attention recently. Synthesis of linear ranking functions over linear loops with multiple paths and assertional transition relations is accomplished via polyhedral manipulation in [4, 5]. In [10], Podelski and Rybalchenko specialize the technique to single-path linear loops without an initial condition, providing an efficient and complete synthesis method for linear ranking functions based on linear programming. We generalize these results in [1]. Cousot shows how polynomial ranking functions can be synthesized over nonlinear loops using nonlinear convex optimization [6]. Tiwari proves that the termination of a class of single-path loops with linear guards and assignments is decidable [14]. Related efforts on *verification diagrams* [9] and *transition invariants* [11] (see also [7, 8, 3]) use automatic termination analysis. These frameworks either abstract the state-space or the transition relation to isolate a finite number of different forms of infinite behavior. Termination analysis can then find the reason for termination of each isolated behavior.

The rest of the paper is organized as follows. Section 2 introduces our loop abstraction and basic concepts. Section 3 describes the polyranking principle. Sections 4 and 5 describe our synthesis technique. Section 6 concludes.

2 Preliminaries

We define our abstraction of loops, present several basic concepts, and recall Farkas's Lemma, a mathematical result that we employ in synthesis.

Definition 1 (Polynomial Assertion). A *real variable* is a variable x that ranges over the reals, \mathbb{R} . A *polynomial term* has the form $c \prod_i x_i^{d_i}$ for constant $c \in \mathbb{R}$, real variables x_i , and degrees $d_i \in \mathbb{N}$ ranging over the nonnegative integers. A *polynomial expression* P is the sum of polynomial terms. A *polynomial atom* is the comparison $P_1 \bowtie P_2$ of two polynomial expressions, for $\bowtie \in \{<, \leq, =, \geq, >\}$. A *polynomial assertion* is the conjunction of polynomial atoms.

Definition 2 (Polynomial Loop). A *polynomial loop* $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ consists of variables \mathcal{V} , *initial condition* θ , and set of *transitions* \mathcal{T} . $\theta(\mathcal{V})$ is a polynomial

assertion over \mathcal{V} expressing what is true before entering the loop. A transition $\tau(\mathcal{V}, \mathcal{V}')$ over variables $\mathcal{V} \cup \mathcal{V}'$ is a polynomial assertion over unprimed and primed variables, where a primed variable x' represents the next-state value of x .

Definition 3 (Linear Loop). A *linear loop* is a polynomial loop in which all assertions and expressions are affine.

When discussing affine expressions, assertions, and loops, we use the notation $\mathbf{c}^T \mathbf{x} \geq 0$ to mean a linear atom, where $\mathbf{x} = (x_1, x_2, \dots, x_m, 1)^T$ is a homogenized vector corresponding to the variables \mathcal{V} . A linear assertion is then $A\mathbf{x} \geq 0$, for homogenized matrix A . By $\tau(\mathbf{xx}') \geq 0$, we mean the linear assertion corresponding to τ 's transition relation, where (\mathbf{xx}') stands for the homogenized vector corresponding to $\mathcal{V} \cup \mathcal{V}'$: $(\mathbf{xx}') = (x_1, x_2, \dots, x_m, x'_1, x'_2, \dots, x'_m, 1)^T$.

Definition 4 (Loop Satisfaction). A loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ satisfies an assertion φ , written $L \models \varphi$, if φ holds in all reachable states of L .

Definition 5 (Infinitely Often). For infinite computation σ of loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$, $io(\sigma) \subseteq \mathcal{T}$ is the set of transitions that occur *infinitely often* in the computation.

Definition 6 (Lexicographic Polynomial Ranking Function). A *lexicographic polynomial ranking function* for a loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ is an n -tuple of polynomial expressions $\langle r_1(\mathcal{V}), \dots, r_n(\mathcal{V}) \rangle$ such that for some $\epsilon > 0$ and for each $\tau \in \mathcal{T}$, for some $i \in \{1, \dots, n\}$,

(Bounded) $L \models \tau(\mathcal{V}, \mathcal{V}') \rightarrow r_i(\mathcal{V}) \geq 0$,

(Ranking) $L \models \tau(\mathcal{V}, \mathcal{V}') \rightarrow r_i(\mathcal{V}') - r_i(\mathcal{V}) \leq -\epsilon$;

(Unaffected) for $j < i$, $L \models \tau(\mathcal{V}, \mathcal{V}') \rightarrow r_j(\mathcal{V}') - r_j(\mathcal{V}) \leq 0$.

If $n = 1$, then the result is simply a polynomial ranking function.

For some loops, invariants are necessary to show that a ranking function (and, more generally, a polyranking function) is bounded in the loop; we say such invariants are *supporting* invariants.

Definition 7 (Polynomial Inductive Invariant). A formula φ is an invariant of a loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ if it satisfies the following conditions:

(Initiation) $\theta(\mathcal{V}) \rightarrow \varphi(\mathcal{V})$, and

(Consecution) for every $\tau \in \mathcal{T}$, $\varphi(\mathcal{V}) \wedge \tau(\mathcal{V}, \mathcal{V}') \rightarrow \varphi(\mathcal{V}')$.

Example 1. Consider the loop SIMPLE in Figure 1. Initially, $x + y$ is nonnegative. Transitions τ_1 and τ_2 are both guarded by $x \leq N$. Termination is relatively straightforward: τ_2 at least increments x , while τ_1 increases x if $x + y > 0$ and always increases y . Discovering the invariant $x + y \geq 0$ shows that incrementing y makes $x + y > 0$. However, a linear ranking function over $\{x, y, N\}$ cannot prove termination, as, for example, τ_1 does not change x when $x = -y < 0$.

$$\begin{aligned} \theta &: \{x + y \geq 0\} \\ \tau_1 &: \{x \leq N\} \Rightarrow \{x' \geq 2x + y, y' \geq y + 1, N' = N\} \\ \tau_2 &: \{x \leq N\} \Rightarrow \{x' \geq x + 1, y' = y, N' = N\} \end{aligned}$$

Fig. 1. Program SIMPLE, written as a loop

$$\begin{aligned} \theta &: \{p \geq 0, q \geq 1, x = 0, y = 0\} \\ \tau_1 &: \{x + y \leq N\} \Rightarrow \left\{ \begin{array}{l} x + e - q \leq x' \leq x + e + q, \\ y + n - q \leq y' \leq y + n + q, \\ n + e + 1 \leq n' + e' \leq n + e + p, \\ p' = p, q' = q, N' = N \end{array} \right\} \\ \tau_2 &: \{x + y \leq N, n + e \geq 2q + 1\} \Rightarrow \left\{ \begin{array}{l} x + e - q \leq x' \leq x + e + q, \\ y + n - q \leq y' \leq y + n + q, \\ n' = n, e' = e, p' = p, q' = q, N' = N \end{array} \right\} \\ \tau_3 &: \{p \geq 0\} \Rightarrow \left\{ \begin{array}{l} n' + e' \leq -(n + e), \\ p' = p - 1, q' = \frac{1}{2}q, \\ x' = x, y' = y, N' = N \end{array} \right\} \end{aligned}$$

Fig. 2. Description of the erratic robot as the program ERRATIC

Example 2. Consider the program in Figure 2, written as a loop. It defines the behavior of an erratic robot on a partially-bounded plane. Its current position is given by (x, y) ; its tendency to move *north* is given by n (which may be negative), while its tendency to move *east* is given by e (which may also be negative). In τ_1 and τ_2 , the robot’s next position is determined by its current position and (e, n) , along with an error parameter q . In τ_1 , n and e change so that their new sum is at least one greater than previously, but in τ_2 , n and e remain constant. Finally, τ_3 adjusts parameters p and q and makes $n + e$ potentially negative (countering τ_1), but it does not change the robot’s position.

Does the robot’s program eventually halt? Intuitively, τ_3 may only be taken a finite number of times, while τ_1 and τ_2 eventually make $x + y$ only increase.

Finally, for synthesis, Farkas’s Lemma [12] will serve both as a device for generating constraint systems and as the foundation for completeness claims.

Theorem 1 (Farkas’s Lemma). Consider the following system of linear inequalities over real variables $\mathcal{V} = \{x_1, \dots, x_m\}$:

$$S : \begin{bmatrix} A_{1,1}x_1 + \dots + A_{1,m}x_m + A_{1,m+1} \geq 0 \\ \vdots \\ A_{n,1}x_1 + \dots + A_{n,m}x_m + A_{n,m+1} \geq 0 \end{bmatrix}$$

If S is satisfiable, it entails linear inequality $c_1x_1 + \dots + c_mx_m + c_{m+1} \geq 0$ iff there exist real numbers $\lambda_1, \dots, \lambda_n \geq 0$ such that

$$c_1 = \sum_{i=1}^n \lambda_i A_{i,1} \quad \dots \quad c_m = \sum_{i=1}^n \lambda_i A_{i,m} \quad c_{m+1} \geq \left(\sum_{i=1}^n \lambda_i A_{i,m+1} \right).$$

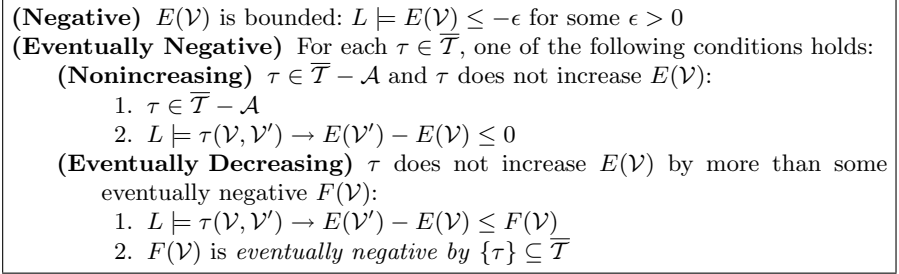

Fig. 3. $E(\mathcal{V})$ is eventually negative by $\mathcal{A} \subseteq \overline{\mathcal{T}}$ on loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$

Furthermore, S is unsatisfiable iff S entails $-1 \geq 0$.

3 The Polyranking Principle

The polyranking principle is based on the following recursive definition of what it means for an expression $E(\mathcal{V})$ to be *eventually negative*.

Definition 8 (Eventually Negative by $\mathcal{A} \subseteq \overline{\mathcal{T}}$). Given loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ over \mathcal{V} , an expression $E(\mathcal{V})$ is *eventually negative by $\mathcal{A} \subseteq \overline{\mathcal{T}} (\subseteq \mathcal{T})$* , for $\mathcal{A} \neq \emptyset$, if either case **Negative** or case **Eventually Negative** holds in Figure 3. For case **Eventually Negative** to hold, the recursion must have finite depth.

Intuitively, transitions in \mathcal{A} should make progress toward decreasing $E(\mathcal{V})$, while transitions in $\overline{\mathcal{T}}$ should not interfere counterproductively.

We represent an application of this definition as a tree of expressions, called an *EN-tree*. $E(\mathcal{V})$ is the root; the **Negative** case introduces the $-\epsilon$ expressions as leaves; the **Nonincreasing** case introduces 0-leaves; and the **Eventually Decreasing** case introduces $F(\mathcal{V})$ expressions as inner nodes. Branches are labeled by transitions.

Example 3. Figure 4 shows three examples of EN-trees. The tree in Figure 4(a) for SIMPLE represents the property that $N - x$ is eventually negative by $\{\tau_1, \tau_2\} \subseteq \{\tau_1, \tau_2\}$. The first difference of $N - x$ by τ_1 is at most $-x - y$, which is itself eventually negative. The supporting invariant $x + y \geq 0$ is required for proving that the first difference of $-x - y$ by τ_1 is at most -1 .

Lemma 1. *If for loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$, $E(\mathcal{V})$ is eventually negative by $\mathcal{A} \subseteq \overline{\mathcal{T}} (\subseteq \mathcal{T})$, then on any nonterminating computation of L , γ , such that $io(\gamma) \subseteq \overline{\mathcal{T}}$ and $io(\gamma) \cap \mathcal{A} \neq \emptyset$, eventually henceforth $E(\mathcal{V}) \leq -\epsilon$ for some $\epsilon > 0$.*

Proof. We proceed by induction on the structure of Definition 8 and the depth of the recursion, which we know is finite. As the base case, consider when **Negative** applies to $E(\mathcal{V})$; then the conclusion is immediate. For the inductive case,

Eventually Negative applies. Consider $\tau \in \mathcal{T}$. If $\tau \notin io(\gamma)$, then we can, without loss of generality, assume that τ is never taken in γ — just skip a finite prefix — so that τ has no effect on $E(\mathcal{V})$. Otherwise, $\tau \in io(\gamma)$. There are two cases. If $\tau \notin \mathcal{A}$ and **Nonincreasing** applies to τ , then τ does not increase $E(\mathcal{V})$. Otherwise, **Eventually Decreasing** applies to τ , so that τ increases $E(\mathcal{V})$ by at most $F(\mathcal{V})$, while $F(\mathcal{V})$ is eventually negative by $\{\tau\} \subseteq \overline{\mathcal{T}}$. Since $io(\gamma) \cap \{\tau\} \neq \emptyset$, we have by induction that eventually henceforth $F(\mathcal{V}) \leq -\epsilon$ for some $\epsilon > 0$. By assumption, there is at least one $\tau \in \mathcal{A} \cap io(\gamma)$. Once each of these τ 's $F(\mathcal{V})$ is henceforth negative, $E(\mathcal{V})$ is decreased by at least some $\epsilon > 0$ infinitely many times. Since no other transition can increase $E(\mathcal{V})$, eventually henceforth $E(\mathcal{V}) \leq -\epsilon$.

Example 4. SIMPLE always terminates because the expression $N - x$ is bounded from below by 0 in the loop and eventually negative, as shown in Figure 4(a).

Definition 9 (Lexicographic Polyranking Function). The ℓ -tuple of functions $\langle r_1(\mathcal{V}), r_2(\mathcal{V}), \dots, r_\ell(\mathcal{V}) \rangle$ is a *lexicographic polyranking function* of loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ if for some $\pi : \mathcal{T} \rightarrow \{1, \dots, \ell\}$,

(Bounded) for $\tau \in \mathcal{T}$, $L \models \tau(\mathcal{V}, \mathcal{V}') \rightarrow r_{\pi(\tau)}(\mathcal{V}) \geq 0$;

(Polyranking) $r_i(\mathcal{V})$ is *eventually negative* by $\{\tau : \pi(\tau) = i\} \subseteq \{\tau : \pi(\tau) \geq i\}$ for $i \in \{1, \dots, \ell\}$.

Theorem 2. *If loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ has a lexicographic polyranking function, then it always terminates.*

Proof. Suppose L does not always terminate, yet $\langle r_1(\mathcal{V}), r_2(\mathcal{V}), \dots, r_\ell(\mathcal{V}) \rangle$ with map $\pi : \mathcal{T} \rightarrow \{1, \dots, \ell\}$ is a lexicographic polyranking function for L . Let γ be an infinite computation, and let $i \in \{1, \dots, \ell\}$ be the lexicographic index such that $i = \min_{\tau \in io(\gamma)} \pi(\tau)$. By Definition 9, $r_i(\mathcal{V})$ is eventually negative by $\{\tau : \pi(\tau) = i\} \subseteq \{\tau : \pi(\tau) \geq i\}$. Moreover, by selection of i , $\{\tau : \pi(\tau) = i\} \cap io(\gamma) \neq \emptyset$; and by selection of i and Definition 9, $io(\gamma) \subseteq \{\tau : \pi(\tau) \geq i\}$. Then by Lemma 1, $r_i(\mathcal{V})$ eventually becomes negative and stays negative, disabling transitions in $\{\tau : \pi(\tau) = i\}$ and thus increasing i for the remaining computation. Repeating this argument at most ℓ times proves that all transitions are eventually disabled, a contradiction.

Fig. 4. EN-trees for (a) SIMPLE and (b) ERRATIC

$\mathbb{I} : \begin{array}{l} \Theta \mathbf{x} \geq \mathbf{0} \\ \mathbf{I} \mathbf{x} \geq \mathbf{0} \end{array}$	$\mathbb{D}_i : \begin{array}{l} \mathbf{I} \mathbf{x} \geq \mathbf{0} \\ \tau_i(\mathbf{x}\mathbf{x}') \geq \mathbf{0} \\ -1 \geq \mathbf{0} \end{array}$	$\mathbb{C}_i : \begin{array}{l} \mathbf{I} \mathbf{x} \geq \mathbf{0} \\ \tau_i(\mathbf{x}\mathbf{x}') \geq \mathbf{0} \\ \mathbf{I} \mathbf{x}' \geq \mathbf{0} \end{array}$
$\mathbb{B}_{ij} : \begin{array}{l} \mathbf{I} \mathbf{x} \geq \mathbf{0} \\ \tau_i(\mathbf{x}\mathbf{x}') \geq \mathbf{0} \\ \mathbf{c}_j^T \mathbf{x} \geq \mathbf{0} \end{array}$	$\mathbb{R}_{ij} : \begin{array}{l} \mathbf{I} \mathbf{x} \geq \mathbf{0} \\ \tau_i(\mathbf{x}\mathbf{x}') \geq \mathbf{0} \\ \mathbf{c}_j^T \mathbf{x} - \mathbf{c}_j^T \mathbf{x}' - \epsilon \geq \mathbf{0} \end{array}$	$\mathbb{U}_{ij} : \begin{array}{l} \mathbf{I} \mathbf{x} \geq \mathbf{0} \\ \tau_i(\mathbf{x}\mathbf{x}') \geq \mathbf{0} \\ \mathbf{c}_j^T \mathbf{x} - \mathbf{c}_j^T \mathbf{x}' \geq \mathbf{0} \end{array}$
$\mathbb{D}_{ijk}^* : \begin{array}{l} \mathbf{I} \mathbf{x} \geq \mathbf{0} \\ \tau_i(\mathbf{x}\mathbf{x}') \geq \mathbf{0} \\ \mathbf{c}_k^T \mathbf{x} + \mathbf{c}_j^T \mathbf{x} - \mathbf{c}_j^T \mathbf{x}' \geq \mathbf{0} \end{array}$		

Fig. 5. Farkas’s Lemma specializations

Example 5. ERRATIC has lexicographic linear polyranking function $\langle p, N - x - y \rangle$ where $\pi : \{\tau_1 \mapsto 2, \tau_2 \mapsto 2, \tau_3 \mapsto 1\}$. Clearly, $N - x - y$ is bounded from below by 0 by both τ_1 and τ_2 , while p is bounded from below by 0 by τ_3 . Figure 4(b) presents the EN-trees representing the proofs that $N - x - y$ is eventually negative by $\{\tau_1, \tau_2\} \subseteq \{\tau_1, \tau_2\}$ and p is eventually negative by $\{\tau_3\} \subseteq \{\tau_1, \tau_2, \tau_3\}$. No supporting invariants are required.

4 Constraint Generation

The remainder of this paper focuses on a complete method of synthesizing lexicographic linear polyranking functions with supporting linear invariants for linear loops. We adapt the machinery of [1] to this more general setting. The main idea is to invoke a set of Farkas’s Lemma *specializations* on a loop and a set of *template* ranking functions and invariants.

Definition 10 (Template Expression). A *template expression* over \mathcal{V} is a linear expression $\mathbf{c}^T \mathbf{x}$, with unknown coefficients \mathbf{c} . A *template assertion* is a linear assertion $\mathbf{C} \mathbf{x} \geq \mathbf{0}$ with matrix of unknown coefficients \mathbf{C} .

Farkas’s Lemma takes a system of linear assertions and templates and returns a *dual* numeric constraint system over the λ -multipliers and the unknown template coefficients. Given a loop $L : \langle \mathcal{V}, \theta, T \rangle$, the supporting invariant template $\mathbf{I} \mathbf{x} \geq \mathbf{0}$, and template expressions $\{\mathbf{c}_1^T \mathbf{x}, \dots, \mathbf{c}_n^T \mathbf{x}\}$, the following Farkas’s Lemma *specializations* are applied to encode the appropriate conditions.

Definition 11 (Farkas’s Lemma Specializations). See Figure 5.

- \mathbb{I} (*Initiation*): The supporting invariant includes the initial condition.
- \mathbb{D}_i (*Disabled*): Transition $\tau_i \in \mathcal{T}$ and the invariant may contradict each other, indicating “dead code.”
- \mathbb{C}_i (*Consecution*): For transition $\tau_i \in \mathcal{T}$, if the invariant holds and the transition is taken, then the invariant holds in the next state.

Fig. 6. (a) Template tree. (b) Generating tree constraints

- \mathbb{B}_{ij} (*Bounded*): For transition $\tau_i \in \mathcal{T}$ and template expression $\mathbf{c}_j^T \mathbf{x}$, the invariant and transition imply the nonnegativity of the expression.
- \mathbb{R}_{ij} (*Ranking*): For transition $\tau_i \in \mathcal{T}$ and template expression $\mathbf{c}_j^T \mathbf{x}$, taking the transition decreases the value of the expression by at least some positive amount ($\epsilon > 0$).
- \mathbb{U}_{ij} (*Unaffected*): For transition $\tau_i \in \mathcal{T}$ and template expression $\mathbf{c}_j^T \mathbf{x}$, taking the transition does not increase the value of the expression.
- \mathbb{D}_{ijk}^* (*Decreasing*): For transition $\tau_i \in \mathcal{T}$ and template expressions $\mathbf{c}_j^T \mathbf{x}$ and $\mathbf{c}_k^T \mathbf{x}$, the first difference of $\mathbf{c}_j^T \mathbf{x}$ over τ_i is upper bounded by $\mathbf{c}_k^T \mathbf{x}$.

All specializations except \mathbb{D}_{ijk}^* are used in [1] for synthesizing linear ranking functions, and thus explained in greater depth there. \mathbb{D}_{ijk}^* is the key specialization for polyranking function synthesis. It allows us to express the condition that the difference $\mathbf{c}_j \mathbf{x}' - \mathbf{c}_j \mathbf{x}$ is upper bounded by the expression $\mathbf{c}_k \mathbf{x}$, which in turn is constrained to be eventually negative.

Applying a set of specializations to a loop and a set of template expressions induces a numeric constraint system. However, we must define how to apply the specializations. For now, we assume that we are given a tuple of *template trees* and a map π mapping transitions to tuple components. The i^{th} template gives the form of an EN-tree for the property that the root expression is eventually negative by $\{\tau : \pi(\tau) = i\} \subseteq \{\tau' : \pi(\tau') \geq i\}$.

Definition 12 (Template Tree). A *template tree* for loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ and $\mathcal{A} \subseteq \overline{\mathcal{T}}$ gives the form of an EN-tree for the property that the root expression is eventually negative by $\mathcal{A} \subseteq \overline{\mathcal{T}}$. The root node and inner nodes are **Decreasing** nodes (corresponding to the root expression and **Eventually Decreasing** case of Definition 8, respectively) labeled with template expressions, while leaves are **Ranking** nodes (the **Negative** case) or **Unaffected** nodes (the **Nonincreasing** case). Non-root nodes are also labeled with some $\tau \in \overline{\mathcal{T}}$. Each inner node has $|\overline{\mathcal{T}}|$ children.

Definition 8 indicates when a leaf node must be **Ranking** $^\tau$ or **Unaffected** $^\tau$. Specifically, if the node is a child of the root and $\tau \in \mathcal{A}$, or if its parent is a node labeled by τ , then the node is **Ranking** $^\tau$; otherwise, it is **Unaffected** $^\tau$.

Example 6. The template tree for $\{\tau_1, \tau_2\} \subseteq \{\tau_1, \tau_2\}$ of SIMPLE in Figure 6(a) includes the EN-tree in Figure 4(a).

Definition 13 (Tree Constraints). Given a loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ and a template tree for $\mathcal{A} \subseteq \overline{\mathcal{T}}$, the *tree constraints* are generated by applications of the Farkas’s Lemma specializations as follows:

$$\begin{aligned}
 &\text{Parent is } \mathbf{Decreasing}_{\mathbf{c}_j}^* \text{ and node is } \dots \\
 &\dots \mathbf{Ranking}^{\tau_i} \Rightarrow \mathbb{D}_i \vee \mathbb{R}_{ij} \\
 &\dots \mathbf{Unaffected}^{\tau_i} \Rightarrow \mathbb{D}_i \vee \mathbb{U}_{ij} \\
 &\dots \mathbf{Decreasing}_{\mathbf{c}_k}^{\tau_i} \Rightarrow \mathbb{D}_i \vee \mathbb{D}_{ijk}^* \\
 &\text{Node is } \textit{root} \text{ and } \mathbf{Decreasing}_{\mathbf{c}_j} \Rightarrow \mathbb{D}_i \vee \mathbb{B}_{ij} \text{ for each } \tau_i \in \mathcal{A}
 \end{aligned}$$

Example 7. The tree constraints of the template tree in Figure 6(a) are generated as in Figure 6(b). The *disabled* cases are often ignored in practice, so the template tree induces numerical constraints corresponding to $\mathbb{B}_{1,1} \wedge \mathbb{B}_{2,1} \wedge \mathbb{D}_{1,1,2}^* \wedge \mathbb{R}_{1,2} \wedge \mathbb{U}_{2,2} \wedge \mathbb{R}_{2,1}$.

We use template trees and tree constraints to formalize the synthesis of lexicographic linear polyranking functions. This theorem mimics Definition 9 in the context of synthesis.

Theorem 3. Loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$ has an ℓ -lexicographic linear polyranking function supported by an n -conjunct linear inductive invariant iff there exists a mapping $\pi : \mathcal{T} \rightarrow \{1, \dots, |\mathcal{T}|\}$ and an ℓ -tuple of template trees $\langle T_1, T_2, \dots, T_\ell \rangle$ such that (1) the i^{th} template tree is for $\{\tau : \pi(\tau) = i\} \subseteq \{\tau' : \pi(\tau') \geq i\}$, and (2) the ℓ numeric constraint systems induced by

$$\mathbb{I} \wedge \bigwedge_{\tau_i \in \mathcal{T}} (\mathbb{D}_i \vee \mathbb{C}_i) \wedge \textit{tree_constraints}(T_j) \text{ for } j \in \{1, \dots, \ell\}$$

are satisfiable.

5 Synthesis

Theorem 3 applies to a given tuple of template trees. But in practice, we must find this tuple of templates. This section addresses this issue with an effective search, which seeks a tuple of trees such that the root expressions form a lexicographic linear polyranking function for a loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$. Three different forms of constraints are handled by the full algorithm. The *lexicographic constraints* induce the transition sets \mathcal{A} and $\overline{\mathcal{T}}$ for each component tree. These transition sets plus the *well-formedness constraints* from the definition of EN-trees induce a *numeric constraint system* via the tree constraints. Only when the two sets of structural constraints and the induced numeric constraints are satisfied is a solution found.

The first algorithm searches for EN-trees. Its input is a loop; an n -conjunct invariant template; the two sets of transitions, \mathcal{A} and $\overline{\mathcal{T}}$; and a maximum tree height. It returns whether an EN-tree exists of at most the maximum height, possibly supported by an n -conjunct invariant. Its search strategy consists of

```

let exists_tree  $\mathcal{A} \overline{\mathcal{T}}$  =
  let initial_tree =
    Decreasingc1 ( {ShouldRank $\tau$  :  $\tau \in \mathcal{A}$ }  $\cup$ 
                     {ShouldUnaffect $\tau$  :  $\tau \in \overline{\mathcal{T}} - \mathcal{A}$ } )
  in
  let sat en = num_sat (inv_cts  $\wedge$  (tree_cts en)) in
  let next_tree en extend = ... in
  let rec search en =
    height en  $\leq$  max_height
  and sat en
  and ( complete (en)
        or search (next_tree en false)
        or search (next_tree en true) )
  in
  search initial_tree

```

Fig. 7. ($exists_tree \mathcal{A} \overline{\mathcal{T}}$) searches for an EN-tree proving that there is a bounded expression $E(\mathbf{x})$ that is eventually negative by $\mathcal{A} \subseteq \overline{\mathcal{T}}$

incrementally building partial template trees. A partial template tree induces a numeric constraint system that is satisfiable if some completion of the tree induces a satisfiable constraint system. Thus, solving partial constraint systems guides the search. If a complete template tree is found that induces a satisfiable constraint system, the algorithm reports success.

Partial template trees are represented as in Section 4, except that two additional nodes are introduced. **ShouldRank** and **ShouldUnaffect** nodes are directions for making a partial template tree complete. In a complete template tree, all such nodes are replaced by one of the three original nodes. Indeed, complete trees must have a form obeying Definition 12. The definition of tree constraints is extended to the new nodes by simply ignoring them: **ShouldRank** and **ShouldUnaffect** nodes do not induce constraints. In this section, we represent the children of **Decreasing** nodes as a set labeling the node, rather than as figures like Figure 6(a).

Figure 7 describes the procedure as the function $exists_tree$. It searches for an EN-tree of at most the specified maximum height, max_height , corresponding to the property that the root expression is eventually negative by $\mathcal{A} \subseteq \overline{\mathcal{T}}$. It defines the initial tree, $initial_tree$, as a **Decreasing** node with **ShouldRank** \mathcal{A} children and **ShouldUnaffect** $\overline{\mathcal{T}} - \mathcal{A}$ children. The function sat builds the numerical constraint system induced by the given tree en and returns its satisfiability. The constraints include those on the template invariant (inv_cts).

The search proceeds by exploring the space of partial template trees via $next_tree$. For current tree en and boolean $extend$, ($next_tree \ en \ extend$) returns the next tree in the search space. The next tree is constructed by replacing some **ShouldRank** ^{τ} (**ShouldUnaffect** ^{τ}) node with a **Ranking** ^{τ} (**Unaffecting** ^{τ}) or a **Decreasing**_{c_k} ^{τ} node. The choice is controlled by $extend$. When $extend$ is **true**, the tree is “extended” by replacing the node with a **Decreasing**_{c_k} ^{τ}

node, which has a fresh template expression \mathbf{c}_k and a set of **ShouldRank** $^{\tau'}$ and **ShouldUnaffected** $^{\tau'}$ children, where a child is **ShouldRank** $^{\tau'}$ only if $\tau = \tau'$.

Example 8. Consider ERRATIC with a linear transition order $\tau_3 \prec \tau_1 \prec \tau_2$. The initial partial template trees for the lexicographic components of τ_1 , τ_2 , and τ_3 are the following:

$$\begin{aligned} \tau_1 &: \text{Decreasing}_{\mathbf{c}_1} \{ \text{ShouldRank}^{\tau_1}, \text{ShouldUnaffected}^{\tau_2} \} \\ \tau_2 &: \text{Decreasing}_{\mathbf{c}_2} \{ \text{ShouldRank}^{\tau_2} \} \\ \tau_3 &: \text{Decreasing}_{\mathbf{c}_3} \{ \text{ShouldUnaffected}^{\tau_1}, \text{ShouldUnaffected}^{\tau_2}, \text{ShouldRank}^{\tau_3} \} \end{aligned}$$

The next tree for τ_1 , without extending the tree, could be

$$\text{Decreasing}_{\mathbf{c}_1} \{ \text{Ranking}^{\tau_1}, \text{ShouldUnaffected}^{\tau_2} \};$$

however, the corresponding numeric constraint system is unsatisfiable. Therefore, with extension, the next tree is

$$\text{Decreasing}_{\mathbf{c}_1} \left\{ \text{Decreasing}_{\mathbf{c}_4}^{\tau_1} \{ \text{ShouldRank}^{\tau_1}, \text{ShouldUnaffected}^{\tau_2} \}, \text{ShouldUnaffected}^{\tau_2} \right\}.$$

Finally, the search runs as follows. It checks that the given template tree, *en*, has a height at most *max_height* and that the numeric constraint system induced by *en* is feasible. If the system is infeasible, then no extension of *en* can induce a feasible constraint system, so the search halts on the branch. If both checks are satisfied and the tree is *complete*, then a satisfying tree has been found, so the search returns **true**. If the tree is still incomplete, it recurses on the next tree, first without extension and then with extension. Each of the two calls to *next_tree* should modify the same node.

Lemma 2. *If num_sat is a decision procedure, (exists_tree $\mathcal{A} \bar{T}$) returns true iff there is an expression $E(\mathbf{x})$ and an n -conjunct supporting linear invariant $I\mathbf{x} \geq 0$ such that (1) $E(\mathbf{x})$ is lower bounded by 0 by each $\tau \in \mathcal{A}$ relative to $I\mathbf{x} \geq 0$, and (2) $E(\mathbf{x})$ is eventually negative by $\mathcal{A} \subseteq \bar{T}$ relative to $I\mathbf{x} \geq 0$, and the associated EN-tree has height at most *max_height*.*

Example 9. After several more iterations for each template tree in Example 8, each **ShouldRank** (**ShouldUnaffected**) node is replaced by a **Ranking** (**Unaffected**) node. One possible solution is discussed in Example 4, where the trees for τ_1 and τ_2 have been merged into one tree.

The second algorithm, *lex*, adapted from [1], works on top of the first to find a lexicographic function. It associates with each transition $\tau \in \mathcal{T}$ a template expression $T(\tau)$. It seeks a linear order among the transitions by incrementally searching over partial orders. A partial order \prec over \mathcal{T} induces a set of constraints: for each τ , $T(\tau)$ must be eventually negative by $\{\tau\} \subseteq \{\tau' : \tau' \prec \tau \vee \tau' = \tau\}$; and $T(\tau)$ must be lower bounded by 0 when τ is enabled. These constraints

are checked by the first algorithm. If \prec induces an unsatisfiable constraint system, then no linear extension can induce a satisfiable constraint system. Thus, solving partial constraint systems guides this search, as well. If a linear order is found that induces a satisfiable constraint system, the second algorithm has found a lexicographic polyranking function.

Proposition 1. *Consider loop $L : \langle \mathcal{V}, \theta, \mathcal{T} \rangle$, an n -conjunct template invariant, and maximum tree height `max_height`. $(\text{lex } L)$ returns `true` iff L has a lexicographic linear polyranking function such that the associated EN-trees have height at most `max_height` and are each supported by an n -conjunct linear invariant.*

6 Conclusion

We implemented the lexicographic linear polyranking approach to proving termination of linear loops in our tool, `linsys`. The implementation found the polyranking function and supporting invariant described in Example 4 in about 2 seconds and the lexicographic polyranking function described in Example 5 in about 1 second. The primary challenge in scaling our synthesis method to assertional polynomial loops is solving the polynomial constraint systems. Approximation methods like in [6] may address scalability.

We believe that two ideas from this paper are useful in domains other than termination analysis. First, the recursive definition of an eventually negative expression may be of interest for hybrid system analysis and control theory. Second, the form of our synthesis method for solving structural and numeric constraints should be applicable to other constraint solving and synthesis tasks.

Acknowledgments. We thank the reviewers for their insightful comments.

Approximate Guarding of Monotone and Rectilinear Polygons

Bengt J. Nilsson

Technology and Society, Malmö University College,

Bengt.Nilsson@ts.mah.se

Abstract. We show a constant factor approximation algorithm for interior guarding of monotone polygons. Using this algorithm we obtain an approximation algorithm for interior guarding rectilinear polygons that has an approximation factor independent of the number of vertices of the polygon. If the size of the smallest interior guard cover is OPT for a rectilinear polygon, our algorithm produces a guard set of size $O(OPT^2)$.

1 Introduction

The art gallery problem is perhaps the best known problem in computational geometry. It asks for the minimum number of guards to guard a space having obstacles. Originally, the obstacles were considered to be walls mutually connected to form a closed Jordan curve, hence, a simple polygon. Tight bounds for the number of guards necessary and sufficient were found by Chvátal [7] and Fisk [14]. Subsequently, other obstacle spaces, both more general and more restricted than simple polygons have also been considered for guarding problems, most notably, polygons with holes and simple rectilinear polygons [16, 22].

Art gallery problems are motivated by applications such as line-of-sight transmission networks in polyhedral terrains, e.g., signal communications and broadcasting, cellular telephony, and other telecommunication technologies as well as placement of motion detectors and security cameras.

We distinguish between two types of guarding problems. Vertex guarding considers only guards positioned at vertices of the polygon, whereas interior guarding allows the guards to be placed anywhere in the interior of the polygon.

The computational complexity question of guarding simple polygons was settled by Aggarwal [1] and Lee and Lin [19] independently when they showed that the problem is NP-hard for both vertex guards and interior guards. Further results have shown that already for very restricted subclasses of polygons the problem is still NP-hard [3, 21]. Also, Chen *et al.* [5] claim that vertex guarding a monotone polygon is NP-hard, however the details of their proof are omitted and still to be verified.

The approximation complexity of guarding polygons has been studied by Eidenbenz and others. Eidenbenz [13] shows that polygons with holes cannot be efficiently guarded by fewer than $\Omega(\log n)$ times the optimal number of interior

or vertex guards, unless $P=NP$, where n is the number of vertices of the polygon. Brodén *et al.* and Eidenbenz [3, 12] independently prove that interior guarding simple polygons is APX-hard, thus showing that, unless $P=NP$, no PTAS is possible for this problem.

Any polygon (with or without holes) can be efficiently vertex guarded with logarithmic approximation factor in the number of vertices of the polygon. The algorithm is a simple reduction to SET COVER and goes as follows [15]: compute the arrangement produced by the visibility polygons of the vertices. Next, let each vertex v correspond to a set in the set cover instance consisting of elements corresponding to the faces of the arrangement that lie in the visibility polygon of v . The greedy algorithm for SET COVER will then produce a guard cover having logarithmic approximation factor.

The above result can be improved for simple polygons using randomization, giving an algorithm with expected running time $O(nOPT^2 \log^4 n)$ that produces a vertex guard cover with approximation factor $O(\log OPT)$ with high probability, where n is the size of the polygon and OPT is the smallest vertex guard cover for the polygon [11].

Recently, interesting constant factor approximation algorithms have been developed for the special case of one-dimensional terrains [2, 8]. A terrain is a two-dimensional region above a monotone chain.

We prove polynomial time approximation algorithms for interior guarding of monotone and rectilinear polygons. As mentioned, vertex guarding of monotone polygons is believed to be NP-hard, and furthermore, it is known that covering rectilinear polygons with the minimum number of convex pieces (rectangles) is NP-hard [9]. This suggests that interior guarding these two classes of polygons is difficult and provides the basis for our interest in approximation algorithms for these problems.

The next section contains some useful definitions and in Sections 3 and 4 we describe the algorithms for monotone and rectilinear polygons respectively.

2 Definitions

A polygon \mathbf{P} is *l-monotone* if there is a line of monotonicity l such that any line orthogonal to l has a simply connected intersection with \mathbf{P} . When we talk about monotone polygons, we will henceforth assume that they are *x-monotone*, i.e., the *x*-axis is the line of monotonicity for the polygons we consider.

The boundary of a monotone polygon \mathbf{P} can be subdivided into two chains, the *upper chain* U and the *lower chain* D . Let s and t be the leftmost and rightmost vertices of \mathbf{P} respectively. The chain U consists of the boundary path followed from s to t in clockwise direction, whereas D is the boundary path followed from s to t in counterclockwise direction.

A polygon \mathbf{P} is *rectilinear* if the boundary of \mathbf{P} consists of axis parallel line segments. Hence, at all vertices, the interior angle between segments are either 90 or 270 degrees; see Figure 1(a).

Fig. 1. Illustrating definitions and Lemma 1

Let $\mathbf{VP}(p)$ denote the visibility polygon of \mathbf{P} from the point p , i.e, the set of points in \mathbf{P} that can be connected with a line segment to p without intersecting the outside of \mathbf{P} .

Consider a partial set of guard points g_1, \dots, g_m in \mathbf{P} and the union of their visibility polygons $\bigcup_{i=1}^m \mathbf{VP}(g_i)$, the set $\mathbf{P} \setminus \bigcup_{i=1}^m \mathbf{VP}(g_i)$ is the region of \mathbf{P} not seen by the points g_1, \dots, g_m . This region consists of a set of simply connected polygonal regions called *pockets* bounded by either the polygon boundary or the edges of the visibility polygons.

The following definitions are useful for monotone polygons. Let q be a point in $\mathbf{VP}(p)$ that lies to the right of p . We denote by $\mathbf{VP}_R(p, q)$ the part of $\mathbf{VP}(p)$ that lies to the right of q . Also, $\mathbf{VP}_R(p) = \mathbf{VP}_R(p, p)$.

A pocket in a monotone polygon \mathbf{P} is an *upper pocket* if it is adjacent to the upper boundary U of \mathbf{P} , otherwise it is a *lower pocket*. Note that an upper pocket can be adjacent to D whereas a lower pocket is never adjacent to U .

Let $SP(p, q)$ denote the shortest (Euclidean) path between points p and q inside \mathbf{P} .

Lemma 1. *If q is a point on $SP(p, t)$ inside a monotone polygon \mathbf{P} , then $\mathbf{VP}_R(p, q) \subseteq \mathbf{VP}_R(q)$.*

Proof. Let r be a point to the right of q in \mathbf{P} that is visible from p . To prove that r is seen from q consider the vertical line through r and its intersection point r' with $SP(p, t)$. The three points $p, r,$ and r' define a polygon in \mathbf{P} having three convex vertices and possibly some reflex vertices on the path $SP(p, r')$. Since r sees both p and r' , r sees all of the path $SP(p, r')$ and hence also the point q ; see Figure 1(b). □

3 Interior Guarding Monotone Polygons

Our algorithm for guarding a monotone polygon \mathbf{P} will incrementally guard \mathbf{P} starting from the left and moving right. Hence, we are interested in the structure of the pockets that occur when guarding is done in this way. We first define *kernel expansions* of the pockets given a partial guard cover \mathcal{G}_p , and then taking maximal nonempty intersection of these we produce the main region that we will be interested in. This region is called a *spear* and with this we can define a well behaved guard cover \mathcal{G}^* that has small size. We finally prove that our incremental algorithm produces a guard cover at most a constant times larger than \mathcal{G}^* .

Assume that we have a partial guard cover \mathcal{G}_p in \mathbf{P} and that everything to the left of the rightmost guard is seen. Consider the upper pockets resulting from this guard cover and enumerate them \mathbf{p}_1^U, \dots from left to right. The lower pockets are enumerated from left to right \mathbf{p}_1^D, \dots in the same way; see Figure 2.

Fig. 2. Illustrating pockets and kernel expansions

Let \mathbf{p}^U be an upper pocket. The *kernel expansion* $\mathbf{ke}(\mathbf{p}^U)$ consists of all the points in \mathbf{P} that see everything in \mathbf{p}^U to the left of themselves. For the lower pockets we define the kernel expansion symmetrically. The definition of kernel expansion is valid also when no guards have as yet been placed in the polygon. In this case, we take all of the polygon \mathbf{P} to be an upper pocket.

Let k be the largest index so that $\bigcap_{i=1}^k \mathbf{ke}(\mathbf{p}_i^U)$ is nonempty. This nonempty intersection of kernel expansions is called the *upper spear*, also denoted \mathbf{sp}^U . We can in the same way define the *lower spear* \mathbf{sp}^D as the maximal nonempty intersection of the kernel expansions for the lower pockets.

Given the partial guard cover \mathcal{G}_p the upper spear \mathbf{sp}^U can be computed in linear time as follows. Let r_1^U be the leftmost point of \mathbf{p}_1^U . An edge e of the pocket that is also part of U is defined to have the same direction as when it is traversed during a traversal of U from s to t . Following the boundary of the upper pockets starting at r_1^U , for each edge e of the pocket that is also an edge of U , we issue a half line from e having the same direction as e . When the traversal of a pocket \mathbf{p}_i^U reaches the last edge we establish the last point q_i^U of the edge not seen by \mathcal{G}_p and we extend the directed half line issuing from q_i^U toward the vertex v on U between q_i^U and r_{i+1}^U so that this half line has minimum interior angle and does not intersect the exterior of \mathbf{P} above U . Using these half lines in the order they were computed we incrementally find their right half plane intersection in the same way as is done to compute the kernel of a polygon [17, 18]. This gives us the upper boundary of the spear.

To compute the lower boundary of the spear we follow the lower boundary D of \mathbf{P} from the point having the same x -coordinate as r_1^U toward t and maintain the half lines issuing from r_1^U having maximal interior angle to U and such that they do not intersect the exterior of \mathbf{P} below D ; see Figure 3. The intersection point between the upper and lower boundary of the spear is called the *upper spear tip* and we denote it u^U .

In a similar manner we can compute the lower spear \mathbf{sp}^D and its lower spear tip u^D .

To every spear \mathbf{sp} we also associate a region called the *shadow* of the spear, denoted $\mathbf{shd}(\mathbf{sp})$. If the spear tip lies on the lower boundary D the shadow is

Fig. 3. Computing the upper spear and the shadow

the empty set. If the spear tip lies in the interior of \mathbf{P} , the shadow of the spear is the region to the right of the spear tip between the two half lines bounding the spear that intersect at the spear tip; see Figure 3.

The upper and lower spears are dependent on the placement of the previously placed guards so we will henceforth refer to them as $\mathbf{sp}^U(\mathcal{G}_p)$ and $\mathbf{sp}^D(\mathcal{G}_p)$ given the partial guard set \mathcal{G}_p . For each spear, $\mathbf{sp}^U(\mathcal{G}_p)$ and $\mathbf{sp}^D(\mathcal{G}_p)$ we denote the upper spear tip $u^U(\mathcal{G}_p)$ and the lower spear tip $u^D(\mathcal{G}_p)$. If $\mathcal{G}_p = \emptyset$, the upper spear $\mathbf{sp}^U(\emptyset)$ and the upper spear tip $u^U(\emptyset)$ are well defined.

We prove the following two lemmas.

Lemma 2. *If \mathcal{G}_p and \mathcal{G}'_p are two partial guard covers of \mathbf{P} such that $\mathbf{sp}^U(\mathcal{G}_p)$ and $\mathbf{sp}^U(\mathcal{G}'_p)$ do not intersect, then $\mathbf{shd}(\mathbf{sp}^U(\mathcal{G}_p)) \cap \mathbf{shd}(\mathbf{sp}^U(\mathcal{G}'_p)) = \emptyset$.*

Proof. We make a proof by contradiction and assume that the two shadows intersect. Assume that $\mathbf{sp}^U(\mathcal{G}_p)$ lies to the left of $\mathbf{sp}^U(\mathcal{G}'_p)$ and let p be a point in the intersection of the two shadows. We can connect p to $u^U(\mathcal{G}_p)$ with a line segment and then follow the line segment from $u^U(\mathcal{G}_p)$ back to its starting point r_1^U at the leftmost point of the first upper pocket associated to $\mathbf{sp}^U(\mathcal{G}_p)$. From r_1^U we follow the upper boundary of the pocket to the rightmost point q_k^U of the last upper pocket associated to $\mathbf{sp}^U(\mathcal{G}'_p)$, from this point on to $u^U(\mathcal{G}'_p)$, and then back to p . This traversal bounds a polygon interior to \mathbf{P} that contains completely the lower boundary segment of $\mathbf{sp}^U(\mathcal{G}'_p)$. However, this is not possible because by construction this segment must intersect the lower boundary D of \mathbf{P} , giving us a contradiction; see Figure 4. \square

At this point, it is important to note that a single guard placed in a spear will guard all pockets associated to the spear. However, these pockets can also be guarded by placing one guard above and below the shadow and possibly one or more guards inside the shadow. Now, we are interested in bounding from below the number of guards needed to the right of a spear for the case that no guard is in the spear.

Fig. 4. Illustrating the proof of Lemma 2

Let \mathcal{G} be any guard cover for \mathbf{P} and let $\mathcal{G}_p \subset \mathcal{G}$ be a possibly empty partial guard cover. If \mathcal{G}_p is nonempty assume that it has g as its rightmost guard and assume further that all of \mathbf{P} to the left of g is guarded by \mathcal{G}_p . Let $\mathcal{G}_f = \mathcal{G} \setminus \mathcal{G}_p$ and define the following sets recursively.

$$\begin{aligned} \mathcal{G}_0 &= \mathcal{G}_p \\ \mathcal{G}_i &= \mathcal{G}_{i-1} \cup \{u^U(\mathcal{G}_{i-1})\} \quad \text{for } i > 0 \end{aligned}$$

Lemma 3. *Let \mathcal{G}_f and $\mathcal{G}_0, \dots, \mathcal{G}_k$ be sets as defined above. If all guards of \mathcal{G}_f lie to the right of $u^U(\mathcal{G}_k)$, then \mathcal{G}_f contains at least $k + 2$ guards.*

Proof. By the construction of the sets \mathcal{G}_i , we know that their corresponding spears do not intersect, and hence, from Lemma 4 their shadows do not intersect either. Let g be the rightmost guard of $\mathcal{G}_p = \mathcal{G}_0$.

If some shadow $\text{shd}(\text{sp}^U(\mathcal{G}_i))$ does not intersect the vertical line through $u^U(\mathcal{G}_k)$ then at least one guard is needed in the interval between g and $u^U(\mathcal{G}_k)$, contradicting that \mathcal{G} is a guard cover for \mathbf{P} . Hence, all shadows intersect this vertical line. Now, assume that \mathcal{G}_f contains at most $k + 1$ guards. By the pigeon-hole principle there are two consecutive shadows $\text{shd}(\text{sp}^U(\mathcal{G}_i))$ and $\text{shd}(\text{sp}^U(\mathcal{G}_{i+1}))$ such that at least one of them and the region between them does not contain any guard, i.e., all guards of \mathcal{G}_f lie either above the upper boundary of $\text{shd}(\text{sp}^U(\mathcal{G}_i))$ and below the upper boundary of $\text{shd}(\text{sp}^U(\mathcal{G}_{i+1}))$ or above the lower boundary of $\text{shd}(\text{sp}^U(\mathcal{G}_i))$ and below the lower boundary of $\text{shd}(\text{sp}^U(\mathcal{G}_{i+1}))$. In both cases this means that there are points of the last pocket associated to $\text{sp}^U(\mathcal{G}_i)$ that are not seen by \mathcal{G} , giving us a contradiction; see Figure 5. \square

Fig. 5. Illustrating the proof of Lemma 3

We say that a guard *belongs* to a shadow $\mathbf{shd}(\mathbf{sp}^U(\mathcal{G}_i))$, if it lies in the interior of $\mathbf{shd}(\mathbf{sp}^U(\mathcal{G}_i))$ or it lies below $\mathbf{shd}(\mathbf{sp}^U(\mathcal{G}_i))$ but above all other shadows lying below $\mathbf{shd}(\mathbf{sp}^U(\mathcal{G}_i))$.

We can, of course, prove similar results as those in Lemmas 2 and 3 for the shadows of lower spears.

A guard cover is called *serial*, if the following invariant condition holds when we incrementally place the guards of the cover in \mathbf{P} one by one in order from left to right.

If g_m is the m^{th} guard placed in the order, then g_m either lies in the upper spear or the lower spear of the guards g_1, \dots, g_{m-1} .

The next lemma shows that there is a serial guard cover of small size.

Lemma 4. *If \mathcal{G} is a guard cover for the monotone polygon \mathbf{P} , then there is a serial guard cover \mathcal{G}^* for \mathbf{P} such that $|\mathcal{G}^*| \leq 3|\mathcal{G}|$.*

Proof. Given a guard cover \mathcal{G} we transform it to be serial as follows. Order the guards of $\mathcal{G} = \{g_1, \dots, g_m\}$ from left to right. The transformation incrementally adds guards moving from left to right into two sets \mathcal{G}^U and \mathcal{G}^D ensuring that the next guard place lies in a spear. To make the constructed guard set serial we employ a plane sweep approach moving from left to right. As soon as the sweep line reaches a guard, the guard is attached to the sweep line and moves along it following the shortest path to t . By Lemma 1 this does not decrease visibility to the right. Now, as the sweep proceeds one of two things happen. Either a guard becomes the last guard to leave a spear (with respect to the previously released guards) and it is then released from the sweep line or the sweep reaches the spear tip without having released a guard. In this case, the spear has been completely empty of guards. In this latter case, we add a guard at the spear tip, placing it in \mathcal{G}^U if the spear is an upper spear and in \mathcal{G}^D if the spear is a lower spear. When the sweep line reaches t , those guards still attached to it are removed (except for possibly one) giving us the serial guard cover \mathcal{G}^* .

To count the number of extra guards placed by this process we can associate each new guard placed at a spear tip with one belonging to the shadow of the associated spear. From Lemma 3 we have that a guard belonging to an upper (lower) shadow can at worst belong also to a lower (upper) shadow. Hence, $|\mathcal{G}^U| \leq |\mathcal{G}|$ and $|\mathcal{G}^D| \leq |\mathcal{G}|$ giving us that $|\mathcal{G}^*| \leq |\mathcal{G}| + |\mathcal{G}^U| + |\mathcal{G}^D| \leq 3|\mathcal{G}|$. \square

We can now give the details of the incremental algorithm, displayed in Figure 6, and prove its correctness, approximation factor and time complexity.

To prove the complexity of the algorithm we note that the loops of Steps 2 and 3 are performed $O(n)$ times. Computing the spear and its spear tip can be done in linear time as we showed before. Hence, it remains to show how to do Step 2.4 efficiently. Let $\mathbf{VP}(\mathcal{G})$ be the part of the polygon seen so far. We begin by placing g' at the top of the line segment l and compute the upper spear with g' in the guard set. Then, we slide g' along l continuously updating the point $u^U(\mathcal{G} \cup \{g'\})$ as we go along. The structural changes of $\mathbf{sp}^U(\mathcal{G} \cup \{g'\})$ occur at certain key points on l . These are

Algorithm *Guard-Monotone-Polygons*
Input: A monotone polygon \mathbf{P}
Output: A guard cover for \mathbf{P}

- 1 Let $\mathcal{G} := \emptyset$
- 2 **while** not all upper pockets are guarded **do**
- 2.1 Compute $\mathbf{sp}^U(\mathcal{G})$ and $u^U(\mathcal{G})$
- 2.2 Place a guard g at $u^U(\mathcal{G})$; $\mathcal{G} := \mathcal{G} \cup \{g\}$
- 2.3 Compute $\bigcup_{g \in \mathcal{G}} \mathbf{VP}(g)$, let \mathbf{p}^U be the first upper pocket in \mathbf{P} , and let l be the vertical line segment through the leftmost boundary point of \mathbf{p}^U
- 2.4 Place a guard g' on l so that $u^U(\mathcal{G} \cup \{g'\})$ lies as far to the right as possible; $\mathcal{G} := \mathcal{G} \cup \{g'\}$
- endwhile**
- 3 Repeat Step 2 for the lower pockets to guard these
- return** \mathcal{G}

End *Guard-Monotone-Polygons*

Fig. 6. The algorithm for monotone polygons

1. when the convex vertex of $\mathbf{VP}(\mathcal{G}) \cup \mathbf{VP}(g')$ on an edge adjacent to an upper pocket becomes incident to a vertex of the polygon boundary U .
2. when an edge of the boundary of $\mathbf{sp}^U(\mathcal{G} \cup \{g'\})$ becomes incident to two vertices of the upper boundary U .
3. when three consecutive half lines issuing from pockets intersect at the same point.

The key points occur at an at most cubic number of discrete points on l . (The maximum number of possible common intersection points between three lines among n lines.) Moving g' in between the key points will make $u^U(\mathcal{G} \cup \{g'\})$ move monotonically to the right or to the left. Hence, by computing the key points, which can be done incrementally in at most linear time, we can find the point on l where $u^U(\mathcal{G} \cup \{g'\})$ lies as far to the right as possible; see Figure 7.

Fig. 7. Computing the rightmost spear tip

We have the following theorem.

Theorem 1. *The algorithm Guard-Monotone-Polygons computes a guard cover for a monotone polygon \mathbf{P} of size at most $12OPT$ in polynomial time, where OPT is the size of the smallest guard cover for \mathbf{P} .*

Proof. To prove correctness, the algorithm incrementally guards everything to the left of the rightmost guard, hence, it will completely guard the polygon.

To prove the approximation factor, consider any serial guard cover $\mathcal{G}^* = \{g_1^*, \dots, g_m^*\}$ ordered from left to right in the polygon. We prove by induction that after the i^{th} iteration of the loop at Step 2, the last guard placed thus far lies further to the right than g_i^* . For the base case, after the first iteration of the loop, note that the algorithm places a guard at the first spear tip, the rightmost point of the first spear, and hence, to the right of g_1^* . Assume now that after the i^{th} iteration of the loop, the guard g lies to the right of g_i^* . Since we place g' so that the rightmost point $u^U(\mathcal{G} \cup \{g'\})$ of $\text{sp}^U(\mathcal{G} \cup \{g'\})$ lies as far to the right as possible it has to lie at least as far to the right as g_{i+1}^* . Associating g and g' during the i^{th} iteration to g_i^* we see that the loop will place at most $2|\mathcal{G}^*|$ guards in the polygon. Thus, a total of at most $4|\mathcal{G}^*|$ guards are placed. By Lemma 4 we can choose \mathcal{G}^* as the smallest serial guard cover which in turn is bounded by $3OPT$.

The complexity of the algorithm follows from the previous discussion. □

4 Interior Guarding Rectilinear Polygons

The algorithm for computing a guard cover in a simple rectilinear polygon consists of two main steps. First, we find a subdivision of the polygon into monotone pieces, second, we use the previously given algorithm to compute a guard cover in each monotone piece.

Consider a simple rectilinear polygon \mathbf{P} . To every reflex vertex v we can associate two *extensions*, i.e., the two maximal line segments in \mathbf{P} through v and collinear to the two edges adjacent to v . We associate a direction to an extension e collinear to an edge e_v by giving e the same direction as e_v gets when \mathbf{P} is traversed in counterclockwise order. This allows us to refer to the regions to the left and right of an extension, meaning to the left or right of e if e is directed upward.

Given two extensions e and e' , we say that e *dominates* e' , if all points in \mathbf{P} to the left of e are also to the left of e' . Using the algorithm of Chin and Ntafos [6] in conjunction with Chazelle’s triangulation algorithm [4], we can in linear time compute the most dominant extensions that we call the *essential extensions*. Assume that this computation gives us k essential extensions. An essential extension e_i is collinear to an edge with one reflex and one convex vertex. Let v_i denote the convex vertex. This gives us k convex vertices and we choose one of them, say v_k , as root in a shortest rectilinear path tree T_R to each of the other vertices v_i , for $1 \leq i < k$, that can be computed in linear

time [10]. The shortest rectilinear path tree consists of paths that are shortest in the L_1 -metric connecting v_k to all the other vertices v_i , for $1 \leq i < k$.

To each rectilinear path $SP_R(v_i, v_k)$ connecting v_i with v_k we define a vertical and a horizontal *histogram expansion*. The horizontal histogram expansion H_i^H consists of those points in \mathbf{P} that can be connected to the path $SP_R(v_i, v_k)$ with vertical line segments contained in \mathbf{P} . We define the vertical histogram expansion H_i^V in a similar manner. A histogram expansion can be computed in linear time using an algorithm by Levcopoulos [20]. Each horizontal histogram expansion consists of a number of x -monotone polygons with the property that no guard in one monotone polygon can see anything in any of the others. Similarly a vertical histogram expansion subdivides into y -monotone pieces with the same property; see Figure 8.

Fig. 8. Illustrating the algorithm

Lemma 5. *If \mathbf{P} can be guarded with OPT guards, then a histogram expansion can also be guarded with at most OPT guards interior to the region.*

Proof. Let p be a point that sees into a monotone piece \mathbf{R} of a histogram expansion. Assume that \mathbf{R} is x -monotone and that p lies in a region adjacent to the lower boundary D of \mathbf{R} . Let l be the line segment that separates \mathbf{R} from the piece containing p . Consider the intersection $\mathbf{VP}(p) \cap \mathbf{R}$. The intersection subdivides \mathbf{R} into left pockets and right pockets. Traversing the boundary of $\mathbf{VP}(p)$ clockwise starting at a point outside \mathbf{R} will first reach the edges that are incident to left pockets, then a boundary chain C of \mathbf{R} , and finally the edges that are incident to right pockets of \mathbf{R} . Take any point q of C and let p' be the intersection of the line segment between p and q with l . Any point in \mathbf{R} seen by p will also be seen by p' , which proves the lemma. \square

We use the *Guard-Monotone-Polygon* algorithm of the previous section to guard each monotone piece with at most $12m$ guards, where m is the smallest guard cover for the monotone piece. From Lemma 5 we know that each histogram expansion can be guarded with OPT guards interior to the histogram expansion, and hence, our algorithm guards it with at most $12OPT$ guards.

Furthermore, one guard can see at most two of the vertices v_i , for $1 \leq i \leq k$, hence, $k/2 \leq OPT$. Since we construct a total of $2k$ horizontal and vertical histogram expansions, the union $\bigcup_{i=1}^{k-1} H_i^H \cup H_i^V$ can be guarded by at most $48OPT^2$ guards.

Fig. 9. Illustrating the proof of Lemma 5

The set $\mathbf{P} \setminus (\bigcup_{i=1}^{k-1} \mathbf{H}_i^H \cup \mathbf{H}_i^V)$ partitions into a number of connected regions. These *extra pieces*; see Figure 10; are monotone with respect to both the x - and the y -axis and we can guard each of them with one extra guard. An extra piece is also adjacent to one horizontal and one vertical histogram expansion and each monotone piece in a histogram expansion can be adjacent to at most two extra pieces. Hence, to count the number of extra pieces, i.e., the number of additional guards we place, we associate each extra piece with the horizontal or vertical monotone piece of a histogram expansion that is closer to v_k . Thus, the number of guards placed to see all of \mathbf{P} has at most doubled.

Fig. 10. Handling the extra pieces

We have proved the following theorem.

Theorem 2. *There is a polynomial time algorithm that computes a guard cover of size $96OPT^2$ in a rectilinear polygon \mathbf{P} , where OPT is the size of the smallest guard cover for \mathbf{P} .*

5 Conclusions

We have proved polynomial time algorithms for approximate interior guarding of monotone and rectilinear polygons. Our contribution is that the approximation factors for both algorithms is independent of the size of the polygon. Interesting open problems are to improve the approximation bounds for monotone and rectilinear polygons, to find approximation algorithms for other classes of polygons, and ultimately approximate guarding of the general class of simple polygons.

Abstract. We generalize the k -means algorithm presented by the authors [14] and show that the resulting algorithm can solve a larger class of clustering problems that satisfy certain properties (*existence of a random sampling procedure* and *tightness*). We prove these properties for the k -median and the discrete k -means clustering problems, resulting in $O(2^{(k/\varepsilon)^{O(1)}} dn)$ time $(1 + \varepsilon)$ -approximation algorithms for these problems. These are the first algorithms for these problems linear in the size of the input (nd for n points in d dimensions), independent of dimensions in the exponent, assuming k and ε to be fixed. A key ingredient of the k -median result is a $(1 + \varepsilon)$ -approximation algorithm for the 1-median problem which has running time $O(2^{(1/\varepsilon)^{O(1)}} d)$. The previous best known algorithm for this problem had linear running time.

1 Introduction

The problem of clustering a group of data items into similar groups is one of the most widely studied problems in computer science. Clustering has applications in a variety of areas, for example, data mining, information retrieval, image processing, and web search ([5, 7, 16, 9]). Given the wide range of applications, many different definitions of clustering exist in the literature ([8, 4]). Most of these definitions begin by defining a notion of distance (similarity) between two data items and then try to form clusters so that data items with small distance between them get clustered together.

Often, clustering problems arise in a geometric setting, i.e., the data items are points in a high dimensional Euclidean space. In such settings, it is natural to define the distance between two points as the Euclidean distance between them. Two of the most popular definitions of clustering are the *k -means clustering problem* and the *k -median clustering problem*. Given a set of points P ,

the k -means clustering problems seeks to find a set K of k centers, such that $\sum_{p \in P} d(p, K)^2$ is minimized, whereas the k -median clustering problems seeks to find a set K of k centers, such that $\sum_{p \in P} d(p, K)$ is minimized. Note that the points in K can be arbitrary points in the Euclidean space. Here $d(p, K)$ refers to the distance between p and the closest center in K . We can think of this as each point in P gets assigned to the closest center. The points that get assigned to the same center form a cluster. These problems are NP-hard for even $k = 2$ (when dimension is not fixed). Interestingly, the center in the optimal solution to the 1-mean problem is the same as the center of mass of the points. However, in the case of the 1-median problem, also known as the Fermat-Weber problem, no such closed form is known. We show that despite the lack of such a closed form, we can obtain an approximation to the optimal 1-median in $O(1)$ time (independent of the number of points). There exist variations to these clustering problems, for example, the discrete versions of these problems, where the centers that we seek are constrained to lie on the input set of points.

1.1 Related Work

A lot of research has been devoted to solving these problems exactly (see [11] and the references therein). Even the best known algorithms for the k -median and the k -means problem take at least $\Omega(n^d)$ time. Recently, some work has been devoted to finding $(1 + \varepsilon)$ -approximation algorithm for these problems, where ε can be an arbitrarily small constant. This has led to algorithms with much improved running times. Further, if we look at the applications of these problems, they often involve mapping subjective features to points in the Euclidean space. Since there is an error inherent in this mapping, finding a $(1 + \varepsilon)$ -approximate solution does not lead to a deterioration in the solution for the actual application.

The following table summarizes the recent results for the problems, in the context of $(1 + \varepsilon)$ -approximation algorithms. Some of these algorithms are randomized with the expected runing time holding good for any input.

Problem	Result	Reference
1-median	$O(n/\varepsilon^2)$	Indyk [12]
k -median	$O(n^{O(1/\varepsilon)+1})$ for $d = 2$ $O(n + \varrho k^{O(1)} \log^{O(1)} n)$ (discrete also) where $\varrho = \exp[O((1 + \log 1/\varepsilon)/\varepsilon)^{d-1}]$ $O(2^{(k/\varepsilon)^{O(1)}} d^{O(1)} n \log^{O(k)} n)$	Arora [1] Har-Peled et al. [10] Badoiu et al. [3]
discrete k -median	$O(\varrho n \log n \log k)$	Kolliopoulos et al. [13]
k -means	$O(n/\varepsilon^d)$ for $k = 2$ $O(n\varepsilon^{-2k^2} d \log^k n)$ $O(g(k, \varepsilon) n \log^k n)$ $g(k, \varepsilon) = \exp[(k^3/\varepsilon^8)(\ln(k/\varepsilon)\ln k)]$ $O(n + k^{k+2} \varepsilon^{-(2d+1)k} \log^{k+1} n \log^k \frac{1}{\varepsilon})$ $O(2^{(k/\varepsilon)^{O(1)}} dn)$	Inaba et al. [11] Matousek [15] de la Vega et al. [6] Har-Peled et al. [10] Kumar et al. [14]

1.2 Our Contributions

In this paper, we generalize the algorithm of authors [14] to a wide range of clustering problems. We define a general class of clustering problems and show that if certain conditions are satisfied, we can get linear time $(1 + \varepsilon)$ -approximation algorithms for these problems. We then use our general framework to get the following results. Given a set of n points P in \mathbb{R}^d , we present

1. a randomized algorithm that generates a candidate center set of size $O(2^{1/\varepsilon^{O(1)}})$, such that at least one of the points in this set is a $(1 + \varepsilon)$ -approximate 1-median of P with constant probability. The running time of the algorithm is $O(2^{1/\varepsilon^{O(1)}}d)$, assuming that the points are stored in a suitable data structure such that a point can be randomly sampled in constant time. This improves on the algorithm of Badoiu et al. [3] which generates a candidate center set of size $O(2^{1/\varepsilon^4} \log n)$ in time $O(d2^{1/\varepsilon^4} \log n)$.
2. a randomized $(1 + \varepsilon)$ -approximation algorithm for the 1-median problem which runs in time $O(2^{1/\varepsilon^{O(1)}}d)$, assuming that the points are stored in a suitable data structure such that a point can be randomly sampled in constant time.
3. a randomized $(1 + \varepsilon)$ -approximation algorithm for the k -median problem which runs in $O(2^{(k/\varepsilon)^{O(1)}}nd)$ time.
4. a randomized $(1 + \varepsilon)$ -approximation algorithm for the discrete k -means clustering which runs in $O(2^{(k/\varepsilon)^{O(1)}}nd)$ time.

All our algorithms yield the desired result with constant probability (which can be made as close to 1 as we wish by a constant number of repetitions). As mentioned earlier, we generalize the result of the authors in [14] to solve a larger class of clustering problems satisfying a set of conditions (c.f. section 2). We then show that the k -median problem and the discrete k -means problem fall in this class of clustering problems. One important condition that the clustering problems must satisfy is that there should be an algorithm to generate a candidate set of points of size independent of n , such that at least one of these points is a close approximation to the optimal center when we desire only one cluster. Armed with such a subroutine, we show how to approximate all the centers in the optimal solution in an iterative manner.

It is easy to see that our algorithms for the k -median and the discrete k -means problems have better running time than the previously known algorithms for these problems, specially when d is very large. In fact, these are the first algorithms for the k -median and the discrete k -means clustering that have running time linear in the size of the input for fixed k and ε .

For the 1-median problem, the candidate center set generation and the actual approximation algorithm have better running time than all previously known algorithms. The algorithms in this paper have the additional advantage of simplicity inherited from generalizing the approach of Kumar et al. [14].

The remaining paper is organized as follows. In Section 2, we describe a general approach for solving clustering problems efficiently. In the subsequent

sections we give applications of the general method by showing that this class of problems includes the k -median, the k -means and the discrete k -means problems. In section 4.3, we also describe an efficient approximation algorithm for the 1-median problem.

2 Clustering Problems

In this section, we give a general definition of clustering problems. Our algorithms will work on any of these problems provided certain conditions are satisfied. We will state these conditions later in the section.

We shall define a clustering problem by two parameters – an integer k and a real-valued cost function $f(Q, x)$, where Q is a set of points, and x is a point in an Euclidean space. We shall denote this clustering problem as $\mathcal{C}(f, k)$. The input to $\mathcal{C}(f, k)$ is a set of points in a Euclidean space.

Given an instance P of n points, $\mathcal{C}(f, k)$ seeks to partition them into k sets, which we shall denote as *clusters*. Let these clusters be C_1, \dots, C_k . A solution also finds k points, which we call *centers*, c_1, \dots, c_k . We shall say that c_i is the center of cluster C_i (or the points in C_i are assigned to c_i). The objective of the problem is to minimize the quantity $\sum_{i=1}^k f(C_i, c_i)$.

This is a fairly general definition. Let us see some important special cases.

- k -median : $f(Q, x) = \sum_{q \in Q} d(q, x)$.
- k -means : $f(Q, x) = \sum_{q \in Q} d(q, x)^2$.

We can also encompass the discrete versions of these problems, i.e., cases where the centers have to be one of the points in P . In such problems, we can make $f(Q, x)$ unbounded if $x \notin Q$.

As stated earlier, we shall assume that we are given a constant $\varepsilon > 0$, and we are interested in finding $(1 + \varepsilon)$ -approximation algorithms for these clustering problems.

We now state the conditions the clustering problems should satisfy. We begin with some definitions first. Let us fix a clustering problem $\mathcal{C}(f, k)$. Although we should parameterize all our definitions by f , we avoid this because the clustering problem will be clear from the context.

Definition 1. *Given a point set P , let $\text{OPT}_k(P)$ be the cost of the optimal solution to the clustering problem $\mathcal{C}(f, k)$ on input P .*

Definition 2. *Given a constant α , we say that a point set P is (k, α) -irreducible if $\text{OPT}_{k-1}(P) \geq (1 + 150\alpha)\text{OPT}_k(P)$. Otherwise we say that the point set is (k, α) -reducible.*

Reducibility captures the fact that if P is (k, α) -reducible for a small constant α , then the optimal solution for $\mathcal{C}(f, k - 1)$ on P is close to that for $\mathcal{C}(f, k)$ on P . So if we are solving the latter problem, it is enough to solve the former one. In fact, when solving the problem $\mathcal{C}(f, k)$ on the point set P , we can assume

that P is (k, α) -irreducible, where $\alpha = \epsilon/1200k$. Indeed, suppose this is not the case. Let i be the highest integer such that P is (i, α) -irreducible. Then, $\text{OPT}_k(P) \leq (1 + 150k\alpha)^{k-i} \text{OPT}_i(P) \leq (1 + \epsilon/4) \text{OPT}_i(P)$. Therefore, if we can get a $(1 + \epsilon/4)$ -approximation algorithm for $\mathcal{C}(f, i)$ on input P , then we have a $(1 + \epsilon)$ -approximation algorithm for $\mathcal{C}(f, k)$ on P . Thus it is enough to solve instances which are irreducible.

The first property that we want $\mathcal{C}(f, k)$ to satisfy is a fairly obvious one – it is always better to assign a point in P to the nearest center. We state this more formally as follows :

Closeness Property : Let Q and Q' be two disjoint set of points, and let $q \in Q$. Suppose x and x' are two points such that $d(q, x) > d(q, x')$. Then the cost function f satisfies the following property

$$f(Q, x) + f(Q', x') \geq f(Q - \{q\}, x) + f(Q' \cup \{q\}, x').$$

This is essentially saying that in order to find a solution, it is enough to find the set of k centers. Once we have found the centers, the actual partitioning of P is just the Voronoi partitioning with respect to these centers. It is easy to see that the k -means problem and the k -median problem (both the continuous and the discrete versions) satisfy this property.

Definition 3. Given a set of points P and a set of k points C , let $\text{OPT}_k(P, C)$ be the cost of the optimal solution to $\mathcal{C}(f, k)$ on P when the set of centers is C .

We desire two more properties from $\mathcal{C}(f, k)$. The first property says that if we are solving $\mathcal{C}(f, 1)$, then there should be a simple random sampling algorithm. The second property says that suppose we have approximated the first i centers of the optimal solution closely. Then we should be able to easily extract a large number of points in P which get assigned to these centers. We describe these properties in more detail below :

- **Random Sampling Procedure :** There exists a procedure \mathcal{A} that takes a set of points $Q \in \mathbb{R}^d$ and a parameter α as input. \mathcal{A} first randomly samples a set R of size $(\frac{1}{\alpha})^{O(1)}$ points from Q . Starting from R , \mathcal{A} produces a set of points, which we call $\text{core}(R)$, of size at most $2(\frac{1}{\alpha})^{O(1)}$. \mathcal{A} satisfies the condition that with constant probability there is at least one point $c \in \text{core}(R)$ such that $\text{OPT}_1(Q, \{c\}) \leq (1 + \alpha) \text{OPT}_1(Q)$. Further the time taken by \mathcal{A} to produce $\text{core}(R)$ from R is at most $O(2(\frac{1}{\alpha})^{O(1)} \cdot dn)$.
- **Tightness Property :** Let P be a set of points which is (k, α) -irreducible for some constant α . Consider an optimal solution to $\mathcal{C}(f, k)$ on P – let $C = \{c_1, \dots, c_k\}$ be the centers in this solution. Suppose we have a set of i points $C'_i = \{c'_1, \dots, c'_i\}$, such that $\text{OPT}_k(P, C') \leq (1 + \alpha/k)^i \text{OPT}_k(P)$, where $C' = \{c'_1, \dots, c'_i, c_{i+1}, \dots, c_k\}$. Let P'_1, \dots, P'_k be the partitioning of P if we choose C' as the set of centers (in other words this is the Voronoi partitioning of P with respect to C'). We assume w.l.o.g. that P'_{i+1} is the largest cluster amongst P'_{i+1}, \dots, P'_k . Then there exists a set of points S such that the following conditions hold :

- (a) S is contained in $P'_1 \cup \dots \cup P'_i$.
- (b) Let $x \in S, x' \in P - S$. Then, $d(x, \{c'_1, \dots, c'_i\}) \leq d(x', \{c'_1, \dots, c'_i\})$.
- (c) $P - S$ contains at most $\frac{|P'_{i+1}|}{\alpha^{O(1)}}$ points of $P'_1 \cup \dots \cup P'_i$.

3 A General Algorithm for Clustering

We can show that if a clustering problem $\mathcal{C}(f, k)$ satisfies the conditions stated in the previous section, then there is an algorithm which with constant probability produces a solution within $(1 + \varepsilon)$ factor of the optimal cost. Further the running time of this algorithm is $O(2^{\frac{k}{\varepsilon}})^{O(1)} \cdot dn$. The techniques are very similar those in [14] and are omitted. We now give applications to various clustering problems. We show that these clustering problems satisfy the tightness property and admit a random sampling procedure as described in the previous section.

4 The k -Median Problem

As described earlier, the clustering problem $\mathcal{C}(f, k)$ is said to be the k -median problem if $f(Q, x) = \sum_{q \in Q} d(q, x)$. We now exhibit the two properties for this problem.

4.1 Random Sampling Procedure

Badoiu et al. [3] showed that a small random sample can be used to get a close approximation to the optimal 1-median solution. Given a set of points P , let $\text{AvgMed}(P)$ denote $\frac{\text{OPT}_1(P)}{|P|}$, i.e., the average cost paid by a point towards the optimal 1-median solution.

Lemma 1. [3] *Let P be a set of points in \mathbb{R}^d , and ε be a constant between 0 and 1. Let X be a random sample of $O(1/\varepsilon^3 \log 1/\varepsilon)$ points from P . Then with constant probability, the following two events happen: (i) The flat $\text{span}(X)$ contains a point x such that $\text{OPT}_1(P, \{x\}) \leq (1 + \varepsilon)\text{OPT}_1(P)$. and (ii) X contains a point y at distance at most $2\text{AvgMed}(P)$ from x .*

We now show that if we can upper and lower bound $\text{AvgMed}(P)$ upto constant factors, then we can construct a small set of points such that at least one of these is a good approximation to the optimal center for the 1-median problem on P .

Lemma 2. *Let P be a set of points in \mathbb{R}^d and X be a random sample of size $O(1/\varepsilon^3 \log 1/\varepsilon)$ from P . Suppose we happen to know numbers a and b such that $a \leq \text{AvgMed}(P) \leq b$. Then, we can construct a set Y of $O(2^{(1/\varepsilon)^{O(1)}} \log(b/\varepsilon a))$ points such that with constant probability there is at least one point $z \in X \cup Y$ satisfying $\text{OPT}_1(P, \{z\}) \leq (1 + 2\varepsilon)\text{OPT}_1(P)$. Further, the time taken to construct Y from X is $O(2^{(1/\varepsilon)^{O(1)}} d)$.*

Proof. Our construction is similar to that of Badoiu et al. [3]. We can assume that the result stated in Lemma 1 holds (because this happens with constant probability). Let x and y be as in Lemma 1.

We will carefully construct candidate points around the points of X in $\text{span}(X)$ in an effort to get within close distance of x .

For each point $p \in X$, and each integer i in the range $[\lceil \log_{\frac{\varepsilon}{4}} a \rceil, \lceil \log b \rceil]$ we do the following – let $t = 2^i$. Consider the grid $G_p(t)$ of side length $\varepsilon t / (4|X|) = O(t\varepsilon^4 \log(1/\varepsilon))$ in $\text{span}(X)$ centered at p . We add all the vertices of this grid lying within distance at most $2t$ from p to our candidate set Y . This completes the construction of Y . It is easy to see that the time taken to construct Y from X is $O(2^{(1/\varepsilon)^{O(1)}} d)$.

We now show the existence of the desired point $z \in X \cup Y$. Consider the following cases:

1. $d(y, x) \leq \varepsilon \text{AvgMed}(P)$: Using triangle inequality, we see that

$$f(P, y) \leq f(P, x) + |P|d(y, x) \leq (1 + 2\varepsilon)\text{OPT}_1(P).$$

Therefore y itself is the required point.

2. $d(y, x) > \varepsilon \text{AvgMed}(P)$: Consider the value of i such that $2^{i-1} \leq \text{AvgMed}(P, 1) \leq 2^i$ – while constructing Y , we must have considered this value of i for all points in X . Let $t = 2^i$. Clearly, $t/2 \leq \text{AvgMed}(P) \leq t$.

Observe that $d(y, x) \leq 2\text{AvgMed}(P) \leq 2t$. Therefore, by the manner in which we have constructed $G_y(t)$, there must be a point $p \in G_y(t)$ for which $d(p, x) \leq \varepsilon t/2 \leq \varepsilon \text{AvgMed}(P)$. This implies that

$$f(P, p) \leq f(P, x) + |P|d(x, p) \leq (1 + 2\varepsilon)\text{OPT}_1(P).$$

Therefore p is the required point.

This completes the proof of the lemma.

We now show the existence of the random sampling procedure.

Theorem 1. *Let P be a set of n points in \mathbb{R}^d , and let ε be a constant, $0 < \varepsilon < 1/12$. There exists an algorithm which randomly samples a set R of $O((\frac{1}{\varepsilon})^{O(1)})$ points from P . Using this sample only, it constructs a set of points $\text{core}(R)$ such that with constant probability there is a point $x \in \text{core}(R)$ satisfying $f(P, x) \leq (1 + O(\varepsilon))\text{OPT}_1(P)$. Further, the time taken to construct $\text{core}(R)$ from R is $O(2^{(1/\varepsilon)^{O(1)}} d)$.*

Proof. Consider the optimal 1-median solution for P – let c be the center in this solution. Let T denote $\text{AvgMed}(P)$. Consider the ball B_1 of radius T/ε^2 around c . Let P' be the points of P contained in B_1 . It is easy to see that $|P'| \geq (1 - \varepsilon^2)n$.

Sample a point p at random from P . With constant probability, it lies in P' . Randomly sample a set Q of $1/\varepsilon$ points from P . Again, with constant probability, these points lie in P' . So we assume that these two events happen. Let $v = \sum_{q \in Q} d(q, p)$. We want to show that v is actually close to $\text{AvgMed}(P)$.

Let B_2 denote the ball of radius εT centered at p . One of the following two cases must happen :

- There are at least $2\varepsilon|P'|$ points of P' outside B_2 : In this case, with constant probability, the sample Q contains a point outside B_2 . Therefore, $v \geq \varepsilon T$. Also notice that any two points in B_1 are at distance at most $2T/\varepsilon^2$ from each other. So, $v \leq 2T|Q|/\varepsilon^2$. We choose $a = \frac{v\varepsilon^2}{2|Q|}$ and $b = v/\varepsilon$. Notice that b/a is $O(1/\varepsilon^{O(1)})$. We can now use the Lemma 2 to construct the desired core set.
- There are at most $2\varepsilon|P'|$ points of P' outside B_2 : Suppose $d(p, c) \leq 4\varepsilon T$. In this case $f(P, p) \leq (1 + O(\varepsilon))\text{OPT}_1(P)$ and we are done. So assume this is not the case. Note that the number of points outside B_2 is at most $|P - P'| + 2\varepsilon|P'| \leq \varepsilon^2 n + 2\varepsilon(1 - \varepsilon^2)n \leq 3\varepsilon n$. Now suppose we assign all points of P from c to p . Let us see the change in cost. The distance the points in B_2 have to travel decreases by at least $d(c, p) - 2\varepsilon T$. The increase in the distance for points outside B_2 is at most $d(c, p)$. So the overall decrease in cost is at least

$$|B_2|(d(c, p) - 2\varepsilon T) - (n - |B_2|)d(c, p) > 0$$

if we use $|B_2| \geq n(1 - 3\varepsilon)$ and $d(c, p) \geq 4\varepsilon T$. This yields a contradiction because c is the optimal center. Thus we are done in this case as well.

4.2 Tightness Property

We now show the existence of tightness property. We will use the same notation as used while defining the tightness property in Section 2. We need to show the existence of the desired set S .

Consider the closest pair of centers between the sets $C' \setminus C'_i$ and C'_i – let these centers be c_l and c'_r respectively. Let $t = d(c_l, c'_r)$. Let S be the set of points $\mathcal{B}(c'_1, t/4) \cup \dots \cup \mathcal{B}(c'_i, t/4)$, i.e., the points which are distant at most $t/4$ from $C'_i = \{c'_1, \dots, c'_i\}$.

Clearly, S is contained in $P'_1 \cup \dots \cup P'_i$. This shows (a). Also, for any $x \in S, x' \in P - S, d(x, \{c'_1, \dots, c'_i\}) \leq d(x', \{c'_1, \dots, c'_i\})$. This proves (b).

Suppose $P - S$ contains more than $|P_l|/\alpha$ points of $P'_1 \cup \dots \cup P'_i$. In that case, these points are assigned to centers at distance at least $t/4$. It follows that $\text{OPT}_k(P, C')$ is at least $\frac{t|P_l|}{4\alpha}$. This implies that $t|P_l| \leq 4\alpha \text{OPT}_k(P, C')$. But then if we assign all the points in P_l to c'_r , the cost increases by at most

$$|P_l|t \leq 4\alpha \text{OPT}_k(P, C') \leq 4\alpha(1 + \alpha/k)^i \text{OPT}_k(P) \leq 4\alpha(1 + \alpha/k)^k \text{OPT}_k(P) \leq 12\alpha \text{OPT}_k(P).$$

But this contradicts the fact that P is (k, α) -irreducible.

4.3 Applications to the 1-Median Problem

In this section, we present an algorithm for the 1-median problem. Given a set of n points in \mathbb{R}^d , the algorithm with constant probability produces a solution of cost at most $(1 + \varepsilon)$ of the optimal cost for any constant $\varepsilon > 0$. The running time of the algorithm is $O(2^{1/\varepsilon^{O(1)}} d)$, assuming that it is possible to randomly sample a point in constant time.

Our algorithm is based on the following idea presented by Indyk [12].

Lemma 3. [12] Let X be a set of n points in \mathbb{R}^d . For a point $a \in \mathbb{R}^d$ and a subset $Q \subseteq X$, define $S_Q(a) = \sum_{x \in Q} d(a, x)$ and $S(a) = S_X(a)$. Let ε be a constant, $0 \leq \varepsilon \leq 1$. Suppose a and b are two points such that $S(b) > (1 + \varepsilon)S(a)$. Then,

$$\Pr \left(\sum_{x \in Q} d(a, x) \geq \sum_{x \in Q} d(b, x) \right) < e^{-\varepsilon^2 |Q| / 64}.$$

We now show the existence of a fast algorithm for approximating the optimal 1-median solution.

Theorem 2. Let P be a set of n points in \mathbb{R}^d , and let ε be a constant, $0 < \varepsilon < 1$. There exists an algorithm which randomly samples a set R of $O((\frac{1}{\varepsilon})^{O(1)})$ points from P . Using this sample only, it finds a point p such that $f(P, p) \leq (1 + O(\varepsilon))\text{OPT}_1(P)$ with constant probability (independent of ε). The time taken by the algorithm to find such a point p from R is $O(2^{(1/\varepsilon)^{O(1)}} d)$.

Proof. We first randomly sample a set R_1 of $O((\frac{1}{\varepsilon})^{O(1)})$ points from P and using Theorem 1, construct a set $\text{core}(R_1)$ of $O(2^{(1/\varepsilon)^{O(1)}})$ points such that with constant probability, there is a point $x \in \text{core}(R_1)$ satisfying $f(P, x) \leq (1 + O(\varepsilon))\text{OPT}_1(P)$.

Now we randomly sample a set R_2 of $O((1/\varepsilon)^{O(1)})$ points and find the point $p \in \text{core}(R_1)$ for which $S_{R_2}(p) = f(R_2, p)$ is minimum. By Lemma 3, p is with constant probability a $(1 + O(\varepsilon))$ -approximate median of P .

Clearly, the time taken by the algorithm is $O(2^{(1/\varepsilon)^{O(1)}} d)$.

Also note that we can boost the success probability to an arbitrarily small constant by selecting a large enough (yet constant) sample R .

5 k -Means Clustering

In this problem, $f(Q, x) = \sum_{q \in Q} d(q, x)^2$. The two properties for the k -means problem were shown by the authors in [14]. For a set of points T , let $c(T)$ denote their centroid. The random sampling property follows from the following fact showed by Inaba et al. [11].

Lemma 4. [11] Let T be a set of m points obtained by independently sampling m points uniformly at random from a point set P . Then, for any $\delta > 0$,

$$f(S, c(T)) < \left(1 + \frac{1}{\delta m}\right) \text{OPT}_1(P)$$

holds with probability at least $1 - \delta$.

The proof of tightness property is similar to that for the k -median problem.

6 Discrete k -Means Clustering

This is same as k -means problem with the extra constraint that the centers must be from the input point set only. We now show the two properties here.

6.1 Random Sampling Procedure

We first show that given a good approximation to the center of the optimal (continuous) 1-means problem, we can get a good approximation to the center of the optimal discrete 1-means problem. Let us have some notation first. Let P be a set of n points in \mathbb{R}^d . Let c be the center of the optimal solution to the (continuous) 1-means problem on P .

Lemma 5. *Let α be a constant, $0 < \alpha < 1$, and c' be a point in \mathbb{R}^d such that $\sum_{p \in P} d(p, c')^2 \leq (1 + \alpha) \sum_{p \in P} d(p, c)^2$. Let x' be the point of P closest to c' . Then $\text{OPT}_1(P, \{x'\}) \leq (1 + O(\sqrt{\alpha}))\text{OPT}_1(P)$.*

Proof. Let x be the center of the optimal discrete 1-means solution, i.e., $\text{OPT}_1(P, \{x\}) = \text{OPT}_1(P)$. Let T be the average cost paid by the points of P in the optimal 1-means solution, i.e., $T = \frac{\sum_{p \in P} d(p, c)^2}{|P|}$.

Then $\text{OPT}_1(P) = |P|(T + d(c, x)^2)$ and $\text{OPT}_1(P, \{x'\}) = |P|(T + d(c, x')^2)$. From the definition of c' , we know that $d(c, c')^2 \leq \alpha T$. Notice that

$$d(c, x') \leq d(c, c') + d(c', x') \leq d(c, c') + d(c', x) \leq 2d(c, c') + d(c, x).$$

We know that $f(P, x) = |P|(T + d(c, x)^2)$ and $f(P, x') = |P|(T + d(c, x')^2)$. So

$$\begin{aligned} f(P, x') - f(P, x) &= |P|(d(c, x')^2 - d(c, x)^2) \leq |P|((2d(c, c') + d(c, x))^2 - d(c, x)^2) \\ &\leq 4|P|(d(c, c')^2 + d(c, c')d(c, x)) \leq 4|P|(\alpha T + \sqrt{\alpha T}d(c, x)) \\ &\leq 4|P|(\alpha T + \sqrt{\alpha}(T + d(c, x)^2)) \leq O(\sqrt{\alpha})\text{OPT}_1(P). \end{aligned}$$

We now show the existence of the random sampling procedure.

Theorem 3. *Let α be a constant, $0 < \alpha < 1$. There exists an algorithm which randomly samples a set R of $O(\frac{1}{\alpha})$ points from P . Using this sample, it finds a singleton set $\text{core}(R)$ such that with constant probability the point $x \in \text{core}(R)$ satisfies $f(P, x) \leq (1 + O(\sqrt{\alpha}))\text{OPT}_1(P)$. Further, the time taken to construct $\text{core}(R)$ from R is $O((\frac{1}{\alpha} + n)d)$.*

Proof. Using Lemma 4, we can get a point c' such that $\sum_{p \in P} d(p, c')^2 \leq (1 + \alpha) \sum_{p \in P} d(p, c)^2$. As mentioned in the lemma, we do this by taking the centroid of a random sample of $O(1/\alpha)$ points of P . This takes time $O(\frac{1}{\alpha} \cdot d)$.

The rest follows from the previous lemma.

6.2 Tightness Property

We now show the existence of tightness property. We will use the same notation as used while defining the tightness property in Section 2. We need to show the existence of the desired set S .

Consider the closest pair of centers between the sets $\{c'_1, \dots, c'_i\}$ and $\{c_{i+1}, \dots, c_k\}$ – let these centers be c'_r and c_l respectively. Let $t = d(c_l, c'_r)$. Let S be the set of points $\mathcal{B}(c'_1, t/4) \cup \dots \cup \mathcal{B}(c'_i, t/4)$, i.e., the points which are distant at most $t/4$ from $C'_i = \{c'_1, \dots, c'_i\}$.

Clearly, S is contained in $P'_1 \cup \dots \cup P'_i$. This shows (a). Also, for any $x \in S, x' \in P - S$, $d(x, \{c'_1, \dots, c'_i\}) \leq d(x', \{c'_1, \dots, c'_i\})$. This proves (b).

Suppose $P - S$ contains more than $|P_l|/\alpha^2$ points of $P'_1 \cup \dots \cup P'_i$. In that case, these points are assigned to centers at distance at least $t/4$. It follows that $\text{OPT}_k(P, C')$ is at least $\frac{t^2|P_l|}{16\alpha^2}$. This implies that $t^2|P_l| \leq 16\alpha^2 \text{OPT}_k(P, C')$.

Let m_l and m'_r be the centers of the optimal (continuous) 1-means solution of P_l and P'_r respectively. Let T_l and T'_r be the average cost paid by P_l and P'_r in this optimal solution respectively, i.e., $T_l = \frac{\sum_{p \in P_l} d(p, m_l)^2}{|P_l|}$ and $T'_r = \frac{\sum_{p \in P'_r} d(p, m'_r)^2}{|P'_r|}$. Observe that $f(P_l, c_l) = |P_l|(T_l + d(c_l, m_l)^2)$ and $f(P_l, c'_r) = |P_l|(T_l + d(c'_r, m_l)^2)$. Therefore, if we assign the points in P_l from c_l to c'_r , the increase in cost is

$$\begin{aligned} |P_l| (d(c'_r, m_l)^2 - d(c_l, m_l)^2) &\leq |P_l| ((d(c'_r, c_l) + d(c_l, m_l))^2 - d(c_l, m_l)^2) \\ &\leq |P_l| (t^2 + 2td(c_l, m_l)) \end{aligned}$$

We know that the first term above, i.e., $|P_l|t^2$ is at most $16\alpha^2 \text{OPT}_k(P, C')$. We now need to bound the second term only. We consider two cases

- $t \leq \alpha d(c_l, c_m)$: In this case, $|P_l| \cdot 2td(c_l, m_l) \leq 2\alpha d(c_l, m_l)^2 |P_l| \leq 2\alpha f(P_l, c_l) \leq 2\alpha \text{OPT}_k(P, C')$.
- $t > \alpha d(c_l, c_m)$: In this case, $|P_l| \cdot 2td(c_l, m_l) \leq \frac{2t^2|P_l|}{\alpha} \leq 32\alpha \text{OPT}_k(P, C')$.

Thus, in either case, the cost increases by at most

$$48\alpha \text{OPT}_k(P, C') \leq 48\alpha(1+\alpha/k)^i \text{OPT}_k(P) \leq 48\alpha(1+\alpha/k)^k \text{OPT}_k(P) \leq 144\alpha \text{OPT}_k(P).$$

But this contradicts the fact that P is (k, α) -irreducible.

7 Concluding Remarks

The framework in this paper can be extended to handle the situation when each of the points has an associated (integral) weight. The solution to the above clustering problems for the weighted version is the same as the solution to the unweighted version where a point p with weight w is replaced by w points of unit weight. It can be verified that for handling the weighted case: the closeness property remains unchanged; in condition (c) for the tightness property, the size of the set gets replaced by the weight of the set; The random sampling procedure requires time at most linear in n (number of remaining distinct points) in order to perform the required weighted sampling.

The running time thus obtained for the algorithm in the weighted case is $O(2^{(k/\varepsilon)^{O(1)}} n \cdot d \log^k W)$ where W is the sum of all the weights.

Abstract. We consider the problem of dynamic load balancing in arbitrary (connected) networks on n nodes. Our load generation model is such that during each round, n tasks are generated on arbitrary nodes, and then (possibly after some balancing) one task is deleted from every non-empty node. Notice that this model *fully saturates* the resources of the network in the sense that we generate just as many new tasks per round as the network is able to delete. We show that even in this situation the system is *stable*, in that the total load remains bounded (as a function of n alone) over time. Our proof only requires that the underlying “communication” graph be connected. (It of course also works if we generate less than n new tasks per round, but the major contribution of this paper is the fully saturated case.) We further show that the upper bound we obtain is asymptotically tight (up to a moderate multiplicative constant) by demonstrating a corresponding lower bound on the system load for the particular example of a linear array (or path). We also show some simple negative results (i.e., instability) for work-stealing based diffusion-type algorithms in this setting.

1 Introduction

The use of parallel and distributed computing is established in many areas of science, technology, and business. One of the most crucial parameters of parallel machines is the efficient utilization of resources. Of greatest importance here is an even distribution of the workload among the processors. In particular applications exposing some kind of “irregularity” require the use of a load balancing mechanism.

A well known and much studied load balancing approach is the so-called *diffusion load balancing*, first introduced by Cybenko and Boillat ([11], [10]). The algorithm works in synchronized rounds. The basic idea is that in every

* A portion of this work was performed during a visit to the School of Computing Science at Simon Fraser University. Supported in part by the EPSRC grant “Discontinuous Behaviour in the Complexity of Randomized Algorithms”.

round, every processor p balances load with all its neighbors (independently, i.e., pair-wise). Let ℓ_p be the load of p , ℓ_q the load of some of p 's neighbor q , and let Δ denote the maximum degree of the underlying graph. In the discrete setting, p transfers $\max\{0, \lfloor (\ell_p - \ell_q) / (\Delta + 1) \rfloor\}$ tasks to q . Some of many advantages of diffusion-type algorithms are the *locality* (no global knowledge regarding the overall load situation, or, in fact, anything except the strict neighborhood of any vertex is needed), its *simplicity*, and its *neighborhood preservation* (tasks tend to stay close to the processors where they are generated, which may help to maintain small communication overhead).

The diffusion load balancing algorithm has been thoroughly analyzed for *static* scenarios, where each processor has some initial number of tasks, and the objective is to distribute *this* load evenly among the processors as quickly as possible. Much work has been done under the assumption that every edge is only allowed to forward one task per round [16, 17, 19] or when a constant number of tasks can be passed by each processor [15]. We refer to these scenarios as *token distribution problems*. In addition [12, 13, 14] have studied the diffusion algorithm where tasks can be split arbitrarily.

In contrast to the static case of load balancing and token distribution, in the dynamic setting during each time step new tasks are generated (in some manner) on the set of processors, load is balanced amongst neighbors, then tasks are deleted from non-empty processors.

Much of the past work has studied the dynamic token distribution problem. Muthukrishnan and Rajaraman [18] studied a dynamic version where processors can forward a single task in each round. They assume an adversarial load generation model. The adversary is allowed to generate and to delete tokens from the network in every round. The simple and elegant algorithm they consider is due to [2]: A node sends a task to its neighbor if the load difference between them is at least $2\Delta + 1$. They show that the system is stable if the load change in every subset S of the nodes minus $a|S|$ is at most $(1 - \epsilon)e(S)$ for $\epsilon > 0$. Here $e(S)$ is the number of outgoing edges of S and a is the change in the average load. Their system is said to be stable if the deviation of the load of any processor from the average load can be bounded. Muthukrishnan and Rajaraman left open the question whether the system is also stable for $\epsilon = 0$.

Anshelevich, Kempe, and Kleinberg [4] gave a positive result for token distribution when $\epsilon = 0$. They showed that under the above load generation model no processor has more than average load $\pm(2\Delta + 1) \cdot n$. Anshelevich, et al. also showed how their result can be generalized for edges that can forward c tokens per time step. A node sends $\min\{c, \rho\}$ tasks to its neighbor if the load difference is at least $2\Delta c + \rho$. In this setting no processor has more than average load $\pm(2\Delta + 1)c \cdot n$ as long as the load change in every subset S of the nodes minus $a|S|$ is at most $c \cdot e(S)$. Additionally, they showed that a generalization of the algorithm is stable for two distinct types of jobs, and they extended their results to related flow problems.

In [6, 7] Awerbuch and Leighton use a variant of the token distribution model under the assumption that tokens can be split into arbitrarily sized parts. They

use a “balancing” algorithm to approximate the multi-commodity flow problem with capacitated edges. Their method is an iterative approach where flow is queued at the vertices of the graph. In each step, the commodity which has the largest excess is shipped from one vertex to another, and then new flow is injected into the system. In this balancing process, edge capacities must always be respected. These edge capacities are analogous to the restrictions on the number of tasks that can be passed over any single edge in the token distribution problems. Furthermore, their model does not actually allow full use of those edge capacities, which is similar to the case in [18] where $\epsilon > 0$ was required to ensure stability. The work in [1] and [5] expands the results of Awerbuch and Leighton for packet routing, but again in these cases only a constant number of tasks can be moved across any edge in a single time step.

Clearly the condition that processors can forward only a single task (or a constant number) per edge in each round significantly restricts the number and distribution of tasks that can be generated on (or deleted from) processors in each round and still obtain a stability result. Thus, in the results of [18] and [4] some dependence on the quantity $e(S)$ (or some measure of the “edge expansion”) is to be expected.

Anagnostopoulos et al. [3] consider the setting where there are no restrictions on the number of tasks balanced between processors in a time step, and they allow a broad range of injection models. Their protocol is similar to that studied in [15] for a static setting, but is not the typical diffusion load balancing procedure. In their setting, in each step nodes are matched randomly with adjacent neighbors and matched nodes equalize their load. Hence, every processor is only involved in a single load balancing action. They show that the system is stable as long as at most $wn\lambda$ tasks (in expectation) are generated in a time interval of length w , where $\lambda < 1$. Their proof method unfortunately cannot be generalized to the case of *full saturation* when $\lambda = 1$, which is the main focus of this paper.

1.1 Our Results

In this paper we present the first analysis of the simple diffusion scheme for the dynamic load balancing problem that allows full saturation of the resources. We assume that n new tasks are generated per round and, after load balancing, every non-empty processor deletes one task each round. (With small modifications our proofs will carry through to the case when we generate *at most* n tasks per round.) In contrast to [4] and [18], the newly generated tasks may be arbitrarily distributed among the nodes of the network, regardless of any “edge expansion” type of condition as in those models. For example, the tasks may always be generated on the same processor, or all tasks may be generated on one processor but the processor can change from round to round, or alternatively, the tasks may be allocated at random each round. Note that, obviously, without load balancing the total number of tasks in the system may grow unboundedly with time (in the worst case, we generate n new tasks per step but delete only one).

We show that the system of processors is *stable* under the diffusion load balancing scheme and the generation model described above. By stable, we mean

that the total load in the system does not grow with time. In particular, we show that the total system load can be upper-bounded by $O(\Delta n^3)$, where Δ denotes the maximum degree of the network. Furthermore, we present a simple, asymptotically matching lower bound when the network is a path.

Our technique also captures a different scenario, similar to that in [4, 18], where stability is defined in terms of deviation of any processor's load from the average. In this scenario we have two separate phases, the first where tasks are generated on and/or deleted from nodes, and the second where tasks are then balanced amongst nodes. Let $\bar{L}^t(S)$ denote the total load of the nodes in the set S after the task generation/deletion phase, and $L^t(S)$ denote the total load of S after the balancing step at time t . Assume that the generation/deletion phase satisfies the following condition:

$$(L(S)^t - \bar{L}(S)^{t-1}) \leq (\text{avg}(t) - \text{avg}(t-1)) \cdot |S| + \rho,$$

where $\text{avg}(t)$ denotes the average system load in step t . Then the total load of S can be bounded by $|S| \cdot \text{avg}(t) + 5\Delta n\rho$.

For both proofs of our results we use a potential function. Although the potential function we use looks similar to the one used in [4], the proof technique is very different. The proof method in [4] very much relies upon the restriction of their generation/deletion model, where the number of tasks inserted into/deleted from a set S is bounded by a function of $e(S)$, the number of edges that join the set S to its complement \bar{S} . This, together with the bounded capacities on the edges of the graph, allows for a direct analysis of how the loads of sets might change in a single step of their process. The arbitrary distribution of tasks in our generation model and the unrestricted capacity of the edges in our network (i.e. unknown bounds on load transferred into a set S in a single step) does not allow us to directly obtain similar results, so we need a different proof to show stability under our model.

Another approach to show our results would be to demonstrate an upper bound on the number of tasks that can be moved over a single edge during any time step of our algorithm. If this is possible, the results in [4] could then be used to prove stability under either model that we have described. However, the authors of this paper feel that showing this result is not easier than the proof method we used, especially in the second model where the number of tasks inserted into the system at any time can be unbounded.

In the final part of our paper we discuss a different method of load balancing, one which is commonly referred to as *work stealing*. In this framework, processors that are empty after task generation will balance with processors that are not empty, but no other balancing actions are permitted.

We show that for this work-stealing protocol there are graphs for which the system cannot be stable for a significant class of generation parameters. These results show that restricting balancing actions to empty processors is not sufficient in general.

In contrast, Berenbrink, Friedetzky, and Goldberg [8] showed stability of a work stealing algorithm under a load generation model that is similar to many

of those already mentioned. They consider a flexible distribution of n generators among the nodes of the network, where each generator is allowed to generate a task with probability *strictly smaller* than one. In this setting a very simple, parameterized work-stealing algorithm achieves stability (in our sense) for a wide range of parameters. The important point to note is that their model applies only when the set of processors (and their communication linkages) forms a complete graph, and their results only hold for the case where strictly less than n tasks (in expectation) are generated during any time step.

Our model is defined in the next section, and the formal definition of the diffusion approach to load balancing is given following that.

1.2 Our Model

Our parallel system is modeled by a connected graph $G = (V, E)$. The nodes V of the graph model our processors $\mathcal{P} = \{P_1, \dots, P_n\}$, and the edges E model the underlying communication structure. If two nodes are connected with each other, this means that the processors modeled by the nodes can communicate directly. For us, this means that they are allowed to exchange tasks. Nodes not connected by an edge have to communicate via message passing. Furthermore, let Δ be the maximum degree of the graph. We assume that each processor maintains a queue in which yet-to-be-processed tasks are stored. One round looks as follows:

1. n generators are arbitrarily distributed over the processors, and each generator generates one task at the beginning of every time round. For $1 \leq i \leq n$, let $k_i^t = j$ if generator i is allocated to processor P_j in round t , and $k_i^t = 0$ if the generator is not allocated to any processor in that round.
2. Every processor balances its load with some or all its neighbors in the network (according to a well-defined scheme for doing this operation).
3. Every non-empty processor deletes one task.

Let $\hat{\ell}_i^t$ be the load of P_i directly after the load deletion phase in round t . A system is called *stable* if the number of tasks $\hat{L}^t(\mathcal{P}) = \sum_{i=1}^n \hat{\ell}_i^t$ that are in the system at the end of round t does not grow with time, i.e. the total load $\hat{L}^t(\mathcal{P})$ is bounded by a number that might depend on n , but not on the time t .

We will mainly focus on one load balancing method called the *diffusion approach*. Every processor is allowed to balance its load with all its neighbors. As mentioned previously, we briefly consider a second approach in Section 4 where only empty processors are allowed to take load from their non-empty neighbors. We call this second method the *work stealing approach*.

Diffusion approach. We begin with a detailed description of the first approach, an integral variant of the *First Order Diffusion scheme*. Let $\hat{\ell}_i^t$ be the load of processor P_i directly before the load balancing phase, and ℓ_i^t the load directly after the load balancing phase. Let $\alpha_{i,j}^t$ be the load that is to be sent from P_i to P_j in round t for $(i, j) \in E$ ($\alpha_{i,j}^t = 0$ otherwise). Then $\alpha_{i,j}$ and ℓ_i are calculated as follows:

$$\alpha_{i,j}^t := \max \{0, \lfloor (\bar{\ell}_i^t - \bar{\ell}_j^t) / 2\Delta \rfloor \} \quad \ell_i^t := \bar{\ell}_i^t - \sum_{(i,j) \in E} \alpha_{i,j}^t + \sum_{(j,i) \in E} \alpha_{j,i}^t.$$

To compute $\hat{\ell}_i^t$, the load of processor P_i after load deletion, it remains to subtract one if $\ell_i^t > 0$, thus $\hat{\ell}_i^t := \max\{0, \ell_i^t - 1\}$. Note that the “standard” diffusion approach divides $\bar{\ell}_i^t - \bar{\ell}_j^t$ by $\Delta + 1$ instead of 2Δ . We need the 2Δ for our analysis.

Our main contributions are as follows. In Section 2, we prove Theorem 1, which states that we can upper-bound the total system load by $3\Delta n^3$. This generalizes the results of [4] to the case of unbounded edge capacities and, hence, analyzes the standard diffusion approach. Theorem 8 in Section 3 provides an asymptotically matching lower bound, showing that our upper bound is tight, up to a multiplicative constant. In Section 4 we discuss the problem of combining the diffusion-approach with the work-stealing approach and show that certain assumptions necessarily lead to instability.

2 Analysis of the Dynamic Diffusion Algorithm

In this section we will show that the diffusion approach yields a stable system. Moreover, we are able to upper bound the maximum load that will be in the system by $O(\Delta n^3)$. Throughout, we assume that $n \geq 2$ and $\Delta \geq 2$. Apart from what has been defined above, we will also use notation like $\bar{L}^t(S) = \sum_{i: P_i \in S} \bar{\ell}_i^t$ for a subset $S \subseteq \mathcal{P}$, with similar definitions for $L^t(S)$ and $\hat{L}^t(S)$. Our main result about the diffusion approach to load balancing is

Theorem 1. *Let $n \geq 2$ denote the number of processors in the system, and an upper bound on the number of tasks that are generated during each time round. Let $\Delta \geq 2$ denote the maximum degree of the graph G that specifies the communication linkages in the network. Then, starting with an empty system, for all $t \geq 1$ we have $\hat{L}^t(\mathcal{P}) = \sum_{i=1}^n \hat{\ell}_i^t \leq 3\Delta n^3$.*

We will prove this theorem by first giving a series of preliminary results. The proof of Theorem 1 uses a similar potential function as the one that was used in [4] (though what follows is very different). This idea is to prove an invariant that for all $t \geq 1$, every subset $S \subseteq \mathcal{P}$ satisfies the following inequality:

$$\hat{L}^t(S) \leq \sum_{i=n-|S|+1}^n i \cdot (4\Delta) \cdot n. \quad (1)$$

Then, Inequality (1) will immediately imply Theorem 1 (by taking $S = \mathcal{P}$). We will often have occasion to refer to the right hand side of Inequality (1) for many sets, so to make our proofs that follow easier to read, we define the following function $f : \{1, \dots, n\} \rightarrow \mathbb{N}$ in this way

$$f(k) = \sum_{i=n-k+1}^n i \cdot (4\Delta) \cdot n. \quad (2)$$

Definition 2. *In what follows, we will refer to sets as being bad after load generation in round t , or after the load balancing phase of round t , etc., meaning that the load of the set at that particular time violates Inequality (1). For example, if we say that a set S is bad after load generation in round t , we mean that $\bar{L}^t(S) > f(|S|)$.*

Conversely, we will also refer to a set as being good (after load generation, or load balancing, etc.) if it satisfies Inequality (1) (at the time in question).

The first lemma states that if we consider any (non-empty) set S at the end of round t , there must have existed a set S' so that the load of S' before load balancing was at least as large as the load of S after load balancing, i.e. $\bar{L}^t(S') \geq L^t(S) \geq \hat{L}^t(S)$. The fact that might not be obvious is that we can assert that the two sets contain the same number of processors. This is the statement of the following lemma.

Lemma 3. *Let $\emptyset \neq S \subseteq \mathcal{P}$ denote an arbitrary subset of processors. There exists a set $|S'|$ such that*

1. $|S'| = |S|$, and
2. $\bar{L}^t(S') \geq L^t(S)$.

Proof. The claim is clear if $S = \mathcal{P}$, since in this case we have $L^t(\mathcal{P}) \geq \hat{L}^t(\mathcal{P})$ and $\bar{L}^t(\mathcal{P}) = L^t(\mathcal{P})$. Taking $S' = \mathcal{P}$ then satisfies the conclusions of the theorem.

So we suppose that S is not the entire set of processors. Then let $S_{in} = \{v : v \in S \text{ and } \exists w \notin S \text{ with } \alpha_{wv}^t > 0\}$. In other words, S_{in} is the subset of S consisting of processors that received tasks from *outside* of S during load balancing.

Case 1: $S_{in} = \emptyset$. This case is essentially the same as when $S = \mathcal{P}$. Since no processors in S received load from outside of S , the elements of S can only exchange load among themselves or send load to processors outside of S . Then it is clear that $\bar{L}^t(S) \geq L^t(S)$, so taking $S' = S$ again satisfies the desired conclusions.

Case 2: $S_{in} \neq \emptyset$. Let $R = \{w : w \notin S \text{ and } \exists v \in S_{in} \text{ with } \alpha_{wv}^t > 0\}$. In other words, R is the set of nodes *not* in S that pushed tasks into S during load balancing. The main idea of what follows is that we are going to swap some elements of R for elements of S_{in} on a one-for-one basis to find the set S' we desire. More formally, let $L_{in} = \sum_{w \in R, v \in S_{in}} \alpha_{wv}^t$ denote the total flow from R to S during load balancing. We aim to find sets $R_1 \subseteq R$ and $S_1 \subseteq S_{in}$ with (i) $|R_1| = |S_1|$, and (ii) $\bar{L}^t(R_1) \geq L^t(S_1) + L_{in} + (\text{flow from } S_1 \text{ to } S \setminus S_1)$. Then we will take $S' = S \setminus S_1 \cup R_1$. Our choice of the set R_1 guarantees that S' will satisfy $\bar{L}^t(S') \geq L^t(S)$, since the elements of R_1 account for all flow that enters S during load balancing, plus all flow that passes from elements in S_1 to elements in $S \setminus S_1$ as well.

To do this, let $E_1 = \{(w, v) : w \in R, v \in S_{in}, \alpha_{wv}^t > 0\}$. Consider an edge $e_1 = (w_1, v_1) \in E_0$ where $\alpha_{e_1}^t$ is largest. Then, from the definition of α_{wv}^t , we see that $\bar{\ell}_{w_1}^t \geq 2\Delta\alpha_{w_1v_1}^t + \ell_{v_1}^t$. The key observation is that by choosing the largest edge, the expression $\ell_{w_1}^t$ accounts for all possible load that v_1 could

have received during load balancing, *and* all tasks that w_1 pushes into the set S too (and any tasks that v_1 might happen to pass to other elements in S , since this is counted in the term $\bar{\ell}_{v_1}^t$). We set $R_1 := \{w_1\}$ and $S_1 := \{v_1\}$, and $E_2 = E_1 \setminus (\{(w_1, v') : v' \in S_{in}\} \cup \{(w', v_1) : w' \in R\})$.

Then, we iteratively apply this argument, i.e., take a largest edge $e_2 = (w_2, v_2) \in E_2$. (Note that $w_2 \neq w_1$ and $v_2 \neq v_1$.) The choice of largest edge then allows us to swap w_2 for v_2 , again accounting for all tasks that w_2 pushes into S during load balancing, all tasks that v_2 receives, and any tasks that v_2 passes to other elements in S . Then, we add w_2 to R_1 , i.e. $R_1 := R_1 \cup \{w_2\}$, add v_2 to S_1 , so $S_1 := S_1 \cup \{v_2\}$, and delete the appropriate set of edges from E_1 . Thus, $E_2 = E_1 \setminus (\{(w_2, v') : v' \in S_{in}\} \cup \{(w', v_2) : w' \in R\})$.

We continue to iterate this procedure, selecting an edge with largest α_{wv}^t value, and performing an exchange as before, until we finish step k with a set $E_k = \emptyset$. It is possible that this procedure terminates at a step when $R_1 = R$ or $S_1 = S_{in}$ (or both), or with one or both of R_1, S_1 being proper subsets of their respective sets. In any case, we have constructed sets R_1 and S_1 (each with $k \leq \min\{|S_{in}|, |R|\}$ elements), so that by taking $S' = (S \setminus S_1) \cup R_1$, this set S' satisfies the two conditions of the theorem.

From the previous lemma, we see that we have proven an inequality about the load of the sets of highest loaded processors, before and after load balancing (which, of course, need not be equal to each other). Thus we can conclude the following result:

Corollary 4. *For $i \in [n]$, let \bar{M}_i^t denote a set of i largest loaded processors before load balancing (in round t). Also let M_i^t denote a corresponding set of i largest loaded processors after load balancing. Then $\bar{L}^t(\bar{M}_i^t) \geq L^t(M_i^t)$.*

We also conclude another result from Lemma 3.

Corollary 5. *Fix $i \in \{1, \dots, n\}$. Suppose that every subset with i processors is good after the load generation phase of round t . Then, after the load balancing phase (and thus after the task deletion phase), every subset with i processors is still good. (Of course, provided that \bar{M}_i^t is good after load generation, we actually get the same conclusion from Corollary 4.)*

Our next result tells us that if a set is made bad by load generation, then the load balancing and deletion phases are sufficient to make that set good again. The proof is omitted due to space limitations.

Lemma 6. *Suppose that at the end of round t , every set $S \subseteq \mathcal{P}$ satisfies (1). Further, suppose that after the load generation phase in round $t + 1$, there is some set $S \subseteq \mathcal{P}$ such that $\bar{L}^{t+1}(S) > f(|S|)$. Then, at the end of round $t + 1$, S again satisfies Inequality (1).*

Lemma 6 tells us that if a set is made bad by the load generation phase, then the load balancing and deletion phases are sufficient to make this set good. The essential task that remains to be shown is that load balancing cannot, in some

way, change a good set into a bad one. Corollary 5 tells us half the story. We need a little more to cover all possible sets. The proof of the following lemma is omitted due to space limitations.

Lemma 7. *Suppose that all sets are good at the end of round t , but that after load generation in round $t + 1$, there exists a bad set S with $|S| = i$. Then after load balancing and deletion, there exists no bad set with i processors.*

Now we are prepared to prove our main result.

Proof. [**Theorem 1**] We prove this theorem by induction on t . Inequality (1) holds when $t = 1$, for however we inject the first n tasks into the system, all sets are good at the end of the first round. So assume that at the end of round t , all sets are good. Fix $i \in \{1, \dots, n\}$. If all sets of i processors are good after the load generation phase, then from Corollary 5 they are all good at the end of round $t + 1$. If there is some bad set of i processors after load generation, then Lemmas 6 and 7 show that all sets of size i are still good at the end of round $t + 1$. Finally, it is not possible that during load balancing a (good or bad) set of i processors will lead to the creation of a bad set of $j (\neq i)$ processors. For suppose there is some bad set of $j (\neq i)$ processors at the end of round $t + 1$. Lemma 3 tells us that there must exist a set of j processors that was bad before the load balancing phase, but then Lemmas 6 and 7 again tell us that there is no bad set of j processors at the end of round $t + 1$, a contradiction to our assumption that there was a bad set of j processors at the end of the round.

On the first glance it might look as if our proof strategy is overly complicated and that there is a much simpler proof. In the course of proving our result, we show that there is a gap of $4n\Delta$ tasks between a processor in the bad set S and a processor outside of the bad set before balancing whenever S is bad after balancing. Hence, at least n tasks were sent away from S in this step and the invariant could not have been violated by S . But unfortunately it is possible to create a different bad set of processors during load balancing (possibly with a different number of processors), and we have to discount this case too. Hence, we have to show that if we can find a bad set after load balancing, then there was another bad set S' before load balancing, which leads us to a contradiction through our series of lemmas above.

3 A Matching Lower Bound

In this section we provide a simple example that asymptotically matches the upper bound from Section 2. Consider the linear array $G = (V, E)$ with $V = \{P_0, \dots, P_{n-1}\}$ and $E = \{(P_i, P_{i+1}) | 0 \leq i < n - 1\}$. Furthermore, suppose that during every time step, n new tasks are generated on processor P_{n-1} .

Theorem 8 below implies that the preceding analysis of our algorithm is tight up to a multiplicative constant, because the line graph has maximum degree $\Delta = 2$, and thus we have an upper bound of $O(n^3)$ on the system load. The proof is omitted due to space constraints.

Theorem 8. *The system described above on the linear array is stable with a total steady-state system load of $\Theta(n^3)$.*

4 Some Instability Results for Work Stealing

In this section we will consider a variation of our load balancing process where we may transfer tasks to empty processors only. This method is usually referred to as *work stealing*. It is similar to the diffusion approach, only the computation of the $\alpha_{i,j}^t$ is different. The value of $\alpha_{i,j}^t$, the load that is sent from P_i to P_j , is larger than zero iff P_j is empty (and P_i non-empty). A frequently used transfer function is $\alpha_{i,j}^t = \lfloor \frac{\bar{\ell}_i^t}{\Delta+1} \rfloor$ and $\alpha_{i,j}^t = 0$ otherwise. Note that the result below also hold when we divide by 2Δ instead of $\Delta + 1$. We use the above definition as worst case assumption. In [8] the authors showed that simple work stealing yields a stable system. They assumed that there are at most $(1 - \epsilon)n$ new tasks generated per round, for some $\epsilon \in (0, 1]$. The important point to note is that in [8], the processor communication links correspond to a complete graph on n vertices. Here we will see that the work stealing method can fail (in the sense that the total load is unbounded over time) if the graph is no longer the complete graph. We consider the line network, i.e., nodes P_1, \dots, P_n and edges between nodes P_i and P_{i+1} for $1 \leq i \leq n - 1$. Hence, the maximum degree is 2. Due to space limitations, we state the following observation without proof.

Observation 9. *Assume we have n processors connected as a line and n generators are all on processor 1. Then the diffusion work stealing system is not stable.*

In a similar manner, under adversarial injection schemes, it is easy to show that the work stealing protocol will not be stable for many classes of graphs, even under a probabilistic injection pattern. For example, we can simply define the process in a way such that the expected load of a processor increases between two load balancing actions.

5 A Different Model for Task Generation/Deletion

In this section we define a load generation model similar to [18] and [4]. Rather than bounding the total number of tasks that are generated per round, we bound the *load change* in any subset of the processors. During each round, tasks can be added or deleted from processors, subject to the restriction in Inequality (3) below. The processors then balance load amongst themselves as before.

In the following, $\bar{\ell}_i^t$ (respectively, $\bar{L}^t(S)$) denotes the load of processor P_i (resp. the total load of all processors in set the S) after we have generated and deleted tasks, and ℓ_i^t (resp. $L^t(S)$) is the load of processor P_i (resp. the total load of all processors in the set S) immediately after the load balancing phase. Let $\text{avg}(t)$ be the average load of the processors in round t after load generation

and deletion, i.e. $\text{avg}(t) = \frac{1}{n} \cdot \sum_{i=1}^n \bar{\ell}_i^t$. Again, $L^t(\mathcal{P})$ denotes the total system load at the end of step t . One round looks now as follows:

1. Tasks are generated and deleted according to the following *generation restriction*:

$$\bar{L}^t(S) - L^{t-1}(S) \leq |S| \cdot (\text{avg}(t) - \text{avg}(t-1)) + n. \quad (3)$$

2. Every processor balances its load with some or all its neighbors in the network using the diffusion operation defined in Section 1.2.

We can show the following result, the proof of which is not included in this extended abstract due to space constraints.

Theorem 10. *Let $n \geq 2$ denote the number of processors in the system. Let $\Delta \geq 2$ denote the maximum degree of the graph G that specifies the communication linkages in the network. Assume the load generation and deletion fulfills the generation restriction in (3). Then, starting with an empty system, for all $t \geq 1$ and all $S \subseteq \mathcal{P}$ we have $L^t(S) \leq |S| \cdot \text{avg}(t) + 5\Delta n^3$. Furthermore, the maximum number of tasks per processor is $\text{avg}(t) + 5\Delta n^2$.*

5.1 Further Extensions

We can easily generalize our results to other load generation processes, and the proofs of the following results are much like those of Theorem 10 and are omitted due to space limitations.

Theorem 11. *Let $n \geq 2$ denote the number of processors in the system. Let $\Delta \geq 2$ denote the maximum degree of the graph G that specifies the communication linkages in the network. Assume the load generation and deletion fulfills the generation restriction $\bar{L}^t(S) - L^{t-1}(S) \leq |S| \cdot (\text{avg}(t) - \text{avg}(t-1)) + K$. Then, starting with an empty system, for all $t \geq 1$ and all $S \subseteq \mathcal{P}$ we have $L^t(S) \leq |S| \cdot \text{avg}(t) + 5\Delta nK$. Furthermore, the maximum number of tasks per processor is $\text{avg}(t) + 5\Delta nK$.*

Furthermore, we can improve our results to a load generation model where the imbalance that we allow to be generated in any set depends on the number of outgoing edges.

Theorem 12. *Let $n \geq 2$ denote the number of processors in the system. Let $\Delta \geq 2$ denote the maximum degree of the graph G that specifies the communication linkages in the network. Let $e(S)$ be the number of outgoing edges of the set S . Assume the load generation and deletion fulfills the generation restriction $\bar{L}^t(S) - L^{t-1}(S) \leq |S| \cdot (\text{avg}(t) - \text{avg}(t-1)) + K \cdot e(S)$. Then, starting with an empty system, for all $t \geq 1$ and all $S \subseteq \mathcal{P}$ we have $L^t(S) \leq |S| \cdot \text{avg}(t) + 5\Delta nK$. Furthermore, the maximum number of tasks per processor is $\text{avg}(t) + 5\Delta nK$.*

Abstract. The hidden subgroup problem (HSP) offers a unified framework to study problems of group-theoretical nature in quantum computing such as order finding and the discrete logarithm problem. While it is known that Fourier sampling provides an efficient solution in the abelian case, not much is known for general non-abelian groups. Recently, some authors raised the question as to whether post-processing the Fourier spectrum by measuring in a random orthonormal basis helps for solving the HSP. Several negative results on the shortcomings of this *random strong* method are known. In this paper however, we show that the random strong method can be quite powerful under certain conditions on the group G . We define a parameter $r(G)$ and show that $O((\log |G|/r(G))^2)$ iterations of the random strong method give enough classical information to solve the HSP. We illustrate the power of the random strong method via a concrete example of the HSP over finite Heisenberg groups. We show that $r(G) = \Omega(1)$ for these groups; hence the HSP can be solved using polynomially many random strong Fourier samplings followed by a possibly exponential classical post-processing without further queries. The quantum part of our algorithm consists of a polynomial computation followed by measuring in a random orthonormal basis. As an interesting by-product of our work, we get an algorithm for solving the *state identification problem* for a set of nearly orthogonal pure quantum states.

1 Introduction

The hidden subgroup problem (HSP) is defined as follows: We are given a function $f : G \rightarrow S$ from a group G to a set S with the promise that there exists a subgroup $H \leq G$ such that f is constant on the left cosets of H and takes distinct values on distinct cosets. Here, f is given via a black box. The task is to find a set of generators for H while making as few queries to f as possible. The abelian HSP (i. e. G is abelian) encompasses several interesting problems such as finding the order of an element in a group and the discrete logarithm problem. Factoring an integer n can be reduced to order finding in the group \mathbb{Z}_n^* . The problems of graph isomorphism and graph automorphism can be cast as hidden subgroup problems over the non-abelian group S_n .

Given the success of Fourier sampling in solving the abelian HSP, one can similarly ask whether Fourier sampling over the non-abelian group G helps in solving the HSP over G . The Fourier transform over a (in general, non-abelian) group G gives us a superposition over (ρ, i, j) where ρ is an irreducible unitary representation of G and i, j are the row and column indices of the matrix ρ . The choice of basis for ρ gives us a degree of freedom in defining the Fourier transform over G . This is in contrast to the abelian case, where all representations are one-dimensional and hence only their names ρ matter. Exploiting the symmetries in the above quantum state, one can show that (see e.g. [Kup03], [Ip03], [MRS05]) the optimal measurement to recover the hidden subgroup from a coset state consists of applying the Fourier transform to the first register, measuring the name of an irreducible representation ρ , followed by a POVM on the column space of the resulting state. By *strong Fourier sampling*, we usually mean that we measure the column space using some orthonormal basis instead of a general POVM. In *weak Fourier sampling*, one measures the names ρ of the representations only, and ignores the row and column indices (i, j) .

Hallgren, Russell and Ta-Shma [HRTS03] showed that polynomially many iterations of weak Fourier sampling give enough information to reconstruct normal hidden subgroups. More generally, they show that the normal core of the hidden subgroup can be reconstructed via the weak method. Grigni, Schulman, Vazirani and Vazirani [GSVV04] and Gavinsky [Gav04] extend the weak method to some more cases of group/subgroup pairs. The main shortcoming of the weak method is that it gives exactly the same probability distribution if the hidden subgroup is H or a conjugate gHg^{-1} of H . This leads us to consider the *strong* method where we measure both representation names as well as column indices (ρ, j) . The amount of additional information about the hidden subgroup H that can be extracted by measuring j depends in general on the basis used for ρ . In a recent paper, Moore, Russell and Schulman [MRS05] showed that for the symmetric group S_n , for *any* choice of bases for the representations, there are order two subgroups that require exponential number of Fourier samplings in order to distinguish them from the identity subgroup. Grigni, Schulman, Vazirani and Vazirani [GSVV04] study the *random strong* method where a random basis is used for each representation ρ . They define a group-theoretic parameter α depending on G and H and show that if α is exponentially large, the additional advantage of the random strong method over the weak method is exponentially small. In particular, this is case when $G = S_n$ and $H \leq S_n$, $|H| = 2^{O(n \log n)}$.

Our contributions. In this paper, we analyze the power of the random strong method and show, for the first time, that under certain (different) general conditions on G polynomially many iterations of the random strong method do give enough classical information to identify H . We illustrate the power of the random strong method via a concrete example of the HSP over finite Heisenberg groups \mathcal{H}_p of order p^3 , p prime. \mathcal{H}_p is defined as the following set of upper triangular matrices:

$$\mathcal{H}_p := \left\{ \begin{pmatrix} 1 & x & z \\ 0 & 1 & y \\ 0 & 0 & 1 \end{pmatrix} : x, y, z \in \mathbb{F}_p \right\}. \quad (1)$$

A convenient encoding for the elements of \mathcal{H}_p is to write (x, y, z) , where $x, y, z \in \mathbb{F}_p$ match the components in equation (1). It is easy to see that the classical randomised query complexity of the HSP on \mathcal{H}_p is $\Theta(p)$. The generic quantum algorithm of Ettinger, Høyer and Knill [EHK04] achieves $O(\log p)$ query complexity, but at the expense of $p^{O(\log p)}$ quantum operations. An algorithm with $2^{\Theta(\sqrt{\log p})}$ quantum operations can be obtained by using the orbit coset reduction of [FIM⁺03] together with the algorithm of [Kup03] to solve orbit coset over the group \mathbb{Z}_p . However, the query complexity of this algorithm is also $2^{\Theta(\sqrt{\log p})}$. It seems non-trivial to design a quantum algorithm with $(\log p)^{O(1)}$ query complexity and total running time $p^{O(1)}$. Various existing methods for non-abelian HSP fail to achieve this goal. We show how the random strong method attains this goal, illustrating the power of random bases in Fourier sampling.

It can be shown that \mathcal{H}_p is a semidirect product of the form $\mathbb{Z}_p \ltimes (\mathbb{Z}_p \times \mathbb{Z}_p)$, where the normal subgroup is given by $N_\infty := \{(0, y, z) : y, z \in \mathbb{F}_p\}$ and the complement by $A_{0,0} := \{(x, 0, 0) : x \in \mathbb{F}_p\}$. The commutator subgroup of \mathcal{H}_p is given by $[\mathcal{H}_p, \mathcal{H}_p] = \{(0, 0, z) : z \in \mathbb{F}_p\}$, which is also the centre $\zeta(\mathcal{H}_p)$. The commutator subgroup is isomorphic to \mathbb{Z}_p ; hence it is abelian but not *smoothly abelian* [FIM⁺03]. The *Baer subgroup* [GSVV04] turns out to be $\zeta(\mathcal{H}_p)$. Thus, the methods of [Gav04, IMS03, FIM⁺03] are not applicable in order to solve the HSP for \mathcal{H}_p efficiently. For more details about the Heisenberg group, see Section 2.

The chief obstacle to finding hidden subgroups in \mathcal{H}_p arises from the order p subgroups of \mathcal{H}_p other than its centre. There are $(p^2 + p)$ such order p subgroups; we shall call them $A_{i,j}$, $i \in \mathbb{F}_p \cup \{\infty\}$, $j \in \mathbb{F}_p$. The *forgetful abelian method* (i. e. Fourier sampling over the abelian group $\mathbb{Z}_p \times (\mathbb{Z}_p \times \mathbb{Z}_p)$ instead of the non-abelian group $\mathcal{H}_p \cong \mathbb{Z}_p \ltimes (\mathbb{Z}_p \times \mathbb{Z}_p)$), weak Fourier sampling, strong Fourier sampling in the natural representation basis of \mathcal{H}_p (i. e. the representation basis adapted to the distinguished subgroup tower $\{1\} \triangleleft N_\infty \triangleleft \mathcal{H}_p$) as well as strong Fourier sampling in the \mathbb{Z}_p -Fourier transform of the natural representation basis give exponentially small information about the index i of $A_{i,j}$. The details are left for the full version of the paper. For now, we give an intuitive description of the main difficulty posed by these subgroups. Suppose the hidden subgroup is $A_{i,j}$ for some $i \in \mathbb{F}_p \cup \{\infty\}$, $j \in \mathbb{F}_p$. With exponentially high probability, Fourier sampling over \mathcal{H}_p gives us a representation uniformly at random from one of the $(p - 1)$ irreducible representations ρ_k of degree p for $k = 1, \dots, p - 1$ of \mathcal{H}_p . Suppose one such representation ρ_k shows up. The state essentially collapses to a vector $|\psi_{k,i,j}\rangle \in \mathbb{C}^p$, i. e., $(\mathcal{H}_p, A_{i,j})$ is a Gelfand pair for all i, j (see also [MR05] for Gelfand pairs in the context of the HSP). The vectors $|\psi_{k,i,j}\rangle$ have the property that

$$|\langle \psi_{k,i,j} | \psi_{k,i',j'} \rangle| = \begin{cases} \frac{1}{\sqrt{p}} & : i \neq i', \text{ for all } j, j', \\ \delta_{j,j'} & : i = i', \end{cases}$$

i. e., they form a set of $(p + 1)$ mutually unbiased bases of \mathbb{C}^p [WF89]. The main difficulty is that it is not clear a priori that there is any orthonormal basis that can pairwise distinguish between these $(p^2 + p)$ vectors with inverse polynomial probability. Note that the so-called *hidden conjugate problem* [MRRS04] is easy to solve information-theoretically for \mathcal{H}_p ; the conjugacy classes of the order p groups are defined by i and the above property says that $\{|\psi_{k,i,j}\rangle\}_j$ is an orthonormal basis of \mathbb{C}^p , so given the

conjugacy class i one can measure in this orthonormal basis to determine the actual hidden subgroup $A_{i,j}$. In view of this, the main challenge in solving the HSP for \mathcal{H}_p is to identify the conjugacy class i .

In this paper however, we show that a random representation basis for ρ_k does in fact pairwise distinguish between $|\psi_{k,i,j}\rangle$ with constant probability. In fact, we refine the method of random measurement bases to distinguish between families of nearly orthogonal subspaces. We combine the geometric ideas of random measurement bases together with representation-theoretic techniques and exhibit a parameter $r(G)$ of a group G and show that it is a lower bound on the total variation distance between the distributions on pairs (ρ, j) of representation names and column indices obtained by the random strong method for possible candidate hidden subgroups H . The parameter $r(G)$ is defined in terms of the ranks and overlaps of the projectors obtained by averaging representations ρ over various subgroups H . We show that $O\left(\frac{\log s(G)}{r^2(G)}\right)$ iterations of the random strong method give sufficient classical information to identify the hidden subgroup H , where $s(G)$ denotes the number of distinct subgroups of G . Note that $s(G) \leq 2^{\log^2 |G|}$ for any group G .

We will see later in Section 2 that $s(\mathcal{H}_p) = O(p^2)$. In Section 4, we show that $r(\mathcal{H}_p) = \Omega(1)$, implying that $O(\log p)$ iterations of the random strong method give sufficient information to extract the hidden subgroup in \mathcal{H}_p . This gives us an algorithm solving the HSP over \mathcal{H}_p with $O(\log p)$ query complexity, $O(\log^3 p)$ quantum operations for implementing the non-abelian Fourier transforms, $\tilde{O}(p^2)$ quantum operations to measure in a random basis, and $\tilde{O}(p^4)$ classical post-processing operations. This gives the first example of a group where random representation bases do help in solving the HSP and for which no explicit representation bases are known that solve the problem with $(\log p)^{O(1)}$ Fourier samplings.

As an interesting by-product of our work, we get an algorithm for solving the following *quantum state identification* problem: Consider a set of pure quantum states $\{|\psi_1\rangle, \dots, |\psi_m\rangle\} \in \mathbb{C}^n$ with the property that $|\langle\psi_i|\psi_j\rangle| \leq \delta$ for all $i \neq j$, where δ is a sufficiently small constant (and typically $m \gg n$). We are given t independent copies of $|\psi_i\rangle$. The task is to identify the index i . We show that $t = O(\log m)$ independent random complete von Neumann measurements in \mathbb{C}^n suffice to identify i with high probability.

Relation to other work. Moore, Rockmore, Russell and Schulman [MRRS04] use non-abelian strong Fourier sampling to give an efficient algorithm for the HSP over the q -hedral group $\mathbb{Z}_q \times \mathbb{Z}_p$ when p, q are prime, $q \mid (p-1)$ and $(p-1)/q = (\log p)^{O(1)}$. Our techniques show that for p, q prime, $q \mid (p-1)$, $q = \Omega(\sqrt{p})$, $r(\mathbb{Z}_q \times \mathbb{Z}_p) = \Omega(1)$, which proves that polynomially many random strong Fourier samplings suffice to find an arbitrary hidden subgroup of $\mathbb{Z}_q \times \mathbb{Z}_p$ in this case. For prime p , $q \mid (p-1)$, $q = \Omega(p^{3/4})$, subgroups H_1, H_2 conjugate to $\mathbb{Z}_q \leq \mathbb{Z}_{p-1}$, our techniques show that $r(\mathbb{Z}_{p-1} \times \mathbb{Z}_p; H_1, H_2) = \Omega\left(\sqrt{\frac{q}{p}}\right)$. Moore et al. [MRRS04] prove a nearly matching upper bound of $r(\mathbb{Z}_{p-1} \times \mathbb{Z}_p; H_1, H_2) = O\left(\sqrt{\frac{q}{p} \log p}\right)$. Thus, a polynomial amount of random strong Fourier sampling can solve the hidden conjugate problem for subgroup $\mathbb{Z}_q \leq \mathbb{Z}_{p-1}$ of the affine group $\mathbb{Z}_{p-1} \times \mathbb{Z}_p$ if and only if $p/q = (\log p)^{O(1)}$.

In this paper, we confine ourselves to random strong Fourier sampling. Our quantum operations always factor into a tensor product over the coset states obtained by querying the function oracle. This distinguishes the Heisenberg group from the symmetric group for which Moore, Russell and Schulman [MRS05] show that single register Fourier sampling is not sufficient to solve the HSP. The quantum part of our algorithm consists of a polynomial computation followed by measuring in a random orthonormal basis. In fact, if a suitable kind of pseudo-random unitary transformation can be generated and implemented efficiently, then the quantum part of the algorithm can be made fully polynomial. Various notions of pseudo-random unitary transformations have been studied (see e.g. [EWS⁺03], [Eme04]), but it has to be investigated whether they are sufficient for our purposes.

Very recently, Bacon, Childs, and van Dam [BCvD05] have given a fully polynomial time quantum algorithm for the HSP in the Heisenberg group. Their algorithm is based on the square root measurement (also known as “pretty good measurement”) on a pair of registers as opposed to the single register experiments considered in this paper.

2 Heisenberg Groups over \mathbb{Z}_p

Subgroup Lattice. Since the order of \mathcal{H}_p is p^3 we can expect to find subgroups of order p and p^2 besides the trivial subgroup $\{1\}$ and \mathcal{H}_p . The centre of \mathcal{H}_p is given by $\zeta(\mathcal{H}_p) = \langle(0, 0, 1)\rangle = \{(0, 0, z) : z \in \mathbb{F}_p\}$. Note that $|\zeta(\mathcal{H}_p)| = p$. There are $p + 1$ subgroups N_i of order p^2 , where $i \in \mathbb{F}_p \cup \{\infty\}$. They are given by $N_i := \langle(1, i, 0), (0, 0, 1)\rangle = \{(x, xi, z) : x, z \in \mathbb{F}_p\}$, $\forall i \in \mathbb{F}_p$. The group N_∞ is given by $N_\infty := \langle(0, 1, 0), (0, 0, 1)\rangle = \{(0, y, z) : y, z \in \mathbb{F}_p\}$. It is easy to see that for all $i \in \mathbb{F}_p \cup \{\infty\}$, $\zeta(\mathcal{H}_p) \triangleleft N_i$. Furthermore the N_i are normal subgroups, $N_i \triangleleft \mathcal{H}_p$ and $N_i \cong \mathbb{Z}_p \times \mathbb{Z}_p$. For each $i \in \mathbb{F}_p \cup \{\infty\}$, we have that N_i contains p subgroups $A_{i,j}$ for $j \in \mathbb{F}_p$. The subgroups $A_{i,j}$ satisfy $|A_{i,j}| = p$, whence $A_{i,j} \cong \mathbb{Z}_p$. For $i, j \in \mathbb{F}_p$ we have the following explicit description of the elements of $A_{i,j}$: $A_{i,j} := \langle(1, i, j)\rangle = \{(\mu, \mu i, \binom{\mu}{2}i + \mu j) : \mu \in \mathbb{F}_p\}$. For $i = \infty, j \in \mathbb{F}_p$ we obtain $A_{\infty,j} := \langle(0, 1, j)\rangle = \{(0, \mu, \mu j) : \mu \in \mathbb{F}_p\}$. It is easy to see that $A_{i,j} \not\leq N_{i'}$ if $i \neq i'$, and their normalizer in \mathcal{H}_p is given by $N_{\mathcal{H}_p}(A_{i,j}) = N_i$. The above groups form a complete list of distinct subgroups of \mathcal{H}_p .

The Irreducible Representations of \mathcal{H}_p . Since we want to perform Fourier analysis on the groups \mathcal{H}_p we have to determine the irreducible representations of \mathcal{H}_p . The reader not familiar with the standard notations of representation theory is referred to standard references like [CR62] or [Ser77]. Observe that $\mathcal{H}_p = A_{0,0} \rtimes N_\infty \cong \mathbb{Z}_p \times (\mathbb{Z}_p \times \mathbb{Z}_p)$. This semidirect product structure can be used to construct the irreducible representations of \mathcal{H}_p . First, there are p^2 one-dimensional representations $\chi_{a,b}$ for $a, b \in \mathbb{F}_p$ which come from the factor group $\mathcal{H}_p/\zeta(\mathcal{H}_p) \cong \mathbb{Z}_p^2$. In the following, let ω denote a fixed p th root of unity in the complex numbers. Then the one-dimensional irreducible representations of \mathcal{H}_p are given by $\chi_{a,b}((x, y, z)) := \omega^{ax+by}$ $a, b \in \mathbb{F}_p$.

Let \mathbb{F}_p^* denote the group of non-zero elements of \mathbb{F}_p under multiplication. There are $p - 1$ irreducible representations ρ_k , $k \in \mathbb{F}_p^*$ of degree p . They are obtained in the

following way: Take a nontrivial character of the centre $\zeta(\mathcal{H}_p)$, extend it to the abelian group N_∞ , and induce it to \mathcal{H}_p . Explicitly, we obtain the following representations: For each $k \in \mathbb{F}_p^*$, we have a nontrivial character ϕ_k of $\zeta(\mathcal{H}_p)$ given by $\phi_k((0, 0, z)) := \omega^{kz}$. Since $\zeta(\mathcal{H}_p) \triangleleft N_\infty$ and N_∞ is abelian, we can extend ϕ_k to a character $\bar{\phi}_k$ of N_∞ by simply defining $\bar{\phi}_k((0, y, 0)) := 1$. We choose the elements of $A_{0,0}$ as transversals for N_∞ in \mathcal{H}_p . Then ρ_k is defined to be the induction $\rho_k := \bar{\phi}_k \uparrow_{A_{0,0}} \mathcal{H}_p$. On the generators of \mathcal{H}_p , we find that ρ_k takes the following values: $\rho_k((1, 0, 0)) = \sum_{a \in \mathbb{F}_p} |a\rangle\langle a+1|$, $\rho_k((0, 1, 0)) = \sum_{a \in \mathbb{F}_p} \omega^{ka} |a\rangle\langle a|$ and $\rho_k((0, 0, 1)) = \omega^k \mathbf{1}_p$, where $\mathbf{1}_p$ denotes the identity operator in \mathbb{C}^p . Since $(x, y, z) = (0, 0, z)(0, y, 0)(x, 0, 0)$ for all $x, y, z \in \mathbb{F}_p$, we obtain that $\rho_k((x, y, z)) = \omega^{kz} \sum_{a \in \mathbb{F}_p} \omega^{kya} |a\rangle\langle a+x|$. It can be readily checked that the $\chi_{a,b}$, for $a, b \in \mathbb{F}_p$ and ρ_k , for $k \in \mathbb{F}_p^*$ form a complete set of inequivalent irreducible representations of \mathcal{H}_p .

Calculating Rank and Overlap of the Projectors. Define the projector $P_{k;i,j} := \frac{1}{p} \sum_{a \in A_{i,j}} \rho_k(a)$. In order to calculate the parameter $r(\mathcal{H}_p)$ (see Section 4 for the details of the calculation) we have to compute the ranks of $P_{k;i,j}$ and pairwise overlaps $\|P_{k;i,j} P_{k;i',j'}\|$ (the reason for the nomenclature of *overlap* will become clear later). For $i, j \in \mathbb{F}_p$, we obtain that $P_{k;i,j} = \frac{1}{p} \sum_{\mu, \nu \in \mathbb{F}_p} \omega_p^{k \binom{\mu}{2} i + \mu j - \binom{\nu}{2} i - \nu j} |\nu\rangle\langle \mu|$. Hence, $P_{k;i,j} = |\psi_{k;i,j}\rangle\langle \psi_{k;i,j}|$, where $|\psi_{k;i,j}\rangle = \frac{1}{\sqrt{p}} \sum_{\mu \in \mathbb{F}_p} \omega^{-k \binom{\mu}{2} i + \mu j} |\mu\rangle$, $i, j \in \mathbb{F}_p, k \in \mathbb{F}_p^*$. In the case $i = \infty, j \in \mathbb{F}_p$, we get $P_{k;\infty,j} = |\psi_{k;\infty,j}\rangle\langle \psi_{k;\infty,j}|$, where $|\psi_{k;\infty,j}\rangle = | -j\rangle$ $j \in \mathbb{F}_p, k \in \mathbb{F}_p^*$. Thus for all $k \in \mathbb{F}_p^*, i \in \mathbb{F}_p \cup \{\infty\}, j \in \mathbb{F}_p$, $\text{rank}(P_{k;i,j}) = 1$ and $P_{k;i,j}$ is an orthogonal projection onto $|\psi_{k;i,j}\rangle$. For $j, j' \in \mathbb{F}_p$, $\|P_{k;\infty,j} P_{k;\infty,j'}\| = \delta_{j,j'}$. For $i, i', j' \in \mathbb{F}_p$, we get $\|P_{k;i,j} P_{k;\infty,j'}\| = \frac{1}{\sqrt{p}}$. For $i, i', j, j' \in \mathbb{F}_p$, we get $\|P_{k;i,j} P_{k;i',j'}\| = |\langle \psi_{k;i,j} | \psi_{k;i',j'} \rangle| = \frac{1}{p} \sum_{\mu \in \mathbb{F}_p} \omega^{k \left(\binom{\mu}{2} (i-i') + \mu (j-j') \right)}$. To evaluate the last term above, we need the following fact about quadratic Weil sums in \mathbb{F}_p .

Fact 1 ([LN94–Theorem 5.37]). Let $h(X) \in \mathbb{F}_p[X]$ be a degree two polynomial. Then, $\left| \sum_{x \in \mathbb{F}_p} \omega^{h(x)} \right| = \sqrt{p}$.

By Fact 1, if $i \neq i'$, $|\langle \psi_{k;i,j} | \psi_{k;i',j'} \rangle| = \frac{1}{\sqrt{p}}$ irrespective of j and j' . If $i = i'$, it is easy to see that $|\langle \psi_{k;i,j} | \psi_{k;i',j'} \rangle| = \delta_{j,j'}$. To summarise, we have shown the following result:

Lemma 1. Suppose p is an odd prime. Let $i, i' \in \mathbb{F}_p \cup \{\infty\}, j, j' \in \mathbb{F}_p$ and $A_{i,j}, A_{i',j'}$ be two order p subgroups of \mathcal{H}_p other than the centre $\zeta(\mathcal{H}_p)$. Let ρ_k , where $k \in \mathbb{F}_p^*$, be an irreducible representation of \mathcal{H}_p of degree p . Let $P_{k;i,j}$ be defined by $P_{k;i,j} := \frac{1}{p} \sum_{a \in A_{i,j}} \rho_k(a)$ and let $P_{k;i',j'}$ be defined similarly. Then $P_{k;i,j}, P_{k;i',j'}$ are rank one orthogonal projections, and their overlap is given by

$$\|P_{k;i,j} P_{k;i',j'}\| = \begin{cases} \frac{1}{\sqrt{p}} & : i \neq i', \text{ for all } j, j', \\ \delta_{j,j'} & : i = i'. \end{cases}$$

Thus, for any $k \in \mathbb{F}_p^*$, the vectors $|\psi_{k;i',j'}\rangle$ form a set of $(p+1)$ mutually unbiased bases for \mathbb{C}^p .

3 Random Bases and Fourier Sampling

Nearly orthogonal vectors. In this subsection, we state some results about sets of nearly orthogonal unit vectors in a Hilbert space. We use $\|\cdot\|$ to denote the ℓ_2 -norm of vectors as well as the ℓ_2 -induced operator norm of matrices. We use $\|v\|_1$ to denote the ℓ_1 -norm of a vector v . We let $\|M\|_{\text{tr}} = \text{Tr}\sqrt{M^\dagger M}$ denote the trace norm of a matrix M . For subspaces V_1, V_2 having trivial intersection, their *overlap* is defined as $\text{ovlap}(V_1, V_2) = \max_{v_1, v_2} |\langle v_1 | v_2 \rangle|$, where v_i range over unit vectors in V_i . Let Π_i denote the orthogonal projection operator onto V_i . It is easy to see that $\text{ovlap}(V_1, V_2) = \|\Pi_1 \Pi_2\|$.

Proposition 1. *Let V_1, V_2 be subspaces of a Hilbert space having trivial intersection. Let σ_2 denote the totally mixed state in V_2 . Let V'_2 denote the orthogonal complement of V_1 in $V_1 + V_2$ and σ'_2 denote the totally mixed state in V'_2 . Let $\delta = \text{ovlap}(V_1, V_2)$. Then, $\|\sigma_2 - \sigma'_2\|_{\text{tr}} \leq 2\delta^{1/2}(1 - \delta^2)^{-1/4}$.*

Proposition 2. *Let v'_1, \dots, v'_n be unit vectors in a Hilbert space. Let $0 \leq \delta < \frac{1}{2n}$. Suppose for all $i, j, i \neq j$, $|\langle v_i | v_j \rangle| \leq \delta$. Let v_1, \dots, v_n be unit vectors obtained by Gram-Schmidt orthonormalising v'_1, \dots, v'_n . Then $\|\langle v_i | v_j \rangle - \langle v'_i | v'_j \rangle\|_{\text{tr}} < 2\sqrt{6} \cdot \delta \sqrt{n}$, for any $i, 1 \leq i \leq n$,*

The proofs of the above propositions are left to the full version of the paper.

Random orthonormal vectors. In this subsection, we state some facts about random orthonormal sets of vectors in \mathbb{C}^d . One way of generating a random unit vector in \mathbb{C}^d is as follows: Consider $(y_1, \dots, y_{2d}) \in \mathbb{R}^{2d}$, where each y_i is independently chosen according to the one dimensional Gaussian distribution with mean 0 and variance 1 (i. e. y_i is a real valued random variable with probability density function $\frac{1}{\sqrt{2\pi}} \exp(-y^2/2)$). Normalise to get the unit vector (x_1, \dots, x_{2d}) , where $x_i = \frac{y_i}{\sqrt{y_1^2 + \dots + y_{2d}^2}}$ (note that any $y_i = 0$ with zero probability). We thus get a random unit vector in \mathbb{R}^{2d} . Identifying a pair of real numbers with a single complex number, we get a random unit vector (z_1, \dots, z_d) in \mathbb{C}^d . To generate a random orthonormal ordered set $\{v_1, \dots, v_m\}$ of vectors in \mathbb{C}^d , we can first sample m unit vectors $\{v'_1, \dots, v'_m\}$ in \mathbb{C}^d and then do Gram-Schmidt orthonormalisation on them to get $\{v_1, \dots, v_m\}$ (note that with probability 1, $\{v'_1, \dots, v'_m\}$ are linearly independent).

The following fact follows by combining Theorem 14.3.2 and Proposition 14.3.3 of [Mat02–Chapter 14] and using the concavity of the square-root function.

Fact 2. Let $t > 0$, and $|v\rangle, |w\rangle$ independent random unit vectors in \mathbb{C}^d . Then,

$$\Pr \left[|\langle v | w \rangle| > t + \frac{10}{\sqrt{d}} \right] \leq 2 \exp(-t^2 d).$$

We will require the following upper and lower bounds on the tails of the chi-square distribution (the chi-square distribution with d degrees of freedom is the sum of squares of d independent Gaussians with mean 0 and variance 1).

Fact 3. Let (X_1, \dots, X_d) be independent random variables such that X_i is Gaussian with mean 0 and variance 1. Let $X^2 = X_1^2 + \dots + X_d^2$. Let $0 \leq \epsilon < 1/2$. There exists a universal constant $\gamma > 0$ such that

1. $\Pr[|X^2 - d| > d\epsilon] < 2 \exp(-d\epsilon^2/6)$,
2. $\Pr[X^2 > d + \sqrt{d}] > \gamma, \Pr[X^2 < d - \sqrt{d}] > \gamma$.

The following result follows easily from Fact 3. A similar result appears as Lemma 5.1 in [MRRS04].

Fact 4. Let $V = \{a^1, \dots, a^p\}$ be a random orthonormal set of p vectors in \mathbb{C}^d . Let a_j^i denote the j th coordinate of vector a^i . Define the d -dimensional probability vector S as follows: $S_j = \frac{1}{p} \sum_{i=1}^p |a_j^i|^2$. Let $0 \leq \epsilon < 1/2$. Suppose $p = \Omega(\epsilon^{-2} \log d)$. Let U denote the uniform probability distribution on $\{1, \dots, d\}$. Then, with probability at least $1 - \exp(-\Omega(\epsilon^2 p))$ over the choice of V , $\|S - U\|_1 \leq \epsilon$.

We will also need the following Chernoff upper bounds on the tail of the sum of d independent identically distributed binary random variables.

Fact 5 ([AS00–Cor. A.7, Theorem A.13]). Suppose (X_1, \dots, X_d) are independent binary random variables such that $\Pr[X_i = 1] = p$. Let $X = X_1 + \dots + X_d$. Let $0 \leq \epsilon < 1/2$. Then,

1. $\Pr\left[\left|\frac{X}{d} - p\right| > \epsilon\right] < 2 \exp(-2\epsilon^2 d)$,
2. $\Pr[X < \frac{dp}{2}] < \exp(-dp/8)$.

Hidden subgroup problem and Fourier sampling. In this subsection, we recall the standard approach to solving the hidden subgroup problem based on Fourier sampling. The quantum Fourier transform over G , QFT_G , is the \mathbb{C} -linear map defined as follows:

$$|g\rangle \mapsto \sum_{\rho} \sqrt{\frac{d_{\rho}}{|G|}} \sum_{i,j=1}^{d_{\rho}} \rho_{ij}(g) |\rho, i, j\rangle,$$

where ρ runs over inequivalent irreducible unitary representations of G , d_{ρ} denotes the dimension of ρ and i, j run over the row and column indices of ρ . For a subset $T \subseteq G$, define $|T\rangle = \frac{1}{\sqrt{|T|}} \sum_{t \in T} |t\rangle$ to be the uniform superposition over elements of T . For a representation ρ , define the matrix $\rho(T) = \frac{1}{\sqrt{|T|}} \sum_{t \in T} \rho(t)$. If $H \leq G$, it can be shown (see e.g. [HRTS03]) that $\frac{1}{\sqrt{|H|}} \rho(H)$ is an orthogonal projection onto the subspace V_H^{ρ} of the representation space of ρ consisting of all vectors $|v\rangle$ such that $\rho(h)|v\rangle = |v\rangle$ for all $h \in H$. Thus, $\text{rank}(\rho(H)) = \dim V_H^{\rho}$.

In the standard Fourier sampling method for the hidden subgroup problem, we begin by forming the uniform superposition $\frac{1}{\sqrt{|G|}} \sum_{g \in G} |g\rangle |0\rangle$ and then query f to get the superposition $\frac{1}{\sqrt{|G|}} \sum_{g \in G} |g\rangle |f(g)\rangle$. We then measure the second register to get a uniform mixture over vectors $|gH\rangle$ in the first register. Assuming the first register is in state $|gH\rangle$ for some particular $g \in G$, its state after the application of QFT_G

becomes $\frac{1}{\sqrt{|G||H|}} \sum_{\rho, i, j} \sqrt{d_\rho} \sum_{h \in H} \rho_{ij}(gh) |\rho, i, j\rangle$. If we now measure the representation name and column index, we sample (ρ, j) with probability

$$P_H^G(\rho, j) = \frac{d_\rho}{|G|} \sum_i |\rho_{ij}(gH)|^2 = \frac{d_\rho}{|G|} \|\rho(gH)|j\rangle\|^2 = \frac{d_\rho}{|G|} \|\rho(H)|j\rangle\|^2.$$

The third equality above follows from the fact that $\|\rho(gH)|j\rangle\| = \|\rho(g)\rho(H)|j\rangle\| = \|\rho(H)|j\rangle\|$, since $\rho(g)$ is unitary. Thus, as long as we measure just the representation name and column index (ρ, j) , the probabilities are independent of the actual coset gH that we find ourselves in. This fact can be viewed as the non-abelian generalisation of the fact that in abelian Fourier sampling the probability distribution on the characters is independent of the actual coset that we land up in. Also, it can be shown that (see [GSVV04])

$$P_H^G(\rho) = \sum_{j=1}^{d_\rho} \frac{d_\rho}{|G|} \|\rho(H)|j\rangle\|^2 = \frac{d_\rho |H|}{|G|} \text{rank}(\rho(H)) = \frac{d_\rho |H|}{|G|} \dim V_H^\rho.$$

In *weak Fourier sampling*, we only measure the names ρ of the representations and ignore the column indices j . It can be shown (see e.g. [HRTS03]) that for normal hidden subgroups H , no more information about H is contained in the column space of the resulting state after the measurement of ρ . Thus, weak Fourier sampling is the optimal measurement to recover a normal hidden subgroup starting from the uniform mixture of coset states.

Define a distance measure $w(G; H_1, H_2) = \sum_\rho |P_{H_1}^G(\rho) - P_{H_2}^G(\rho)|$ between subgroups $H_1, H_2 \leq G$. Hence, $w(G; H_1, H_2)$ is the total variation distance between the probability distributions, when the hidden subgroup is H_1 or H_2 , on the names of the representations obtained via weak Fourier sampling. Hallgren, Russell and Ta-Shma [HRTS03] showed that $O(\log |G|)$ weak Fourier samplings suffice to reconstruct the *normal core* $c(H)$ of the hidden subgroup H , where $c(H)$ is the largest normal subgroup of G contained in H . Adapting their arguments, we prove the following result.

Proposition 3. *Let $H_1, H_2 \leq G$, $c(H_1) \neq c(H_2)$. Then, $w(G; H_1, H_2) \geq 1/2$.*

The proof is left to the full version of the paper. For a normal subgroup $N \triangleleft G$, define the *normal core family* of N , $\text{ncf}(N) = \{H : H \leq G, c(H) = N\}$. In view of Proposition 3, the remaining challenge is to distinguish between subgroups H_1, H_2 from the same normal core family.

The success of strong Fourier sampling depends on how much statistical information about H is present in the probability distribution $P_H^G(\rho, j)$. The amount of information, in general, depends on the choice of basis for each representation ρ , i. e., on the choice of basis for j ; see [MRRS04] for more details. Grigni et al. [GSVV04] show that under certain conditions on G and H , the *random strong* Fourier sampling method, where a random choice of basis is made for each representation, gives exponentially small information about distinguishing H from the identity subgroup. In the next section, we prove a complementary result viz. under different conditions on G , $(\log |G|)^{O(1)}$ random strong Fourier samplings do give enough information to reconstruct the hidden subgroup H with high probability.

4 Power of the Random Strong Method

We now define a parameter $r(G)$ for a group G which, if at least $(\log |G|)^{-O(1)}$, suffices for the random strong method to identify the hidden subgroup with $(\log |G|)^{O(1)}$ Fourier samplings. Let $H_1, H_2 \leq G$. We first define a distance measure $r(G; H_1, H_2)$ between H_1, H_2 . In what follows, we use the notation of Section 3.

Definition 1 ($r(G; H_1, H_2; \rho)$). *Suppose ρ is an irreducible d_ρ -dimensional unitary representation of G . Let Π_i denote the orthogonal projection onto $V_{H_i}^\rho$ i.e. $\Pi_i = \frac{1}{|H_i|} \sum_{h \in H_i} \rho(h)$. Let $\Pi_{1,2}$ denote the orthogonal projection onto $V_{H_1}^\rho \cap V_{H_2}^\rho$. It is easy to check that $V_{H_1}^\rho \cap V_{H_2}^\rho = V_{\langle H_1, H_2 \rangle}^\rho$, where $\langle H_1, H_2 \rangle$ denotes the subgroup of G generated by H_1 and H_2 . Thus, $\Pi_{1,2} = \frac{1}{|\langle H_1, H_2 \rangle|} \sum_{h \in \langle H_1, H_2 \rangle} \rho(h)$. Define $\Pi'_i = \Pi_i - \Pi_{1,2}$. Π'_i is the orthogonal projection onto the subspace V'_i defined as the orthogonal complement of $V_{H_1}^\rho \cap V_{H_2}^\rho$ in $V_{H_i}^\rho$. V'_1 and V'_2 have trivial intersection. Define $r_i = \text{rank}(\Pi_i)$ and $r'_i = \text{rank}(\Pi'_i)$. Define $\hat{h} = \max\{|H_1|r_1, |H_2|r_2\}$, $\tilde{h} = |(|H_1|r_1 - |H_2|r_2)|$ and $\delta = \|\Pi'_1 \Pi'_2\|$. Recall that $\delta = \text{ovlap}(V'_1, V'_2)$. Consider the following three cases:*

1. When $\frac{\sqrt{d_\rho}}{\log |G|} = \Omega((r_1 + r_2)^{3/2})$. Loosely speaking, r_1, r_2 are both small. In this case, define

$$r(G; H_1, H_2; \rho) = \max \left\{ \frac{\hat{h}}{2} \left(\Omega \left(\frac{\sqrt{r'_1}}{r_1} + \frac{\sqrt{r'_2}}{r_2} \right) - 2\delta^{1/2}(1 - \delta^2)^{-1/4} \right), \tilde{h} \right\}.$$

2. When $\frac{\sqrt{d_\rho}}{\log |G|} = \Omega(r_1)$ and $\frac{r_2}{r_1} = \Omega(\log^2 |G|)$. Loosely speaking, r_1 is small and r_2 is relatively large with respect to r_1 . In this case, define

$$r(G; H_1, H_2; \rho) = \max \left\{ \frac{\hat{h}}{2} \cdot \Omega \left(\frac{1}{\sqrt{r_1}} \right), \tilde{h} \right\}.$$

3. Otherwise, define $r(G; H_1, H_2; \rho) = \tilde{h}$.

Definition 2 ($r(G; H_1, H_2), r(G)$). *Let $H_1, H_2 \leq G$. Define $r(G; H_1, H_2) = \sum_\rho \frac{d_\rho}{|G|} \cdot r(G; H_1, H_2; \rho)$ and $r(G) = \min_{H_1, H_2} r(G; H_1, H_2)$.*

Definition 3 ($P_{H, \mathcal{B}}^G$). *Let \mathcal{B} be a set of orthonormal bases for the irreducible unitary representations of G . Suppose $H \leq G$. $P_H^{G, \mathcal{B}}$ denotes the probability distribution on the representation names and column indices (ρ, j) got by strong Fourier sampling the state $|H\rangle$ according to \mathcal{B} .*

The significance of $r(G; H_1, H_2)$ arises from the following theorem.

Theorem 1. *With probability at least $1 - \exp(-\Omega(\log^2 |G|))$ over the choice of random representation bases \mathcal{B} for Fourier sampling, $\|P_{H_1}^{G, \mathcal{B}} - P_{H_2}^{G, \mathcal{B}}\|_{\text{tr}} \geq r(G; H_1, H_2)$.*

Using this theorem, we can apply a ‘minimum-finding-like’ algorithm to identify the hidden subgroup.

Corollary 1. *Let $s(G)$ denote the number of distinct subgroups of G . With probability at least $2/3$ over the choice of random bases for representations of G , $O\left(\frac{\log s(G)}{r^2(G)}\right)$ random strong Fourier samplings give enough classical information to identify a hidden subgroup in G . In particular, $O\left(\left(\frac{\log |G|}{r(G)}\right)^2\right)$ random strong Fourier samplings suffice.*

The proof is left to the full version of the paper. The rest of the section is devoted to proving Theorem 1. We first state some necessary technical lemmas.

Lemma 2. *Let $W = \{a^1, \dots, a^p\} \cup \{b^1, \dots, b^q\} \cup \{c^1, \dots, c^r\}$ be a random orthonormal set of $p + q + r$ vectors in \mathbb{C}^d . Let a_j^i denote the j th coordinate of vector a^i ; similar notations will be used for the vectors b^i, c^i too. Define two d -dimensional probability vectors S, T as follows:*

$$S_j = \frac{1}{p+r} \left(\sum_{i=1}^p |a_j^i|^2 + \sum_{i=1}^r |c_j^i|^2 \right), T_j = \frac{1}{q+r} \left(\sum_{i=1}^q |b_j^i|^2 + \sum_{i=1}^r |c_j^i|^2 \right).$$

Then there exists $\delta = \Theta((p+q+r)^{-3/2})$ such that the following holds: Define $\alpha = d\delta^2 - 2\log(p+q+r)$. Suppose $\alpha = \Omega(1)$. Then, with probability at least $1 - \exp(-\Omega(\alpha))$ over the choice of W , $\|S - T\|_1 = \Omega\left(\frac{\sqrt{p}}{p+r} + \frac{\sqrt{q}}{q+r}\right)$.

Lemma 3. *Let $W = \{a^1, \dots, a^p\}$ be a random orthonormal set of p vectors in \mathbb{C}^d . Let a_j^i denote the j th coordinate of vector a^i . Define the d -dimensional probability vector S as follows: $S_j = \frac{1}{p} \sum_{i=1}^p |a_j^i|^2$. Then there exists $\delta = \Theta(p^{-1})$ such that the following holds: Define $\alpha = d\delta^2 - 2\log p$. Suppose $\alpha = \Omega(1)$. Let U denote the uniform probability distribution on $\{1, \dots, d\}$. Then, with probability at least $1 - \exp(-\Omega(\alpha))$ over the choice of V , $\|S - U\|_1 = \Omega(p^{-1/2})$.*

We are now in a position to finally prove Theorem 1.

Proof. (of Theorem 1, sketch) Note that \tilde{h} describes the efficiency of the weak standard method, and so the total variation distance between the probability distributions $P_{H_1}^G(\rho, j)$ and $P_{H_2}^G(\rho, j)$ is always lower bounded by $w(G; H_1, H_2)$. When case 1 of Definition 1 applies, we use Lemma 2, Proposition 1 and symmetry arguments to prove the lower bound on the total variation distance. When case 2 of Definition 1 applies, we use Lemma 3, Fact 4 and symmetry arguments. For each representation ρ , the confidence bound in applying the above random basis arguments is at least $1 - \exp(-\Omega(\log^2 |G|))$. Since there are at most $|G|$ representations, the total confidence bound is at least $1 - \exp(-\Omega(\log^2 |G|))$.

We now have all the tools to prove that $r(\mathcal{H}_p) = \Omega(1)$. In fact, we can now prove the following theorem. The proof is left for the full version of the paper.

Theorem 2. *The random strong method is sufficient to solve the hidden subgroup problem in the Heisenberg group \mathcal{H}_p . The query complexity of this algorithm is $O(\log p)$. The quantum part of the algorithm consists of a circuit of size $O(\log^4 p)$ followed by a circuit of size $\tilde{O}(p^2)$ for implementing the measurement in a random orthonormal basis. The classical post-processing does not make any queries and has a running time of $\tilde{O}(p^4)$.*

Abstract. We improve hardness results for the problem of embedding one finite metric into another with minimum distortion. This problem is equivalent to optimally embedding one weighted graph into another under the shortest path metric. We show that unless $P = NP$, the minimum distortion of embedding one such graph into another cannot be efficiently approximated within a factor less than $9/4$ even when the two graphs are unweighted trees. For weighted trees with the ratio of maximum edge weight to the minimum edge weight of α^2 ($\alpha \geq 1$) and all but one node of constant degree, we improve this factor to $1 + \alpha$. We also obtain similar hardness results for extremely simple line graphs (weighted). This improves and complements recent results of Kenyon et al. [13] and Papadimitriou and Safra [18].

1 Introduction

For two n -point metric spaces (X, ρ) and (Y, σ) , the *expansion* of a bijection $\varphi : X \rightarrow Y$ is defined as $exp(\varphi) = \max_{a \neq b \in X} \frac{\sigma(\varphi(a), \varphi(b))}{\rho(a, b)}$. The *distortion* of φ , denoted $dist(\varphi)$, is the product of $exp(\varphi)$ and $exp(\varphi^{-1})$. The expansion of φ^{-1} is also referred to as the *contraction* of φ and denoted $con(\varphi)$. The *distortion between X and Y* , denoted $dist(X, Y)$, is the minimum distortion over all such bijections and may be thought of as a difference measure between these metric spaces. This paper addresses the computational hardness of the problem of embedding one finite metric space into another with minimum distortion.

The notion of distortion was originally studied for infinite metrics [12] in the analysis of Banach spaces. More recently the embedding of finite metrics into Euclidean and other L_p metrics has been very successful for applications in theoretical computer science, including approximation, learning, on-line algorithms, high-dimensional geometry, and others [6, 17, 16, 11]. This notion has been extended in such directions as embedding a finite metric into a distribution of metrics which has again found great success in approximation algorithms [1, 8]. This continues to be an active area of research [2, 15].

We point out that the problems addressed in the works mentioned above are combinatorial in nature— that is, they are concerned with embedding a finite metric into another *class* of metrics and the focus is on providing bounds for the distortion itself. However, we are interested in the algorithmic problem of embedding a *specific* metric into another *specific* metric— i.e. we are interested in the worst case ratio of the distortion obtained by the algorithm under consideration and the best possible distortion. This problem was introduced by Kenyon et al. [13]. The recent work of Bădoiu et. al. [3] considers the algorithmic question of finding embeddings of a specific metric into a class of metrics.

In addition to the fact that the problem of finding low-distortion embeddings between two finite metrics is a very natural question that by itself merits investigation, the problem is also likely to have much wider use than theoretical computer science. To mention three examples, theorem proving and symbolic computation [20], database problems such as queries over heterogeneous structured databases [21], and matching gels from electrophoresis [10] can all be expressed as tree embedding problems. The problem has several other applications as well [13].

We note a basic fact that any n -point metric may be realized as the shortest path metric of a weighted undirected graph over n nodes, for example by making a complete graph whose adjacency matrix is the matrix of metric distances. Due to this correspondence, we will exclusively focus on the problem of optimally embedding one graph into another. We will implicitly identify a graph with the metric given by shortest paths on that graph. For a set of weighted graphs, their *weight ratio* is the ratio of the maximum to the minimum weights of edges in the graphs.

1.1 Previous Results

The only upper bounds on this problem known to us are by Kenyon et al. [13]. Given two point sets on the real line with the L_1 distance metric that have distortion less than $3 + 2\sqrt{2}$, there is a polynomial time algorithm to find an embedding with the minimum distortion. Their second result finds the minimum distortion between an arbitrary graph and a tree, in polynomial time if the degree of the tree and the distortion are constant. Their algorithm is exponential in the degree of the tree and doubly-exponential in the distortion. Both algorithms are based on dynamic programming; the latter is similar to those based on tree decompositions of graphs.

The situation for hardness results is a little more clear. Determining if there is an isometry—a distortion 1 embedding—between two graphs is the graph isomorphism problem, which is not known to be in P but which is probably not NP-hard either. Kenyon et al. [13] show the problem is NP-hard to approximate within a factor of 2 for general graphs and a factor of $4/3$ in the case where one of the graphs is an unweighted tree and the other is a weighted graph with weights $1/2$ or 1. Papadimitriou and Safra [18] show that it is NP-hard to approximate within a factor of 3 the distortion between any two finite metrics realized as point sets in \mathbb{R}^3 where the distance metric is the L_2 norm.

1.2 Our Results

Unweighted Trees (Section 3.3) The problem is NP-hard to approximate within a factor less than $9/4$ for unweighted trees. As far as we know, this is the first hardness result for embedding an unweighted graph into another. It also improves the factor of 2 result for general graphs [13] even when the graphs are unweighted.

Weighted Trees (Section 3.2) The problem is NP-hard to approximate within a factor less than $1 + \alpha$ for any $\alpha \geq 1$ and tree graphs with weight ratio $\Omega(\alpha^2)$. This is the first hardness result for embedding trees into trees and improves the bound of 2 for general graphs [13] at the expense of a larger weight ratio. Our result also holds when all but one node of the underlying graphs have degree ≤ 4 ; the problem is known to be easy in the unweighted case when all nodes have constant degree and the distortion is small [13]. This result also improves the bound of 3 by Papadimitriou and Safra [18].

Weighted Line Graphs (Section 4) The problem is NP-hard to approximate within a factor of α for any $\alpha > 1$ and line graphs with weight ratio $\Omega(\alpha^2 n^4)$, where n is the number of nodes in the two graphs. This is the only bound known for graphs with constant degrees and large weights.

2 Preliminaries

We begin with some basic properties of the distortion resulting from embedding a weighted undirected graph G into another such graph H . Let $[m]$ denote the set of integers from 1 to m . Let d_G and d_H denote the shortest path distances in G and H , respectively. Fix a bijection $\varphi : G \rightarrow H$. We state the following results for $\text{exp}(\varphi)$. Analogous results hold for $\text{con}(\varphi)$ which is nothing but $\text{exp}(\varphi^{-1})$.

Lemma 1 ([13]). φ achieves its maximum expansion at some edge in G , i.e., $\text{exp}(\varphi) = \max_{\{a,b\} \in E(G)} \frac{d_H(\varphi(a), \varphi(b))}{d_G(a,b)}$.

Corollary 1. If G and H are unweighted then $\text{exp}(\varphi)$ is an integer.

Lemma 2. If G and H are unweighted and H has no edge-subgraph that is isomorphic to G then $\text{exp}(\varphi) \geq 2$.

Proof. Let u and v be nodes of G such that $(u, v) \in E(G)$ but $(\varphi(u), \varphi(v)) \notin E(H)$. Such nodes must exist because H has no edge-subgraph isomorphic to G . $d_G(u, v) = 1$ and $d_H(\varphi(u), \varphi(v)) \geq 2$, implying an expansion of at least 2. \square

We now state the problem we use in the reductions for our NP-hardness proofs. It is a generalization of the Hamiltonian cycle problem [9]. Let $\mathcal{G} = (V, E)$ be a directed graph over n vertices. \mathcal{G} has a *disjoint cycle cover* if there is a collection of vertex-disjoint cycles in \mathcal{G} that contain every node in V , i.e., there exists a permutation $\sigma : [n] \rightarrow [n]$ such that for all $i \in [n]$, $(v_i, v_{\sigma(i)}) \in E$. \mathcal{G}

has a *loose* disjoint cycle cover if it has a disjoint cycle cover after adding two arbitrarily chosen edges to E .

The *loose directed disjoint cycle cover testing* problem is a property testing problem defined as follows. Given a directed graph \mathcal{G} , output 1 if \mathcal{G} has a disjoint cycle cover and 0 if \mathcal{G} does not even have a loose disjoint cycle cover. Note that in the remaining scenario, one is allowed to output anything.

Lemma 3. *The loose directed disjoint cycle cover testing problem is NP-hard for graphs with indegree ≤ 4 and outdegree $= 3$.*

Proof. This can be shown by an extension of the ideas used in the NP-completeness proof of the directed disjoint cycle cover problem in an earlier paper by the authors [5] using in addition the fact that the Vertex Cover problem is hard to approximate [7]. We omit the details. \square

Finally, we mention a combinatorial result about sum-free sequences that is used in one of our constructions. A sequence of n integers is *k-way sum-free* if all n^k sums of k integers (not necessarily distinct) in it are distinct. Khanna et al. [14] suggest a greedy algorithm to construct 3-way sum-free sequences. Their result can be generalized to the following.

Lemma 4. *There exists a strictly increasing sequence of size n in $[n^{2k-1}]$ that is *k-way sum-free* and is computable in time $O(n^{2k-1})$.*

3 Hardness of Embeddings Between Tree Graphs

Consider the problem of finding a minimum distortion embedding between two given undirected tree graphs. We give reductions from the loose directed disjoint cycle cover testing problem to the decision version of this embedding problem on weighted as well as unweighted trees. The result for the weighted case holds even for graphs with all but one node of degree at most 4. We begin with a general construction that will be used in both reductions.

Given a directed graph \mathcal{G} with outdegree $= 3$ and indegree ≤ 4 , we will construct a source tree \mathcal{S} and a destination tree \mathcal{D} with the property that there exist $0 < a < b$ such that

1. if \mathcal{G} has a disjoint cycle cover then $\text{dist}(\mathcal{S}, \mathcal{D}) \leq a$, and
2. if \mathcal{G} has no *loose* disjoint cycle cover then $\text{dist}(\mathcal{S}, \mathcal{D}) \geq b$.

It follows from Lemma 3 that it is NP-hard to approximate $\text{dist}(\mathcal{S}, \mathcal{D})$ within a factor less than b/a .

3.1 The Construction

We describe in this section the construction of \mathcal{S} and \mathcal{D} from \mathcal{G} . Let \mathbb{Z}^+ denote the set of positive integers and $s : \mathbb{Z}^+ \rightarrow \mathbb{Z}^+$ be a strictly increasing monotonic function. Let v_1, \dots, v_n be the vertices of \mathcal{G} .

We will need two types of gadgets, a *center gadget* and for each $i \in [n]$, a *size gadget* T_i . The center gadget is a rooted tree consisting of n leaves, all at depth 1. All edges in this gadget have weight $y \in \mathbb{Z}^+$. Its root is denoted by c_r and leaves by c_ℓ . The size gadget T_i is a rooted tree consisting of $s(i)$ leaves, all at depth 1. All edges in T_i have weight 1. The root of T_i is denoted by g_r and the leaves by g_ℓ .

The source tree \mathcal{S} is constructed as follows (see Fig. 1). Start with a copy of the center gadget and associate with each c_ℓ node of it a distinct vertex v_i of \mathcal{G} . For any $i \in [n]$, let the successors of v_i in \mathcal{G} be the vertices v_{i_1}, v_{i_2} , and v_{i_3} . Attach to the c_ℓ node corresponding to v_i copies of the three size gadgets T_{i_1}, T_{i_2} , and T_{i_3} by adding edges with weight $x \in \mathbb{Z}^+$ to the g_r nodes of these gadgets. Copies of any size gadget T_i in \mathcal{S} will henceforth be denoted by S_i .

Fig. 1. A directed graph and the source and destination trees corresponding to it. For simplicity of depiction, $s(i) = i$. Unmarked edges have a weight of 1

The destination tree \mathcal{D} is constructed similarly. As before, start with a copy of the center gadget. Fix an arbitrary ordering of its c_ℓ nodes. For all $i \in [n]$, attach to the i^{th} c_ℓ node a copy of the size gadget T_i by adding an edge of weight x to its g_r node. These n size gadgets are called *non-spare* size gadgets. Now let \mathcal{P} be the multi-set $\{i \mid \text{gadget } T_i \text{ is used in } \mathcal{S}\}$. We may assume that $\mathcal{P} \supseteq [n]$, otherwise a disjoint cycle cover cannot exist. For each $i \in \mathcal{P} \setminus [n]$, attach a copy of the size gadget T_i directly to the c_r node by adding edges of weight $z \in \mathbb{Z}^+$ to their g_r node. These are called *spare* size gadgets. Copies of any size gadget T_i in \mathcal{D} will henceforth be denoted by D_i .

Note that both \mathcal{S} and \mathcal{D} have the same number of nodes and for every $i \in [n]$, the same number of copies of the size gadget T_i . Further, \mathcal{S} and \mathcal{D} each have exactly one c_r node, n c_ℓ nodes, and $3n$ g_ℓ nodes (recall the outdegree of every vertex of \mathcal{G} is 3). Consider a mapping φ from \mathcal{S} to \mathcal{D} . Let A and B be sets of nodes in \mathcal{S} and \mathcal{D} , respectively. φ *fully* maps A to B if $\{\varphi(u) \mid u \in A\} = B$. φ maps A *exactly* to B if A and B are size gadgets with g_r nodes a and b , respectively, φ fully maps A to B , and $\varphi(a) = b$.

The basic idea of the construction is that \mathcal{S} encodes the input graph \mathcal{G} while \mathcal{D} is setup so that the relationships between the c_ℓ nodes and the non-spare size

gadgets induce (via a low distortion embedding) a permutation on the vertices of \mathcal{G} . This construction balances two conflicting desires. On one hand, it must be possible to match unused size gadgets to the spare gadgets with small distortion when a disjoint cycle cover exists. Thus, the spare gadgets cannot be too far from the successor-selection part \mathcal{D} . On the other hand, a node corresponding to a vertex in \mathcal{G} must be far enough from size gadgets not corresponding to its own successors so that choosing a predecessor incorrectly gives large distortion.

Lemma 5. *If \mathcal{G} has a disjoint cycle cover then $\text{dist}(\mathcal{S}, \mathcal{D}) \leq (y+z)(x+y)/(xz)$.*

Proof. As \mathcal{G} has a disjoint cycle cover, there is a permutation $\sigma : [n] \rightarrow [n]$ such that for all $i \in [n]$, $(i, \sigma(i))$ is an edge in \mathcal{G} . We construct a small distortion embedding φ of \mathcal{S} into \mathcal{D} . Consider any $i \in [n]$. By the definition of σ , an S_i gadget A is attached to the c_ℓ node u corresponding to $v_{\sigma(i)}$ in \mathcal{S} . Let φ map A exactly to the non-spare D_i gadget B of \mathcal{D} and u to the c_ℓ node attached to B . This leaves $2n$ size gadgets of \mathcal{S} not yet mapped. Map each of these exactly to spare size gadgets of \mathcal{D} . Finally, let φ map the c_r node of \mathcal{S} to the c_r node of \mathcal{D} .

We claim that $\text{exp}(\varphi) = (y+z)/x$. By Lemma 1, we only need to consider the expansion of the edges of \mathcal{S} . The (g_r, g_ℓ) and (c_r, c_ℓ) edges in \mathcal{S} have an expansion of 1. A (g_r, c_ℓ) edge in \mathcal{S} has an expansion of 1 if the corresponding S_i gadget is mapped to a non-spare D_i gadget and $(y+z)/x$ otherwise. This proves the claim. We further claim that $\text{exp}(\varphi^{-1}) = (x+y)/x$. Again using Lemma 1, the only edges in \mathcal{D} that have expansion different from 1 are the (c_r, g_r) edges in \mathcal{D} that give an expansion of $(x+y)/z$. This completes the proof. \square

Let φ be any embedding of \mathcal{S} into \mathcal{G} . Since both \mathcal{S} and \mathcal{D} contain edges of weight 1 and all edge weights are in \mathbb{Z}^+ , we have the following.

Proposition 1. *$\text{exp}(\varphi) \geq 1$ and $\text{con}(\varphi) \geq 1$.*

Lemma 6. *If \mathcal{G} has no disjoint cycle cover and φ fully maps every non-spare D_i gadget from an S_i gadget and c_ℓ nodes from c_ℓ nodes, then both $\text{exp}(\varphi)$ and $\text{con}(\varphi)$ are at least $1 + 2y/x$.*

Proof. For $i \in [n]$, consider the S_i gadget A_i that maps to the non-spare D_i gadget B_i of \mathcal{D} . Let A_i be attached to the c_ℓ node u_j of \mathcal{S} corresponding to vertex v_j of \mathcal{G} . Let B_i be attached to the c_ℓ node w_i of \mathcal{D} . If u_j maps to w_i and $(v_j, v_i) \in E(\mathcal{G})$, think of vertex v_i being chosen as the successor of vertex v_j in \mathcal{G} . Since \mathcal{G} does not have a disjoint cycle cover, there must exist $i \in [n]$ such that u_j , as defined above, does not map to w_i . Fix such i and j . Let $\varphi(u_j) = w_{k_1}$ and $\varphi(u_{k_2}) = w_i$, where $k_1 \neq i$ and $k_2 \neq j$. Let r be the g_r node of A_i and r' be that of B_i . The edge (u_j, r) in \mathcal{S} gives an expansion of at least $(x+2y)/x = 1 + 2y/x$ because φ maps u_j to w_{k_1} and r to a node within B_i . Similarly, the edge (w_i, r') in \mathcal{D} gives a contraction of at least $1 + 2y/x$ because φ^{-1} maps w_i to u_{k_2} and r' to a node within A_i . \square

Lemma 7. *If \mathcal{G} has no loose disjoint cycle cover and φ fully maps every S_i gadgets to a D_i gadget, then both $\text{exp}(\varphi)$ and $\text{con}(\varphi)$ are at least $1 + 2y/x$.*

Proof. Since every S_i gadget fully maps to a D_i gadget, the center gadget of \mathcal{S} fully maps to the center gadget of \mathcal{D} . We first consider the case when φ maps the c_r node of \mathcal{S} to the c_r node in \mathcal{D} . Every c_ℓ node of \mathcal{S} must then map to a c_ℓ node of \mathcal{D} and Lemma 6 completes the proof.

Now suppose that φ maps the c_r node of \mathcal{S} to a c_ℓ node w_i of \mathcal{D} . As all gadgets are fully mapped, there is a c_ℓ node u_j of \mathcal{S} corresponding to vertex v_j of \mathcal{G} be mapped to the c_r node of \mathcal{D} . Let B_i be the D_i gadget attached to w_i . From the arguments we made above, it follows that if we want at least one of $\text{exp}(\varphi)$ and $\text{con}(\varphi)$ to be strictly less than $1 + 2y/x$, then only one of two things can happen. First, a size gadget A_i in \mathcal{S} that does not correspond to a successor of v_j is mapped to B_i and every other size gadget maps correctly w.r.t. the successor relationship in \mathcal{G} . In this case, $\text{exp}(\varphi) \geq 1 + 2y/x$ while $\text{con}(\varphi)$ may be at most $1 + y/x$. However, if A_i corresponds to vertex v_i , by adding the edge (v_j, v_i) , we have a disjoint cycle cover, contradicting the absence of a loose cycle cover. Second, B_i and at most two other non-spare size gadgets B_k and B_ℓ in \mathcal{D} are mapped from size gadgets in \mathcal{S} that correspond to successors v_i, v_k and v_ℓ of v_j , and every other size gadget maps correctly w.r.t. the successor relationship in \mathcal{G} . In this case, $\text{con}(\varphi) \geq 1 + 2y/x$ while $\text{exp}(\varphi)$ may be at most $1 + y/x$. The successor of v_j is well-defined in this case, but v_k and v_ℓ may not be successors of the c_ℓ nodes in \mathcal{S} mapped to the c_ℓ nodes of B_k and B_ℓ . If those nodes are v_s and v_t , by adding edges (v_s, v_k) and (v_t, v_ℓ) , we have a disjoint cycle cover, again contradicting the absence of a loose cover. \square

3.2 Hardness for Weighted Trees

We first consider general weighted trees with unbounded degree and then modify the reduction so that exactly one node in both \mathcal{S} and \mathcal{D} has non-constant degree. Let φ be an embedding of \mathcal{S} into \mathcal{D} . We begin by showing that for suitably weighted \mathcal{S} and \mathcal{D} , the distortion is large if φ does not map size gadgets correctly.

Lemma 8. *If $s(1) > n$ and φ does not fully map every S_i gadget to a D_i gadget, then $\text{dist}(\varphi) \geq x \cdot \min\{x, z\}$.*

Proof. Suppose $\text{exp}(\varphi) < \min\{x, z\}$. For $i \in [n]$, $s(i) \geq s(1) > n$. Since the center gadgets have only $n + 1$ nodes, every size gadget in \mathcal{S} must have at least one node that φ maps to a size gadget in \mathcal{D} . Recall that all edges within size gadgets in \mathcal{S} have weight 1 while every edge going out of size gadgets in \mathcal{D} has weight $\min\{x, z\}$. To keep $\text{exp}(\varphi) < \min\{x, z\}$, every node of any size gadget in \mathcal{S} must map within a single size gadget in \mathcal{D} . Since for all $i \in [n]$, \mathcal{S} and \mathcal{D} have the same number of S_i and D_i gadgets, respectively, this can happen only if every S_i gadget fully maps to a D_i gadget. A similar argument shows that $\text{exp}(\varphi^{-1}) < x$ only if every D_i gadget fully maps to an S_i gadget. \square

Theorem 1. *For $\alpha \geq 1$, it is NP-hard to approximate the distortion between two trees with weight ratio $O(\alpha^2)$ within a factor less than $1 + \alpha$.*

Proof. Let \mathcal{G} , \mathcal{S} , and \mathcal{D} be as in Section 3.1 with $x = \alpha + 1$, $y = \alpha(\alpha + 1)/2$, $z = x + y = (\alpha + 1)(\alpha + 2)/2$, and $s(i) = i + n$ for $i \in [n]$. The weight ratio of $\{\mathcal{S}, \mathcal{D}\}$ is $(\alpha + 1)(\alpha + 2)/2$. If \mathcal{G} has a disjoint cycle cover then by Lemma 5 $\text{dist}(\mathcal{S}, \mathcal{D}) \leq 1 + 2y/x = 1 + \alpha$. If \mathcal{G} does not have a loose disjoint cycle cover then by Lemmas 7 and 8, $\text{dist}(\mathcal{S}, \mathcal{D}) \geq \min\{x \cdot \min\{x, z\}, (1 + 2y/x)^2\}$, which is $(1 + \alpha)^2$. The result follows from Lemma 3. \square

Let N be the number of nodes in \mathcal{S} (and \mathcal{D}). In the above construction, $N = \Theta(n^2)$. The c_r nodes of \mathcal{S} and \mathcal{D} have degrees n and $3n$, respectively, which is $\Theta(\sqrt{N})$. The c_ℓ nodes have degrees 4 and 2, respectively. The g_r nodes have degrees between $n = \Theta(\sqrt{N})$ and $2n$, while the g_ℓ nodes have degree 1. By replacing each S_i and D_i gadget with a line graph, we can show the following theorem. The complete proof may be found in the full version of the paper [4].

Theorem 2. *For $0 < \epsilon \leq 1/2$ and $\alpha \geq 1$, it is NP-Hard to approximate the distortion between two trees with N nodes, weight ratio $\Omega(\alpha^2)$, exactly one node of degree $\Theta(N^\epsilon)$, and all other nodes of degree ≤ 4 within a factor less than $1 + \alpha$.*

3.3 Hardness for Unweighted Trees

The construction from Section 3.1 needs slight modification in order to obtain hardness results for the unweighted case. Let \mathcal{G} , \mathcal{S} , and \mathcal{D} be as in Section 3.1 with $x = y = z = 1$ and $s(i) = 2c \cdot (f(i) + 2n^5)$, where $c = 4n + 2$ and f is a strictly increasing 3-way sum-free sequence of size n in $[n^5]$ guaranteed by Lemma 4. These parameters imply six useful properties of s , namely, $s(\cdot)$ is even, $s(\cdot)$ is a multiple of c , $2s(1) \gg s(n)$, $2s(n) < 3s(1)$, $|s(i) - s(j)|$ is large for $i \neq j$, and $s(1), s(2), \dots, s(n)$ is a strictly increasing 3-way sum-free sequence. Furthermore, we have that $c > |\text{Edges}(\mathcal{G})| = 3n$. We will repeatedly use the fact that \mathcal{S} and \mathcal{D} each have $n + 1$ center gadget nodes and $3n g_r$ nodes.

The only change to the construction is to modify the non-spare size gadgets in \mathcal{D} . Instead of being depth one trees with $s(i)$ leaves, they are now depth two trees with $s(i)/2$ nodes at depth one, each of which has a single depth two leaf. The root and depth one nodes are denoted by g_r and g_ℓ as before, the depth two leaves are denoted by g'_ℓ , and the depth one and two nodes are together denoted by \overline{g}_ℓ . All other notation is unchanged. Like the original construction, both \mathcal{S} and \mathcal{D} have the same number of nodes and for each S_i gadget there is a corresponding D_i gadget with the same number of nodes.

Let φ be any embedding of \mathcal{S} into \mathcal{D} . We will prove the following lemmas in the rest of this section using Propositions 2 and 3, respectively.

Lemma 9. *If \mathcal{G} has no disjoint cycle cover and φ does not fully map every S_i gadget to a D_i gadget, then $\text{exp}(\varphi) \geq 3$.*

Lemma 10. *If \mathcal{G} has no disjoint cycle cover and φ does not fully map every S_i gadget to a D_i gadget, then either $\text{con}(\varphi) \geq 3$ or $\text{exp}(\varphi) \geq 5$.*

Theorem 3. *It is NP-Hard to approximate the distortion between two unweighted trees within a factor less than $9/4$.*

Proof. If \mathcal{G} has a disjoint cycle cover then by an argument similar to Lemma 5, $\text{dist}(\mathcal{S}, \mathcal{D}) \leq 4$. Assume that \mathcal{G} does not have a loose disjoint cycle cover (and hence no disjoint cycle cover either). If φ fully maps every S_i gadget to a D_i gadget then by an argument similar to Lemma 7, $\text{dist}(\varphi) \geq 9$. If it does not then Lemmas 2, 9, and 10 imply $\text{dist}(\varphi) \geq 9$. The result follows from Lemma 3. \square

Proposition 2. *If any of the following fail, $\text{exp}(\varphi) \geq 3$.*

1. *No size gadget in \mathcal{S} maps to the $\overline{g_\ell}$ nodes of two distinct size gadgets in \mathcal{D} .*
2. *Nodes of no two size gadgets in \mathcal{S} are both mapped to the $\overline{g_\ell}$ nodes of a single size gadget in \mathcal{D} .*
3. *No node of an S_i gadget maps to a $\overline{g_\ell}$ node of a D_j gadget for $j \neq i$.*
4. *The g_r node of any S_i gadget A maps within the unique D_i gadget B whose $\overline{g_\ell}$ nodes A maps to, or possibly to the c_r node of \mathcal{D} if B is a spare gadget.*
5. *The c_r node of \mathcal{S} is not mapped to a non-spare gadget or the g_ℓ nodes of a spare gadget in \mathcal{D} .*
6. *No c_ℓ node in \mathcal{S} is mapped to a non-spare gadget or the g_ℓ nodes of a spare gadget in \mathcal{D} .*

Proof. Suppose (1) fails and a size gadget A in \mathcal{S} maps to the $\overline{g_\ell}$ nodes of two distinct size gadgets B and C in \mathcal{D} . Any $\overline{g_\ell}$ node of B is at least distance 5 away from any $\overline{g_\ell}$ node of C , while all nodes in A are within distance 2 of each other. Hence, $\text{exp}(\varphi) \geq 5/2$. By Corollary 1, $\text{exp}(\varphi) \geq 3$.

Suppose (2) fails with an S_i gadget A and an S_k gadget C mapping to the $\overline{g_\ell}$ nodes of a single D_j gadget B . A and C together have at least $s(i) + s(k) - s(j) \geq 2s(1) - s(n) \geq 2c(2 + n^5)$ nodes mapped outside B . Since there are only $4n + 1$ non- $\overline{g_\ell}$ nodes in \mathcal{D} ($n + 1$ in the center gadget and $3n$ g_r nodes), a node of A or C must map to a $\overline{g_\ell}$ node of a size gadget in \mathcal{D} other than B . This violates (1).

The proofs of the remaining cases are similar and may be found in [4]. \square

Proof of Lemma 9. By Proposition 2 (1), (4), (5), and (6), no node other than that of a unique S_i gadget can be mapped to any non-spare D_i gadget or the g_ℓ nodes of a spare D_i gadget. It follows that all non-spare gadgets are fully mapped. We further claim that all c_ℓ nodes of \mathcal{S} are mapped to c_ℓ nodes of \mathcal{D} , in which case the proof is complete by Lemma 6. The claim holds because of the following. Observe that since all non-spare gadgets are fully mapped, all c_ℓ nodes of \mathcal{S} must map within the center gadget of \mathcal{D} to ensure $\text{exp}(\varphi) \leq 2$. Further, by the assumption in the lemma, at least one spare gadget B is partially mapped from a gadget A in \mathcal{S} . By (4), the g_r node of A must map to the c_r node of \mathcal{D} , making the latter unavailable for the c_ℓ nodes of \mathcal{S} . \square

We begin the contraction argument by stating a straightforward but crucial property of the g'_ℓ nodes of the size gadgets in \mathcal{D} .

Observation 1 *If a g'_ℓ node of a size gadget B in \mathcal{D} does not have as its image under φ^{-1} in \mathcal{S} a node with neighbors only those nodes that are images of nodes of B , the c_ℓ node attached to B , or the c_r node of \mathcal{D} , then $\text{exp}(\varphi) \geq 5$.*

Define the *successor cluster* X corresponding to a vertex v of \mathcal{G} to be the c_ℓ node u of \mathcal{S} corresponding to v and the three size gadgets A_{i_X}, A_{j_X} , and A_{k_X} attached to it. Let $Q_X^\varphi \subseteq \{1, \dots, n\}$ be the *multi-set* defined by $Q_X^\varphi = \{r \mid \text{some non-}g'_\ell \text{ node of a } D_r \text{ gadget maps under } \varphi^{-1} \text{ to a non-}c_\ell \text{ node of } X\}$. The multiplicity of r in Q_X^φ is the number of D_r 's that map in this way to X . Since the number of center gadget nodes in \mathcal{D} is only $n + 1$, $s_X^\varphi = \sum_{r \in Q_X^\varphi} s(r)$ can be less than $s_X = s(i_X) + s(j_X) + s(k_X)$ by at most $n + 1$. However, since s_X^φ and s_X are both multiples of $c > n + 1$, $s_X^\varphi \geq s_X$.

Proposition 3. *If any of the following fail, $\text{con}(\varphi) \geq 3$ or $\text{exp}(\varphi) \geq 5$.*

1. $Q_X^\varphi = \{i_X, j_X, k_X\}$.
2. The g_r node of any D_i gadget B is mapped within the unique successor cluster X to which B 's non- g'_ℓ nodes map.
3. The c_r node of \mathcal{D} maps to the c_r node of \mathcal{S} .
4. The g_ℓ nodes of \mathcal{S} are occupied only by the size gadget nodes of \mathcal{D} .
5. If a c_ℓ node of \mathcal{D} is mapped to a node of a successor cluster X , then nodes from exactly three size gadgets of \mathcal{D} map into X . (X may have other c_ℓ nodes of \mathcal{D} mapped into it as well.)
6. If a c_ℓ node of \mathcal{D} is mapped to the c_ℓ node of a successor cluster X , then three size gadgets of \mathcal{D} fully map to the non- c_ℓ nodes of X .
7. If no c_ℓ node of \mathcal{D} is mapped to a node of a successor cluster X , then nodes from exactly three size gadgets of \mathcal{D} map into X and the c_ℓ node of X is occupied by a node from a fourth size gadget of \mathcal{D} .
8. Every successor cluster in \mathcal{S} is fully mapped from exactly one c_ℓ node and three size gadgets of \mathcal{D} .
9. If a c_ℓ node v in \mathcal{D} is mapped to a successor cluster X , then the root r of the size gadget B attached to v is mapped to X .

Proof. Unless mentioned otherwise the mapping under consideration in this proof is φ^{-1} . We refer the reader to the full version [4] for most cases of the proof.

If (5) fails, let v be a c_ℓ node of \mathcal{D} that is mapped to a node u of X . By (4), u is either a c_ℓ node or a g_r node. Suppose first that it is a c_ℓ node. Since (5) fails, there is a size gadget B in \mathcal{D} that has a node mapping to X and another adjacent node mapping outside X . Then B contains two nodes that are mapped at least distance 3 apart because they cannot map to the c_ℓ node of X or to the c_r node of \mathcal{S} .

Suppose on the other hand that u is the g_r node of size gadget A in X . Consider the set \mathcal{Z} of size gadgets in \mathcal{D} that have a node mapping to a g_ℓ node of A . Since the size of each gadget in \mathcal{Z} is $1 \pmod c$, the number of g_ℓ nodes of A is $0 \pmod c$, and $|\mathcal{Z}| \leq |\text{Edges}(\mathcal{G})| = 3n < c$, there exists a size gadget $B \in \mathcal{Z}$ that also maps outside A . In particular, B must have a node mapped to the c_ℓ node of X which is the only node of \mathcal{S} outside A within distance 2 of the g_ℓ nodes

of A . Since by (4) the c_r node of \mathcal{S} is already occupied by the c_r node of \mathcal{D} , no size gadget (other than possibly B) mapping to a node outside X can also map within X without causing $\exp(\varphi^{-1}) \geq 3$. (5) now follows from (1). \square

Proof of Lemma 10. From Proposition 3 (8) and (9), any non-spare size gadget in \mathcal{D} and the c_ℓ node of \mathcal{D} it is attached to must map within the same successor cluster in \mathcal{S} under φ^{-1} . Consequently, Proposition 3 (8) can be strengthened to say that every successor cluster in \mathcal{S} corresponding to a node v is fully mapped from exactly one c_ℓ node in \mathcal{D} , the size gadget B attached to it, and two spare size gadgets. As $s(\cdot)$ is sum-free, B must correspond to a successor of v . Since there are exactly n c_ℓ nodes in \mathcal{D} , this assigns a unique successor to each node v , establishing a disjoint cycle and the contradiction which proves the lemma. \square

4 Hardness of Embeddings Between Line Graphs with Large Weights

A *line graph* is an acyclic connected graph of maximum degree two, that is, a line of vertices. We have the following result whose proof appears in the full version of the paper [4].

Theorem 4. *Given two line graphs with n nodes and weight ratio $\Omega(b^2)$, for any $k > 1$ and b with $b = \Omega(kn^2)$, it is NP-hard to determine if the distortion between them is less than b/k or at least b .*

Corollary 2. *For $\alpha > 0$, it is NP-hard to approximate the distortion between two line graphs with n nodes and weight ratio $\Omega(\alpha^2 n^4)$ within a factor of α .*

5 Conclusion

We have shown that the problem of finding a minimum distortion embedding between two metrics is hard to approximate within constant factors on even extremely simple graphs, such as weighted lines or unweighted trees. While our constants improve previous results, we believe they are still far from the true story: it seems likely that even approximating distortion in unweighted graphs is much harder than what we know.

One natural relaxation to the graph embedding problem is to find the distortion of embedding a constant fraction of one graph to another. While this quantity will in general be far from the true distortion, it may provide a good enough measure of graph difference for certain applications. Other notions of distortion may also be useful. Rabinovich [19] has used average distortion to study the MinCut-MaxFlow gap in uniform-demand multicommodity flow. Other possibly interesting measures are max-distortion, which is the maximum of expansion and contraction rather than the product, and Gromov-Hausdorff distance, which has applications in analysis. The problem remains open in all these scenarios.

Improved Lower Bounds for Locally Decodable Codes and Private Information Retrieval

Stephanie Wehner* and Ronald de Wolf*

CWI, Kruislaan 413, 1098 SJ, Amsterdam, the Netherlands
{wehner, rdewolf}@cwi.nl

Abstract. We prove new lower bounds for *locally decodable codes* and *private information retrieval*. We show that a 2-query LDC encoding n -bit strings over an ℓ -bit alphabet, where the decoder only uses b bits of each queried position, needs code length $m = \exp\left(\Omega\left(\frac{n}{2^b \sum_{i=0}^b \binom{\ell}{i}}\right)\right)$. Similarly, a 2-server PIR scheme with an n -bit database and ℓ -bit queries, where the user only needs b bits from each of the two ℓ -bit answers, unknown to the servers, satisfies $t = \Omega\left(\frac{n}{2^b \sum_{i=0}^b \binom{\ell}{i}}\right)$. This implies that several known PIR schemes are close to optimal. Our results generalize those of Goldreich et al. [8], who proved roughly the same bounds for *linear* LDCs and PIRs. Like earlier work by Kerenidis and de Wolf [12], our classical bounds are proved using quantum computational techniques. In particular, we give a tight analysis of how well a 2-input function can be computed from a quantum superposition of both inputs.

1 Introduction

1.1 Locally Decodable Codes

Error correcting codes allow reliable transmission and storage of information in noisy environments. Such codes often have the disadvantage that one has to read almost the entire codeword, even if one is only interested in a small part of the encoded information. A *locally decodable* code $C : \{0, 1\}^n \rightarrow \Sigma^m$ over alphabet Σ is an error-correcting code that allows efficient decoding of individual bits of the encoded information: given any string y that is sufficiently close to the real codeword $C(x)$, we can probabilistically recover any bit x_i of the original input x , while only looking at k positions of y . The code length m measures the cost of the encoding, while k measures the efficiency of decoding individual bits. Such codes have had a number of applications in recent computer science research, including PCPs and worst-case to average-case reductions. One can also think of applications encoding a large chunk of data in order to protect it from noise, where we are only interested in extracting small pieces at a time. Imagine for

* Supported by EU project RESQ IST-2001-37559 and NWO Vici grant 2004-2009.

example an encoding of all books in a library, where we would like to retrieve only the first paragraph of this paper.

The main complexity question of interest is the tradeoff between m and k . With $k = \text{polylog}(n)$ queries, the code length can be made polynomially small, even over the binary alphabet $\Sigma = \{0, 1\}$ [3]. However, for fixed k , the best upper bounds are superpolynomial. Except for the $k = 2$ case with small alphabet Σ , no good lower bounds are known. Katz and Trevisan [10] showed superlinear but at most quadratic lower bounds for constant k . Goldreich et al. [8] showed an exponential lower bound for *linear* codes with $k = 2$ queries and constant alphabet, and Kerenidis and de Wolf [12] extended this to *all* codes, using techniques from quantum computing. For $\Sigma = \{0, 1\}^\ell$ they prove $m = 2^{\Omega(n/2^{5\ell})}$. They also slightly improved the polynomial bounds of [10] for $k > 2$.

Clearly the above lower bound becomes trivial if each position of the code-word has $\ell \geq \log(n)/5$ bits. In this paper we analyze the case where ℓ can be much larger, but the decoder uses only b bits out of the ℓ bits of a query answer. The b positions that he uses may depend on the index i he is interested in and on his randomness. This setting is interesting because many existing constructions are of this form, for quite small b . Goldreich et al. [8] also analyzed this situation, and showed the following lower bound for *linear* codes: $m = 2^{\Omega(n/\sum_{i=0}^b \binom{\ell}{i})}$. Here we prove a slightly weaker lower bound for all codes: $m = 2^{\Omega(n/2^b \sum_{i=0}^b \binom{\ell}{i})}$. In particular, if $b = \ell$ (so the decoder can use all bits from the query answers) we improve the bound from [12] to $m = 2^{\Omega(n/2^{2\ell})}$. We lose a factor of 2^b compared to Goldreich et al. This factor can be dispensed with if the decoder outputs the parity of a subset of the bits he receives. All known LDCs are of this type.

Our proofs are completely different from the combinatorial approach of Goldreich et al. Following [12], we proceed in two steps: (1) we reduce the two classical queries to one *quantum* query and (2) show a lower bound for the induced one-quantum-query-decodable code by deriving a *random access code* from it. The main novelty is a tight analysis of the following problem. Suppose we want to compute a Boolean function $f(a_0, a_1)$ on $2b$ bits, given a quantum superposition $\frac{1}{\sqrt{2}}(|0, a_0\rangle + |1, a_1\rangle)$ of both halves of the input. We show that *any* Boolean f can be computed with advantage $1/2^{b+1}$ from this superposition, and that this is best-achievable for the parity function. This may be of independent interest. In fact, Kerenidis [11] recently used it to exhibit an exponential quantum-classical separation in multiparty communication complexity, and in an interesting new approach to improve depth lower bounds for *classical* circuits.

1.2 Private Information Retrieval

There is a very close connection between LDCs and the setting of *private information retrieval*. In PIR, the user wants to retrieve some item from a database without letting the database learn anything about what item he asked for. In the general model, the user retrieves the i th bit from an n -bit database $x = x_1 \dots x_n$ that is replicated over $k \geq 1$ non-communicating servers. He communicates with

each server without revealing any information about i to individual servers, and at the end of the day learns x_i . This is a natural cryptographic problem that has applications in systems where privacy of the user is important, for example databases providing medical information. Much research has gone into optimizing the communication complexity of one-round PIR schemes. Here the user sends a t -bit message (“query”) to each server, who responds with an ℓ -bit message (“answer”), from which the user infers x_i . A number of non-trivial upper bounds have been found [7, 1, 4, 6], but, as in the LDC case, the optimality of such schemes is wide open. In fact, the best known constructions of LDCs with constant k come from PIR schemes with k servers. Roughly speaking, concatenating the servers’ answers to all possible queries gives a codeword $C(x)$ of length $m = k2^t$ over the alphabet $\Sigma = \{0, 1\}^\ell$ that is decodable with k queries. The privacy of the PIR scheme translates into the error-correcting property of the LDC: since many different sets of k queries have to work for recovering x_i , we can afford some corrupted positions. Conversely, we can turn a k -query LDC into a k -server PIR scheme by asking one query to each server (so $t = \log m$). The privacy of the resulting PIR scheme follows from the fact that an LDC can be made to have a “smoothness” property, meaning that most positions are about equally likely to be queried, independent of i .

Here we restrict attention to 2 servers, which is probably the most interesting case. The paper by Chor et al. [7] that introduced PIR, gave a PIR scheme where both the queries to the servers and the answers from the servers have length $\Theta(n^{1/3})$ bits. Later constructions gave alternative ways of achieving the same complexity, but have not given asymptotic improvements for the 2-server case (in contrast to the case of 3 or more servers [6] and the case of 2 *quantum* servers [12]). Though general lower bounds for 2-server PIRs still elude us, reasonably good lower bounds can be proved for schemes that only use a small number b of bits from each possibly much longer answer string. This b is sometimes called the *probe complexity* of the scheme. As stated in [5], small probe complexity is a desirable property of a PIR scheme for a number of reasons: the user needs less space; the schemes can be more easily applied recursively as in [6]; and such PIR schemes induce locally decodable codes where the code-length m is relatively small while the codeword entries are allowed to have many bits each, but the decoder needs only few bits from each codeword entry it read.

As was implicitly stated by Katz and Trevisan [10] and formalized by Goldreich et al. [7], it is possible to translate 2-server PIRs to 2-query LDCs, where the property of only using b bits from each ℓ -bit string carries over. Combining this lemma with our LDC lower bounds gives the following bound for 2-server PIRs with t -bit queries, ℓ -bit answers, and probe complexity b : $t = \Omega(n/2^b \sum_{i=0}^b \binom{\ell}{i})$. In particular, for fixed b the overall communication is $C = 2(t + \ell) = \Omega(n^{1/(b+1)})$. This is tight for $b = 1$ (we describe an $O(\sqrt{n})$ scheme in Section 2) and close to optimal for $b = 3$, since a small variation of the Chor et al. scheme achieves $C = O(n^{1/3})$ using only 3 bits from each

answer¹, while our bound is $\Omega(n^{1/4})$. Similar results were established for *linear* PIR schemes by Goldreich et al., but our results apply to *all* PIR schemes. They imply that in improved 2-server PIR schemes, the user needs to use more bits from the servers' answers. For general schemes, where $b = \ell$, we obtain $t = \Omega(n/2^{2\ell})$. This improves the $n/2^{5\ell}$ bound from [12]. It implies a lower bound of $5 \log n$ on the total communication $C = 2(t + \ell)$. This is incredibly weak, but without any assumptions on how the user handles the answers, and still improves what was known [13, 12].

2 Preliminaries

We use $a_{|S}$ to denote the string a restricted to a set of bits $S \subseteq [n] = \{1, \dots, n\}$, e.g., $11001_{|\{1,4,5\}} = 101$. We identify a set $S \subseteq [n]$ with n -bit string $S = S_1 \dots S_n$, where $i \in S$ if and only if the i th bit $S_i = 1$. We use e_i for the n -bit string corresponding to the singleton set $S = \{i\}$. If $y \in \Sigma^m$ where $\Sigma = \{0, 1\}^\ell$, then $y_j \in \Sigma$ denotes its j th entry, and $y_{j,i}$ with $i \in [\ell]$ is the i th bit of y_j . We assume general familiarity with the quantum model [15]. Our proofs depend heavily on the notion of a quantum query. We consider queries with ℓ -bit answers, where $\ell \geq 1$. For $\Sigma = \{0, 1\}^\ell$, a quantum query to a string $y \in \Sigma^m$ is the unitary map $|j\rangle|z\rangle \mapsto |j\rangle|z \oplus y_j\rangle$, where $j \in [m]$, $z \in \{0, 1\}^\ell$ is called the target register, and $z \oplus y_j$ is the string resulting from the xor of the individual bits of z and y_j , i.e. $z \oplus y_j = (z_1 \oplus y_{j,1}) \dots (z_\ell \oplus y_{j,\ell})$. It is convenient to get the query result in the phase of the quantum state. To this end, define $|z_T\rangle = \frac{1}{\sqrt{2^\ell}} \bigotimes_{i=1}^\ell (|0\rangle + (-1)^{T_i} |1\rangle)$ where T_i is the i th bit of the ℓ -bit string T . Since $|0 \oplus y_{j,i}\rangle + (-1)^{T_i} |1 \oplus y_{j,i}\rangle = (-1)^{T_i \cdot y_{j,i}} (|0\rangle + (-1)^{T_i} |1\rangle)$, a query maps $|j\rangle|z_T\rangle \mapsto |j\rangle(-1)^{T \cdot y_j} |z_T\rangle$.

A locally decodable code is an error-correcting code that allows efficient decoding of individual bits.

Definition 1. $C : \{0, 1\}^n \rightarrow \Sigma^m$ is a (k, δ, ε) -locally decodable code (LDC), if there exists a classical randomized decoding algorithm A with input $i \in [n]$ and oracle access to a string $y \in \Sigma^m$ such that

1. A makes k distinct queries j_1, \dots, j_k to y , non-adaptively, gets query answers $a_1 = y_{j_1}, \dots, a_k = y_{j_k}$ and outputs a bit $f(a_1, \dots, a_k)$, where f depends on i and A 's randomness.
2. For every $x \in \{0, 1\}^n$, $i \in [n]$ and $y \in \Sigma^m$ with Hamming distance $d(y, C(x)) \leq \delta m$ we have $\Pr[f(a_1, \dots, a_k) = x_i] \geq 1/2 + \varepsilon$.

Here probabilities are taken over A 's internal randomness. For $\Sigma = \{0, 1\}^\ell$, we say the LDC uses b bits, if A only uses b predetermined bits of each query answer: it outputs $f(a_{1|S_1}, \dots, a_{k|S_k})$ where the sets S_1, \dots, S_k are of size b each and are determined by i and A 's randomness.

¹ A polynomial-based $O(n^{1/3})$ -scheme from [4] does not have this ‘‘small b ’’-property.

In our arguments we will use *smooth* codes. These are codes where the decoding algorithm spreads its queries “smoothly” across the codeword, meaning it queries no code location too frequently.

Definition 2. $C : \{0, 1\}^n \rightarrow \Sigma^m$ is a (k, c, ε) -smooth code (SC) if there is a randomized algorithm A with input $i \in [n]$ and oracle access to $C(x)$ s.t.

1. A makes k distinct queries j_1, \dots, j_k to $C(x)$, non-adaptively, gets query answers $a_1 = C(x)_{j_1}, \dots, a_k = C(x)_{j_k}$ and outputs a bit $f(a_1, \dots, a_k)$, where f depends on i and A 's randomness.
2. For every $x \in \{0, 1\}^n$ and $i \in [n]$ we have $\Pr[f(a_1, \dots, a_k) = x_i] \geq 1/2 + \varepsilon$.
3. For every $x \in \{0, 1\}^n$, $i \in [n]$ and $j \in [m]$, $\Pr[A \text{ queries } j] \leq c/m$.

The smooth code uses b bits, if A only uses b predetermined bits of each answer.

Note that the decoder of smooth codes deals only with valid codewords $C(x)$. The decoding algorithm of an LDC on the other hand can deal with corrupted codewords y that are still sufficiently close to the original. Katz and Trevisan [10–Theorem 1] showed that LDCs and smooth codes are closely related:

Theorem 1 (Katz & Trevisan). If $C : \{0, 1\}^n \rightarrow \Sigma^m$ is a (k, δ, ε) -LDC, then C is also a $(k, k/\delta, \varepsilon)$ -smooth code (the property of using b bits carries over).

The following definition of a one-query *quantum* smooth code is rather ad hoc and not the most general possible, but sufficient for our purposes.

Definition 3. $C : \{0, 1\}^n \rightarrow \Sigma^m$ is a $(1, c, \varepsilon)$ -quantum smooth code (QSC), if there is a quantum algorithm A with input $i \in [n]$ and oracle access to $C(x)$ s.t.

1. A probabilistically picks a string r , makes a query of the form

$$|Q_{ir}\rangle = \frac{1}{\sqrt{2}} \left(|j_{1r}\rangle \frac{1}{\sqrt{2^b}} \sum_{T \subseteq S_{1r}} |z_T\rangle + |j_{2r}\rangle \frac{1}{\sqrt{2^b}} \sum_{T \subseteq S_{2r}} |z_T\rangle \right)$$

and returns the outcome of some measurement on the resulting state.

2. For every $x \in \{0, 1\}^n$ and $i \in [n]$ we have $\Pr[A \text{ outputs } x_i] \geq 1/2 + \varepsilon$.
3. For every x, i, j , $\Pr[A \text{ queries } j \text{ with non-zero amplitude}] \leq c/m$.

The QSC uses b bits, if the sets S_{1r}, S_{2r} have size b .

PIR allows a user to obtain the i th bit from an n -bit database x , replicated over $k \geq 1$ servers, without revealing anything about i to individual servers.

Definition 4. A one-round, $(1 - \eta)$ -secure, k -server private information retrieval (PIR) scheme for a database $x \in \{0, 1\}^n$ with recovery probability $1/2 + \varepsilon$, query size t , and answer size ℓ , consists of a randomized algorithm (user) and k deterministic algorithms S_1, \dots, S_k (servers), such that

1. On input $i \in [n]$, the user produces k t -bit queries q_1, \dots, q_k and sends these to the respective servers. The j th server returns ℓ -bit string $a_j = S_j(x, q_j)$. The user outputs a bit $f(a_1, \dots, a_k)$ (f depends on i and his randomness).

2. For every $x \in \{0, 1\}^n$ and $i \in [n]$ we have $\Pr[f(a_1, \dots, a_k) = x_i] \geq 1/2 + \varepsilon$.
3. For all $x \in \{0, 1\}^n$, $j \in [k]$, and any two indices $i_1, i_2 \in [n]$, the two distributions on q_j (over the user's randomness) induced by i_1 and i_2 are η -close in total variation distance.

The scheme uses b bits if the user only uses b predetermined bits from each a_i .

If $\eta = 0$, then the server gets no information at all about i . All known non-trivial PIR schemes have $\eta = 0$, perfect recovery ($\varepsilon = 1/2$), and one round of communication. We give two well-known 2-server examples from [7].

Square scheme. Arrange $x = x_1 \dots x_n$ in a $\sqrt{n} \times \sqrt{n}$ square, then index i is given by two coordinates (i_1, i_2) . The user picks a random string $A \in \{0, 1\}^{\sqrt{n}}$, and sends \sqrt{n} -bit queries $q_1 = A$ and $q_2 = A \oplus e_{i_1}$ to the servers. The first returns \sqrt{n} -bit answer $a_1 = q_1 \cdot C_1, \dots, q_1 \cdot C_{\sqrt{n}}$, where $q_1 \cdot C_c$ denotes the inner product mod 2 of q_1 with the c th column of x . The second server sends a_2 analogously. The user selects the bit $q_1 \cdot C_{i_2}$ from a_1 and $q_2 \cdot C_{i_2}$ from a_2 and computes $(A \cdot C_{i_2}) \oplus ((A \oplus e_{i_1}) \cdot C_{i_2}) = e_{i_1} \cdot C_{i_2} = x_i$. Here $t = \ell = \sqrt{n}$ and $b = 1$.

Cube scheme. A more efficient scheme arranges x in a cube, so $i = (i_1, i_2, i_3)$. The user picks 3 random strings T_1, T_2, T_3 of $n^{1/3}$ bits each, and sends queries $q_1 = T_1, T_2, T_3$ and $q_2 = (T_1 \oplus e_{i_1}), (T_2 \oplus e_{i_2}), (T_3 \oplus e_{i_3})$. The first server computes the bit $a = b_{T_1 T_2 T_3} = \bigoplus_{j_1 \in T_1, j_2 \in T_2, j_3 \in T_3} x_{j_1, j_2, j_3}$. Its answer a_1 is the $n^{1/3}$ bits $b_{T'_1 T_2 T_3} \oplus a$ for all T'_1 differing from T_1 in exactly one place, and similarly all $b_{T_1 T'_2 T_3} \oplus a$ and $b_{T_1 T_2 T'_3} \oplus a$. The second server does the same with its query q_2 . The user now selects those 3 bits of each answer that correspond to $T'_1 = T_1 \oplus e_{i_1}$, $T'_2 = T_2 \oplus e_{i_2}$, $T'_3 = T_3 \oplus e_{i_3}$ respectively, and xors those 6 bits. Since every other x_{j_1, j_2, j_3} occurs exactly twice in that sum, what is left is $x_{i_1, i_2, i_3} = x_i$. Here $t, \ell = O(n^{1/3})$ and $b = 3$.

3 Computing $f(a_0, a_1)$ from Superposed Input

To prove the lower bound on LDCs and PIRs, we first construct the following quantum tool. Consider a state $|\Psi_{a_0 a_1}\rangle = \frac{1}{\sqrt{2}}(|0, a_0\rangle + |1, a_1\rangle)$ with a_0, a_1 both b -bit strings. We show that we can compute any Boolean function $f(a_0, a_1)$ with bias $1/2^{b+1}$ given one copy of this state. After that we show that bias is optimal if f is the $2b$ -bit parity function. The key to the algorithm is the following:

Lemma 1. For every $f : \{0, 1\}^{2b} \rightarrow \{0, 1\}$ there exist non-normalized states $|\varphi_a\rangle$ such that $U : |a\rangle|0\rangle \rightarrow \frac{1}{2^b} \sum_{w \in \{0, 1\}^b} (-1)^{f(w, a)} |w\rangle|0\rangle + |\varphi_a\rangle|1\rangle$ is unitary.

Proof. Let $|\psi_a\rangle = (1/2^b) \sum_{w \in \{0, 1\}^b} (-1)^{f(w, a)} |w\rangle|0\rangle + |\varphi_a\rangle|1\rangle$. It is easy to see that U can be extended to be unitary if and only if $\langle \psi_a | \psi_{a'} \rangle = \delta_{aa'}$ for all a, a' . We will choose $|\varphi_a\rangle$ to achieve this. First, since $\langle w | w' \rangle = \delta_{ww'}$ and $\langle w, 0 | \varphi_a, 1 \rangle = 0$:

$$\langle \psi_a | \psi_{a'} \rangle = \frac{1}{2^{2b}} \sum_{w \in \{0, 1\}^b} (-1)^{f(w, a) + f(w, a')} + \langle \varphi_a | \varphi_{a'} \rangle.$$

Let C be the $2^b \times 2^b$ matrix with entries $C_{aa'} = (1/2^{2b}) \sum_{w \in \{0,1\}^b} (-1)^{f(w,a) + f(w,a')}$ where the indices a and a' are b -bit strings. From the definition of $C_{aa'}$ we have $|C_{aa'}| \leq 1/2^b$. By [9–Corollary 6.1.5], the largest eigenvalue is

$$\lambda_{max}(C) \leq \min \left\{ \max_a \sum_{a' \in \{0,1\}^b} |C_{aa'}|, \max_{a'} \sum_{a \in \{0,1\}^b} |C_{aa'}| \right\} \leq \sum_{a \in \{0,1\}^b} \frac{1}{2^b} = 1.$$

However, $\lambda_{max}(C) \leq 1$ implies that $I - C$ is positive semidefinite and hence, by [9–Corollary 7.2.11], $I - C = A^\dagger A$ for some matrix A . Now define $|\varphi_a\rangle$ to be the a th column of A . Since the matrix $C + A^\dagger A = I$ is composed of all inner products $\langle \psi_a | \psi_{a'} \rangle$, we have $\langle \psi_a | \psi_{a'} \rangle = \delta_{aa'}$ and it follows that U is unitary. \square

Theorem 2. *Suppose $f : \{0, 1\}^{2b} \rightarrow \{0, 1\}$ is a Boolean function. There exists a quantum algorithm to compute $f(a_0, a_1)$ with success probability exactly $1/2 + 1/2^{b+1}$ using one copy of $|\Psi_{a_0 a_1}\rangle = \frac{1}{\sqrt{2}}(|0, a_0\rangle + |1, a_1\rangle)$, with $a_0, a_1 \in \{0, 1\}^b$.*

Proof. First we extend the state $|\Psi_{a_0 a_1}\rangle$ by a $|0\rangle$ -qubit. Let U be as in Lemma 1. Applying the unitary transform $|0\rangle\langle 0| \otimes I^{\otimes b+1} + |1\rangle\langle 1| \otimes U$ to $|\Psi_{a_0 a_1}\rangle|0\rangle$ gives

$$\frac{1}{\sqrt{2}} \left(|0\rangle|a_0\rangle|0\rangle + |1\rangle \left(\frac{1}{2^b} \sum_{w \in \{0,1\}^b} (-1)^{f(w,a_1)} |w\rangle|0\rangle + |\varphi_{a_1}\rangle|1\rangle \right) \right).$$

Define $|I\rangle = |a_0\rangle|0\rangle$ and $|A\rangle = \frac{1}{2^b} \sum_w (-1)^{f(w,a_1)} |w\rangle|0\rangle + |\varphi_{a_1}\rangle|1\rangle$. Then $\langle I|A\rangle = \frac{1}{2^b} (-1)^{f(a_0, a_1)}$ and the above state is $\frac{1}{\sqrt{2}}(|0\rangle|I\rangle + |1\rangle|A\rangle)$. We apply a Hadamard transform to the first qubit to get $\frac{1}{2}(|0\rangle(|I\rangle + |A\rangle) + |1\rangle(|I\rangle - |A\rangle))$. The probability that a measurement of the first qubit yields a 0 is $\frac{1}{4} \langle I + A | I + A \rangle = \frac{1}{2} + \frac{1}{2} \langle I|A\rangle = \frac{1}{2} + \frac{(-1)^{f(a_0, a_1)}}{2^{b+1}}$. Thus by measuring the first qubit we obtain $f(a_0, a_1)$ with bias $1/2^{b+1}$. \square

To prove that this algorithm is optimal for the parity function, we need to consider how well we can distinguish two density matrices ρ_0 and ρ_1 , i.e., given an unknown state determine whether it is ρ_0 or ρ_1 . Let $\|A\|_{tr}$ denote the trace norm of matrix A , which equals the sum of its singular values.

Lemma 2. *Two density matrices ρ_0 and ρ_1 cannot be distinguished with probability better than $1/2 + \|\rho_0 - \rho_1\|_{tr}/4$.*

Proof. The most general way of distinguishing ρ_0 and ρ_1 is a POVM [15] with two operators E_0 and E_1 , such that $p_0 = tr(\rho_0 E_0) \geq 1/2 + \varepsilon$ and $q_0 = tr(\rho_1 E_0) \leq 1/2 - \varepsilon$. Then $|p_0 - q_0| \geq 2\varepsilon$ and likewise, $|p_1 - q_1| \geq 2\varepsilon$, for similarly defined p_1 and q_1 . By [15–Theorem 9.1], $\|\rho_0 - \rho_1\|_{tr} = \max_{\{E_0, E_1\}} (|p_0 - q_0| + |p_1 - q_1|)$ and thus $\|\rho_0 - \rho_1\|_{tr} \geq 4\varepsilon$. Hence $\varepsilon \leq \|\rho_0 - \rho_1\|_{tr}/4$. \square

Theorem 3. *Suppose that f is the parity of $a_0 a_1$. Then any quantum algorithm for computing f from one copy of $|\Psi_{a_0 a_1}\rangle$ has success probability $\leq 1/2 + 1/2^{b+1}$.*

Proof. Define ρ_0 and ρ_1 by $\rho_c = \frac{1}{2^{2b-1}} \sum_{a_0 a_1 \in f^{-1}(c)} |\Psi_{a_0 a_1}\rangle \langle \Psi_{a_0 a_1}|$, with $c \in \{0, 1\}$. A quantum algorithm that computes parity of $a_0 a_1$ with probability $1/2 + \varepsilon$ can be used to distinguish ρ_0 and ρ_1 . Hence by Lemma 2: $\varepsilon \leq \|\rho_0 - \rho_1\|_{tr}/4$. Let $A = \rho_0 - \rho_1$. It is easy to see that the $|0, a_0\rangle \langle 0, a_0|$ -entries are the same in ρ_0 and in ρ_1 , so these entries are 0 in A . Similarly, the $|1, a_1\rangle \langle 1, a_1|$ -entries in A are 0. In the off-diagonal blocks, the $|0, a_0\rangle \langle 1, a_1|$ -entry of A is $(-1)^{|a_0|+|a_1|}/2^{2b}$. For $|\phi\rangle = \frac{1}{\sqrt{2^b}} \sum_{w \in \{0,1\}^b} (-1)^{|w|} |w\rangle$ we have $|\phi\rangle \langle \phi| = \frac{1}{2^b} \sum_{a_0, a_1} (-1)^{|a_0|+|a_1|} |a_0\rangle \langle a_1|$ and $A = \frac{1}{2^b} (|0, \phi\rangle \langle 1, \phi| + |1, \phi\rangle \langle 0, \phi|)$. Let U and V be unitary transforms such that $U|0, \phi\rangle = |0, 0^b\rangle$, $U|1, \phi\rangle = |1, 0^b\rangle$ and $V|0, \phi\rangle = |1, 0^b\rangle$, $V|1, \phi\rangle = |0, 0^b\rangle$, then $UAV^\dagger = \frac{1}{2^b} (U|0, \phi\rangle \langle 1, \phi| V^\dagger + U|1, \phi\rangle \langle 0, \phi| V^\dagger) = \frac{1}{2^b} (|0, 0^b\rangle \langle 0, 0^b| + |1, 0^b\rangle \langle 1, 0^b|)$. The two nonzero singular values of UAV^\dagger are both $1/2^b$, hence $\|\rho_0 - \rho_1\|_{tr} = \|A\|_{tr} = \|UAV^\dagger\|_{tr} = 2/2^b$. Therefore $\varepsilon \leq \|\rho_0 - \rho_1\|_{tr}/4 = 1/2^{b+1}$. \square

4 Lower Bounds for LDCs That Use Few Bits

We now make use of the technique developed above to prove new lower bounds for 2-query LDCs over non-binary alphabets. First we construct a 1-query quantum smooth code (QSC) from a 2-query smooth code (SC), and then prove lower bounds for QSCs. In the sequel, we will index the two queries by 0 and 1 instead of 1 and 2, to conform to the two basis states $|0\rangle$ and $|1\rangle$ of a qubit.

Theorem 4. *If $C : \{0, 1\}^n \rightarrow (\{0, 1\}^\ell)^m$ is a $(2, c, \varepsilon)$ -smooth code that uses b bits, then C is a $(1, c, \varepsilon/2^b)$ -quantum smooth code that uses b bits.*

Proof. Fix index $i \in [n]$ and encoding $y = C(x)$. The 1-query quantum decoder will pick a random string r with the same probability as the 2-query classical decoder. This r determines two indices $j_0, j_1 \in [m]$, two b -element sets $S_0, S_1 \subseteq [\ell]$, and a function $f : \{0, 1\}^{2b} \rightarrow \{0, 1\}$ such that $\Pr[f(y_{j_0|S_0}, y_{j_1|S_1}) = x_i] = p \geq \frac{1}{2} + \varepsilon$, where the probability is taken over the decoder's randomness. Assume for simplicity that $j_0 = 0$ and $j_1 = 1$, and define $a_0 = y_{j_0|S_0}$ and $a_1 = y_{j_1|S_1}$. We now construct a 1-query quantum decoder that outputs $f(a_0, a_1)$ with probability $1/2 + 1/2^{b+1}$, as follows. The result of a quantum query to j_0 and j_1 is

$$\frac{1}{\sqrt{2}} \left(\underbrace{|0\rangle}_{j_0} \frac{1}{\sqrt{2^b}} \sum_{T \subseteq S_0} (-1)^{a_0 \cdot T} |z_T\rangle + \underbrace{|1\rangle}_{j_1} \frac{1}{\sqrt{2^b}} \sum_{T \subseteq S_1} (-1)^{a_1 \cdot T} |z_T\rangle \right).$$

Note that we write $a_0 \cdot T$ instead of $y_{j_0} \cdot T$, since $T \subseteq S_0$ and therefore the inner product will be the same. We can unitarily transform this to $\frac{1}{\sqrt{2}} (|0\rangle |a_0\rangle + |1\rangle |a_1\rangle)$. By Theorem 2, we can compute an output bit o from this such that $\Pr[o = f(a_0, a_1)] = 1/2 + 1/2^{b+1}$. The probability of success is then given by $\Pr[o = x_i] = \Pr[o = f(a_0, a_1)] \Pr[x_i = f(a_0, a_1)] + \Pr[o \neq f(a_0, a_1)] \Pr[x_i \neq f(a_0, a_1)] = (1/2 + 1/2^{b+1})p + (1/2 - 1/2^{b+1})(1 - p) \geq 1/2 + \varepsilon/2^b$. Since no j

is queried with probability more than c/m by the classical decoder, the same is true for the quantum decoder. \square

Our lower bound for 2-query LDCs uses the following notion, due to [2].

Definition 5. A quantum random access code is a mapping $x \mapsto \rho_x$ of the n -bit strings x into m -qubit states ρ_x , such that any bit x_i can be recovered with some probability $p \geq 1/2 + \varepsilon$ from ρ_x

Note that we need not be able to recover all x_i 's simultaneously from ρ_x , just any one x_i of our choice. Nayak [14] proved a tight bound on m :

Theorem 5 (Nayak). Every quantum random access code has $m \geq (1 - H(p))n$.

The main idea of our proof is to show how the following state $|U(x)\rangle$ induces a quantum random access code. For $u = \sum_{i=0}^b \binom{\ell}{i}$ define the pure states

$$|U(x)_j\rangle = \frac{1}{\sqrt{u}} \sum_{|T|\leq b} (-1)^{T \cdot C(x)_j} |z_T\rangle \text{ and } |U(x)\rangle = \frac{1}{\sqrt{m}} \sum_{j=1}^m |j\rangle |U(x)_j\rangle.$$

Lemma 3. Suppose $C : \{0, 1\}^n \rightarrow (\{0, 1\}^\ell)^m$ is a $(1, c, \varepsilon)$ -quantum smooth code that uses b bits. Then given one copy of $|U(x)\rangle$, there is a quantum algorithm that outputs 'fail' with probability $1 - 2^{b+1}/(cu)$ with $u = \sum_{i=0}^b \binom{\ell}{i}$, but if it succeeds it outputs x_i with probability at least $1/2 + \varepsilon$.

Proof. Let us fix $i \in [n]$. Suppose the quantum decoder of C makes query $|Q_{ir}\rangle$ to indices j_{0r} and j_{1r} with probability p_r . Consider the following state

$$|V_i(x)\rangle = \sum_r \sqrt{p_r} |r\rangle \frac{1}{\sqrt{2}} (|j_{0r}\rangle |U(x)_{j_{0r}}\rangle + |j_{1r}\rangle |U(x)_{j_{1r}}\rangle).$$

We first show how to obtain $|V_i(x)\rangle$ from $|U(x)\rangle$ with some probability. Rewrite $|V_i(x)\rangle = \sum_{j=1}^m \alpha_j |\phi_j\rangle |j\rangle |U(x)_j\rangle$, where the α_j are nonnegative reals, and $\alpha_j^2 \leq c/(2m)$ because C is a QSC (the $1/2$ comes from the amplitude $1/\sqrt{2}$). Using the unitary map $|0\rangle |j\rangle \mapsto |\phi_j\rangle |j\rangle$, we can obtain $|V_i(x)\rangle$ from the state $|V'_i(x)\rangle = \sum_{j=1}^m \alpha_j |j\rangle |U(x)_j\rangle$. We thus have to show that we can obtain $|V'_i(x)\rangle$ from $|U(x)\rangle$. Define operator $M = \sqrt{2m/c} \sum_{j=1}^m \alpha_j |j\rangle \langle j| \otimes I$ and consider a POVM with operators $M^\dagger M$ and $I - M^\dagger M$. These operators are positive because $\alpha_j^2 \leq c/2m$. Up to normalization, $M|U(x)\rangle = |V'_i(x)\rangle$. The probability that the measurement succeeds (takes us from $|U(x)\rangle$ to $|V'_i(x)\rangle$) is $\langle U(x) | M^\dagger M | U(x) \rangle = \frac{2m}{c} \langle U(x) | \left(\sum_j \alpha_j^2 |j\rangle \langle j| \otimes I \right) | U(x) \rangle = \frac{2}{c} \sum_j \alpha_j^2 = \frac{2}{c}$. Now given $|V_i(x)\rangle$ we can measure r , and then project the last register onto the sets S_{0r} and S_{1r} that we need for $|Q_{ir}\rangle$, by means of the measurement operator $|j_{0r}\rangle \langle j_{0r}| \otimes \sum_{T \subseteq S_{0r}} |T\rangle \langle T| + |j_{1r}\rangle \langle j_{1r}| \otimes \sum_{T \subseteq S_{1r}} |T\rangle \langle T|$. This measurement succeeds with probability $2^b/u$, but if it succeeds we have the state corresponding

to the answer to query $|Q_{ir}\rangle$, from which we can predict x_i . Thus, we succeed with probability $(2^b/u) \cdot (2/c)$, and if we succeed, we output x_i with probability $1/2 + \varepsilon$. \square

We can avoid failures by taking many copies of $|U(x)\rangle$:

Lemma 4. *If $C : \{0, 1\}^n \rightarrow (\{0, 1\}^\ell)^m$ is a $(1, c, \varepsilon)$ -quantum smooth code, then $|W(x)\rangle = |U(x)\rangle^{\otimes cu/2^{b+1}}$ is a $cu(\log(m) + \log(u))/2^{b+1}$ -qubit random access code for x with recovery probability $1/2 + \varepsilon/2$ where $u = \sum_{i=0}^b \binom{\ell}{i}$.*

Proof. We do the experiment of the previous lemma on each copy of $|U(x)\rangle$ independently. The probability that all experiments fail simultaneously is $(1 - 2^{b+1}/(cu))^{cu/2^{b+1}} \leq 1/2$. In that case we output a fair coin flip. If at least one experiment succeeds, we can predict x_i with probability $1/2 + \varepsilon$. This gives overall success probability at least $1/2(1/2 + \varepsilon) + (1/2)^2 = 1/2 + \varepsilon/2$. \square

The lower bound for 2-query SCs and LDCs over non-binary alphabets is then:

Theorem 6. *If $C : \{0, 1\}^n \rightarrow \Sigma^m = (\{0, 1\}^\ell)^m$ is a $(2, c, \varepsilon)$ -smooth code where the decoder uses only b bits of each answer, then $m \geq 2^{dn - \log(u)}$ for $d = (1 - H(1/2 + \varepsilon/2^{b+1}))2^{b+1}/(cu) = \Theta(\varepsilon^2/(2^b cu))$ and $u = \sum_{i=0}^b \binom{\ell}{i}$. Hence $m = 2^{\Omega(\varepsilon^2 n / (2^{2\ell} c))}$ if $b = \ell$.*

Proof. Theorem 4 implies that C is a $(1, c, \varepsilon/2^b)$ -quantum smooth code. Lemma 4 gives us a random access code of $cu(\log(m) + \log(u))/2^{b+1}$ qubits with recovery probability $p = 1/2 + \varepsilon/2^{b+1}$. Finally, the random access code lower bound, Theorem 5, implies $cu(\log(m) + \log(u))/2^{b+1} \geq (1 - H(p))n$. Rearranging and using that $1 - H(1/2 + \eta) = \Theta(\eta^2)$ gives the result. \square

Since a $(2, \delta, \varepsilon)$ -LDC is a $(2, 2/\delta, \varepsilon)$ -smooth code (Theorem 1), we obtain:

Corollary 1. *If $C : \{0, 1\}^n \rightarrow \Sigma^m = (\{0, 1\}^\ell)^m$ is a $(2, \delta, \varepsilon)$ -locally decodable code, then $m \geq 2^{dn - \log(u)}$ for $d = (1 - H(1/2 + \varepsilon/2^{b+1}))\delta 2^b/u = \Theta(\delta \varepsilon^2 / (2^b u))$ and $u = \sum_{i=0}^b \binom{\ell}{i}$. Hence $m = 2^{\Omega(\delta \varepsilon^2 n / 2^{2\ell})}$ if $b = \ell$.*

In all known non-trivial constructions of LDCs and SCs, the decoder outputs the parity of the bits that he is interested in. Then, we can prove:

Theorem 7. *If $C : \{0, 1\}^n \rightarrow \Sigma^m = (\{0, 1\}^\ell)^m$ is a $(2, c, \varepsilon)$ -smooth code where the decoder outputs $f(g(a_{0|S_0}), g(a_{1|S_1}))$, with $f, g : \{0, 1\}^2 \rightarrow \{0, 1\}$ fixed functions, then $m \geq 2^{dn - \log(\ell')}$ for $d = \Omega(\varepsilon^2 / (c\ell'))$ and $\ell' = \binom{\ell}{b}$.*

Proof. Transform C into a smooth code $C' : \{0, 1\}^n \rightarrow (\{0, 1\}^{\ell'})^m$ with $\ell' = \binom{\ell}{b}$ by defining $C'(x)_j$ to be the value of g on all $\binom{\ell}{b}$ possible b -subsets of the original ℓ bits of $C(x)_j$. We need only 1 bit of each $C'(x)_j$, and can apply Theorem 6. \square

5 Lower Bounds for Private Information Retrieval

Here we derive improved lower bounds for 2-server PIRs from our LDC bounds. We use the following [8–Lemma 7.1] to translate PIR schemes to smooth codes:

Lemma 5 (GKST). *Suppose there is a one-round, $(1 - \eta)$ -secure PIR scheme with two servers, database size n , query size t , answer size ℓ , and recovery probability at least $1/2 + \varepsilon$. Then there is a $(2, 3, \varepsilon - \eta)$ -smooth code $C : \{0, 1\}^n \rightarrow (\{0, 1\}^\ell)^m$, where $m \leq 6 \cdot 2^t$. If the PIR scheme uses only b bits of each server answer, then the resulting smooth code uses only b bits of each query answer.*

We now combine this with Theorem 6 to slightly improve the lower bound given in [12] and to extend it to the case where we only use b bits of each server reply.

Theorem 8. *A classical 2-server $(1 - \eta)$ -secure PIR scheme with t -bit queries, ℓ -bit answers that uses b bits and has recovery probability $1/2 + \varepsilon$ satisfies $t = \Omega\left(\frac{n(\varepsilon - \eta)^2}{2^b u}\right)$ with $u = \sum_{i=0}^b \binom{\ell}{i}$. In particular, if $b = \ell$, then $t = \Omega(n(\varepsilon - \eta)^2 / 2^{2\ell})$.*

Proof. Using Lemma 5 we turn the PIR scheme into a $(2, 3, \varepsilon - \eta)$ -smooth code $C : \{0, 1\}^n \rightarrow (\{0, 1\}^\ell)^m$ that uses b bits of ℓ where $m \leq 6 \cdot 2^t$. From Theorem 6 we have $m \geq 2^{dn - \log(u)}$ with $d = \Theta((\varepsilon - \eta)^2 / (2^b u))$. □

If b is fixed, $\varepsilon = 1/2$ and $\eta = 0$, this bound simplifies to $t = \Omega(n/\ell^b)$, hence

Corollary 2. *A 2-server PIR scheme with t -bit queries and ℓ -bit answers has communication $C = 2(t + \ell) = \Omega\left(n^{1/(b+1)}\right)$.*

For $b = 1$ this gives $C = \Omega(\sqrt{n})$, which is achieved by the square scheme of Section 2. For $b = 3$ we get $C = \Omega(n^{1/4})$, which is close to the $C = O(n^{1/3})$ of the cube scheme. As in Theorem 7, we can get the better bound $t = \Omega(n(\varepsilon - \eta)^2 / \binom{\ell}{b})$ for PIR schemes where the user just outputs the parity of b bits from each answer. All known non-trivial PIR schemes have this property.

The previous lower bounds on the query length of 2-server PIR schemes were significant only for protocols that use few bits from each answer. Here we slightly improve the best known bound of $4.4 \log n$ [12] on the overall communication complexity of 2-server PIR schemes, by combining our Theorem 8 and Theorem 6 of Katz and Trevisan [10]. We restate their theorem for the PIR setting, assuming for simplicity that $\varepsilon = 1/2$ and $\eta = 0$.

Theorem 9 (Katz & Trevisan). *Every 2-server PIR with t -bit queries and ℓ -bit answers has $t \geq 2 \log(n/\ell) - O(1)$.*

We now prove the following lower bound on the total communication $C = 2(t + \ell)$ of any 2-server PIR scheme with t -bit queries and ℓ -bit answers:

Theorem 10. *Every 2-server PIR scheme has $C \geq (5 - o(1)) \log n$.*

Proof. We distinguish three cases, depending on the answer length. Let $\delta = \log \log n / \log n$.

case 1: $\ell \leq (0.5 - \delta) \log n$. Theorem 8 implies $C \geq t = \Omega(n^{2\delta}) = \Omega((\log n)^2)$.

case 2: $(0.5 - \delta) \log n < \ell < 2.5 \log n$. Then from Theorem 9 we have $C = 2(t + \ell) > 2(2 \log(n/(2.5 \log n)) - O(1) + (0.5 - \delta) \log n) = (5 - o(1)) \log n$.

case 3: $\ell \geq 2.5 \log n$. Then $C = 2(t + \ell) \geq 5 \log n$. \square

6 Conclusion and Future Work

Here we improved the best known lower bounds on the length of 2-query locally decodable codes and the communication complexity of 2-server private information retrieval schemes. Our bounds are significant whenever the decoder uses only few bits from the two query answers, even if the alphabet (LDC case) or answer length (PIR case) is large. This contrasts with the earlier results of Kerenidis and de Wolf [12], which become trivial for logarithmic alphabet or answer length, and those of Goldreich et al. [8], which only apply to *linear* schemes.

Still, general lower bounds without constraints on alphabet or answer size completely elude us. Clearly, this is one of the main open questions in this area. Barring that, we could at least improve the dependence on b of our current bounds. For example, a PIR lower bound like $t = \Omega(n/\ell^{\lceil b/2 \rceil})$ might be feasible using some additional quantum tricks. Such a bound for instance implies that the total communication is $\Omega(n^{1/3})$ for $b = 3$, which would show that the cube scheme of [7] is optimal among all schemes of probe complexity 3. Another question is to obtain strong lower bounds for the case of $k \geq 3$ queries or servers. For this case, no superpolynomial lower bounds are known even if the alphabet or answer size is only one bit.

Abstract. A class of relational structures is said to have the extension preservation property if every first-order sentence that is preserved under extensions on the class is equivalent to an existential sentence. The class of all finite structures does not have the extension preservation property. We study the property on classes of finite structures that are better behaved. We show that the property holds of classes of acyclic structures, structures of bounded degree and more generally structures that are *wide* in a sense we make precise. We also show that the preservation property holds for the class of structures of treewidth at most k , for any k . In contrast, we show that the property fails for the class of planar graphs.

1 Introduction

The subject of model theory is concerned with the relationship between syntactic and semantic properties of logic. Among classical results in the subject are preservation theorems which relate syntactic restrictions on first-order logic with structural properties of the classes of structures defined. A key example is the Łoś-Tarski Theorem which asserts that a first-order formula is preserved under extensions on all structures if, and only if, it is logically equivalent to an existential formula (see [7]). One direction of this result is easy, namely that any formula that is purely existential is preserved under extensions, and this holds on any class of structures. The other direction, going from the semantic restriction to the syntactic restriction makes key use of the compactness of first-order logic and hence of infinite structures.

In the early development of finite-model theory, when it was realized that finite structures are the ones that are interesting from the point of view of studying computation, it was observed that most classical preservation theorems from model theory fail when only finite structures are allowed. In particular, the Łoś-Tarski theorem fails on finite structures [9, 6]. These results suggest that the class of finite structures is not well-behaved from the point of view of model theory. However, when one considers the computational structures that arise in practice and are used as interpretations for logical languages (for instance, program models interpreting specifications or databases interpreting queries), in many cases they are not only finite but satisfy other structural

restrictions as well. This motivates the study, not just of the class of finite structures, but of well-behaved subclasses of this class.

There are certain structural restrictions that have proved especially useful from an algorithmic point of view. For instance, many intractable computational problems become tractable when restricted to planar graphs or structures of bounded treewidth [2]. This is also the case in relation to evaluation of logical formulas [5]. A common generalization of classes of bounded treewidth and planar graphs are classes of structures that exclude a minor which have also been extensively studied.

A study of preservation properties for such restricted classes of finite structures was initiated in [1]. There, the focus was on the homomorphism preservation theorem, whose status on the class of finite structures was open. It was shown that this preservation property holds on any class of structures of bounded degree, bounded treewidth or that excludes some minor (and has certain other closure properties). In the present paper, we investigate the Łoś-Tarski extension preservation property on these classes of finite structures. Note that the failure of the property on the class of all finite structures does not imply its failure on subclasses. If one considers the non-trivial direction of the preservation theorem on a class \mathcal{C} , it says that any sentence φ that is preserved under extensions *on* \mathcal{C} is equivalent *on* \mathcal{C} to an existential sentence. Thus, restricting to a subclass \mathcal{C}' of \mathcal{C} weakens both the hypothesis and the consequent of the statement.

We show that the extension preservation theorem holds on any class of finite structures closed under substructures and disjoint unions that is also *wide* in the sense that any sufficiently large structure in the class contains a large number of elements that are far apart. This includes, for instance, any class of structures of bounded degree. While classes of structures of bounded treewidth are not wide, they are nearly so in that they can be made wide by removing a small number of elements. We use this property and show that it implies the extension preservation theorem for the class \mathcal{T}_k —the class of structures of treewidth k or less (note this is not as general as saying that the property holds for all classes of bounded treewidth). Finally, we show that the construction does not extend to classes defined by excluded minors. Indeed, the extension preservation theorem does not hold for the class of planar graphs, as we show through a counterexample. This contrasts with the results obtained for the homomorphism preservation property in [1] as this property was shown to hold on all classes excluding a graph minor and closed under substructures and disjoint unions.

The main methodology in establishing the preservation property for a class of structures \mathcal{C} is to show an upper bound on the size of a minimal model of a first-order sentence φ that is preserved under extensions on \mathcal{C} . The way we do this is to show that for any sufficiently large model \mathbf{A} of φ , there is a proper substructure of \mathbf{A} and an extension of \mathbf{A} that cannot be distinguished by φ . In Section 3 we establish this for the relatively simple case of acyclic structures by means of a Hanf locality argument. Section 4 contains the main combinatorial argument for wide structures which uses Gaifman locality and an iterated construction of the substructure of \mathbf{A} . In Section 5, the combinatorial argument is adapted to the classes \mathcal{T}_k . Finally, in Section 6 we conclude and discuss the existence of a counterexample in the case of planar graphs. We begin in Section 2 with some background and definitions.

2 Preliminaries

Our notation and terminology is standard (see [3]).

Relational structures. A *relational vocabulary* σ is a finite set of *relation symbols*, each with a specified *arity*. A σ -*structure* \mathbf{A} consists of a *universe* A , or *domain*, and an *interpretation* which associates to each relation symbol $R \in \sigma$ of some arity r , a relation $R^{\mathbf{A}} \subseteq A^r$. A *graph* is a structure $\mathbf{G} = (V, E)$, where E is a binary relation that is symmetric and anti-reflexive. Thus, our graphs are undirected, loopless, and without parallel edges.

A σ -structure \mathbf{B} is called a *substructure* of \mathbf{A} if $B \subseteq A$ and $R^{\mathbf{B}} \subseteq R^{\mathbf{A}}$ for every $R \in \sigma$. It is called an *induced substructure* if $R^{\mathbf{B}} = R^{\mathbf{A}} \cap B^r$ for every $R \in \sigma$ of arity r . Notice the analogy with the graph-theoretical concept of *subgraph* and *induced subgraph*. A substructure \mathbf{B} of \mathbf{A} is proper if $\mathbf{A} \neq \mathbf{B}$. If \mathbf{A} is an induced substructure of \mathbf{B} , we say that \mathbf{B} is an *extension* of \mathbf{A} . If \mathbf{A} is a proper induced substructure, then \mathbf{B} is a proper extension. If \mathbf{B} is the disjoint union of \mathbf{A} with another σ -structure, we say that \mathbf{B} is a *disjoint extension* of \mathbf{A} . If $S \subseteq A$ is a subset of the universe of \mathbf{A} , then $\mathbf{A} \cap S$ denotes the *induced substructure generated by S* ; in other words, the universe of $\mathbf{A} \cap S$ is S , and the interpretation in $\mathbf{A} \cap S$ of the r -ary relation symbol R is $R^{\mathbf{A}} \cap S^r$.

The *Gaifman graph* of a σ -structure \mathbf{A} , denoted by $\mathcal{G}(\mathbf{A})$, is the (undirected) graph whose set of nodes is the universe of \mathbf{A} , and whose set of edges consists of all pairs (a, a') of elements of A such that a and a' appear together in some tuple of a relation in \mathbf{A} . The *degree* of a structure is the degree of its Gaifman graph, that is, the maximum number of neighbors of nodes of the Gaifman graph.

Neighborhoods and treewidth. Let $\mathbf{G} = (V, E)$ be a graph. Moreover, let $u \in V$ be a node and let $d \geq 0$ be an integer. The *d -neighborhood* of u in \mathbf{G} , denoted by $N_d^{\mathbf{G}}(u)$, is defined inductively as follows:

1. $N_0^{\mathbf{G}}(u) = \{u\}$;
2. $N_{d+1}^{\mathbf{G}}(u) = N_d^{\mathbf{G}}(u) \cup \{v \in V : (v, w) \in E \text{ for some } w \in N_d^{\mathbf{G}}(u)\}$.

If \mathbf{A} is a σ -structure, a is a point in \mathbf{A} , and \mathbf{G} is the Gaifman graph of \mathbf{A} , we let $N_d^{\mathbf{A}}(a)$ denote the d -neighborhood of a in \mathbf{G} . Where it causes no confusion, we also write $N_d^{\mathbf{A}}(a)$ for the substructure of \mathbf{A} generated by this set.

A *tree* is an acyclic connected graph. A *tree-decomposition* of \mathbf{G} is a labeled tree \mathbf{T} such that

1. each node of \mathbf{T} is labeled by a non-empty subset of V ;
2. for every edge $\{u, v\} \in E$, there is a node of \mathbf{T} whose label contains $\{u, v\}$;
3. for every $u \in V$, the set X of nodes of \mathbf{T} whose labels include u forms a connected subtree of \mathbf{T} .

The *width* of a tree-decomposition is the maximum cardinality of a label in \mathbf{T} minus one. The *treewidth* of \mathbf{G} is the smallest k for which \mathbf{G} has a tree-decomposition of width k . The *treewidth* of a σ -structure is the treewidth of its Gaifman graph. Note that trees have treewidth one.

First-order logic, monadic second-order logic, and types. Let σ be a relational vocabulary. The *atomic formulas* of σ are those of the form $R(x_1, \dots, x_r)$, where $R \in \sigma$ is a relation symbol of arity r , and x_1, \dots, x_r are first-order variables that are not necessarily distinct. Formulas of the form $x = y$ are also atomic.

The collection of *first-order formulas* is obtained by closing the atomic formulas under negation, conjunction, disjunction, universal and existential first-order quantification. The collection of *existential first-order formulas* is obtained by closing the atomic formulas and the negated atomic formulas under conjunction, disjunction, and existential quantification. The semantics of first-order logic is standard.

The collection of *monadic second-order formulas* is obtained by closing the atomic formulas under negation, conjunction, disjunction, universal and existential first-order quantification, and universal and existential second-order quantification over sets. The semantics of monadic second-order logic is also standard.

The quantifier rank of a formula, be it first-order or monadic second-order, is the maximum nesting of quantifiers of its subformulas.

Let \mathbf{A} be a σ -structure, and let a_1, \dots, a_n be points in \mathbf{A} . If $\varphi(x_1, \dots, x_n)$ is a formula with free variables x_1, \dots, x_n , we use the notation $\mathbf{A} \models \varphi(a_1, \dots, a_n)$ to denote the fact that φ is true in \mathbf{A} when x_i is interpreted by a_i . If m is an integer, the first-order m -type of a_1, \dots, a_n in \mathbf{A} is the collection of all first-order formulas $\varphi(x_1, \dots, x_n)$ of quantifier rank at most m , up to logical equivalence, for which $\mathbf{A} \models \varphi(a_1, \dots, a_n)$. The monadic second-order m -type of a_1, \dots, a_n in \mathbf{A} is defined analogously.

Preservation under extensions and minimal models. Let \mathcal{C} be a class of finite σ -structures that is closed under induced substructures. Let φ be a first-order sentence. We say that φ is *preserved under extensions* on \mathcal{C} if whenever \mathbf{A} and \mathbf{B} are structures in \mathcal{C} such that \mathbf{B} is an extension of \mathbf{A} , then $\mathbf{A} \models \varphi$ implies $\mathbf{B} \models \varphi$. We say that \mathbf{A} is a *minimal model* of φ if $\mathbf{A} \models \varphi$ and every proper induced substructure \mathbf{A}' of \mathbf{A} is such that $\mathbf{A}' \not\models \varphi$. The following Lemma states that the existential sentences are precisely those that have finitely many minimal models. Its proof is part of the folklore:

Lemma 1. *Let \mathcal{C} be a class of finite σ -structures that is closed under induced substructures. Let φ be a first-order sentence. Then, the following are equivalent:*

1. φ is equivalent on \mathcal{C} to an existential sentence,
2. φ has finitely many minimal models in \mathcal{C} .

In the rest of the paper, we use several times the implication from 2. to 1. Just for completeness, this is proved by taking the disjunction of the existential closure of the atomic types of the finitely many minimal models.

3 Acyclic Structures

We begin with the simple case of acyclic structures, by which we mean structures whose Gaifman graph is acyclic. We show that any class of such structures satisfying certain closure properties admits the extension preservation property. Note, for structures whose Gaifman graphs are acyclic, there is no loss of generality in assuming that the vocabulary σ consists of unary and binary relations only.

The proof is based on Hanf locality and will be presented in detail in the journal version of the paper. Here we only present an overview. We begin by considering structures whose Gaifman graph consists of a simple path. In a large enough structure \mathbf{A} of this type, we can find a segment \mathbf{C} of the path such that the structure \mathbf{A}' obtained by removing \mathbf{C} and the structure $\mathbf{B} = \mathbf{A} \oplus \mathbf{C}$ are equivalent under \equiv^m .

Lemma 2. *For every vocabulary σ and every $m > 0$ there is a p such that if \mathbf{A} is a σ -structure whose Gaifman graph is connected, acyclic and of degree at most 2 and $|A| > p$, then there is a disjoint extension \mathbf{B} of \mathbf{A} and a proper substructure \mathbf{A}' of \mathbf{A} such that $\mathbf{A}' \equiv^m \mathbf{B}$.*

A reduction extends this result to acyclic structures without a degree bound.

Lemma 3. *For every vocabulary σ and every $m > 0$ there is a p such that if \mathbf{A} is a structure whose Gaifman graph is connected and acyclic and which contains a path with more than p elements, then there is a disjoint extension \mathbf{B} of \mathbf{A} and a proper substructure \mathbf{A}' of \mathbf{A} such that $\mathbf{A}' \equiv^m \mathbf{B}$.*

This lemma covers the key case in the proof of the main theorem of this section.

Theorem 4. *Let \mathcal{C} be a class of acyclic finite structures, closed under substructures and disjoint unions. Then, on \mathcal{C} , every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

4 Wide Structures

This section will focus on structures that are *wide*, meaning that they contain many points that are pairwise far apart from each other. The goal is to show that the preservation under extensions property holds for classes of such structures. The precise definition will be introduced later on in this section. At this point let us just mention that an interesting particular case is the class of all structures of degree bounded by a constant.

Unfortunately, the techniques and arguments of Section 3 based on Hanf locality will not be enough for our current purpose. Instead, we will have to resort to Gaifman locality, for which we provide the necessary background first.

For every integer $r \geq 0$, let $\delta(x, y) \leq r$ denote the first-order formula expressing that the distance between x and y in the Gaifman graph is at most r . Let $\delta(x, y) > r$ denote the negation of this formula. A *basic local sentence* is a sentence of the form

$$(\exists x_1) \cdots (\exists x_n) \left(\bigwedge_{i \neq j} \delta(x_i, x_j) > 2r \wedge \bigwedge_i \psi^{N_r(x_i)}(x_i) \right), \tag{1}$$

where ψ is a first-order formula with one free variable. Here, $\psi^{N_r(x_i)}(x_i)$ stands for the relativization of ψ to $N_r(x_i)$; that is, the subformulas of ψ of the form $(\exists x)(\theta)$ are replaced by $(\exists x)(\delta(x, x_i) \leq r \wedge \theta)$, and the subformulas of the form $(\forall x)(\theta)$ are replaced by $(\forall x)(\delta(x, x_i) \leq r \rightarrow \theta)$. The *locality radius* of a basic local sentence is r . Its *width* is n . Its *local quantifier rank* is the quantifier rank of ψ . We will use the fact

that basic local sentences are preserved under disjoint extensions. Note, however, that they may not be preserved under plain extensions since in that case the neighborhoods can grow.

The main result about basic local sentences is that they form a building block for first-order logic. This is known as Gaifman’s Theorem (for a proof, see, for example, [3–Theo. 2.5.1]):

Theorem 5 (Gaifman Locality). *Every first-order sentence is equivalent to a Boolean combination of basic local sentences.*

We reach now the main technical part of the paper. Let us say that a set of points B in a σ -structure \mathbf{A} is d -scattered if for every pair of distinct $a, b \in B$ we have $N_d^{\mathbf{A}}(a) \cap N_d^{\mathbf{A}}(b) = \emptyset$. We say that a class of finite σ -structures \mathcal{C} is *wide* if for every d and m there exists an N such that every structure in \mathcal{C} of size at least N contains a d -scattered set of size m .

Theorem 6. *Let \mathcal{C} be a class of finite σ -structures that is wide and closed under sub-structures and disjoint unions. Then, on \mathcal{C} , every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

Proof. Let φ be a first-order sentence that is preserved under extensions on \mathcal{C} . By Gaifman’s Theorem we may assume that $\varphi = \bigvee_{i \in I} \tau_i$, with

$$\tau_i = \bigwedge_{j \in J_i} \theta_j^i \wedge \bigwedge_{k \in K_i} \neg \theta_k^i, \tag{2}$$

where each θ_h^i is a basic local sentence. Now we define a list of parameters that we need in the proof (the reader may skip this list now and use it to look up the values when they are needed):

- r is the maximum of the locality radii of all θ_h^i ,
- s is the sum of all widths of all θ_h^i ,
- m is the maximum of the local quantifier ranks of all θ_h^i ,
- ℓ is the number of disjuncts in φ , so $\ell = |I|$.
- $n = (\ell + 2)s$,
- $M = m + 4r + 1$,
- $d = 2(r + 1)(\ell + 1)s + 6r + 2$,
- q is the number of monadic second-order M -types with one free variable,
- N is such that every structure in \mathcal{C} of size at least N contains a $(4dq + 2r + 1)$ -scattered set of size $(n - 1)q + s + \ell s + 1$.

Our goal is to show that the minimal models of φ have size less than N . Suppose on the contrary that \mathbf{A} is a minimal model of φ of size at least N . The *type* of a point $a \in A$ is the monadic second-order M -type of a in $\mathbf{A} \cap N_d(a)$. We say that a realizes its type. The reason we consider monadic second-order types, instead of first-order types, will become clear later in the proof. Let t_1, \dots, t_q be all possible types. We need a couple of definitions. Let C be a subset of A and t a type. We say that t is *covered* by C if for all realizations a of t we have $N_d(a) \subseteq C$. We say that t is *free over* C if there are at least n realizations a_1, \dots, a_n of t such that $N_d(a_i)$ and $N_d(a_j)$ are pairwise disjoint and do not intersect C .

Claim 1. *There exists a radius $e \leq 2dq$ and a set D of at most $(n - 1)q$ points in A such that all types are either covered by $N_e(D)$ or free over $N_e(D)$.*

Proof. We define D and e inductively. Let $D_0 = \emptyset$ and $e_0 = 0$. Suppose now that D_i and e_i are already defined. Let $C = N_{e_i}(D_i)$. If all types are either covered by C or free over C , then let $D = D_i$ and $e = e_i$. Otherwise, let j be minimal such that type t_j is neither covered by C nor free over C . We define a set E inductively as follows. Let $E_0 = \emptyset$. Suppose now that E_t is already defined. If there is no realization of t_j outside $N_{2d}(C \cup E_t)$, then let $E = E_t$ and we are done with the construction of E . Otherwise, let a_{t+1} be a realization of t_j outside $N_{2d}(C \cup E_t)$ and let $E_{t+1} = E_t \cup \{a_{t+1}\}$. Note that this iteration cannot continue beyond $n - 1$ steps since otherwise t_j would be free over C . This means that the iteration stops, and when it does $|E| \leq n - 1$ and t_j is covered by any set that contains $N_{2d}(C \cup E)$, and in particular by $N_{e_i+2d}(D_i \cup E)$. Let $D_{i+1} = D_i \cup E$ and $e_{i+1} = e_i + 2d$. The construction stops after at most q steps because at each step one new type is covered and remains covered for the rest of the construction. This shows that $|D| \leq (n - 1)q$ and $e \leq 2dq$, which proves the claim. \square

In the following, we fix e and D according to Claim 1. We say that a type t is *frequent* if it is not covered by $N_e(D)$. Otherwise we say that t is *rare*.

We shall build a finite sequence of sets $S_0 \subseteq S_1 \subseteq \dots \subseteq S_p \subseteq A$, with $p \leq \ell$, so that the last set S_p in the sequence will be such that the substructure of \mathbf{A} induced by S_p is a proper substructure of \mathbf{A} that satisfies φ . This will contradict the minimality of \mathbf{A} and will prove the theorem. The sequence S_i is constructed inductively together with a second sequence of sets $C_0 \subseteq C_1 \subseteq \dots \subseteq C_p \subseteq A$ called the *centers*, and a sequence of sets of indices $I_0 \subseteq I_1 \subseteq \dots \subseteq I_p \subseteq I$ (recall that φ is the disjunction of the formulas τ_i from (2) for $i \in I$). Moreover, the following conditions will be preserved by the inductive construction for every $i < p$.

- (a) The type of each $a \in C_i$ is frequent.
- (b) $S_i \subseteq N_r(C_i)$.
- (c) $|C_i| \leq is$.
- (d) No disjoint extension of $\mathbf{A} \cap S_i$ satisfies $\bigvee_{j \in I_i} \tau_j$.
- (e) $N_e(D)$ and $N_d(C_i)$ are disjoint.
- (f) $|I_i| = i$.

Let $S_0 = C_0 = I_0 = \emptyset$, and let us assume that S_i , C_i and I_i have already been defined with the properties above. We construct S_{i+1} , C_{i+1} , and I_{i+1} . Let \mathbf{B} be the disjoint union of \mathbf{A} with a copy of $\mathbf{A} \cap S_i$.

Since \mathbf{B} is an extension of \mathbf{A} , it satisfies φ . (3)

Therefore, there exists an $i' \in I$ such that \mathbf{B} satisfies $\tau_{i'}$. By (d), since the extension is disjoint, we know that $i' \notin I_i$. Let $I_{i+1} = I_i \cup \{i'\}$. For the rest of the proof, the index i' will be fixed so we drop any reference to it. For example, we will write τ instead of $\tau_{i'}$ and θ_h instead of $\theta_h^{i'}$. Recall that

$$\tau = \bigwedge_{j \in J} \theta_j \wedge \bigwedge_{k \in K} \neg \theta_k.$$

Since \mathbf{B} satisfies τ , in particular it satisfies the positive requirements: $\mathbf{B} \models \bigwedge_{j \in J} \theta_j$. Let W_j be a minimal set of witnesses in \mathbf{B} for the outermost existential quantifiers in θ_j , and let $W = \bigcup_{j \in J} W_j$. We have $|W| \leq s$. Some of these witnesses may be in \mathbf{A} and some may be in the disjoint copy of $\mathbf{A} \cap S_i$ in \mathbf{B} . Let $W_A \cup W_B = W$ be such a partition, with W_A being the witnesses in A . The following claim shows that W_A can be chosen far from C_i . This will be needed later.

Claim 2. *There is a set W of witnesses such that $N_{r+1}(C_i) \cap N_r(W_A) = \emptyset$.*

Proof. Fix a set W of witnesses so that the number of points b in W_A for which $N_{r+1}(C_i)$ and $N_r(b)$ are not disjoint is minimal. Suppose that this number is not zero, and let $b \in W_A$ with $N_{r+1}(C_i) \cap N_r(b) \neq \emptyset$. Let $a \in C_i$ be such that $N_{r+1}(a) \cap N_r(b) \neq \emptyset$. Then $N_r(b) \subseteq N_{3r+1}(a) \subseteq N_d(a)$. By property (a), the type t of a is frequent. So let a' be a realization of t such that $N_{r+1}(W \cup C_i)$ and $N_{3r+1}(a')$ are disjoint. Such an a' exists because t is frequent and thus, by Claim 1, is free over $N_e(D)$ and thus has

$$n > (\ell + 1)s = |W \cup C_i|$$

realizations whose d -neighborhoods are pairwise disjoint and disjoint from $N_e(D)$.

Now, since $N_d(a)$ and $N_d(a')$ have the same monadic second-order M -type and $N_r(b) \subseteq N_{3r+1}(a) \subseteq N_d(a)$, there must exist a b' such that $N_r(b') \subseteq N_{3r+1}(a') \subseteq N_d(a')$ such that b and b' have the same first-order m -type on $\mathbf{A} \cap N_r(b)$ and $\mathbf{A} \cap N_r(b')$ respectively. Here we use $M = m + 4r + 1$ and the fact that we considered second-order types; this has the effect that every subset of $N_d(a)$ has an *equivalent* subset in $N_d(a')$. But then b' can replace b as a witness in W_A , and since $N_{r+1}(W \cup C_i)$ and $N_{3r+1}(a')$ are disjoint, so are $N_{r+1}(C_i)$ and $N_r(b')$. This contradicts the minimality of W . □

In the following, we fix a set W of witnesses such that $N_{r+1}(C_i) \cap N_r(W_A) = \emptyset$. We let \mathbf{C} be the substructure of \mathbf{A} induced by $N_e(D) \cup N_r(W_A) \cup S_i$. We claim that \mathbf{C} satisfies the positive requirements of τ :

Claim 3. *\mathbf{C} is a substructure of \mathbf{A} such that $\mathbf{C} \models \bigwedge_{j \in J} \theta_j$.*

Proof. It is obvious that \mathbf{C} is a substructure of \mathbf{A} . The point, however, is that \mathbf{C} is in fact the disjoint union of the substructure induced by $N_e(D) \cup N_r(W_A)$ and the substructure induced by S_i . This is because $S_i \subseteq N_r(C_i)$ and $N_{r+1}(C_i)$ is disjoint from $N_e(D)$ by property (e) and also disjoint from $N_r(W_A)$ by Claim 2. It follows that the witnesses from \mathbf{B} in W_B can also be found in \mathbf{C} . Obviously, also the witnesses from \mathbf{B} in W_A can be found in \mathbf{C} . This proves that \mathbf{C} satisfies the positive requirements of τ . □

Consider φ on \mathbf{C} . If \mathbf{C} is a model of φ , let $S_p = N_e(D) \cup N_r(W_A) \cup S_i$ and we are done. Notice that \mathbf{C} is a proper substructure of \mathbf{A} because \mathbf{A} contains $(n - 1)q + s + \ell s + 1$ points that are $(4dq + 2r + 1)$ -scattered, but $S_p \subseteq N_{2dq+r}(D \cup W_A \cup C_i)$ and

$$|D \cup W_A \cup C_i| \leq (n - 1)q + s + \ell s.$$

If \mathbf{C} is not a model of φ it cannot satisfy τ . However, by Claim 3, \mathbf{C} satisfies the positive requirements $\bigwedge_{j \in J} \theta_j$. Therefore, \mathbf{C} does not satisfy $\bigwedge_{k \in K} \neg \theta_k$. Let $k \in K$ such that $\mathbf{C} \models \theta_k$. In the next claim we find a substructure of \mathbf{A} that extends $\mathbf{A} \cap S_i$ and forces all its disjoint extensions to satisfy θ_k .

Claim 4. *There exist $C_{i+1} \supseteq C_i$ and $S_{i+1} \supseteq S_i$ as required by conditions (a)–(e).*

Proof. We have $\mathbf{C} \models \theta_k$. Let V be a minimal set of witnesses in \mathbf{C} for the outermost existential quantifiers in θ_k . We have $|V| \leq s$.

Necessarily, the type t of some $a \in V$ is frequent. Otherwise $N_r(V) \subseteq N_e(D) \subseteq \mathbf{A}$, so $\mathbf{A} \models \theta_k$, and thus $\mathbf{B} \models \theta_k$, because \mathbf{B} is a disjoint extension of \mathbf{A} . However, this is impossible because $\mathbf{B} \models \tau$.

So let $a \in V$ have frequent type t . Let Z be a set of s realizations of t such that

- (i) $N_d(b) \cap N_d(b') = \emptyset$ for every pair of distinct $b, b' \in Z$,
- (ii) $N_e(D) \cap N_d(Z) = \emptyset$,
- (iii) $N_{r+1}(C_i) \cap N_r(Z) = \emptyset$.

Such a set Z exists because t is frequent, $n = (\ell + 2)s$, and $|C_i| \leq \ell s$ by property (c).

Now, let $F = N_r(a) \cap C$ be the subset of $N_r(a)$ that actually appears in \mathbf{C} . Note that $a \in F$. Since each $b \in Z$ has the same monadic second-order M -type as a , for every $N_r(b)$ there exists a set $F_b \subseteq N_r(b)$, equivalent to F in $N_r(a)$, so that a and b have the same first-order m -type in $\mathbf{A} \cap F$ and $\mathbf{A} \cap F_b$ respectively. This is the other place we use monadic second-order types. Define $C_{i+1} = C_i \cup Z$ and

$$S_{i+1} = S_i \cup \bigcup_{b \in Z} F_b.$$

Let us prove that C_{i+1} and S_{i+1} satisfy the properties (a), (b), (c), (d), and (e). Property (a) is clear since the type of each $b \in Z$ is t , and t is frequent. Property (b) is also clear since $F_b \subseteq N_r(b)$. For property (c) we have $|C_{i+1}| = |C_i| + s = (i + 1)s$. Property (e) is satisfied by (ii) in our choice of Z .

Finally, for property (d) we argue as follows. First note that $\mathbf{A} \cap S_{i+1}$ is a disjoint extension of $\mathbf{A} \cap S_i$ because $N_{r+1}(C_i) \cap N_r(Z) = \emptyset$ by (iii) and $S_i \subseteq N_r(C_i)$ by (c). Therefore, no disjoint extension of $\mathbf{A} \cap S_{i+1}$ satisfies τ_j for any $j \in I_i$. It remains to show that no disjoint extension of $\mathbf{A} \cap S_{i+1}$ satisfies τ . However, this is clear from the construction because every disjoint extension of $\mathbf{A} \cap S_{i+1}$ will contain witnesses for the outermost existential quantifiers in θ_k ; namely any subset of Z of size $|V|$. \square

Note that I_{i+1} is constructed to satisfy property (f) as well. This completes the definition of the inductive construction. All it remains to see is that the construction stops in at most ℓ steps. Because suppose for contradiction that we have constructed S_ℓ , C_ℓ , and I_ℓ satisfying (a)–(f). Then $I_\ell = I$ by (f), and by (d), no disjoint extension of $\mathbf{A} \cap S_\ell$ satisfies $\varphi = \bigvee_{i \in I} \tau_i$. However,

$$\text{the disjoint union } \mathbf{B} \text{ of } \mathbf{A} \cap S_\ell \text{ with } \mathbf{A} \text{ is an extension of } \mathbf{A} \text{ and hence} \quad (4)$$

does satisfy φ .

This is a contradiction. \square

As a direct application of Theorem 6, let us consider the class \mathcal{D}_r of all finite σ -structures of degree bounded by r . Clearly, this class is both wide and closed under substructures and disjoint unions.

Theorem 7. *Let r be an integer. Then, on \mathcal{D}_r , every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

In the following section we show how the argument of Theorem 6 can be extended, in some cases, to classes of structures that are *almost wide*.

5 Bounded Treewidth Structures

The goal of this section is to show that the preservation under extensions property holds for the class \mathcal{T}_k of all finite σ -structures of treewidth less than k . In other words, we want to prove the following result:

Theorem 8. *Let k be an integer. Then, on \mathcal{T}_k , every first-order sentence that is preserved under extensions is equivalent to an existential sentence.*

The proof of this result requires three ingredients. The first ingredient is a generalization of the disjoint union operation on structures by allowing some non-empty intersection. Let \mathbf{A} and \mathbf{B} be σ -structures, and let $C \subseteq A \cap B$ be such that $\mathbf{A} \cap C = \mathbf{B} \cap C$. The *union of \mathbf{A} and \mathbf{B} through C* , denoted by $\mathbf{A} \oplus_C \mathbf{B}$ is a new σ -structure defined as follows. The universe of $\mathbf{D} = \mathbf{A} \oplus_C \mathbf{B}$ is $A' \cup B' \cup C$, where A' is a disjoint copy of $A - C$ and B' is a disjoint copy of $B - C$. The relations of \mathbf{D} are defined in the obvious way: If a_1, \dots, a_r are points in A and a'_1, \dots, a'_r are the corresponding points in $A' \cup C$, then $(a'_1, \dots, a'_r) \in R^{\mathbf{D}}$ if and only if $(a_1, \dots, a_r) \in R^{\mathbf{A}}$. Similarly, if b_1, \dots, b_r are points in B and b'_1, \dots, b'_r are the corresponding points in $B' \cup C$, then $(b'_1, \dots, b'_r) \in R^{\mathbf{D}}$ if and only if $(b_1, \dots, b_r) \in R^{\mathbf{B}}$. Observe that this construction is precisely the disjoint union of \mathbf{A} and \mathbf{B} when $C = \emptyset$.

The next Lemma is a straightforward generalization of the obvious fact that \mathcal{T}_k is closed under disjoint unions. The Lemma states, roughly, that \mathcal{T}_k is closed under unions through *subsets of bags of tree-decompositions*. More precisely:

Lemma 9. *Let k be an integer. Let \mathbf{A} and \mathbf{B} be two σ -structures, let $C \subseteq A \cap B$ be such that $\mathbf{A} \cap C = \mathbf{B} \cap C$, and let (T, L) and (T', L') be tree-decompositions of width k of \mathbf{A} and \mathbf{B} , respectively. Then, if there exists nodes $u \in T$ and $u' \in T'$ such that $C \subseteq L(u) \cap L'(u')$, then the union of \mathbf{A} and \mathbf{B} through C has treewidth at most k .*

Proof: The tree-decomposition of the union is $(T'', L \cup L')$, where $T'' = T \cup T'$ with a new tree edge joining u and u' . □

The second ingredient is the fact that the class of structures of treewidth less than k is *almost wide*, in the sense that there exists a small set of vertices whose removal produces a large scattered set. Such a set is henceforth called a *bottleneck*. This was proved in [1] but here we state the stronger claim that the bottleneck can be found in the bag of a tree-decomposition. The proof is the same as in [1].

Lemma 10. *For every k , and for every d and m , there exists an N such that if \mathbf{A} is a σ -structure of size at least N and (T, L) is a tree-decomposition of \mathbf{A} of width k , then there exist $u \in T$ and $B \subseteq L(u)$ such that $\mathbf{A} - B$ contains a d -scattered set of size m .*

The third ingredient in the proof is a first-order interpretation of a wide structure inside an almost-wide structure. From now on we focus on graphs; the construction extends easily to the general case. Let $P_1, \dots, P_k, Q_1, \dots, Q_k$ be unary relation symbols and $\sigma = \{E, P_1, \dots, P_k, Q_1, \dots, Q_k\}$. For every graph $\mathbf{G} = (V, E^{\mathbf{G}})$ and every tuple $\mathbf{a} = (a_1, \dots, a_k) \in V^k$ we define a σ -structure $\mathbf{A} = \mathbf{A}(\mathbf{G}, \mathbf{a})$ as follows:

1. $A = V$,
2. $E^{\mathbf{A}} = E^{\mathbf{G}} - \{(a, b) \in A^2 : \{a, b\} \cap \{a_1, \dots, a_k\} \neq \emptyset\}$,
3. $P_i^{\mathbf{A}} = \{a_i\}$,
4. $Q_i^{\mathbf{A}} = \{b \in A : (a_i, b) \in E^{\mathbf{A}}\}$.

Let us call a σ -structure \mathbf{A} *derived* if $E^{\mathbf{A}}$ is a symmetric and anti-reflexive binary relation, and there are elements $a_1, \dots, a_k \in A$ such that $P_i^{\mathbf{A}} = \{a_i\}$ for $1 \leq i \leq k$ and a_i is isolated in the graph underlying \mathbf{A} ; that is, for $1 \leq i \leq k$ there is no b such that $(a_i, b) \in E^{\mathbf{A}}$. Note that for every derived structure \mathbf{A} there is a unique graph $\mathbf{G}(\mathbf{A})$ and a unique k -tuple $\mathbf{a}(\mathbf{A})$ of vertices of $\mathbf{G}(\mathbf{A})$ such that

$$\mathbf{A} = \mathbf{A}(\mathbf{G}(\mathbf{A}), \mathbf{a}(\mathbf{A})).$$

The point behind the construction of $\mathbf{A} = \mathbf{A}(\mathbf{G}, \mathbf{a})$ is that if $B = \{a_1, \dots, a_k\}$ is a bottleneck of \mathbf{G} in the sense that $\mathbf{G} - B$ contains a large scattered set, then \mathbf{A} itself has a large scattered set and maintains all the information to reconstruct \mathbf{G} . Indeed, $\mathbf{G}(\mathbf{A})$ is first-order interpretable in \mathbf{A} , and thus we get the following lemma:

Lemma 11. *For every first-order sentence φ of vocabulary $\{E\}$ there is a sentence $\tilde{\varphi}$ of vocabulary σ such that for all σ -structures \mathbf{A} we have:*

1. If $\mathbf{A} \models \tilde{\varphi}$ then \mathbf{A} is derived.
2. If \mathbf{A} is derived, then $\mathbf{A} \models \tilde{\varphi}$ if and only if $\mathbf{G}(\mathbf{A}) \models \varphi$.

This follows at once from a standard result on syntactical interpretations (cf., for example, Theorem VIII.2.2 of [4]).

Equipped with these three ingredients we are ready for the main argument.

Proof (of Theorem 8). Let φ be a first-order sentence that is preserved under extensions in \mathcal{T}_k . It suffices to show that φ has finitely many minimal models. Let $\mathbf{G} = (V, E^{\mathbf{G}})$ be a graph in \mathcal{T}_k that is a minimal model of φ . Suppose for contradiction that \mathbf{G} is very large. Let (T, L) be a tree-decomposition of width k of \mathbf{G} , and let $B = \{b_1, \dots, b_k\} \subseteq V$ be a bottleneck; that is, a set such that $\mathbf{G} - B$ contains a large scattered set. By Lemma 10 we may assume that $B \subseteq L(u)$ for some $u \in T$. Let $\mathbf{A} = \mathbf{A}(\mathbf{G}, \mathbf{b})$, where $\mathbf{b} = (b_1, \dots, b_k)$. The idea is to work with \mathbf{A} and $\tilde{\varphi}$ instead of \mathbf{G} and φ and proceed as in the proof of Section 4. The difference is that $\tilde{\varphi}$ is *not* preserved under extensions. However, preservation under extensions is used only twice in the proof of

Section 4 (in (3) and (4)), both times to prove that the disjoint union \mathbf{B} of the structure \mathbf{A} with $\mathbf{A} \cap S_i$ is a model of φ . Claim 5 shows that in both cases, \mathbf{B} is a model of $\tilde{\varphi}$.

Claim 5. *Let $C \subseteq A$ such that the type of each $a \in C$ is frequent. Let $S \subseteq N_r(C)$ and let \mathbf{B} be the disjoint union of \mathbf{A} with a disjoint copy of $\mathbf{A} \cap S$. Then \mathbf{B} is derived, \mathbf{G} is an induced subgraph of $\mathbf{G}(\mathbf{B})$, and $\mathbf{G}(\mathbf{B})$ belongs to \mathcal{T}_k .*

Proof. Note that \mathbf{B} is derived because the bottleneck points are not in S since their type is not frequent. Let $\mathbf{H} = \mathbf{G}(\mathbf{B})$. Clearly, \mathbf{G} is an induced subgraph of \mathbf{H} . Thus all we have to prove is that \mathbf{H} belongs to \mathcal{T}_k . Let $\mathbf{A}' = \mathbf{A} \cap (S \cup B)$, where B is the bottleneck of \mathbf{G} . Again, \mathbf{A}' is derived. Let $\mathbf{G}' = \mathbf{G}(\mathbf{A}')$. Clearly, \mathbf{G}' is an induced subgraph of \mathbf{G} . In particular, \mathbf{G}' is in \mathcal{T}_k so it has a tree-decomposition of width k . More importantly, since $B \subseteq L(u)$, we can assume as well that B is a subset of some bag of the tree-decomposition of \mathbf{G}' . These two facts together imply that the union of \mathbf{G} and \mathbf{G}' through B , which is precisely \mathbf{H} , is in \mathcal{T}_k by Lemma 9. \square

This shows then that the \mathbf{B} in (3) and (4) is a model of $\tilde{\varphi}$. The proof proceeds until we construct a structure \mathbf{C} that satisfies $\tilde{\varphi}$ and is a proper substructure of \mathbf{A} . We claim that \mathbf{C} is derived. This is because all bottleneck points have rare type, so they belong to D . Let $\mathbf{H} = \mathbf{G}(\mathbf{C})$. Note now that \mathbf{H} is the union of two subgraphs \mathbf{G}_1 and \mathbf{G}_2 of \mathbf{G} through the bottleneck B . Again B is a subset of a bag of the tree-decompositions of \mathbf{G}_1 and \mathbf{G}_2 , so \mathbf{H} belongs to \mathcal{T}_k by Lemma 9. Moreover \mathbf{H} is a proper induced subgraph of \mathbf{G} and $\mathbf{H} \models \varphi$ by Lemma 11. This contradicts the minimality of \mathbf{G} , which concludes the proof. \square

6 Conclusions

The proof that the extension preservation theorem holds on the classes \mathcal{T}_k is based on somewhat different properties to the proof in [1] that the homomorphism preservation theorem holds on all classes of bounded treewidth. Indeed, our proof requires stronger closure conditions. A natural question is whether the result could extend, as in the case of the homomorphism preservation theorem to all classes that are defined by excluding a graph minor. It turns out this is not the case. We are able to construct a counterexample that shows that the extension preservation does not hold on the class of planar graphs. This construction will be presented in the journal version of the paper.

Abstract. We show that the problem of checking if an infinite tree generated by a higher-order grammar of level 2 (hyperalgebraic) satisfies a given μ -calculus formula (or, equivalently, if it is accepted by an alternating parity automaton) is decidable, actually 2-EXPTIME-complete. Consequently, the monadic second-order theory of any hyperalgebraic tree is decidable, so that the safety restriction can be removed from our previous decidability result. The last result has been independently obtained by Aehlig, de Miranda and Ong. Our proof goes *via* a characterization of possibly unsafe second-order grammars by a new variant of higher-order pushdown automata, which we call *panic automata*. In addition to the standard pop_1 and pop_2 operations, these automata have an option of a destructive move called *panic*. The model-checking problem is then reduced to the problem of deciding the winner in a parity game over a suitable 2nd order pushdown system.

1 Introduction

Context-free tree grammars constitute the basic level in an infinite hierarchy of higher-order grammars introduced by W. Damm [8] (built on the earlier ideas of [11]). Courcelle [6] proved decidability of the monadic second-order (MSO) theory of any tree generated by an *algebraic* (context-free) tree grammar. Later Knapik *et al* [13, 14] attempted to extend this decidability result to all levels of the Damm hierarchy. This has been achieved partially, namely with an additional syntactic restriction imposed on the grammars, called *safety*: the MSO theory of any tree generated by a safe grammar of level n is decidable.

Higher-order grammars can be seen as program schemes, where functions can take higher-order arguments. The tree generated by such a grammar describes completely the semantics of the program scheme. Thus decidability of

*** The 2nd and the 4th author were also supported by the EC Research Training Network *Games*.

the MSO theory of such a tree implies decidability for a large class of properties of behaviours of higher-order program schemes.

The safety requirement, roughly speaking, prevents the use of individual parameters in the functional arguments of higher-order functions. The concept of safe (tree) grammars has been further justified by a characterization in terms of higher-order pushdown automata originally introduced by Maslov [16]: the trees generated by safe higher-order grammars of level n coincide with the trees recognized (in suitable sense) by pushdown automata of level n [14]. See [5, 7] for another characterization of this hierarchy.

Monadic second-order logic is extremely succinct, which yields the non-elementary complexity of the MSO theories, even for regular trees. However, over trees, the MSO logic has the same expressive power as the μ -calculus, which is much better tractable algorithmically. Cachat [3] showed that the model-checking problem for the μ -calculus and the trees recognized by the pushdown automata of level n is in n -EXPTIME, actually n -EXPTIME-complete [4].

In this paper we show that for the level 2 (hyperalgebraic), the model checking problem remains decidable, actually 2-EXPTIME-complete, also for grammars *without* safety restriction.

To this end, we first find an automata-theoretic counterpart of unsafe hyperalgebraic grammars, which is an extension of second-order pushdown automata by a new destructive operation that we call *panic*. This operation allows us to simulate the change of environment needed to evaluate parameters of unsafe productions. We further introduce 2nd order pushdown systems with panic (equipped with alternation and ranks), which can be viewed as a generalization of pushdown systems studied in [20, 3]. The model-checking problem then reduces to the problem of deciding the winner in a parity game over such a system. The key step is a reduction of this game to a game over a 2nd order pushdown system *without* panic, for which a 2-EXPTIME procedure is already known [3].

An immediate consequence of our result is that the model checking problem for the hyperalgebraic grammars is decidable also for the monadic second-order logic, consequently the MSO theory of any hyperalgebraic tree is decidable. This result has been recently independently obtained by Aehlig, de Miranda and Ong [2], by a different proof, based on transformations of infinite lambda terms. Compared to [2], the present paper has two new elements: (1) it gives a characterization of unsafe grammars by panic automata, (2) the actual proof yields an optimal decision procedure for the μ -calculus model checking.

At present we do not know if the safety requirement really restricts the generating power of the tree grammars. Recently, Aehlig, de Miranda and Ong have studied the safety restriction [1]. They have shown that it is inessential for the *word* grammars of level 2, where a grammar, as usual, can generate a set of words. To simulate a non-safe grammar by a safe one, they use nondeterminism in an essential way, hence their result is not directly applicable for trees.

Due to space limitations, many arguments are omitted or sketchy; they will appear in the full paper (see [15] for a preliminary version).

2 Trees

Types, terms, and trees. We fix the set of simple types τ constructed from a unique *basic* type $\mathbf{0}$, by the rules $\tau ::= \mathbf{0} \mid (\tau_1 \rightarrow \tau_2)$. The level of a type is defined by $\ell(\mathbf{0}) = 0$, and $\ell(\tau_1 \rightarrow \tau_2) = \max(1 + \ell(\tau_1), \ell(\tau_2))$. Thus $\mathbf{0}$ is the only type of level 0 and each type of level 1 is of the form $\mathbf{0}^n \rightarrow \mathbf{0}$ for some $n > 0$ (which abbreviates $(\mathbf{0} \rightarrow (\mathbf{0} \rightarrow (\dots (\mathbf{0} \rightarrow \mathbf{0}) \dots)))$, with $n + 1$ occurrences of $\mathbf{0}$).

A *typed alphabet* is a set Γ of symbols, each γ in Γ given with its type, $\gamma : \tau$. We inductively extend Γ to the set $T(\Gamma)$ of (*applicative*) terms over Γ ; if $t : \tau_1 \rightarrow \tau_2$ and $s : \tau_1$ then $(ts) : \tau_2$. As usual we abbreviate $(\dots ((t_0 t_1) t_2) \dots) t_n$ by $t_0 t_1 \dots t_n$. For terms t, t_1, \dots, t_m , and symbols z_1, \dots, z_m , of appropriate types, term $t[z_1 := t_1, \dots, z_k := t_k]$ results from simultaneous replacement in t of z_i by t_i .

The set of natural numbers is denoted by ω . A *tree* (over a set X) is any nonempty prefix-closed subset T of the free monoid X^* , with ε as the *root*. If $u \in T$, $x \in X$, and $ux \in T$, then ux is a *successor* of u in T .

Now let Σ be a *signature*, i.e., a typed alphabet of symbols of level ≤ 1 . A Σ -*tree* is a mapping $t : \text{dom } t \rightarrow \Sigma$, where $\text{dom } t \subseteq \omega^*$ is a tree, and if $t(w)$ is a symbol of type $\mathbf{0}^k \rightarrow \mathbf{0}$ then w has exactly k successors, $w1, \dots, wk$ (hence w is a leaf if $t(w) : \mathbf{0}$). The set of Σ -trees is written $T^\infty(\Sigma)$.

A *limit* of a sequence t_0, t_1, \dots of Σ -trees is defined, provided that for any k , there is $m = m(k)$, such that $t_n \upharpoonright k$ and $t_{n'} \upharpoonright k$ coincide, for all $n, n' \geq m(k)$ (where, in general, $t \upharpoonright k$ is restriction of t to the set $\{w \in \text{dom } t : |w| \leq k\}$). Then $\lim t_n \in T^\infty(\Sigma)$ is just the set-theoretical union of the functions $t_n \upharpoonright m(n)$.

Grammars. We fix an infinite typed alphabet of *variables* (or *parameters*), \mathcal{X} . A *grammar* is a tuple $\mathcal{G} = (\Sigma, N, \mathcal{S}, E)$, where Σ is a *signature*, N is a finite typed alphabet of *nonterminals*¹, $\mathcal{S} \in N$ is a *start symbol* of type $\mathbf{0}$, and E is a set of productions of the form

$$\mathcal{F} z_1 \dots z_m \Rightarrow w$$

where $\mathcal{F} : \tau_1 \rightarrow \tau_2 \dots \rightarrow \tau_m \rightarrow \mathbf{0}$ is a nonterminal, z_i a variable of type τ_i , and w an applicative term in $T(\Sigma \cup N \cup \{z_1 \dots z_m\})$ of type $\mathbf{0}$. The *level* of a grammar is the highest level of its nonterminals. Since we are interested in grammars as generators of (single) Σ -trees, we assume that for each \mathcal{F} , there is exactly one production with \mathcal{F} on the left-hand side.

The single-step reduction relation $\rightarrow_{\mathcal{G}}$ between terms over $\Sigma \cup N$ is defined inductively by the following clauses.

1. $\mathcal{F} t_1 \dots t_k \rightarrow_{\mathcal{G}} t[z_1 := t_1, \dots, z_k := t_k]$ if there is a production $\mathcal{F} z_1 \dots z_k \Rightarrow t$ with $z_i : \rho_i$, and $t_i \in T(\Sigma \cup N)$, where $t_i : \rho_i$, for $i = 1, \dots, k$.
2. If $t \rightarrow_{\mathcal{G}} t'$ then $(st) \rightarrow_{\mathcal{G}} (st')$ and $(tq) \rightarrow_{\mathcal{G}} (t'q)$, whenever the expressions in question are applicative terms.

¹ Without loss of generality, we assume that the types of nonterminals are *homogeneous*, i.e., $\mathbf{0}$ or $\tau_1 \rightarrow \dots \rightarrow \tau_n \rightarrow \mathbf{0}$, where if each τ_i is homogeneous and $\ell(\tau_1) \geq \ell(\tau_2) \geq \dots \geq \ell(\tau_n)$.

That is, $t \rightarrow_{\mathcal{G}} t'$ whenever t' is obtained from t by replacing some occurrence of a nonterminal F by the right-hand side of the appropriate production in which all parameters are in turn replaced by the actual arguments of F .

In order to define the result of an infinite derivation, we extend Σ to $\Sigma^\perp = \Sigma \cup \{\perp\}$, with $\perp : \mathbf{0}$. With any term t over $\Sigma \cup N$, we inductively associate an expression t^\perp over Σ^\perp , by setting $f^\perp = f$ (for $f \in \Sigma$), $X^\perp = \perp$ (for $X \in N$), and $(st)^\perp = (s^\perp r^\perp)$ whenever $s^\perp \neq \perp$, otherwise $(st)^\perp = \perp$. Then, we define relation $t \twoheadrightarrow_{\mathcal{G}}^\infty t'$, where t is a term in $T(\Sigma \cup N)$ and t' a tree in $T^\infty(\Sigma^\perp)$, by

- t' is finite, and there is reduction sequence $t = t_0 \rightarrow_{\mathcal{G}} \dots \rightarrow_{\mathcal{G}} t_n = t'$, or
- t' is infinite, and there is an infinite reduction sequence $t = t_0 \rightarrow_{\mathcal{G}} t_1 \rightarrow_{\mathcal{G}} \dots$ such that $t' = \lim t_n^\perp$.

To define a unique tree produced by the grammar, we recall a standard *approximation ordering* on $T^\infty(\Sigma^\perp)$: $t' \sqsubseteq t$ if $\text{dom } t' \subseteq \text{dom } t$ and, for each $w \in \text{dom } t'$, $t'(w) = t(w)$ or $t'(w) = \perp$. Then the tree generated by \mathcal{G} is defined by

$$[[\mathcal{G}]] = \sup\{t \in T^\infty(\Sigma^\perp) : S \twoheadrightarrow_{\mathcal{G}}^\infty t\}$$

It is easy to see that, by the Church-Rosser property of our grammar, the above set is directed, and hence $[[\mathcal{G}]]$ is well defined since $T^\infty(\Sigma^\perp)$ with the approximation ordering is a cpo.

In this paper we only study grammars of level 2, which we call *hyperalgebraic*, as they constitute the next level above the algebraic (context-free) grammars.

Parity games. A *parity game* is a perfect information game of possibly infinite duration played by two players, say Eve and Adam. We present it as a tuple $(V_\exists, V_\forall, E, p_1, \Omega)$, where V_\exists and V_\forall are (disjoint) sets of positions of Eve and Adam, respectively, $E \subseteq V \times V$ is the relation of possible moves, with $V = V_\exists \cup V_\forall$, $p_1 \in V$ is a designated initial position, and $\Omega : V \rightarrow \omega$ is the ranking function.

The players start a play in the position p_1 and then move the token according to relation E (always to a successor of the current position), thus forming a path in the graph (V, E) . The move is selected by Eve or Adam, depending on who is the owner of the current position. If a player cannot move, she/he loses. Otherwise, the result of the play is an infinite path in the graph, v_0, v_1, v_2, \dots . Eve wins the play if $\limsup_{n \rightarrow \infty} \Omega(v_n)$, is even, otherwise Adam wins.

Parity games, introduced by Emerson and Jutla [9, 17], have been recognized as a combinatorial essence of many model checking problems. A crucial property is the *positional determinacy*: any position is winning for one of the players, and moreover a winning strategy of player θ can be made *positional*, i.e., represented by a (partial) function $\sigma : V_\theta \rightarrow V$.² We say simply that Eve *wins* the game \mathcal{G} if

² Positional strategy σ is *winning* for θ if every play $p_1 = q_1, q_2, \dots$ is won by θ , provided that $q_\ell \in V_\exists$ follows $q_{\ell+1} = \sigma(q_\ell)$.

she has a winning strategy, the similar for Adam. We refer the reader to [19, 12] for an introduction to parity games.

Model checking. The model checking problem in our consideration is to verify if the tree generated by a given grammar \mathcal{G} satisfies a property φ expressed in some logical language, in symbols $\llbracket \mathcal{G} \rrbracket \models \varphi$. The most expressive logics considered in literature are the *monadic second-order logic* (MSO) or the μ -calculus; both have the same expressive power over Σ -trees [18]. In this paper we avoid a logical machinery by using an equivalent formalism of *alternating parity automata* (defined below). A polynomial-time translation from the μ -calculus to alternating automata, $\varphi \mapsto A_\varphi$, is known [9], such that, for any tree t , $t \models \varphi$ iff t is recognized by A_φ .

An alternating parity tree automaton over signature Σ can be presented as a tuple

$$\mathcal{B} = \langle \Sigma, Q_\exists, Q_\forall, q_1, \delta, \Omega \rangle$$

where $Q_\exists \cup Q_\forall = Q$ is a finite set of states with the initial state q_1 , $\Omega : Q \rightarrow \omega$ is a ranking function, and δ is a set of transitions of the form $q \rightarrow f(q_1, \dots, q_k)$, where $q, q_1, \dots, q_k \in Q$ and $f \in \Sigma$ with type $f : \mathbf{0}^k \rightarrow \mathbf{0}$.

The acceptance of a tree $t \in T^\infty(\Sigma)$ by the automaton \mathcal{B} can be presented by a suitable parity game. We first define a the computation tree, $r : \text{dom } r \rightarrow Q$ with $\text{dom } r \subseteq (\omega \times \omega)^*$, such that, for any $u \in \text{dom } r$, the projection $u \downarrow_1$ on the first component is a node in $\text{dom } t$. We let $r(\epsilon) = q_1$, and whenever $r(u) = q$ and $t(u \downarrow_1) = f$, then, for any transition of the form $q \rightarrow f(q_1, \dots, q_k)$, the node u has a successor $u(i, j)$ with $r(u(i, j)) = q_i$, for some j , and $i = 1, \dots, k$. Now consider a parity game $\text{Game}(\mathcal{B}, t)$ with $V = \text{dom } r$ partitioned such that $u \in V_\exists$ iff $r(u) \in Q_\exists$, the initial configuration ϵ , and $\Omega(u) = \Omega(r(u))$. We let \mathcal{B} accept the tree t iff Eva wins this game.

The model checking problem addressed in this paper will be the following.

Problem 1. Given a 2nd order grammar \mathcal{G} and an alternating parity tree automaton \mathcal{B} . Does \mathcal{B} accept $\llbracket \mathcal{G} \rrbracket$?

3 Panic Automata

Classically the content of a pushdown store is just a word over the pushdown alphabet. For our purpose, it is convenient to consider pushdown symbols with “time stamps” (sort of). We let a *level 1 pushdown store* (or a 1-*pds* or 1-stack) over an alphabet Γ be a non-empty word $a_1 \dots a_k$ over $\Gamma \times \omega$. A *level 2 pds* (2-*pds*, 2-stack) is a non-empty sequence $s_1 \dots s_l$ of 1-*pds*’s, which may also be written as $[s_1][s_2] \dots [s_l]$ or as $s'[s_l]$, where s' stands for $[s_1][s_2] \dots [s_{l-1}]$. The 1-stack s_i is called the *i-th row* of s . We assume that push-down stores grows to the *right*, so that, for instance, the item (a, m) is on top of the 2-*pds* $s'[w(a, m)]$. By $\text{top}(s)$ we denote the topmost Γ -symbol of s , i.e., $\text{top}(s'[w(a, m)]) = a$.

The following operations are possible on level 2 push-down stores.

$$\begin{aligned}
 push_1\langle a \rangle([s_1][s_2] \dots [s_l][w]) &= [s_1][s_2] \dots [s_l][w(a, l)] \\
 pop_1(\alpha[w\xi]) &= \alpha[w] \\
 push_2(\alpha[w]) &= \alpha[w][w] \\
 pop_2(\alpha[v][w]) &= \alpha[v] \\
 panic([s_1][s_2] \dots [s_m] \dots [s_l][w(a, m)]) &= [s_1][s_2] \dots [s_m] \\
 skip(s) &= s
 \end{aligned}$$

The operation pop_2 (resp. pop_1) is undefined on a 2-stack s if it contains only one row (resp. the top row of s has only one element).

Let \perp be a symbol in Γ . It is easy to see that if a 2-pds $[s_1] \dots [s_m]$ is generated from $[(\perp, 0)]$ by the above operations, and $s_i = (a_{i,1}, m_{i,1}) \dots (a_{i,k_i}, m_{i,k_i})$ then $m_{i,j} \leq i - 1$, and $j \leq j'$ follows $m_{i,j} \leq m_{i,j'}$. Intuitively, whenever a new symbol $a \in \Gamma$ is placed on the top of the stack, the second component registers the number of the stack row which is directly below the current top row. Later the symbol can be duplicated several times by subsequent executions of $push_2$, but the second component keeps record of the level when it has first appeared in the stack. The *panic* operation returns to the 2-stack previous to the first appearance of the actual top symbol.

Now let Σ be a signature, and let $\Sigma_r \subseteq \Sigma$ be the set of symbols of type $0^r \rightarrow 0$. A *panic automaton* is defined as a tuple

$$\mathcal{A} = \langle \Sigma, Q, \Gamma, q_1, \delta, \perp \rangle,$$

where Q is a finite set of *states*, with an *initial state* q_1 , Γ is a stack alphabet, with a distinguished *bottom symbol* \perp , and $\delta : Q \times \Gamma \rightarrow \mathcal{I}$ is a *transition function*, where \mathcal{I} is the set of possible instructions,

$$\mathcal{I} \subseteq Op^\Gamma \times Q \cup \bigcup_r \Sigma_r \times Q^r,$$

where $Op^\Gamma = \{push_1\langle a \rangle : a \in \Gamma\} \cup \{pop_1, push_2, pop_2, panic, skip\}$.

A *configuration* of an automaton \mathcal{A} as above is a pair (q, s) , where $q \in Q$, and s is a 2-stack (over Γ). The *initial configuration* is $(q_1, [(\perp, 0)])$. We define the relation $\rightarrow_{\mathcal{A}}$ on configurations as follows. Let $s = [s_1] \dots [s_l][w(a, m)]$.

1. If $\delta(q, a) = \langle \alpha, q' \rangle$ with $\alpha \in Op^\Gamma$ then $\langle q, s \rangle \rightarrow_{\mathcal{A}} \langle q', \alpha(s) \rangle$.
2. If $\delta(q, a) = \langle f, p_1, \dots, p_r \rangle$ then $\langle q, s \rangle \rightarrow_{\mathcal{A}} \langle p_i, s \rangle$, for all $i = 1, \dots, r$.

In the first case we write $\rightarrow_{\mathcal{A}}^\circ$ instead of $\rightarrow_{\mathcal{A}}$. The symbol $\twoheadrightarrow_{\mathcal{A}}^\circ$ stands for the reflexive and transitive closure of $\rightarrow_{\mathcal{A}}^\circ$.

Let $t : dom\ t \rightarrow \Sigma$ be a Σ -tree. A *partial run* of \mathcal{A} on t is a partial function ϱ from an initial segment of $dom\ t$ to the set of all configurations, such that if $\varrho(w) = \langle q, s \rangle$, for some $w \in dom\ t$, then $\delta(q, a) = \langle f, p_1, \dots, p_r \rangle$, where $f = t(w)$ and $a = top(s)$. In addition $\langle p_i, s \rangle \twoheadrightarrow_{\mathcal{A}}^\circ \varrho(wi)$, for each $i = 1, \dots, r$ when $\varrho(wi)$ is defined.

If a partial run is a total function over $dom t$, we call it a *run*. As our automaton is deterministic, there can be at most one tree over which \mathcal{A} has a run. This is the *tree recognized by \mathcal{A}* .

4 Automata vs Grammars

Theorem 4.1. *For any panic automaton \mathcal{A} , one can construct a hyperalgebraic grammar $\mathcal{G}_{\mathcal{A}}$, such that if the automaton recognizes a tree t in $T^\infty(\Sigma)$ then $t = \llbracket \mathcal{G}_{\mathcal{A}} \rrbracket$. Conversely, for a hyperalgebraic grammar \mathcal{G} , one can construct a panic automaton $\mathcal{A}_{\mathcal{G}}$ such that if the grammar generates a tree in $T^\infty(\Sigma)$, this is the (unique) tree recognized by $\mathcal{A}_{\mathcal{G}}$. Both constructions can be realized in polynomial time.*

Here we only sketch the direction $\mathcal{G} \mapsto \mathcal{A}_{\mathcal{G}}$, which is essential for the upper bound result.

Let \circ_1, \circ_2, \dots be fresh identifiers of type $\mathbf{0}$, which we call *holes*. The push-down alphabet Γ of $\mathcal{A}_{\mathcal{G}}$ consists of subterms of the right-hand sides of the productions of \mathcal{G} , possibly applied to some holes, so that the result is of type $\mathbf{0}$. More precisely, let $u = Ft_1 \dots t_d$ be such a subterm, where F is an operator (variable or nonterminal) of type $\tau_1 \rightarrow \dots \rightarrow \tau_d \rightarrow \mathbf{0}^k \rightarrow \mathbf{0}$. Then $u \circ_1 \dots \circ_k \in \Gamma$. In particular, if $u : \mathbf{0}$ then simply $u \in \Gamma$.

The holes \circ_1, \dots, \circ_k represent “missing arguments” of the operator F . Since holes are new identifiers, one can safely identify $Ft_1 \dots t_d \circ_1 \dots \circ_k$ with $Ft_1 \dots t_d$ if this is convenient.

The idea of our simulation is that the top of pds (an expression u) represents a variable-free expression u' occurring in a derivation of \mathcal{G} . Since the pds alphabet must be finite, the term u can only be an “approximation” of u' . This approximation is “evaluated” to yield an approximate representation of the next step of reduction. The contents of the pds represents an environment in which the evaluation takes place. The environment is searched if one needs to find the meaning of a variable, or to find a missing argument.

The bottom pds symbol is \mathcal{S} , the initial nonterminal. This is our approximation in the first step of reduction. The automaton then works in phases, each phase beginning and ending in the distinguished state q_1 . We define automaton informally, by describing the possible behaviour in a phase, beginning with a configuration (q_1, s) .

- T1** Let $top(s) = \mathcal{F}u_1 \dots u_n$, where \mathcal{F} is a nonterminal, and let the corresponding production be $\mathcal{F}x_1 \dots x_n \Rightarrow u$. The automaton executes the instruction $\delta(q_1, \mathcal{F}u_1 \dots u_n) = (push_1 \langle u \rangle, q_1)$, so that our next approximation is u .
- T2** If $top(s) = ft_1 \dots t_r$ where f is a terminal, then the automaton executes the instruction $\delta(q_1, ft_1 \dots t_r) = (f, p_1, \dots, p_r)$, followed (at the i -th branch of the run) by a pop_1 and $push_1 \langle t_i \rangle$. Thus the next approximation at the i -th branch is t_i . (If f is a constant, there is no further step.)
- T3** Let $top(s) = x$, where x is an (ordinary) variable of type $\mathbf{0}$. To “evaluate” x , the automaton restores the environment where x was defined. It executes

pop_1 and inspects the new top symbol. It should be of the form $\mathcal{F}t_1 \dots t_e$, where \mathcal{F} is a nonterminal. In addition, the variable x should be one of the formal parameters of \mathcal{F} , say, the j -th one. The next approximation is t_j , and it should be evaluated in the present environment (that of the caller). Another pop_1 is now executed, followed by a $push_1\langle t_j \rangle$, and the machine returns to state q_1 .

- T4** Let $top(s) = \varphi u_1 \dots u_h$ where φ is a variable of type $\mathbf{0}^h \rightarrow \mathbf{0}$. If we now executed a pop_1 as above then the information about the actual parameters u_1, \dots, u_h would be lost. Instead, a $push_2$ is executed, followed by a pop_1 . As in the previous case, the top of the stack should be of the form $\mathcal{F}t_1 \dots t_e$ and φ should be one of the formal parameters of \mathcal{F} , say, the j -th one. However now the new approximant t_j is an expression of a functional type and we actually place $t_j \circ_1 \dots \circ_h$ on the pds rather than t_j .
- T5** The last case is when $top(s)$ is a hole, say \circ_i . The automaton gets now into a panic. After the panic move the top of the pds should be $\psi v_1 \dots v_l$ for some variable ψ . The new approximation is v_i . We execute in order pop_1 and $push_1\langle v_i \rangle$ and return to state q_1 .

To explain the last case let us first observe that holes (missing arguments) are created when we attempt to evaluate a function variable (the fourth case). Holes correspond to the arguments (actual parameters) of this function variable that were “left behind” for a while. Later, a hole is found at top of the pds when we need to evaluate such a missing argument of an operator. In order to do so, we must restore the situation from the time of the call. The crucial thing is that the “time stamp” of the topmost item points out to exactly the moment in the past we need, namely to the stage when the hole was created.

5 Pushdown Systems

By now, we have considered panic automata as tree acceptors, with the aim to characterize hyperalgebraic grammars. For the model-checking applications, it is convenient to use a related concept of pushdown systems which do not take inputs, but are equipped with ranks and alternation (c.f. [3, 20]).

A *2nd order pushdown system with panic* (or 2-PPDS, for short) is a tuple $\mathcal{C} = (P, P_{\exists}, P_{\forall}, \Gamma, p_1, \Delta, \Omega)$ where P is a finite set of control locations partitioned into P_{\exists} and P_{\forall} , Γ is a finite store alphabet, $p_1 \in P$ is the initial location, $\Omega : P \rightarrow \omega$ is the rank function, and $\Delta \subseteq P \times \Gamma \times P \times Op^{\Gamma}$ is the finite set of (unlabeled) transition rules (where Op^{Γ} is as in Sect. 3). A transition $(p, a, p', \alpha) \in \Delta$ is often written by $p, a \rightarrow_{\Delta} p', \alpha$.

A *configuration* of a 2-PPDS \mathcal{C} is a pair (p, s) where $p \in P$ and s is a 2-stack over Γ . A 2-PPDS \mathcal{C} induces a parity game $Game(\mathcal{C}) = (V_{\exists}, V_{\forall}, E, (p_1, [\perp, 0]), \Omega)$, where

- V_{\exists} is the set of configurations of \mathcal{C} with a location from P_{\exists} , similarly for V_{\forall} ;
- $(p, s)E(p', s')$ iff $\exists(p, a, p', \alpha) \in \Delta$, $top(s) = a$ and $s' = \alpha(s)$;
- $\Omega(p, s) = \Omega(p)$.

Problem 2. Given a 2-PPDS \mathcal{C} , decide if Eva wins the game $Game(\mathcal{C})$.

Proposition 5.2. *Problem 1 and Problem 2 are polynomial-time equivalent.*

Proof: (*Sketch*) By Theorem 4.1, we reduce Problem 1 to the question if a tree recognized by a panic automaton \mathcal{A} is accepted by an alternating tree automaton \mathcal{B} . Then a suitable 2-PPDS \mathcal{C} is obtained by a standard product construction, such that Eve wins $Game(\mathcal{C})$ if and only if she wins $Game(\mathcal{B}, t_{\mathcal{A}})$

The converse transformation of Problem 2 to Problem 1 is also easy, after introduction of a suitable functional signature Σ (depending on given \mathcal{C}). \square

Before proceeding to the proof of our main result, we show a useful transformation of 2-PPDS's, which will allow us to control the dynamics of ranks by the topmost symbols on the pushdown store.

Let $Tr(\mathcal{C})$ be the tree obtained by unfolding the graph of $Game(\mathcal{C})$. That is, the root of $Tr(\mathcal{C})$ is labeled by the initial configuration, and a node labeled by (p, s) has a successor labeled (p', s') , whenever $(p, s)E(p', s')$. Note that a node of the tree determines a computation up to this node.

Definition 5.3 *Let a node v of $Tr(\mathcal{C})$ be labeled with $\langle q, s \rangle$ such that $panic(s)$ is defined. Let v' be the closest to v ancestor of v labeled with $\langle q', panic(s) \rangle$, for some q' . We call v' the panic ancestor of v . The panic rank of v is the maximal rank of a state occurring between the panic ancestor of v and v , including the rank of v and excluding the rank of the panic ancestor of v .*

A 2-PPDS \mathcal{C} is rank-aware iff there exists a function $Rank : \Gamma \rightarrow Rg(\Omega)$ such that the panic rank of every node v of $Tr(\mathcal{C})$ labeled (q, s) is equal to $Rank(top(s))$. That is, the panic rank is determined by the top of the stack.

Lemma 5.4. *For every 2-PPDS \mathcal{C} , one can construct in polynomial time a rank-aware 2-PPDS \mathcal{C}' , such that Eve wins $Game(\mathcal{C}')$ iff she wins in $Game(\mathcal{C})$.*

Proof: (*Idea*) The stack alphabet of \mathcal{C}' is defined as $\Gamma' = \Gamma \times \{0, \dots, d\}^2$, where d is the highest rank in $Rg(\Omega)$. The construction ensures that if (a, m_p, m_l) is currently on top of the stack, then m_p is the panic rank of the node, and m_l is the highest rank of a state seen since the creation of the current top row.

The construction of transitions of \mathcal{C}' goes naturally case by case. The correctness proof is straightforward, but tedious. \square

6 Deciding the Winner in $Game(\mathcal{C})$

A 2nd order pushdown system (or 2-PDS, for short) is like a 2-PPDS defined in section 5, but *without* panic, that is, $\Delta \subseteq P \times \Gamma \times P \times (Op^{\Gamma} - \{panic\})$. Then a level 1 pushdown store can be viewed just as a word over Γ (not $\Gamma \times \omega$). The concepts of 2-pds, configuration, and $Game(\mathcal{C})$ are simplified accordingly.

Games over such pushdown systems have been considered by Engelfriet [10], Cachat [3], and others.

Lemma 6.5 ([10, 3, 4]). *It is decidable if Eve wins $\text{Game}(\mathcal{C})$ for a given 2nd-order pushdown system $\mathcal{C} = (P, P_{\exists}, P_{\forall}, \Gamma, p_1, \Delta, \Omega)$. There is an algorithm working in time $e^3 \cdot 2^{|\Gamma|} 2^{\mathcal{O}(|P|)}$, moreover the problem is 2-EXPTIME-complete.*

We now transform a rank-aware 2nd order pushdown system with panic $\mathcal{C} = (P, P_{\exists}, P_{\forall}, \Gamma, p_1, \Delta, \Omega)$ into a 2nd order pushdown system without panic $\mathcal{C}' = (P', P'_{\exists}, P'_{\forall}, \Gamma', p'_1, \Delta', \Omega')$, such that Eve wins $\text{Game}(\mathcal{C})$ iff she wins $\text{Game}(\mathcal{C}')$.

For technical convenience, we assume that a transition $p, a \rightarrow_{\Delta} p', \alpha$ with $\alpha \neq \text{skip}$ is possible only for $p \in P_{\exists}$. Clearly, we can always achieve this property by duplicating locations and using *skip* operation.

Let $\text{Rank} : \Gamma \rightarrow \text{Rg}(\Omega) = \{0, \dots, d\}$ be the function of Definition 5.3. We introduce an ordering on ranks: $m \preceq n$ iff $(-1)^m \cdot m \leq (-1)^n \cdot n$ (e.g., for $d = 6$, this yields an ordering 5, 3, 1, 0, 2, 4, 6).

We define the set of *returns* as

$$\text{Ret} = P \dot{\rightarrow} \{0, \dots, d\} .$$

The intention is that a partial function $R \in \text{Ret}$ assigns to a location p the worst, in \preceq -order, panic rank still acceptable for the panic moves *ending* in position p . We let

$$\begin{aligned} P'_{\exists} &= P_{\exists} \cup \{\perp\}, \\ P'_{\forall} &= P_{\forall} \cup \{p_{\text{push}}, p_{\text{ver}}, p_{\text{rank}=i} : p \in P, i \in \{0, \dots, d\}\} \cup \{\top\} \cup \{\text{ver}\} \cup \text{Aux} \\ \Gamma' &= \text{Ret} \cup (\Gamma \times \text{Ret}). \end{aligned}$$

The rank function Ω' is 0 for all the locations except for

$$\Omega'(p) = \Omega(p), \quad \Omega'(p_{\text{rank}=i}) = i; \quad \text{for all } p \in P.$$

The transition rules Δ' are defined by the following clauses.

- If $p, a \rightarrow_{\Delta} p', \text{skip}$ then $p, (a, R) \rightarrow_{\Delta'} p', \text{skip}$, for all $R \in \text{Ret}$.
- If $p, a \rightarrow_{\Delta} p', \text{push}_1\langle a \rangle$ then $p, (a, R) \rightarrow_{\Delta'} p'_{\text{ver}}, \text{push}_1\langle (a', R') \rangle$, for all $R, R' \in \text{Ret}$. Additionally we have $p'_{\text{ver}}, (a', R') \rightarrow_{\Delta'} \text{ver}, \text{skip}$, and $p'_{\text{ver}}, (a', R') \rightarrow_{\Delta'} p', \text{skip}$.
- From the location *ver* the moves are defined in such a way that Eve wins iff R in the top letter of the top-most 1-stack is the same as R at the top of 1-stack just below the top-most 1-stack.
- If $p, a \rightarrow_{\Delta} p', \text{push}_2$ then $p, (a, R) \rightarrow_{\Delta'} p'_{\text{push}}, \text{push}_1\langle R' \rangle$, for all $R, R' \in \text{Ret}$. Additionally we put in Δ' the rules⁴ $p'_{\text{push}}, R' \rightarrow_{\Delta'} p', \text{push}_2; \text{pop}_1$, as well as

³ The single exponential dependence on $|\Gamma|$ is not made explicit in these references, but it follows from the analysis of level 1 pushdown systems in [20].

⁴ Notation like $p, a \rightarrow_{\Delta'} p', \alpha_1; \alpha_2$ clearly abbreviates two rules.

- $p'_{push}, R' \rightarrow_{\Delta'} p''_{rank=R'(p'')}, pop_1$, and $p''_{rank=R'(p'')}, (a, R) \rightarrow_{\Delta'} p'', skip$, for all p'' such that $R'(p'')$ is defined.
- If $p, a \rightarrow_{\Delta} p', pop_1$ then $p, (a, R) \rightarrow_{\Delta'} p', pop_1$, for all $R \in Ret$.
 - If $p, a \rightarrow_{\Delta} p', pop_2$ then $p, (a, R) \rightarrow_{\Delta'} p', pop_2; pop_1$, for all $R \in Ret$.
 - If $p, a \rightarrow_{\Delta} p', panic$ then $p, (a, R) \rightarrow_{\Delta'} \top, skip$ if $Rank(a) \succ R(p')$, and we have $p, (a, R) \rightarrow_{\Delta'} \perp, skip$ otherwise, i.e., when $Rank(a) \prec R(p')$ or $R(p')$ is undefined.
 - There are no transitions from states \top and \perp . This implies that Eve wins in \top and loses in \perp .

Proposition 6.6. *Eve wins in $Game(\mathcal{C}')$ iff she wins in $Game(\mathcal{C})$.*

Proof: (*Idea*) The construction guarantees that a 2-pds in a reachable configuration of \mathcal{C}' has a form $v = [w_1 R_1] \dots [w_k R_k][w_{k+1}]$, where $w_i \in (\Gamma \times Ret)^*$ and $R_i \in Ret$. We say that v represents a 2-pds $s = [s_1] \dots [s_{k+1}]$ of \mathcal{C} if, for all i , $s_i \downarrow_1 = w_i \downarrow_1$, and if $s_i \downarrow_2 = \ell$ then $w_i \downarrow_2 = R_\ell$. Note that a possibly infinite domain of “time stamps” (in \mathcal{C}) is represented here by the finite set Ret . Both players can ensure that the 2-stacks reachable in $Game(\mathcal{C}')$ represent the 2-stacks of \mathcal{C} . Together with the mechanism of returns, this allows them to transfer the strategies from $Game(\mathcal{C})$ to $Game(\mathcal{C}')$. \square

We are now ready to state our main result.

Theorem 6.7. *The problem of checking if Eva wins $Game(\mathcal{C})$, for a given 2nd order pushdown system with panic \mathcal{C} , is 2-EXPTIME-complete (Problem 2). Consequently, so is the problem of checking if an alternating parity tree automaton \mathcal{B} accepts the tree $\llbracket \mathcal{G} \rrbracket$ generated by an hyperalgebraic grammar \mathcal{G} (Problem 1).*

Proof: The 2-EXPTIME hardness result follows from Lemma 6.5, and Proposition 5.2. To show the upper bound, let \mathcal{C} be a 2-PPDS. By Lemma 5.4 we can assume that \mathcal{C} is rank-aware. To solve $Game(\mathcal{C})$ we construct a 2-PDS \mathcal{C}' (without panic), as in Proposition 6.6. The system \mathcal{C}' has the number of stack letters which is exponential in the size of \mathcal{C} , but the number of locations of \mathcal{C}' is linear in the number of locations of \mathcal{C} . By the first part of Lemma 6.5, the winner in the game $Game(\mathcal{C}')$ can be decided in time doubly exponential in the number of states and singly exponential in the number of stack symbols, which gives us the desired complexity. \square

By the relation between automata, μ -calculus, and monadic logic (cf. Section 2), we obtain the following.

Corollary 6.8. *It is 2-EXPTIME-complete to check if $\llbracket \mathcal{G} \rrbracket \models \varphi$, for a given 2nd order grammar \mathcal{G} , and a given μ -calculus formula φ . Consequently, the analogous problem for the monadic second-order logic (MSO) is decidable, in particular the MSO theory of any hyperalgebraic tree is decidable.*

Abstract. We introduce a new model of membrane computing system (or P system), called signaling P system. It turns out that signaling systems are a form of P systems with promoters that have been studied earlier in the literature. However, unlike non-cooperative P systems with promoters, which are known to be universal, non-cooperative signaling systems have decidable reachability properties. Our focus in this paper is on verification problems of signaling systems; i.e., algorithmic solutions to a verification query on whether a given signaling system satisfies some desired behavioral property. Such solutions not only help us understand the power of “maximal parallelism” in P systems but also would provide a way to validate a (signaling) P system in vitro through digital computers when the P system is intended to simulate living cells. We present decidable and undecidable properties of the model of non-cooperative signaling systems using proof techniques that we believe are new in the P system area. For the positive results, we use a form of “upper-closed sets” to serve as a symbolic representation for configuration sets of the system, and prove decidable symbolic model-checking properties about them using backward reachability analysis. For the negative results, we use a reduction via the undecidability of Hilbert’s Tenth Problem. This is in contrast to previous proofs of universality in P systems where almost always the reduction is via matrix grammar with appearance checking or through Minsky’s two-counter machines. Here, we employ a new tool using Diophantine equations, which facilitates elegant proofs of the undecidable results. With multiplication being easily implemented under maximal parallelism, we feel that our new technique is of interest in its own right and might find additional applications in P systems.

1 Introduction

P systems [18, 19] are abstracted from the way the living cells process chemical compounds in their compartmental structure. A P system consists of a finite number of

membranes, each of which contains a multiset of objects (symbols). The membranes are organized as a Venn diagram or a tree structure where a membrane may contain other membranes. The dynamics of the P system is governed by a set of rules associated with each membrane. Each rule specifies how objects evolve and move into neighboring membranes. In particular, a key feature of the model of P systems is that rules are applied in a nondeterministic and maximally parallel manner. Due to the key feature inherent in the model, P systems have a great potential for implementing massively concurrent systems in an efficient way that would allow us to solve currently intractable problems (in much the same way as the promise of quantum and DNA computing). It turns out that P systems are a powerful model: even with only one membrane (i.e., 1-region P systems) and without priority rules, P systems are already universal [18, 22]. In such a one-membrane P system, rules are in the form of $u \rightarrow v$, which, in a maximally parallel manner, replaces multiset u (in current configuration which is a multiset of symbol objects) with multiset v .

Signals are a key to initiate biochemical reactions between and inside living cells. Many examples can be found in a standard cell biology textbook [3]. For instance, in signal transduction, it is known that guanine-nucleotide binding proteins (G proteins) play a key role. A large heterotrimeric G protein, one of the two classes of G proteins, is a complex consisting of three subunits: G_α , G_β , and G_γ . When a ligand binds to a G protein-linked receptor, it serves as a signal to activate the G protein. More precisely, the GDP, a guanine nucleotide, bound to the G_α subunit in the unactivated G protein is now displaced with GTP. In particular, the G protein becomes activated by being dissociated into a G_β - G_γ complex and a G_α -GTP complex. Again, the latter complex also serves as a signal by binding itself to the enzyme adenylyl cyclase. With this signal, the enzyme becomes active and converts ATP to cyclic AMP. As another example, apoptosis (i.e., suicide committed by cells, which is different from necrosis, which is the result from injury) is also controlled by death signals such as a CD95/Fas ligand. The signal activates caspase-8 that initiates the apoptosis. Within the scope of Natural Computing (which explores new models, ideas, paradigms from the way nature computes), motivated by these biological facts, it is a natural idea to study P systems, a molecular computing model, augmented with a signaling mechanism.

In this paper, we investigate one-membrane signaling P systems (signaling systems in short) where the rules are further equipped with signals. More precisely, in a signaling system M , we have two types of symbols: object symbols and signals. Each configuration is a pair consisting of a set S of signals and a multiset α of objects. Each rule in M is in the form of $s, u \rightarrow s', v$ or $s, u \rightarrow \Lambda$, where s, s' are signals and u, v are multisets of objects. The rule is enabled in the current configuration (S, α) if s is present in the signal set S and u is a sub-multiset of the multiset α . All the rules are fired in maximally parallel manner. In particular, in the configuration as a result of the maximally parallel move, the new signal set is formed by collecting the set of signals s' that are emitted from all the rules actually fired during the move (and every signal in the old signal set disappears). Hence, a signal may trigger an unbounded number of rule instances in a maximally parallel move.

We focus on verification problems of signaling systems; i.e., algorithmic solutions to a verification query on whether a given signaling system does satisfy some desired

behavioral property. Such solutions not only help us understand the power of the maximally parallelism that is pervasive in P systems but also would provide a way to validate a (signaling) P system in vitro through digital computers when the P system is intended to simulate living cells. However, since one-membrane P systems are Turing-complete, so are signaling systems. Therefore, to study the verification problems, we have to look at restricted signaling systems. A signaling system is non-cooperative if each rule is in the form of $s, a \rightarrow A$ or in the form of $s, a \rightarrow s', bc$, where a, b, c are object symbols. All the results can be generalized to non-cooperative signaling systems augmented with rules $s, a \rightarrow s', v$. We study various reachability queries for non-cooperative signaling systems M ; i.e., given two formulas $Init$ and $Goal$ that define two sets of configurations, are there configurations C_{init} in $Init$ and C_{goal} in $Goal$ such that C_{init} can reach C_{goal} in zero or more maximally parallel moves in M ? We show that, when $Init$ is a Presburger formula (roughly, in which one can compare integer linear constraints over multiplicities of symbols against constants) and $Goal$ is a region formula (roughly, in which one can compare multiplicities of symbols against constants), the reachability query is decidable. Notice that, in this case, common reachability queries like halting and configuration reachability are expressible. We also show that introducing signals into P systems indeed increases its computing power; e.g., non-cooperative signaling systems are strictly stronger than non-cooperative P systems (without signals). On the other hand, when $Goal$ is a Presburger formula, the query becomes undecidable. Our results generalize to queries expressible in a subclass of a CTL temporal logic and to non-cooperative signaling systems with rules $S, a \rightarrow S', v$ (i.e., the rule is triggered with a set of signals in S). We also study the case when a signal has bounded strength and, in this case, non-cooperative signaling systems become universal.

Non-cooperative signaling systems are also interesting for theoretical investigation, since the signaling rules are context-sensitive and the systems are still nonuniversal as we show. In contrast to this, rules $a \rightarrow v$ in a non-cooperative P system are essentially context-free. It is difficult to identify a form of restricted context-sensitive rules that are still nonuniversal. For instance, a communicating P system (CPS) with only one membrane [21] is already universal, where rules are in the form of $ab \rightarrow a_x b_y$ or $ab \rightarrow a_x b_y c_{come}$ in which a, b, c are objects (the c comes from the membrane's external environment), x, y (which indicate the directions of movements of a and b) can only be *here* or *out*. Also one membrane catalytic systems with rules like $Ca \rightarrow Cv$ (where C is a catalyst) are also universal. More examples including non-cooperative signaling systems with promoters, which will be discussed further in this section, are also universal. Our non-cooperative signaling systems use rules in the form of $s, a \rightarrow s', v$, which are in a form of context-sensitive rules, since the signals constitute part of the triggering condition as well as the outcome of the rules.

At the heart of our decidability proof, we use a form of upper-closed sets to serve as a symbolic representation for configuration sets and prove that the symbolic representation is invariant under the backward reachability relation of a non-cooperative signaling system. From the studies in symbolic model-checking [7] for classic transition systems, our symbolic representation also demonstrates a symbolic model-checking procedure at least for reachability. In our undecidability proofs, we use the well-known result on the Hilbert's Tenth Problem: any r.e. set (of integer tuples) is also Diophantine. We

note that, for P systems that deal with symbol objects, proofs for universality almost always use the theoretical tool through matrix grammar with appearance checking [16] or through Minsky's two-counter machines. Here, we employ a new tool using Diophantine equations, which facilitates elegant proofs of the undecidable results. With multiplication being easily implemented under maximal parallelism, we feel that our new technique is of interest in its own right and might find additional applications in P systems.

Signaling mechanisms have also been noticed earlier in P system studies. For instance, in a one-membrane P system with promoters [4], a rule is in the form of $u \rightarrow v|p$ where p is a multiset called a promoter. The rule fires as usual in a maximally parallel manner but only when objects in the promoter all appear in the current configuration. Notice that, since p may not be even contained in u , a promoter, just as a signal, may trigger an unbounded number of rule instances. Indeed, one can show that a signaling system can be directly simulated by a one-membrane P system with promoters. However, since one-membrane non-cooperative P systems with promoters are known to be universal [4], our decidability results on non-cooperative signaling systems have a nice implication: our signals are strictly weaker than promoters (and hence have more decidable properties). The decidability results also imply that, as shown in the paper, non-cooperative signaling systems and vector addition systems (i.e., Petri nets) have incomparable computing power, though both models have a decidable configuration-to-configuration reachability. This latter implication indicates that the maximal parallelism in P systems and the "true concurrency" in Petri nets are different parallel mechanisms. Other signaling mechanisms such as in [2] are also promoter-based.

2 Preliminaries

We use \mathbf{N} to denote the set of natural numbers (including 0) and use \mathbf{Z} to denote the set of integers. Let $\Sigma = \{a_1, \dots, a_k\}$ be an alphabet, for some k , and α be a (finite) multiset over the alphabet. In this paper, we do not distinguish between different representations of the multiset. That is, α can be treated as a vector in \mathbf{N}^k (the components are the multiplicities of the symbols in Σ); α can be treated as a word on Σ where we only care about the counts of symbols (i.e., its Parikh map). For a $\sigma \subseteq \Sigma$, we use σ^* to denote the set of all multisets on σ .

A set $S \subseteq \mathbf{N}^k$ is a *linear set* if there exist vectors v_0, v_1, \dots, v_t in \mathbf{N}^k such that $S = \{v \mid v = v_0 + a_1 v_1 + \dots + a_t v_t, a_i \in \mathbf{N}\}$. A set $S \subseteq \mathbf{N}^k$ is *semilinear* if it is a finite union of linear sets. Let x_1, \dots, x_k be variables on \mathbf{N} . A *Presburger formula* is a Boolean combination of linear constraints in the following form: $\sum_{1 \leq i \leq k} t_i \cdot x_i \sim n$, where the t_i 's and n are integers in \mathbf{Z} , and $\sim \in \{>, <, =, \geq, \leq, \equiv_m\}$ with $0 \neq m \in \mathbf{N}$. It is known that a set of multisets (treated as vectors) is semilinear iff the set is definable by a Presburger formula. Also, Presburger formulas are closed under quantification.

A signaling system is simply a P system [18] augmented with signals. Formally, a (1-membrane) *signaling system* M is specified by a tuple $\langle \Sigma, Sig, R \rangle$, where $\Sigma = \{a_1, \dots, a_k\}$ is the alphabet, Sig is a nonempty finite set of *signals*, and R is a finite set of *rules*. Each rule is in the form of $s, u \rightarrow s', v$, where $s, s' \in Sig$ and u and v are

multisets over alphabet Σ . (Notice that a rule like $s, u \rightarrow v$ (without emitting signal) can be treated as a short hand of $s, u \rightarrow s_{\text{garbage}}, v$ where s_{garbage} is a “garbage” signal that won’t trigger any rules.) A *configuration* C is a pair consisting of a set S of signals and a multiset α on Σ . As with the standard semantics of P systems [18, 19, 20], each evolution step, called a *maximally parallel move*, is a result of applying all the rules in M in a maximally parallel manner. More precisely, let $s_i, u_i \rightarrow s'_i, v_i$, $1 \leq i \leq m$, be all the rules in M . We use $\mathbf{R} = (r_1, \dots, r_m) \in \mathbf{N}^m$ to denote a multiset of rules, where there are r_i instances of rule $s_i, u_i \rightarrow s'_i, v_i$, for each $1 \leq i \leq m$. Rule $s_i, u_i \rightarrow s'_i, v_i$ is *actually fired* in \mathbf{R} if $r_i \geq 1$ (there is at least one instance of the rule in \mathbf{R}). Let $C = (S, \alpha)$ and $C' = (S', \alpha')$ be two configurations. The rule multiset \mathbf{R} is *enabled* under configuration C if

- multiset α contains multiset $\cup_{1 \leq i \leq m} r_i \cdot u_i$ (i.e., the latter multiset is the multiset union of r_i copies of multiset u_i , for all $1 \leq i \leq m$), and
- set $S \supseteq \{s_i : r_i > 0, 1 \leq i \leq m\}$ (i.e., for every rule actually fired in \mathbf{R} , the signal s_i that triggers the rule must appear in the set S of the configuration C).

(We say that a rule is enabled under configuration C if the rule multiset that contains exactly one instance of the rule is enabled under the configuration.) The result $C' = (S', \alpha')$ of applying \mathbf{R} over $C = (S, \alpha)$ is as follows: set S' is obtained by replacing the entire S by the new signal set formed by collecting all the signals s'_i emitted from the rules that are actually fired in \mathbf{R} , and, multiset α' is obtained by replacing, in parallel, each of the r_i copies of u_i in α with v_i . The rule multiset \mathbf{R} is *maximally enabled* under configuration C if it is enabled under C and, for any other rule multiset \mathbf{R}' that properly contains \mathbf{R} , \mathbf{R}' is not enabled under the configuration. Notice that, for the same C , a maximally enabled rule multiset may not be unique (i.e., M is in general nondeterministic). C can reach C' through a maximally parallel move, written $C \rightarrow_M C'$, if there is a maximally enabled rule multiset \mathbf{R} such that C' is the result of applying \mathbf{R} over C . We use $C \rightsquigarrow_M C'$ to denote the fact that C' is reachable from C ; i.e., for some n and C_0, \dots, C_n , we have $C = C_0 \rightarrow_M \dots \rightarrow_M C_n = C'$. We simply say that C is reachable if the initial configuration C' is understood. We say that configuration C is *halting* if there is no rule enabled in C .

When the signals are ignored in a signaling system, we obtain a 1-membrane P system. Clearly, signaling systems are universal, since, as we have mentioned earlier, 1-membrane P systems are known to be universal. A non-cooperative signaling system is a signaling system where each rule is either a *split-rule* in the form of $s, a \rightarrow s', bc$ or a *die-rule* in the form of $s, a \rightarrow \Lambda$, where $s, s' \in \text{Sig}$ and symbols $a, b, c \in \Sigma$. The two rules are called *a-rules* (since a appears at the LHS). Intuitively, the split-rule, when receiving signal s , makes an a -object split into a b -object and a c -object with signal s' emitted. On the other hand, the die-rule, when receiving signal s , makes an a -object die (i.e., becomes null). In particular, for a configuration C , an a -object is *enabled* in C if there is an enabled a -rule in C ; in this case, we also call a to be *an enabled symbol* in C . In the rest of the paper, we will focus on various reachability queries for non-cooperative signaling systems.

3 Configuration Reachability

We first investigate the *configuration-reachability* problem that decides whether one configuration can reach another.

Given: a non-cooperative signaling system M and two configurations C_{init} and C_{goal} ,

Question: Can C_{init} reach C_{goal} in M ?

In this section, we are going to show that the problem is decidable. The proof performs backward reachability analysis. That is, we first effectively compute (a symbolic representation of) the set of all configurations C' such that $C' \rightsquigarrow_M C_{\text{goal}}$. Then, we decide whether the initial configuration C_{init} is in the set.

Before proceeding further, we first introduce the symbolic representation. Let \mathcal{C} be a set of configurations. We say that \mathcal{C} is *upper-closed* if $\mathcal{C} = \{(S, \alpha) : \alpha \text{ is the multiset union of } \beta \text{ and some multiset in } \sigma^*\}$, for some $S \subseteq \text{Sig}$, multiset β and some symbol-set $\sigma \subseteq \Sigma$. In this case, we use $[S, \beta, \sigma^*]$ to denote the set \mathcal{C} . We say that \mathcal{C} is *m-bounded* if $|\beta| \leq m$. Let \mathcal{C} be a finite union of upper-closed sets of configurations. The *pre-image* of \mathcal{C} is defined as $\text{Pre}_M(\mathcal{C}) = \{C' : C' \rightarrow_M C \in \mathcal{C}\}$. We use $\text{Pre}_M^*(\mathcal{C})$ to denote the set of all configurations C' such that $C' \rightsquigarrow C$ for some $C \in \mathcal{C}$. The main result of this section is as follows.

Theorem 1. *Let \mathcal{C} be a finite union of upper-closed sets of configurations in M . Then, $\text{Pre}_M^*(\mathcal{C})$ can also be effectively represented as a finite union of upper-closed sets of configurations in M .*

The complex proof of Theorem 1 constructs an intermediate signaling system \hat{M} whose $\text{Pre}_{\hat{M}}^*$ is easier to compute. The theorem can be established after we prove that Pre_M^* -computation can be realized by $\text{Pre}_{\hat{M}}^*$ -computation and that $\text{Pre}_{\hat{M}}^*(\mathcal{C})$ can be effectively represented as a finite union of upper-closed sets.

Now, we can show that the configuration-reachability problem for non-cooperative signaling systems is decidable. This result implies that non-cooperative signaling systems are not universal (the set of reachable configurations is recursive). Notice that $\mathcal{C} = \{C_{\text{goal}}\}$ is an upper-closed set. Since, from Theorem 1, $\text{Pre}_M^*(\mathcal{C})$ is effectively a finite union of upper-closed sets, one can also effectively answer the reachability at the beginning of this Section by checking whether C_{init} is an element in one of the upper-closed sets. Hence,

Theorem 2. *The configuration reachability problem for non-cooperative signaling systems is decidable.*

Reachability considered so far is only one form of important verification queries. In the rest of this section, we will focus on more general queries that are specified in the computation tree logic (CTL) [6] interpreted on an infinite state transition system [5]. To proceed further, more definitions are needed.

Let M be a non-cooperative signaling system with symbols Σ and signals Sig . We use variables $\#(a), a \in \Sigma$, to indicate the number of a -objects in a configuration and use variable S over 2^{Sig} to indicate the signal set in the configuration. A *region formula* F (the word ‘‘region’’ is borrowed from [1]) is a Boolean combination of formulas in the following forms: $\#(a) > n$, $\#(a) = n$, $\#(a) < n$, $S = \text{sig}$, where $a \in \Sigma$, $n \in \mathbb{N}$, and $\text{sig} \subseteq \text{Sig}$. Region-CTL formulas f are defined using the following grammar:

$f ::= F \mid f \wedge f \mid f \vee f \mid \neg f \mid \exists \circ f \mid \forall \circ f \mid f \exists \mathcal{U} f \mid f \forall \mathcal{U} f$, where F is a region formula. In particular, the eventuality operator $\exists \diamond f$ is the shorthand of $true \exists \mathcal{U} f$, and, its dual $\forall \square f$ is simply $\neg \exists \diamond \neg f$. We use Region-CTL $^\diamond$ to denote a subset of the Region-CTL, where formulas are defined with: $f ::= F \mid f \wedge f \mid f \vee f \mid \neg f \mid \exists \circ f \mid \forall \circ f \mid \exists \diamond f \mid \forall \square f$, where F is a region formula. Each f is interpreted as a set $[f]$ of configurations that satisfy f , as follows:

- $[F]$ is the set of configurations that satisfy the region formula F ;
- $[f_1 \wedge f_2]$ is $[f_1] \cap [f_2]$; $[f_1 \vee f_2]$ is $[f_1] \cup [f_2]$; $[\neg f_1]$ is the complement of $[f_1]$;
- $[\exists \circ f_1]$ is the set of configurations C_1 such that, for some execution $C_1 \rightarrow_M C_2 \rightarrow_M \dots$, we have $C_2 \in [f_1]$;
- $[\forall \circ f_1]$ is the set of configurations C_1 such that, for any execution $C_1 \rightarrow_M C_2 \rightarrow_M \dots$, we have $C_2 \in [f_1]$;
- $[f_1 \exists \mathcal{U} f_2]$ is the set of configurations C_1 such that, for some execution $C_1 \rightarrow_M C_2 \rightarrow_M \dots$, we have C_1, \dots, C_n are all in $[f_1]$ and C_{n+1} is in $[f_2]$, for some n ;
- $[f_1 \forall \mathcal{U} f_2]$ is the set of configurations C_1 such that, for any execution $C_1 \rightarrow_M C_2 \rightarrow_M \dots$, we have C_1, \dots, C_n are all in $[f_1]$ and C_{n+1} is in $[f_2]$, for some n .

Below, we use P to denote a Boolean combination of Presburger formulas over the $\#(a)$'s and formulas in the form of $S = sig$, where $sig \subseteq Sig$. The Region-CTL model-checking problem for non-cooperative signaling systems is to answer the following question:

Given: a non-cooperative signaling system M , a Region-CTL formula f , and a Presburger formula P ,

Question: Does every configuration satisfying P also satisfy f ?

It is known that the Region-CTL model-checking problem for non-cooperative P systems with rules $a \rightarrow b$ is undecidable [8]. From this result, one can show that the Region-CTL model-checking problem for non-cooperative signaling systems is undecidable as well.

Theorem 3. *The Region-CTL model-checking problem for non-cooperative signaling systems is undecidable.*

In contrast to Theorem 3, the subset, Region-CTL $^\diamond$, of Region-CTL is decidable for non-cooperative signaling systems:

Theorem 4. *The Region-CTL $^\diamond$ model-checking problem for non-cooperative signaling systems is decidable.*

Using Theorem 4, the following example property can be automatically verified for a non-cooperative signaling system M :

“From every configuration satisfying $\#_a - \#_b < 6$, M has some execution that first reaches a configuration with $\#_a > 15$ and then reaches a halting configuration containing the signal s_1 and with $\#_b < 16$.”

Notice that, above, “halting configurations” (i.e., none of the objects is enabled) form a finite union of upper-closed sets.

4 Presburger Reachability

Let M be a non-cooperative signaling system and C_{init} be a given initial configuration. In this section, we are going to investigate a stronger form of reachability problems. As we have mentioned earlier, a multiset α (over alphabet Σ with k symbols) of objects can be represented as a vector in \mathbf{N}^k . Let $P(x_1, \dots, x_k)$ be a Presburger formula over k nonnegative integer variables x_1, \dots, x_k . The multiset α satisfies P if $P(\alpha)$ holds. A configuration (S, α) of the non-cooperative signaling system M satisfies P if α satisfies P . An equality is a Presburger formula in the form of $x_i = x_j$, for some $1 \leq i, j \leq k$. An equality formula, which is a special form of Presburger formulas, is a conjunction of a number of equalities. The Presburger-reachability problem is to decide whether a non-cooperative signaling system has a reachable configuration satisfying a given Presburger formula:

Given: a non-cooperative signaling system M , an initial configuration C_{init} , and a Presburger formula P ,

Question: is there a reachable configuration satisfying P ?

In contrast to Theorem 2, we can show that the Presburger-reachability problem is undecidable. The undecidability holds even when M has only one signal (i.e., $|\text{Sig}| = 1$) and P is an equality formula (i.e., the equality-reachability problem). In fact, what we will show is a more general result that characterizes the set of reachable configurations in M satisfying P exactly as r.e. sets. Notice that, for P systems that deal with symbol objects, proofs for universality almost always use the theoretical tool through matrix grammar with appearance checking [16]. Here, we employ a new tool using Diophantine equations. Before we proceed further, we recall some known results on Diophantine equations (the Hilbert's Tenth Problem).

Let $m \in \mathbf{N}$, $Q \subseteq \mathbf{N}^m$ be a set of natural number tuples, and $E(z_1, \dots, z_m, y_1, \dots, y_n)$ be a Diophantine equation system. The set Q is definable by E if Q is exactly the solution set of $\exists y_1, \dots, y_n. E(z_1, \dots, z_m, y_1, \dots, y_n)$; i.e., $Q = \{(z_1, \dots, z_m) : E(z_1, \dots, z_m, y_1, \dots, y_n) \text{ holds for some } y_1, \dots, y_n\}$. An atomic Diophantine equation is in one of the following three forms: $z = xy + \frac{1}{2}x(x+1)$, $z = x + y$, $z = 1$, where x, y, z are three distinct variables over \mathbf{N} . A conjunction of these atomic equations is called a Diophantine equation system of atomic Diophantine equations. It is well known that Q is r.e. iff Q is definable by some Diophantine equation system [17]. From here, it is not hard to show the following:

Lemma 1. For any set $Q \subseteq \mathbf{N}^m$, Q is r.e. iff Q is definable by a Diophantine equation system of atomic Diophantine equations.

We now build a relationship between Diophantine equations and non-cooperative signaling systems. Recall that Q is a subset of \mathbf{N}^m . We say that Q is (M, C_{init}, P) -definable if there are designated symbols Z_1, \dots, Z_m in M such that, for any numbers $\#(Z_1), \dots, \#(Z_m)$,

$(\#(Z_1), \dots, \#(Z_m))$ is in Q iff there is a reachable configuration from C_{init} in M satisfying P and, for each i , the number of Z_i -objects in the configuration is $\#(Z_i)$.

When P is *true* and C_{init} is understood, we simply say that Q is definable by M . The non-cooperative signaling system M is *lazy* if, for any reachable configuration and any number n , if the configuration is reachable from C_{init} in n maximally parallel moves, then it is reachable in t maximally parallel moves for any $t \geq n$. We first show that solutions to each atomic Diophantine equation can be defined with a lazy non-cooperative signaling system M with only one signal.

Lemma 2. *The solution set to each atomic Diophantine equation is definable by some lazy non-cooperative signaling system M (starting from some C_{init}) with only one signal.*

Now, we can show the following characterization.

Theorem 5. *For any set $Q \subseteq \mathbb{N}^m$, Q is r.e. iff Q is (M, C_{init}, P) -definable for some non-cooperative signaling system M with one signal, some configuration C_{init} , and some equality formula P .*

From Theorem 5, we immediately have

Theorem 6. *The equality-reachability problem for non-cooperative signaling systems with only one signal is undecidable. Therefore, the Presburger-reachability problem for non-cooperative signaling systems is undecidable as well.*

All the decidable/undecidable results presented so far can be generalized to the case when non-cooperative signaling systems are augmented with rules in the following forms: $s, a \rightarrow s', v$, where v is a multiset. From now on, we let non-cooperative signaling systems contain these rules by default.

The results in Theorem 5 and Theorem 6 can be used to obtain a new result on non-cooperative P systems \hat{M} where \hat{M} has only one membrane and each rule is in the form of $a \rightarrow v$, where v is a multiset. Notice that \hat{M} is very similar to a non-cooperative signaling system M with only one signal. Indeed, one can easily show that they are effectively equivalent in the following sense:

Lemma 3. *For any set $Q \subseteq \mathbb{N}^m$, Q is definable by some non-cooperative P system \hat{M} iff Q is definable by some non-cooperative signaling system M with only one signal.*

It is known that \hat{M} is not a universal P system model; multisets generated from \hat{M} form the Parikh map of an ETOL language [15]. We now augment \hat{M} with a *Presburger tester* that, nondeterministically at some maximally parallel move during a run of \hat{M} , tests (for only once) whether the current multiset satisfies a given Presburger formula P . When P is an equality formula, the tester is called an *equality tester*. If yes, the tester outputs the multiset and \hat{M} shuts down. Otherwise, \hat{M} crashes (with no output). Let X_1, \dots, X_m be designated symbols in \hat{M} . We say that $Q \subseteq \mathbb{N}^m$ is *output-definable* by \hat{M} if Q is exactly the set of tuples $(\#(X_1), \dots, \#(X_m))$ in the output multisets. Directly from Lemma 3 and Theorem 5, one can show that non-cooperative P systems (as well as non-cooperative signaling systems with only one signal) with an equality tester are universal:

Theorem 7. *For any set $Q \subseteq \mathbb{N}^m$, Q is r.e. iff Q is the output-definable by a non-cooperative P system (as well as a non-cooperative signaling system with only one signal) with an equality (and hence Presburger) tester.*

Hence,

Corollary 1. *The equality-reachability problem for non-cooperative P systems is undecidable. Therefore, the Presburger-reachability problem is undecidable as well.*

With the current technology, it might be difficult to implement the equality tester device to achieve the universality, which requires, e.g., external multiset evaluation during an almost instantaneous chemical reaction process. As we already know, a more natural way to perform the evaluation is to wait until the system *halts*; i.e., none of the objects in the current configuration is enabled. In this way, one can similarly formulate the halting-definability and the Presburger/equality-halting-reachability problems for non-cooperative signaling systems as well as for non-cooperative P systems, which concern halting and reachable configurations (instead of reachable configurations). We first show that non-cooperative signaling systems with only one signal has semilinear halting-definable reachability sets. This result essentially tells us that the number of signals matters, as far as halting configurations are considered: non-cooperative signaling systems with multiple signals are strictly stronger than non-cooperative signaling systems with only one signal (as well as non-cooperative P systems). This is because a non-semilinear set like $\{(n, 2^n) : n \geq 0\}$ can be easily halting-definable by a non-cooperative signaling system.

Theorem 8. *For any $Q \subseteq \mathbb{N}^m$, Q is a semilinear set iff Q is halting-definable by a non-cooperative signaling system with only one signal (as well as by a non-cooperative P system).*

One can similarly augment \hat{M} as well as \hat{M} with a Presburger tester but only test and output when a halting configuration is reached; i.e., a *Presburger halting tester*. The following result shows that non-cooperative signaling systems with only one signal and with a Presburger halting tester are not universal, while non-cooperative signaling systems with two signals and with an equality halting tester are universal. That is, again, the number of signals matters.

Theorem 9. *For any $Q \subseteq \mathbb{N}^m$, (1). Q is a semilinear set iff Q is output-definable by a non-cooperative signaling system with only one signal (as well as a non-cooperative P system) and with a Presburger halting tester. (2). Q is r.e. iff Q is output-definable by a non-cooperative signaling system with two signals and with an equality (and hence Presburger) halting tester.*

From Theorem 9, we immediately have:

Theorem 10. *(1). The halting Presburger reachability problem for non-cooperative signaling systems with two signals is undecidable. (2). The halting Presburger reachability problem for non-cooperative signaling systems with only one signal is decidable.*

5 Discussions and Future Work

In our set-up, a signal in a non-cooperative signaling system M has unbounded strength; i.e., it can trigger an unbounded number of instances of an enabled rule. If we restrict the

strength of each signal in M to be B (where B is a constant), the resulting M is called a B -bounded non-cooperative signaling system. A move in such M is still maximally parallel. However, each signal can fire at most B instances of rules. From Theorem 2, we know that (unbounded) non-cooperative signaling systems are not universal. In contrast to this fact, we can show that bounded non-cooperative signaling systems are universal. The universality holds even when $B = 2$. The case for $B = 1$ is open.

There is an intimate relationship between some classes of P systems and VAS (vector addition systems, or, equivalently, Petri nets)[13, 14]. Though non-cooperative signaling systems as well as VAS are not universal, they are incomparable in terms of the computing power. This is because, the Presburger-reachability problem of VAS is decidable [9] while, as we have shown, the same problem for non-cooperative signaling systems is undecidable. On the other hand, the Pre^* -image of a non-cooperative signaling system is always upper-closed while this is not true for VAS.

In the definition of a non-cooperative signaling system, a rule is in the form of $s, a \rightarrow s', v$, where s and s' are signals. Now, we generalize the definition by allowing rules in the form of $S, a \rightarrow S', v$ where S and S' are sets of signals (instead of signals). The maximally parallel semantics of the rules can be defined similarly. The differences are that the rule is enabled when every signal in S is in the current configuration and, after the rule is fired, every signal in S' is emitted. Hence, the rule now is triggered by exactly all of the signals in S . Such a rule is called a *multi-signal rule*. Let M be such a non-cooperative signaling system with multi-signal rules. The proof of Theorem 1 can be adapted easily for such an M . Therefore, Theorem 2 and Theorem 4 still hold for non-cooperative signaling system with multi-signal rules. In fact, the results can be further generalized as follows.

Our study of non-cooperative signaling system was restricted to one membrane. We can generalize the model to work on multiple membranes (as in the P system), where each membrane has a set of rules, and in each rule $S, a \rightarrow S', v$ (we are using multi-signal rules) we specify the “target” membranes where each object in v as well as each signal in S' are transported to. Notice that we do not use priority rules nor membrane dissolving rules. We call this generalized model as a multimembrane non-cooperative signaling system with multi-signal rules. Observe that multimembranes can be equivalently collapsed into one membrane through properly renaming (signal and object) symbols in a membrane. That is, each membrane is associated with a distinguished set of symbols. Of course, in doing so, the number of distinct symbols and signals in the reduced one-membrane system will increase as a function of the number of membranes in the original system. Therefore, Theorem 2 and Theorem 4 can be further generalized to multimembranes non-cooperative signaling systems with multi-signal rules.

It is known that there are nonuniversal P systems where the number of membranes induces an infinite hierarchy in terms of computing power [12]. However, the above generalization says that the hierarchy collapses for non-cooperative signaling systems. Is there a hierarchy in terms of the number of membranes for a restricted and nonuniversal form of signaling systems (which is stronger than non-cooperative signaling systems)? We might also ask whether for one-membrane signaling systems, there is a hierarchy in terms of the numbers of symbols and signals used (since the conversion described above from multimembrane to one membrane increases the number of sym-

bols and signals). As defined, a non-cooperative signaling system is a “generator” of multisets. For a given configuration C , there may be many configurations C' that satisfy $C \rightarrow_M C'$. Hence, a (maximally parallel) move is nondeterministic. Can we define an appropriate model of non-cooperative signaling system e.g., an “acceptor” of multisets (rather than a generator) such that the next move is unique (i.e., deterministic)? Deterministic P systems have been found to have some nice properties [11].
