Abstract. It is well known that the base composition along eukaryotic genomes is long-range correlated. Here, we investigate the effect of such long-range correlations on alignment score statistics. We model the correlated score-landscape by means of a Gaussian approximation. In this framework, we can calculate the corrections to the scale parameter λ of the extreme value distribution of alignment scores. To evaluate our approximate analytic results, we perform a detailed numerical study based on a simple algorithm to efficiently generate long-range correlated random sequences. We find that the mean and the exponential tail of the score distribution are in fact influenced by the correlations along the sequences. Therefore, the significance of measured alignment scores in biological sequences will change upon incorporation of the correlations in the null model.

1 Introduction

Recent years have witnessed an impressive advance of bioinformatics sequence analysis tools, aiming at deeper insight to the functional organization and evolutionary dynamics of genomic DNA sequences. Popular examples include algorithms for genome annotation, homology detection between genomic regions of different organisms, or the prediction of transcription factor binding sites [1, 2].

Bioinformatics methods frequently yield probabilistic statements. Usually the statistical significance of a computational prediction is characterized by a p-value, specifying the likelihood that this prediction could have arisen by chance. The calculation of p-values requires an appropriate null model of DNA, which reflects our assumptions about the "background" statistical features of the sequence under consideration. The challenging task is to decide on the set of statistical features a suitable null model should obey. Ideally, one incorporates those features into the null model which describe the background "noise" of the DNA sequence, but still allow to discern the specific signal the computational analysis tries to detect.

The simplest DNA background model is an *iid* model, given by a random sequence with letters drawn independently from an identical distribution [2]. The iid model can incorporate the length and the average composition of the sequences under consideration, but it lacks any specific structure concerning the

© Springer-Verlag Berlin Heidelberg 2006

arrangement of the nucleotides along the DNA. In particular, it is not capable of incorporating correlations in base composition along the sequences. Up to a certain degree, this additional complexity can be taken into account by an nth order Markov model, specifying the transition probabilities $P(a_{i+1}|a_{i-n+1}, \cdots, a_i)$ in a genomic sequence $\boldsymbol{a} = a_1, \ldots, a_N$ [2]. Assuming the sequences to be generated by Markov processes already allows to incorporate a multitude of spatial statistical features into the model, like e.g. the preferential occurrence of DNA motifs, local peculiarities in genomic composition, or specific dinucleotide frequencies. In contrast to iid sequences, where all letters are uncorrelated, Markov processes lead to, so called, *short-range correlations* in the nucleotide composition [3]. They are characterized by an exponential decay of the correlations between two different bases with increasing distance along the sequence.

A statistical measure of the correlations in genomic base composition is the autocorrelation function $C(r)$. It quantifies the deviations in the joint probability of finding equal bases at a distance of r basepairs along the DNA backbone compared to that in a random sequence of independent letters with the same nucleotide frequencies $p_{a\in\{A,C,T,G\}}$,

$$C(r) \equiv \sum_a \left[P(a_i = a_{i+r} = a) - p_a^2 \right]. \tag{1}$$

We have $C(r) = 0$ $(r > 0)$ for iid sequences, while $C(r) \propto \exp(-\beta r)$ for short-range correlated sequences, e.g. those generated by Markov processes.

With the rapidly growing availability of whole-genome sequence data the correlations along genomic DNA can nowadays be studied systematically over a wide range of scales and organisms. A striking observation in this field was the finding of *long-range correlations* in the base composition of genomes more than a decade ago [4, 3, 5]. They are characterized by a power-law decay of the correlation function for large r,

$$C(r) \propto r^{-\alpha}, \tag{2}$$

and therefore decay much slower compared to short-range correlations. By now it is well established that long-range correlations in base composition appear in the genomes of most eukaryotic species [6, 7, 8] with two examples shown in Fig. 1. Little is known about the origin of genomic long-range correlations, so far. However, their ubiquity among eukaryotic genomes points towards a universal mechanism. A likely dynamical scenario is that they are generated by the stochastic processes of molecular sequence evolution, as has been discussed in [9, 10, 11].

The widespread presence of long-range correlations in genomes raises the question if they need to be incorporated into an accurate null model of eukaryotic DNA and how that would change the p-value calculations. In this article, we address this question in the context of sequence alignment, which constitutes the most commonly used computational tool of molecular biology today [12, 13]. We tackle the problem of calculating sequence alignment significance values for null models with long-range sequence composition correlations with both, analytical, as well as numerical methods. On the analytical side, we introduce a novel

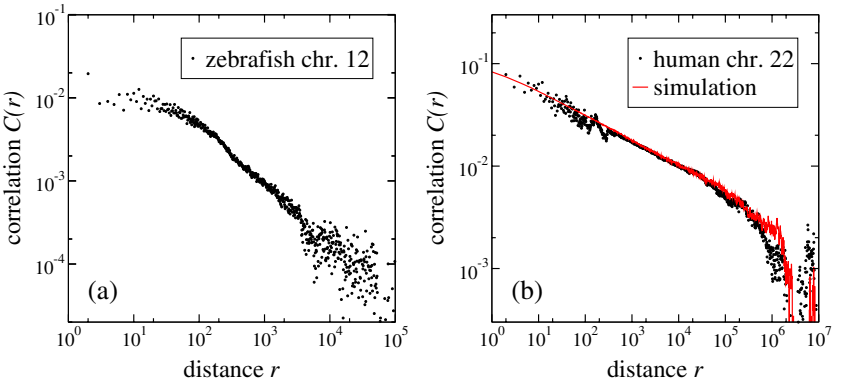

Fig. 1. Long-range correlations in the base composition of two eukaryotic chromosomes. In the double-logarithmic plots, power-law correlations $C(r) \propto r^{-\alpha}$ show up as straight lines with slope α. They extend over distances of several orders of magnitude. In (b) we demonstrate our capability of simulating long-range correlated sequences with similar amplitude and correlation exponent $\alpha \approx 0.232$, as measured in Human chr. 22.

approach, the Gaussian approximation, which allows us to calculate the corrections to the scale parameter λ of the alignment score distribution for correlated sequences. Long-range correlated sequences cannot be generated by an nth order Markov process with finite n [3]. The numerical approach therefore only recently has come within reach due to results derived in [10, 11], where we proposed a biologically motivated algorithm capable of efficiently generating long-range correlated sequences with arbitrary correlation parameters. As the main result of our analysis, it turns out that long-range correlations in the sequences lead to considerable deviations in the score statistics of sequence alignment.

After presenting a short review of sequence alignment in section 2, we analytically treat the alignment of long-range correlated sequences in section 3. A numerical evaluation of the approximative analytic results is presented in section 4. In section 5, we discuss the relevance of this effect for genomic sequence alignment by analyzing the magnitude of the corrections to the score significance values using correlation parameters, measured in eukaryotic genomes. The implications of our findings in a bioinformatics context are discussed at the end of this article.

2 Sequence Alignment and Significance Assessment

The goal of DNA sequence alignment is to assign to a given pair of genomic sequences $\boldsymbol{a} = a_1, \cdots, a_N$ and $\boldsymbol{b} = b_1, \cdots, b_M$ a measure of their similarity. The simplest version of sequence alignment is *gapless* alignment. A local gapless alignment $\mathcal{A}$ of the two sequences consists of a substring $a_{i-l+1} \cdots a_i$ of length l of sequence $\boldsymbol{a}$ and a substring $b_{j-l+1} \cdots b_j$ of sequence $\boldsymbol{b}$ of the same length. Each such alignment is assigned a score $S_{\mathcal{A}} = \sum_{k=0}^{l-1} s(a_{i-k}, b_{j-k})$, where $s(a, b)$

is some given scoring matrix measuring the mutual degree of similarity of the different letters of the alphabet. For DNA sequence comparison, one often uses the simple match-mismatch matrix [14]

$$s(a,b) = \begin{cases} 1 & : \quad a = b \\ -\mu & : \quad a \neq b \end{cases} . \tag{3}$$

The computational task is to find the alignment $\mathcal{A}$, which gives the highest total score

$$S \equiv \max S_{\mathcal{A}}. \tag{4}$$

For the purpose of detecting weak sequence homologies, alignment algorithms can also take into account insertions and deletions in either one of the two sequences during biological evolution [14]. For such *gapped* alignments, each gap contributes a (negative) gap cost γ to the total score of the alignment. Using affine gap costs, one additionally distinguishes between the gap initiation cost γ_i and the gap extension cost γ_e.

Since an alignment score S is assigned to any pair of sequences, also to biologically completely unrelated ones, it is helpful to know the distribution of S in an appropriate null model. The knowledge of this distribution gives the possibility to assign p-values to alignment results; they specify the probability that a high score could have arisen by chance in order to be able to distinguish true evolutionary relationship from random similarities. As already mentioned in the introduction, a frequently used null model for that purpose is the iid model. For ungapped alignment of long sequences ($M, N \gg 1$), the distribution of S for the iid model has been worked out rigorously [15, 16, 17]; it is a Gumbel or extreme value distribution, with its probability density function given by

$$\mathrm{pdf}(S) = KMN\lambda \exp\left(-\lambda S - KMNe^{-\lambda S}\right). \tag{5}$$

The distribution is characterized by the two parameters λ and K. In the iid case, the scale parameter λ is the unique positive solution of the equation

$$\langle \exp(\lambda s) \rangle = \sum_{a,b} p_a p_b \exp\left[\lambda s(a,b)\right] = 1. \tag{6}$$

The other parameter K then determines the mean of the distribution.

For gapped alignment, no rigorous theory for the distribution of S exists, so far. However, numerical evidence strongly suggests that the distribution is still of Gumbel form [18, 19, 20, 21]. Using this empirical applicability, it has been shown in [22, 23, 24] that λ for local gapped alignment in the iid model can be derived solely from studying the much simpler global alignment, where one is interested in the path with the highest score $h \equiv \max h_{\mathcal{A}}$, connecting the beginning (a_1, b_1) to the end (a_N, b_N) of a given pair of sequences $\boldsymbol{a}$ and $\boldsymbol{b}$ (we set $M = N$, from now on). One defines a *generating function*

$$Z_N(\lambda) \equiv \langle \exp(\lambda h) \rangle, \tag{7}$$

where the brackets $\langle\cdot\rangle$ denote an average over all possible pairs of random sequences $\boldsymbol{a}$ and $\boldsymbol{b}$ of length N. The *central conjecture* in [22] then states that λ is determined by the solution of the equation

$$\lim_{N\to\infty} \frac{1}{N} \log Z_N(\lambda) = 0. \tag{8}$$

Following the results of [25, 26], this allows for a very efficient computation of λ for gapped alignment in the iid model.

3 The Gaussian Approximation

In this section, we derive approximate analytical results for the parameter λ of the score distribution one obtains for alignment of random sequences with long-range correlations. We restrict ourselves to gapless alignment, since we expect qualitatively similar results for the gapped case. This will also be confirmed by the numerical data we present in section 5. For simplicity, we furthermore assume a uniform distribution of the four nucleotides; a generalization to sequences with biased composition is straightforward.

The approach employed in the following is based on the assumption that for local gapless alignment of correlated sequences the distribution of the maximal scores obeys Gumbel form, and λ is still determined by Eq. (8). The score of the global alignment is given by the sum over all elementary scores $s_i = s(a_i, b_i)$ along the diagonal of the alignment-lattice. Defining $\boldsymbol{s} = (s_1, \ldots, s_N)$, we have

$$h = \sum_{i=1}^{N} s_i = \mathbf{1}^{\mathrm{t}} \boldsymbol{s}. \tag{9}$$

The ensemble average of Eq. (7) over all realizations of the two sequences $\boldsymbol{a}$ and $\boldsymbol{b}$ can therefore be expressed in terms of an average over all score vectors $\boldsymbol{s}$. While the probability of a score vector factorizes in the iid model, $P(\boldsymbol{s}) = \prod_i P(s_i)$, this is no longer the case for correlated sequences. However, approximate values for the probabilities $P(\boldsymbol{s})$ in the correlated case can still be derived by a Gaussian approximation. The idea of this approach is to replace the discrete variables s_i by continuous Gaussian variables. More precisely, an individual discrete score $s_i = \{1, -\mu\}$ at position i along the diagonal of the alignment-lattice will now be allowed to take continuous values, distributed according to a normal distribution

$$\mathrm{pdf}(s_i) = \frac{1}{\sqrt{2\pi\sigma^2}} \exp \frac{-(s_i - \langle s\rangle)^2}{2\sigma^2}. \tag{10}$$

Mean and variance are chosen in accordance with the original discrete score distribution, i.e., $\langle s\rangle = 1/4 - 3\mu/4$, and $\sigma^2 = 3(1+\mu)^2/16$.

The probability $P(\boldsymbol{s})$ of a score vector $\boldsymbol{s}$ is then determined by an N-dimensional Gaussian distribution

$$\begin{aligned} P(\boldsymbol{s}) = {} & [(2\pi)^N \det \boldsymbol{\sigma}]^{-1/2} \\ & \exp\left[-\frac{1}{2}(\boldsymbol{s} - \langle \boldsymbol{s}\rangle)^{\mathrm{t}} \boldsymbol{\sigma}^{-1} (\boldsymbol{s} - \langle \boldsymbol{s}\rangle)\right], \end{aligned} \tag{11}$$

with $\langle \boldsymbol{s} \rangle = (\langle s \rangle, \ldots, \langle s \rangle)$ and the covariance matrix $\boldsymbol{\sigma}$, defined by

$$\boldsymbol{\sigma}_{ij} = \langle s(i)s(j) \rangle - \langle s(i) \rangle \langle s(j) \rangle. \tag{12}$$

The diagonal elements of $\boldsymbol{\sigma}$ are given by the variance of an individual score, $\boldsymbol{\sigma}_{ii} = \sigma^2$. The non-diagonal elements $\boldsymbol{\sigma}_{i \neq j}$ can be expressed in terms of the correlation function $C(r)$ of the sequences $\boldsymbol{a}$ and $\boldsymbol{b}$,

$$\boldsymbol{\sigma}_{ij} = \frac{1}{3}(1+\mu)^2 C^2(|i-j|). \tag{13}$$

In this expression the correlation function $C(r)$ is squared, since (13) describes the correlations of the similarity scores which arise from a comparison of two sequences. The non-diagonal elements vanish for iid sequences.

Using the distribution (11), the calculation of the generating function (7) amounts to the evaluation of an N-dimensional Gaussian integral, which can be solved explicitly,

$$\begin{aligned} Z_N(\lambda) &= \int d\boldsymbol{s}\; P(\boldsymbol{s}) \exp\left(\lambda \mathbf{1}^{\mathrm{t}} \boldsymbol{s}\right) \\ &= [(2\pi)^N \det \boldsymbol{\sigma}]^{-1/2} \\ &\quad \int d\boldsymbol{s}\; e^{-\frac{1}{2}(\boldsymbol{s}-\langle \boldsymbol{s} \rangle)^{\mathrm{t}} \boldsymbol{\sigma}^{-1} (\boldsymbol{s}-\langle \boldsymbol{s} \rangle) + \lambda \mathbf{1}^{\mathrm{t}} \boldsymbol{s}} \\ &= \exp\left(\lambda \mathbf{1}^{\mathrm{t}} \langle \boldsymbol{s} \rangle + \frac{1}{2}\lambda^2 \mathbf{1}^{\mathrm{t}} \boldsymbol{\sigma} \mathbf{1}\right). \end{aligned} \tag{14}$$

The central conjecture (8) then implies

$$0 = \lim_{N \to \infty} \frac{1}{N} \left(\lambda \mathbf{1}^{\mathrm{t}} \langle \boldsymbol{s} \rangle + \frac{1}{2}\lambda^2 \mathbf{1}^{\mathrm{t}} \boldsymbol{\sigma} \mathbf{1}\right). \tag{15}$$

Notice that this expression coincides with the result obtained by applying the central conjecture to the Taylor series approximation of the generating function (7) up to second order. Using Eq. (13) yields

$$\lambda = \frac{-2\langle s \rangle}{\sigma^2 + \frac{2}{3}(1+\mu)^2 \lim_{N \to \infty} \sum_{i=1}^{N} C^2(i)}. \tag{16}$$

The first term σ^2 in the denominator of (16) is related to the individual fluctuations of a single score element, irrespective of correlations along the sequences. The second term, on the other hand, vanishes for iid sequences and determines the corrections to λ due to correlations.

In case of long-range correlations, i.e., $C(r) = cr^{-\alpha}$, and assuming $\alpha > 1/2$, we obtain

$$\lambda = \frac{-2\langle s \rangle}{\sigma^2 + \frac{2}{3}(1+\mu)^2 c^2 \zeta(2\alpha)}, \tag{17}$$

where $\zeta(x)$ is the Riemann zeta function. Consequently, the Gaussian approximation predicts deviations in λ for the alignment of long-range correlated sequences

compared to iid sequences. A detailed numerical analysis of this analytic result will be performed in section 4. Notice that for $\alpha \leq 1/2$ the sum $\sum_{i=1}^{\infty} C^2(i)$ diverges, resulting in $\lambda = 0$. This might indicate a transition from local to global alignment in the Gaussian approximation, which will be discussed in section 4.3.

As a first evaluation of the Gaussian approximation, we investigate its predictions for sequences $\boldsymbol{a} = (a_1, \ldots, a_N)$ generated by a Markov process. We consider a first order process with four different states $A_i \in \{A, C, T, G\}$. Starting with a random nucleotide a_1, the transition probabilities are defined by

$$P(a_{i+1}|a_i) = \begin{cases} p & : \quad a_{i+1} = a_i \\ \frac{1}{3}(1-p) & : \quad a_{i+1} \neq a_i \end{cases} . \tag{18}$$

This process generates short-range correlations in the sequences of the form $C(r) = c \exp(-\beta r)$ with $\beta = -\log(4p/3 - 1/3)$ and $c = 3/4$. For this case, the Gaussian approximation (16) yields

$$\lambda = \frac{-2\langle s \rangle}{\sigma^2 + \frac{2}{3}(1+\mu)^2 c^2/(\exp(2\beta) - 1)}. \tag{19}$$

This can be compared to an exact analytical result for λ obtained by equating the largest eigenvalue of a modified λ-dependent transition matrix of the underlying Markov process to one [16]. As is shown in Fig. 2, the Gaussian approximation (19) fits well to the exact resuls; deviations for large β vanish for decreasing β. Notice that the limit $\beta \to \infty$ corresponds to $p \to 1/4$, describing the asymptotics of an uncorrelated iid sequence. The deviations of the Gaussian

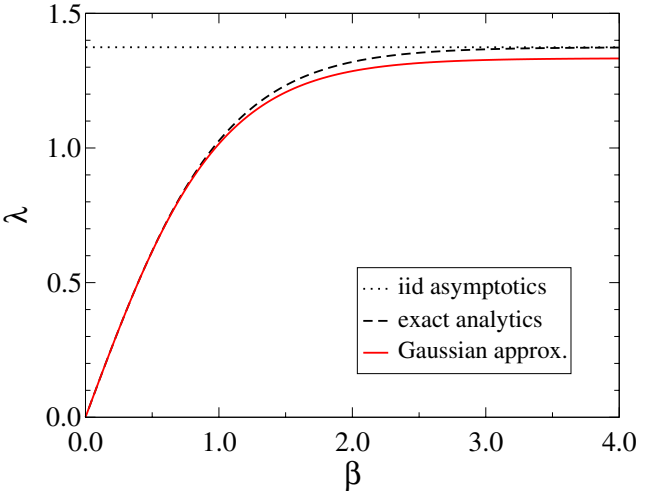

Fig. 2. λ for sequences with short-range correlations generated by a Markov process. The dashed line is the exact result [16] for the Markov process defined in (18), using $\mu = 3$. The solid line is the corresponding result of the Gaussian approximation, as derived in Eq. (19). Solving Eq. (6) yields the iid asymptotics $\lambda \approx 1.374$ (dotted line).

approximation for this regime result from the fact that the third and all higher cumulants of the distribution (10) vanish, which they do not for the discrete distribution.

4 Numerical Results

4.1 Generation of Long-Range Correlated Random Sequences

Numerical evaluation of the results obtained in the previous section hinges on the knowledge of the score distribution $\mathrm{pdf}(S)$ for local gapless alignment of pairs of long-range correlated random sequences. However, the efficient generation of such sequences is quite intricate. In [10], we have proposed a biologically motivated model of sequence evolution which generates sequences with the desired statistical features. Furthermore, it has recently been shown [11] that there exists a much larger class of dynamical processes, so called, *expansion-randomization* processes, which allow for the efficient generation of sequences with arbitrary long-range correlations.

Based on [11], we use a single-site duplication-mutation algorithm to generate long-range correlated sequences. We start with a sequence of one random nucleotide a_1, and the dynamics of the model is defined by the following update rules:

1. A random position j of the sequence is chosen.
2. The nucleotide a_j is either mutated to a random but different nucleotide with probability P_{mut}, or duplicated with probability $P_{\mathrm{dup}} = 1 - P_{\mathrm{mut}}$. The duplication process inserts a copy of a_j at position $j + 1$, thereby increasing the sequence length by one.

This process generates sequences of arbitrary length N in a time $O[N \log(N)]$ with asymptotic long-range correlations in their nucleotide composition. The correlation function of the generated sequences is given in terms of the Euler beta function $B(x, y)$ by [10]

$$C(r) = \frac{3}{4}\alpha B(r + 1, \alpha). \tag{20}$$

In the large r limit, this yields $C(r) \propto r^{-\alpha}$. By varying the mutation probability $0 < P_{\mathrm{mut}} < 1$, the decay exponent α of the long-range correlations can be tuned to any desired positive value, as it is determined by

$$\alpha = \frac{8}{3}\frac{P_{\mathrm{mut}}}{1 - P_{\mathrm{mut}}}. \tag{21}$$

Using this model, we are now in the position to efficiently generate large ensembles of long-range correlated sequences needed for an accurate measurement of the tail of the distribution $\mathrm{pdf}(S)$. For the alignment, we use the standard Smith-Waterman dynamic programming algorithm [14] with scoring matrix (3) and $\mu = 3$.

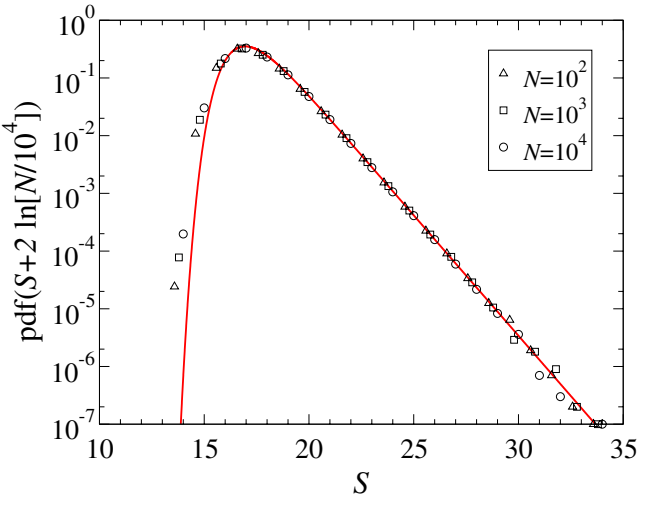

Fig. 3. Convergence of the distribution pdf(S) for long-range correlated sequences with $\alpha = 2.0$ to a Gumbel form. The solid line is a Gumbel distribution, as specified in Eq. (5) with $N = M = 10^4$ and fitted parameters $\lambda = 0.9614$ and $K = 0.119$. λ was obtained by fitting a linear function to log[pdf(S)] for $21 < S < 31$, K has then been estimated by fitting the data to (5) in the same interval. In order to be able to compare the shape of pdf(S) for different N, the distributions have to be rescaled by a transformation pdf(S) $\rightarrow$ pdf($S + 2\ln[N/N_0]$) with reference length $N_0 = 10^4$.

4.2 The Gumbel Distribution of Alignment Scores

The Gaussian model is based on the assumption that the score distribution pdf(S) is of Gumbel form for long-range correlated sequences. Consequently, our first numerical analysis aims at a verification of this conjecture. In Fig. 3, we show the measured pdf(S) for long-range correlated sequences with $\alpha = 2.0$, estimated from ensembles of 10^7 pairs of random sequence realizations generated by the above specified algorithm. For large N, the distribution asymptotically approaches a Gumbel form. As is the case for the iid model, finite-size corrections come into play for short sequence lengths [20, 27, 28]. These deviations primarily show up in the small S regime, while the more relevant large S regime converges fast for increasing N.

Now, that we have verified the shape of the score distribution to be of Gumbel form, we can test the accuracy of the analytic predictions for λ derived by the Gaussian approximation. Here we restrict ourselves to the discussion of the regime $\alpha > 1/2$, where the Gaussian approximation predicts finite values of λ; the regime $\alpha \leq 1/2$ will be investigated below.

We compare our numerical data to Eq.(16), using correlations of the form (20). Results are shown in Fig. 4. The Gaussian approximation captures the qualitative behavior of the numerical data. Again, the right side of the plot reveals the deviations of the Gaussian approximation concerning its iid asymptotics given by $\alpha \rightarrow \infty$. With increasing correlation strength, i.e., smaller values of

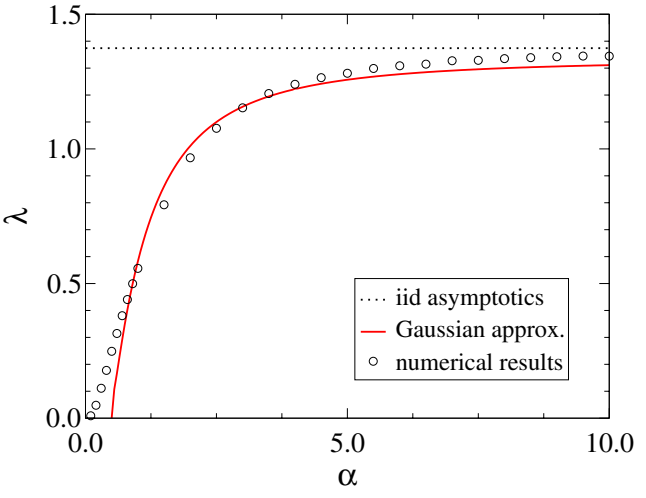

Fig. 4. λ for a null model with long-range correlated sequences in dependence of the correlation exponent α. The solid line is the analytic result of the Gaussian approximation, one obtains by estimating Eq. (16) using the correlations (20) of our simulated sequences. Numerically measured values of λ for different correlation parameters α are denoted by symbols. For our simulation, we use sequences of length $N = 10^3$ and average over ensembles of 10^8 pairs of sequences.

α, λ decreases, confirming that long-range correlations systematically raise the probability of measuring high alignment scores.

So far, our investigations of the alignment score distribution for long-range correlated sequences have focused on the exponential tail of pdf(S). We now turn to the second parameter K. For that purpose, we recall that the mean of a Gumbel distribution (5) is determined by

$$\langle S \rangle = \frac{\Gamma + \log(KN^2)}{\lambda}, \tag{22}$$

Table 1. Dependence of $\langle S \rangle$ and K on the exponent α. We use simulated sequences of length $N = 10^3$ and average over ensembles of 10^8 pairs of sequences for each value of α to obtain numerical values of λ and $\langle S \rangle$. The values of K have been calculated using Eq. (22).

α	λ	$\langle S \rangle$	K
(iid)	1.374	9.71	3.50×10^{-1}
4.0	1.240	10.61	2.90×10^{-1}
2.0	0.967	12.65	1.15×10^{-1}
1.0	0.556	18.07	1.30×10^{-2}

where $\Gamma \approx 0.5772$ is the Euler-Mascheroni constant. Thus, knowing λ, the parameter K can easily be calculated by measuring the mean $\langle S \rangle$ of the score distribution. As shown in Table 1, K is significantly affected by the presence of long-range correlations in the sequences to be aligned; it decreases with increasing correlation-strength. However, the mean of the distribution is, as expected, shifted to larger values of S for decreasing values of α, since K contributes only logarithmically in Eq. (22) and the change in $\langle S \rangle$ is dominated by the decrease of λ.

4.3 The Score Distribution for $\alpha \leq 1/2$

In the regime $\alpha > 1/2$, the score distribution is of Gumbel form and the Gaussian approximation suitably fits the numerical values of λ. For values of $\alpha \leq 1/2$, the Gaussian approximation yields $\lambda = 0$, which might indicate a transition from local to global alignment. For simulated sequences of finite length, on the other hand, one still measures finite values of λ (Fig. 4). The numerical investigation of this regime is complicated by a distinct finite size effect: according to the results derived in [11], an individual alignment of two finite sequences will have a systematic bias of $\langle s \rangle$ towards either $\langle s \rangle = 1$, or $\langle s \rangle = -\mu$, depending on whether by chance the two initial random letters a_1 and b_1 of our sequence generation algorithm were equal for the two sequences to be aligned, or not. This effect causes strong deviations of $\mathrm{pdf}(S)$ from a Gumbel form for small S. However, the tail of the distribution is still exponential for finite sequences, and therefore allows for a measurement of λ. It is dominated by those realizations of the ensemble, where both sequences started with the same letter since they lead to systematically higher values of $\langle s \rangle$ and therefore also higher scores S.

As can be seen in Fig. 4, λ approaches zero for finite sequences not until the "infinite" correlation strength limit $\alpha \to 0$. Further analysis is needed to decide on whether there actually is a transition to global alignment for a particular $\alpha > 0$ in the limit $N \to \infty$, or not. If this is the case, then the rate of convergence for $\lambda \to 0$ is at most logarithmically.

However, for practical applications this transition is irrelevant. Finite sequences always have a positive λ, also in the regime $\alpha \leq 1/2$. For these particular choices of parameters, λ needs to be measured numerically.

5 Consequences for Alignments of Genomic Sequences

It has been shown that long-range correlations in base composition increase the probability of measuring high scores for pairwise sequence alignment. In a biological context, this raises the question whether the effect causes a significant change of the p-values for DNA alignment? In order to address this issue, we investigate the deviations of the score distribution for correlation parameters of genomic magnitude compared to iid sequences. As an example, we consider the measured correlation function of Human chromosome 22, shown in Fig. 1(b). Using the simulation algorithm introduced in section 4.1 we can generate long-range correlated random sequences with the corresponding exponent $\alpha \approx 0.232$.

By randomly mutating 85% of the sites after sequence build up, the correlation amplitude is reduced to the genomic value, while the exponent remains unchanged [11]. As can be seen in Fig. 1(b), this procedure allows us to generate random sequences featuring comparable correlations as Human chr. 22.

We perform ungapped, as well as gapped alignment with affine gap costs for 10^7 pairs of random sequences with length $N = 10^3$ from the above specified ensemble. Alignment parameters are chosen in accordance with the NCBI default values $\mu = 3$, gap initiation cost $\gamma_i = 5$, and gap extension cost $\gamma_e = 2$ [29]. In Fig. 5 we show the measured score distributions for the simulated chr. 22 sequences compared to iid sequences. The resulting parameters λ and $\langle S \rangle$ are presented in Table 2. It turns out that the difference in the score distributions between ungapped and gapped alignment is negligible for the parameters used.

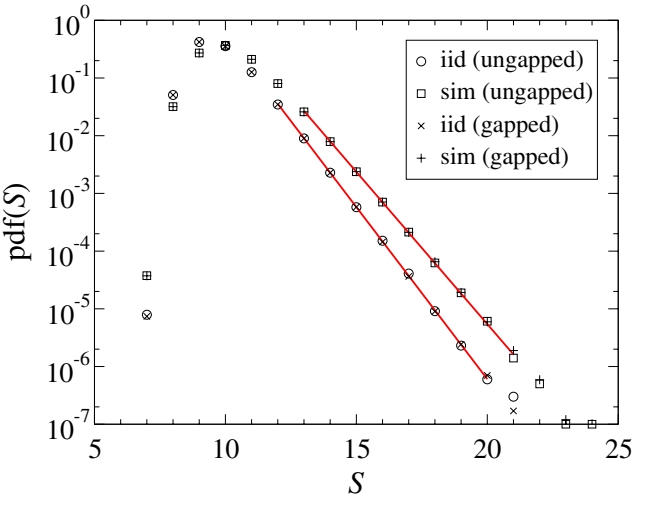

Fig. 5. The score distribution for ungapped and gapped alignment of simulated sequences with correlations comparable to those of Human chromosome 22. The straight lines are the fits to the exponential tails of the score distributions, obtained by fitting a linear function to log[pdf(S)] in the depicted intervals.

Table 2. Fitted parameters λ and $\langle S \rangle$ for the iid ensemble and simulated Human chr. 22 sequences of length $N = 10^3$. In the last column, exemplary p-values of a score $S' = 18$ are shown.

ensemble	λ	$\langle S \rangle$	$P(S \geq 18)$
iid (ungapped)	1.374	9.714	3.3×10^{-6}
sim. chr. 22 (ungapped)	1.191	10.164	2.8×10^{-5}
iid (gapped)	1.373	9.714	3.2×10^{-6}
sim. chr. 22 (gapped)	1.215	10.163	2.7×10^{-5}

The deviations in λ between the iid ensemble and the simulated Human chr. 22 sequences are approximately 15% in both cases, and the mean of the score distributions for the correlated sequences is significantly higher. In combination, both effects substantially change the p-values of high scores compared to the iid model, as can be seen in Table 2. The p-value of a specific score S' is thereby defined by the integral $P(S \geq S') = \int_{S'}^{\infty} \mathrm{pdf}(S)dS$. For an exemplary score $S' = 18$, this p-value will be increased by almost one order of magnitude if one incorporates the genomic correlations into the null model.

6 Discussion

Long-range correlations are a widespread statistical feature of eukaryotic DNA. In this article, it has been shown that incorporation of this feature into the null model substantially influences the score statistics of sequence alignment. While the p-values of the scores are systematically increased, the ranking of hits will not be significantly changed. The effect is therefore relevant whenever one is actually interested in p-values, e.g., when specifying a cutoff in order to distinguish true evolutionary relationship from random similarities.

One has to keep in mind that genomic DNA is a highly heterogeneous environment: it consists of genes, noncoding regions, repetitive elements etc., and all of these substructures may imprint their signature on the amount of correlations found in a particular genomic region. Long-range correlations are by definition a feature on larger scales. Our findings are therefore naturally applicable to the alignment of larger genomic regions. This includes the identification of duplicated regions, or conserved syntenic segments between chromosomes of different species, which often extend over many kilobases up to several megabases. However, long-range correlations will also influence the statistics of search algorithms for short DNA motifs if the query sequences are large enough for long-range correlations to be measured.

Moreover, it will be interesting to analyze possible effects of long-range correlations on the statistics of other widely used sequence analysis tools, e.g., the prediction of transcription factor binding sites. Further investigation is needed to assess the relevance of long-range correlations for other statistical predictions. Finally, more accurate null models of DNA sequences utilizing quantitative correlation features will help to reduce the often encountered high false-positive rate of bioinformatics analysis tools.
