Abstract. The fundamental operation in elliptic curve cryptographic schemes is the multiplication of an elliptic curve point by an integer. This paper describes a new method for accelerating this operation on classes of elliptic curves that have efficiently-computable endomorphisms. One advantage of the new method is that it is applicable to a larger class of curves than previous such methods. For this special class of curves, a speedup of up to 50% can be expected over the best general methods for point multiplication.

1 Introduction

Let E be an elliptic curve defined over a finite field \mathbb{F}_q . The dominant cost operation in elliptic curve cryptographic schemes is *point multiplication*, namely computing kQ where Q is an elliptic curve point and k is an integer. This operation is the additive analogue of the exponentiation operation α^k in a general (multiplicative-written) finite group. The basic technique for exponentiation is the repeated square-and-multiply algorithm. Numerous methods for speeding up exponentiation and point multiplication have been discussed in the literature; for a survey, see [11,12,17]. These methods can be categorized as follows:

1. Generic methods which can be applied to speed up exponentiation in any finite abelian group, including:
 - a) Comb techniques (e.g. [15]) which precompute tables which depend on Q . Such techniques are applicable when the base point Q is fixed and known a priori, for example in ECDSA signature generation.
 - b) Addition chains which are useful when k is fixed, for example in RSA decryption.
 - c) Windowing techniques which are useful when the base point Q is not known a priori, for example in Diffie-Hellman key agreement.
 - d) Simultaneous multiple exponentiation techniques for computing expressions $k_1Q_1 + k_2Q_2 + \dots + k_tQ_t$, for example in ECDSA signature verification.
2. Exponent recoding techniques which replace the binary representation of k with a representation which has fewer non-zero terms (e.g. [10,19]).
3. Methods which are particular to elliptic curve point multiplication such as:

- a) Selection of an underlying finite field which enables faster field arithmetic. For example, selection of a prime field \mathbb{F}_p where p is a Mersenne prime or a Mersenne-like prime [31], or an optimal field extension [2].
- b) Selection of a representation of the underlying finite field which enables faster field arithmetic. For example, selection of an irreducible trinomial as the reduction polynomial for binary extension fields.
- c) Selection of a point representation which enables faster elliptic curve arithmetic [6].
- d) Selection of an elliptic curve with special properties, for example Koblitz curves [13].

Koblitz curves are elliptic curves defined over \mathbb{F}_2 , and were first proposed for cryptographic use in [13]. The primary advantage of Koblitz curves is that the Frobenius endomorphism can be exploited to devise fast point multiplication algorithms that do not use any point doublings [30,32]. These techniques can be generalized to use arbitrary endomorphisms but are generally not efficient.

The contribution of this paper is a new technique for speeding up point multiplication of elliptic curves having an efficiently-computable endomorphism. While the technique is not as efficient as the methods of Solinas [30,32] for Koblitz curves, they are useful for speeding up point multiplication on a larger class of elliptic curves, for example certain curves over prime fields. Such elliptic curves over prime fields have been included in the WAP WTLS (Wireless Transport Layer Security) standard [33]. We believe the ideas discussed in this paper are new (though not difficult). In particular, we believe that the approach of decomposing k modulo n , and applying just one application of the endomorphism is different than the methods of previous papers. The result is a technique which works on a wider class of curves (in particular, curves defined over prime fields), and works with endomorphisms whose computational cost is not necessarily cheaper than a point operation. For this class of curves, a speedup of up to 50% can be expected over the best general methods for point multiplication.

The remainder of this paper is organized as follows. §2 defines an endomorphism and reviews how the Frobenius endomorphism can be used to speed up point multiplication on Koblitz curves. Our new work for speeding up point multiplication on elliptic curves which have efficiently-computable endomorphisms is described in §3 and §4. The security of the new method is considered in §5. Finally, we draw our conclusions and discuss avenues for future work in §6.

2 Endomorphisms

Let E be an elliptic curve defined over the finite field \mathbb{F}_q . The point at infinity is denoted by \mathcal{O} . For any $n \geq 1$, the group of \mathbb{F}_{q^n} -rational points on E is denoted by $E(\mathbb{F}_{q^n})$.

An *endomorphism* of E is a rational map $\phi : E \rightarrow E$ satisfying $\phi(\mathcal{O}) = \mathcal{O}$ [27]. If the rational map is defined over \mathbb{F}_q , then the endomorphism ϕ is also said to be defined over \mathbb{F}_q . In this case, ϕ is a group homomorphism of $E(\mathbb{F}_q)$, and also of $E(\mathbb{F}_{q^n})$ for any $n \geq 1$.

Example 1. Let E be an elliptic curve defined over \mathbb{F}_q . For each $m \in \mathbb{Z}$ the *multiplication by m* map $[m] : E \rightarrow E$ defined by $P \mapsto mP$ is an endomorphism defined over \mathbb{F}_q . A special case is the *negation* map defined by $P \mapsto -P$.

Example 2. Let E be an elliptic curve defined over \mathbb{F}_q . Then the q^{th} power map $\phi : E \rightarrow E$ defined by $(x, y) \mapsto (x^q, y^q)$ and $\mathcal{O} \mapsto \mathcal{O}$ is an endomorphism defined over \mathbb{F}_q , called the *Frobenius* endomorphism. Since exponentiating to the q^{th} power is a linear operation in \mathbb{F}_{q^n} , computation of $\phi(P)$ is normally quite fast. For example, if a normal basis of \mathbb{F}_{q^n} over \mathbb{F}_q is used, this computation can be implemented as a cyclic shift of the vector representation.

Example 3 (§7.2.3 of [5]). Let $p \equiv 1 \pmod{4}$ be a prime, and consider the elliptic curve

$$E_1 : y^2 = x^3 + ax \tag{1}$$

defined over \mathbb{F}_p . Let $\alpha \in \mathbb{F}_p$ be an element of order 4. Then the map $\phi : E_1 \rightarrow E_1$ defined by $(x, y) \mapsto (-x, \alpha y)$ and $\mathcal{O} \mapsto \mathcal{O}$ is an endomorphism defined over \mathbb{F}_p . If $P \in E(\mathbb{F}_p)$ is a point of prime order n , then ϕ acts on $\langle P \rangle$ as a multiplication map $[\lambda]$, i.e., $\phi(Q) = \lambda Q$ for all $Q \in \langle P \rangle$, where λ is an integer satisfying $\lambda^2 \equiv -1 \pmod{n}$. Note that $\phi(Q)$ can be computed using only one multiplication in \mathbb{F}_p .

Example 4 (§7.2.3 of [5]). Let $p \equiv 1 \pmod{3}$ be a prime, and consider the elliptic curve

$$E_2 : y^2 = x^3 + b \tag{2}$$

defined over \mathbb{F}_p . Let $\beta \in \mathbb{F}_p$ be an element of order 3. Then the map $\phi : E_2 \rightarrow E_2$ defined by $(x, y) \mapsto (\beta x, y)$ and $\mathcal{O} \mapsto \mathcal{O}$ is an endomorphism defined over \mathbb{F}_p . If $P \in E(\mathbb{F}_p)$ is a point of prime order n , then ϕ acts on $\langle P \rangle$ as a multiplication map $[\lambda]$, where λ is an integer satisfying $\lambda^2 + \lambda \equiv -1 \pmod{n}$. Note that $\phi(Q)$ can be computed using only one multiplication in \mathbb{F}_p .

Example 5 (§7.2.3 of [5]). Let $p > 3$ be a prime such that -7 is a perfect square in \mathbb{F}_p , and let $\omega = (1 + \sqrt{-7})/2$, and let $a = (\omega - 3)/4$. Consider the elliptic curve

$$E_3 : y^2 = x^3 - \frac{3}{4}x^2 - 2x - 1 \tag{3}$$

defined over \mathbb{F}_p . Then the map $\phi : E_3 \rightarrow E_3$ defined by

$$(x, y) \mapsto \left(\omega^{-2} \frac{x^2 - \omega}{x - a}, \omega^{-3} y \frac{x^2 - 2ax + \omega}{(x - a)^2} \right)$$

and $\mathcal{O} \mapsto \mathcal{O}$ is an endomorphism defined over \mathbb{F}_p . Computing the endomorphism is a little harder than doubling a point.

Example 6 (§14B of [7]). Let $p > 3$ be a prime such that -2 is a perfect square in \mathbb{F}_p , and consider the elliptic curve

$$E_4 : y^2 = 4x^3 - 30x - 28 \tag{4}$$

defined over \mathbb{F}_p . Then the map $\phi : E_4 \rightarrow E_4$ defined by

$$(x, y) \mapsto \left(-\frac{2x^2 + 4x + 9}{4(x + 2)}, -\frac{2x^2 + 8x - 1}{4\sqrt{-2}(x + 2)^2}y \right)$$

and $\mathcal{O} \mapsto \mathcal{O}$ is an endomorphism defined over \mathbb{F}_p . Computing the endomorphism is a little harder than doubling a point.

The existing methods [13,14,20,29,32] for point multiplication which exploit efficiently-computable endomorphisms all use the Frobenius endomorphism. Let E be an elliptic curve defined over a small field \mathbb{F}_q , and let ϕ be the Frobenius endomorphism. To compute kP , where $P \in E(\mathbb{F}_{q^n})$, these methods first compute $k' = k \bmod (\phi^n - 1)$ in the ring $\mathbb{Z}[\phi]$. Then, one computes a ϕ -adic expansion $k' = \sum_{i=0}^t c_i \phi^i$, where the c_i are elements of a small set, e.g., $\{-q/2, \dots, q/2\}$, and $t \approx n$. Finally, kP can be efficiently computed as follows:

$$kP = k'P = \sum_{i=0}^t c_i \phi^i(P). \tag{5}$$

The expression (5) can be evaluated using traditional windowing techniques. Observe that the (slow) point doublings in traditional repeated add-and-double algorithms have been replaced by (fast) evaluations of the Frobenius map.

The methods based on Frobenius map expansions can in principle be extended to an arbitrary endomorphism ψ . However, these techniques will no longer be efficient if computing ψ is more expensive than a point doubling. Furthermore, one may not have $\psi^n - 1 = 0$, so the ψ -adic expansion of k may be significantly longer than the binary expansion of k . Finally, the existing techniques do not apply when $\text{Norm}(\psi) = 1$ (as is the case in Examples 3 and 4) since these techniques require a division operation by ψ which yield a nontrivial remainder having norm less than $\text{Norm}(\psi)$.

In the next section, we present a new method that exploits efficiently-computable endomorphisms such as the ones in Examples 3, 4, 5 and 6 to speed up point multiplication.

3 Using Efficient Endomorphisms

Let E be an elliptic curve defined over \mathbb{F}_q , and let $P \in E(\mathbb{F}_q)$ be a point of prime order n . Let ϕ be an endomorphism defined over \mathbb{F}_q , and suppose that the characteristic polynomial of ϕ has a root λ modulo n —since the characteristic polynomial of an endomorphism has degree two we expect that roughly half of all curves will have a root modulo n . The map ϕ acts on $\langle P \rangle$ as a multiplication map $[\lambda]$.

The methods described will be advantageous if computing ϕ costs less than computing about $(\log_2 n)/3$ point doublings. In practice, we expect the algorithm to be applied when the cost of ϕ is less than (say) 5 point doubles.

The problem we consider is that of computing kP for k selected uniformly at random from the interval $[1, n-1]$. The basic idea of the paper is as follows. Suppose that we can efficiently write $k = k_1 + k_2\lambda \bmod n$, where $k_1, k_2 \in [0, \lceil \sqrt{n} \rceil]$ (see §4). Then we have

$$\begin{aligned} kP &= (k_1 + k_2\lambda)P \\ &= k_1P + k_2(\lambda P) \\ &= k_1P + k_2\phi(P). \end{aligned} \tag{6}$$

Now (6) can be computed using any of the ‘simultaneous multiple exponentiation’ type algorithms¹, the simplest of which we review below. In the following, $(u_{t-1}, \dots, u_1, u_0)_2$ denotes the binary representation of the integer u , and w is the window width.

Algorithm 1. Simultaneous multiple point multiplication

INPUT: $w, u = (u_{t-1}, \dots, u_1, u_0)_2, v = (v_{t-1}, \dots, v_1, v_0)_2, P, Q$.

OUTPUT: $uP + vQ$.

1. Compute $iP + jQ$ for all $i, j \in [0, 2^w - 1]$.
 2. Write $u = (u^{d-1}, \dots, u^1, u^0)$ and $v = (v^{d-1}, \dots, v^1, v^0)$ where each u^i and v^i is a bitstring of length w , and $d = \lceil t/w \rceil$.
 3. $R \leftarrow \mathcal{O}$.
 4. For i from $d-1$ downto 0 do
 - 4.1 $R \leftarrow 2^w R$.
 - 4.2 $R \leftarrow R + (u^i P + v^i Q)$.
 5. Return(R).
-

Analysis. Since the bitlengths of k_1 and k_2 in (6) are half the bitlength of k , we might expect to obtain a significant speedup because we have eliminated a significant number of point doublings at the expense of a few point additions. A precise analysis is complicated due to the large number of point multiplication techniques available. Nevertheless, the following provides some indication of the relative benefits of our method.

Assume that k is a randomly selected t -bit integer. When $t = 160$, Algorithm 2 of [18] (an exponent recoding and sliding window algorithm) is among the best algorithms for computing kP . This method costs approximately 157 point doubles and 34 point additions using windows of size 4 [18]. To compare this traditional method with the proposed method, we need an algorithm for computing $k_1P + k_2Q$ (where in our case $Q = \phi(P)$). The following is straightforward and useful for our purposes, but we cannot find a reference for it.

¹ These are also known as ‘exponentiation using vector-addition chains’, ‘Shamir’s trick’, or ‘multi-exponentiation’.

Algorithm 2 of [18] can be combined with the simultaneous multiple exponentiation technique of Algorithm 1 to give an algorithm which is among the best [24] for computing $k_1P + k_2Q$. Essentially, this combined algorithm computes ϵP and ϵQ for the integers ϵ corresponding to allowable windows, then writes each of k_1 and k_2 in signed windowed-NAF form as in [18]. Finally a left-to-right algorithm is used to iteratively double a common accumulator and add in an ϵP or ϵQ as appropriate. After $\max\{\log_2 k_1, \log_2 k_2\}$ iterations, the accumulator holds the desired $k_1P + k_2Q$.

Using this algorithm in the proposed method to compute $kP = k_1P + k_2(\lambda P)$ costs approximately 79 point doubles and 38 point additions (when using windows of size 3 [18]) plus 1 evaluation of the map ϕ . If the cost of a point doubling is 8 field multiplications and the cost of a point addition is 11 field multiplications (as is the case with Jacobian coordinates [4]), then the ratio of the running times of the proposed method to the traditional method is ≈ 0.66 . Thus the new method for point multiplication is roughly 50% faster than the traditional method when $t = 160$. As the bitlength of k increases, the ratio essentially decreases² and so the relative performance of the new method gets better. For example, with a bitlength of $t = 512$, the ratio is about .62.

Remark. If computing ϕ is cheaper than a point addition, then a few additions can be saved as follows. In the above ‘simultaneous windowed-NAF’ method for computing $k_1P + k_2Q$, we initially compute and store points ϵP and ϵQ for small values of ϵ . If $Q = \phi(P)$, and computing ϕ is cheaper than a point addition, then we can instead compute $\epsilon Q = \epsilon\phi(P) = \phi(\epsilon P)$. For example, in the width-3 windowed method of [18], computing $k_1P + k_2\phi(P)$ saves 3 additions at the expense of 3 additional applications of ϕ .

Example 7. An example of an elliptic curve for which our new method is applicable is

$$E : y^2 = x^3 + 3$$

over the prime field \mathbb{F}_p , where

$$p = 1461501637330902918203684832716283019655932313743$$

is a 160-bit prime, and

$$\#E(\mathbb{F}_p) = 1461501637330902918203687013445034429194588307251$$

is prime. This curve is included in the WAP specification of the WTLS protocol [33].

² There are occasional minor bumps corresponding to window size changes.

4 Decomposing k

In this section we describe an algorithm which takes as input integers n , λ and $k \in_R [1, n - 1]$, and returns integers k_1 and k_2 such that $k \equiv k_1 + k_2\lambda \pmod{n}$. The integers k_1 and k_2 returned are distinguished in that they are both small or, equivalently, the vector $(k_1, k_2) \in \mathbb{Z} \times \mathbb{Z}$ has small Euclidean norm. The term “small” will be made precise below.

Let $G = \mathbb{Z} \times \mathbb{Z}$ and consider the homomorphism $f : G \rightarrow \mathbb{Z}_n$ defined by $(i, j) \mapsto (i + \lambda j) \pmod{n}$. We wish to find a short vector $u \in G$ such that $f(u) = k$; the components of u can then be used as the required k_1 and k_2 . Note that it is easy to find a vector $v \in G$ such that $f(v) = k$; $v = (k, 0)$ is such a vector. The problem is in finding a vector that is also short.

Our approach is the following. We first find linearly independent short vectors $v_1, v_2 \in G$ such that $f(v_1) = f(v_2) = 0$. We then find a vector v in the integer lattice generated by v_1 and v_2 that is close to $(k, 0)$. It then follows that $u = (k, 0) - v$ is a short vector with $f(u) = f((k, 0)) - f(v) = k$. Note that both subproblems can be solved using lattice basis reduction algorithms. However, the direct methods presented here are far less cumbersome to implement.

Finding v_1 and v_2 . The problem of finding two independent short vectors v_1, v_2 such that $f(v_1) = f(v_2) = 0$ can be solved using the extended Euclidean algorithm. We apply the extended Euclidean algorithm to find the greatest common divisor of n and λ . (This gcd is 1 since n is prime.) The algorithm produces a sequence of equations

$$s_i n + t_i \lambda = r_i, \text{ for } i = 0, 1, 2, \dots, \tag{7}$$

where $s_0 = 1, t_0 = 0, r_0 = n, s_1 = 0, t_1 = 1, r_1 = \lambda$, and $r_i \geq 0$ for all i . The following properties of the extended Euclidean algorithm are well-known and can be easily proven by induction.

Lemma 1. *Let s_i, t_i, r_i be the sequence of variables in (7) produced by an application of the extended Euclidean algorithm to positive integers n and λ .*

- (i) $r_i > r_{i+1} \geq 0$ for all $i \geq 0$.
- (ii) $|s_i| < |s_{i+1}|$ for $i \geq 1$.
- (iii) $|t_i| < |t_{i+1}|$ for $i \geq 0$.
- (iv) $r_{i-1}|t_i| + r_i|t_{i-1}| = n$ for all $i \geq 1$.

Let m be the greatest index for which $r_m \geq \sqrt{n}$. Then $r_m|t_{m+1}| + r_{m+1}|t_m| = n$, and $|t_{m+1}| < \sqrt{n}$. We take $v_1 = (r_{m+1}, -t_{m+1})$. By (7) we have $f(v_1) = 0$. Also, since $|t_{m+1}| < \sqrt{n}$ and $|r_{m+1}| < \sqrt{n}$, we have $\|v_1\| \leq \sqrt{2n}$. We also take v_2 to be the shorter of $(r_m, -t_m)$ and $(r_{m+2}, -t_{m+2})$. Again by (7), we have $f(v_2) = 0$. Heuristically one expects that v_2 is also short.³ Observe that v_1 and v_2 are linearly independent since otherwise if $v_2 = (r_m, -t_m)$ (say), then

³ Experiments with various values of λ also validate this assumption. It is impossible to prove this without further restrictions; for example consider $\lambda = n - 1$.

$$\frac{r_{m+1}}{r_m} = \frac{-t_{m+1}}{-t_m} = \frac{t_{m+1}}{t_m};$$

but $r_{m+1}/r_m < 1$ by Lemma 1(i) and $|t_{m+1}/t_m| > 1$ by Lemma 1(iii).

Notice that since v_1 and v_2 only depend on n and λ (and not on k), they can be precomputed if n and λ are shared domain parameters.

Finding v . A vector v in the integer lattice generated by v_1 and v_2 that is close to $(k, 0)$ can be easily found using elementary linear algebra[1]. By considering $(k, 0)$, v_1 and v_2 as vectors in $\mathbb{Q} \times \mathbb{Q}$, we can write $(k, 0) = \beta_1 v_1 + \beta_2 v_2$, where $\beta_1, \beta_2 \in \mathbb{Q}$. Then round β_1, β_2 to the nearest integers: $b_1 = \lfloor \beta_1 \rfloor, b_2 = \lfloor \beta_2 \rfloor$. Finally, let $v = b_1 v_1 + b_2 v_2$.

The following proves that the vector u is indeed short.

Lemma 2. *The vector $u = (k, 0) - v$, where v is constructed as above, has norm at most $\max(\|v_1\|, \|v_2\|)$.*

Proof. We have

$$\begin{aligned} u &= (k, 0) - v \\ &= (\beta_1 v_1 + \beta_2 v_2) - (b_1 v_1 + b_2 v_2) \\ &= (\beta_1 - b_1) v_1 + (\beta_2 - b_2) v_2. \end{aligned}$$

Finally, since $|\beta_1 - b_1| \leq \frac{1}{2}$ and $|\beta_2 - b_2| \leq \frac{1}{2}$, by the Triangle Inequality we have

$$\begin{aligned} \|u\| &\leq \frac{1}{2}\|v_1\| + \frac{1}{2}\|v_2\| \\ &\leq \max(\|v_1\|, \|v_2\|). \end{aligned}$$

□

5 Security Considerations

Elliptic curves having efficiently-computable endomorphisms should be regarded as “special” elliptic curves. Using “special” instances of cryptographic schemes is sometimes done for efficiency reasons (for example the use of low encryption-exponent RSA, or the use of small subgroups hidden in a larger group as with DSA). However in any instance of a cryptographic scheme, there is always the chance that an attack will be forthcoming that applies to the special instance and significantly weakens the security. Such is the case here as well.

When selecting an elliptic curve E over \mathbb{F}_q for cryptographic use, one must ensure that the order $\#E(\mathbb{F}_q)$ of the elliptic curve is divisible by a large prime number n (say $n \geq 2^{160}$) in order to prevent the Pohlig-Hellman [22] and Pollard’s rho [23,21] attacks. In addition, one must ensure that $\#E(\mathbb{F}_q) \neq q$ in order to prevent the Semaev-Satoh-Araki-Smart attack [26,25,28], and that n does not divide $q^i - 1$ for all $1 \leq i \leq 20$ in order to prevent the Weil pairing [16] and Tate pairing attacks [8]. Given a curve satisfying these conditions, there is no attack known that significantly reduces the time required to compute elliptic

curve discrete logarithms. Many such curves having efficient endomorphisms exist and hence appear suitable for cryptographic use. One attack on the elliptic curve discrete logarithm problem on such curves is along the lines of [9] and [34]. The application of such ideas does not reduce the time to compute a logarithm by more than a small factor.

The number of curves for which this technique applies seems to be reasonably large. For instance, one of the Examples 3, 4, 5 and 6 provide a candidate for most primes p .

6 Conclusions and Further Work

We described a new method for accelerating point multiplication on classes of elliptic curves that have efficiently-computable endomorphisms. The new method for point multiplication is roughly 50% faster than the best general methods. One advantage of the new method is that it is applicable to a larger class of curves than previous such methods. For example, the method is applicable to classes of curves over prime fields and, in particular, is well suited to two curves over prime fields included in the WAP WTLS specification.

One direction in which our method can be generalized is to use higher powers of the endomorphism. For example, one could write $k \equiv k_1 + k_2\lambda + k_3\lambda^2 \pmod n$ for $t/3$ -bit integers k_1, k_2, k_3 . This could be done by first finding three linearly independent vectors v_1, v_2, v_3 in $\mathbb{Z} \times \mathbb{Z} \times \mathbb{Z}$ each of length roughly $n^{1/3}$, and lying in the kernel of the homomorphism $f : \mathbb{Z} \times \mathbb{Z} \times \mathbb{Z}$ defined by $(x, y, z) \mapsto x + y\lambda + z\lambda^2 \pmod n$. Experimentally, we found that if λ satisfies $\lambda^2 - T\lambda + N \equiv 0 \pmod n$ for a random prime n , random T (Trace) and random N (Norm), then the application of LLL to the lattice generated by $\{(\lambda^2, 0, -1), (\lambda, -1, 0), (0, \lambda, -1), (n, 0, 0), (0, n, 0), (0, 0, n)\}$ results in 3 independent vectors of length about $n^{1/3}$, *provided* at least one of N, T has magnitude at least $n^{1/3}$. In this case the application of ‘simultaneous multiple exponentiation’ type techniques yield an even better improvement over traditional algorithms, with the relevant ratio around 1/2.

We warn that generating k by simply choosing k_1, k_2, k_3 first requires care: for example, if $\lambda^2 + \lambda + 1 \equiv 0 \pmod n$ (as in Example 4) then $k_1 + k_2\lambda + k_3\lambda^2 \equiv (k_1 - k_3) + (k_2 - k_3)\lambda \pmod n$. Thus simply choosing k_1, k_2, k_3 randomly in $[0, n^{1/3}]$ and setting $k \equiv k_1 + k_2\lambda + k_3\lambda^2 \pmod n$ will result in a k having a considerable bias, and consequently the resulting cryptographic scheme may be susceptible to an attack like Bleichenbacher’s attack [3] on the DSA as specified in FIPS 186.

Acknowledgements. The authors would like to thank Charles Lam, Alfred Menezes, and John Proos for several very helpful comments and suggestions.
