On the other hand, however, there should be no time delay in starting an investigation if there is an opportunity to prevent more cases or the potential to identify a system failure which can be caused, for example, by poor food preparation in a restaurant or poor infection control practices in a hospital or to prevent future outbreaks by acquiring more knowledge of the epidemiology of the agent involved. Additional reasons to investigate include the interest of the media, politicians, and the public in the disease cluster and the pressure to provide media updates on a regular basis. Another fact to consider is that outbreak investigations are good training opportunities for newly hired epidemiologists.

Sometimes lack of data and lack of sufficient background information make it difficult to decide early on if there is an outbreak or not. The best approach then is to assume that it is an outbreak until proven otherwise.

51.6.1.4 Prevention Comes First

Prevention of more cases is the most important goal in outbreak investigations, and therefore a rapid evaluation of the situation is necessary. If there are precautionary measures to be recommended to minimize the impact of the outbreak and the spread to more persons, they should be implemented before a thorough investigation is completed. Most likely control measures implemented by public health professionals in foodborne outbreaks are:

- Recall or destruction of contaminated food items
- Restriction of infected food handlers from food preparation
- Correction of any deficiency in food preparation or conservation

51.6.1.5 Natural History

After taking immediate control measures, the next step is to know more about the epidemiology of the suspected agent. The most popular books for public health professionals include the "Red Book" (American Academy of Pediatrics 2006), the "Control of Communicable Diseases Manual" from the American Public Health Association (APHA 2008), or other infectious disease epidemiology books as well as the CDC website (www.cdc.gov). If the disease of interest is a reportable disease or a disease where surveillance data are available, baseline incidence rates can be calculated. Then a comparison is made to determine if the reported numbers constitute a real increase or not. Furthermore, the seasonal and geographical distribution of the disease is important as well as the knowledge of risk factors. Many infectious diseases show a seasonal pattern such as rotavirus or *Neisseria meningitides*. For example, in suspected outbreaks where cases are associated with raw oyster consumption, the investigator should know that in the US Gulf states, *Vibrio* cases increase in the summer months because the water conditions are optimal for the growth of the bacteria in water and in seafood. This kind of information will help to determine if the case numbers show a true increase and if it seems likely to be a real outbreak.

51.6.1.6 Number of Cases

For certain diseases, numbers are not important. Depending on the severity of the disease, its transmissibility, and its natural occurrence, certain diseases should raise a red flag for every health professional, and even a single case should warrant a thorough public health investigation. For example, a single confirmed case of a rabid dog in a city (potential dog-to-dog transmission within a highly populated area), a case of dengue hemorrhagic fever, or a presumptive case of smallpox would immediately trigger an outbreak investigation.

51.6.1.7 Artifact

Sometimes an increase of case numbers is artificial and not due to a real outbreak. In order to differentiate between an artificial and a natural increase in numbers, the following changes have to be taken into consideration:

- Alterations in the surveillance system
- A new physician who is interested in the disease and therefore more likely to diagnose or report the disease
- A new health officer strengthening the importance of reporting
- New procedures in reporting (from paper to web-based reporting)
- Enhanced awareness or publicity of a certain disease that might lead to increased laboratory testing
- New diagnostic tests

- A new laboratory
- An increase in susceptible population such as a new summer camp

51.6.1.8 Misclassification

It is important to be sure that reported cases of a disease actually have the correct diagnosis and are not misdiagnosed. Is there assurance that all the cases have the same diagnosis? Is the diagnosis verified and were other differential diagnoses excluded? In order to be correct, epidemiologists have to know the basis for the diagnosis. Are laboratory samples sufficient? If not, what kind of specimens should be collected to ascertain the diagnosis? What are the clinical signs and symptoms of the patient?

In an outbreak of restaurant-associated botulism in Canada, only the 26th case was correctly diagnosed. The slow progression of symptoms and misdiagnosis of the dispersed cases made it very difficult to link these cases and identify the source of the outbreak (CDC 1985, 1987).

51.6.1.9 Case Definition

The purpose of a case definition is to standardize the identification and counting of the number of cases. The case definition is a standard set of criteria and is not a clinical diagnosis. In most outbreaks, the case definition has components of person, place, and time, such as the following: persons with symptoms of X and Y after eating at the restaurant Z between Date1 and Date2. The case definition should be broad enough to get most of the true cases but not too narrow so that true cases will not be misclassified as controls. A good method is to analyze the data, identify the frequency of symptoms, and include symptoms that are more reliable than others. For example, diarrhea and vomiting are more specific than nausea and headache in the case definition of a food-related illness.

51.6.1.10 Database

What kind of information is necessary to be collected? It is sufficient to have a simple database with basic demographic information such as name, age, sex, and information for contacting the patient. More often, date of reporting and date of onset of symptoms are also important. Depending on the outbreak and the potential exposure or transmission of the agent involved, further variables such as school, grade of student, or occupation in adults might be interesting and valuable.

51.6.1.11 Case Finding

During an outbreak investigation, it is important to identify additional cases that may not have been known or were not reported. There are several approaches:

- Interview known cases and ask them if they know of any other friends or family members with the same signs or symptoms.
- Obtain a mailing list of frequent customers in an event where a restaurant is involved.
- Set up an active surveillance with physicians or emergency departments.
- Call laboratories and ask for reports of suspected and confirmed cases.

Another possibility is to review surveillance databases or to establish enhanced surveillance for prospective cases. Occasionally, it might be worthwhile to include the media for finding additional cases through press releases. However, the utility of that technique depends on the outbreak and the etiological agent; the investigator should always do a benefit risk analysis before involving the media.

51.6.1.12 Descriptive Epidemiology

After finding additional cases, entering them in the database, and organizing them, the investigator should try to get a better understanding of the situation by performing some basic descriptive epidemiology techniques such as sorting the data by time, place, and person. For a better visualization of the data, an epidemic or "epi" curve should be graphed. The curve shows the number of cases by date or time of onset of symptoms. This helps to understand the nature and dynamic of the outbreak as well as to get a better understanding of the incubation period if the time of exposure is known. It also helps to determine whether the outbreak had a single exposure and no secondary transmission (single peak) or if there is a continuous source and ongoing transmission. Figures 51.10 and 51.11 show "epi" curves of two different outbreaks: a foodborne outbreak in a school in Louisiana (Fig. 51.10) and the number of WNV human cases, stratified by clinical diagnosis of fever only and meningoencephalitis, in Louisiana in the 2002 outbreak (Fig. 51.11), respectively.

Sometimes it is useful to plot the cases on a map to get a better idea of the nature and the source of an outbreak. Mapping may be useful to track the spread by water (see John Snow's cholera map) or by air or even a person-to-person transmission. If a contaminated food item was the culprit, food distribution routes with new cases identified may be helpful. Maps, however, should be taken with caution and carefully interpreted. For example, WNV cases are normally mapped by residency but do not take into account that people might have been exposed or bitten

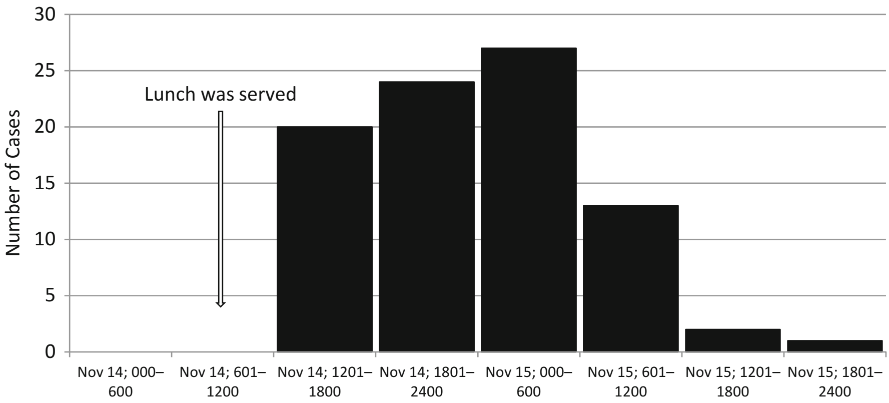

Fig. 51.10 Gastroenteritis outbreak in a school in Louisiana, 2001

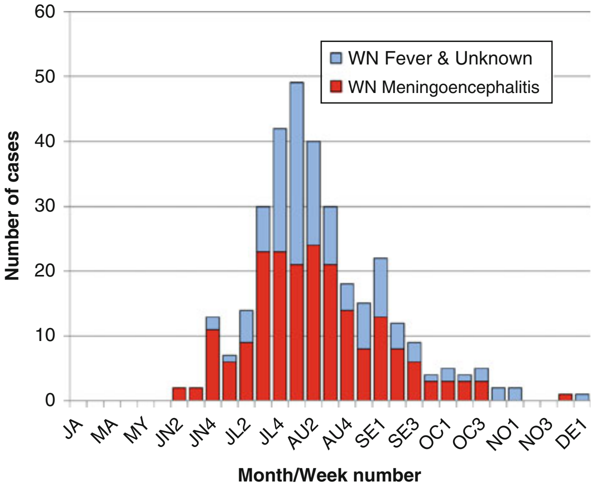

Fig. 51.11 Human West Nile virus cases, Louisiana 2002

by an infective mosquito far away from where they live. For outbreak investigations, spot maps are usually more useful than rate maps or maps of aggregate data.

Depending on the outbreak, it might be useful to characterize the outbreak by persons' demographics such as age, sex, address, occupation, and health status. Are the cases at increased susceptibility or at high risk of infection? These kinds of variables might give the investigator a good idea if the exposure is not yet known. For typical foodborne outbreaks, however, demographic information is not very useful because the attack rates will be independent of age and sex. More details on methods used in descriptive epidemiology are given in chapter ▶Descriptive Studies of this handbook.

51.6.1.13 Hypothesis Forming

Based on the results of basic descriptive epidemiology and the preliminary investigation, some hypotheses should be formulated in order to identify the cause of the outbreak. A hypothesis will be most likely formulated such as "those who attended the luncheon and ate the chicken salad are at greater risk than those who attended and did not eat the chicken salad." It is always easier to find something after knowing what to look for, and therefore a hypothesis should be used as a tool. However, the epidemiologist should be flexible enough to change the hypothesis if the data do not support it. If data clues are leading in another direction, the hypothesis should be reformulated such as "those who attended the luncheon and ate the baked chicken are at greater risk than those who attended and did not eat the baked chicken."

To verify or deny hypotheses, measures of risk association such as the relative risk (*RR*) or the odds ratio (*OR*) have to be calculated (as described in chapters ▶Rates, Risks, Measures of Association and Impact, ▶Cohort Studies, and

►Case-Control Studies of this handbook). The CDC has developed the software program “Epi Info” which is easy to use in outbreak investigations and, even more importantly, free of charge. It can be downloaded from the CDC website (http://www.cdc.gov/epiinfo/). Measures of association, however, should be carefully interpreted; even a highly significant measure of association cannot give enough evidence of the real culprit or the contaminated food item. The measure of association is only as good and valid as the data. Most people have recall problems when asked what they ate, when they ate, and when their symptoms started. Even more biases or misclassifications of cases and controls can hide an association. A more confident answer comes usually from the laboratory samples from both human samples and food items served at time of exposure. Agents isolated from both food and human samples that are identified as the same subtype, in addition to data results supporting the laboratory findings, are the best evidence beyond reasonable doubt.

51.6.1.14 Final Report

As the last step in an outbreak investigation, the epidemiologist writes a final report on the outbreak and communicates the results and recommendations to the public health agency and facilities involved (see Table 51.12). In the USA, public health departments also report foodborne outbreaks electronically to CDC via a secure web-based reporting system, the National Outbreak Reporting System (NORS).

51.6.2 Types of Outbreaks

51.6.2.1 The “Traditional” Foodborne Outbreak

The “traditional” foodborne outbreak is usually a small local event such as family picnic, wedding reception, or other social event and occurs often in a local restaurant or school cafeteria. This type of outbreak is highly local with a high attack rate in the group exposed to the source. Because it is immediately apparent to those in the local group such as the group of friends who ate at the restaurant or the students’ parents, public health authorities are normally notified early in the outbreak, while most of the cases are still symptomatic. Epidemiologists can start early on with their investigation and therefore have a much better chance to collect food eaten and stool samples of cases with gastroenteritis for testing and also to detect the etiological agent in both of them.

In a 2001 school outbreak in Louisiana, 87 persons (67 students and 20 faculty members) (see Fig. 51.10) experienced abdominal cramps after eating at the school’s annual “Turkey Day” the day before. Stool specimens and the turkey with the gravy were both positive for *Clostridium perfringens* with the same pulse field gel electrophoresis (PFGE) pattern (Merlos 2002). The inspection of the school cafeteria revealed several food handling violations such as storing, cooling, and reheating of the food items served. Other than illnesses among food handlers, these types of improper food handling or storage are the most common causes of foodborne outbreaks.

51.6.2.2 New Types of Outbreaks

A different type of outbreak is emerging as the world is getting smaller. In other words, persons and food can travel more easily and faster from continent to continent and so do infectious diseases with them. Foodborne outbreaks related to imported contaminated food items are normally widespread, involving many states and countries, and therefore are frequently identified. In 1996, a large outbreak of *Cyclospora cayetanensis* occurred in 10 US states and Ontario, Canada, and was linked to contaminated raspberries imported from South America. Several hundred laboratory-confirmed cases were reported, most of them immunocompetent persons (CDC 1996).

A very useful molecular tool to identify same isolates from different geographical areas is subtyping enteric bacteria with PFGE. In the USA, the PulseNet database allows state health departments to compare their isolates with other states and therefore increase the recognition of nationwide outbreaks linked to the same food item (Swaminathan et al. 2001).

In a different scenario, a widely distributed food item with low-level contamination might result in an increase of cases within a large geographical area and therefore might be not get detected on a local level. This kind of outbreak might only be detected by chance if the number of cases increased in one location and the local health department alerts other states to be on the lookout for a certain isolate.

Another type of outbreak is the introduction of a new pathogen into a new geographical area as it happened in 1991 when *Vibrio cholerae* was inadvertently introduced in the waters off the Gulf Coast of the United States.

Food can not only be contaminated by the end of the food handling process, that is, by infected food handlers, but also can be contaminated by any event earlier in the chain of food production. In 1996, an outbreak of *Salmonella enteritidis* in a national brand of ice cream resulted in 250,000 illnesses. The outbreak was detected by routine surveillance because of a dramatic increase of *Salmonella enteritidis* in South Minnesota. The cause of the outbreak was a basic failure on an industrial scale to separate raw products from cooked products. The ice-cream premix was pasteurized and then transported to the ice-cream factory in tanker trucks which had been used to haul raw eggs. This resulted in the contamination of the ice cream and subsequent salmonella cases (Hennessy et al. 1996).

51.7 Surveys

Surveys are useful to provide information for which there is no data source or no reliable data source. Surveys are time consuming and are often seen as a last choice to obtain information. However, too often unreliable information is used because it is easily available. For example, any assessment of the *Legionella* problem using passive case detection will be unreliable due to underdiagnosis and underreporting. Most cases of legionellosis are treated empirically as community-acquired pneumonias and are never formally diagnosed.

In developing countries, surveys are often necessary to evaluate health problems since data collected routinely (disease surveillance, hospital records, case registers) are often incomplete and of poor quality. In industrialized nations, although many sources of data are available, there are some circumstances where surveys may be necessary.

Prior to carrying out surveys involving human subjects, special procedures need to be followed. In industrialized countries, a human subject investigation review board has to evaluate the project's value and ethics. In developing countries, however, such boards may not be formalized, but it is important to obtain permission from medical, national, and local political authorities before proceeding.

51.7.1 Survey Methods

Surveys of human subjects are carried out by mail, telephone, personal interviews, and behavioral observations. In infectious diseases, the collection of biological specimens in humans (i.e., blood for serological surveys) or the collection of environmental samples (food, water, environmental surfaces) is very common. Personal interviews and specimen collection require face-to-face interaction with the individual surveyed. These are carried out in offices or by house-to-house surveys.

Non-respondents are an important problem for infectious disease surveys. Those with an infection may be absent from school, may not answer the door, or may be unwilling to donate blood for a serological survey, thus introducing a systematic bias into the survey results.

Since surveys are expensive, they cannot be easily repeated. All field procedures, questionnaires, biological sample collection methods, and laboratory tests should be tested prior to launching the survey itself. Feasibility, acceptability, and reliability can be tested in a small-scale pilot study. More details on survey methods are to be found in chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook.

51.7.2 Sampling

Since surveys are labor intensive, they are rarely carried out on an entire population but rather on a sample. To do a correct sampling, it is necessary to have a sampling base (data elements for the entire population) from which to draw the sample. Examples of sampling bases are population census, telephone directory (for the phone subscriber population), school roster, or a school list. In developing countries, such lists are not often available and may have to be prepared before sampling can start. More information on sampling designs can be found in chapter ▶Epidemiology in Developing Countries of this handbook.

51.7.3 Community Surveys (House-to-House Surveys)

Most community surveys are carried out in developing countries because reliable data sources are rare. The sampling base often ends up to the physical layout of the population. A trip and geographical reconnaissance of the area are necessary. The most common types of surveys undertaken in developing countries are done at the village level; they are based on maps and a census of the village.

In small communities, it is important to obtain the participation of the population. Villagers are often wary of government officials counting people and going from door to door. To avoid misinterpretations and rumors, influential people in the community should be told about the survey. Their agreement is indispensable, and their help is needed to explain the objectives of the survey and particularly its potential benefits. Increasing the knowledge about disease, disease prevention and advancing science are abstract notions that are usually poorly understood or valued by villagers who are, in general, very practical people. If a more immediate benefit can be built into the survey, there will be an increase in cooperation of the population. Incentives such as offering to diagnose and treat an infection or drugs for the treatment of common ailments such as headaches or malaria enhance the acceptance of the survey.

In practically all societies, the household is a primary economic and social unit. It can be defined as the smallest social unit of people who have the same residency and maintain a collective organization. The usual method for collecting data is to visit each household and collect samples or administer a questionnaire.

Medical staff may feel left out or even threatened whenever a medical intervention (such as a survey) is done in their area. A common concern is that people will go to their medical care provider and ask questions about the survey or about specimen collection and results. It is therefore important to involve and inform local medical providers as much as practical.

A rare example of a house-to-house survey in an industrialized nation was carried out in Slidell, Louisiana, for the primary purpose of determining the prevalence of West Nile infection in a southern US focus. Since the goal was to obtain a random sample of serum from humans living in the focus, the only method was a survey of this type. A cluster-sampling design was used to obtain a representative number of households. The area was not stratified because of its homogeneity. Census blocks were grouped so that each cluster contained a minimum of 50 households. The probability of including an individual cluster was determined by the proportion of houses selected in that cluster and the number of persons participating given the number of adults in the household. A quota sampling technique was used, with a goal of enlisting ten participating households in each cluster.

Inclusion criteria included age (at least 12 years of age) and length of residence (at least 2 years). The household would be included only if an adult household resident was present. A standardized questionnaire was used to interview each participant. Information was collected on demographics, any recent febrile illness, knowledge, attitudes, and behaviors to prevent WNV infection and potential exposures to mosquitoes. A serum sample for WNV antibody testing was drawn.

In addition, a second questionnaire regarding selected household characteristics and peridomestic mosquito reduction measures was completed. Informed consent was obtained from each participant, and all participants were advised that they could receive notification of their blood test results if they wished. Institutional review board approvals were obtained.

Logistics for specimen collection, preservation, and transportation to the laboratory were arranged. Interpretation of serological tests and necessary follow-up were determined prior to the survey and incorporated in the methods submitted to the ethics committee.

Sampling weights, consisting of components for block selection, household-within-block selection, and individual-within-household participation, were used to estimate population parameters and 95% confidence intervals (CI). Statistical tests were performed incorporating these weights and the stratified cluster sampling design.

In this survey, 578 households were surveyed (a 54% response rate), including 1,226 participants. There were 23 Immunoglobulin M (IgM) seropositive persons, for a weighted seroprevalence of 1.8% (with a 95% confidence interval of 0.9–2.7%) (Michaels et al. 2005).

51.8 Microbiological and Serological Issues

51.8.1 Case Confirmation

Definitive confirmation of a case relies on the identification of the infectious agent in the patient in some specific body sites. The site is important for agents that may be pathogens or colonizers. For example, identification of *Neisseria meningitidis* in an upper respiratory fluid could be due to colonization, while isolation from cerebrospinal fluid or blood would mean definite invasive disease.

Identification of infectious agents is more frequently done by genotyping of the agent nowadays. The reliability of these identifications depends on the methods being used. Many of the tests are developed "in house." The tests that identify a single gene are less reliable than those that identify several specific genes.

51.8.2 Serological Issue and Seroepidemiology

Serological tests have long been used to diagnose the cause of an infectious disease. In most instances, these methods are reliable, but this is not always so. The old serological methods (agglutination, hemagglutination, complement fixation, etc.) often resulted in a false-positive/false-negative result. Dilutions were used to quantify the reactions. In general, positive reactions at low titers were meaningless, while positivity at high dilutions was indicative of a recent infection. A fourfold increase of positivity (e.g., from a 1:16 to 1:64 dilution) over a 2-week period was usually considered confirmatory based on the dilution factor that meets the criteria for positivity in the laboratory test. A good example for this is *Brucella* sp. (a zoonotic disease where humans are accidental hosts) where a fourfold or greater rise in the *Brucella* agglutination titer between acute (specimen taken while patient is symptomatic) and convalescent (specimen taken while patient is recovering from the disease) serum specimens obtained 2 or more weeks apart is considered positive. Serological diagnosis is often discouraged because of difficulties of collecting follow-up serum samples if the patient has recovered and is not in medical care anymore.

Newer techniques such as enzyme immunoassays (EIA) do quantify the amount of antibodies present, but do not allow for the "fourfold increase."

The serological response to an infection consists of several types of antibodies: IgM at first, Immunoglobulin G (IgG) antibodies later, and also Immunoglobulin A (IgA) antibodies. The usual assumption is that IgM antibodies are produced early (before IgG antibodies) and for a limited length of time (usually 2–3 months). However, the postulate "IgM means recent infection" is not always true. Onset and length of production of IgM antibodies depend on the infectious agent. For West Nile infections, IgM production starts a few days after infection but may last for several years; in fact, 1 year after infection, 40% of the patients are still reported IgM positive by most criteria established by laboratory definitions.

51.8.3 Sensitivity, Specificity, and Predictive Value of a Positive Test

Issues of sensitivity, specificity, and predictive value are particularly relevant to serological testing. The methods are similar to those described in chapter ▶Clinical Epidemiology and Evidence-Based Health Care of this handbook. The predictive value of a positive test (*PVPT*) depends on its sensitivity, specificity, and prevalence. Its formula is the following:

$$PVPT = \frac{PR^{*}SE}{(PR^{*}SE) + [(1 - PR)^{*}(1 - SP)]},$$

where *PR* denotes the prevalence, *SE* the sensitivity, and *SP* the specificity.

It is heavily influenced by the prevalence. Even if the tests have the highest sensitivity and specificity (99% for both in Table 51.13), the predictive value is poor

Table 51.13 Predictive value of a positive test

Sensitivity (%)	Specificity (%)	Prevalence (%)	*PVPT* (%)
99	99	5	83.9
99	99	1	50
99	99	0.1	9
95	95	5	50
95	95	1	16.1
95	95	0.1	1.9

when the prevalence is low. This has implications for case definitions in situations of very low prevalence or disappearing infectious diseases (example of measles and rubella in the USA).

51.9 Nosocomial Infection Epidemiology

Epidemiology plays a major part in prevention programs against nosocomial (hospital-acquired) infections. Surveillance should provide systematic and continuous observations on the occurrence and distribution of nosocomial infections within the hospital population. Surveillance is the focal point for infection control activities. The term surveillance implies that the observational data are regularly analyzed.

Surveillance activities may provide valuable epidemiological data such as the identification of outbreaks, priorities for infection control activities, and the elucidation of important secular trends, such as shifts in microbial pathogens, infection rates, or outcomes of hospital-acquired infection. Surveillance activities provide the additional benefits of increasing the visibility of the infection control team in the hospital during the infection control practitioners' ward rounds and of allowing an opportunity for informal consultation and education for both nurses and physicians.

Ideally, the surveillance of hospital-acquired infection should be a continuous process that consists of the following elements:

1. Definition of categories of infection
2. Systematic case finding and data collection
3. Tabulation of data
4. Analysis and interpretation of data
5. Reporting of relevant infection surveillance data to individuals and groups for appropriate action

51.9.1 Definitions

The use of consistent definitions of nosocomial infection is critical in developing data on endemic infection rates. Definitions must be simple, requiring only clinical information or readily available laboratory data.

51.9.1.1 General Definitions

A nosocomial infection is either:

1. An infection which is acquired during hospitalization and which was not present or incubating at the time of admission or
2. An infection which is acquired in the hospital and becomes evident after discharge from the hospital or
3. A newborn infection which is the result of passage through the birth canal.

An infection is defined as hospital acquired if the patient (1) has an infection, not a simple colonization, (2) was not infected at the time of admission, and (3) had sufficient time to develop infection.

True Infection and Not Colonization or Contamination Infections are accompanied by signs and symptoms of infection (fever, malaise) and in localized infections: swelling due to inflammation, heat, pain, and erythema (tumor, dolor, rubor, or calor). Immunocompromised patients do not show signs of infection as easily as normal patients. Neutropenic patients ($\leq$500 neutrophils/cubic millimeter) show no pyuria, no purulent sputum, little infiltrate, and no large consolidation on chest X-ray. An antibiotic treatment by a physician is a presumption of infection.

No Infection at Time of Admission Several criteria may be used to establish prior negativity: history, symptoms and signs documented at the time of admission, lab tests, and chest X-rays done in the early days in the hospital. Normal physical examination, absence of signs and symptoms, normal chest X-ray, negative culture, and lack of culture are useful.

Sufficient Time to Develop Infection For diseases which have a specific incubation period, the hospital-acquired infection can only develop if the patient has stayed in the hospital for a stay $\geq$ incubation period. Numerous infections do not have well set incubation periods (e.g., staphylococci and *E. coli* infections). However, these infections rarely develop in less than 2 days.

To establish a nosocomial infection meeting the definition criteria, it is sufficient that there is no need to have proof beyond the shadow of a doubt.

51.9.1.2 Specific Definitions

To carry out surveillance, very specific definitions are necessary, not only regarding the major nosocomial infections (surgical site infection, bloodstream infections, pneumonia, and urinary tract infections) but regarding all possible sites of nosocomial infections.

51.9.2 Scope/Strategy of Surveillance

Active surveillance is much more effective than *passive surveillance*. Using active surveillance increases the sensitivity of identifying infections.

51.9.2.1 Case Finding

Case finding can be *retrospective*, *prospective*, or both. Prospective or concurrent surveillance means monitoring the patient during hospitalization. Prospective surveillance may include the post-discharge period. In contrast, retrospective surveillance involves review of the medical record after the patient has been discharged. Prospective surveillance provides increased visibility for infection control personnel and timely analysis of data and feedback to clinical services, but this type of surveillance is more expensive. Retrospective methodology is cheaper to implement but requires more controls to verify how effective the infection control personnel are as follows:

- Patient-based case finding relies on evaluating medical records and doing rounds in hospital wards. It allows assessing risk factors, procedures, and practices related to patient care.
- Laboratory-based surveillance relies on identifying positive cultures for pathogens. Then, further investigations are necessary to verify if this is a health-care facility-associated infection, a community-associated infection, a colonization, or a contamination.

A major issue is determining the scope of surveillance. Choices can include three major strategies: hospital-wide surveillance, surveillance by objective, and limited or targeted surveillance.

51.9.2.2 Hospital-Wide Surveillance

Comprehensive or hospital-wide surveillance implies a continuous surveillance of all patients for all types of nosocomial infections in all hospital wards.

This strategy is time consuming. Efficiency is increased by using "clues" to identify patients whose charts should be reviewed. A hospital-wide surveillance provides a global view of the hospital, but the cost and the labor involved may be prohibitive. Critics of whole-house surveillance argue that collecting and analyzing data may be overwhelming; time may not permit developing objectives for surveillance, and many of the identified infections may not be preventable. A modification of this strategy includes doing hospital-wide surveillance for 1 year, or part of a year.

51.9.2.3 Surveillance by Objectives

Surveillance by objectives focuses on specific outcome objectives defined for surveillance purposes. Levels of surveillance effort are prioritized. Prioritization focuses on types of infections to be prevented, and levels of effort may be adjusted to the relative seriousness of the problem. Considerations in setting these priorities would include morbidity and mortality data, costs of treating infections, length of stay, frequency of occurrence of infection, and percentage of infections that are thought to be preventable. If baseline rates (before objectives are met) are not established, the identification of clusters and epidemics would be difficult. Areas that were not included in the objectives could not be evaluated.

51.9.2.4 Targeted Surveillance

Targeted surveillance can be site specific, unit specific, rotating, or limited to outbreak surveillance.

Site-specific surveillance focuses on specific infection sites such as surgical wounds or urinary tract infections. In contrast to surveillance by objective, this strategy lacks a defined objective. It is flexible, because this strategy can be used concurrently with alternating components such as continuous and rotating surveillance as well as special projects.

Unit-directed surveillance targets specific units or areas with highest risk. Surveillance activities are limited to the areas of highest risks such as intensive care units, burn units, and hematology and oncology units. Targeting critical care and oncology units, for example, would capture the majority of all bloodstream infections. The rate of infection in these units is high, yet a relatively small number of patients are actually treated. This approach may prevent infections in patients at greatest risk.

Rotating surveillance is periodic and systematic surveillance in a given unit for a specific time period. This technique is less time consuming and more cost effective than other forms of surveillance because all areas of the hospital are covered at sequential periodic intervals using careful continuous surveillance. Ideally, rotating surveillance involves an annual, detailed, and directed infection-control evaluation for each hospital unit. One type of rotating surveillance, the prevalence survey, can identify infection control risks; however, it can also miss clusters in areas that are not currently under surveillance.

Outbreak surveillance requires an alert hospital staff who report any unusual cluster of events that, when based on surveillance data, extend beyond threshold units.

Whichever surveillance strategies are selected, they should allow personnel to recognize and workup clusters of infections or events.

51.9.3 Calculating Rates

51.9.3.1 Numerator

The numerators may be the number of infections or the number of patients infected. Decisions must be made on how to count infections caused by multiple organisms at the same site (usually counted as one infection), infections in a patient with a second nosocomial infection, a patient with an extension of another infection, and so forth.

51.9.3.2 Denominators

If incidence rates are warranted, a common denominator is number of patients admitted or discharged. If incidence density rates are calculated, number of hospital days or numbers of device days are usually used. The choice of denominator depends on the purpose of calculating these rates.

Hospital-Wide Nosocomial Infection Rate per 100 Admissions A hospital-wide nosocomial infection rate/100 admissions for a given period (month, quarter, or year) is commonly calculated but has little significance because it does not take into account (1) the risk posed to the patient by procedures (intravenous (IV) lines, urinary catheters, or ventilators) and (2) the severity of the patients' conditions. A small hospital with little use of invasive procedures and relatively healthier patients will have lower rates of infection.

In this rate, a patient who has two infections is actually counted twice. This rate can be calculated as

$$\frac{\text{number of nosocomial infections}^{*}100}{\text{number of patients admitted}}.$$

Hospital-Wide Patient Infection Rate per 100 Admissions Hospital-wide patient infection rate/100 admissions are used to avoid the pitfall of multiple infections in the same patient. This rate may be calculated for a given period: month, quarter, and year. In this rate, a patient with two infections is counted only once:

$$\frac{\text{number of patients infected}^{*}100}{\text{number of patients admitted}}.$$

Patient Infection Rate per 1,000 Hospital Days The risks of infections are much higher in some units of the hospital such as intensive care units (ICUs) and coronary care units. Calculating ward-specific rates is useful to look at the trends in specific units or compare between units. The number of patients admitted to an ICU may be difficult to determine because some patients are admitted in the ward 1 day, spend a few days, be discharged to a regular ward, and after a few days be readmitted into ICU. To avoid the problem posed by the same patient admitted and discharged several times from the ICU to the wards, the rate of infection is expressed in number of patients infected/1,000 hospital days. This rate also takes into account the duration of hospitalization which is a risk factor for nosocomial infection. It allows comparison between wards where duration is different and can be calculated as

$$\frac{\text{number of infections}^{*}100}{\text{number of hospital days}}.$$

Device-Specific Rates and Procedure-Specific Rates The risk of infection is related to the extrinsic risk factors (use of devices such as ventilator, central line intravascular catheter, urinary catheter, surgical operation). To compare the risk associated with these devices or procedures, the following rates are best suited:

$$\text{surgical site infection rate} = \frac{\text{number of surgical site infections}^{*}100}{\text{number of patients operated on}},$$

$$\begin{aligned}&\text{ventilator associated pneumonia rate}\\&= \frac{\text{number of ventilator associated pneumonia}^{*}1{,}000}{\text{number of patients on ventilator days}},\end{aligned}$$

$$\text{catheter related bloodstream infection (BSI) rate} \\ = \frac{\text{number of catheter related BSI}^* 100}{\text{number of patients on IV line days}},$$

where it may be difficult to obtain the number of intravascular line days. Ideally, the number should be line specific, for example, central line (which is a catheter (tube) that is passed through a vein to end up in the thoracic (chest) portion of the vena cava or in the right atrium of the heart) days and peripheral line (which is a catheter (tube) placed into a peripheral vein) days

$$\text{utilization rate} = \frac{\text{number of device days }^* 100}{\text{number of patients days}},$$

where the device utilization rate (DUR) is the proportion of patient days for which a certain device is used. The DUR is specific to a certain device: catheter, IV line, and ventilator. The DUR reflects the amount of devices used and is a reflection of the patient severity.

51.10 Epidemiological Aspects of Infectious Disease Prevention

51.10.1 Antibiotic Resistance

There are an almost daily increasing number of publications on antibiotic resistance creating the impression that the resistance is growing worldwide. However, there is no comprehensive surveillance system for antibiotic sensitivity and no comprehensive database documenting the spread of resistance in the USA or worldwide. One of the best data sources for the USA comes from the *National Nosocomial Infection Surveillance* (NNIS), now the *National Healthcare Safety Network* surveillance which documents sensitivity of nosocomial infections, an estimated 4% of bacterial infections occurring in the USA.

On a very global aspect, antibiotics are still very effective. For many hospitals, antibiotic sensitivity patterns are not very different nowadays than what they were 10 years ago, except for very few pathogens. Reports obtained from the medical literature are not representative of the whole hospitals, and even of the whole “world” of bacteria. Many of the resistance reports from the literature come from single institutions where antibiotic resistance was the consequence of overuse of an antibiotic. Very few reports attempt to compare several institutions. There is no randomized, non-selective, multicentered data to evaluate the scope of resistance and its evolution. Most of the US data is reported from large metropolitan hospitals affiliated with medical schools in the northern USA. These hospitals treat the more severely ill patients who often have been treated unsuccessfully at community hospitals and have probably become resistant during previous attempts at treatment.

The impression is that the most severe cases of resistance are generated in the tertiary care hospitals (these are specialty hospitals dedicated to specific subspecialty care including ICUs). It may well be that resistance is generated in primary (health care was provided by a general practitioner or other health professional) and secondary care facilities (health care provided by hospital clinicians) and those cases who did not respond to antibiotics were referred to tertiary care hospitals.

51.10.1.1 Active Surveillance

The goal of an antibiotic sensitivity active surveillance system is to estimate the proportion of selected bacteria that are resistant to antibiotics by the reporting of laboratory aggregate data. This surveillance system can only monitor a few pathogens. In the USA, the most common pathogens monitored in such programs are methicillin-resistant *Staphylococcus aureus* (MRSA), drug-resistant *Streptococcus pneumoniae* (DRSP), and vancomycin-resistant *Enterococcus* (VRE). Laboratories are asked to report:

1. The total number of drug-resistant or drug intermediate-resistant isolates excluding duplicates (one isolate per patient per month if possible) (numerator)
2. The total number of isolates of the bacterial species of concern (denominator) from a given laboratory for each month

51.10.1.2 Antibiograms

Another approach to establish an antibiotic sensitivity surveillance system is to use the hospital antibiograms. In 2001, the *National Committee on Clinical Laboratory Standards* (NCCLS) now known as the *Clinical and Laboratory Standards Institute* (CLSI) issued guidelines on how to analyze and present cumulative antimicrobial sensitivity test data from antibiotic sensitivity testing performed on health-care facility patients. The data show the percent sensitivity for the first isolate from a patient within an analysis period (generally 1 year), the specimen source, and the total number of isolates tested (minimum ten for each organism to avoid describing sensitivity on a sample of less than ten patients).

The compilation of individual hospital antibiograms over time is useful in monitoring antibiotic sensitivity. The CDC conducted a study to compare data from the resource-intensive active surveillance collection of antibiotic resistance patterns to the data collected using hospital antibiograms. The study found the proportions of drug-resistant isolates from antibiograms were within ten percentage points of those from isolates obtained through active surveillance, thereby providing a relatively simple and accurate way to monitor antibiotic resistance (Van Beneden et al. 2003).

Limitations of hospital antibiograms are that they do not sort out community-acquired infections from nosocomial infections and some laboratories may not thoroughly unduplicate their data, thus giving a picture of a larger number of resistant isolates than it is the case.

51.10.2 Immunization

Epidemiology plays a major role at several stages in immunization programs.

51.10.2.1 At the Development Stage

Once a vaccine has been developed, it has to go through a rigorous process to be recognized as safe and efficacious. Once information on the vaccine composition, manufacturing, stability and sterility, and animal testing results have been submitted for review, the vaccine has to go through preclinical and clinical trials. In the preclinical studies, assays are carried out in animals to determine the humoral and cellular responses, the optimal administration route, the dose-response relationship, and the dosing schedule and the adverse or toxic effects. This is followed by the clinical studies. Phase I studies are intended to determine the efficacious dose and safety of the vaccine in a small number of healthy adults. Phase II studies are more extensive "open-label" prospective cohort studies or small randomized controlled trials on all relevant age groups. Their goal is to establish safety and immunogenicity. Phase III studies are randomized double-blind placebo-controlled vaccine efficacy trials. A comparison is made for the incidence rate of a disease in the standard versus a placebo group. The goal is to confirm the efficacy and obtain a comprehensive list of side effects.

51.10.2.2 At the Implementation Stage

Once in public use, the populations receiving the vaccine are much less controlled than during the trials. The designs of epidemiological studies must be adapted to these new conditions. Descriptive studies, surveys, case-control, and cohort studies are then performed with a goal to evaluate efficacy, side effects, and success of a vaccination campaign. The study of outbreaks among unvaccinated populations becomes a very useful tool to evaluate efficacy.

51.10.2.3 When Vaccine Led to Disappearing Illness: Eradication

Once a vaccine has been widely distributed among the population and the herd immunity is very high, the incidence of disease will decrease until elimination. Epidemiological studies are useful to determine if the widespread use of vaccine has led to suppression of disease with continuation of circulation of the agent or to the total disappearance of the infectious agent. With poliomyelitis, the killed vaccine led to elimination of the disease, but the virus was still circulating. The live oral vaccine on the other hand led to a complete elimination of the circulating virus. Epidemiological methods are instrumental in gathering this evidence.

During the final stages of a disappearing illness, active surveillance and detailed case investigation are necessary to detect every suspect and confirm the diagnosis with a definitive laboratory test (under these circumstances, identification of the infectious agent is preferred to a serological/immunological test). For poliomyelitis eradication, surveillance for acute flaccid paralysis is implemented before declaring a country free of the disease.

51.11 Program Evaluation

Program evaluation is a systematic way to determine if prevention or intervention programs for the infectious disease of interest are effective and to see how they can be improved. It is beyond the scope of this chapter to explain program evaluation in detail; however, there is abundant information available, that is, the CDC's Framework for Program Evaluation in Public Health (CDC 1999) as well as many valuable text books on program evaluation.

Most importantly, evaluators have to understand the program such as the epidemiology of the disease of interest, the program's target population and their risk factors, program activities, and resources. They have to identify the main objectives of the control actions and determine the most important steps. Indicators define the program attributes and translate general concepts into measurable variables. Data are then collected and analyzed so that conclusions and recommendations for the program are evidence based.

Evaluating an infectious disease control program requires a clear understanding of the microorganism, its mode of transmission, the susceptible population, and the risk factors. The following example of evaluation of tuberculosis control shows the need to clearly understand the priorities.

Most of tuberculosis transmission comes from active pulmonary tuberculosis cases that have positive sputum smears (confirmed as *Mycobacterium tuberculosis* on culture). To a lesser extent, smear-negative, culture-positive pulmonary cases are also transmitting the infection. Therefore, priority must be given to find sputum-positive pulmonary cases. The incidence of smear-positive tuberculosis cases is the most important incidence indicator. Incidences of active pulmonary cases and of all active cases (pulmonary and extrapulmonary) are also calculated but are of lesser interest. The proportion of all cases of tuberculosis that are pulmonary versus extrapulmonary, smear-positive culture-positive pulmonary versus culture-positive only pulmonary, or culture-negative pulmonary is used to detect anomalies in case finding or case ascertainment. A low proportion of smear-positive cases may result from poor laboratory techniques or excessive diagnosis of tuberculosis with reliance on chest X-rays and low interest in obtaining sputa for smears or cultures.

Once identified, tuberculosis cases are placed under treatment. Treatment of infectious cases is an important preventive measure. Treatment efficacy is evaluated by sputum conversion (both on smear and culture) of the active pulmonary cases. After 2 months of an effective regimen, 85% of active pulmonary cases should have converted their sputum from positive to negative. Therefore, the rate of sputum conversion at 2 months becomes an important indicator of program effectiveness. This indicator must be calculated for those who are smear positive and with a lesser importance for the other active pulmonary cases.

To ensure adequate treatment and prevent the development of acquired resistance, tuberculosis cases are placed under directly observed therapy (DOT). This measure is quite labor intensive. Priority must therefore be given to those at highest risk of relapse. These are the smear-positive culture-proven active pulmonary cases. DOT on extrapulmonary cases is much less important from a public health standpoint because they are not infectious and the major objectives of any public health program are to prevent transmission.

The same considerations apply to contact investigation and preventive treatment in countries that can afford a tuberculosis contact program. A recently infected contact is at the highest risk of developing tuberculosis the first year after infection; hence, the best preventive return is to identify contacts of infectious cases. Those contacts are likely to have been recently infected. Systematic screening of large population groups would also identify infected individuals, but most would be "old" infections at lower risk of developing disease. Individuals infected with tuberculosis and HIV are at extremely high risk of developing active tuberculosis. Therefore, the tuberculosis control program should focus on the population at high risk of HIV infection.

Often, program evaluation is performed by epidemiologists who have not taken the time to understand the dynamics of a disease in the community. Rates or proportions are calculated, no priorities are established, and precious resources are wasted on activities with little preventive value. For example, attempting to treat all tuberculosis cases, whether pulmonary or not with DOT, investigating all contacts regardless of the bacteriological status of the index case would be wasteful.

51.12 Mathematical Models

51.12.1 Aims of Mathematical Modeling

Mathematical models are an important tool for understanding the transmission dynamics of infectious diseases. In contrast to statistical models, dynamic transmission models are based on first principles. They aim at deriving population level phenomena from a mechanistic description of transmission between individuals of the population. The centerpiece of a dynamic transmission model consists of a term that quantifies the rate with which susceptible and infectious persons have contact with each other and the probability that transmission takes place during such a contact. In its simplest form, this term is modeled as a mass action term. In analogy to the mass action law in chemistry, the underlying assumption is that susceptible and infectious persons mix homogeneously and contact each other with a rate that is proportional to the concentrations of either population group. In more formal terms, if we denote by $X(t)$ the fraction of susceptible persons, and by $Y(t)$ the fraction of infected and infectious persons at time t, the rate at which infectious contacts take place is proportional to $X(t)^*Y(t)$. The proportionality factor β is a product of the contact rate – the number of contacts per unit time – and the probability that upon contact transmission of infection takes place. With the assumption that recovery from the infectious state into the immune state occurs with a constant rate γ, we can now formulate a first simple mathematical model:

$$\begin{aligned}\frac{dX(t)}{dt} &= -\beta X(t)Y(t),\\ \frac{dY(t)}{dt} &= \beta X(t)Y(t) - \gamma Y(t),\\ \frac{dZ(t)}{dt} &= \gamma Y(t),\end{aligned}$$

where $Z(t)$ is the fraction of immune or recovered individuals at time t. This set of equations is the simplest version of the so-called *susceptible-infected-removed* model that was first introduced in a more elaborate form by Kermack and McKendrick (1927; reprinted 1991). Since then, numerous variants of this simple model have been formulated and analyzed (Anderson and May 1991).

The primary aim of such a model is to gain a better understanding of the dynamics of the system. For example, in the above system of equations, we are interested in how an outbreak evolves in the population after introduction of a small number of index cases. The epidemic curve will depend on the parameters of the model, which in this case are the transmission rate β and the recovery rate γ. Let us see what we can say by just looking at the equations. Let us assume that we start at $t = 0$ in a situation where almost the entire population is susceptible, a small fraction of the population is infected, and nobody is immune. First, we observe that the fraction of susceptibles in the population can only decrease, because the right-hand side of the equation for $X(t)$ is negative. Furthermore, we see that $Y(t)$ will increase if the right-hand side of the equation for $Y(t)$ is positive, which is the case if $\beta X(0)Y(0) > \gamma Y(0)$. This leads to the insight that an outbreak is only possible if $\beta/\gamma > 1$. Here β/γ is the so-called basic reproduction number denoted by R_0 (see also Sect. 51.12.2). We will come back to this important concept later. Finally, we see that the fraction of immune persons in the population is continuously increasing as long as there are infected persons in the population. Figure 51.12 shows the typical time course of an outbreak for the parameters $\beta = 5$ and $\gamma = 1$.

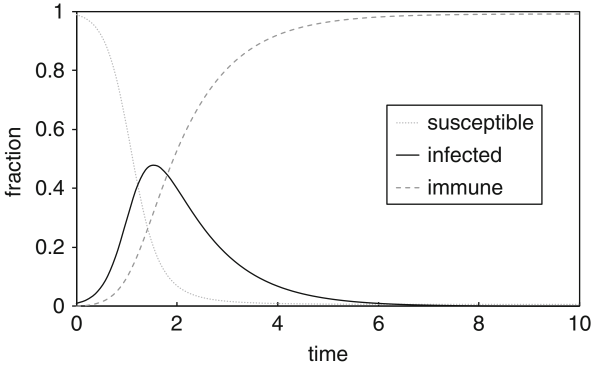

Fig. 51.12 The time course of an epidemic when there is no inflow of new susceptible individuals

After the outbreak has swept through the population and has left a certain fraction of the population immune, no further dynamics are possible in this system. This can only change if new susceptible individuals enter the population.

We want to extend the above model to include a simple demographic process, that is, births into the population with a rate ν and a per capita mortality rate μ. We assume that the mortality is not disease related, but applies to all population groups in the same way. For populations that grow or decrease in size, there are different ways of taking population size into account in the model formulation (Keeling and Rohani 2008). For simplicity, we assume here that $\nu = \mu$, meaning that the population is neither growing nor decreasing in size. With these additions, our model equations can be written as

$$\begin{aligned}\frac{dX(t)}{dt} &= \nu - \beta X(t)Y(t) - \mu X(t),\\ \frac{dY(t)}{dt} &= \beta X(t)Y(t) - \gamma Y(t) - \mu Y(t),\\ \frac{dZ(t)}{dt} &= \gamma Y(t) - \mu Z(t).\end{aligned}$$

These additions to the model change the long-term dynamic behavior of the model completely. The demographic process allows for a flow of new susceptible individuals into the population, thereby providing fuel for the transmission process to continue. In the long run, if the transmission rate β is large enough, the system will settle down to an endemic steady state with a prevalence of infection that is constant in time. It is not difficult to compute the endemic prevalence as a function of the model parameters. The result in terms of fractions X, Y, and Z of the population is

$$\begin{aligned}X &= \frac{1}{R_0},\\ Y &= \left(1 - \frac{1}{R_0}\right)\frac{\mu}{\gamma + \mu},\\ Z &= 1 - X - Y.\end{aligned}$$

In other words, the fraction of susceptible individuals is completely determined by the basic reproduction number R_0, with higher values of R_0 leading to a smaller proportion of susceptible individuals in the population. The endemic prevalence Y increases with increasing R_0 but is also determined by the duration of the infection $1/(\gamma + \mu)$.

Whether to use a model with or without demographic parameters depends on the time scale on which the outbreak takes place. For example, on the time scale of an influenza outbreak that takes a few weeks, the demographic process in the population will hardly influence the shape of the outbreak, and we might also not be interested in what will happen after the first wave. However, for an infection like

HIV, transmission dynamics evolves on the time scale of decades and will therefore strongly interact with the demographic process in the population.

This short introduction into the susceptible-infected-removed (SIR) model shows that (a) the model can provide insight into qualitative features of the transmission process on population level and (b) the exact form of the model to be used depends on the time scale and properties of the specific infection.

51.12.2 Important Concepts

Insights into the dynamics of the SIR model have led to the definition of a number of important concepts that are universal for all models and all infectious diseases. The most important of these concepts is the *basic reproduction number* R_0. The basic reproduction number R_0 is the number of secondary cases caused by one index case during his/her entire infectious period in a susceptible population. In other words, the basic reproduction number is given by the product of the transmission rate (number of new infections per time unit) and the duration of the infectious period. In the above model, the number of new infections per unit time is given by β, while the duration of the infectious period can be computed as $1/(\gamma + \mu)$. Therefore, for the SIR model with demographic process, we get

$$R_0 = \frac{\beta}{\gamma + \mu}.$$

We easily see from the equation describing the dynamics of $Y(t)$ that $Y(t)$ will increase in size if $R_0 > 1$ and decrease otherwise. This is the so-called threshold property that was already in 1927 formulated by Kermack and McKendrick (reprinted 1991) in a more general form. If $R_0 > 1$ an infected individual replaces himself by more than 1 new infected persons, which leads to an expansion of the epidemic. If $R_0 < 1$ the infection cannot establish itself in the population and will die out.

In more generality, one talks about the reproduction number $R(t)$ that describes the number of secondary cases per infected individual in a population that is not necessarily completely susceptible. $R(t)$ depends on the time, because with unfolding of the epidemic outbreak, the proportion of susceptibles in the population decreases and the proportion of immune individuals increases. Therefore, $R(t)$ will decrease with time. If there is no replenishment of the susceptible population, the transmission will stop at some point. The total number or fraction of the population that was infected during the entire course of the outbreak is called the *final size* of the epidemic. In epidemiological terms, the final size is called the attack rate; we denote it by A. The final size can be expressed in terms of the basic reproduction number as $A = 1 - \exp(-R_0 A)$ (Fig. 51.13).

If there is replenishment of the susceptible population by birth or recruitment into the population, the reproduction number may eventually converge to 1 in the endemic steady state. The prevalence in endemic steady state depends on the basic reproduction number with a larger R_0 leading to higher prevalence in steady state.

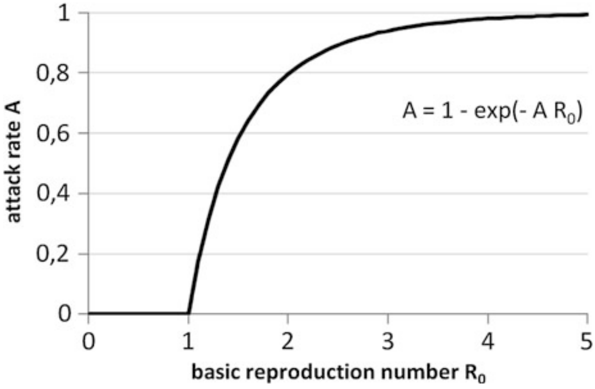

Fig. 51.13 The attack rate A as a function of the basic reproduction number R_0

Incorporating a simple term for infant vaccination with coverage p into the model makes it possible to determine the *critical vaccination coverage*. A model with vaccination is given by

$$\frac{dX(t)}{dt} = \nu(1-p) - \beta X(t)Y(t) - \mu X(t),$$
$$\frac{dY(t)}{dt} = \beta X(t)Y(t) - \gamma Y(t) - \mu Y(t),$$
$$\frac{dZ(t)}{dt} = \nu p + \gamma Y(t) - \mu Z(t),$$

where a fraction p of all newborns enters into the immune compartment immediately at birth, while the remaining fraction $1-p$ remains susceptible. Based on the endemic prevalence for this system of equations, the critical vaccination coverage can be derived as

$$p_{\text{crit}} = 1 - \frac{1}{R_0}.$$

This relationship gives valuable information about the vaccination effort needed to eliminate an infection from a population. It explains why it has been possible to eradicate smallpox with an estimated R_0 of around 5 (Gani and Leach 2001) in contrast to measles, for which the R_0 is estimated at around 20 (Wallinga et al. 2003).

Since the introduction of the SIR model, many different models have been formulated, and the diversity of models has vastly increased. Models have been designed for many specific infectious diseases, and they have incorporated population structure such as age, gender, spatial distribution, and differences in risk behavior. Also, stochastic models have been used to account for effects of chance events.

When choosing a model to answer a particular question in epidemiology or public health, different aims can be achieved, and the model of choice has to be accommodated to the aim. For answering questions about the qualitative dynamics of an infection, it is preferable to turn to a relatively simple model for which mathematical analysis is possible, while for the purpose of generating quantitative estimates or projections, more complex models are necessary that incorporate more details of the population structure (e.g., age) and more details about the transmission and course of infection. The latter can be simulation models that are implemented as computer code and cannot be formulated in terms of mathematical equations.

51.12.3 Use of Mathematical Models in Epidemiological Studies

Although mathematical modeling has been around for a long time, until recently, it was not much used as a tool for public health, but was considered a specialized research area for applied mathematicians and theoretical biologists. This started to change with the advent of the HIV pandemic, when mathematical models were first used to predict future epidemic spread, and to analyze the impact of behavior change on HIV incidence (Kaplan and Brandeau 1994). However, the breakthrough for mathematical modeling as a public health tool came with the concerns that smallpox virus could be used in a deliberate release and lead to devastating outbreaks in the only partially immune populations of present societies. How can public health policy be developed against threats with pathogens that are not circulating at present? There is no way to conduct epidemiological investigations, and the only available data in the case of smallpox were from before the eradication era. Therefore, to design policy, knowledge from historical smallpox outbreaks had to be combined with data about present-day society, and possible interventions had to be tested on the basis of this available information. Mathematical modeling provided a flexible tool to do that and was used to analyze possible vaccination strategies and other interventions (Ferguson et al. 2003).

Later, the experience with the global spread of SARS – the severe acute respiratory syndrome caused by a novel strain of corona virus – and the threat of a future pandemic with a new strain of influenza A initiated national and international efforts to better prepare for large outbreaks of emerging infections. Mathematical modeling was widely used for investigating optimal strategies for dealing with a new influenza pandemic (Longini et al. 2004; Ferguson et al. 2006). These response plans came into action during the pandemic with new influenza A|H1N1 emanating from Mexico in the spring of 2009. Even as the pandemic was still unfolding, first mathematical modeling studies started to deliver valuable data analyses almost in real time (Fraser et al. 2009).

Besides supporting public health policy in designing prevention and intervention strategies, mathematical modeling of infectious diseases has contributed greatly to increasing the understanding of the intricate relationships between clinical and biological determinants of infection and human contact and risk behavior patterns that lead to transmission. The importance of core groups of high sexual activity in the transmission dynamics of sexually transmitted infections (Hethcote and Yorke 1984), the impact of concurrent partnerships on the spread of HIV (Morris and Kretzschmar 1997), the importance of hosts being infectious before the appearance of symptoms for disease control (Fraser et al. 2004), and the connectedness of modern societies in a small world network (Watts and Strogatz 1998) are just some examples for how mathematical modeling has shaped the present paradigms of infectious disease epidemiology.

51.13 Conclusions

Today, the world is smaller than ever before, and international travel and a worldwide food market make us all potentially vulnerable to infectious diseases no matter where we live.

New pathogens are emerging such as the SARS or spreading through new territories such as WNV. WNV introduced in the USA in 1999 became endemic in the USA over the next years. Hospital-associated and community-associated methicillin-resistant *Staphylococcus aureus* (MRSA) and resistant tuberculosis cases and outbreaks are on the rise. Public health professionals are concerned that a novel recombinant strain of influenza will cause a new pandemic.

But not only the world and the etiological agents are changing; the world population is changing as well. In industrialized countries, the life expectancy is increasing, and the elderly are more likely to acquire a chronic disease, cancer, or diabetes in their lifetime. Because of underlying conditions or the treatment of these diseases, older populations also have an increased susceptibility for infectious diseases and are more likely to develop life-threatening complications.

Knowledge in the field of infectious disease epidemiology is expanding. While basic epidemiological methods and principles still apply today, improved laboratory diagnoses and techniques help to confirm cases faster, see how cases are related to each other, and therefore can support the prevention of spread of the specific disease. Better computers can improve the data analysis, and the Internet allows access to in-depth disease-specific information. Computer connectivity improves disease reporting for surveillance purposes, and the epidemiologist can implement faster preventive measures if necessary and is also able to identify disease clusters and outbreaks on a timelier basis.

The global threat of bioterrorism adds a new dimension. The intentional release of anthrax spores and the infection and death of persons who contracted the disease created a scare of contaminated letters in the US population.

With all these changes, there is renewed emphasis on infectious disease epidemiology and makes it a challenging field to work in.

52.1 Introduction

Worldwide, coronary heart disease (CHD) and stroke are the first and second leading causes of death, major contributors to disability, and the most common conditions – following hypertension or high blood pressure – comprising the cardiovascular diseases (CVDs) (Mazzati et al. 2006). Together these conditions rank among the foremost public health challenges of our time. They have been under extensive epidemiological investigation for more than a half century. As a result, with parallel clinical and laboratory research, understanding of the causation and means of prevention of CVDs have become well established. Their present and future global impact is becoming recognized. Calls for action to prevent heart disease and stroke are widespread at national and global levels (Labarthe 2011).

Three resources of potential interest to readers are (1) a comprehensive public health textbook on cardiovascular epidemiology and prevention (Labarthe 2011); (2) an extensive historical archive of materials regarding people, studies, essays, oral history, and audiovisuals from the field of cardiovascular epidemiology, found on this dedicated website: www.epi.umn.edu/cvdepi/ (Blackburn 2012); and (3) an annotated bibliography of some 150 classic and contemporary publications on public health aspects of heart disease (Labarthe 2013).

This chapter begins with a discussion of the scope and basic concepts of cardiovascular epidemiology. As the main focus of this chapter, the atherosclerotic and hypertensive diseases are defined, the main types of studies are illustrated, and a public health perspective on cardiovascular health and disease is presented. Against this backdrop, the brief sections that follow address these aspects of cardiovascular epidemiology:

- An epidemiological description
- Determinants
- Causation and prevention
- Research needs

52.2 Scope and Basic Concepts

52.2.1 Atherosclerotic and Hypertensive Diseases

CHD and stroke are the main consequences of atherosclerosis and hypertension. Also termed ischemic heart disease (IHD), CHD is a manifestation of reduced blood supply – and hence reduced oxygen supply – via the coronary arteries to the myocardium (muscle of the heart). Sudden loss of oxygen supply may result in injury or death to the muscle cells, constituting a myocardial infarction (heart attack). Disturbance of normal rhythmic contraction of the heart may occur, and this arrhythmia often causes sudden death unless effective emergency aid is administered promptly. A less severe – but also ominous, perhaps equally painful, and recurring – condition is unstable angina, which represents transient impairment of blood flow. The typical culprit lesion in the artery wall is the atherosclerotic plaque, which may itself grow gradually over years to narrow or occlude the artery or may suddenly rupture and trigger the rapid formation of an occlusive thrombus (blood clot) within the artery. Survival from an acute coronary event may be accompanied by disability from residual cardiac impairment and entails a high risk of recurrent cardiovascular events or progressive heart failure.

Stroke results from injury to the brain in a manner sometimes analogous to myocardial infarction: interruption of the arterial blood supply by a thrombotic occlusion. But other mechanisms may also cause stroke, chiefly occlusion by lodging of an embolus (a blood clot that has arisen, e.g., in a damaged heart and has been carried through the circulation to the brain) or by hemorrhage (when a blood vessel within the brain ruptures). Regardless of the mechanism, interruption of blood flow may produce injury and death of brain cells. The event may be rapidly fatal or may be followed by survival, with a high risk of recurrence and often with significant disability. The main underlying condition leading to thrombosis is atherosclerosis, whereas hemorrhage is especially attributable to hypertension.

Chronic heart failure may develop as a consequence of either CHD or hypertension, greatly increases the risk of stroke, and causes disability due to impaired circulatory function. It may also result from several other cardiac disorders, but in populations where CHD is a frequent condition, heart failure as a late consequence of CHD has become increasingly common, especially among older adults.

These five interrelated conditions – atherosclerosis and hypertension and consequent CHD, stroke, and heart failure – comprise the greater part of CVD, as used throughout this chapter. Other important cardiovascular conditions, such as atherosclerotic peripheral arterial disease, aortic aneurysm, cardiomyopathies, rheumatic heart disease, Chagas' disease, congenital heart disease, deep vein thrombosis, and pulmonary embolism, while important vascular conditions, are beyond the scope of this chapter.

A recent development in the global health arena, commonly reflected in national-level discussions as well, is a focus on several chronic diseases together, rather than separately. Thus, "non-communicable diseases (NCDs)" include CVDs, cancer, chronic respiratory diseases, and diabetes (World Health Organization 2011; Bloom et al. 2011). These discussions are directly relevant to CVDs, even when they are not addressed explicitly, because they are a major, often dominant, component of the NCDs. This explains reference to the NCDs at the close of the chapter, in relation to policy and research in the field of cardiovascular health.

52.2.2 Types of Studies

Measures of CVD in the population are fundamental to epidemiological investigation and understanding. Terms such as mortality, incidence, or prevalence introduced, for example, in Part I (Concepts and Designs in Epidemiology) of this handbook have their particular use and importance in CVD epidemiology. *CVD mortality* can be studied insofar as deaths are registered and classified in accordance with reliable and standardized procedures and the current census of the underlying population is known. Such data have been collected for several decades in many countries but have yet to be recorded at all in many others. The most informative data are those presented for specific age and sex groups within a population and for other demographic subgroups as appropriate. Adherence to practices for the *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* (World Health Organization 1992) is now required for national death registration systems. (The next revision, the 11th, is scheduled for release in 2015 – see World Health Organization (2012).) For epidemiological research, cause-of-death validation can be conducted through well-standardized procedures such as those of the WHO MONICA Project (World Health Organization MONICA Project Principal Investigators 1988). Validation is especially important for unobserved and out-of-hospital deaths in which CHD or stroke is suspected, but documentation regarding diagnostic criteria is unavoidably incomplete.

The CVD burden of a population may be estimated, and comparisons among populations made, by surveys to determine the proportion of the population affected, or *CVD prevalence*. Prevalence of CVD is influenced by both the rate at which new cases occur and the duration of their survival in the population. Sampling methods and selective factors in survey participation, such as disease-related disability that prevents participation (and therefore precludes complete and unbiased representation of the study population), must be taken into account in evaluating findings. Standard cardiovascular survey methods have been published since the 1960s (Blackburn et al. 1960; Rose and Blackburn 1968; Luepker et al. 2004). The prevalence of CVD and related conditions such as high blood pressure, high blood cholesterol concentration, and smoking history, as well as such major underlying factors as diet and physical activity, can be assessed with reasonable efficiency.

The frequency with which newly detected cases of CVD occur in a population, or *CVD incidence*, is measured by long-term (several years) follow-up among persons found at a baseline survey to be disease-free and for whom first events can be ascertained by periodic reexamination, continuous surveillance of hospitalizations or deaths, or a combination of these approaches. Issues in evaluation of findings relate especially to chances for missed or misdiagnosed cases and losses to follow up. Detection of new cases also allows assessment of the proportion of events leading to death in the short-term (*case fatality*; usually within 28 days of symptom onset) and *long-term survival* (for any specified period beyond 28 days post-event).

The now familiar types of epidemiological studies of chronic diseases were devised or refined over the decades since the 1950s, often through research on CVDs. They can be described as follows (see also Part I (Concepts and Designs in Epidemiology) of this handbook):

- *Analysis of vital statistics*, specifically comparison of death rates (mortality) from cardiovascular causes, was an early strategy in CVD epidemiology. It continues to be of value in demonstrating differences between population groups, or trends over time, in national or other geopolitical areas. *Examples*: Gordon (1957) recognized that men of Japanese ancestry living in Japan, Hawaii, and California experienced strikingly different patterns of mortality from CHD and stroke (CHD being low in Japan, intermediate in Hawaii, and high in California, in contrast to the opposite gradient for stroke). This analysis stimulated more intensive investigation through other epidemiological methods (Kagan and Yano 1996). Thom and others (1992) showed marked short-term variation and revealing patterns in CHD and stroke death rates in 27 countries over four decades. A major strength of this approach is ready availability of vital data over decades or longer for many countries and their subdivisions. Serious limitations include the lack of data especially for many low- and middle-income countries and the need to take into account changes in classification of causes of death over time and data reliability.

- *Population surveys* (or "cross-sectional studies") are conducted in principle at a point in time (ongoing, continuous surveys are better regarded as *population surveillance*) and typically in a defined geographical area. In their simplest design, they can provide essential information about the proportion of a population affected by a particular disease (disease prevalence) and the population distribution of related factors. More extensive surveys can include multiple-population comparisons or repetition at intervals of years, thereby addressing population differences or secular trends. Prediction of findings permits testing of prior hypotheses, as well. *Examples*: The INTERSALT Study demonstrated an association between the slope of increasing blood pressure with age and urinary sodium and potassium excretion in adults among 52 study centers in 32 countries (INTERSALT Co-operative Research Group 1986). The Kenyan Luo Migration Study showed rapid change in blood pressure, over only weeks to months, among Luo tribesmen migrating from rural to urban Kenya (Poulter et al. 1990). From serial surveys representative of the United States population, favorable trends were seen in the distribution of systolic blood pressure over 40 years, from the 1960s to the mid-1990s (Goff et al. 2001). Comparison of national survey data on blood pressure revealed higher prevalence of hypertension and lower prevalence of hypertension control, in six European countries than in Canada and the United States (Wolf-Maier et al. 2003). Strengths of the population survey include versatility of design, fundamental simplicity, and relative expediency of execution. Limitations include the cross-sectional property that necessarily restricts observation to prevalent cases and constrains collection of historical data on exposures that may have preceded onset of disease.
- *Cohort studies* are designed to determine the rate of occurrence of new cases among persons free of disease at first, or "baseline" observation and to measure disease incidence in relation to baseline characteristics of interest. Cohort studies were initiated in the late 1940s and after to yield insights into causes of CHD and stroke. *Examples*: The Framingham Heart Study, begun in 1948, now includes some 60 years of multigenerational observation of CVD in one US community (Dawber et al. 1951). The Whitehall Study of British civil servants also provided long-term follow-up and insight to individual risks (Rose and Shipley 1986). The Seven Countries Study demonstrated major factors accounting for population differences in CHD rates between Northern and Southern Europe, Japan, and North America (Keys 1980). The several ongoing, long-term cardiovascular cohort studies in the USA are described periodically in government publications

(National Heart, Lung, and Blood Institute 2006). Cohort studies are unique among observational designs in permitting direct assessment of disease incidence in relation to baseline or interim risk characteristics, or relative risk. In the CVD arena, they require large populations, long-term follow-up, or both to generate sufficient person-years of experience to afford reliable estimates of incidence and risk and are correspondingly demanding of resources and skill.

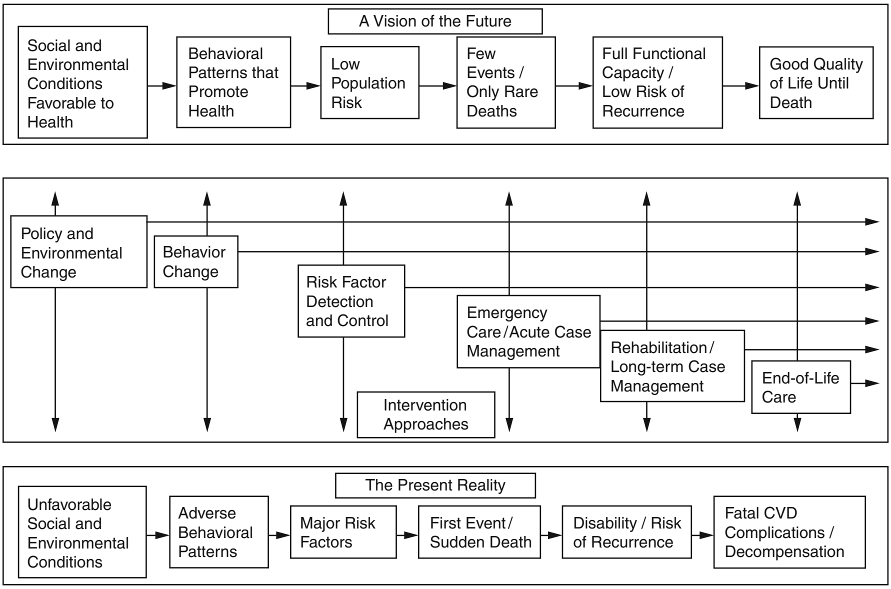
- The *case-control study* is used to identify already affected persons (the case group) in order to assess characteristics of interest among them; comparable assessment is then conducted among a suitable non-affected group (the control group). Comparative analysis permits judgment whether an exposure is sufficiently greater (or less) among cases and therefore may be linked in a meaningful way with the presence or absence of disease. *Examples*: The case-control approach has been applied in large-scale multinational collaborative studies. The association between the presence of stroke and other vascular conditions among women by their history of oral contraceptive use was investigated in the WHO Collaborative Study of Cardiovascular Disease and Steroid Hormone Contraception (World Health Organization 1996). More recently several factors of interest were studied in relation to the presence or absence of myocardial infarction among men and women in 52 countries throughout the world (Yusuf et al. 2004). This approach is widely used to study conditions of relatively low incidence, a situation in which demands of cohort studies noted above are difficult to satisfy. The fundamental issue in design, conduct, and interpretation of case-control studies is evaluation of possible bias or confounding in the comparison of cases and controls (see chapters ▶Confounding and Interaction and ▶Sensitivity Analysis and Bias Analysis of this handbook).
- *Combinations of approaches* have also been used to monitor CHD and stroke in populations. *Example*: An especially comprehensive study of this kind was the WHO MONICA Project, a major collaboration including 38 populations in 21 countries, chiefly in Europe (Monitoring Trends and Determinants in Cardiovascular Disease Project) (World Health Organization MONICA Project Principal Investigators 1988; Sarti et al. 2003; Tunstall-Pedoe 2003). Repeated *cross-sectional surveys* were used to assess trends in risk factors and treatment of cases, continuous *community-wide and hospital-based surveillance* identified new and recurring cases and case fatality, and *vital statistics* systems supported analysis of death rates based on validated cause of death in accordance with the MONICA Project surveillance protocol. In some centers, *cohort designs* were incorporated as well. Composite study designs combine both advantages and limitations of each approach that is included.
- The many "clues to causation" generated from the types of studies described here, characterized collectively as "observational studies," have led to a very large body of experimental research, such as the intervention trials addressed in chapters ▶Intervention Trials, ▶Cluster Randomized Trials, and ▶Community-Based Health Promotion of this handbook. In CVD epidemiology, this research includes *clinical trials* among selected individuals, to evaluate the efficacy of treatments among patients (*secondary prevention trials*) or of measures to reduce risk of first events (*primary prevention trials*). It also includes *community-based*

trials, and *demonstration projects* to test the effectiveness of interventions for the population at large (see, e.g., chapter ▶Community-Based Health Promotion of this handbook. *Examples*: Among early clinical trials that stimulated subsequent population-based trials and strongly influenced policy and practice is the US Veterans Administration trial of the treatment of hypertension (Freis 1990). Community trials and demonstrations are well illustrated by the North Karelia Project (Puska et al. 1998) and by later examples in the United States and elsewhere (Blackburn 1992; Labarthe 2011).

52.2.3 A Public Health Perspective

Extensive knowledge of the natural history of CVDs, and of interventions to modify their course, has accrued through application of all of the types of studies illustrated above. A synthesis of this knowledge from a public health perspective was undertaken a decade ago to provide a framework for public health action to prevent heart disease and stroke (Fig. 52.1) (US Department of Health and Human Services 2003). Concepts basic to CVD epidemiology, illustrated in Fig. 52.1, relate to the progression from cardiovascular health to disease and the corresponding array of intervention strategies and approaches that apply across this continuum. They are addressed briefly here as background for the sections that follow.

The lower panel of Fig. 52.1 represents as “the present reality” a well-established series of connections characterizing the progression from unfavorable social and



A Vision of the Future
Social and Environmental Conditions Favorable to Health
Behavioral Patterns that Promote Health
Low Population Risk

Policy and Environmental Change
Behavior Change
Risk Factor Detection and Control
Emergency Care / Acute Case Management
Rehabilitation / Long-term Case Management
End-of-Life Care
Intervention Approaches
The Present Reality
Unfavorable Social and Environmental Conditions
Adverse Behavioral Patterns
Major Risk Factors
First Event / Sudden Death
Disability / Risk of Recurrence
Fatal CVD Complications / Decompensation

Fig. 52.1 Action framework for a comprehensive public health strategy to prevent heart disease and stroke (Adapted from US Department of Health and Human Services 2003)

environmental conditions, through the adverse behavioral patterns that they foster, to the emergence of the major CVD risk factors. (Not shown, for simplicity, are the typical long-term development of subclinical, or undetected, disease and the immediate precipitating factors that link the major risk factors to the first event – whether heart attack, stroke, or episode of heart failure.) Sudden death may rapidly end the course, or survival may extend it, often with significant disability and high risk of recurrent CVD events. Paralleling this progression is the dimension of the life course of CVD, from possible maternal and fetal influences where earliest environmental factors may operate to childhood and adolescence where behavioral patterns often become established and risk factors begin to emerge and to early, middle, and late adulthood with the acute events and their consequences (see also chapter ▶Life Course Epidemiology of this handbook).

The counter to this present reality is a vision of the future (upper panel), in which the opposite of each of these states has been achieved. The means of change toward this vision are the intervention approaches identified in the center panel of this figure. Each approach has potential application from its first point of intervention throughout the further progression of CVD. For example, policy and environmental change can be applied to health-care settings, work sites, and schools as well as to society at large (Association of State and Territorial Directors of Health Promotion and Public Health Education 2001). Risk factor detection and control applies not only in advance of any clinical event but also, for persons who survive them, to lifelong care to prevent recurrent CVD events. These and the more familiar concepts of secondary, primary, and primordial prevention and of high-risk and population-wide strategies are discussed further below.

The epidemiological underpinnings of this framework derive from decades of research through the foregoing approaches. The public health implications of the framework and the plans of action that follow derive in turn from clinical and community trials, experience in public health practice, and knowledge gained through many years of policy development, implementation, and evaluation. The following picture of cardiovascular health and disease at the population level demonstrates the importance, for population health, of taking action on a large scale on the basis of this evidence.

52.3 An Epidemiological Description

52.3.1 Overview

More than a half century of CVD epidemiology, developing and applying the methods highlighted above, has provided a comprehensive understanding of the natural history of these conditions (see, e.g., Marmot and Elliott 2005; Labarthe 2011). Several broad features of this understanding are:

- CVD is pervasive throughout the world. In the mid-twentieth century, CVD, and especially CHD, came to be regarded as a public health problem of the Western industrialized nations. Before the end of the century, CVD (principally expressed as CHD or stroke) was recognized as a public health problem of global importance and a significant deterrent to social and economic development in low- and middle-income countries.

- Change in population burdens of CVD, as reflected in the crude, late measure of cause-specific mortality, can occur rapidly and with abrupt and unpredicted change in direction. Such rapid change is unequivocal evidence of powerful environmental factors whose impact is highly variable over time and place. In addition, migration of population subgroups has demonstrated change in CVD rates such that rates for migrants come to resemble those of the new population setting in contrast to rates for the non-migrating members of the source population. Such observations suggest that environmental factors are potentially subject to interventions to establish or maintain social and environmental conditions protective against CVD.
- Epidemiological investigation of the pathology of atherosclerosis strongly supports the view of early-life onset and lifelong progression of CVD. Studies of military casualties dying of non-CVD causes have shown that unrecognized coronary atherosclerosis may be extensive even in early adulthood. Thus, true prevention of atherosclerosis and its complications requires effective intervention as early as childhood and adolescence.
- National vital statistics systems that provide reliable data on cause-specific mortality are sometimes adequate for gauging the population burden of CVD, but these data are incomplete or lacking for many countries. Additional information is needed to fully characterize a population's CVD profile, and efforts to compile such data on a worldwide basis have revealed serious shortcomings even in high-income countries, such as the United States, where data on disease incidence are typically lacking except in specific localities with special epidemiological studies. Characterizing the global burden more definitively thus faces serious obstacles.
- Notwithstanding these limitations, serious efforts to project the global burden of CVD and other major causes of death and disability, and the potential impact of selected interventions against these conditions, have provided a view of the world's health two decades or more hence. The results indicate that CHD and stroke have been the first and second leading causes of death worldwide since 1990 and would remain so through 2020, barring greatly intensified public health efforts in prevention.

Selected examples below illustrate a twentieth-century historical perspective, the "geographical pathology" of CVD, and forecasts of the global CVD burden.

52.3.2 Illustrations

52.3.2.1 Historical Perspective

Studying long-term CVD mortality trends in one or more countries can provide valuable epidemiological insight. A leading example of this approach is the work of Omran (1971), who studied mortality from multiple causes in the United States

Table 52.1 The epidemiological transition (Source: Pearson et al. 1993)

Phase of epidemiological transition	Deaths from circulatory disease (%)	Circulatory problems	Risk factors
Age of pestilence and famine	5–10	Rheumatic heart disease; infectious and deficiency-induced cardiomyopathies	Uncontrolled infection; deficiency conditions
Age of receding pandemics	10–35	As above, plus hypertensive heart disease and hemorrhagic stroke	High-salt diet leading to hypertension; increased smoking
Age of degenerative and man-made diseases	35–55	All forms of stroke; ischemic heart disease	Atherosclerosis from fatty diets; sedentary lifestyle; smoking
Age of delayed degenerative diseases	Probably under 50	Stroke and ischemic heart disease[a]	Education and behavioral changes leading to lower levels of risk factors

[a] At older ages. Represents a smaller proportion of deaths

and elsewhere from 1900 through 1970. On the basis of these observations, he presented the concept of "epidemiological transition" to describe a relative shift in frequency between infectious and circulatory diseases as causes of death over long periods of cultural development. In an era where causes of death were dominated by "pestilence and famine," few deaths would be due to circulatory causes, that is, CVD. Successive eras of "receding pandemics" and rise of "degenerative and man-made diseases" would reach a peak in the proportion of deaths from CVD, followed by a decline brought about by "education and behavioral changes leading to lower levels of risk factors" (Table 52.1) (Pearson et al. 1993). This "theory" has become more a descriptor of historical trends than predictor of change, as it has been expanded to take more recent variations into account (Olshansky and Ault 1986; Yusuf et al. 2001). A further, serious limitation of the concept is its foundation in *proportionate* mortality: Where rates of infectious disease and maternal and infant mortality remain high, the proportion of CVD deaths may remain low, masking the true absolute increase in the CVD burden and delaying public health recognition of the urgency of this development.

A more recent analysis, noted above, focused on national secular trends in CHD and stroke mortality from the 1950s to the 1980s in 27 countries (Thom et al. 1992). For CHD, rates for men consistently exceeded those for women; rates ranged widely among countries, as much as six-fold; rates changed markedly within countries over successive 5-year intervals; and trends were generally similar for women and men in the same country (see Fig. 52.2). These observations indicate strong time-dependent and regionally or nationally distinct environmental influences that commonly, though not invariably, affected women and men in similar ways. The rapid pace of change excludes population genetics as an explanation.

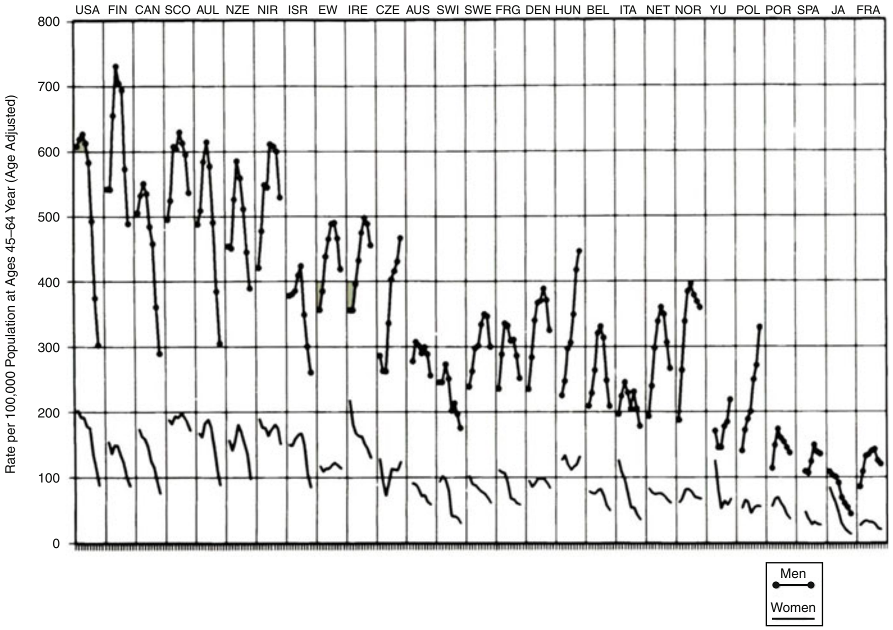

Fig. 52.2 Coronary heart disease mortality in 27 countries (USA, United States; FIN, Finland; CAN, Canada; SCO, Scotland; AUL, Australia; NZE, New Zealand; NIR, Northern Ireland; ISR, Israel; EW, England and Wales; IRE, Ireland; CZE, Czechoslovakia; AUS, Austria; SWI, Switzerland; SWE, Sweden; FRG, Federal Republic of Germany; DEN, Denmark; HUN, Hungary; BEL, Belgium; ITA, Italy; NET, Netherlands; NOR, Norway; YU, Yugoslavia; POL, Poland; POR, Portugal; SPA, Spain; JA, Japan; FRA, France. Each point represents the sex-specific average annual mortality for one period. Countries are arrayed in descending order of mortality for men in the first interval), 1950–1987 (Source: Thom et al. 1992)

For stroke, the same 27 countries appeared in quite different rank order (e.g., Japan was highest for stroke, though next to lowest for CHD), rates for men and women were generally similar within each country, and overall rates and trends were quite homogeneous among countries, excepting mainly several central European countries. Stroke does not closely match CHD epidemiologically. It does, however, share the aspect of marked change in mortality in a rather short historical period that indicates strong environmental influences, here (vs. CHD) operating in a generally similar way between sexes and among countries.

52.3.2.2 "Geographical Pathology" of Atherosclerosis

The term "geographical pathology" was coined and applied to atherosclerosis at least as early as 1934, being discussed in a conference with this title in the Netherlands in that year (Epstein 2005). Epidemiological study of atherosclerosis has included a substantial body of work by pathologists that is well represented by three studies – one in the true vein of geographical variation and the others each uniquely designed for study of postmortem epidemiology. The International

Atherosclerosis Project was essentially a cross-sectional multinational survey of coronary and aortic atherosclerosis (Tejada et al. 1968). Sections of coronary arteries and aortas were obtained from more than 23,000 autopsies for non-CVD deaths at ages 10–69 years in 14 countries, including Latin America as well as the United States and South Africa. Wide variation among the populations was found in the average extent of coronary atherosclerosis at any given age, and this measure and the CHD mortality rates corresponded closely within countries. Males had more extensive lesions than females did in countries where the extent of coronary atherosclerosis was greatest.

A strong age gradient in degree of atherosclerosis at death was also observed in six of the countries studied: From a range of 0–25% of intimal surface involvement with fibrous plaques at age 20, the percentage approximately doubled by age 30 in each population and continued to increase, although less steeply, to later ages at death. These findings confirmed marked population differences in the extent of coronary atherosclerosis, especially at early ages. They also supported earlier observations indicating that onset of atherosclerosis was common before age 20 and that males exhibited more extensive coronary atherosclerosis than females did (Holman et al. 1958).

The second example is the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) Study, not geographical in orientation but aimed at the early development of atherosclerosis (Pathobiological Determinants of Atherosclerosis in Youth (PDAY) Research Group 1990). PDAY conducted standardized postmortem examinations of coronary and aortic specimens among black or white decedents aged 15–34 years from non-CVD causes at eight centers in the United States. Beyond pathology alone, this study introduced assessment of CVD risk factors based on blood samples and other materials obtained at death. The extent and severity of atherosclerosis at these early ages was strongly related to adverse blood lipid profiles and to smoking (as assessed by serum thiocyanate concentration). Earlier, as a third example, the Bogalusa Heart Study had begun conducting postmortem studies of atherosclerosis in participants in their school-based surveys who died years later from non-CVD causes (Berenson et al. 1992). Risk factor measurements in school, including blood lipids, blood pressure, smoking, and obesity, were associated with the extent and severity of coronary atherosclerosis at death. The findings from these two studies established a critical link between risk factors and pathology at ages well before clinical CVD typically appears. This link is important for strategies of CVD prevention and strengthened evidence for the progressive development of atherosclerosis in early life, as conceptualized decades earlier by Holman and colleagues (1958).

52.3.2.3 Forecasts of the Global CVD Burden

The global dimension of CVD is increasingly recognized, especially in low- and middle-income countries, and misconceptions about the epidemiological transition are beginning to be overcome. For example, the World Heart Federation (WHF) assessed the global situation in a report that addressed the need for international co-operation, the role of the WHF, the profile and magnitude of the global CVD burden, current activities and resources, and strategies for global action (Chockalingam and

Table 52.2 Estimated numbers of deaths and numbers of DALYs lost due to ischemic heart disease and cerebrovascular disease by WHO region, 2001 (Source: World Health Organization 2002)

	WHO region						
Measure of burden	AFR	AMR	EMR	EUR	SEAR	WPR	Total
Deaths (×1,000)							
Ischemic heart disease	333	967	523	2,423	1,972	963	7,181
Cerebrovascular disease	307	454	218	1,480	1,070	1,926	5,455
DALYs lost (×1,000)							
Ischemic heart disease	3,258	6,506	5,353	16,000	20,236	7,373	58,726
Cerebrovascular disease	3,318	4,057	2,364	10,443	9,952	15,736	45,870

Balaguer-Vintró 1999; see also World Heart Federation 2012). It compiled results of surveys from member WHF countries concerning existing policies, programs, and guidelines for CVD prevention, resource requirements and funding sources, human resources, and cardiology infrastructure and practices. Data for 1990 for established market economies, economies in transition (chiefly the countries of the former USSR and others in Eastern Europe), and developing countries demonstrated that the latter contribute far the greatest share of deaths from CVD. This reflects both the virtually ubiquitous occurrence of CVD and the large contribution to the world population from the developing countries.

The World Health Report 2002: Reducing Risks, Promoting Healthy Life provided estimates of both death and disability (in numbers of disability-adjusted life years, or DALYs[1] lost), attributable to IHD and to stroke for the year 2001 (World Health Organization 2002; see also www.who.int; data compiled by the author from Annex Table 2, pp 188–189) for each of the six WHO regions (AFR = Africa, AMR = the Americas, EMR = Eastern Mediterranean, EUR = Europe, SEAR = South-East Asia, and WPR = Western Pacific). Although each region is subclassified by mortality pattern in the source tables, data are summarized here for entire WHO regions, for ischemic heart disease and cerebrovascular disease (Table 52.2).

Of all deaths worldwide, 22.3% were estimated to be due to these two conditions, as were 7.1% of all DALYs lost. Each region contributed substantial numbers to these measures of the CVD burden. Relative contributions of IHD and stroke varied strikingly among regions: Stroke predominated in the Western Pacific, IHD and stroke contributed about equally in Africa, and IHD exceeded stroke in all other regions. The WHO report also provided an extensive analysis of the major risks to health, strategies to reduce these risks, and needs for policies and action to prevent risks.

Through a joint undertaking of WHO, the World Bank, and the Harvard University School of Public Health, the Global Burden of Disease Study first estimated incidence, prevalence, mortality, and disability related to more than 100 diseases and causes of injury as of the year 1990 and projected the global disease burden

[1] 1 DALY lost = 1 full year of life expectancy lost, 2 years lived with 50% disability, etc.

to the year 2020 (Murray and Lopez 1996). IHD and stroke were identified as leading causes of death and disability worldwide in both 1990 and 2020. Among the many findings of importance in the CVD projections were, for change in total CVD death rates from 1990 to 2020: world, +16.2%; established market economies, +1.8%; economies in transition, +19.4%; and developing countries, +28.2%. Again, the relative disadvantage of the developing countries is apparent.

This point was further emphasized in the report, *A Race Against Time: The Challenge of Cardiovascular Disease in Developing Economies* (Leeder et al. 2004). Comparative forecasts of the CVD burden among Brazil, China, India, Russia, and South Africa from 2000 to 2030 demonstrated a significant potential loss by death and disability from the working age population of each country over this period, absent major new efforts in CVD prevention. Loss of workforce translates into slowing of economic and social development, considerations that add strongly to the case for investing in prevention, especially in such countries. Calls for global action from the International Heart Health Society are reflected in their synthesis of successive declarations, *International Action on Cardiovascular Disease: A Platform for Success* (International Heart Health Society 2005).

The worldwide impact of CVDs continues to be assessed, as in the ongoing Global Burden of Disease Project, last reported in 2006 and scheduled for a further update in the near future (Mazzati et al. 2006). Yet the magnitude of the challenge for developing countries is an increasingly dominant theme, well illustrated by World Bank's *Disease Control Priorities in Developing Countries*, in its second edition, and by a report from the Institute of Medicine, *Promoting Cardiovascular Health in the Developing World: A Critical Challenge to Achieve Global Health* (Jamison et al. 2006; IOM 2010a). This concern is intensified in the context not only of CVDs but of NCDs together, as discussed below.

52.4 Determinants

52.4.1 Overview

Many factors contribute to development of CVD. They may be as remote as conditions of fetal development or as immediate as precipitators of plaque rupture in a coronary artery. They may be as distal in their influences as community-level poverty and lack of education or as proximate as an individual's blood pressure. "Determinants," "risk factors," and related terms are often used interchangeably. Here, "determinants" is generally used for the whole array of these influences, from social determinants (such as income or relative poverty, education, and housing quality) to personal risk factors (such as behavioral, metabolic, and physiologic characteristics). Each determinant can potentially impact both CVD rates in populations and CVD risks in individuals. For example, the social determinants (which are population characteristics) affect individuals, and the risk factors (which are individual traits) have their corresponding distributions and trends in populations. The major established risk factors for CVD are highlighted briefly here, with the origins of evidence for these factors discussed elsewhere (Stamler 1992).

A coherent orientation to determinants of CVD begins by distinguishing environmental from genetic factors; addresses variation in CVD rates and risks by demographic characteristics; proceeds by describing the major underlying factors of diet and physical activity, followed by obesity as an outcome of dietary imbalance; considers physiologic consequences of these factors (adverse blood lipid profile, high blood pressure, and diabetes); and concludes with other personal characteristics and social and physical environmental factors. The current epidemiology of each is addressed chapter by chapter in a recent review (Labarthe 2011).

52.4.2 Illustrations

52.4.2.1 Genes and Environment

Methods of genetic, or genomic, epidemiology and its public health implications are presented clearly in recent texts (e.g., Khoury et al. 2004; see also chapter ►Statistical Methods in Genetic Epidemiology of this handbook). Applications to prevention and treatment of CVD were reviewed in a scientific statement of the American Heart Association, with the conclusion that to date the knowledge of greatest utility in this area is that of family history (Arnett et al. 2007). Long-standing awareness of familial resemblance in characteristics related to CVD supports this view, though uncommon conditions such as familial hypercholesterolemia have well-established genetic bases. Meanwhile challenges to study of such "complex" diseases as CVD continue to limit progress in contemporary population-level genomic investigations. Evidence reviewed above demonstrates the strong influence of environmental factors on population differences and secular trends in CVD mortality, patterns of variation that cannot be explained by change in population genetics.

52.4.2.2 Age, Sex, and Race/Ethnicity

Universal demographic characteristics such as age, sex, and race/ethnicity are associated with all aspects of CVD – including both rates and risks of cardiovascular events and the distributions of other determinants. (Note: The term "race" as used here, and in the US public health context, is discussed in Chap. 2, Distributions and Disparities, in Labarthe (2011).) Variation in these measures by age and sex is so ubiquitous that data are rarely presented without age-sex specificity. Measures specific to groups defined by race/ethnicity are also customary, because of both prior knowledge of important group differences and concern to identify and address the disparities in CVD burden that typically accompany disadvantage of some racial or ethnic groups. While these characteristics are often regarded as "unmodifiable," as fixed personal traits, they may serve as markers of particular exposures that, through their modification, can reduce the associated risks.

52.4.2.3 Dietary Imbalance

Dietary patterns to maintain optimum cardiovascular health concern balance, both among components of the diet and between total energy intake and expenditure. The concept of dietary imbalance, then, embraces undesirable patterns of both nutrition and physical activity. The nutritional aspects of CVD, including both atherosclerosis and hypertension, focus on specific nutrients (e.g., saturated, mono- and polyunsaturated, and total fats and specific fatty acids; sodium; fiber; sugar-sweetened beverages; and others) as well as on overall dietary patterns. The American Heart Association, for example, has defined ideal cardiovascular health to include a dietary pattern whose indicators for population monitoring are intakes of fruits and vegetables, fish, whole grains (generally to be increased), sodium, and sugar-sweetened beverages (to be decreased) (Lloyd-Jones et al. 2010). Methods for assessing population-level nutrient intakes are well developed but difficult to implement in large population studies due to constraints of cost and feasibility. The fundamental role of nutrition in CVD and other NCDs warrants substantially increased investment in monitoring population intakes and the policy and environmental contexts that determine food production, distribution, accessibility, price, and choice (see chapter ▶Nutritional Epidemiology of this handbook).

52.4.2.4 Physical Inactivity/Sedentariness

Physical inactivity, the other component of dietary imbalance, contributes to CVD risk through the now-commonplace failure to match energy expenditure with energy intake. Numerous biological mechanisms related to cardiac metabolism and physiology are affected. As a consequence of reduced physical work for personal locomotion and physical exertion in most occupations, research attention turned from occupational to leisure time physical activity (Blackburn 1983). But leisure-time, like occupational activity, has increasingly become devoted to sedentary pursuits (such as watching television), so that average population levels of physical activity have become very low in many countries (President's Council on Physical Fitness and Sports 1996). Standardized instruments have long been available to assess physical activity in population studies, with recent development of the International Physical Activity Questionnaire (IPAC) that permits valid comparisons among countries (Guthold et al. 2008). Physical activity corresponding to "ideal cardiovascular health" equals at least 150 minutes (min) per week of moderate or moderate plus vigorous activity, or 75 min of entirely vigorous activity, for adults; for children the standard is at least 60 min of vigorous activity every day (Lloyd-Jones et al. 2010) (see also chapter ▶Physical Activity Epidemiology of this handbook).

52.4.2.5 Obesity

A direct consequence of the energy component of dietary imbalance is excessive weight gain, measured in its simplest form by the relation of weight to height, expressed as the body mass index (BMI, weight in kilogram/square height in square meter). The World Health Organization classifies BMI levels as chronic energy deficiency (BMI less than 18.5), normal (BMI 18.5–25), or obese (grade 1, BMI 25–30; grade 2, 30–40; grade 3, 40 and greater) (World Health Organization Study Group 1990). Rising prevalence of obesity, beginning in childhood, is a growing global health concern, because of its role in development of multiple NCDs and other determinants of CVD – adverse blood lipid profiles, excessive blood pressure and blood glucose, and type 2 diabetes at ever-earlier ages, now including adolescence (World Health Organization 1999; Koplan et al. 2005; Daniels et al. 2005; International Obesity Task Force 2006) (see chapter ▸Epidemiology of Obesity of this handbook).

52.4.2.6 Adverse Blood Lipid Profile

Early studies in CVD epidemiology identified high blood cholesterol concentration as a "risk factor" for CHD (e.g., Kannel et al. 1961). Over the following decades, deeper insight into lipid metabolism and its relation to atherosclerosis established a more complex role of blood lipids, including high concentrations of low-density lipoprotein (LDL) cholesterol and triglycerides and low concentrations of high-density lipoprotein (HDL) cholesterol. Each of these components of the blood lipid profile was found to predict CVD events and interventions to modify these factors reduced risk. Because total cholesterol concentration is readily tested in non-fasting blood samples, it is a relatively convenient measure for population surveys and is most widely reported. On this basis it has been described as accounting for 45% of IHD mortality and 13% of cerebrovascular (stroke) mortality worldwide (Mazzati et al. 2006).

52.4.2.7 High Blood Pressure

High blood pressure also became established in the earliest epidemiological studies of CVD as a major risk factor for both CHD and stroke. Measured reliably through training of observers in standard auscultatory methods, blood pressure was consistently found to predict CVD events, and treatment of individuals with high blood pressure (and over time, with successively lower starting levels) to reduce the risks. The estimated contributions of high blood pressure to the worldwide burden of IHD and stroke are 45% and 54%, respectively – indicating a particularly serious impact on stroke (Mazzati et al. 2006). High blood pressure results in part from dietary imbalance, through obesity, but is also a specific consequence of high sodium intake. For this reason, national and global health recommendations for CVD prevention place a prominent emphasis on population-wide sodium reduction through changes in food production, preparation, and consumption, as well as changes in health-care systems to improve long-term management (World Health Organization 2007; Asaria et al. 2007; IOM 2010b, c).

52.4.2.8 Diabetes and the Metabolic Syndrome

Diabetes mellitus, especially its predominant form of "type 2 diabetes mellitus," constitutes one of the major NCDs in itself (Narayan et al. 2011). However, it is included here because of its relation to other determinants of CVD and its own contribution to risk of CVD events. "Diabetes" as used here represents a complex set of conditions concerning dietary patterns, energy balance, obesity, production of insulin and its function in glucose metabolism, and interrelations of these factors with blood lipids and blood pressure to comprise what has come to be known as "the metabolic syndrome." Globally, changes in patterns of nutrition and physical activity are regarded as the main drivers of increasing prevalence of diabetes (Yach et al. 2006). Interventions to reduce excess weight through improved diet and physical activity have been shown to prevent progression from the precursor stage of "prediabetes" to diagnosed diabetes and to improve blood lipid and blood pressure levels as well (Diabetes Prevention Program Research Group 2002) (see chapter ▸Epidemiology of Diabetes of this handbook).

52.4.2.9 Smoking and Other Tobacco Use

Cigarette smoking became recognized as a cause of lung cancer in the mid-1960s; only several years later was its causal link with CVD clearly established. More recently still, risk to non-smokers from exposure to tobacco smoke ("secondhand smoke") has become recognized as increasing the risk of acute coronary events (US Department of Health and Human Services 2006). Altogether, the global public health impact of smoking and other tobacco use is in fact several times greater for CVD than for cancer. Smoking becomes a habitual, addictive behavior typically in adolescence, in consequence of the marketing and promotional practices of the tobacco industry. Once addicted, smokers have great difficulty in quitting the habit, and prevention is therefore a high priority in addition to support for smoking cessation (Centers for Disease Control and Prevention 2007). Preventive policies emphasize price increases through taxation to discourage purchase of tobacco products. Systems to facilitate quitting include "quitlines" for telephone contact with personnel trained to support the individual smoker through withdrawal and other obstacles to successful quitting. Community-level or broader laws or regulations promote clean air by restricting smoking in public places, worksites, and other points of exposure (Glantz 2008). Globally, the WHO Framework Convention for Tobacco Control includes many provisions to enable countries to combat the pressures of the tobacco industry to increase the marketing of their products (World Health Organization 2003, 2008). The March 2012 issue of the journal *Tobacco Control* was devoted to a 20-year retrospective on progress in this field and presents numerous perspectives of interest (Tobacco Control 2012).

52.4.2.10 Other Personal Characteristics

Many other personal characteristics have been associated with CVD risk – a 1981 report listed 246 of them, each having been found significantly related to CHD in at least one epidemiological study (Hopkins and Williams 1981). Clearly that number would be far greater today. Three such factors or groups of factors stand out: alcohol consumption, adverse psychological factors, and hemostatic factors. *High alcohol intake* is adversely related to both CHD and stroke. However, the lowest risk of CHD has regularly been found not at the lowest level, but at so-called moderate intake. Interpretation of this pattern has been discussed extensively, and some have advocated low-level alcohol consumption for CVD prevention; official guidelines and recommendations generally avoid such recommendations, rather admonishing those who do use alcohol to do so in moderation, in view of the numerous potential adverse consequences of alcohol use. *Adverse psychosocial factors* of particular interest currently range from feelings of hostility as triggers for acute coronary events to chronic excess of demands over control of one's situation in the workplace. Depression has also become a recognized factor in occurrence of CVD, as has lack of social support from the network in which one lives. *Hemostatic factors* concern the complex interactions of pro- and anti-thrombotic factors that influence formation and resolution of blood clots in the circulation. For example, widespread recommendations for use of aspirin in prevention of CVD events reflect the current understanding of this area. Among other areas of extensive research are inflammation, "novel" markers of risk, and predictive models to assess CVD risk based on multiple baseline factors.

52.4.2.11 Social and Physical Environment

The social and physical environment is distinct from all the foregoing determinants, which are personal characteristics; however, the latter characteristics are largely conditioned by the social and physical environment. The social environment encompasses such aspects as social structure, population diversity, distributions of income and education, and occupational types (World Health Organization 2006). The physical environment may be considered in terms as specific as fine particle air pollution or as broad as the food environment, neighborhood characteristics, transportation systems, walkability as a characteristic of the built environment, and others. These aspects are implicit in Fig. 52.1 above where, in "the present reality," they are reflected in the adverse social and environmental conditions and resulting adverse behavioral patterns that contribute to development of the major CVD risk factors. Alternatively, "a vision of the future" in the figure contemplates social and environmental conditions favorable to health and behavioral patterns that promote health, with consequently reduced risk and rates and severity of CVD events in the population (US Department of Health and Human Services 2003). These determinants of health are addressed in some detail in chapter ►Social Epidemiology of this handbook).

52.5 Causation and Prevention

52.5.1 Overview

Given the plethora of factors possibly associated with the development of CVD, only a few of which are discussed above the question might be posed: Which of these are causal factors? Identifying causes on the basis of associations found in observational epidemiological studies generally rests on the outcome of what might be termed the "differential diagnosis of causation," in three essential steps (Labarthe 2011): (1) Critical assessment identifies apparent or suspected flaws, bias, or confounding that may underlie a spurious association (see relevant chapters in Part II (Methodological Approaches in Epidemiology) of this handbook); (2) statistical assessment addresses the potential role of chance that may produce a chance association (see relevant chapters in Part III (Statistical Methods in Epidemiology) of this handbook); and (3) consideration of several properties of the evidence supports judgment whether an association is best interpreted as causal. The properties to be considered were elaborated through a series of commentaries appearing in the *Journal of Chronic Diseases* in the late 1950s, culminating in a contribution by Sartwell (1959). They became codified especially in the 1964 report on smoking and health in the USA and the paper by Hill that followed (Advisory Committee to the Surgeon General of the Public Health Service 1964; Hill 1965). To the Advisory Committee list, traceable to Sartwell and predecessors (consistency, strength, specificity, temporal relation, and coherence), Hill's list added four others (biological gradient, plausibility, experiment, and analogy).

Such differential diagnosis of causation is not always applied, however, and how many of the 246 factors listed by Hopkins and Williams, cited above, might have passed this more stringent procedure, then or now, is unknown. Even the first reported use of the term "risk factor" noted that evidence was insufficient to conclude that the associations described were causal and that further study was needed (Kannel et al. 1961). Thus, it would be inappropriate to interpret references to "risk factors" throughout the literature of CVD epidemiology as necessarily meaning "causal factors" in the strict sense suggested above. Further, what constitutes a causal explanation of associations between exposures and diseases depends in part on the question being asked. Different questions imply different concepts of causation and require different kinds of causal answers, as follows.

52.5.2 Illustrations

52.5.2.1 Concepts of Causation

One Cause or Many? Conditions such as CHD and stroke are generally accepted to be consequences of multiple factors acting in concert ("multifactorial causation"). Admitting multiple risk factors, however, may deny credibility to any one of them (McCormick and Skrabanek 1988; Stehbens 1992). This view stems from the ancient concept of one "necessary and sufficient cause" as the whole explanation of a phenomenon. This concept was generally abandoned for the chronic diseases during the 1950s and 1960s in the effort to explain the consistently incomplete conjunction of any one exposure and disease. That is, exposure and disease overlap when they are causally related, but neither does every case result from the same exposure nor does exposure uniformly produce the same disease. Models of CVD causation have advanced by taking into account the multivariate setting, in which single causal factors operating together tend to multiply risk above that attributable to the sum of effects of the individual factors. As a result, multivariate risk scores have been calculated for use both as the outcome variable in intervention studies and as a tool for assessing risk of a future CVD event as a basis for deciding whether treatment is warranted (Farquhar et al. 1990; De Backer et al. 2003). Currently the multifactorial view strongly prevails.

One Outcome or Many? A theme of CVD epidemiology in its early years, rediscovered only recently, was that increased susceptibility resulting from any social factor should not be expected to be narrowly specific in its disease expression. Therefore, factors increasing the risk of CHD should be studied as factors in illness generally and not for CHD alone. In this view, causes could have quite varied outcomes, so that a causal model specific to one disease outcome must be inherently incomplete and therefore subject to misinterpretation or misunderstanding. Echoing this theme, Stallones (1980) argued that models of causation that converge on a single disease outcome should be superseded by considering "the interdependence of a number of diseases, characteristics of individuals, and environmental and social variables as elements in a constellation which is *n*-dimensional" (p 76). The tendency to focus on single diseases is yielding in some degree to embracing the NCDs, in part because of the recognized contribution of causal factors for CVDs to other NCDs as well. Wider appreciation of the "*n*-dimensional" constellation of elements in a causal framework is also consonant with the recent resurgence of concepts of "social determinants of health" and "population health."

Immediate Causes or "Fundamental Causes?" Here the argument is that a focus on immediate or proximal causes of disease, and interventions to mitigate their effects, is inherently flawed. For example, high blood pressure may be causally associated with rates and risks of stroke, but to concentrate public health efforts on detection and control of high blood pressure is to miss the greater public health need. This need is to address population characteristics such as poverty, illiteracy, unemployment, and other social ills that would diminish health and well-being by countless other mechanisms, even if high blood pressure was completely removed as a public health problem. The differential diagnosis of causation includes specificity of an association as one consideration, in the sense that an association which uniquely links a particular exposure with a particular disease may more reasonably be thought causal than one in which both the exposure and the disease are related to multiple other conditions. The "fundamental causes" are in principle non-specific and partly for that reason fail to satisfy narrower, more immediate, and disease-specific concepts of "cause."

All Causes or Only a Few? The all-inclusive view of CVD causes recognizes that innumerable factors influence risk, some in adverse and others in protective ways. This view finds excitement in the "emerging risk factors" whose novelty and interest reinforce confidence in the advances of science and the sense of being at the leading edge. In this view, CVD epidemiology may be at the threshold of an era of unprecedented discovery with the advent of population genomics. One causal model for CHD portrays, in one tier, simply "genes"; an indefinitely large array of individual genes is linked through multiple connections from the first to the second tier, a "network of intermediate traits" (hemostasis, lipid metabolism, carbohydrate metabolism, and blood pressure regulation); and these four traits converge to act on the third tier, the "probability of CHD," which is represented graphically as a surface that represents age and environment (Sing et al. 1992). The biological complexity depicted by this scheme represents a rich body of knowledge whose growth is almost inevitable as science advances at all three levels and the connections between them are continually elaborated. And this represents only the convergence of factors on one outcome, not the "*n*-dimensional array" conceived by Stallones (1980).

The "only a few" point of view focuses on only those factors regarded as useful for widespread intervention to arrest and reverse the CVD epidemic around the world. Those few factors, variously termed the major or established or traditional risk factors, consistently include blood lipids, blood pressure, and smoking. Stamler 1992 identifies four factors: "... 'rich' diet, diet-related above-optimal levels of serum total cholesterol (TC) and blood pressure (BP), and cigarette smoking." He explains (p 36):

> All four of these risk factors are designated *established* because substantial amounts of data from many disciplines have demonstrated their significant role in the etiology of epidemic CHD. They are designated *major* for three reasons: their high prevalence in populations, particularly in Western industrialized countries, their strong impact on coronary risk, and their preventability and reversibility, primarily by safe improvements in population lifestyles, from early childhood on. (Age and male gender are known risk factors, but are not amenable to influence and hence are not designated major; diabetes is a known risk factor, but of lower prevalence than cigarette smoking and elevated TC and BP in most populations, and hence is not designated major.) ... "Rich" diet is pivotal among these four – the primary and essential cause of the coronary epidemic.

These two views, all versus few, are commonly seen as conflicting. From the "all" point of view, the "few" perspective ignores evidence for many new and emerging factors and fails to see the potential of genetic epidemiology, for example, to provide invaluable and perhaps radically new insights about causation and prevention of CVD. On the other hand, from the "few" perspective, preoccupation with these factors is a significant and unwelcome distraction from the needed focus on applying knowledge of the major risk factors and research to make that application as effective as possible for prevention. Perhaps from the perspective of "fundamental causes," this polarity of views is irrelevant, as the main issues are the broadest social determinants of health and quality of life, of which CVD is only one aspect.

A resolution of these seemingly conflicting views is found in the point made by Stallones (1980), who suggested that models of causation depend for their value on their utility and that utility depends in turn on the purpose for which a model is used. If the dual purposes of intellectual pursuit and public health practice are accepted as complementary in CVD epidemiology and prevention, the views of "all" and "few" can both be embraced. "Epidemiology and public health have the luxury as well as the necessity of entertaining both views of causation in pursuit of the complementary purposes of advancing knowledge and serving the health of the public" (Labarthe 1998, p 463).

Causes of Cases or Causes of Incidence? This last contrast addresses a distinction between two kinds of causal questions posed by Rose (1985, p 33):

> The first seeks the causes of cases, and the second seeks the causes of incidence. "Why do some individuals have hypertension?" is a quite different question from "Why do some populations have much hypertension, whilst in others it is rare?" The questions require different kinds of study, and they have different answers.

The distinction emphasizes that what appear to be causal factors (from studies of individual risks within populations) may instead be only markers of susceptibility to true causal factors to which exposure is very common throughout the population and that detection of true causal factors requires comparison of populations with different incidence rates to identify the determinants of those differences. As with each of the preceding contrasts, this distinction relates closely to concepts of prevention and has direct implications for thinking about individual and population-wide levels of intervention.

52.5.2.2 Concepts of Prevention

As the foundation of epidemiological knowledge about CVD expanded, recommended approaches to CVD prevention evolved correspondingly. For example, under the aegis of the former WHO Cardiovascular Disease Unit, expert meetings were convened on many occasions from the 1960s through the mid-1990s to address CHD prevention, primary prevention of hypertension, prevention in childhood and youth of adult CVD, and other topics. Official recommendations and intervention guidelines have been developed by such national organizations as the American Heart Association and American College of Cardiology and the US National Heart, Lung, and Blood Institute and at a regional level by such joint efforts as those of the European Society of Cardiology, the European Atherosclerosis Society, the European Society of Hypertension, and the South Asian Association for Regional Cooperation.

Concepts of prevention reflected in these many recommendations and guidelines often embrace two broad approaches articulated in the early 1980s by Rose (1981) – the individual (or high-risk) approach and the population-wide approach. The first approach addresses reduction of risk for cardiovascular events among persons with already manifest CVD or risk factors, and the second addresses risk factor reduction across the whole population. These two approaches are complementary. "The 'high-risk' strategy of prevention is an interim expedient, needed in order to protect susceptible individuals, but only for so long as the underlying causes of incidence remain unknown or uncontrollable; if causes can be removed, susceptibility ceases to matter" (Rose 1981, p 38).

The high-risk approach has been considerably refined so as to identify, on the basis of multiple factors (such as sex, current smoking, age, systolic blood pressure, and total cholesterol concentration), persons whose combined risk characteristics predict a specified probability of a major cardiovascular event within the ensuing 10 years (De Backer et al. 2003). Based on such scoring, policy decisions are made regarding which interventions will be recommended, and perhaps financed, for which risk levels.

The population-wide approach has evolved to include not only interventions to shift unfavorable distributions of the major risk factors across the whole population but also prevention of adverse levels and distributions of these risk factors in the first place, in populations where this remains possible. This latter concept of "primordial prevention" contemplates prevention of risk factor epidemics themselves as an essential approach to CVD prevention, especially in developing countries (Strasser 1978).

The high-risk approach to risk reduction as conceived by Rose (1981) would today encompass both secondary prevention (applied to individuals already manifesting CHD or stroke) and primary prevention (applied to individuals at high risk but without manifest CVD). The population-wide approach to risk reduction would consist of that part of primary prevention applied to the population as a whole; it may be complemented by prevention of risk factors in the first place (primordial prevention). Broadly these may be contrasted as "remedial" and "primordial" strategies, for CVD prevention and cardiovascular health promotion, respectively (Labarthe and Dunbar 2012).

In relation to the intervention approaches represented in Fig. 52.1, the remedial strategies extend from risk factor detection and control through end-of-life care at the individual level and include the population-level approaches, from policy and environmental change through behavior change, insofar as these are undertaken to reverse already increased risk. The primordial strategies, for health promotion, are also population-wide, undertaken with the intent to preserve cardiovascular health by fostering favorable social and environmental conditions and health behaviors.

The scope of CVD prevention and relevance of this framework for public health action take added meaning from the heightened appreciation of the collective global burden of NCDs, beyond CVDs alone (United Nations General Assembly 2011). Both the case for prevention and estimates of the health impact of strategic interventions gain substantially from this more inclusive perspective.

52.5.3 The Role of Trials

Epidemiological evidence for causation of CVD has come primarily from observational studies and has sometimes been supported indirectly by experimental studies in which exposure to suspected factors has been reduced by intervention. The balance of evidence for causation is heavily weighted toward observational studies. How is evidence for CVD prevention obtained? Evidence from observational studies may be considered sufficient to establish causation, but different requirements are often, perhaps typically, applied to prevention – primarily experimental evidence of the efficacy and safety of a proposed intervention.

This question thus calls attention to the role of trials or, more broadly, intervention studies. These studies encompass a wide variety of study questions and designs and include clinical trials of secondary or primary prevention, population-based trials of primary prevention or health promotion, and community demonstrations of intervention that may include combinations of health promotion, primary prevention, and secondary prevention. It is beyond the scope of this review to detail the evidence for prevention; such commentaries are available elsewhere (Blackburn 1992; Labarthe 2011). It is useful, however, to summarize briefly the general types of intervention studies on which CVD prevention is based (see chapters ▶Intervention Trials, ▶Confounding and Interaction, and ▶Epidemiological Field Work in Population-Based Studies of this handbook):

- The great preponderance of experimental studies in CVD prevention have been *clinical trials in secondary prevention*. These are designed to test the efficacy and safety of individual-level interventions to prevent recurrent CVD events or related outcomes among survivors of first events or persons otherwise known to have preexisting CVD. The typical multicenter organization of such trials, the recruitment and enrollment of hundreds or thousands of participants, and the multi-year periods of follow-up combine to make these studies epidemiological in scale, even though they may be altogether clinically based and not referable to any definable population beyond the participating institutions.
- *Primary prevention trials* are designed to test the efficacy and safety of individual-level interventions, but the participants are initially free of known CVD. The outcome is usually the first qualifying CVD event, be it an acute coronary event, stroke, or other defined outcomes, depending on the question under study. For example, in studies of primary prevention of high blood pressure, progression of blood pressure levels may be the outcome of interest. Study participants may be identified in clinical settings or drawn from defined communities, as volunteers or through systematic sampling, such as from work sites or geographical residential areas. Eligible participants must be apparently well, so only interventions relatively free of known adverse effects or other impediments to long-term adherence to study treatment guidelines are good candidates for evaluation. Because participants' average risk of CVD outcomes is relatively lower in primary than in secondary prevention trials, thousands of participants and follow-up periods of several years are typically needed to observe a sufficient number of outcomes for satisfactory analysis.
- *Community trials* in CVD prevention are used to study intervention in whole populations defined by geographical area of residence, place of work, or otherwise. If insufficient numbers of study units such as schools or factories are involved to permit true random allocation, as is usually the case, the term "quasi-experimental study" is sometimes used. Systematic comparison among similar communities with and without intervention is still implied, even if the number of intervention and comparison units is small. Fatal or non-fatal CVD events could be the primary endpoint in such trials, but these studies are often designed to address risk factors or behavioral outcomes instead. The choice of interventions shares the same considerations as described for primary prevention trials.
- A *community demonstration* of intervention represents a distinct shade of meaning from "community trials" in that intervention may be implemented in a single community, with or without a control community for comparison. Community

demonstrations may combine multiple intervention strategies into a secondary and primary prevention program to influence individuals' practices as well as community-wide aspects whose target is the population as a whole. Evaluating the impact of such an intervention may be based on CVD events, but practical constraints often arise. Evaluation may therefore be limited to the procedures by which the intervention was delivered and such proximate outcomes as changes in behavior or risk factor levels.

Analogous to the question of causation in epidemiological studies is the question whether a given intervention actually produces the intended outcome. The most convincing evidence comes from well-designed and properly conducted randomized trials; however, population-wide public health interventions may only rarely be amenable to evaluation through studies of this kind. This circumstance leads to the seeming dilemma of holding population-wide interventions to a standard of evidence that can rarely, if ever, be attained in practice and therefore giving rise to the perception that population-wide interventions are only rarely, if ever, scientifically justified. However, the essence of the question for a proposed public health intervention is whether it is better supported by all the relevant scientific evidence than is the status quo, as represented by current conditions or policies. If so, intervention would be appropriate if other due considerations were met, and rigorous evaluation of the intervention's effect once implemented could provide further evidence as to its benefit, cost-effectiveness, and long-term feasibility.

Among a great many potential examples of intervention studies, one with broad implications for prevention policy is especially convenient for illustration. The North Karelia Project provides a classic example; detailed published accounts of its organization, design, implementation, and evaluation are provided elsewhere (Vartiainen et al. 1994; Puska et al. 1998; Puska 2002).

As shown in Fig. 52.2, Finnish men experienced exceptionally high CHD mortality that had increased sharply in the 1950s. Since 1959, studies in Eastern and Western Finland as part of the Seven Countries Study had documented the problem in some detail and confirmed the highest CHD rates to be in Eastern Finland. Concern about this led to implementation in 1972 of a multifaceted community-based prevention project in which North Karelia (population 210,000) and Kuopio (population 250,000), both in Eastern Finland, would be intervention and control communities, respectively. Among the many components of the project were programs targeting high blood cholesterol concentration, high blood pressure, and smoking. Extensive community involvement and engagement with health services were major aspects of these programs. Risk factor distributions and other characteristics in both communities were assessed by sample surveys among adults aged 30 to 59 years in 1972 and every 5 years until 1992, and mortality was monitored from 1969 to 1992.

Twenty-year changes in risk factors for women included reductions in cholesterol concentration by 18% and in diastolic blood pressure by 13%, while smoking increased from 11% to 25%. Corresponding changes for men were reductions of 13% and 9% and a decrease in smoking from 53% to 37%. Changes in dietary habits and physical activity underlying the change in risk factor distributions have also been described.

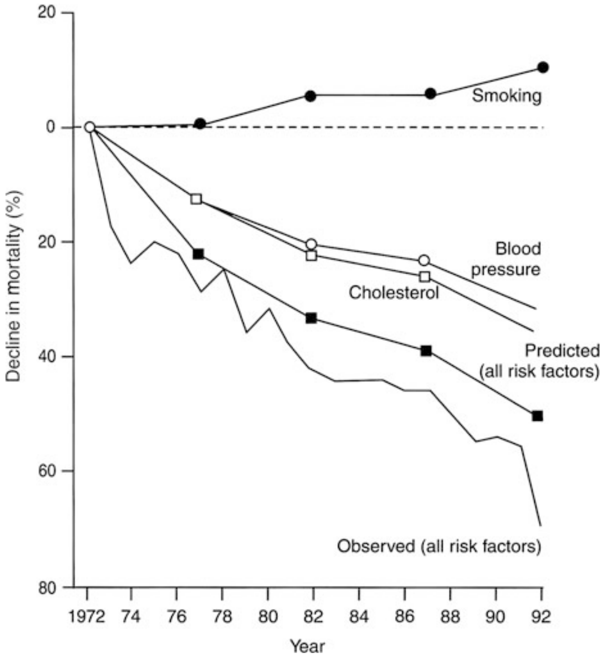

Fig. 52.3 Observed and predicted decline in mortality from ischemic heart disease in women aged 35–64 in Finland (Source: Vartiainen et al. 1994)

Changes in CHD mortality were predicted from the actual risk factor distributions observed in the serial cross-sectional surveys. These results are displayed in Fig. 52.3 for women and Fig. 52.4 for men. The predicted mortality effects of change in each risk factor separately and together are shown in each figure, as well as the observed decrease in mortality (by 68% for women and 55% for men) which closely paralleled but actually exceeded the cumulative predicted changes.

What was the contribution of intervention to these changes? Changes in risk factors were greater in the intervention area, North Karelia, than in the control area, Kuopio, only in the first 5 years; thereafter, they were similar. Change in mortality was not limited to the study areas: Overall, in the whole of Finland, CHD mortality declined by 50% from 1970 to 1992 and stroke mortality declined markedly. Interpretation of the effect of intervention in North Karelia is conditioned by the study design (comparison of two selected communities and not a randomized trial in a large number of communities), but the investigators addressed these issues and supported the conclusion that the mortality decline was a direct consequence of the risk factor changes (Vartianinen et al. 1994; Puska et al. 1998). That the project began to influence policy nationwide after its first 5 years probably accounts for the broader evidence of risk factor and mortality change in Finland as a whole that has continued to the present and makes it difficult to isolate the intervention effects to North Karelia alone. It was recognized that improvements in treatment of coronary

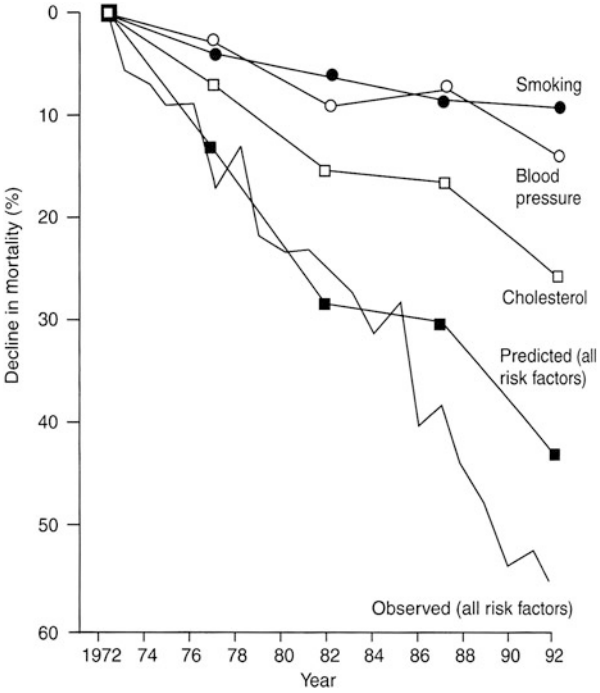

Fig. 52.4 Observed and predicted decline in mortality from ischemic heart disease in men aged 35–64 in Finland (Source: Vartiainen et al. 1994)

events could also have contributed, a factor that would be evaluated further with Finland's participation in the WHO MONICA Project.

From the perspective advanced by Rose (1981), the Finnish experience supports the view that the major determinants of incidence have been identified, and population-wide efforts to modify these determinants have made it possible to prevent the mass occurrence of CVD in whole populations. At the broadest level of community change and population-wide intervention, coupled with health-care system interventions to improve services for risk factor detection and control, the North Karelia Project is a powerful demonstration of the potential for an integrated, coordinated, and sustained public health effort to affect the major cardiovascular conditions of our time, CHD and stroke.

52.6 Research Needs

This chapter has focused on knowledge of the epidemiology of CVD based on decades of research through application of the methods outlined above, under "Scope and Basic Concepts." It would be incomplete without reference to current and future research needs, in terms of potential topics as well as infrastructure requirements. Among the many topics that could be considered in relation to research priorities in CVD prevention and cardiovascular health promotion, from the public health perspective, two questions are selected for emphasis here, with additional attention to questions of research capacity and organizational arrangements for research.

52.6.1 How Can Healthy Dietary Patterns for All Be Achieved?

Food production, distribution, accessibility, price, and choice must be aligned with nutritional requirements for good health, including cardiovascular health, if the burden of CVD and other NCDs is to be reduced, from local to national, regional, and global levels. Research is needed to monitor changes in the food supply, content of specific food products (e.g., sodium), and patterns of food consumption at the population level, over time. The roles and strategies of multinational food corporations must be better understood and anticipated in order for effective policy initiatives to be developed by responsible governmental agencies and interested private organizations. At the same time, factors that more immediately influence what people consume – within the range of available choice – must also be considered. In sum, research is needed to evaluate comprehensively policies, programs, and practices designed to overcome widely prevalent dietary imbalance. To the extent that this is unfamiliar ground to epidemiologists, collaboration with others is required.

52.6.2 How Can Cardiovascular Health Be Preserved from Childhood Onward?

Atherosclerosis begins in childhood and youth, and the major risk factors – high cholesterol concentration, high blood pressure, and smoking – contribute beginning from adolescence or earlier (Berenson 1986; Mahoney et al. 1991). Further, retaining low CVD risk at middle age greatly reduces morbidity in later years (Stamler et al. 1999; Lloyd-Jones et al. 2006). Yet this knowledge has failed to stimulate the needed programs on a sufficient scale to avert development of risk factors and subclinical disease in the whole population. Guidelines to address CVD risk factors in early life have been published repeatedly, but few large-scale programs have been mounted to assess the impact of the recommended interventions (World Health Organization Expert Committee 1990). The recent focus of the American Heart Association and others on improving cardiovascular health of the population has called attention to the measurable *loss of cardiovascular health* beginning in childhood (Roger et al. 2011). Therefore, the need to continue to advance policy development in CVD prevention seems clear, and research in this area – beginning with implementation and evaluation of currently available approaches – is a high priority.

New approaches, building on recent work in positive health, may offer additional insights into potential interventions to preserve cardiovascular health from childhood onward (Boehm and Kubzansky 2012). The question of how important maternal and fetal influences are on development of CVD, from risk factor levels in childhood to overt CVD in adults, continues to be debated (see Barker 1992, 1998). In view of the potential impact on health generally as well as CVD in particular, resolving this question by conducting trials of optimum nutritional and other supportive maternal care, coupled with postnatal nutrition to evaluate benefits on metabolic and physiologic mechanisms involved in later risk factor development, is important.

52.6.3 How Can Research Capacity Be Increased?

The need for applied research in CVD epidemiology far exceeds current capacity. This is due in part to the persistence of CVD as leading cause of death throughout the world and forecasts for its continuation in this position at least through the next two decades. Training and engagement in substantial epidemiological research projects and programs, as well as ongoing and expanding activities in monitoring and surveillance, are essential for building this capacity. A model program for such training is illustrated by the International Ten-Day Teaching Seminars on Epidemiology and Prevention of Cardiovascular Diseases, a program now in its 37th year, and sponsored principally by a local host in various countries, year by year (Labarthe et al. 1998). Other international training programs (such as that conducted in developing countries under the auspices of the Department of Social and Preventive Medicine, University of Lausanne) offer additional models, all of which should be replicated many times over to reach much-increased numbers of health professionals. It is of course also necessary to develop funded research to provide settings where trained epidemiologists and others in CVD prevention can do the needed work, extend their skills, and provide mentorship and training to others.

52.6.4 What Organizational Arrangements Are Required?

The role of supporting organizations and agencies in CVD epidemiology and prevention has been critical in the past and may be even more so in the immediate future. WHO, WHF, the World Bank, the Global Forum for Health Research, and other agencies with global reach are essential partners for the kind of network cited by WHO Director-General Brundtland in her proposed global strategy for NCD prevention and control (World Health Organization 1999). National organizations in many countries are also important. In the United States, for example, the National Center for Chronic Disease Prevention and Health Promotion of the Centers for Disease Control and Prevention, Department of Health and Human Services, is committed to global health efforts. This interest is an integral part of *A Public Health Action Plan to Prevent Heart Disease and Stroke* (US Department of Health and Human Services 2003), source of Fig. 52.1 above, which provides for regional and global partnerships in cardiovascular health in pursuit of common aims and in the expectation of mutual gain from sharing information and experience. Out of this *Action Plan*, a public-private partnership organization emerged, the National Forum for Heart Disease and Stroke Prevention (2012, see www.nationalforum.org). Guided by this framework, the National Forum sets priorities and advocates for policy development in such areas as addressed here. Potentially through implementation of a nascent Policy Depot for sharing CVD-related policy interests globally, the National Forum can contribute to support of epidemiological research on the global level (Mason et al. 2012).

52.7 Conclusions

Having discussed potential determinants, approaches for prevention, and the priorities in the research of CVD, one question remains to be addressed: *How can epidemiology contribute to societal change?* CVD epidemiology over the past half century has established understanding of the causes of epidemic CHD and stroke as well as strategies to prevent these diseases. The challenge that lies immediately ahead is to apply this knowledge effectively to the benefit of the world's population. Societal change is needed to achieve the goals of longer, healthier life free of significant disability due to CVD and other NCDs and free of disparities in the occurrence of these conditions within and among countries. Societal change will occur regardless whether epidemiology and public health are considered, as change is a continuing – albeit sometimes fitful and unpredictable – process with its own powerful impetus from many sources. But change that is best will be informed and influenced by knowledge of consequences for CVD, for other NCDs, and for health generally. Positive change can be accomplished best to the extent that epidemiologists and others who hold that knowledge contribute to the direction of this change.

53.1 Introduction

Cancer encompasses a family of several hundreds of diseases which are distinguished by site, morphology, clinical behavior, and response to therapy. Whether considered from a biological, a clinical, or a public health point of view, it is the malignant and invasive nature of many of these diseases and their ability to spread to distant organs (metastasis) that are of dominant importance.

Although the words “cancer” and “carcinoma” refer to malignant tumors arising from epithelial tissues, they are often used to include all malignant neoplasms. These are characterized by progressive and variable growth of tissue with structural and functional changes with respect to the normal tissue. In many cases, the alterations can be so important that it becomes difficult to identify the organ or the tissue of origin.

Knowledge about the causes of and the possible preventive strategies for malignant neoplasms has greatly advanced during the last decades. This was largely due to the findings from cancer epidemiology. In parallel to the identification of the causes of cancer, primary preventive strategies have been developed. Secondary preventive approaches have also been proposed, and, in some cases, they have been shown to be effective. A careful consideration of the achievements of cancer research, however, suggests that the advancements in knowledge about the causes of cancer have not been followed by an equally important reduction in the burden of cancer. Part of this paradox is explained by the long latency occurring between exposure to carcinogens and development of the clinical disease. Changes in exposure to risk factors are not followed immediately by changes in disease occurrence. The main reasons for the gap between knowledge and public health action rest with the cultural, societal, and economic aspects of exposure to carcinogens.

53.2 Scope and Approaches of Cancer Epidemiology

Cancer epidemiology investigates the distribution and determinants of the incidence, mortality, and prevalence of cancer in human populations (Lagiou et al. 2008). Many approaches have been used in cancer epidemiology which can be classified according to different dimensions, as shown in Table 53.1. Although most studies in cancer epidemiology are observational in nature, intervention (experimental) studies are conducted to evaluate the efficacy of prevention strategies, such as screening programs and chemoprevention trials (clinical trials are usually considered to be outside the scope of cancer epidemiology). Observational studies are traditionally classified in descriptive, analytical (or etiological), and ecological studies (for a detailed description of the different types of epidemiological studies, see chapters ►Descriptive Studies, ►Cohort Studies, ►Case-Control Studies, ►Modern Epidemiological Study Designs, ►Intervention Trials, and ►Use of Health Registers of this handbook).

Table 53.1 Approaches used in cancer epidemiology

Dimension	Approaches	Examples
Nature of observation	Experimental	Chemoprevention trial
	Observational	Cohort study
Purpose of investigation	Description	Time-trend analysis
	Etiological research	Case-control study
	Evaluation	Community trial of screening modalities
Unit of observation	Grouped data	Ecological study of environmental exposure
	Individual data	Case-control study with questionnaire data
Sampling strategy[a]	Census-based	Cohort study
	Sample-based	Case-control study
Source of information on exposure	Routine collection	Record-linkage study
	Ad hoc collection	Questionnaire-based study

[a] In studies based on individual data

Descriptive cancer epidemiology is a particularly flourishing branch of the discipline, thanks to the availability of high-quality population-based cancer registries in many areas of the world and to the possibility to use mortality data to estimate the incidence of highly lethal cancers. As an illustration, Fig. 53.1 shows the estimated incidence of cancer among women in all countries of the world: these estimates are derived from cancer registries and mortality statistics. Although subject to various sources of error, such estimates are more precise than those available for any other chronic disease. A useful distinction of etiological studies concerns the nature of the information on exposure: while some studies use data routinely collected for other purposes, such as census records and hospital files, in other circumstances, ad hoc information on exposure is collected following a variety of approaches, including record abstraction, questionnaires, pedigree reconstruction, environmental monitoring, and measurement of biological markers.

Given the importance of cancer in high-income countries and the efforts to prevent it, cancer epidemiology has acquired a recognized status in medicine and has developed into a separate profession. For this reason, and thanks to the availability of high-quality data on the outcomes of interest, it has played an important role in the development of modern epidemiology. The criteria for causal inference in observational research (with the corollary of methodological studies on bias, confounding, and statistical power) have been largely shaped following the discovery of the important role of tobacco smoking as a human carcinogen (Doll 1998), modern statistical approaches such as multivariable logistic and Poisson regressions have originally been proposed for use in cancer studies (Breslow and Day 1980, 1987, see also chapter ▶Regression Methods for Epidemiological Analysis of this handbook); molecular epidemiology has developed as a discipline

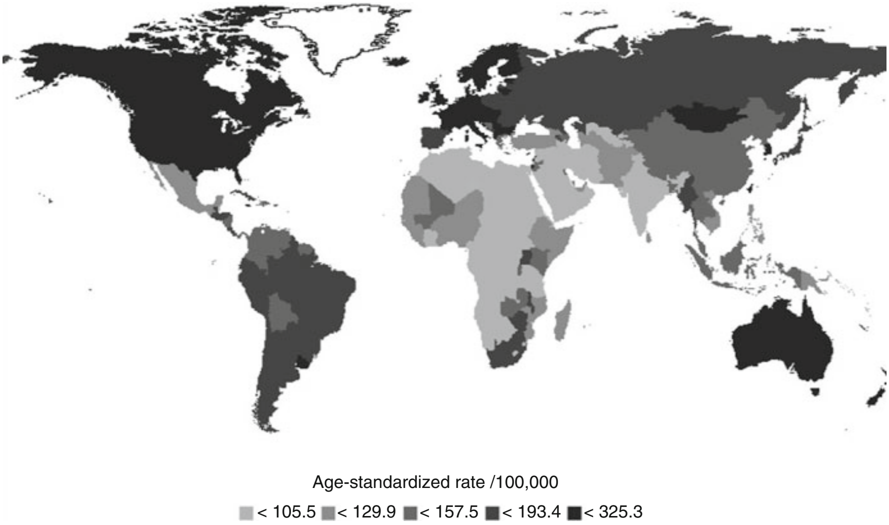

Fig. 53.1 Estimated incidence rate of cancer in women, by country (year 2008) (From Ferlay et al. (2010))

bridging different areas of cancer research (Rothman et al. 2012; see also chapter ▶Molecular Epidemiology of this handbook), and methodological advances in genetic epidemiology have stemmed from familial studies of cancer (Thomas 2000; see also chapter ▶Statistical Methods in Genetic Epidemiology of this handbook).

53.3 The Global Burden of Cancer

The number of new cases of cancer that occurred worldwide in 2008 has been estimated at about 12.7 million (Table 53.2) (Ferlay et al. 2010), including 5.3 million in men and 4.7 million in women. About 5.6 million cases occurred in high-income countries (North America, Japan, Europe including Russia, Australia, and New Zealand) and 7.1 million in middle- and low-income countries. Among men, lung, prostate, colorectal, stomach, and liver cancers are the most common malignant neoplasms (Fig. 53.2), while breast, colorectal, cervical, lung, liver, and ovarian cancers are the most common neoplasms among women (Fig. 53.3).

Such global statistics are of limited interest, given the complexity of the factors affecting the risk of each neoplasm, and the reader is referred to specialized publications for a more detailed review (Jemal et al. 2011). Some general trends can however be identified:

- A decrease in stomach cancer incidence in most countries
- A decrease in the incidence of lung cancer and, to some extent, other tobacco-related cancers among men from high-income countries and a

Table 53.2 Estimated number of new cases of cancer (incidence) and of cancer deaths (mortality) in 2000, by sex and type of country (Ferlay et al. 2010)

	Men	Women	Total
Incidence			
High-income countries	2,964,000	2,591,000	5,555,000
Low-/medium-income countries	3,654,000	3,454,000	7,107,000
Total	6,618,000	6,045,000	12,663,000
Mortality			
High-income countries	1,522,000	1,222,000	2,745,000
Low-/medium-income countries	2,697,000	2,123,000	4,820,000
Total	4,219,000	3,345,000	7,565,000

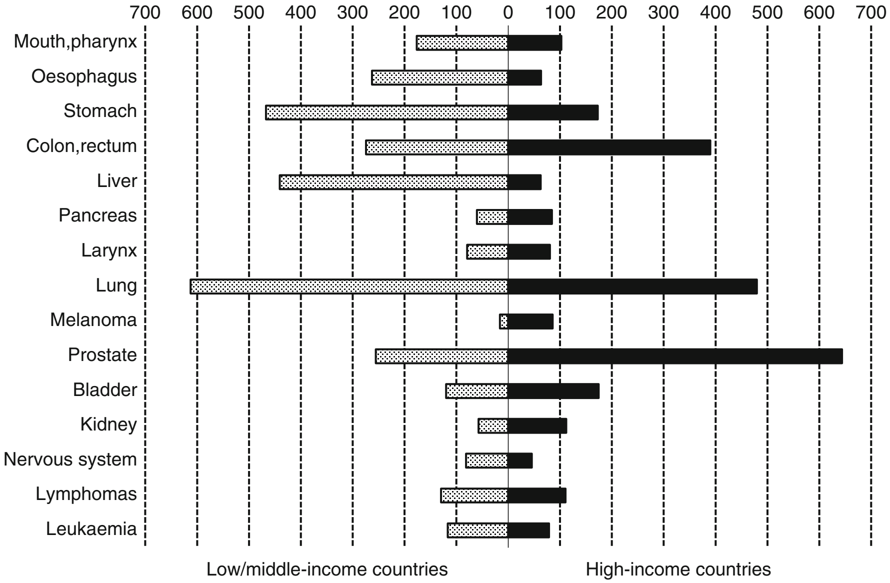

Fig. 53.2 Estimated number of new cancer cases (×1,000) in men (year 2008) (From Ferlay et al. (2010))

corresponding increase among men in middle- and low-income countries and women in high-income countries

- An improvement in survival from low-lethality cancers (e.g., prostate and breast cancer) and a very modest improvement in survival for highly lethal cancers (e.g., esophageal, lung, and liver cancer)

The number of deaths from cancer was estimated at about 7.6 million in 2008 (Table 53.2) (Ferlay et al. 2010). No global estimates of survival from cancer are available: data from selected registries suggest wide disparities between high- and middle-/low-income countries for neoplasms with effective but expensive treatment, such as leukemia, while the gap is narrow for

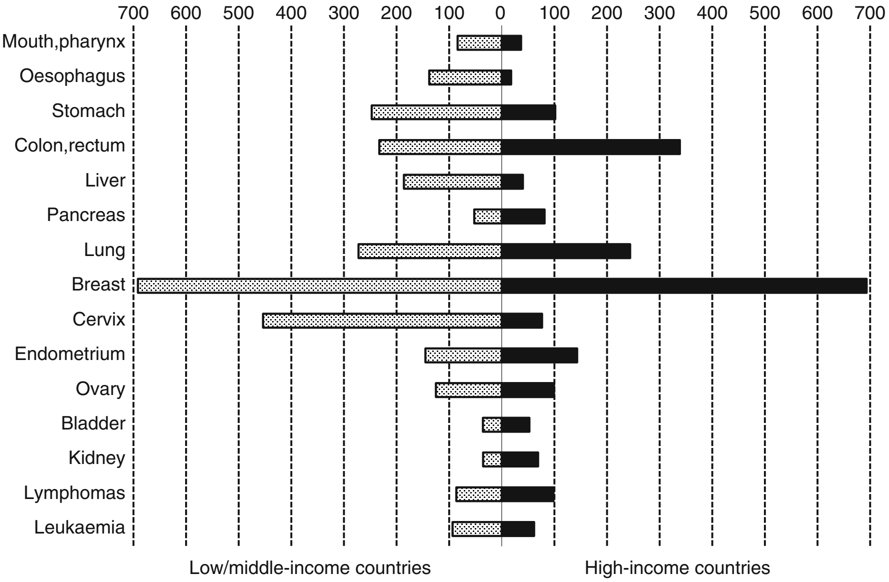

Fig. 53.3 Estimated number of new cancer cases (×1,000) in women (year 2008) (From Ferlay et al. (2010))

neoplasms without an effective therapy, such as lung cancer (Sant et al. 2009; Sankaranarayanan et al. 2011) (Fig. 53.4). The overall 5-year survival of cases diagnosed during 1995–1999 in European Union countries was 50.3% (Sant et al. 2009).

53.4 Causes and Prevention of Human Cancer

In the following sections, the current knowledge about the risk factors and the strategies for primary and secondary prevention of cancer is summarized. For more details, the reader is referred to systematic reviews (Adami et al. 2008; Schottenfeld and Fraumeni 2006).

Several authors have provided estimates of the contribution of known causes to the cancer burden (e.g., Doll and Peto 1981, 2005; HCCP 1996; Boffetta et al. 2009; Parkin et al. 2011; Wang et al. 2012). Such estimates are subject to assumptions and uncertainties and should be interpreted as approximations. In particular, some estimates aimed at attributing all cancers between different causes (e.g., HCCP 1996), while others restricted the exercise to established causes, leaving a substantial fraction of cancers unexplained (e.g., Boffetta et al. 2009; Wang et al. 2012). Table 53.3 shows the results of some of these reviews. It is worth noting that the estimate of the relative importance of the major causes of cancer (e.g., tobacco smoking)

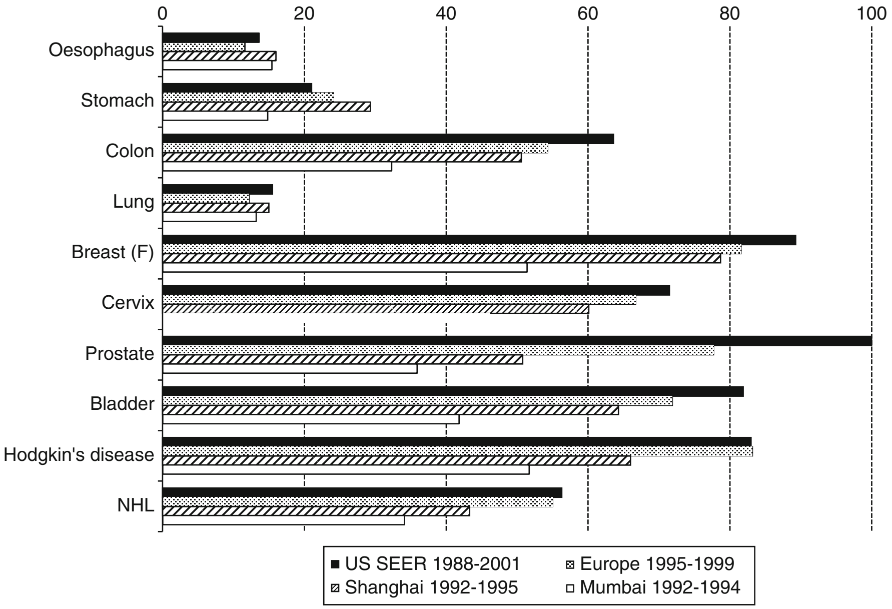

Fig. 53.4 Five-year relative survival (%) from selected cancers (From Ries et al. (2007), Sant et al. (2009), and Sankaranarayanan et al. (2011))

Table 53.3 Selected quantifications of the contribution of major causes to human cancer burden (attributable fractions in percent)

Cause	Boffetta et al. (2009) (France)	Doll and Peto (2005) (UK)	Wang et al. (2012) (China)

is fairly consistent. The major role played by infectious agents in China (Wang et al. 2012), as well as in other low- and middle-income countries (de Martel et al. 2012), is an important feature of the important global cancer burden (see Sect. 53.4.7).

53.4.1 Tobacco Smoking

Tobacco smoking is the main single cause of human cancer worldwide. It is a cause of cancers of the oral cavity, pharynx, esophagus, stomach, liver, pancreas, nasal cavity, larynx, lung, cervix, kidney and bladder, and of myeloid leukemia (IARC 2003). It is commonly considered that tobacco smoking causes up to one-third of human cancers (Table 53.3); a detailed review of the number of cancers attributable to tobacco smoking in 1985, which was based on very strict criteria for attribution of cases, resulted in the estimate of at least 15% (Parkin et al. 1994), corresponding to about 1.9 million new cases per year. The estimates were 25% in men and 4% in women, and, in both sexes, they were 16% in developed countries and 10% in developing countries. The low attributable risk in women (and, to a lesser extent, in developing countries) is due to the low consumption of tobacco in past decades: the recent upward trend that has taken place among women and in many developing countries will obviously result in a much greater number of cancers in the future.

The risk of tobacco-related cancers among smokers relative to non-smokers depends on the different characteristics of the habit; in Table 53.4 are reported relative risks found for ever-smokers in Europe and North America. In different populations, risk estimates have been produced for increasing levels of duration and amount of tobacco smoking: in general, a separate effect has been shown for both dimensions of smoking, with a stronger role of the former (USDHHS 2004).

Table 53.4 Relative risk of current smoking and proportion of cancer attributable to tobacco smoking

		Attributable risk (%)[b]	
Cancer	Relative risk for current smoking[a]	Men	Women
Oral cavity	3.4	63	21
Pharynx	6.8	76	47

Myeloid leukemia	1.1	N/A	N/A

N/A not available

[a] Gandini et al. (2008)

[b] Boffetta et al. (2009)

The effect of duration of smoking on the risk of smoking-related cancers, and of lung cancer in particular, is so strong that it is difficult to determine whether there is an independent contribution of other factors, such as age and age at starting smoking. Smoking of filtered cigarettes and cigarettes with reduced tar content results in a lower risk of lung and other cancers than smoking of cigarettes without filter and with high tar content, although by no means, the former products should be seen as “risk-free” (USDHHS 2004). Smoking of black tobacco cigarettes appears to entail a higher risk of most smoking-related cancers than smoking of blond tobacco cigarettes. A carcinogenic effect of cigar and pipe smoking has been demonstrated for cancers of the oral cavity, pharynx, larynx, lung, and bladder. Similarly, smoking of local tobacco products, such as hookah in North Africa and West Asia and bidis in South Asia, entails an increased risk of cancer of the lung and other organs.

A benefit of quitting tobacco smoking in adulthood has been shown for most cancers causally associated with the habit. This result emphasizes the need to devise anti-smoking strategies that address avoidance of the habit among the young as well as reduction of smoking and quitting among adults. There is strong evidence of a protective effect of quitting smoking at any age (Peto et al. 2000). The decline in tobacco consumption that has taken place during the last 20 years among men in North America and several European countries, and which has resulted in decreased incidence of and mortality from lung cancer, has resulted primarily from the increase in the number of smokers quitting at middle age.

With the identification of tobacco as a carcinogen for the lung, the causal nature of an association between a chronic disease and a risk factor was for the first time established beyond doubt, representing an important contribution to the development of epidemiology. The association was replicated in various populations, using different approaches, namely, cohort and case-control studies. This discovery was facilitated by several aspects of tobacco smoking: firstly, it is a potent carcinogen, containing – at high concentrations – several agents acting on different stages of the carcinogenic process; secondly, a sizable group in most populations is composed of heavy smokers, exposing themselves to high doses; and thirdly, exposure is easier to quantify compared to most other agents, since smokers can report with a good degree of precision their present and past consumption.

53.4.2 Use of Smokeless Tobacco Products

There is strong epidemiological evidence that use of smokeless tobacco products is associated with an increased risk of head and neck cancer (Boffetta et al. 2008a). Chewing of tobacco-containing products is particularly prevalent in Southern Asia, where it represents a major cause of cancer of the oral cavity, pharynx, esophagus, and larynx, either alone or in combination with smoking. An increased risk of pancreatic cancer has also been suggested.

53.4.3 Dietary Factors

Despite considerable research efforts in cancer epidemiology, the exact role of dietary factors in causing human cancer remains largely obscure. The World Cancer Research Fund (WCRF 1997, 2007) has published two systematic reviews of the evidence of an association between intake of foods, food groups and nutrients, and different cancers. The second set of evaluations are summarized in Table 53.5. In general, according to WCRF, there are few evaluations of convincing evidence: for fruits and vegetables, the evidence was considered suggestive only for cancers of upper digestive organs and lung. In recent years, the evidence has grown for a carcinogenic role of excess caloric intake, disregarding the source of calories, resulting in overweight and obesity (see Sect. 53.4.4).

The mechanisms of dietary-related carcinogenesis are not well understood. Dietary factors may play a role in most if not all steps of the process, including genotoxicity, interference in the metabolism of other carcinogens, methylation of cancer genes, alteration of DNA repair and apoptotic mechanisms, alteration of DNA and cell replication, and cell proliferation (for a review, see WCRF 2007). In particular, it is plausible that nutrients in fresh fruits and vegetables act at least in part via control of endogenously formed radical oxygen species. In addition, insulin and insulin-like Growth Factor-I (IGF-I), which are linked to caloric intake from diet, may inhibit apoptosis and stimulate cell proliferation (see Sect. 53.4.11).

Several suspected dietary carcinogens have been widely studied in cancer epidemiology. Grilled and barbecued meat and fish contain carcinogenic polycyclic aromatic hydrocarbons and heterocyclic amines: high intake of these foods has been

Table 53.5 Assessment of associations between dietary factors and human cancer (WCRF 2007)

Factor (high intake)	Oral cavity, pharynx, larynx	Esophagus	Stomach	Colon, rectum	Lung	Prostate
Non-starchy vegetables	(−)	(−)	(−)			
Allium vegetables			(−)	(−)		
Fruits	(−)	(−)	(−)		(−)	
Red meat				+		
Processed meat				+		
Maté		(+)				
Salt			(+)			
β-carotene					(+)	
Lycopene						(−)
Selenium						(−)
Calcium				(−)		

Direction of the effect: + increased risk; − decreased risk

Strength of the evidence: *no brackets*: convincing evidence of an association; *brackets*: possible association suggested to increase the risk of stomach and colorectal cancer. Similarly, high intake of cured and processed meat is a probable cause of digestive tract cancer: nitrosamines might be among the relevant carcinogens. High intake of salt probably increases the risk of stomach cancer, and that of fermented fish (e.g., Cantonese-style salted fish) may increase the risk of cancer of the nasopharynx (WCRF 2007).

In several areas of Asia and Africa, high incidence of liver cancer is due to food contamination by mycotoxins, including aflatoxins (WCRF 2007). In Central Europe, a chronic renal disease called Balkan endemic nephropathy has been described, which is associated with an increased risk of kidney cancer and is due to contamination of foodstuff with aristolochic acid, derived from herbs of the *Aristolochia* genus (Grollman et al. 2007). The same agent is responsible for kidney cancer in Taiwan and China, where exposure occurs mainly as result of use of traditional herb-based medicines (Chen et al. 2012).

Intake of large amounts (more than 1 liter per day) of hot maté, a herbal tea, is a possible risk factor for esophageal cancer in Southern Brazil, Uruguay, and Northern Argentina (WCRF 2007). It is unclear, however, whether the effect is due to components of maté or to the high temperature: studies from other regions suggest that intake of hot beverages (e.g., hot tea in Iran, Singapore, and Japan; hot coffee in Puerto Rico; and hot drinks or soups in Hong Kong) increases the risk of esophagitis and esophageal cancer, although the evidence is less consistent than in the case of maté (Nyrén and Adami 2008a).

The investigation of dietary carcinogens presents major challenges because of the difficulties to assess precisely the relevant carcinogenic (or preventive) factors. In most populations, diet varies greatly during the life of an individual, because of changes in personal choices and in societal aspects (availability of different food items, modification of eating patterns, etc.). Furthermore, many nutritional factors are strongly correlated, making it difficult to disentangle the effect of each factor, and variability in exposure within relatively homogeneous populations might not be large enough to allow the detection of carcinogenic effects. Dietary retrospective exposure assessment is complicated by recall bias and unavailability of valid biomarkers, making the case-control approach particularly unsuitable. Even the evidence derived from prospective (e.g., cohort) studies, however, is far from being unequivocal: as an example, the fairly established notion that high intake of fat, mainly of saturated fat from animal foods, might be a risk factor for breast cancer was challenged by the results of prospective studies based on detailed dietary assessment Holmes et al. (1999). In recent years, there is growing interest in the study of the effects of dietary patterns on cancer risk (Verberne et al. 2010). For a general discussion of nutritional epidemiology, see chapter ▸Nutritional Epidemiology of this handbook.

53.4.4 Overweight and Obesity

Overweight, defined as body mass index (BMI) over 25 kilograms per square meter, increases the risk of colon, pancreas, breast (postmenopausal), endometrial, and kidney cancer and of adenocarcinoma of the esophagus (WCRF 2007). The risk of these cancers is linearly related to severity of overweight and obesity, where obesity is defined as BMI over 30 kg/m^2; adult weight gain is a strong and consistent predictor of risk. In the case of colon cancer, body fat distribution expressed as waist-to-hip circumference ratio resulting in abdominal fatness might have an effect independent from that of body mass. It is likely that obesity exerts a carcinogenic effect via alteration of endogenous hormone metabolism, involving in particular insulin resistance and chronic hyperinsulinemia, modulation of adrenal cortical hormones, and increased bioavailability of estrogens. Other possible mechanisms include interference with carcinogen metabolism, accumulation of reactive oxygen species, and alteration of mechanisms regulating cell proliferation, resulting in enhanced proliferation and reduced apoptosis, as well as induction of angiogenesis in tissues other than the fat. The magnitude of the excess risk is not very high (for most cancers, the relative risk ranges between 1.1 and 1.5 for an increase of 5 kg/m^2); however, the attributable risk in high-income countries is large because of the high prevalence of overweight people: estimates for Europe suggest that about 2.5% of all cancers in women and 4.1% in men are attributable to overweight and obesity (Renehan et al. 2008). For the epidemiology of overweight and obesity, see chapter ▸Epidemiology of Obesity of this handbook.

53.4.5 Physical Activity

Regular sustained workplace or recreational physical activity (e.g., at least 30 minutes per day) decreases the risk of colon cancer; a protective effect is also likely for postmenopausal breast cancer and endometrial cancer (WCRF 2007). The magnitude of risk reduction for colon and breast cancer is in the order of 40%, and a dose-response relationship has been shown for both neoplasms. Although regular physical activity contributes to weight control, the epidemiological evidence suggests that two factors also act independently. The mechanisms through which physical activity contributes to cancer prevention are not fully understood, but they may include enhancement of immune function, interference with sex steroids, and insulin and IGF-I pathways (WCRF 2007). For a detailed description of studies on and methods to assess physical activity, see chapter ▸Physical Activity Epidemiology of this handbook.

53.4.6 Alcohol Drinking

There is convincing epidemiological evidence that the consumption of alcoholic beverages increases the risk of cancers of the oral cavity and pharynx, esophagus, liver, colorectum, larynx, and breast (Boffetta and Hashibe 2006). The risks tend to increase with the amount of ethanol drunk, in the absence of any clearly defined threshold below which no effect is evident; an interaction has been shown between alcohol drinking and tobacco smoking. The evidence of differences in carcinogenicity among alcoholic beverages is not conclusive. Alcohol might act as cocarcinogen, enhancing the effect of tobacco and dietary carcinogens; in addition, a direct carcinogenic effect of acetaldehyde, the main metabolite of ethanol, cannot be excluded. The relative risk for breast cancer is in the order of 1.07 for each 10 grams per day increase in alcohol intake; however, this association is of importance because of the apparent lack of a threshold, the large number of women drinking moderate or large amounts of alcohol, and the high incidence of the disease.

The carcinogenic effect of alcohol should be considered in the light of other health effects, notably the increased mortality from chronic digestive diseases and accidents and the reduced mortality from cardiovascular diseases among moderate drinkers (Ronksley et al. 2011). In middle-aged and old people, the benefit on cardiovascular disease is likely to offset the increased cancer risk, up to a level of approximately 20 g/day among men and 10 g/day among women.

53.4.7 Infectious Agents

There is growing epidemiological evidence that chronic infection with some viruses, bacteria, and parasites represents a major cause of human cancer, in particular, in developing countries. A number of infectious agents have been evaluated within the IARC Monograph Programme (Table 53.6), and the evidence of a causal association has been classified as sufficient for several of them. Human papilloma virus (HPV) is detected in almost all cases of cervical cancer: several oncogenic HPV types have been identified, with HPV 16 and 18 being the most prevalent ones. Chronic infection with Hepatitis B virus (HBV) or Hepatitis C virus (HCV) is a major cause of liver cancer worldwide; an interaction has been shown between HBV infection and other causes of liver cancer such as aflatoxin exposure. HCV infection has also been associated with an increased risk of non-Hodgkin lymphoma. Additional carcinogenic viruses include Epstein-Barr virus, a major cause of Hodgkin's disease and of some types of non-Hodgkin lymphoma; human herpes virus 8 (HHV8), which causes Kaposi sarcoma; human immunodeficiency virus I, which causes various types of non-Hodgkin lymphoma; and human T-cell leukemia/lymphoma virus I. In addition, childhood leukemia is likely linked to one or more viruses that have not yet been identified.

Infection with Helicobacter pylori is associated with an approximately sixfold increased risk of non-cardia gastric cancer, after controlling for other risk factors of the disease (Nyrén and Adami 2008b). Unplanned control of Helicobacter infection via widespread antibiotic use and improved living conditions may have contributed to the decline in stomach cancer incidence, which occurred in many countries during recent decades. Infestation with several parasites has been linked with occurrence of human cancer in tropical countries: the evidence is particularly strong for Schistosoma haematobium, causing bladder cancer in North Africa and the Middle East, and Clonorchis sinensis, causing cholangiocarcinoma in Southeast Asia (IARC 2010).

Table 53.6 Assessment of associations between infections and human cancer (IARC 2010)

	Evidence[a]	Target organs[b]
Viruses		
Hepatitis B virus	S	Liver
Hepatitis C virus	S	Liver, lymphoma
Hepatitis D virus	I	Liver
Human papilloma virus types 16, 18, 31, 33, 35, 39, 45, 51, 52, 58, 59	S	Cervix, anus, penis, oral cavity
Human papilloma virus type 68	L	(Cervix)
Human papilloma virus types 6, 11, β, γ	I	
Human immunodeficiency virus	S	Kaposi sarcoma, non-Hodgkin lymphoma
Human T-cell lymphotropic virus I	S	Adult T-cell leukemia/lymphoma
Human T-cell lymphotropic virus II	I	
Epstein-Barr virus	S	Burkitt lymphoma, Hodgkin disease, nasopharynx
Human herpes virus 8	S	Kaposi sarcoma
Bacterium		
Helicobacter pylori	S	Stomach cancer, gastric lymphoma
Parasites		
Schistosoma haematobium	S	Bladder
Schistosoma japonicum	L	(Liver, stomach)
Schistosoma mansoni	I	
Opisthorchis viverrini	S	Liver
Opisthorchis felineus	I	
Clonorchis sinensis	S	Liver

[a] *I* inadequate, *L* limited, *S* sufficient
[b] Established target organs *without brackets*; suspected target organs *in brackets*

Global estimates of the number of cases of cancer attributable to biological agents suggest that at least 16% of all neoplasms worldwide are due to infection (Table 53.7) (de Martel et al. 2012). HBV- and HCV-related liver cancer, HPV-related cervical cancer, and Helicobacter-related stomach cancer each account for approximately 30% of the total. Because of the high prevalence of most carcinogenic agents in LMIC, the estimate of the attributable risk is higher in this part of the world (23%).

More than for other causes of cancer, a carcinogenic role of infectious agents is strongly suggested by extreme variability in cancer risk observed among populations in descriptive epidemiological studies. Thus, an infectious agent had been suspected for a long time for a number of human neoplasms (e.g., Kaposi sarcoma), before sensitive and specific assays became available for the identification of the

Table 53.7 Cancer risk attributable to infectious agents (de Martel et al. 2012)

Cancer	Agent	*AF*%	*N* cases
Liver	HBV, HCV	77	580,000
Non-Hodgkin lymphoma	HCV	8	29,000
Stomach, non-cardia	H. pylori	75	650,000
Non-Hodgkin lymphoma, gastric	H. pylori	74	13,000
Cervix	HPV	100	530,000
Vulva	HPV	43	12,000
Vagina	HPV	70	9,000
Penis	HPV	50	11,000
Anus	HPV	88	24,000
Oropharynx	HPV	26	22,000
Nasopharynx	EBV	85	72,000
Hodgkin lymphoma	EBV	49	33,000
Burkitt lymphoma	EBV	63	7,000
Adult T-cell leukemia	HTLV-I	100	2,000
Kaposi sarcoma	HHV8	100	43,000
Bladder	S. haematobium	2	6,000
Total		16	2,000,000

AF attributable fraction

responsible agent. In addition, the investigation of infectious causes of cancer poses special problems of reverse causality: the detection of an agent in a tumor, as compared to the normal tissue of the patients or controls, does not imply an etiological role, since the altered environment resulting from the neoplasm might favor the growth of the microorganism above detection levels. Cohort studies with repeated samples of the target tissue or surrogate material (typically serum) represent the strongest approach to establish causality.

53.4.8 Occupational Exposures

Several occupational agents, groups of agents and mixtures, as well as exposure circumstances, are classified as carcinogenic by IARC (Table 53.8) (IARC 2012a, b). The evidence linking some of the agents (e.g., beryllium, formaldehyde) to cancer is relatively weak, and others (e.g., mustard gas) are mainly of historical interest; however, exposure is still widespread for important carcinogens such as asbestos, coal tar, and other mixtures of polycyclic aromatic hydrocarbons, heavy metals, and silica. Although the overall burden of occupational cancer is relatively small, these cancers concentrate among exposed subjects (mainly male blue-collar workers), among whom they may represent a sizeable proportion of total cancers (Boffetta et al. 1995). Furthermore, unlike lifestyle factors, exposure is involuntary and can be, to a large extent, avoided. In fact, reduction of exposure to occupational and environmental carcinogens has taken place in industrialized countries during recent

Table 53.8 Occupational agents, classified by IARC as carcinogenic to humans

Agents, groups of agents	*Main industry, use*
4-Aminobiphenyl	Pigment
Arsenic and arsenic compounds	Glass, metal, pesticide
Asbestos	Insulation, filter, textile
Benzene	Chemical, solvent
Benzidine, dyes metabolized to benzidine	Pigment
Benzo[a]pyrene	Combustion fumes
Beryllium and beryllium compounds	Aerospace
Bis(chloromethyl)ether and chloromethyl methyl ether[a]	Chemical intermediate
1,3 Butadiene	Plastics, rubber
Cadmium and cadmium compounds	Dye/pigment
Chromium[VI] compounds	Metal plating, dye/pigment
Dioxin	Chemical
Ethylene oxide	Sterilant
Formaldehyde	Plastics, textiles, laboratory agent
Mustard gas[a]	War gas
2-Naphthylamine	Pigment
Nickel compounds	Metallurgy, alloy, catalyst
PCB-126	Chemical
Plutonium-239 and its decay products	Nuclear industry
Radium-226 and its decay products[a]	Luminizing industry
Radium-228 and its decay products[a]	Luminizing industry
Radon-222 and its decay products	Mining
Silica, crystalline	Stone cutting, mining, glass
Solar radiation	Agriculture
Talc containing asbestiform fibers	Paper, paints
Trichloroethylene	Solvent, dry cleaning, metal
Vinyl chloride	Plastics
X- and γ-radiation	Medical
Mixtures	
Coal-tar pitches	Construction, electrode
Coal tars	Fuel, construction, chemical
Diesel engine exhaust	Transport
Leather dust	Leather
Mineral oils, untreated	Metal
Shale oils	Fuel
Soot	Pigment
Wood dust	Wood
Exposure circumstances	
Aluminum production	
Auramine, manufacture of[a]	Pigment
Boot and shoe manufacture and repair	
Coal gasification	
Coal-tar distillation	

(*continued*)

Table 53.8 (continued)

Exposure circumstances	*Main industry, use*
Coke production	
Hematite mining (underground) with exposure to radon	
Iron and steel founding	
Magenta production[a]	Pigment
Painter (occupational exposure as a)	
Rubber industry	
Strong inorganic-acid mists containing sulfuric acid	Metallurgy

[a] Agent mainly of historical interest

decades and represents one of the successes of cancer epidemiology. Exposures in LMIC, however, might still entail an increased risk of cancer, in particular, in the informal sector where control measures are less readily implemented (Santana and Ribeiro 2011).

The epidemiological approach to study occupational causes of cancer was traditionally based on the historical cohort design. Groups of workers were identified via company or union records, and their cancer mortality or incidence was compared with that of a reference population, most commonly that of the country or the region, leading to the estimate of indirectly standardized mortality (or incidence) ratios. The main reasons for the success of the application of epidemiology to the field of occupational cancer are the possibility to identify clearly defined groups of exposed individuals and the availability of historical measures of exposure. For more details on occupational epidemiology, see chapter ▸Occupational Epidemiology of this handbook.

53.4.9 Environmental Agents

Exposure to many occupational carcinogens listed in Table 53.8 also occurs in the general environment; for two additional agents, the naturally occurring fiber erionite and short-lived radioiodine isotopes, the main source of exposure is the general environment. Overall, the available evidence suggests, in most populations, a small role of purely environmental sources of exposure to carcinogens (air, water, soil pollution): global estimates are in the order of 1% or less of total cancers. This is in contrast with public perception, which often identifies environmental pollution as a major cause of human cancer. It should be stressed, however, that in selected areas (e.g., residence near asbestos-processing plants or in areas with drinking water contaminated by arsenic), environmental exposure to carcinogens may represent an important cancer hazard (Boffetta 2006).

The search for environmental causes of cancer has been particularly elusive to the epidemiological approach. The main reason for such relative lack of success lies in several biases affecting the assessment of exposure to most environmental carcinogens and leading to false-negative results: low-level exposure is often widespread and the range of dose is limited, exposure levels vary with time and most available measurements refer to the present or recent past, and individuals are unable to validly and precisely reconstruct their past exposure. For more details on these problems, please refer to chapter ▸Environmental Epidemiology of this handbook.

53.4.10 Reproductive Factors

The epidemiological evidence of a carcinogenic effect of reproductive factors is strongest for breast cancer: early age at menarche, low parity, late age at first pregnancy, and late age at menopause are all associated with an increased risk, while spontaneous and induced abortions are not (Hankinson et al. 2008). In addition, breastfeeding protects from breast cancer. A large pooled analysis resulted in an estimated 4.3% (95% confidence interval (CI) 2.9–5.8) decrease in risk for every 12 months of breastfeeding, in addition to a decrease of 7.0% (95% CI 5.0–9.0) for each birth (CGHFBC 2002). The same reproductive factors seem to exert an effect on endometrial cancer risk similar to that played on breast cancer, while the evidence of an effect on other cancers is inadequate, although there is limited evidence that nulliparity increases the risk of ovarian cancer. No detailed estimates are available on the contribution of reproductive factors to the global burden of cancer, and the range proposed by different authors vary greatly (from 1% to 15%), depending on the underlying assumptions (Boffetta et al. 2009; Doll and Peto 2005). An extensive discussion of methodological problems in reproductive epidemiology can be found in chapter ▸Reproductive Epidemiology of this handbook.

53.4.11 Hormones

Increased levels of endogenous estrogens are associated with an increased risk of breast and endometrial cancers, and a similar effect is likely to be played by endogenous androgens (Hankinson et al. 2008; DeVivo et al. 2008). The role of other hormones, such as progesterone and prolactin, in these cancers is not clearly known, nor is the role of endogenous androgens in prostate cancer.

There is a large body of evidence that growth hormones, in particular, insulin and IGF-I, have a strong effect on the risk of breast, colon, pancreas, endometrium, prostate, and possibly other cancers (Faulds and Dahlman-Wright 2012). An effect of other endogenous hormones such as growth hormone on cancer risk is plausible but not fully elucidated in epidemiological studies (Clayton et al. 2011). There is a large body of epidemiological studies on cancer risk following exposure to exogenous hormones. Current and recent (up to 10 years) use of oral contraceptives entails a small increase in breast cancer risk, but no excess risk is apparent 10 or more years after cessation of use (CGHFBC 1996). Long-term use of oral contraceptives is associated with an increased risk of liver cancer, while the risk of endometrial and ovarian cancer is decreased following oral contraceptive use (IARC 1999).

Postmenopausal hormonal therapy increases the risk of breast and endometrial cancer (CGHFBC 1997). In the case of breast cancer, the effect is stronger for combined estrogen-progestagen combinations than for other types of hormonal therapy (Beral 2003). The evidence for other organs is inconclusive.

Tamoxifen is widely used for treatment of breast cancer: beyond its therapeutic effects, it decreases the risk of contralateral breast cancer, but it increases the risk of endometrial cancer (Hankinson et al. 2008; DeVivo et al. 2008).

53.4.12 Perinatal Factors

Excess energy intake early in life is possibly associated with breast and colon cancer (WCRF 2007). The role of attained height, growth factors, and other factors such as insulin resistance or sensitivity in this association is unclear. In addition, high birth weight is possibly linked with an increased risk of breast cancer (Hankinson et al. 2008). Perinatal factors have been proposed to cause a sizable proportion of human cancers, but the estimate is subject to uncertainty. The implications of these findings for preventive strategies will be clarified by a more detailed understanding of the underlying carcinogenic mechanisms (Xue and Michels 2007).

53.4.13 Ionizing and Non-Ionizing Radiation

The available epidemiological studies of populations exposed to ionizing radiation following military actions, accidents, occupational exposure, and medical treatments represent a very comprehensive database, which has been used beyond the assessment of radiation carcinogenicity, notably to elaborate models of carcinogenesis in humans and of quantitative risk assessment (Moolgavkar et al. 1999). Ionizing radiation causes acute lymphoblastic leukemia, acute myeloid leukemia, chronic myeloid leukemia, and breast, lung, and thyroid cancers (IARC 2012c). Bone, rectal, and brain cancers may develop following prolonged therapeutic exposure. There is evidence of a linear dose-response relationship between radiation dose and cancer risk. However, levels at which people are commonly exposed to man-made radiation in most countries carry little risk, and the main exposure comes from natural radiation, including indoor radon (UNSCEAR 2010). The estimates of the global contribution of ionizing radiation to human cancer range from 1% to 5% (Table 53.3).

The study of cancer risk following exposure to ionizing radiation represented one of the main paradigms of chronic disease epidemiology. In most exposure circumstances, doses – including those in the past – are known with great precision.

In addition, they are characterized by different intensity and dose rates, allowing the separate investigation of different components of the carcinogenic effect.

Solar (ultraviolet) radiation is carcinogenic to the skin and the lip, and it might increase the risk of other neoplasms such as non-Hodgkin lymphoma (IARC 2012c). Over 90% of skin neoplasms are attributable to sunlight; however, because of the low fatality of non-melanocytic skin cancer, solar radiation is responsible for only up to 1% of total cancer deaths (Table 53.3). Epidemiological studies have contributed to elucidate the contribution of dose rate and time of exposure in ultraviolet-related carcinogenesis. There is no consistent evidence of a carcinogenic effect of other types of non-ionizing radiation, in particular electric and magnetic fields (Feychtin et al. 2005). For more details on radiation epidemiology, please refer to chapter ▸Radiation Epidemiology of this handbook.

53.4.14 Medical Procedures and Drugs

In addition to postmenopausal hormonal therapy, oral contraceptives, and tamoxifen, other drugs may cause cancer. Many cancer chemotherapy drugs are active on the DNA, in order to block the replication of cancer cells. This, however, might result in damage to normal cells, including cancer transformation. The main neoplasm associated with chemotherapy treatment is leukemia, although the risk of solid tumors is also increased. A second group of carcinogenic drugs includes immunosuppressive agents, which have been studied in particular in transplanted patients (Melbye et al. 2008). Non-Hodgkin lymphoma is the main neoplasm caused by these drugs. Phenacetin-containing analgesics increase the risk of cancer of the renal pelvis (IARC 2011).

There is strong evidence from observational studies that aspirin reduces the risk of colorectal cancer (Potter and Hunter 2008), an effect probably shared by other non-steroidal anti-inflammatory drugs.

No precise estimates are available for the global contribution of drug use to human cancer. It is unlikely, however, that drugs represent more than 1% in developed countries (Doll and Peto 2005). Furthermore, the benefits of such therapies are usually much greater than the potential cancer risk.

Use of ionizing radiation for diagnostic purposes is likely to carry a small risk of cancer, which has been demonstrated only for childhood leukemia following intrauterine exposure (IARC 2000). Radiotherapy increases the risk of cancer in the irradiated organs. There is no clear evidence of an increased cancer risk following other medical procedures, including surgical implants.

The epidemiological investigation of the carcinogenicity of drugs and medical procedures shares several characteristics of occupational cancer research: well-defined groups of exposed individuals and valid records of exposure, often in the form of prescription or hospital discharge databases, in addition to the strong potency of several medical agents. These factors explain the relatively large number of drugs identified as human carcinogens.

53.4.15 Medical Conditions

Changes in immunological function are likely to play an important role in human cancer, but epidemiological studies have been largely unable to identify specific factors determining an increased or a decreased risk. Both severe immunosuppression and immunostimulation are associated with an elevated risk of cancer (Morgan et al. 2006). On the one hand, individuals infected with the human immunodeficiency virus (HIV) and patients undergoing immunosuppressive treatments, such as transplant recipients, are at increased risk of lymphoma and skin cancer (Morgan et al. 2006). On the other hand, patients suffering from systemic autoimmune diseases are also at increased risk of lymphoma and possibly other neoplasms (Morgan et al. 2006). The significance of less severe disturbances of the immunological competence is poorly known.

Several chronic inflammatory conditions represent a risk factor for cancer: the epidemiological evidence is particularly strong in the case of colorectal cancer following inflammatory bowel disease and of lymphoma following chronic infectious diseases such as tuberculosis, malaria, and herpes zoster. In addition, gastroesophageal reflux is an important cause of adenocarcinoma of the lower esophagus, a neoplasm whose incidence is increasing in developed countries (Nyrén and Adami 2008a).

53.4.16 Genetic Factors

The notion that genetic susceptibility plays an important role in human cancer is well established, and early studies have demonstrated an increased risk of several types of cancer in individuals with a familial history of the same or related cancers. Several familial conditions entailing a very high risk of cancer have been identified, such as the Li-Fraumeni syndrome and familial polyposis of the colon (Haiman and Hunter 2008). It is only recently that, thanks to the development of molecular tools in human genetics, specific high-risk cancer genes have been identified. Inherited mutations of such high-penetrance cancer genes increase dramatically the risk of some neoplasms (Table 53.9). However, these are rare conditions in most populations, and the number of cases globally attributable to them is rather small.

A familial aggregation has been shown for most types of cancers, in non-carriers of known high-penetrance genes. This is notably the case for cancers of the breast, colon, prostate, and lung. The relative risk is in the order of 2 to 4 and is higher for cases diagnosed at young age. Although some of the aggregation can be explained by shared risk factors among family members, it is plausible that a true genetic component exists for most human cancers. This takes the form of an increased susceptibility to exogenous carcinogens. The knowledge of low-penetrance genes responsible for such susceptibility is still very limited, although research has currently focused on genes encoding for metabolic enzymes, DNA repair, cell cycle control, and hormone receptors (Haiman and Hunter 2008). Current estimates of the

Table 53.9 Examples of high-penetrance cancer predisposition genes (Haiman and Hunter 2008)

Gene	Syndrome	Main targets
RET	Multiple endocrine neoplasia 2	Medullary thyroid carcinoma, pheochromocytoma, parathyroid adenoma
MET	Familial papillary renal cancer syndrome	Papillary renal cancer
APC	Familial adenomatous polyposis	Colorectal cancer
VHL	von Hippel-Lindau syndrome	Clear cell renal carcinoma, hemangioblastoma, retinal angioma, pheochromocytoma
WT1	Wilms' tumor syndrome	Bilateral Wilms' tumor
RB1	Hereditary retinoblastoma	Retinoblastoma
NF1	Neurofibromatosis 1	Neurofibroma, neurofibrosarcoma, optic glioma
NF2	Neurofibromatosis 2	Vestibular schwannoma, meningioma
p53	Li-Fraumeni syndrome	Sarcoma, leukemia, breast, brain, lung, pancreas and skin cancers, others
p16/DCK4	Hereditary melanoma syndrome	Melanoma
PTCH	Nevoid basal cell carcinoma syndrome	Basal cell carcinoma
MEN1	Multiple endocrine syndrome 1	Tumors of parathyroids, gastrointestinal endocrine tissues and anterior pituitary
BRCA1	Hereditary breast-ovarian cancer syndrome	Breast, ovary, prostate and colon cancer
BRCA2	Hereditary breast-ovarian cancer syndrome	Breast (also male) and ovary cancer
PTEN	Cowden syndrome	Hamartoma, breast and thyroid cancer
hMSH2, hMLH1, hPMS1, hPMS2	Hereditary non-polyposis colon	Colon, endometrium, ovary, stomach cancers, others
ATM	Ataxia-telangiectasia	Leukemia, lymphoma, breast cancer
XP(A-G)	Xeroderma pigmentosum	Skin cancer
BLM	Bloom syndrome	Leukemia, lymphoma, most cancers
FAC, FAA	Fanconi anemia	Acute myeloid leukemia, others
WRN	Werner syndrome	Sarcoma, melanoma, thyroid carcinoma

global contribution of genetic factors to human cancer are in the range of 5% to 10%, of which less than 1% is attributable to high-penetrance genes.

The investigation of high- and medium-penetrance genetic cancer risk factors relies mostly on specific methodological approaches whose discussion goes beyond the scope of this chapter (please refer to chapter ▶Statistical Methods in Genetic Epidemiology of this handbook for more details). In the case of low-penetrance genes, however, association studies have been successful in identifying genetic susceptibility factors. Given the lack of dependence of genetic markers of time and disease development, the case-control approach is particularly suitable for this type of investigation.

53.5 Molecular Markers in Cancer Epidemiology

The fact that the identification of new carcinogens, characterized by complex exposure circumstances and weak effects, has become increasingly difficult with traditional epidemiological approaches, the increasing understanding of mechanisms of carcinogenesis and technical developments in molecular biology and genetics are the main reasons for the great increase of the use of molecular markers in cancer epidemiology (Boffetta 2010; Rothman et al. 2012). While a distinction is made between biomarkers of exposure, intermediate events, disease, outcome, and susceptibility, they are best understood as part of a unique framework, aimed at reducing misclassification in the assessment of exposures, covariates, and outcomes in epidemiological studies. The use of exposure biomarkers in cancer epidemiology aims at measuring the biologically relevant exposure more validly and precisely. In some instances, there is an obvious improvement in using an exposure biomarker, as in the case of urinary markers of aflatoxin and tobacco-specific nitrosamines. Intermediate (effect) biomarkers measure early – in general non-persistent – biological events that take place in the continuum between exposure and cancer development, including cellular or tissue toxicity; chromosomal alterations; changes in DNA, RNA, and protein expression; and alterations in functions relevant to carcinogenesis (e.g., DNA repair, immunological response). The analysis of acquired *TP53* mutations is an example of this potentially important contribution of biomarkers. Biomarkers should be validated, and consideration of sources of bias and confounding in molecular epidemiology studies should be no less stringent than in other types of epidemiological studies (see also chapter ▶Molecular Epidemiology of this handbook).

53.6 Screening for Cancer

Screening is considered to be an effective approach to reduce cancer mortality, because human neoplasms go through several preneoplastic stages before they become biologically relevant and clinically detectable. For most cancers, this process takes years or even decades. The possibility to detect preclinical lesions with the potential to develop to a full cancer is highly appealing and is an area of very active research. The slow evolution of cancer, however, is a strong argument to avoid intervention on lesions that do not have the potential to develop to a full cancer during the lifespan of the individual, in order to avoid undue medical procedures such as surgery or chemotherapy. Furthermore, any screening technique has to be carefully evaluated in terms of efficacy to reduce mortality, compliance, and costs. Carefully conducted trials with mortality as main outcome are needed to demonstrate the effectiveness of screening. In practice, however, the available evidence is often restricted to observational data.

Oral inspection aimed at identifying preneoplastic lesions might be an effective approach for secondary prevention of oral cancer. The inspection can be performed by medically certified professionals, but also, in particular, in high-risk areas in developing countries such as India, by specifically trained health workers. Large-scale preventive trials have provided evidence in favor or against this approach (Sankaranarayanan et al. 2005).

Surveillance via flexible sigmoidoscopy, involving removal of adenomas, is a recommended measure for secondary prevention of colorectal cancer. An additional approach consists of the detection of occult blood in the feces. The method suffers from low specificity and, to a lesser extent, low sensitivity, in particular, in the ability to detect adenomas. However, trials have shown a reduced mortality from colorectal cancer after annual tests, although this is achieved at a high cost due to an elevated number of false-positive cases. Current recommendations for individuals aged 50 and over include either annual fecal occult blood testing or flexible sigmoidoscopy or colonoscopy every 5 years (ECCSGWG 2013).

The most suitable approach for secondary prevention of breast cancer is mammography. The effectiveness of screening by mammography in women older than 50 years has been demonstrated, and programs have been established in various countries (Smith et al. 2010). The effectiveness of mammography in women younger than 50 is not demonstrated. The benefit of other screening approaches, such as physical examination and self-examination, is not known.

Cytological examination of exfoliated cervical cells (the Papanicolaou smear test) is effective in identifying precursor lesions, resulting in a decrease in incidence of and mortality from invasive cervical cancer. The benefit is in the order of a two- to fourfold decreased incidence. There is no conclusive evidence, however, regarding the optimal timing of the test (Miller 1999). Cytological smears are not applicable, however, in countries with limited availability of cytologists and pathologists, and alternative approaches for secondary prevention have therefore been proposed, including visual inspection of the cervix with possible enhancement of precursor lesions by acetic acid (Cuzick et al. 2012). There is substantial evidence base to support HPV testing both in triage of women with equivocal abnormal cytology, in surveillance after treatment of cervical intraepithelial neoplasia (CIN) lesions, and in primary screening of women aged 30 years or older (Arbyn et al. 2012).

Secondary prevention has been proposed for prostate cancer, based on digital rectal examination and measurement of prostate-specific antigen. There is no evidence from controlled trials that either procedure decreases the mortality from prostate cancer (Schröder et al. 2012; Andriole et al. 2012). Despite this lack of evidence, these procedures, in particular the prostate-specific antigen testing, have gained popularity in many countries.

Spiral computerized tomography scanning has been shown to be able to identify small, subclinical lesions in the lung of high-risk individuals (Henschke et al. 1999) and to reduce lung cancer mortality for at least 20% (NLSTRT 2011). For a general discussion of the methodological problems of screening, see chapter ▸Screening of this handbook.

53.7 Conclusions

The application of principles of modern epidemiology to cancer research leads to some methodological considerations of a more general nature. Cancer epidemiology is relatively young, yet it has gained an important status in medicine and is practiced by many professionals around the world. In many respects, cancer epidemiology exemplifies the strengths and the weaknesses of the discipline at large.

On the one hand, cancer epidemiology has the privilege of complete and good-quality disease registries in many populations, covering a broad spectrum of rates and exposures. The network of cancer registries not only provides important clues in terms of etiological and clinical research, for example, via the analysis of geographical and temporal differences in incidence, mortality, and prevalence of different neoplasms, but also allows in many countries the conduct of large-scale, high-quality (and relatively low-cost) record linkage studies (cf. chapter ▸Use of Health Registers of this handbook). Examples of such studies include the analysis of cancer risk in migrants by region of origin and length of stay in the host country, the linkage between census and cancer registry data to assess risk from employment in specific occupations, the analysis of second primary neoplasms in cancer patients, and the risk of cancer following diagnosis of (or hospitalization for) non-neoplastic conditions.

On several occasions, cancer epidemiology has been the key tool to demonstrate the causal role of important cancer risk factors. The best example is the association between tobacco smoking and lung cancer, which led in the early 1960s to the establishment of criteria for causality in observational research (Doll 1998). Other contributions of epidemiology to the elucidation of important causes of human cancer include the demonstration of the role of HPV in cervical cancer, the role of Helicobacter pylori in stomach cancer, and that of solar radiation exposure in skin cancer, as well as the growing body of evidence for a major role of overweight and obesity in the etiology of several important neoplasms. These findings have brought important regulatory and public health initiatives as well as lifestyle changes in many countries of the world. For example, Box 53.1 shows the European Code Against Cancer, which adequately summarizes the current evidence for cancer prevention: these recommendations are mainly based on evidence accumulated via epidemiological studies.

Box 53.1. European Code Against Cancer, Third Version (Boyle et al. 2003)

Many aspects of general health can be improved, and many cancer deaths prevented, if we adopt healthier lifestyles:

1. Do not smoke; if you smoke, stop doing so. If you fail to stop, do not smoke in the presence of non-smokers.
2. Avoid obesity.
3. Undertake some brisk, physical activity every day.
4. Increase your daily intake and variety of vegetables and fruits: eat at least five servings daily. Limit your intake of foods containing fats from animal sources.
5. If you drink alcohol, whether beer, wine, or spirits, moderate your consumption to two drinks per day if you are a man or one drink per day if you are a woman.
6. Care must be taken to avoid excessive sun exposure. It is specifically important to protect children and adolescents. For individuals who have a tendency to burn in the sun, active protective measures must be taken throughout life.
7. Apply strictly regulations aimed at preventing any exposure to known cancer-causing substances. Follow all health and safety instructions on substances which may cause cancer. Follow advice of National Radiation Protection Offices.

There are public health programs that could prevent cancers developing or increase the probability that a cancer may be cured:

8. Women from 25 years of age should participate in cervical screening. This should be within programs with quality control procedures in compliance with *European Guidelines for Quality Assurance in Cervical Screening*.
9. Women from 50 years of age should participate in breast screening. This should be within programs with quality control procedures in compliance with *European Guidelines for Quality Assurance in Mammography Screening*.
10. Men and women from 50 years of age should participate in colorectal screening. This should be within programs with built-in quality assurance procedures.
11. Participate in vaccination programs against Hepatitis B virus infection.

These epidemiological "discoveries" share two important characteristics: they involve potent carcinogens, and methods are available to reduce misclassification of exposure to the risk factor of interest and to major possible confounders. It has therefore been possible to consistently demonstrate an association in different human populations. It should be noted that it is not necessary for the prevalence of exposure to be high (although this obviously has an impact on the population attributable risk): examples are the many occupational exposures and medical treatments for which conclusive evidence of carcinogenicity has been established on the basis of epidemiological studies conducted in small populations of individuals with well-characterized high exposure.

On the other hand, when these conditions are not met, the evidence accumulated from epidemiological studies is typically inconsistent and difficult to interpret (Taubes 1995; Boffetta et al. 2008b). The history of cancer epidemiology presents many examples of premature conclusions, which have not been confirmed by subsequent investigations and have damaged the reputation of the discipline. Misclassification of the relevant exposure (cf. chapters ▸Exposure Assessment and ▸Misclassification of this handbook), uncontrolled confounding (cf. chapters ▸Basic Concepts and ▸Confounding and Interaction), and inadequate statistical power (cf. chapter ▸Sample Size Determination in Epidemiological Studies) are the most common limitations encountered in cancer epidemiology. Two solutions have been proposed to overcome these problems. First, epidemiological studies should be very large in size. Second, the use of biological markers of exposure and early effect has been proposed to reduce exposure misclassification, increase the prevalence of the relevant outcomes, and shed light on the mechanism of action of the carcinogen under study (Boffetta and Trichopoulos 2008). These approaches might offer avenues to continue the successful contribution of cancer epidemiology to medical science.

54.1 Introduction

Musculoskeletal disorders are a significant public health problem in industrialized countries. They are one of the leading causes of short- and long-term disability and cause high costs due to loss of productivity, burden on health care services, and social security systems. It has been estimated that the cost of back pain only is 1–2% of the gross national product. About 10% is due to direct health care costs and 90% due to indirect costs (Norlund and Waddell 2000). In this chapter, the focus is in morbidity and etiology of musculoskeletal disorders. The social consequences, such as disability, are not discussed, because disability-related issues depend on the societal context, such as cultural factors and social security regulations, to the extent that cross-national comparisons cannot be made. Firstly, an overview is given of the occurrence and risk factors of the most common musculoskeletal disorders, back and neck disorders, osteoarthritis, upper limb disorders, and osteoporosis. Secondly, some methodological problems in epidemiological research, characteristic for musculoskeletal disorders, are discussed including general study design, and assessment of both health outcome and exposure.

54.2 Occurrence and Risk Factors

54.2.1 Back Disorders

Dorsopathies or back disorders are classified in the International Classification of Diseases 10 (ICD-10) (World Health Organisation, WHO 1992) into deforming dorsopathies (kyphosis and lordosis, scoliosis, spinal osteochondrosis, and others), spondylopathies (ankylosing spondylitis, other inflammatory spondyloses, spondylosis, others), and other dorsopathies (intervertebral disc disorders, other dorsopathies not classified elsewhere, and dorsalgia with several subcategories). This classification is not very useful for epidemiological research. For acute back pain, it has been estimated that for 70% of the cases a specific diagnosis cannot be determined, i.e., most of the cases fall into the category dorsalgia in the ICD-10. A large proportion of the societal burden due to back disorders is, however, attributable to non-specific back pain. The origin of such a pain can be in any tissue of the back with pain receptors, but in most cases the origin cannot be determined. An underlying mechanism in back pain is disc degeneration, and the relationship between low back pain and disc degeneration continues to be controversial. Previous pain experience and psychological factors are known to influence pain perception.

Occurrence The prevalence estimates of low back pain (LBP) vary widely from one study to another depending on the population characteristics and assessment methods. It also seems that cultural differences between populations influence perceiving or reporting of back pain (Raspe et al. 2004). In a systematic literature review (Walker 2000), the point prevalence in the general population varied from 12% to 33%, 1-year prevalence from 22% to 65% (Table 54.1), and lifetime

Table 54.1 One-year prevalence of low back pain in community-based good-quality studies (Data from Walker (2000))

Author	Country	Sample size	Age (years)	Prevalence (%)
Harreby et al. (1996)	Denmark	481	38	60/65[a]
Rafnsson et al. (1989)	Iceland	672	16–65	55
Leboeuf-Yde et al. (1996)	Denmark	1,370	30–50	54
Biering-Sorensen (1982)	Denmark	928	30, 40, 50, 60	45
Hillman et al. (1996)	England	3,184	25–64	39
Mason (1994)	England	6,000	16+	37
Walsh et al. (1992)	England	2,667	20–59	36
Lau et al. (1995)	Hong Kong	652	18+	22

[a]men/women

prevalence from 30% to 84% in studies with acceptable quality. A systematic review of LBP prevalence in Africa reported the average 1-year prevalence of 50% among adults (Louw et al. 2007). The prevalence of back pain increases with increasing age, but many studies have shown that after reaching a peak in the middle of the sixth decade, the prevalence declines. A systematic review by Dionne et al. (2006), however, showed that such a curvilinear association between age and back pain prevalence is found only for benign and mixed problems; most studies with severe back pain as the outcome detected an increase of the prevalence with increasing age. Back pain is reported more often by women than men.

A subgroup of back pain, sciatic pain or low back pain radiating to the leg, tends to have a poorer outcome than local low back pain. The prevalence estimates vary considerably from 1.2% to 43% (Konstantinou and Dunn 2008). This is to a great extent due to differences in definitions of the outcome, methods of data collection, and study populations. In only a few studies, clinical assessment has been employed. One example is the Mini-Finland Health Survey, in which a representative sample of 3,322 Finnish men and 3,895 women aged 30 years or more were examined. The point prevalence estimates of clinically verified sciatica or herniated disc were 5.1% in men and 3.7% in women (age-adjusted). For low back pain syndrome, the estimates were 17.5% and 16.3%, respectively (Heliövaara et al. 1991, 1993).

Little data are available on the incidence of low back pain. One reason for this is the episodic nature of back pain which makes it difficult to define the first-time event, and therefore, usually only the incidence of new episodes can be assessed. Biering-Sorensen (1982) reported 6% 1-year cumulative incidence in a Danish community sample aged 20, 30, 40, and 50 years, and Hillman et al. (1996) observed 4.7% annual incidence in an English community sample aged 25–64 years. In an occupational cohort, the 3-year cumulative incidence of LBP was 26.6% (Hoogendoorn et al. 2000a). In a cohort of newly employed workers without LBP at the baseline, new-onset LBP was reported by 19% at 12 and 24 months (Harkness et al. 2003). Most prospective studies among adults have shown no marked influence of age on the incidence of LPB.

Low back pain is common also among children and adolescents. The prevalence seems to reach the level in adults by around 18 years of age. According to a systematic review by Jeffries et al. (2007), the lifetime prevalence of LBP in different populations aged between 7 and 21 years ranged from 7% to 72%. In most cases, symptoms are mild, non-specific, and self-limiting (Blyth et al. 2009). The prevalence is higher among girls than boys, and there is an increasing trend from lower to upper social classes. Low back pain in adolescence seems to predispose to LBP in adulthood, although only a few prospective studies exist. In an 8-year follow-up of nearly 10,000 Danish 12- to 22-year-old twins, those who had persistent LBP at baseline had fourfold risk of reporting LBP during the last year of follow-up as compared with those without LBP (Hestbaek et al. 2006).

A common belief is that the prevalence of back pain has been increasing during the past decades, but the available evidence is somewhat contradictory.

In Finland, 14-year surveillance with annually repeated postal questionnaire surveys among random population samples of 15- to 64-year-old Finns showed no significant change from 1978 to 1992 (Leino et al. 1994). Since then, the surveillance has been continued and, according to unpublished data, the prevalence level has remained rather stable (1-month prevalence of back pain about 35%, 1-year prevalence of back disorder verified by a doctor about 15%). No increase of the 1-month prevalence was obtained either in another 10-year surveillance program (surveyed every fifth year) among random population samples of 30- to 59-year-olds in two eastern provinces in Finland (Heistaro et al. 1998). The prevalence of chronic low back syndrome, diagnosed by a medical doctor, decreased during the 20-year period 1978/1980–2000 from 18.0% to 10.8% in men and from 16.8% to 11.0% in Finnish women aged 30 years or older (Kaila-Kangas 2007).

Contradictory results have been reported in the UK. The General Household Survey has shown fairly constant prevalence rates of self-reported chronic low back pain over a 9-year period (Symmons et al. 2002 as cited by McBeth and Jones 2007). Palmer et al. (2000) carried out two prevalence surveys at an interval of 10 years (1987/8–1997/8) among 20- to 59-year-olds geographically dispersed in Britain. Macfarlane et al. (2000) conducted two studies at a 7-year interval (1991–1998) with 18- to 80-year-old subjects from northwest England. The former study reported that the 1-year prevalence of back pain rose from 36.4% to 49.1%, whereas the latter reported a slight decrease of 1-month prevalence (from 26.1% to 22.6%).

The prevalence rates of radiographically detectable degenerative changes of the lumbar spine in a community sample over 34 years of age were described by Lawrence in 1969. The prevalence of disc degeneration (grades 1–4) was 51% in men aged 35–44, increasing to 91% at 65 or older. In women, the prevalence rates were 40% and 78%, respectively. The corresponding rates for more severe disc degeneration (grades 3 and 4) were 5% and 38% in men and 3% and 24% in women. One possible explanation for the gender difference is men's higher exposure to physical load; the prevalence was highest in men in physically strenuous occupations. A more sensitive method of detection, magnetic resonance imaging (MRI), has revealed high prevalence of disc degeneration even in symptom-free subjects, 6% in women 20 years of age or younger and 79% in those 60 years or older (Powell et al. 1986). In a large MRI study with 1,043 southern Chinese volunteers 18–55 years of age, 43% of the 18- to 29-year-olds had signs of lumbar disc degeneration. The proportion increased linearly with increasing age reaching 87% in 50- to 55-year-olds (Cheung et al. 2009).

The relationship between degenerative changes in the lumbar spine and low back pain is controversial. Van Tulder et al. (1997) found in their systematic review that radiographically detected degeneration of the lumbar spine was associated with non-specific LBP with odds ratios (OR) ranging from 1.2 to 3.3. No association was found between spinal deformities (spondylolysis and spondylolisthesis, spina bifida, transitional vertebra, etc.) and low back pain. In the MRI study by Cheung et al. (2009), self-reported lifetime history of LBP of more than 2 weeks duration and requiring physician consultation or treatment was associated with overall lumbar disc degeneration score (*OR*: 2.2, 95% confidence interval (CI): 1.4–3.4).

Risk Factors It has been estimated that worldwide 37% of LBP can be attributed to occupation. Work-related LBP was estimated to cause 818,000 disability-adjusted life years lost annually (Punnett et al. 2005). Occupational risk factors are to a great extent amendable and, accordingly, much research has been directed to identifying risk factors related to work.

Several comprehensive reviews on risk factors of back disorders have been published. In Table 54.2, the evidence for physical load is given based on the two most recent systematic reviews by Hoogendoorn et al. (1999) and Bakker et al. (2009). The former covered cohort and case-referent studies from 1949-1966 to 1997 and the latter prospective cohort studies of incident LBP (subjects free from LBP at baseline) from 1997 to 2007. These two reviews complement each other. Summarizing the results, the evidence is strong for heavy physical work (in terms of manual materials handling, lifting, forceful movements), bending and twisting postures at work, and whole body vibration being risk factors; evidence is strong for standing or walking and sitting at work not being risk factors; and the evidence is moderate for patient handling or nursing as risk factors.

Current knowledge on the mechanical risk factors of LBP is still mainly qualitative, and little is known about quantitative exposure-response relationships. The available evidence suggests that reduction of occupational physical load carries potential for the prevention of LBP, but data are sparse to define safety levels for exposure. Also little evidence exists of the effectiveness of workplace interventions affecting physical workload (Van der Beek et al. 2009).

Much research has addressed the role of work-related psychosocial factors in back pain, and several systematic reviews have been published. A EULAR Task Force (Macfarlane et al. 2009) evaluated the evidence of associations between back pain and workplace psychosocial factors based on published reviews (Table 54.3). The conclusions of the reviews were inconsistent. The reasons for this were differences in the dates of publication and the body of evidence; differences in methods used for synthesizing the evidence; differences in quality assessment; inclusion of studies (cross-sectional, case-control, cohort studies); and interaction between risk factors. The conclusions were most consistent for an association of

back pain with high work demand, low job satisfaction, and low work support. The most recent review by Hartvigsen et al. (2004) was based on prospective cohort studies only and used defined methods for assessing the strength of association and consistency of evidence. This review concluded that there is moderate evidence of no association of low back pain with perception of work (6 variables, job satisfaction included), work organizational aspects (17 variables, work demand and work control included), and social support at work (8 variables). The evidence was insufficient for stress at work (5 variables).

For leisure time activities, the aforementioned reviews concluded that the evidence is strong of no association with back pain, for overall physical activity the evidence is conflicting, and for car driving and sleeping the evidence is lacking. Also for the psychosocial factors in private life, the evidence is insufficient (Hoogendoorn et al. 2000b).

Of person-related factors, physical fitness is often considered to have potential to protect from back disorders. Hamberg-van Reenen et al. (2007) carried out a systematic review of the evidence of low physical capacity as a predictor of future LBP. The evidence was summarized from prospective cohort studies. They found strong evidence of no relationship between trunk muscle endurance and the risk of LBP and inconclusive evidence for a relationship between trunk muscle strength or mobility of the lumbar spine and the risk of LBP. Recent meta-analyses by Shiri et al. (2010a, b) showed that overweight and obesity increase the risk of LBP with a dose-response relationship (pooled *OR*s ranging from 1.36 to 1.56 depending on the outcome measure) and that current and former smokers have a higher risk of LBP than never smokers (pooled *OR*s ranging from 1.30 to 2.14, accordingly). The association of current smoking with the incidence of LBP proved to be stronger among adolescents than adults and a dose-response relation was found among adolescents. The same group reported in a systematic review that overweight, long smoking history, high physical activity, and a high serum C-reactive protein level are associated with lumbar radicular pain or sciatica (Shiri et al. 2007). Another systematic review considered the association between atherosclerosis and disc degeneration and LBP (Kauppila 2009). It showed that smoking and high serum cholesterol level were quite consistently associated with disc degeneration and LBP.

Twin studies have indicated that both low back pain and disc degeneration have a substantial genetic component. Heritability estimates for low back problems have shown wide variation, explaining from 0% to 57% of the variance (Battié et al. 2007). One reason for the variation is in differences of the outcome definitions used in different studies. Pain is a very complex phenotype for genetic studies. Genetic effects can be linked to genes affecting intervertebral disc degeneration or immune response, or genes involved in pain perception, signaling, and psychological processing. Many candidate genes have been tested in association studies with varying results (Tegeder and Lötsch 2009). Much more research is needed to unravel the role of genetic and environmental factors in the manifestation of low back pain.

There is solid evidence of familial predisposition and a high heritable component in lumbar disc degeneration. The heritability estimates have ranged from 34% to 75% (Kalichmann and Hunter 2008a). A number of genes have been identified as being associated with intervertebral disc degeneration, including genes coding for collagen I, collagen IX (COL9A2, COL9A3), collagen XI (COL11A2), IL-1, aggrecan, vitamin D receptor, MMP-3, and CILP (Kalichmann and Hunter 2008b). Little is known of gene-gene or gene-environment interactions. More research is needed, including linkage studies and genome-wide assessment studies in different populations with full age range in order to understand the influence of genetic and environmental factors in this complex outcome.

Low back disorders are very common in population, and they are complex with multifactorial etiology. In spite of extensive research, primary causative mechanisms are not well understood, and a rather cynical view has been presented that due to the general nature and course of common LBP, there is limited scope for primary prevention (Burton et al. 2006). The body of evidence of the risk factors of low back disorders would warrant action to reduce harmful physical and psychosocial stressors. Also general health promotion in terms of physical exercise but avoiding traumatic injuries, quitting smoking, and controlling body weight may have a favorable effect on back morbidity. Evidence of the effectiveness of preventative interventions is sparse. The only intervention for which there is evidence of a positive effect in preventing low back pain is physical exercise. The effect size estimates range from 0.39 to 0.69 (Bell and Burnett 2009; Bigos et al. 2009). Negative trials have been reported of education, lumbar supports, shoe inserts, and reduced lifting programs. A recent review of the effectiveness of ergonomic workplace interventions on low back pain showed low to moderate quality evidence that physical and organizational ergonomic interventions are not more effective than no ergonomic intervention on LBP (Van der Beek et al. 2009).

54.2.2 Neck Disorders

In the ICD-10, neck disorders are classified as subcategories of back disorders or dorsopathies identifiable at the 3–4 digit level of the classification. The situation is analogous to that for back disorders: in majority of the cases a specific diagnosis cannot be set, but most of them fall into the category of non-specific neck pain (cervicalgia, “tension neck,” etc.). Accordingly, in most epidemiological studies, the health outcome has been unspecified neck pain.

Occurrence Neck pain is nearly equally common as back pain, but the impact in terms of short- and long-term disability is less. Studies based on the general population have shown large variation in prevalence estimates. This is partly accountable to variation in population sample characteristics, case definition, and case ascertainment. According to the review by Hogg-Johnson et al. (2008), lifetime prevalence estimates of any neck pain among adults ranged from 28% to 71%. Among adults 12-month prevalence of any neck pain ranged from 12% to 71% and among children from 34% to 71%. Most estimates of the 12-month prevalence were between 30% and 50%. One-month prevalence of any neck pain ranged from 15% to 45% among adults and from 4% to 8% among children and adolescents. When pain was further specified (frequent, of certain duration, interfering activities), the estimates were considerably lower. The review reported also incidence rate estimates from general population studies: estimates ranged from 0.055 per 1,000 person-years (disc herniation with radiculopathy) to 213 per 1,000 persons (self-reported neck pain).

The prevalence of neck pain among adults increases with increasing age to a peak in the middle age and declines thereafter. Among children and adolescents, the relationship between age and neck pain prevalence varies. Women tend to have higher prevalence of neck pain than men (Hogg-Johnson et al. 2008).

Data on the time trends of the occurrence of neck pain are scarce. In the Mini-Finland Health Survey (1978/80), age-adjusted 1-month prevalence of neck pain was 26.8% among men and 34.7% among women as compared with the Health 2000 Survey (2000–2001) where the corresponding figures were 25.8% and 39.9% indicating only a minor change during the 20 years in the population 30 years or older of age (Riihimäki et al. 2004). In these surveys, also the prevalence of physician-diagnosed chronic neck syndrome was estimated. Among men the prevalence decreased from 9.8% to 5.5% and among women from 13.9% to 7.3% showing a favorable development during the 20 years (Kaila-Kangas 2007).

Risk Factors Two recent systematic reviews addressed risk factors of neck pain, one in the general population (Hogg-Johnson et al. 2008) and the other one in workers (Côté et al. 2008). Both reviews covered literature from 1980 to 2006. A sufficient number of cohort studies were available to conduct the best evidence synthesis of risk factors of incident neck pain. The results are presented in Table 54.4.

For the general population (17 studies), evidence was found only for age, some psychological factors and exposure to passive smoking in childhood as being risk factors of neck pain. A number of other factors were considered in the studies, but the evidence was either preliminary or inconsistent. In worker populations (19 cohort studies, one RCT), a broader range of risk factors has been considered. Preponderance of evidence was found for age, history of musculoskeletal pains, high job strain, low social support at work, prolonged sedentary position, and repetitive or precision work; and evidence for low physical capacity, job insecurity, prolonged neck flexion, upper extremity posture, and key/mouse position.

Heritability of neck pain was estimated in a study of adult female twins in the UK (MacGregor et al. 2004). The estimates ranged from 35% to 58% depending on the definition of neck pain. In general, more severe neck pain definitions were associated with higher heritability estimates. Severe neck pain (lifetime occurrence of neck pain lasting more than 1 month and associated with disability) was most strongly associated with psychological distress (General Health Questionnaire, GHQ score $\geq$ 6%), but GHQ score accounted for only 1% of the genetic variation of severe neck pain. The association between severe neck pain and GHQ score was explained mostly by shared genetic factors than environmental factors. Severe neck pain was only weakly associated with degeneration of the cervical spine. Another twin study reported that genetic factors do not play an important role in the susceptibility to neck pain in persons 70 years of age or older (Hartvigsen et al. 2005).

Back and neck pain seem to share similar complex multifactorial etiology, in which both physical load and psychosocial factors have a role. Available evidence of risk factors suggests that workplace interventions aiming at reducing harmful physical load on the neck region and improving psychosocial aspects of work as well as physical capacity carry potential for the prevention of neck disorders.

Table 54.4 Evidence of risk factors of incident neck pain in general working populations. Data were extracted from the reviews based on cohort and case-referent studies and randomized controlled trials

Risk factor	General population[a] (Hogg-Johnson et al. 2008)	Worker population (Côté et al. 2008)

Keyboard/mouse position		Evidence
Intervention aimed at modifying workers' workstation and posture		Evidence for not reducing risk of neck pain

[a]The level of evidence was defined by this author (HR) based on the results presented by Hogg-Johnson et al. and applying the criteria of Côté et al.

The evidence of the effectiveness of preventive interventions is, however, scarce. In a recent review of ergonomic workplace interventions covering literature from 1988 to 2008, low-quality evidence, based on three RCTs, was found that physical ergonomic workplace intervention has no effect on short- or long-term incidence or prevalence of neck pain as compared with no such intervention (Van der Beek et al. 2009).

54.2.3 Osteoarthritis

Osteoarthritis (OA) is a degenerative process in the joints, in which loss of cartilage is seen as joint space narrowing on radiography. Bony changes include sclerosis in the subchondral bone, osteophyte formation, and bone cysts. Also soft tissue structures are affected. Clinical signs of osteoarthritis include pain and restricted range of motion in the joint, deformities, and sometimes instability. It is not clear whether osteoarthritis is a single disease or several disorders with a similar final common pathway (Felson 2000). Osteoarthritis can be classified as primary when the cause is unknown or secondary when the cause is known (e.g., joint injury). Generalized osteoarthritis may be a distinct disease where systemic genetic factors are more important than local mechanical factors. Support for such an entity was given by a study which showed that hand osteoarthritis predicts future hip or knee osteoarthritis (Dahaghin et al. 2005). In particular, osteoarthritis of the two large weight-bearing joints, the hip and knee, has a major clinical impact; it is common in elderly people causing pain and disability limiting daily activities and worsening the quality of life.

Occurrence The prevalence estimates of hip osteoarthritis (OA) vary considerably (Table 54.5) which is partly explained by different ascertainment methods of osteoarthritis and possibly also by different time periods. According to the Finnish population surveys, however, the overall prevalence of clinically defined hip osteoarthritis has remained quite stable from 1978/1980 to 2000 (Kaila-Kangas 2007): in men aged 30 years or older, the prevalence rates were 5.0% and 5.7% and in women 6.0% and 4.6%, respectively. The prevalence of hip OA increases steeply after the age of 55 years. In a study of the US population aged 45 years or older, the prevalence of radiographic hip osteoarthritis was 25.7% in men and 26.9% in women, whereas the prevalence of symptomatic osteoarthritis (symptoms and radiographic changes) was 8.7% in men and 9.3% in women (Lawrence et al. 2008).

The prevalence of knee OA also increases with age. It is distinctly more common in women than in men (Table 54.5). In various studies, knee OA was detected radiographically in 5–28% of men and in 8–40% of women aged 55–64 years. In the Framingham Study, repeated radiographs were taken in 1983–1985 (baseline) and in 1992–1993 (Felson et al. 1997). The mean age of the subjects without radiographically detectable knee OA at baseline was 70.5 years. During the follow-up, 11.1% of the men and 18.1% of the women developed moderate or severe knee OA.

[a] Clinically defined (Kaila-Kangas 2007)
[b] Radiographically defined (Lawrence et al. 1966)
[c] Radiographically defined (Van Saase et al. 1989; right hip and knee)
[d] Clinically defined (Anderson and Felson 1988)

In Finland, the overall prevalence of men has been stable from 1980 to 2000 (6.1% and 6.1%), but among women, the prevalence has decreased from 15% to 8% (Kaila-Kangas 2007). In the studies of the US population aged 45 years or older, the prevalence of radiographic knee osteoarthritis has ranged from 18.6% to 24.3% in men and from 19.3% to 30.1% in women. The corresponding prevalence of symptomatic osteoarthritis (symptoms and radiographic changes) ranged from 5.9% to 13.5% in men and from 7.2% to 18.7% in women (Lawrence et al. 2008).

The prevalence of OA of the hand joints increases with increasing age, and it is more common in women than in men (Table 54.6). It occurs most frequently in the distal interphalangeal joints. In the Framingham Study, the prevalence of symptomatic hand OA was 26.2% in women and 13.4% in men aged at least 71 years (Zhang et al. 2002). The NHANES III study showed that in adults aged 60 years or more, the prevalence of radiographic and symptomatic hand osteoarthritis was 37.4% and 12.1%, respectively (Dillon et al. 2007).

Risk Factors Severe injury may be sufficient cause for osteoarthritis, but often there is interplay between systemic and local factors (Felson 2000). According to the prevailing understanding, mechanical load is important in the inception and development of OA, but systemic factors, such as obesity, bone density, hormonal status and estrogen use, nutritional factors, and genetics influence the process (Sowers 2001; Felson 2000). Extrinsic local factors include physical activity and injury, and the intrinsic factors include alignment (varus, valgus), muscle strength (quadriceps), joint laxity, and proprioception. Genetics seem to have a strong influence on the development of osteoarthritis (Felson 2000; Sharma 2001).

Several systematic reviews have synthesized the epidemiological evidence of risk factors of (incident) OA. Bierma-Zeinstra and Koes (2007) summarized the evidence for hip and knee osteoarthritis from systematic reviews. They found moderate to strong evidence that (high) physical workload is a risk factor of hip and knee OA, that high intensity sport activity is a the risk factor of hip OA, and that being overweight is a risk factor of clinical hip OA. Surprisingly, evidence for overweight/obesity as a risk factor for knee OA was not found, although traditionally the influence on the knee has been considered to be stronger than on the hip. In a more recent systematic review, three prospective cohort studies of the association between overweight/obesity and severe hip osteoarthritis (arthroplasty) were included in meta-analysis (Guh et al. 2009). The pooled incidence rate ratio (*IRR*) for overweight was 2.8 in men and 1.8 in women and for obesity 4.2 and 2.0, respectively. In one of the studies (Järvholm et al. 2005), the relative risk of severe hip osteoarthritis, as compared with normal weight, was 1.5 for overweight and 2.0 for obesity. For knee OA, the figures were 2.4 and 4.8, respectively. Those subject whose BMI was below normal weight range ($<20\,\mathrm{kg/m^2}$) hade a smaller risk of hip and knee OA than normal weight subjects. For hand OA, a systematic review found in its best evidence synthesis only moderate evidence of an association with overweight (Yusuf et al. 2010).

Another systematic review by Tanamas et al. (2009) showed that there is a paucity of studies on the association between knee malalignment and incident

knee OA, and furthermore, the assumed relationship between the female hormonal aspects and OA of the hip, knee, and hand was not clearly observed in a systematic review by de Klerk et al. (2009).

Recreational physical activity is often recommended for the prevention of OA. In the Framingham Offspring Cohort, the effect of recreational physical activity on the development of knee osteoarthritis was studied (Felson et al. 2007): 1,280 subjects with mean age 53.2 years (range 26–81) were followed up for approximately 9 years. In this study, neither recreational walking, jogging, frequent working up a sweat, nor high activity levels relative to peers were associated with a decrease or increase in the risk of knee OA, even if the subjects were overweight. All earlier prospective cohort studies with inconsistent results have been smaller in size than the Framingham Study.

Hip injuries have been linked to hip OA in several cross-sectional and case-control studies, but prospective cohort studies are rare (Riihimäki and Viikari-Juntura 2000). Gelber et al. (2000) followed 1,321 former medical students, initially 22 years of age, for a median duration of 36 years. Hip and knee injury at cohort entry or during the follow-up increased the risk of OA in the corresponding joint.

In a large prospective cohort study of severe OA of the hip and knee among male employees in construction industry, great differences of risk were observed between occupational groups (Järvholm et al. 2008). In reference to white-collar workers, floor layers had the highest risk: 4.7-fold risk of knee and 1.6-fold risk of hip arthroplasty. Attributable fraction for work-related factors in severe knee osteoarthritis was estimated as 79% among floor layers.

Jensen gave a best evidence synthesis of the association between physical work demands and knee OA (Jensen 2008a) and hip OA (Jensen 2008b). Moderate evidence was found for a relationship between kneeling (*OR*s ranging from 1.1 to 2.9), and heavy lifting (*OR*s ranging from 1.9 to 2.5) and knee OA. For the combination of kneeling/squatting and heavy lifting, the evidence was also moderate and for climbing stairs limited. With regard to hip OA, the evidence was moderate to strong for heavy lifting. The burdens have to be at least 10–20 kg and the duration at least 10–20 years to give a clearly increased risk of hip OA. Working as a farmer for 10 years is associated with a doubled risk of hip OA (evidence is strong to moderate). Evidence for a relation between construction work and hip OA is limited, and there is insufficient or no evidence that climbing stairs or ladders causes hip OA.

Several studies have indicated that occupational factors such as repetitive work with hands increase also the risk of hand OA (Hadler et al. 1978; Lehto et al. 1990; Felson 2000). A study comparing female dentists and teachers showed that hand use may be protective of hand OA, whereas continuing joint overload may lead to joint impairment (Solovieva et al. 2005, 2006).

In classic twin studies, heritability of OA has varied between different sites, and it appears to be greater in women than men. The heritability estimates have been up to 60% for the hip and hand and 40% for the knee (Spector and MacGregor 2004; Felson 2009). Overall in the general population, little knee OA seems to be heritable, but in middle-aged women, heritability of bilateral knee OA reaches 40% (Felson 2009). A recent twin study reported that while genetic factors are important in the variation of the occurrence of OA at the hand, hip, and knee, no evidence was found of common or shared genetic factors determining the occurrence across these skeletal sites (MacGregor et al. 2009).

Several linkage and association studies have been carried out to identify susceptibility genes for OA. Linkage studies have implicated quantitative trait loci regions on chromosomes 2q, 9q, 11q, and 16p, among others, and association studies have implicated a great number of particular gene polymorphisms associated with an increased risk of OA (Spector and MacGregor 2004). Many reported associations by one group have, however, not been replicated by others. According to the review by Felson (2009), the most consistently reported genetic association is for FRZB (a gene coding secreted frizzle-related protein-3). This association has been shown especially for hip OA in women. The association of interleukin-1 (IL-1) gene family with OA has been found in several cohort studies, and genome-wide scans have also suggested that a gene associated with an increased risk of OA lies within the IL-1 cluster on chromosome 2q. For other genes, replications of the associations found for OA are not clear-cut.

It has become evident that multiple genes influence the development of OA, but the associations between single variants of genes and OA are modest. Valdes et al. (2008) used in their study on genetic risk of knee OA 36 single polymorphisms (SNPs) in 17 candidate genes, each of which had been found to be associated with OA in at least one study. Additive genetic risk equation for women included 12 SNPs and for men 8 SNPs, 4 of them being in the equations of both sexes. Women in the top quartile of the genetic risk variable had nearly ninefold risk of knee OA (OR: 8.98) as compared with women in the bottom quartile. The corresponding odds ratio was 5.06 for men. These results indicate that additive information from a number of genetic variants can predict a substantial proportion of risk of knee OA, but the results need to be confirmed in other study populations.

Based of the epidemiological evidence, weight control, avoidance of excessive physical load, and prevention of joint injuries should be the targets in preventive programs of OA. Moderate-level physical activity and exercise is often recommended for prevention of OA, but evidence for its effectiveness is lacking.

54.2.4 Upper Limb Disorders

Upper limb pain is common, and soft tissue syndromes rank high among workers' compensation claims. Non-traumatic upper limb disorders are also one of the leading causes of sick leaves. Over the years, many "umbrella" concepts have been used for these disorders, such as occupational overuse syndrome, repetitive strain injury, and cumulative trauma disorder, implying work-related etiology. Several specific disorders can be diagnosed: rotator cuff syndrome, epicondylitis, neural impingement syndromes (cubital tunnel syndrome, radial tunnel syndrome, carpal tunnel syndrome, Guyon canal syndrome), and tenosynovitis or peritendinitis of the wrist-forearm region (including de Quervain's disease). Yet a great proportion of the problem manifests only as non-specific symptoms. In this chapter, only the most common syndromes are discussed.

Occurrence Prevalence rates of the most common upper limb soft tissue syndromes obtained in general population and working population studies with clinical ascertainment are presented in Table 54.7. Shoulder syndromes have the highest prevalence varying from 2.1% to 8.3% among men and from 1.9% to 10.1% among women in the general population, depending on the specific syndrome studied. Prevalence of other upper limb syndromes ranged from 0.5% to 2.8% among men and from 1.1% to 9.2% among women in the general population. In working population studies, the prevalence rates were quite similar to those found in the general population.

Some data are available on the incidence of clinically confirmed upper limb syndromes. In a French working population survey (age 20–59 years), the Pays de la Loire Study, incidence of carpal tunnel syndrome was 1.00 per 1,000 person-years (0.6 in men and 1.4 in women). The incidence increased with increasing age in both genders (Ha et al. 2009). Nordstrom et al. (1998) reported a higher incidence rate, 3.5 per 1,000 person-years, in a US general population study. In this study, the case definition was based on medical records. In the study by Silverstein et al. (2006) on manufacturing and health care workers, 1-year cumulative incidence of rotator cuff tendinitis was 5.5% in the right and 2.9% in the left shoulder. For hand/wrist tenosynovitis, Kurppa et al. (1991) reported incidence rates ranging from less than 1–25 per 100 workers per year depending on gender and hand strain at work.

Criteria for the upper limb disorders are not standardized, and varying criteria have been used in different studies, which contributes partly to the obtained differences in the occurrence estimates.

Risk Factors All the upper limb disorders discussed above have been associated with repetitive movements of the hand, use of hand force, non-neutral wrist postures, and hand-arm vibration. According to previous reviews, the evidence of repetition and combination of these risk factors is strong for carpal tunnel syndrome but limited for the other risk factors. For epicondylitis and wrist-hand tendon disorders, the evidence is evaluated as moderate to limited for all these risk factors and their combinations (Vingård 2001a, b; Bernard 1997). In the review by the National Research Council, USA (2001), the AF estimates ranged from 44% (vibration) to 93% (repetition+force). The role of psychosocial factors was controversial. Carpal tunnel syndrome has been related to hormonal factors in older women, obesity and previous history of other musculoskeletal complaints.

In a 20-year follow-up of a Finnish general population cohort, self-reported exposure to repetitive movements and vibration at baseline increased the risk of chronic shoulder syndrome with *OR*s of 2.3 and 2.5, respectively (Miranda et al. 2008). The adverse effect of physical work exposures was detectable even among those older than 70 years at follow-up. Age and body mass index modified the effect of physical exposures.

In the Pays de la Loire Study, 11.3% of men and 15.1% of women were diagnosed to have an upper limb syndrome (rotator cuff syndrome, epicondylitis, cubital tunnel syndrome, extensor/flexor tendinitis/tenosynovitis, de Quervain's disease, or carpal tunnel syndrome). Manual workers had an excess risk of upper limb syndromes as compared with non-manual workers; the prevalence ratios ranged from 1.40 to 2.10 (adjusted for individual factors: age, obesity, diabetes, thyroid disease, osteoarthritis). Physical work exposures accounted for over 50% of the overall (any syndrome) differences between manual and non-manual workers, for 62% (in men) to 67% (in women) of rotator cuff syndrome and for 96% (in women) of carpal tunnel syndrome. The authors estimated that under low levels of physical exposures, up to 31% of cases among manual workers could have been prevented (Melchior et al. 2006).

Another recent cross-sectional community-based study has shown that using keyboard at least 1 h per day is associated with an increased risk of hand-wrist tendinitis (Walker-Bone et al. 2006) and the study by Silverstein et al. (2008) on manufacturing and health care workers that long duration of upper arm flexion and either forceful exertions ($OR = 2.4$) or forceful pinch ($OR = 2.7$) are risk factors of rotator cuff syndrome. In the latter study, high job structural constraints were significantly associated with an increased risk of rotator cuff syndrome, but for other psychosocial factors, the associations were marginal.

A substantial gradient across economic sectors and occupations exists for upper limb syndromes and also for workers compensation claims. According to the body of evidence, a large proportion of this morbidity could be prevented by reducing exposure to physical work factors. Evidence for the efficiency of interventions to prevent upper limb disorders is sparse, however.

In a systematic review by Amick et al. (2008), evidence synthesis was done of interventions aiming at primary (subjects without symptoms at baseline) and/or secondary prevention (subjects with symptoms at baseline) of neck and upper limb disorders among workers. Strong evidence of no effect was found for workstation adjustment alone, moderate evidence of no effect for biofeedback training and for job stress management training, and moderate evidence for a positive effect for arm supports. For other interventions (exercise, ergonomics training, workstation adjustment, alternative keyboards or pointing devices, cognitive behavioral training, rest breaks, participatory ergonomics, injury prevention programs miscellaneous work redesign), the evidence was limited, mixed, or insufficient. The number of high-quality studies is small (14 in the review by Amick et al.), and most of them have been carried out in office sector.

54.2.5 Osteoporosis

Osteoporosis has been defined as a systemic skeletal disorder characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture (Consensus Development Conference 1993). Osteoporosis is often identified by the occurrence of characteristic low trauma fractures (fragility fractures), the most serious of which are

Table 54.8 Prevalence of osteoporosis among an age-stratified sample of residents of Rochester, Minnesota. World Health Organization criteria (2.5 SD or more below sex-specific young normal mean) (Adapted from Melton (2003))

Age (years)	*n*	Hip (%)	Lumbar Spine (%)	Wrist (%)	Hip or spine or wrist (%)

[a] Prevalence per 100, age-adjusted to the 1990 US white population ≥ 50 years old

fractures of the hip and vertebrae. One of the strongest risk factors of fractures is low bone mineral density (BMD). High-precision methods to identify BMD are dual energy X-ray absorptiometry (DXA) and quantitative computed tomography. DXA provides an accurate, reproducible, and safe means of measuring BMD, and it is widely accepted as the reference method (Pafumi et al. 2002). For screening purposes, quantitative ultrasonometry (QUS) of the calcaneal bone can be used.

The World Health Organisation (1994) has recommended four categories to classify osteoporosis: normal, BMD not more than 1 standard deviation (SD) below the mean of young adults; and osteopenia, BMD between 1 and 2.5 SD below the mean of young adults; osteoporosis, BMD more than 2.5 SD below the mean of young adults; severe or established osteoporosis, BMD more than 2.5 SD below the mean of young adults and one or more fragility fractures. The criteria are useful in population-based surveys but less useful in assessing individual risks (Jordan and Cooper 2002).

Occurrence In Table 54.8, the prevalence of osteoporosis is presented by age for men and women 50 years or older in a sample of the general population, Rochester, Minnesota. A clear increase with increasing age is seen, but it is less steep for the lumbar spine than for other sites. This may be due to age-related artifacts that mask bone loss from the vertebral body (Melton 2003). Prevalence of osteoporosis in the lumbar spine, wrist, and all sites combined was higher in women than in men, but the genders had similar prevalence rates for the hip. In some other studies, in which the same absolute bone density cut-off level for men and women has been used, lower prevalence rates have been obtained for men (Melton 2003).

Incidence rates of fractures were estimated for the general UK population during the 10-year period 1988–1998 (Van Staa et al. 2001). For women aged 50 years or older, the incidence rate of hip fractures was 37.2 per 10,000 person-years, and the incidence of distal forearm fractures was 54.4 per 10,000 person-years. For men, the corresponding figures were markedly lower, 11.1 and 11.2 per 10,000 person-years. For 50-year-old women, the estimated remaining lifetime risk of a hip fracture was 11%, of the distal forearm 17%, and of the spine 3%. The corresponding estimates for men were 3%, 3%, and 1%. For the spine, the figures may be underestimated because only clinically verified fractures were recorded. In the European Vertebral Osteoporosis Study, overall 12% of women and men aged 50–79 years were reported to have radiographic evidence of vertebral deformities indicating vertebral osteoporosis (O'Neill et al. 1996).

In the Health 2000 Survey (a representative sample of the Finnish general population 30 years or older), QUS at the heel (calcaneal bone) was used to detect osteoporosis (Kaila-Kangas 2007). The mean of those with good or rather good perceived health in the age group 30–44 years of the same gender was used as the reference for women and men. The estimated average BMD was roughly the same in women and men aged 30–54 years (about 0.56–0.57 g/cm^2). In the older age groups, BMD decreased with increasing age and the change was more pronounced among women than men, as expected. In women 80 years or older, the mean BMD was 0.32 g/cm^2 and in men 0.46 g/cm^2. A remarkable difference between genders was detected, when reference value mean-2SDs was used: in the age group 75–84 years, the prevalence of those with a lower value was 36.8% in women and 6.2% in men, and in the age group 85+, the figures were 62.8% and 14.7%, respectively.

Risk Factors Espallargues et al. (2001) carried out a systematic review on bone-mass-related risk factors for fracture. From 94 cohort and 72 case-control studies, they identified 80 risk factors. For more than half of the risk factors, scientific evidence was insufficient or contradictory. Aging (>70–80 years), low body weight, weight loss, physical inactivity, the consumption of corticosteroids or anticonvulsants, primary hyperparathyroidism, diabetes mellitus type I, anorexia nervosa, gastrectomy, pernicious anemia, and previous osteoporotic fracture were associated with high risk (relative risk (RR) ≥ 2) of fractures. Moderate risk ($1 < RR < 2$) was found for female gender, active smoking, low sunlight exposure, family history of osteoporotic fracture, surgical menopause, early menopause, late menarche, short fertile period, no lactation, low calcium intake (<500–850 mg/day), hyperparathyroidism, hyperthyroidism, diabetes mellitus type II, and rheumatoid arthritis.

Early developmental factors such as tall maternal height and low rate of childhood growth seem to have an influence on later osteoporosis risk (Cooper et al. 2001). Sufficient calcium intake and physical activity during the growing years of young people are major determinants of bone mass which reaches its peak around the age of 25. A meta-analysis of the effect of calcium intake on bone mass in 18- to 50-year-olds showed that calcium intake of about 1,000 mg/day can prevent the bone loss of 1% of bone per year at all bone sites except in the ulna in premenopausal women. For men, too few studies were available to draw conclusions (Welten et al. 1995). Another more recent meta-analysis studied the use of calcium or calcium in combination with vitamin D supplementation to prevent bone loss and fractures in people aged 50 years or older (Tang et al. 2007). Supportive evidence was obtained for the use of calcium or calcium in combination with vitamin D. The combination was associated with a reduced bone loss of 0.54% at the hip and 1.19% in the spine. The overall relative risk of fracture was 0.90 for calcium only and 0.87 for the combination.

Meta-analyses on the effect of physical exercise on bone loss in postmenopausal women have shown that regular walking has no significant effect on preservation of BMD at the spine, but it has a significant positive effect at the femoral neck (Martyn-St James and Carroll 2008), whereas mixed loading exercise programs combining jogging with other low-impact loading activities and programs mixing impact activities with high-magnitude resistance training appear to be effective both at the hip and spine (Martyn-St James and Carroll 2009). However, Moayyeri (2008) stated in his review that the positive effects of physical activity on BMD and bone quality are of a questionable magnitude for reduction of fracture risk. The favorable effect of moderate to vigorous physical activity on hip fracture risk reduction (45% among men and 38% among women) was suggested to be mediated by a reduced risk of falling among physically active people.

Osteoporosis is strongly influenced by genetic factors. Twin and family studies have shown that 50–85% of the variance in bone mass is genetically determined (Williams and Spector 2006). Most studies on genetics of osteoporosis have focused on the phenotype of BMD, and it has been demonstrated that heritability of BMD is polygenic (Duncan and Brown 2008). In most studies, a candidate gene approach has been used. The genes most often studied are vitamin receptor gene (VDR), the collagen type 1 alpha 1 gene (COLIA1), and estrogen receptor gene (ER) alpha. They have been found to influence BMD, but the effects are modest and probably account for less than 5% of the heritable proportion of BMD (Williams and Spector 2006). Progress in understanding the genetic influences in osteoporosis is expected from ongoing genome-wide association studies (Duncan and Brown 2008).

With the expected demographic shift toward older age groups in the industrialized countries, the number of affected people, women in particular, will increase substantially. Prevention of osteoporosis is an important public health issue. Optimizing maternal nutrition and fetal growth, improving calcium intake and general nutrition in growing children, and increasing the exercise level throughout the population have been suggested to be included in the preventive population strategies (Walker-Bone et al. 2002).

54.3 Methodological Problems in Epidemiological Research

54.3.1 Aspects of Study Design

Most epidemiological studies have used cross-sectional study design, but the number of cohort and case-control studies has been increasing as can be seen from recent systematic reviews. A wide range of potential determinants have been explored in cross-sectional settings, but advancing the knowledge of risk factors of musculoskeletal disorders requires more rigorous study designs.

Case-control studies of musculoskeletal disorders are rare because of the difficulties in case definition and catchment of cases (cf. chapter ▶Case-Control Studies of this handbook). The majority of people with musculoskeletal problems are treated in primary health care. Generally accepted diagnostic criteria are not available, and the use of diagnostic labels varies remarkably among practitioners. In some studies, cases have been identified from health care providers (e.g., Vingård et al. 2000) or from registers (e.g., Heliövaara et al. 1987). In such studies, one needs to be aware of potential bias in etiological considerations due to differential proneness across exposure groups to file a claim or seek care or to get treatment. This bias can be minimized by restricting the cases to only severe cases, which will be treated in a similar way irrespective of, e.g., social class or demands on physical performance (e.g., Manninen et al. 2002).

Another question to consider in case-control studies is the validity and relevance of exposure assessment (cf. chapter ▶Exposure Assessment of this handbook). Often the only feasible option for data collection is to use retrospective questionnaires or interviews providing data susceptible to recall error. This error can be differential between cases and referents. Due attention should be paid to the relevant time windows for exposure assessment in reference to the inception of the disease of interest and induction period. In very few studies, this matter has been considered, but some examples can be found (Vingård et al. 1991a). In cases where the inception and induction periods are not known, assumptions can be made and tested. For studying transient triggering factors of musculoskeletal disorders, a case-crossover design may be the approach of choice (cf. chapter ▶Modern Epidemiological Study Designs of this handbook). This approach is appropriate, for instance, for sudden-onset overexertion injuries. Even though degenerative process of the spine, chronic in nature, may be the underlying cause for back and neck disorders, these disorders characteristically manifest as painful episodes. Little is known of the possible triggering causes of such spells.

During the past 10 years, an increasing number of cohort studies on musculoskeletal disorders have been published (cf. chapter ▶Cohort Studies of this handbook). The exposures of interest and other determinants have been measured at baseline and used as predictors of new-onset musculoskeletal pain or incident cases of musculoskeletal disorders. According to the general principles of etiological cohort studies, persons already afflicted by the index disorder should be excluded. This simple principle turns out to be quite difficult to follow for disorders with a chronic underlying process, such as disc or cartilage degeneration, which manifest as intermittent pain episodes. The date of inception for such disorders is not easy to define, and operational definitions, preferably based on assumed or known pathomechanisms, should be employed. As an example, for osteoarthritis, a natural proxy is the time of the first occurrence of “arthritic” pain in the afflicted joint.

In prospective cohort studies, health outcome can be assessed using repeated surveys including symptom questionnaires or interviews, imaging or functional performance tests, or clinical tests. When available, register data are useful particularly in large-scale epidemiological studies (e.g., Heliövaara et al. 1987) (cf. chapter ▶Use of Health Registers of this handbook).

54.3.2 Health Outcome Assessment

A major difficulty in conducting systematic literature reviews and meta-analyses of the epidemiological evidence of musculoskeletal disorders is the lack of generally accepted diagnostic or classification criteria of health outcomes. Many of the available criteria are based on a consensus of a group of experts, and validity of the classification criteria has been investigated surprisingly little even for the most common disorders. Among others, this was the conclusion of Reijman et al. (2004) in their investigation of validity, reliability, and applicability of seven definitions of hip osteoarthritis used in epidemiological studies. Likewise, Schiphof et al. (2008) concluded, based on their systematic appraisal of 25 different classification criteria of knee osteoarthritis, that more research is needed to reach uniformity in the classification criteria to be used in epidemiological research. Their recommendation was that meanwhile separate scoring of clinical and radiographical findings, overall scoring and pain registration should be used. In a systematic review and meta-analysis of etiological risk factors for low back pain, Griffith et al. (2007) found altogether 132 outcome definitions in 55 studies. Using an administered Delphi process, a group of experts categorized the definitions and reached a consensus for 20 sets of outcomes (3 sets of pathology outcomes, 2 sets of functional limitation, 2 sets of participation in work, and 13 sets of symptom and care seeking outcomes). These findings emphasize the complexity of low back pain as an outcome in epidemiological studies but also the urgent need for uniform and valid outcome definitions.

Questionnaire Surveys The occurrence of unspecified pain has been the most common outcome measure in epidemiological studies on musculoskeletal disorders. The occurrence parameter has been 1-, 3-, or 12-month or lifetime period prevalence or cumulative incidence. One of the major drawbacks of such symptom data is that mild pain due to occasional overexertion is not differentiated from more chronic and severe conditions, although this would be important in both etiological and prognostic studies. Pain perception is subjective and as such person-dependent and, therefore, modified by several factors like prior pain experience, culture, coping mechanisms, etc. Same personal features can influence other measures based on subjective perception, psychosocial factors as an example. Pain experience may also depend on the level of physical activity at work and leisure, because physical activity provokes musculoskeletal pain. As a result, spurious associations between potential determinants and musculoskeletal disorders can be obtained.

No generally agreed symptom questionnaires are available. One of the most commonly employed forms is the Nordic questionnaire (Kuorinka et al. 1987). Lack of consensus in defining such fundamental concepts as new-onset cases, acute, recurrent, and chronic cases, and an episode hampers the development of

Table 54.9 Characteristics of back pain and their measurement (Adapted from Croft and Raspe (1995))

Characteristic		Measurements

epidemiological research focusing on pain and other symptoms. For low back pain, proposals for the definition of episodes (de Vet et al. 2002), recurrence of episodes (Stanton et al. 2009), and back pain in prevalence studies (Dionne et al. 2008) have been made. Also a scoring system for pain intensity has been presented (von Korff et al. 1990). Nachemson (2000) proposed time limits to define acute (0–3 weeks’ duration of pain or disability), subacute (4–12 weeks’ duration of pain or disability), and chronic back or neck pain (more than 12 weeks’ duration of pain or disability) and recurrent problems (patients seeking help after at least 1 month of not seeking care or not being on sick leave after at least 1 month of working).

Table 54.9 summarizes the characteristics of pain and indicates the most commonly used measuring methods (for references, see the original article).

Clinical Tests Clinical examination, laboratory tests, and functional performance tests usually do not provide very useful information for the case definition of back and neck disorders. For the back, a comprehensive review of the reliability of different function measurements concluded that recommendations for tests to be used in epidemiological studies cannot be made (Essendrop et al. 2002). Another systematic review of physical examination of non-specific low back pain also demonstrated low reliability (May et al. 2006). For upper limb disorders, a criteria document has been published proposing diagnostic criteria based on symptoms and clinical findings (Sluiter et al. 2001). For osteoarthritis, clinical examination has been used for classification, e.g., the American College of Rheumatology has presented classification criteria (www.rheumatology.org/research/classification).

Imaging Radiological site-specific definition of osteoarthritis is recognized as the method of choice in epidemiological studies of osteoarthritis (Hart and Spector 1955, 2000). Exposure to radiation is a matter of concern especially when taking radiographs of the hip, pelvic, or lumbar spine area. Kellgren and Lawrence presented already in 1957 classification criteria (Kellgren and Lawrence 1957; Kellgren 1963), which have been widely used. In this system, osteoarthritis is classified using grades from 0 to 4. The grading is based on a presumption of sequential appearance of osteophytes, loss of joint space, subchondral sclerosis, and cyst formation, but it relies heavily on the presence of osteophytes. Criticism has been presented against this classification, and there is growing consensus that semiquantitative grading of osteophytes and joint space narrowing, using validated atlases, should be separately recorded. Based on these data, also aggregate measures can be constructed (Hart and Spector 1955, 2000).

For the imaging of the spine, magnetic resonance imaging (MRI) is a sensitive method to study the degenerative process of spinal tissues, the intervertebral disc, in particular. Compared to traditional radiography, early stages of degenerative process can be detected. No known adverse health effects are involved, but high costs and availability of the equipment limit the use of MRI in large-scale epidemiological studies. No generally agreed classification criteria exist, but for disc degeneration, a system based on the morphology of the disc (inhomogeneity of disc structure, clarity of the distinction between the annulus and nucleus, and collapse of the disc space) has been proposed (Pfirrmann et al. 2001). Instead of using aggregate grading systems combining different features of disc degeneration, it seems advisable to record the features (morphology, signal intensity, bulging) separately in epidemiological studies. For other musculoskeletal disorders, MRI has not been utilized in many studies, and classification criteria are not available.

Bone Mineral Density Measurements Bone mineral density (BMD) can be measured with high-precision using dual-energy X-ray absorptiometry (DXA). It is based on the attenuation of X-rays passing through the bone. With this technique, it is possible to detect bone mass reduction that carries increased risk of fracture. DXA is widely accepted as the reference method to diagnose osteoporosis and fracture risk (Pafumi et al. 2002). The use of DXA in large epidemiological studies is limited by the availability of the equipment that is usually located in specialized centers. Another method, quantitative ultrasonometry (QUS) of the calcaneal bone, has several advantages. The equipment is cheaper, it is transportable, and the execution of the measurement is rapid. However, QUS is more suitable to assess bone density in younger (up to 55 years) than old people (Pafumi et al. 2002).

Registers Register data of occupational injuries, users of social security benefits such as sick leave and disability pension, or of users of health care services (hospital discharge registers, registers from health care providers) can be used for descriptive epidemiology to find gradients across different population groups (e.g., Leino-Arjas et al. 2002; Vingård et al. 1991b; Silverstein et al. 2002). Register-based case assessment of musculoskeletal disorders in etiological studies carries a potential for bias due to differential proneness across population groups to file a workers' compensation claim, seek or get treatment, to go on sick leave or pension. Another weakness is non-uniform use of diagnostic labels among medical doctors. In some countries, a national register of arthroplasties is being kept, making it easy to identify severe cases of osteoarthritis (Manninen et al. 2002).

54.3.3 Exposure Assessment

Assessment of exposure to mechanical load is a challenge in epidemiological studies. For many other risk factors, such as anthropometric measures and lifestyle factors, standardized and validated methods are available. Also for psychosocial factors, validated questionnaires are available, as an example the widely used Job Content Questionnaire to assess psychosocial job characteristics (Karasek et al. 1998).

Exposure to mechanical load as a risk factor is conceptually problematic. Everybody is "exposed" to materials handling, awkward postures, repetitive movements and many also to vibration, the known risk factors of musculoskeletal disorders. Sedentary lifestyle is becoming more common and has raised concern of too low "exposure" levels to mechanical load leading to deterioration of people's physical condition. A crucial question is, at what level mechanical load starts having adverse effects on the musculoskeletal system.

Mechanical exposure involves exertion, motion, and posture. Each of these can be characterized by level (amplitude), frequency (repetitiveness), and duration. Dynamic movement characteristics, velocity and acceleration, may also be important. Furthermore, for different musculoskeletal disorders, the relative importance of peak and cumulative exposures varies. This makes mechanical exposure very complex to assess, and for the planning of the assessment strategy, one should have prior knowledge or hypotheses of the pathomechanisms of the disorders in question. Using biomechanical modeling, the internal exposure can be estimated. Also common metrics have been proposed for the assessment of physical workload (Wells et al. 1997).

In epidemiological studies, mechanical exposure can be assessed using self-reports, observation methods, or direct measurement. Winkel and Mathiassen (1994) have described the feasibility of different assessment methods. Capacity, versatility, and generality decrease, whereas exactness and cost increase from self-reports to observations to direct measurements. With modern sophisticated measuring technology, it is possible to get accurate measures for current exposure to various dimensions of physical load at work. Direct measurements may not be feasible for large studies, and the accuracy of measurements is of value only if the current exposure is relevant with regard to study objective. Also, if current exposure can be considered as a proxy of past exposure, direct measurements are warranted. However, often this may not be the case, and other means of past exposure assessment, such as interview or expert assessment based on occupational history, must be utilized. Several validation studies of self-assessment of physical exposures, have shown that the accuracy is not always very good, but for some exposures such data are usable in epidemiological studies (Mortimer et al. 1999; Viikari-Juntura et al. 1996).

Different techniques to assess posture, including observational methods, video-taping and computer-aided observational methods, direct measurements, as well as self-reports, have been reviewed and discussed by Li and Buckle (1999). Precision, cost, and feasibility of different techniques to assess postural load, mechanical load, psychophysical load, and physiological load in epidemiological studies have been compared by Burdorf et al. (1997). Also Van der Beek and Frings-Dresen (1998) have reviewed mechanical exposure assessment methods and strategies in epidemiological studies. Direct measurements, such as electromyography, can be used for more accurate assessment. Methods for data reduction have been developed, such as exposure variation analysis (EVA, Mathiassen and Winkel 1991) or its modification, clustered EVA (Anton et al. 2003).

The spectrum of different dimensions of mechanical load and measurement methods poses a problem in conducting systematic reviews and meta-analyses of the association between mechanical load and musculoskeletal disorders. Griffith et al. (2008) developed common metrics for the translation of literature-based workplace mechanical exposures for use in meta-analyses on low back pain among workers. They developed seven-point scales for trunk posture, weight lifted or force exerted and spinal loading, and estimated both peak and cumulative loads. Such metrics can help comparison across studies, but in the future, more consistent measures of mechanical exposure are needed.

54.4 Conclusions

In epidemiology of musculoskeletal disorders, steady progress has been made during the past decades. Even though cohort and case-control studies are still sparse, their number is increasing. Systematic reviews have collected the available evidence of the risk factors of musculoskeletal disorders. Major risk factors have been identified qualitatively, but little is known of the exposure-effect relationships.

More studies with rigorous study designs are needed with valid methods to assess both exposures and health outcomes.

The lack of knowledge on exposure-effect relationships makes it difficult to plan preventative programs and agree on standards and guidelines to reduce the risk of musculoskeletal disorders. The knowledge base is, however, sufficient to plan interventions aiming at prevention. In workplace interventions, a good starting point is to reduce exposure to highest loads. Reviews of intervention studies have revealed that high-quality studies are rare and all the reviews conclude that randomized controlled trials are needed to provide convincing evidence of the effectiveness of the preventative interventions.

For low back and neck pain, it has been shown that both physical load and psychosocial factors play a role. When subjective perception of non-specific pain is the health outcome, the question remains, how much physical load acts as a symptom provoking or aggravating factor and how much it is a causal factor for back morbidity. Likewise, it can be questioned to what extent psychosocial factors modify the pain perception of the subjects. This question is relevant because in experimental studies, it has been shown that pain perception of individuals varies very much when exposed to a standardized pain-inducing stimulus. For the future development of epidemiology of back and neck disorders, it is important that effort is put to identifying more specific and also clinically relevant entities of low back and neck disorders. For upper limb disorders, better diagnostic criteria are available, but the specific diagnoses cover only a part of all upper limb complaints. It is equally important to develop exposure assessment methods that are valid and feasible also for large-scale population-based studies.

Recent studies have revealed that the prevalence of low back and neck disorders starts to increase already in the adolescence. There also seems to be an association between the development of disc degeneration and low back pain among the young (Salminen et al. 1999). These results suggest that follow-up studies of young cohorts are needed to learn more about the temporal relationships between low back and neck pain and the degenerative process of the intervertebral disc. Another question of interest is the inception and natural course of low back and neck disorders from the adolescence through adulthood to older age.

Genetic epidemiology is emerging also in the field of musculoskeletal disorders. Twin studies have provided information of the familial and genetic influences on musculoskeletal disorders of the back and joints, in particular. Many candidate genes have been detected, but much remains to be done to identify the genes involved and their influences. A future challenge is to learn about the interactions between genetic susceptibility and environmental factors.

55.1 Introduction

Obesity results from an imbalance between energy intake and energy expenditure. Factors that influence energy intake include the quantity and quality of foods and beverages consumed, while physical activity levels influence energy expenditure. Energy balance is further influenced by genetic, metabolic, and environmental factors.

Today, obesity affects individuals around the globe. However, the prevalence of obesity is not equally distributed. For example, there are variations in obesity by country and within countries by geographical region, socioeconomics, and demographic variables including race/ethnicity, gender, and age.

Understanding the epidemiological features of obesity is an important step in determining and prioritizing interventions. To this end, this chapter will provide an overview of measures of body composition, definitions of obesity, and prevalence of obesity. Further, there will be a brief discussion of factors that contribute to obesity.

55.2 Body Composition

Adiposity refers to body fat and obesity to an excess of body fat. Fat is stored in the body as adipose tissue and to a lesser degree lipids. The majority of adipose tissue is located subcutaneously (under the skin) and surrounding the viscera (organs including stomach, liver, and heart). An individual's weight, on the other hand, is determined by a combination of adipose and lean body mass. Lean body mass includes muscle, organs, bone, and extracellular water.

One of the challenges in obesity research is discerning the relative contribution of an individual's total body fat to his/her total weight. There are several available methods to measure body composition, and each has its own strengths and limitations in its ability to assess adiposity. These methods have been extensively discussed in nutritional textbooks (Willett 1988; Hu 2008) and will be discussed briefly in this chapter.

55.3 Measures of Body Composition

55.3.1 Hydrodensitometry

Hydrodensitometry also known as underwater weighing, is considered the gold standard for measuring body fatness. Hydrodensitometry is based on the principle that fat is lighter than other body constituents (Willett 1988). The procedure involves weighing individuals in the air, and then again after they are submerged underwater. Following the procedure, calculation of body volume, body density, and percent body fat can be performed (Brozek et al. 1963). Although still the gold standard, hydrodensitometry is used infrequently except in research settings and to assess the validity of other measures (Hu 2008). The cost, time, and requirements for significant cooperation of individuals being weighed are limitations to its use.

55.3.2 Dual Energy X-Ray Absorptiometry (DXA)

DXA uses an x-ray beam combined with a whole body scanner to measure both bone mass and soft tissue composition (Willett 1988). DXA is able to distinguish fat and lean body mass by the differential absorption of x-rays by these tissues (Willett 1988) and can provide whole body or regional estimates. The reproducibility (Lohman 1981; Cordero-MacIntyre et al. 2002), accuracy, and precision (Kiebzak et al. 2000) of DXA in measuring total body fat has increased its use in obesity research settings (Hu 2008). Although there is radiation involved, the dose is sufficiently low to allow its use in all age groups, but its use is avoided during pregnancy. For example, the radiation exposure from a DXA scan is roughly equivalent to an airline flight from Los Angeles, California, to New York, New York. The variability in estimates between machines from different manufacturers should be considered if comparisons are being made (Covey et al. 2010). The expense associated with DXA limits its use in both research and clinical settings.

55.3.3 Bioelectric Impedance Analysis (BIA)

BIA is a relatively low-cost method for estimating percent body fat by measuring the impedance or resistance to an electrical current as it travels though the body (Hu 2008). Incorporating sex, age, and race into models to predict body fat improves the validity of BIA (Sun et al. 2003). However, level of body fatness itself may influence the BIA estimates, with an overestimation of body fat for healthy weight individuals but underestimation of body fat for obese individuals (Sun et al. 2005; Fakhrawi et al. 2009; Savastano et al. 2010). Further, some evidence suggests that body mass index (BMI) provides as much information for predicting adiposity as BIA (Willett et al. 2006). Other factors impacting BIA estimates include hydration status and body shape (Hu 2008). Different BIA devices employ different measurement techniques which impact body fat estimates (Pateyjohns et al. 2006).

55.3.4 Anthropometry

Weight and height measurements, often combined into BMI, are widely used in epidemiological obesity studies. However, other measurements such as waist circumference and skinfold thicknesses are also commonly used.

55.3.4.1 Body Mass Index (BMI)

BMI is calculated as the weight in kilograms divided by the square of height in meters. Lean body mass, in addition to fat, contributes to an individual's weight and therefore BMI. BMI is correlated with body fatness measured by densitometry. However, there are differences by gender, race, and age in the ability of BMI to predict body fat (Gallagher et al. 1996). For example, women have lower muscle (Gallagher et al. 1997) and bone mass (Tuck et al. 2005) than men. Therefore, at the same BMI, women tend to have a higher percent body fat. Similarly, at the same BMI, compared with whites, Asians have more body fat (Deurenberg et al. 2002) and blacks have less body fat (Wagner and Heyward 2000; Flegal et al. 2010b). There are also changes in the fat mass with aging. Among children, there is an increase in fat mass during the first year of life followed by a period of stabilization and subsequent increase between the ages of 3 and 7 years (Rolland-Cachera et al. 1984). Among adults, there are age-related declines in lean body mass and increases in fat mass (Evans and Campbell 1993).

Despite its limitations, the use of BMI has been widely adopted in clinical practice as well as research settings to assess obesity.

Measured Versus Reported BMI

One of the advantages of BMI is its low cost for assessment of obesity when compared with other assessment tools. However, collecting height and weight data is not without associated costs. Self-reported data, rather than data measured by a trained professional, may be more feasible for some surveillance projects. Self-reported height and weight are subject to their own set of limitations which should be considered when evaluating and drawing conclusions from the data. Among adolescents and adults, individuals tend to underreport their weight and overreport their height, which may lead to an underestimation of obesity (Bostrom and Diderichsen 1997; Abraham et al. 2004; Gillum and Sempos 2005). For children, parent-reported height and weight are sometimes collected. In this situation, parents may underreport height among younger children (Akinbami and Ogden 2009).

55.3.4.2 Other Anthropometric Data

Waist circumference and skinfold thicknesses are two other common anthropometric measurements used to assess body fatness. Measurement sites for waist circumference include the natural waist (halfway between the lowest rib and iliac crest) or the level of the umbilicus (Wang et al. 2003). Some research suggests that waist circumference may be more strongly correlated with health outcomes than BMI (Janssen et al. 2004), particularly among Asians, while other research suggests the two have a similar relation to percent body fat (Flegal et al. 2009). The use of waist circumference is limited by the lack of standardization of measurement site and, for children, the lack of reference values. Skinfold measurements are collected using special calipers at specific locations using a standard technique (Hu 2008). Used in combination with prediction equations (Jackson and Pollock 1978), skinfold measurements provide body fat estimates (Peterson et al. 2003). However, measurement error associated with skinfold thickness limits its use in clinical and research settings (Bray et al. 1978; Marks et al. 1989; Ulijaszek and Kerr 1999).

55.3.5 Other Measures of Body Composition

Other measures of body composition include air displacement plethysmology (ADP) and radiographic imaging modalities including computed tomography (CT) and magnetic resonance imaging (MRI). ADP employs a similar technique to hydrodensitometry but does not require individuals to be submerged underwater as it uses air rather than water displacement for its calculations (Hu 2008). Body fat estimates from ADP are considered reliable (Fields et al. 2000; Noreen and Lemon 2006; Anderson 2007). Imaging modalities, including MRI and CT, allow for estimation of adipose tissue and quantification of the distribution of adipose tissue into visceral and subcutaneous deposits (van der Kooy and Seidell 1993; Plourde 1997). Thus, these images allow for fat estimates within individual organs as well as total body fat. However, the cost and inability of most MRI machines and CT scanners to accommodate very large individuals (BMI > 40 kilogram/meter^2) limit their application. Additionally, radiation exposure associated with a CT scan is a consideration (Brenner and Hall 2007).

55.4 Definitions for Obesity

Body mass index, or BMI, is the basis of the definitions for overweight and obesity (National Institutes of Health 1998; World Health Organization 2000) in population studies. Separate definitions are applied for children and adults. These definitions will be reviewed below.

55.4.1 Defining Overweight and Obesity: Adults

In adults, overweight and obesity are defined by fixed BMI values beyond which there are additional health risks, including hypertension, diabetes, and hypercholesterolemia. Obesity is defined similarly by the National Institutes of Health (NIH)/National Heart, Lung, and Blood Institute (NHLBI) in the United States (National Institutes of Health 1998) and by the World Health Organization (WHO) (World Health Organization 2000). Both organizations define obesity as a BMI of 30 kg/m^2 or greater. Cut-offs for obesity have been further divided into classes of obesity with class I corresponding to a BMI of 30–34.9 kg/m^2, class II to a BMI of 35–39.9 kg/m^2, and class III to a BMI greater than or equal to 40 kg/m^2. Class III obesity is sometimes referred to as severe or extreme obesity. NHLBI defines overweight as BMI greater than or equal to 25 kg/m^2 but less than 30 kg/m^2.

55.4.2 Defining Overweight and Obesity: Children

Unlike in adults, there are no single definitions of overweight and obesity for children. Health risks associated with obesity are not commonly detected during childhood. In the absence of such outcomes and because BMI varies with age, a statistical definition of overweight and obesity based on the percentile of BMI-for-age in a specified reference population is often used for children (Himes and Dietz 1994; Barlow and Dietz 1998; Krebs et al. 2007). The use of BMI *z*-score, based on standard deviations observed above the mean, after a normalizing transformation, is also used. Overweight and obesity in children are often defined as a BMI between the 85th and 95th percentiles and a BMI at or above the 95th percentile (Himes and Dietz 1994; Barlow and Dietz 1998; Krebs et al. 2007), respectively, or a BMI z-score between $+2$ and $+3$ and a BMI *z*-score greater than $+3$, respectively (de Onis and Blossner 2003; Flegal and Ogden 2011).

For children, where overweight and obesity are defined in reference to a specified population, the composition of the population to which the children are being compared is important to consider. In the United States (Kuczmarski et al. 2002) and other countries (Cole et al. 1998; Cacciari et al. 2006), the use of historical reference data drawn from a nationally representative sample of children from within the country is a common method by which children are compared in defining overweight and obesity. In the United States, the Centers for Disease Control and Prevention (CDC) 2000 growth charts (Kuczmarski et al. 2002) are commonly used as the reference for defining overweight and obesity. To develop the CDC growth charts, measured heights and weights from a representative sample of children were collected from national survey data in the 1960s, the 1970s, and, for children under 6 years, 1988–1994 (Kuczmarski et al. 2002). An example of the 2000 CDC growth charts is shown in Fig. 55.1, which demonstrates BMI-for-age for boys, ages 2–20 years.

Another reference to define overweight and obesity in children is the 2000 International Obesity Task Force (IOTF) published BMI cut-off values based on six nationally representative data sets with measured heights and weights from Brazil, Great Britain, Hong Kong, the Netherlands, Singapore, and the United States (Cole et al. 2000). These values, often referred to as the International Obesity Task Force cut-off values, were developed to provide a common definition for childhood overweight and obesity and thus facilitate comparisons of prevalence estimates to be used by researchers and policymakers in the international community (Cole et al. 2000). These values were not intended to replace national reference data. The cut-off values themselves were chosen as the percentiles that matched the adult cut-offs for overweight and obesity at age 18 years (i.e., a BMI of 25 kg/m^2 and a BMI of 30 kg/m^2, respectively).

In 2006, the World Health Organization (WHO) released BMI-for-age growth standards for preschool-age children from birth to 5 years of age. The approach for the development of these growth charts was different from that used for the CDC 2000 growth charts and for the IOTF cut-off values. Rather than using a descriptive reference sample, the WHO growth standards were based on data from children living in optimal conditions for growth in selected sites in Brazil, Ghana, India, Norway, Oman, and the United States of America (WHO Multicentre Growth Reference Study Group 2006). Specific inclusion criteria included no known health or environmental constraints to growth, exclusive or predominant breastfeeding for at least 4 months, continued breastfeeding to at least 12 months of age, no maternal smoking before and after delivery, single term birth, and absence of

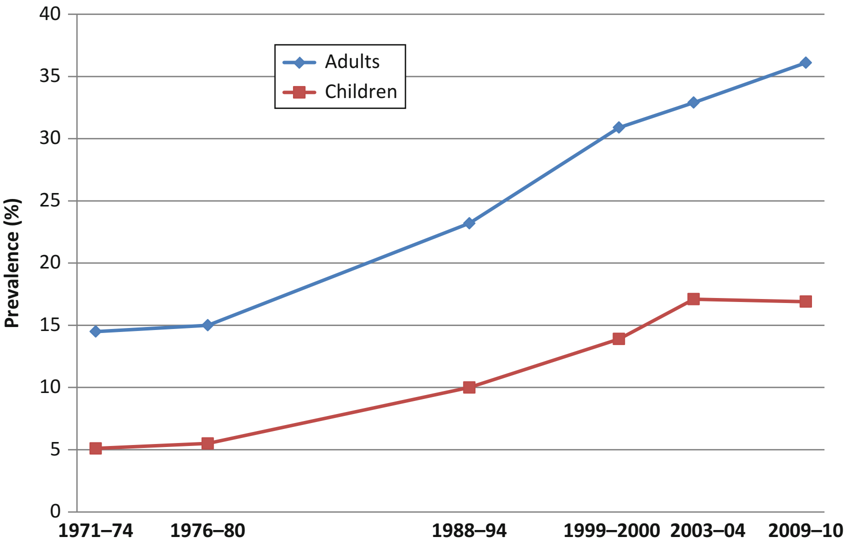

Fig. 55.2 Obesity trends among persons aged 2–19 and 20–74 years, USA, 1971–1974 through 2007–2008. Obesity defined as BMI >= 30 for adults and high BMI as BMI-for-age >= 95th percentile on the sex specific 2000 CDC Growth Charts for 2–19 years (Sources: Fryar et al. (2012a, b))

significant morbidity (de Onis et al. 2004). The WHO growth charts are intended to present a standard of physiologic growth. In 2007, the WHO released growth references for children and adolescents aged 5–19 years (de Onis et al. 2007). Unlike the growth standards for younger children, the WHO growth references for children and adolescents aged 5–19 years are based on national survey data from the United States.

55.5 Prevalence and Trends of Obesity

Temporal trends in obesity prevalence assessed by BMI for adults and children and adolescents in the United States between 1971 and 2010 are presented in Fig. 55.2 Fryar et al. (2012a, b). Generally, the prevalence of obesity in the United States increased between 1976–1980 and 1999–2000 for adults and children and adolescents. However, there are differences in obesity prevalence by demographic variables, including sex and race/ethnicity, which will be discussed below.

55.5.1 Prevalence and Trends of Obesity in the United States: Adults

Using the NHLBI obesity definition, between 1976–1980 and 1999–2000, the prevalence of obesity increased from 12.7% to 27.7% in men and 17.0–33.4% in

Table 55.1 Prevalence of obesity[a] among adults aged 20–74 years by sex, United States, 1971–2010[b]

	Sex	
Survey years[b]	Men(%)	Women(%)
1971–1974	12.1	16.6
1976–1980	12.7	17.0
1988–1994	20.5	25.9
1999–2000	27.7	34.0
2001–2002	28.3	34.1
2003–2004	31.7	34.0
2005–2006	33.8	36.3
2007–2008	32.5	36.2
2009–2010	35.9	36.1

[a] Obesity defined as BMI ≥ 30

Table 55.2 Prevalence of obesity[a] among children aged 2–19 years by sex, United States, 1971–2010[b]

	Sex	
Survey years[b]	Boys(%)	Girls(%)
1971–1974	5.2	5.0
1976–1980	5.4	5.7
1988–1994	10.2	9.8
1999–2000	14.0	13.8
2001–2002	16.4	14.3
2003–2004	18.2	16.0
2005–2006	15.9	14.9
2007–2008	17.7	15.9
2009–2010	18.6	15.0

[a] Obesity defined as BMI ≥ 95th percentile on the 2000 sex- and age-specific CDC growth charts

[b] Based on data from the National Health and Nutrition Examination Surveys reported by Ogden et al. (2010), Moreno et al. (2011), and Fryar et al. (2012a)

women (Table 55.1). In 2005–2006, the prevalence of obesity was 33.3% for men and 35.3% for women. More recently, there has not been a significant increase for women; however, there may be increases in obesity prevalence for men (Flegal et al. 2010a).

55.5.2 Prevalence and Trends of Obesity in the United States: Children and Adolescents

Obesity, defined as a BMI ≥ 95th percentile on sex- and age-specific 2000 CDC growth charts, increased among boys from 5.4% to 14% between 1976–1980 and 1999–2000 (Table 55.2). Among girls, the increase was from 5.7% to 13.8%.

Of note, the estimates of childhood obesity in 1976–1980 are close to 5% by definition; data from this time period were included in the construction of the 2000 CDC growth charts and contributes to the statistical definition of obesity. The prevalence of obesity in 2005–2006 was 15.9% for boys and 15.0% for girls. More recent data suggests among girls that childhood obesity has remained stable in the United States since 2000.

55.5.3 Race/Ethnicity and Obesity in the United States

In the United States, there are differences in BMI-defined obesity by race/ethnicity. Hispanic boys, but not Hispanic girls, have a higher likelihood of obesity than non-Hispanic whites (Ogden et al. 2010). Among girls, non-Hispanic blacks have a higher likelihood of obesity, measured by BMI, than non-Hispanic whites (Ogden et al. 2010). Among men, obesity prevalence is similar across race/ethnic groups (Flegal et al. 2010a). Among women, non-Hispanic blacks and Mexican Americans have a higher likelihood of obesity than non-Hispanic whites (Flegal et al. 2010a). Describing racial and ethnic differences in the prevalence of obesity, defined by BMI, has some limitations as there are differences in body fat between race and ethnic groups at the same BMI level (Deurenberg et al. 2002; Flegal et al. 2010b).

55.5.4 Global Obesity Prevalence

The prevalence of obesity in other North American countries is generally lower than that seen in the United States. For example, in North American studies using measured heights and weights, the prevalence of obesity for adult men was 22.9% in Canada (in 2004) (Tjepkema 2006), 33.8% in the United States (in 2005–2006, Table 55.1), and 24.2% in Mexico (in 2006) (Olaiz-Fernàndez et al. 2006). Likewise among women, the prevalence of obesity is 23.2% in Canada (in 2004) (Tjepkema 2006), 36.3% in the United States (in 2005–2006, Table 55.1), and 34.5% in Mexico (in 2006) (Olaiz-Fernàndez et al. 2006). However, obesity extends beyond North America and is increasingly being referred to as a global epidemic (World Health Organization 2000). To track the global prevalence of adult obesity, the WHO maintains the Global Database on Body Mass Index (World Health Organization 2010). Although obesity prevalence estimates in the database may not be directly comparable because of differences in sampling procedures, sampling years, collection methods, and ages of inclusion, they provide a comprehensive overview of obesity prevalence from around the world. For example, Nauru is noted to have the highest obesity prevalence (78.5%), while Vietnam is noted to have the lowest prevalence of obesity (0.46%) (World Health Organization 2010).

In addition to the challenges in comparing adult obesity prevalence between countries, the challenge is further magnified for children because of differences in definition of obesity used in the studies. One study of children ages 11–15 years from 41 countries conducted in 2005–2006 defined obesity according to the IOTF

Table 55.3 Prevalence of obesity among children by country/region using the IOTF definition[a]

Country	Boys	Girls	Years	Ages
Cyprus	6.9	5.7	1999–2000	6–17
Great Britain	6.9	7.4	2007	2–10
	4.8	6.1	2007	11–18
France	3.8	3.6	2000	7–9
Beijing, China	8.0	3.2	2004	2–18
Canada	8.1	7.2	2004	2–17

[a] Based on measured height and weight as reported by Rolland-Cachera et al. (2002), Savva et al. (2005), Shields and Tremblay (2010), and Stamatakis et al. (2010)

cut-offs using self-reported height and weight (Haug et al. 2009). Results indicated wide ranges of obesity prevalence between countries, with a notably high prevalence in Malta (10.7%) and the United States (8.9%) and notably low prevalence in Latvia (0.9%), Lithuania (0.9%), and Russia (0.9%). Childhood obesity prevalence, using the IOTF definition, for select cities/countries based on measured data collected during a similar time frame is presented in Table 55.3. Like in the United States, the rate of increase of childhood obesity may have slowed in other countries, including Australia (Olds et al. 2010) and Sweden (Sjoberg et al. 2008).

55.6 Contributing Factors to Obesity: Diet

55.6.1 Temporal and Age-Related Trends in Food Availability and Mean Dietary Intakes

The prevalence of obesity in the United States and elsewhere increased during the 1980s and 1990s. During this time period, there were concomitant increases in the per capita food energy availability in the food supply (Balanza et al. 2007). For example, between 1970 and 1994, there was a 15.2% increase in the daily per capita availability of food energy in the United States (Harnack et al. 2000). Fats and oils, caloric sweeteners, carbonated soft drinks, and other food sources contributed to this increase (Putnam et al. 2002).

Among adults in the United States, the increased availability of food energy in the food supply may have translated into an increase in mean energy intake. For men, the mean daily energy intake (in kilocalories) increased from 2,450 to 2,618 kilocalories (kcal) between 1971–1974 and 1999–2000 (Wright et al. 2004). During the same time period, the increase for women was from 1,542 to 1,877 kcal (Wright et al. 2004). In addition to changes in caloric content of American's diet, there have been changes in its composition. For example, among the macronutrients, there was a decrease in the percent of calories from total and saturated fats and an increase in percent of calories from carbohydrates, while there has been a relatively stable contribution of percent of calories from dietary protein (Wright et al. 2004).

As opposed to adults, self- and parent-reported mean energy intake for children aged 1–19 years changed little between 1971–1974 and 1999–2000, except for adolescent females (Briefel and Johnson 2004). For example, among boys 16–19 years, mean energy intake was 3,010 kcal in 1971–1974 and 2,932 kcal in 1999–2000 while among girls 16–19 years, mean energy intake was 1,735 kcal in 1971–1974 and 1,996 kcal in 1999–2000. In more recent analyses, comparing 1988–1994 and 2003–2006, mean caloric intake of adolescent females did not further increase (Lamb et al. 2009).

55.6.2 Global Trends in Nutrition

Similar to the United States, there was an increase (17%) in total food energy availability in Europe between 1961 and 2001 (Schmidhuber and Traill 2006). However, there has also been marked shifts in the structure of diets around the world, including South Korea (Kim et al. 2000), Brazil (Monteiro et al. 1995), China (Popkin 2001a), and India (Popkin et al. 2001). These dietary changes, sometimes referred to as the nutrition transition, are often unique to specific countries but may include increases in the consumption of fat and added sugar and decreases in dietary fiber (Popkin 2001b). Changing nutrition patterns and increasing obesity prevalence pose particularly unique challenges where obesity and undernutrition coexist, including Uzbekistan, Kiribati, and Algeria (de Onis and Blossner 2000).

55.6.3 Influence of Diet on Obesity

Among adults, increases in mean energy intake between 1971 and 2000 may partially explain the increase in obesity prevalence. However, no similar changes were seen among children. Additionally, further evidence suggests an increase in calories *does not* seem to explain the development of obesity among children (Eck et al. 1992; Troiano et al. 2000). One possible explanation for the lack of association between caloric intake and development of obesity is the limitation of the data. For example, much of the data for caloric intake is derived from 24-hour recalls and is subject to recall bias. Consumers' knowledge of the content of food and the ability to recall dietary intake may have changed since the 1970s, thereby limiting comparisons in dietary recall over time. Another possible explanation for the development of obesity may be the quality of one's diet including eating patterns and food composition, in addition to the quantity.

55.6.4 Eating Patterns

Between the 1970s and 1990s, there were increases in the consumption of meals away from home among Americans of all age (Nielsen et al. 2002). Meals consumed outside the home are associated with more calories (Guthrie et al. 2002) and higher dietary fat intake (Kearney et al. 2001; O'Dwyer et al. 2005) than meals consumed at home. One prospective cohort study conducted in Spain found a positive association between eating meals outside the home and the development of overweight and obesity (Bes-Rastrollo et al. 2009).

Between the 1970s and 1990s portion sizes increased in the United States for meals consumed both inside and outside the home (Nestle 2003; Nielsen and Popkin 2003). Larger portion sizes are associated with increased calories consumed during a meal (Diliberti et al. 2004) without compensatory decreases in calories consumed at subsequent meals (Kral and Rolls 2004; Rolls et al. 2004).

55.6.5 Composition of the Diet

55.6.5.1 Breast Milk

Breastfeeding for the first 4–6 months may protect individuals later in life against developing obesity (Institute of Medicine 2005; Owen et al. 2005). It has also been suggested that a longer duration of breastfeeding may further protect against developing obesity (Harder et al. 2005). There are several proposed mechanisms of protection against obesity including better ability to behaviorally respond to satiety cues (Fisher et al. 2000; Dewey 2003) and/or through biological activity of breast milk (Weyermann et al. 2007). In the absence of contraindications to breastfeeding, supporting breastfeeding has important benefits including its role in obesity prevention.

55.6.5.2 Dietary Fiber

Foods high in dietary fiber include fruits, vegetables, whole grains, legumes, and nuts. In cross-sectional studies, intake of dietary fiber is inversely associated with body weight (Miller et al. 1994; Nelson and Tucker 1996). In three prospective studies following participants between 6 and 14 years, diets with higher fiber content have been inversely associated with subsequent weight gain (Ludwig et al. 1999; Liu et al. 2003; Du et al. 2010). Research of specific dietary fiber sources have shown fruits and vegetables (He et al. 2004; Tang et al. 2010), whole grains (Koh-Banerjee et al. 2004), and nuts (Bes-Rastrollo et al. 2007) to also have an inverse association with obesity or weight gain (Hu 2008).

55.6.5.3 Sugar-Sweetened Beverages

In the United States, intake of added sugar accounts for 15.8% of total energy consumed, and the largest source of added sugars is from sugar-sweetened beverages, including carbonated sodas, fruit punch, and sports drinks (Guthrie and Morton 2000; Wang et al. 2008). A systemic review found that in feeding trials of adults, the intake of sugar-sweetened beverages supports weight gain (Malik et al. 2006). In prospective studies, sugar-sweetened beverages were associated with weight gain and obesity in children (Ludwig et al. 2001; Berkey et al. 2004) and adults (Schulze et al. 2004).

55.7 Contributing Factors to Obesity: Physical Activity

55.7.1 Temporal and Age-Related Trends in Physical Activity

In the United States, between the years 1950 and 2000, there were increases in the percent of adults who work in low physical activity occupations and declines in the proportions of persons who walk to work (Brownson et al. 2005). During the same time period, there were increases in the average daily vehicle miles traveled (Brownson et al. 2005). Changes in commuting patterns are not isolated to adults. Between 1969 and 2001, there were declines in the proportion of children who walked or rode a bicycle to school in the United States (McDonald 2007).

Data for national trends in leisure time physical activity in the United States are available from 1988 onward. Much of the physical activity, estimates are based on self-reported physical activity and individuals are characterized as physically inactive, i.e., no reported leisure time physical activity in the preceding month, or meeting recommended physical activity guidelines (United States Department of Health and Human Services 1996, 2008) and/or national goals (United States Department of Health and Human Services 2000). The data for physical inactivity are more comparable across years because of uniformity in the definition of physical inactivity. Trends in physical inactivity in the United States show a decline from 30.5% in 1988 to 25.1% in 2008 (CDC 2010) despite an increase in obesity prevalence.

Based on self-reported data, older Americans are more inactive than younger Americans (Kruger et al. 2005). Results of accelerometer-measured physical activity add to this finding. For example, children spend more time in physical activity than adolescents, and adolescents spend more time in physical activity than adults (Nader et al. 2008; Troiano et al. 2008). Further, accelerometer studies have shown that the age-related decline in physical activity largely occurs between 13 and 18 years and this decline is greater for men than women (Sallis 2000). Despite steeper declines in physical activity with aging for men, women have overall lower participation in physical activity in all age categories (i.e., childhood, adolescence, and adulthood) (Troiano et al. 2008).

55.7.2 Global Trends in Physical Activity

Similar to the United States, decreases in physical activity related to occupation and commute have been observed in other countries including European countries (Stamatakis et al. 2007; Lindahl et al. 2003), New Zealand (Tin Tin et al. 2009), Australia (Bell et al. 2006), and China (Popkin 2008). Increases in leisure time physical activity have been noted in Europe (Simmons et al. 1996; Lindstrom et al. 2003).

55.7.3 Association of Physical Activity with Obesity

Ecological studies comparing physical activity levels in multiple countries reveal an inverse association between physical activity and obesity (Bassett et al. 2008). Moreover, data from cross-sectional and longitudinal studies also demonstrate an inverse association between physical activity and both obesity and weight gain (Seidell et al. 1991; Lahti-Koski et al. 2002; Chan et al. 2003; Bernstein et al. 2004; United States Department of Health and Human Services 2008). However, the strength of these associations is tempered by the limited longitudinal data using direct measures of physical activity (Hu 2008). Objective measures of physical activity are preferable because persons tend to overreport physical activity levels (Troiano et al. 2008).

55.7.4 Sedentary Behaviors

Sedentary behaviors, including television viewing and computer/video game use, may impact health outcomes, including obesity (Dietz and Gortmaker 1985; Tucker and Friedman 1989; Tucker and Bagwell 1991; Ching et al. 1996; Jakes et al. 2003; Stettler et al. 2004), cardiovascular disease (Fung et al. 2000), and diabetes (Hu et al. 2003) independent of level of physical activity. Results from birth cohorts from New Zealand and Great Britain have found an association between early childhood television viewing and obesity in adulthood (Hancox et al. 2004; Viner and Cole 2005). Proposed mechanisms for the association between television viewing and obesity include increased snacking between meals and increased exposure to the effects of commercials (Thomson et al. 2008; Parvanta et al. 2010).

55.8 Contributing Factors to Obesity: Community and Home Environment

55.8.1 Community Factors

There is growing literature evaluating the role of community and home environments in obesity. One area of research that has focused on the community environment specifically examines the role of the "built environment." In the context of obesity, people often refer to the "built environment" as "access to grocery stores selling healthy foods, proximity and safety of playgrounds, and adequate housing" (Singh et al. 2010). Other community factors may impact dietary intake and physical activity levels among individuals. For example, access to affordable (French et al. 1997, 2001) and fresh food can impact food choices. Likewise, recreational facilities and community infrastructure to support bicycling, walking (Owen et al. 2004), and use of public transportation (Besser and Dannenberg 2005) can impact physical activity levels.

A walkability index has been used to research the relationship between the built environment and physical activity. One example of a commonly used walkability index is the Neighborhood Environment Walkability Scale (NEWS) (Saelens et al. 2003), a self-reported survey which assesses the following elements: residential density; proximity to, and ease of access to, non-residential land uses, such as restaurants and retail stores (land use mix-diversity and land use mix-access); street connectivity; walking/cycling facilities, such as sidewalks and pedestrian/bike trails; aesthetics; traffic safety; and crime safety. Other researchers have developed walkability indexes, based on geographic information systems (GIS), which have incorporated diverse measures including residential density, intersection density, and land use mix (Frank et al. 2010). Much of the research suggests that individuals living in a neighborhood with a high walkability index, defined by either NEWS (Saelens et al. 2003) or a GIS-derived scale (Frank et al. 2010; Van Dyck et al. 2010), are more active than individuals living in a neighborhood with a low walkability index.

55.8.2 Home Environment Factors

The association between parental and childhood obesity has been well described and can be attributed in part to a shared home environment (Strauss and Knight 1999; Kral and Rauh 2010) in addition to shared genetic factors (Faith et al. 1999). The home environment provides children an opportunity to model healthy lifestyle behaviors, including food consumption routines (Birch and Davison 2001) and dietary preferences (Fisher et al. 2002). A study examining the eating habits of preschool children showed that the parents' nutrient intake influenced those of their children (Oliveria et al. 1992). Another study, which included children ages 6–19 years, found similar associations (Laskarzewski et al. 1980).

A common feature of today's home environment is the television. American children on average view 1.8–2.8 h of television per day (Marshall et al. 2006). As a result, there is interest in exploring the components of television viewing, including television advertisements, and possible associations with obesity. In the United States (Powell et al. 2007), Mexico (Ramirez-Ley et al. 2009), Bulgaria (Galcheva et al. 2008), and elsewhere, food and beverage commercials are common. There is growing evidence that exposure to food and beverage advertisements may contribute to obesity in childhood and this influence cannot be entirely explained by reduced physical activity (Jackson et al. 2009; Zimmerman and Bell 2010).

55.9 Health Consequences of Obesity

Obesity has been linked to a wide range of health outcomes including hypertension, hypercholesterolemia, diabetes, gallbladder disease, osteoarthritis, sleep apnea, and cancers (National Institutes of Health 1998). Hypertension and hypercholesterolemia are important risk factors for the development of cardiovascular disease

(Clarke et al. 2009). Increased mortality from diabetes (Rogers et al. 2003), cancer (Flegal et al. 2007), and cardiovascular disease (Flegal et al. 2007) also has been attributed to obesity. In this section, mortality associated with overweight and obesity as well as select health consequences of obesity will be discussed. Further, the tracking of childhood obesity into adulthood will be highlighted.

55.9.1 Mortality

Compared with normal weight adults, obese adults have an increased all-cause mortality (Flegal et al. 2005; Berrington de Gonzalez et al. 2010). In a study of a representative sample of the United States population, this association was largely driven by the increased mortality from cardiovascular disease (CVD) among obese adults and, to a lesser extent, diabetes and kidney diseases combined, as well as cancers that have been epidemiologically associated with obesity which included colon, breast, esophageal, uterine, ovarian, kidney, and pancreatic cancers (Flegal et al. 2007). However, mortality from other cancers and non-cancer, non-CVDs were not associated with obesity. In the same study, Flegal et al. reported overweight, compared with normal weight, adults had a decreased all-cause mortality. Analysis of cause-specific mortality showed that overweight was not associated with mortality from cardiovascular disease or cancer and was associated with increased mortality from diabetes and kidney diseases combined and decreased non-cancer, non-CVD mortality. Other studies have reported increased mortality among overweight adults (Berrington de Gonzalez et al. 2010). However, differences in exclusion criteria and reference categories limit the ability to compare results across studies.

55.9.2 Hypertension

Hypertension, often defined as sustained systolic blood pressure of 140 mm of mercury (Hg) or greater or a diastolic blood pressure of 90 mm Hg or greater (Whitworth 2003; Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure 2004), is a risk factor for the development of a range of medical complications including coronary heart disease, cerebrovascular disease, renal disease, and congestive heart failure. Obesity is associated with hypertension in adults (MacMahon et al. 1987; Brown et al. 2000; Kotsis et al. 2010) and children (Kollias et al. 2009; Ostchega et al. 2009). Studies using a prospective cohort design have demonstrated increases in systolic and diastolic blood pressure with increases in BMI (Franklin et al. 2005). Further, clinical trials have shown that weight loss can lower blood pressure (Satterfield et al. 1991; The Trials of Hypertension Prevention Collaborative Research Group 1992, 1997). Worldwide, high blood pressure is responsible for 7.1 million premature deaths per year (World Health Organization 2002).

55.9.3 Hypercholesterolemia

By contributing to the development of arthrosclerosis (Stamler et al. 1986; Wilson et al. 1998), an elevation in serum cholesterol is associated with the development of coronary vascular disease and cerebrovascular disease. High total cholesterol is defined as a value greater than 240 mg/dL (National Cholesterol Education Program 2002). Overweight and obese (BMI $\geq$ 25 kg/m^2) persons are more likely to have an elevation in total cholesterol when compared with those with a healthy weight (Brown et al. 2000). Cholesterol levels track from childhood into adulthood (Lauer et al. 1988), and childhood cholesterol levels may predict the development of arthrosclerosis in adulthood (Li et al. 2003; Raitakari et al. 2003). Hypercholesterolemia has been estimated to be responsible for four million premature deaths per year (World Health Organization 2002).

55.9.4 Diabetes

Prevalence of type II diabetes, a state of hyperglycemia (elevated blood sugar) and relative insulin resistance, is higher among those with higher weight (Hartz et al. 1983; Colditz et al. 1995). In fact, obesity is a leading risk factor for the development of diabetes (National Institutes of Health 1998), and similar to obesity, there was an increased trend in diagnosed diabetes prevalence between 1970 and 1990 (Fox et al. 2006). Diabetes is a risk factor for the development of cardiovascular disease, end-stage renal disease, retinopathy, neuropathy, and other adverse health outcomes. Weight reduction, along with dietary and physical activity modifications and medications, is an important component of guideline-recommended care for diabetes treatment (American Diabetes Association 2010). Worldwide, a BMI above 21 kg/m^2 is estimated to account for approximately 58% of diabetes cases (World Health Organization 2002).

55.9.5 Cancer

Obesity has been associated with increased risk of cancers of the uterus, kidney, gallbladder, breast (postmenopausal women), esophagus, and colon (Calle et al. 2003). Obese individuals have a higher mortality from cancer types known to be epidemiologically associated with obesity (Flegal et al. 2007). Biological mechanisms for cancer risks are not fully understood and are likely different for different cancer types. However, some evidence suggests that there may be obesity-induced hormonal changes (World Health Organization 2002), including sex steroids, insulin, and insulin-like growth factors (Renehan et al. 2008). An estimated 2% of cancer mortality worldwide is associated with overweight and obesity (Danaei et al. 2005).

55.9.6 Tracking of Obesity from Childhood to Adulthood

Weight tracks from childhood into adulthood (Serdula et al. 1993; Fuentes et al. 2003). This means that obese children often become obese adults. Children as young as 2–5 years with an elevated BMI may be at higher risk for obesity during adulthood (Freedman et al. 2005). Further, obese children may have higher than expected levels of morbidity and mortality in adulthood (Mossberg 1989; Must et al. 1992; Gunnell et al. 1998). Given the propensity for young obese children to remain obese in adulthood, there is increased interest in understanding the influences of early childhood experiences in determining obesity outcomes (Reilly et al. 2005; Taveras et al. 2010).

55.10 Socioeconomic Consequences of Obesity

Overweight and obesity have a significant impact on individual economic and social achievements. Additionally, the collective individual health and socioeconomic consequences of obesity have important societal costs, including added health-care costs. While not individually discussed, there are other measures of increased societal cost including reduced work potential as a result of occupational absenteeism (Cawley et al. 2007) and excess morbidity and mortality.

55.10.1 Individuals

Lower achievement of advanced education (Wardle et al. 2002; Karnehed et al. 2006; Hajian-Tilaki and Heidari 2010), rates of employment (Klarenbach et al. 2006; Tunceli et al. 2006), and income (Baum and Ford 2004; Brunello and D'Hombres 2007; Staub et al. 2010) among obese individuals have been described. For example, one study showed that an increase in BMI of 10% was associated with a 3.3% and 1.9% lower hourly wage for men and women, respectively (Brunello and D'Hombres 2007). There are likely multiple mechanisms by which obesity and socioeconomic status are related. However, there has been a suggestion that negative attitudes, stigmatization, and stereotypes toward obese individuals are contributors to these differences (Puhl et al. 2008; Puhl and Heuer 2009).

In addition to differences in educational and economic achievements between obese and non-obese individuals, there are differences in other important social measures, including interpersonal relationships. Among children and adolescents, obesity is associated with lower level of satisfaction with life (Erickson et al. 2000; Franklin et al. 2006; BeLue et al. 2009) and increased difficulty making friends (Strauss and Pollack 2003; Fonseca et al. 2009). Among adults, reduced quality of relationships with friends (Ball et al. 2004) and romantic partners have been reported (Boyes and Latner 2009). Further, obese adults report lower health-related quality of life (Jia and Lubetkin 2005; Sach et al. 2007; Soltoft et al. 2009; Renzaho et al. 2010).

55.10.2 Health-Care System

Increased medical expenditures have been attributed to obesity. Higher use of primary care and other outpatient services (van Dijk et al. 2006), inpatient services (Finkelstein et al. 2009), and prescription medications (van Dijk et al. 2006; Finkelstein et al. 2009; Milder et al. 2010) among obese individuals contribute to the increased medical costs (Wolf and Colditz 1998). Estimates for the percentage of national health expenditures attributable to obesity differ by country. North American, Australian, and European data from the late 1980s and 1990s showed 2–6% of national health expenditures were attributed to obesity (Segal et al. 1994; Levy et al. 1995; Wolf and Colditz 1998; Birmingham et al. 1999). However, more recent data (2006) from both the United States and Canada show increases in national health expenditures attributable to obesity (Anis et al. 2010; Finkelstein et al. 2009).

55.11 Emerging Research

55.11.1 Prenatal and Early Infancy

Prenatal and early infancy factors may influence the development of obesity. For example, higher prevalence of obesity among children exposed in utero to excessive gestational weight gain (Oken et al. 2008; Wrotniak et al. 2008) and diabetes (Gillman et al. 2003; Wright et al. 2009) has been described. Birth weight may also be associated with obesity. However, the relationship between birth weight and obesity is complex and has not been consistently described in the literature. Some studies have found little or no association between birth weight and obesity (Parsons et al. 2001; The et al. 2010), while other research suggests both low birth weight and high birth weight are associated with obesity (Curhan et al. 1996a, b; Sorensen et al. 1997). Factors in early infancy may also be associated with obesity. These factors include duration of breastfeeding, which was previously described in this chapter, timing of introduction of solid foods (Baker et al. 2004; Seach et al. 2010), and rapidity of weight gain (Baird et al. 2005). More research into the prenatal and early infancy experiences is needed.

55.11.2 Sleep

Physiologic responses to sleep deprivation include elevated blood pressure (Tochikubo et al. 1996), impaired glucose tolerance (Spiegel et al. 1999), increased fatigue (Dinges et al. 1997), and increased hunger (Spiegel et al. 2004). Sleep deprivation may also predispose individuals to obesity (Patel and Hu 2008) and growing evidence suggests that shorter sleep duration may be associated with higher obesity prevalence in children (Gupta et al. 2002) and adults

(Gangwisch et al. 2005; Patel and Hu 2008). Further research, including more studies with objective measures of sleep duration, is warranted (Patel and Hu 2008).

55.12 Conclusions

Obesity prevalence has increased over the last 3 decades although the increase appears to have slowed in the United States and elsewhere. The magnitude of obesity is defined not only by its global prevalence but also by its health and socioeconomic consequences. Ongoing research to more fully characterize the dietary and physical activity patterns of individuals and societies continues to provide additional understanding into the factors that contribute to obesity. Knowledge of these factors informs interventions, including the United States' Surgeon General Vision for a Healthy and Fit Nation, 2010 (Benjamin 2010), to achieve maximal benefits.

The findings and conclusions in this report are those of the authors and not necessarily those of the Centers for Disease Control and Prevention.

56.1 Introduction

Asthma has puzzled and confused physicians from the time of Hippocrates to the present day. The word “asthma” comes from a Greek word meaning “panting” (Keeney 1964), but reference to asthma can also be found in ancient Egyptian, Hebrew, and Indian medical writings (Ellul-Micallef 1976; Unger and Harris 1974). There were clear observations of patients experiencing attacks of asthma in the second century and evidence of disordered anatomy in the lung as far back as the seventeenth century (Dring et al. 1689).

More recently, Western countries have experienced an epidemic of respiratory allergy and asthma prevalence (and incidence) that appears to have commenced after the Second World War and has only recently peaked and begun to decline (Pearce et al. 2007). The reasons for the decline remain as mysterious as the reasons for the epidemic itself (Weiland and Pearce 2004). Current WHO estimates suggest that some 300 million persons suffer from asthma, which is the most common chronic disease among children (WHO 2007). In 2010, the annual economic cost of asthma in the United States was estimated to be >$15 billion in direct costs and >$5 billion in indirect costs such as lost productivity (American Lung Association 2010).

Formal epidemiological studies of respiratory allergies and asthma commenced about 50 years ago, and in some respects they have failed to deliver the insight or testable hypotheses that have derived from studies of other common diseases. The roots of this failure lie in the problem of defining asthma, and the consequent difficulty of reproducible and conclusive case ascertainment; in the transient nature of the principal symptoms, the fact that asthma is heterogeneous in its underlying pathophysiology; and in the absence of simple sensitive and specific markers for the condition. However, the epidemiology of asthma and allergy is currently undergoing a rapid expansion and has shifted attention from traditional risk factors which may exacerbate asthma, to protective factors that may prevent respiratory allergies and asthma. This growth of interest is occurring in the context of major concerns about the increasing burden of respiratory allergy and asthma morbidity, and the realization that previous etiological theories based on animal models of asthma and clinical observations do not appear to explain the large global increases in asthma prevalence.

This chapter begins with the definitions and the underlying pathology and physiology of respiratory allergies and asthma, before considering the distinctive features of asthma epidemiology. We subsequently review the global burden of respiratory allergies and asthma and discuss a wide range of potential risk and protective factors. The chapter concludes with a discussion of the role of epidemiology in respiratory allergies and asthma research, and the challenges it is facing, followed by a discussion of the foremost issues for the future of respiratory allergies and asthma epidemiology.

56.2 Definitions of Respiratory Allergies and Asthma

56.2.1 Respiratory Allergy

Allergy can be defined as adverse acute or chronic hypersensitivity reactions resulting from immunologic sensitization with production of immunoglobulin (Ig) E against a specific agent or allergen. Thus, the term "allergy" refers to symptomatic conditions (allergic asthma, rhinitis, etc.), whereas the term "sensitization" refers to an individual's immune status assessed by in vivo or in vitro diagnostic tests (see Sect. 56.4.3). Symptoms can be induced by inhalation of allergens, even at very low concentrations. Individuals that are not sensitized to these allergens will usually not show symptoms even with very high exposure. Symptoms in sensitized subjects are caused by inflammatory reactions initiated by allergen-specific IgE antibodies present in the airways. Only a proportion of sensitized subjects show symptoms and are thus also allergic. It can take weeks to years between the first encounter with an allergen and the development of an allergy.

56.2.2 Atopy

"Atopy" (allergic sensitization) is a common term for IgE-mediated sensitization and/or allergic reactions. In population studies, the term "atopy" is used to indicate the predisposition of individuals to produce increased levels of specific or total IgE after exposure to common allergens such as house dust mite, pet, and various food allergens. It is usually assessed by skin prick tests or specific and/or total serum IgE against common allergens (see Sect. 56.4.3), and it can therefore be defined either in terms of skin prick text positivity or elevated serum IgE levels (Pearce et al. 1999). Depending on the definition, about 20% to 40% of people in affluent countries are atopic. In population studies, atopy is often associated with an increased risk of asthma (Pearce et al. 1999), but the association is stronger in "Westernized" countries than in developing countries (Weinmayr et al. 2007).

56.2.3 Aeroallergens

Many macromolecules (particularly proteins) of non-human origin, including those of animals (e.g., arthropod proteins, animal danders, proteins in excretia), plants (e.g., pollens, latex dust), and microorganisms (e.g., spores of fungi such as *Alternaria, Aspergillus,* and *Penicillium*), can act as allergens by inducing a specific IgE response and provoke allergic reactions in sensitized subjects.

Dust mites produce the predominant inhalant allergens in many parts of the world. The most common mite species that produce allergens are *Dermatophagoides pteronyssinus* and *D. farinae*. The major allergens produced by *D. pteronyssinus* (called Der p 1 and Der p 2) are proteases present in high amounts in fecal pellets. *D. farinae* produces as its major allergen Der f 1. Elevated levels of these allergens have been detected in house dust, mattress dust, and bedding in damp homes (van Strien et al. 1994).

Other important inhalant allergens include proteins associated with cats and dogs, cockroaches, grass and tree pollens, and fungi such as *Alternaria*. Allergens in the occupational environment can range from cow urinary proteins in farming situations to fungal enzymes in the biotechnology and bakery industry. Low molecular weight chemicals such as diisocyanates (e.g., tolueen diisocyanate, TDI) can also cause occupational allergic asthma, but the specific immunological mechanisms have not yet been resolved.

56.2.4 Asthma

The definition of asthma initially proposed at the Ciba Foundation conference in 1959 (Ciba Foundation Guest Symposium 1959) and endorsed by the American Thoracic Society in 1962 (American Thoracic Society Committee on Diagnostic Standards 1962) is that "asthma is a disease characterized by wide variation over short periods of time in resistance to flow in the airways of the lung." Although these features receive lesser prominence in some current definitions, as the importance of airways inflammation is appropriately recognized, they still form the basis of the recent Global Initiative for Asthma (GINA) description of asthma as:

> . . . a chronic inflammatory disorder of the airways in which many cells and cellular elements play a role. The chronic inflammation is associated with airway hyper-responsiveness that leads to recurrent episodes of wheezing, breathlessness, chest tightness, and coughing, particularly at night or in the early morning. These episodes are usually associated with widespread, but variable, airflow obstruction within the lung that is often reversible either spontaneously or with treatment. (GINA 2006)

These three components, chronic airways inflammation, reversible airflow obstruction, and enhanced bronchial reactivity, form the basis of current definitions of asthma. They also represent the major pathophysiological events leading to the symptoms of wheezing, breathlessness, chest tightness, cough, and sputum by which physicians clinically diagnose this disorder.

56.2.5 Clinical Asthma

There is no single test or pathognomic feature which defines the presence or absence of asthma. Furthermore, the variability of the condition means that evidence of it may or may not be present on the day, or at the time, that someone is assessed. Thus, a diagnosis of asthma is made on the basis of the clinical history, combined with physical examination and respiratory function tests over a period of time. Several studies have found the prevalence of physician-diagnosed asthma to be substantially lower than the prevalence of asthma symptoms in the community (e.g., Asher et al. 1998). This is not surprising since a clinical diagnosis of asthma can only be made if a person presents him or herself to a doctor. This requires an initial self-assessment of the symptoms (in terms of severity and frequency), as well as access to a doctor

Table 56.1 GINA classification of asthma severity

Asthma classification	Criteria
Intermittent	Symptoms less than once a week; brief exacerbations; nocturnal symptoms not more than twice a month; FEV_1 or PEF $\geq$80% predicted; FEV_1 or PEF variability <20%
Mild persistent	Symptoms more than once a week but less than once a day; exacerbations may affect activity and sleep; nocturnal symptoms more than twice a month; FEV_1 or PEF $\geq$80% predicted; FEV_1 or PEF variability 20–30%
Moderate persistent	Symptoms daily; exacerbations may affect activity and sleep; nocturnal symptoms more than once a week; daily use of inhaled short-acting β_2-agonist; FEV_1 or PEF 60–80% predicted; FEV_1 or PEF variability >30%
Severe persistent	Symptoms daily; frequent exacerbations; frequent nocturnal asthma symptoms; limitation of physical activities; FEV_1 or PEF $\leq$60% predicted; FEV_1 or PEF variability >30%

FEV_1 Forced Expiratory Volume in one second, *PEF* Peak Expiratory Flow

once a self-assessment has been made. Several medical consultations may then be required. Thus, diagnosed asthma is dependent not only on morbidity but also on patient perceptions, physician practice, and the availability of health care.

There are a number of tests that may facilitate the diagnosis and monitoring of asthma. Measurements of lung function are the most frequently used and provide important information on airflow limitation including variability, reversibility, and severity. Airflow limitation is most often measured using spirometry or a peak (expiratory) flow (PEF) meter. Spirometry is the preferred method and forced expiratory volume in one second (FEV_1), and peak expiratory flow (PEF) can be derived from this method as indicators for airway obstruction. Pre- and postbronchodilator treatment is important since it will establish whether obstruction is reversible and will distinguish it from chronic obstructive pulmonary disease (COPD) in which obstruction is mostly irreversible. Reversibility of airway obstruction defined as FEV_1 of $\geq$12% and $\geq$200mL from the prebronchodilator value is generally accepted as a valid indication of asthma (GINA 2006). However, due to the highly variable nature of the condition, repeated lung function tests are required. PEF meters are inexpensive and easy to use, but they are less precise than spirometry and may underestimate the degree of airflow limitation (Aggarwal et al. 2006).

In subjects with asthma symptoms but normal lung function, bronchial hyperresponsiveness (BHR) testing is often used as a diagnostic aid. BHR constitutes airway narrowing to non-specific stimuli, such as exercise, cold air, and chemical irritants, and can be measured as airway responsiveness to histamine, methacholine, adenosine-5′-monophosphate (AMP), hypertonic saline, or exercise challenge (de Meer et al. 2004a). However, although BHR is related to asthma, it may occur independently of asthma, and vice versa (Pearce et al. 1998a), which makes this test of limited use for individual asthma-diagnostics (see Sect. 56.4.1).

The degree of asthma severity is commonly classified using GINA criteria (GINA 2006) which subdivide asthma into four categories based on frequency and severity of symptoms and lung function (with the worst feature determining the severity classification) (see Table 56.1). However, as emphasized in the updated

2010 GINA guidelines (GINA 2010), asthma involves both the severity of the disease and its responsiveness to treatment. Therefore, asthma could present with severe symptoms and poor lung function but could become completely controlled with low-dose treatment. Thus, the classification of severity had poor predictive value for what treatment was required and what the response to treatment might be. As a consequence, the 2010 guidelines do no longer include the 2006 asthma severity classification. However, it is still a commonly used classification in many epidemiological studies.

56.2.6 Defining Asthma in Epidemiological Surveys

Defining asthma in population-based epidemiological surveys of asthma prevalence or incidence poses even greater difficulties than defining asthma in individual patients. As a result, comparisons of diagnosed asthma between populations are fraught with difficulty, as the differences in diagnostic practice may be greater in magnitude than the real differences in asthma morbidity.

Thus, asthma prevalence surveys usually focus on self-reported (or parental reported) "asthma symptoms" rather than diagnosed asthma. Standardized questionnaires on asthma symptoms have therefore become the cornerstone of large studies of the incidence or prevalence of asthma (Burney et al. 1994; Asher et al. 1995). This approach allows a large number of participants to be surveyed without great cost, in a short time period. Wheezing, chest tightness, breathlessness, and coughing are all symptoms clinically associated with asthma, but epidemiological studies have shown that wheezing is the most important symptom for the identification of asthma, and the majority of questionnaires used to assess asthma prevalence are based on this symptom (Pearce et al. 1998a) (see Sect. 56.4.1 for more detail).

An alternative approach to symptom questionnaires has been to use more "objective" measures such as bronchial responsiveness testing, either alone or in combination with questionnaires (Toelle et al. 1992). However, some have questioned the validity of BHR for the assessment of asthma (Pearce et al. 1998a) (see Sect. 56.4 for more detail).

56.3 Mechanisms of Respiratory Allergies and Asthma

56.3.1 Asthma Phenotypes

Ten years ago it was widely believed that asthma was an atopic disease caused by allergen exposure. The fundamental etiological mechanism was that allergen exposure, particularly in infancy, produced atopic sensitization, and continued exposure resulted in asthma through the development of eosinophilic airways inflammation, bronchial hyperresponsiveness and reversible airflow obstruction. In recent years, it has become increasingly evident that this picture is, at best, too simplistic (Ronchetti et al. 2007; Weinmayr et al. 2007). A systematic review of population-based studies (Pearce et al. 1999) has shown that the proportion of asthma cases that are attributable to atopy (defined as skin prick test positivity) is usually less than one-half. Standardized comparisons across populations or time periods also show only weak and inconsistent associations between the prevalence of asthma and the prevalence of atopy. For instance, a comparison of asthma and atopy in 9- to 11-year-olds in Albania and the United Kingdom (Priftanji et al. 2001) showed large differences in the prevalence of current wheeze (4.4% and 9.7%, respectively) and exercise-induced bronchial reactivity (0.8% and 5.4%), but not in skin prick test positivity (15.0% and 17.8%), suggesting that large variations in asthma prevalence can occur without differences in frequency of atopy. This was confirmed by the International Study of Allergies and Asthma in Children (ISAAC; see Sects. 56.5.3 and 56.5.4) which showed that the association between atopy and asthma symptoms differed strongly among populations but increased with the level of economic development (Weinmayr et al. 2007). In this study, the proportion of current wheeze attributable to atopy ranged from 0% in Ankara (Turkey) to 93.8% in Guangzhou (China); the overall proportion of asthma cases that were attributable to atopy was only 41% in affluent countries and 20% in non-affluent countries. This is consistent with a recent study among 3,960 children in Ecuador which found a population attributable fraction of only 2.4% for recent wheeze and atopy (Moncayo et al. 2010). A similar study in Salvador, Brazil suggested the proportion of asthma attributable to atopy to be 24.5% (Souza da Cunha et al. 2010), which, although higher than in Ecuador, is substantially lower than the 50% in most Western countries. The European Community Respiratory Health Survey (see Sects. 56.5.2 and 56.5.4) found that the proportion of asthma attributable to atopy in adults ranged from 4% to 61% between individual study centers with an overall estimate of only 30% for all centers combined (Sunyer et al. 2004). Finally, time trend studies have shown different patterns for atopy and astma in the same geographical areas. For example, a recent study in Sweden in 7- to 8-year-olds showed a significant increase in allergic sensitization over a 10-year period (1996–2006) despite asthma symptoms remaining stable over the same period (Bjerg et al. 2010).

Recent studies using sputum induction and/or bronchoalveolar lavage (BAL) techniques to measure and characterize airways inflammation in asthmatics have also demonstrated that less than 50% of asthma cases are attributable to eosinophilic airway inflammation, the hallmark of allergic asthma (Douwes et al. 2002a; Simpson et al. 2006). Thus, evidence from studies of eosinophilia and asthma is consistent with that from studies of atopy and asthma: in both instances, at most about one-half of asthma cases appears to be due to "allergic" mechanisms. This further adds to the evidence that allergic mechanisms may not be the only, or the most important, underlying mechanism for asthma.

56.3.2 Immunology

56.3.2.1 Allergic Asthma

Allergic asthma is caused by IgE-mediated inflammatory mechanisms in which a large number of cells play a role including mast cells, eosinophils, T lymphocytes, dendritic cells, and macrophages. Briefly, the sensitization process involves the adaptive (or acquired) immune system whereby allergens interact with dendritic cells in the airway mucosa which migrate to the regional lymph nodes where the allergens are presented to B and T cells. This results (through T-helper-2 (Th_2) responses) in the production of allergen-specific IgE. Once allergic, a subject can develop symptoms minutes after being exposed. This is known as the early phase allergic reaction, and symptoms develop as a result of mast cell degranulation and release of inflammatory mediators through allergen IgE antibody complexes at the surface of the mast cells, causing contraction of bronchial smooth muscle and edema in the airways. Clinically, this results in a decreased lung function and symptoms of wheeze, shortness of breath, chest tightness, and coughing.

During the late phase of the allergic reaction (4 to 8 h after exposure), eosinophil-related inflammatory reactions are particularly important. A critical step in this late phase reaction is the activation of Th_2 cells which release several proinflammatory cytokines including IL-5 resulting in the influx and activation of eosinophils. This reaction is characterized by the development of a non-specific BHR that can continue for several days. Repeated exposures can result in more permanent BHR.

56.3.2.2 Non-Allergic Asthma

As noted above, a substantial proportion of all asthma cases have an underlying pathology that is different from that observed in “classic” allergic asthma (Douwes et al. 2002a; Simpson et al. 2006). Patients may have severe and persistent asthma in the absence of eosinophilic inflammation and may experience an exacerbation of asthma without an increase in eosinophilic inflammation (Turner et al. 1995). Repeated assessments of airway inflammation over time have shown that the non-eosinophilic asthma phenotype is reproducible both in the short (4 weeks) and long term (1 to 5 years) (Simpson et al. 2006). However, the underlying mechanisms of non-eosinophilic/non-allergic asthma are not fully understood. One study in 93 non-smoking adult asthmatics found elevated sputum airway eosinophilia in 41% of all asthma cases, 20% had elevated levels of neutrophils, 8% had a mixed inflammatory profile with both cell types being elevated, and the remainder (31%) had no signs of airway inflammation with eosinophil and neutrophil levels both being within the normal range (Simpson et al. 2006). This suggests that asthma can be categorized into four inflammatory subtypes based on the sputum eosinophil and neutrophil proportions: eosinophilic asthma, neutrophilic asthma, mixed granulocytic asthma, and paucigranulocytic asthma (Simpson et al. 2006).

The common pathophysiological features of neutrophilic asthma involve an IL-8-mediated neutrophil influx, and the subsequent neutrophil activation is a potent stimulus to increased airway hyperresponsiveness (Simpson et al. 2007). Although the stimuli that trigger this response are diverse (endotoxin, ozone, particulates, virus infection), the common features are consistent with activation of innate immune mechanisms (involving Toll-like receptors and CD14) rather than IgE-mediated activation of acquired immunity.

There is also the potential for combined activation of both innate and allergen-specific inflammatory mechanisms in asthma. This may be the case in mixed granulocytic asthma and may explain the ability of ozone and NO2 to potentiate allergen-induced asthmatic responses (Jenkins et al. 1999). The pathophysiological mechanisms involved in paucigranulocytic asthma are not clear.

Clinically, the eosinophilic and non-eosinophilic phenotypes appear very similar with only small differences in lung function, airway hyperreactivity, corticosteroid use, and β_2 agonist-induced reversibility in FEV_1 (Simpson et al. 2006; Berry et al. 2007). However, there are also distinct differences: non-eosinophilic asthmatics appear to be less atopic, have normal subepithelial layer thickness, and perhaps most importantly, they have a poor short-term response to treatment with inhaled corticosteroids (Berry et al. 2007). Thus, despite clinical similarities they represent distinct pathological phenotypes.

Non-allergic occupational asthma is also very common. For instance, in many occupational environments where workers are exposed to organic dust (e.g., farmers, grain workers), the majority of asthma cases are non-IgE-mediated and are related to chronic exposure to environmental irritants. The underlying inflammatory mechanisms involve innate immune responses which are often directed against constituents of bacteria and fungi (Douwes et al. 2002a, b).

56.4 How to Measure Respiratory Allergies and Asthma in Epidemiological Studies

56.4.1 Measuring Incidence and Prevalence

Ideally, we would wish to measure incidence in epidemiological studies of asthma. However, in practice, asthma incidence is very difficult to measure, both because of the intensive long-term monitoring required and because of the difficulty of establishing the date of onset of the condition. Therefore, most studies involve prevalence rather than incidence. Similar techniques to those described in this section can be used in incidence studies, although incidence studies may involve more intensive monitoring to enable a diagnosis of asthma to be more firmly established. Asthma prevalence reflects both the incidence of asthma and the average duration of the condition. Thus, a population may have a high prevalence of asthma either due to a high exposure to factors (genetic or environmental) which induce asthma or because of high exposure to factors which incite, exacerbate, or prolong asthma symptoms in those who have previously developed the disease (Dolovich and Hargreave 1981).

56.4.1.1 Diagnosed Asthma

Although asthma can be conceptualized either in terms of symptoms such as wheezing or in terms of the underlying bronchial inflammation, the essential feature of asthma (at least in clinical and epidemiological terms) is variable airflow obstruction which can be reversed by treatment or is self-limiting (see Sect. 56.2.4). This poses several problems with the use of “diagnosed asthma” in asthma prevalence studies, since the diagnosis of “variable airflow obstruction” usually requires several medical consultations over an extended period. It is therefore not surprising that several studies have found the prevalence of physician-diagnosed asthma to be substantially lower than the prevalence of asthma symptoms. For example, Ehrlich et al. (1995), in a survey in school children in Cape Town, found that among children with more than 12 attacks of wheezing in the previous 12 months, only 60% were reported as asthmatic and only 55% as receiving regular treatment.

These problems with using "diagnosed asthma" as an outcome measure in epidemiological studies not only affect prevalence estimates but also affect time trends (Hill et al. 1989) and geographical and social patterns of asthma prevalence. For example, some studies (e.g., Peckham and Butler 1978) have found diagnosed asthma to be more common in upper social class children, possibly because of greater access to health care and therefore greater likelihood of being labeled as asthmatic. The same concerns apply, perhaps to a greater extent, in surveys of use of asthma medication or health services. Although such information may be of value in asthma morbidity studies, it is of very limited use in prevalence studies (Pearce and Beasley 1999).

These issues are of particular concern in geographical prevalence comparisons since there are major international and regional differences in access to health care and labeling of asthma. Thus, some international comparisons have found differences in diagnosed asthma to be much greater than differences in reported asthma symptoms (e.g., Pearce et al. 1993), these differences in diagnosed asthma may partially reflect differences in access to health services and diagnostic practice rather than genuine differences in asthma prevalence. For example, Dodge and Burrows (1980) suggest that "the epidemiology of asthma is a reflection of the diagnostic habits of physicians in the locale, as well as an indicator of the frequency of a specific syndrome."

Such problems of differences in diagnostic practice could be minimized by using a standardized protocol for asthma diagnosis in prevalence studies. However, this is rarely a realistic option since it requires repeated contacts between the study participants and physicians, and this is often not possible or affordable in large-scale epidemiological studies. Although self-reported histories of physician-diagnosed asthma have been found to be relatively valid, this relates to diagnosed asthma rather than true asthma prevalence.

56.4.1.2 Symptoms

Questionnaires on asthma symptoms are the cornerstone of large-scale epidemiological surveys of asthma prevalence. These have the advantage of being inexpensive and simple to administer to large numbers of participants on a single day and will discriminate those with variable airflow obstruction that causes noticeable symptoms. The key issue is that questionnaires should obtain information in a standardized manner on symptoms which are directly related to "variable airflow obstruction." This definition of asthma implies a condition in which symptoms occur from time to time, rather than the presence or absence of symptoms on a particular day. Thus, operational definitions of asthma involve specification of the time period during which symptoms may have occurred. In particular, “current symptoms” are usually defined as symptoms at any time in the previous 12 months. Although there has been concern that repeated questioning of subjects could increase awareness of respiratory symptoms, a comparison of findings from an intensive longitudinal study and a prevalence study within similar populations found very similar symptom prevalence suggesting that repeated questioning of the longitudinal study population had not biased the prevalence estimates (Sears et al. 1997).

Standard written questionnaires have been the principal instrument for measuring asthma symptom prevalence in community surveys, and in homogeneous populations these have been standardized, validated, and shown to be reproducible (Burney et al. 1989). A number of symptoms including wheezing, chest tightness, breathlessness, and coughing with or without sputum are recognized by physicians as indicative of asthma. Of these the most important symptom for the identification of asthma in epidemiological studies is wheezing, and most questionnaires have focused on this.

Symptoms may be absent despite variable airflow obstruction (asthma), and symptoms may also occur in the absence of asthma. Thus, wheezing is not synonymous with diagnosed asthma; in some instances, wheezing may indicate asthma which has not been diagnosed, but it may also indicate other diseases (particularly chronic bronchitis and emphysema in persons aged 45 years or more) or may be unrelated to other symptoms or disease; conversely, diagnosed asthmatics may not experience or recognize wheeze as a symptom. Nevertheless, wheezing remains the symptom which is most characteristic of asthma, particularly in persons aged 5 to 34 years where asthma is less likely to be confused with bronchitis or emphysema. Thus, most asthma symptom prevalence questionnaires focus on “current wheezing” (defined as wheezing at any time in the previous 12 months), but they usually also include additional questions on the frequency of wheezing and the circumstances in which wheezing occurs (wheezing while at rest, wheezing after exercise, wheezing in the absence of a cold, waking with wheezing), as well as questions on related symptoms (e.g., waking with cough or severe episodes of breathlessness).

A large number of such questions have been used in epidemiological surveys in the last decades. In particular, the questionnaires for the European Community Respiratory Health Survey (ECRHS) in adults (Burney et al. 1994) and the International Study of Asthma and Allergies in Childhood (ISAAC) (Asher et al. 1995) have now become established as the standard questionnaires for use in prevalence surveys.

One of the major problems with the use of written questionnaires in international comparisons is with their translation into the different languages of the communities studied. This is particularly problematic for language groups (e.g., German, French, Dutch) which have no colloquial term for “wheezing.” To ensure that data regarding the frequency and severity of symptoms is comparable in international comparisons of asthma prevalence, it is important that the questionnaire is translated in a manner that ensures that the terms describing symptoms correspond as closely as possible to the international recommended questions.

56.4.1.3 Physiological Measures

The problems of validity, repeatability, and translation of questionnaires have led to attempts to find more "objective" physiological measures for use in prevalence studies. These measures carry with them their own set of limitations both with regard to their "objectivity" (i.e., they are not unequivocally measures of asthma prevalence) and their practicality in large population-based surveys. Nevertheless, they form a useful complement to symptom questionnaires.

Diminished lung function, besides being used as an outcome measure in prevalence studies, is also a risk factor for the development of wheezing and/or asthma (Martinez et al. 1988). Lung function measurements include forced expiratory volume in one second (FEV_1), forced vital capacity (FVC), and peak expiratory flow (PEF). These are all forced expiratory maneuvers undertaken following a maximum inspiratory maneuver. While maximum inspiratory and expiratory maneuvers may lead to small transient changes in airway calibre, the simplicity, standardization, and reproducibility of such maximal expiratory manoeuvres (particularly FEV_1 and FVC) make them the measurements of choice in epidemiological studies (Quanjer et al. 1993), and standardized guidelines are available (American Thoracic Society 1987).

However, such measures may have limited use in prevalence studies, since the airflow obstruction in asthma is reversible over short periods of time and may not be present on the day of assessment. Indeed, one of the characteristic features of reversible airflow obstruction in asthma is its diurnal variation, in that the degree of airflow obstruction is greatest at night or on wakening and least during the day when lung function testing is likely to be undertaken. Thus, a significant proportion of asthmatics may have lung function within normal limits on any one day, and not exhibit the 15% postbronchodilator improvement in FEV_1 or PEF values that is required for a physiological diagnosis of asthma to be made.

A better approach is to undertake repeat measurements of lung function before and after bronchodilator, at different times of the day over a period of time (e.g., two weeks); however, this is difficult and expensive in practice. It is this variation and reversibility of changes in lung function which typifies asthma, and this cannot be captured in a one-off prevalence survey on a particular day. Similarly, a one-off clinical examination with auscultation of the chest to identify the proportion of subjects with wheeze is also of limited value.

Measurements of bronchial hyperresponsiveness (BHR) in epidemiological studies of obstructive respiratory disease have been increasingly used in the past decades, and standard procedures are now well established (James and Ryan 1997). Bronchial hyperresponsiveness (BHR) testing was originally developed in a clinical setting and has conventionally been defined in terms of the dose of agonist producing a 15 or 20% fall in FEV_1. Although BHR is often defined in terms of a dichotomy (e.g., subjects are defined as having BHR if they experience a 15 or 20% fall in FEV_1 at a dose of agonist below a specified level), it can also be regarded as a continuous measure using the dose-response slope (de Meer et al. 2005).

BHR tests are neither wholly sensitive nor specific for asthma (Pekkanen and Pearce 1999), and recent results of the ISAAC Phase II study (see Sect. 56.5.3) involving BHR testing in 6,826 school children in 16 countries showed that, although BHR and asthma symptoms were associated within individual centers, a poor correlation was found between the level of BHR and wheeze across all participating centers ($\rho = 0.23$, $p = 0.294$) and high prevalences of BHR were not confined to centers with high prevalences of asthma symptoms (Buchele et al. 2010). The same study also showed that BHR (assessed by using hypertonic saline) was more closely associated with atopic asthma with a significant correlation between center-specific mean level of BHR and wheeze in atopic ($\rho = 0.64$, $p = 0.002$), but not in non-atopic children ($\rho = 0.21$, $p = 0.35$). Also, several studies have reported an absence of BHR in a substantial proportion of subjects with asthma, and BHR has also been reported in those without asthma (Josephs et al. 1990). BHR also occurs in chronic bronchitis and in tobacco smokers (Burney et al. 1987).

Perhaps the fundamental problem is that persons with non-specific BHR may have a greater tendency to experience asthma symptoms if they are exposed to the relevant stimulus in the laboratory but whether they do actually experience asthma symptoms in daily life, will depend on whether exposure occurs and at what level. Thus, the severity of airflow obstruction may be determined by the interaction of non-specific reactivity and the strength of a provoking bronchoconstrictor stimulus (Josephs et al. 1990). Furthermore, BHR is only one mechanism contributing to the clinical expression of variable airflow obstruction and may contribute to a greater or lesser extent in different individuals and within the same individual at different times (Josephs et al. 1990).

Thus, although BHR is related to asthma and may be involved in many of the pathways by which variable airflow obstruction may occur, variable airflow obstruction may occur independently of BHR, and vice versa (Pearce et al. 2000a). Also, using BHR to define asthma as has been suggested by some (Toelle et al. 1992), risks not only introducing error but will also bias the asthma sample toward one particular asthma phenotype (i.e., atopic asthma). Thus, asthma and BHR remain separate phenomena which both may involve inflammation of the airways, and which are both worthy of study in their own right.

56.4.2 Measuring Risk Factors

Asthma epidemiology studies typically involve measuring the effect of an exposure (e.g., air pollution) on a particular outcome (e.g., asthma, severe asthma, asthma hospital admission, asthma death) in a population. Strictly speaking, the term *exposure* refers to the presence of a substance (e.g., house dust mite allergen) in the external environment, whereas the term *dose* refers to the amount of substance that reaches susceptible targets within the body, such as the airways. In some situations (e.g., in a coal mine), measurements of external exposures may be strongly correlated with internal dose, whereas in other situations (e.g., indoor exposure to house dust mite allergen), the dose may depend on individual lifestyle and activities and may therefore be only weakly correlated with the environmental exposure levels. However, in this chapter we use the term “exposure” in the very general sense to denote any attribute or agent which may increase the risk of experiencing the outcome under study. It includes demographic factors (age, sex, ethnicity, social class) and genetic factors as well as environmental risk factors (measured externally and/or internally).

The environmental exposures most commonly associated with asthma (development or exacerbation) in the general population include a wide range of bioaerosols such as non-allergenic microbial agents, including bacterial endotoxin, house dust mite, pet, and cockroach allergens, and allergenic and non-allergenic fungal agents (see Sect. 56.6.1). Also, more than 250 agents have been identified as causes of occupational asthma (see Sect. 56.6.1) with most of these being biological in origin.

Exposure levels can be assessed with regard to the *concentration* of the substance in the environment (e.g., allergen concentration in the air) and the *duration* of time for which exposure occurs. The risk of developing sensitization to an allergen may be much greater if the duration of exposure is long and/or the exposure is high, and the total *cumulative exposure* may therefore be important. However, once a person has become sensitized, then the concentration may be crucial in provoking an acute attack, and such attacks may occur after exposure of a relatively short duration. For protracted etiological processes, the time pattern of exposure may be important, and it is possible to assess this by examining the separate effects of exposures in various time windows prior to the occurrence and recognition of clinical disease (Pearce 1992). For example, several studies have found that exposure to environmental tobacco smoke in the first years of life may be as relevant as current exposures with regard to current asthma symptoms (e.g., Shaw et al. 1994). Similarly, it has been suggested that occupational asthma is most likely to occur after about 1 to 3 years of exposure to a sensitizing agent (Anto et al. 1996).

Epidemiological studies rarely have optimal exposure/dose data and often rely on relatively crude measures of exposure. The key issue is that the exposure data need not be perfect but that it must be of similar quality for the various groups being compared. Provided that this principle is followed, then any bias from misclassification of exposure will be non-differential and will tend to produce “false-negative” findings. Thus, if positive findings do occur, one can be confident that these are not due to inaccuracies in the exposure data; however, if no association (or only a weak association) is found between exposure and disease, then the possibility of non-differential information bias should be considered. In general, the aim of exposure assessment (see also chapter ▶Exposure Assessment of this handbook) is to (1) ensure that the exposure data is of equal quality in the groups being compared and (2) ensure that the data is of the best possible quality given the former restriction.

Methods of exposure measurement include personal interviews or self-administered questionnaires, diaries, observation, routine records, physical or chemical measurements on the environment, or physical or chemical measurements on the person. Measurements on the person can relate either to exogenous exposure (e.g., airborne dust) or internal dose (e.g., plasma cotinine as a biomarker of tobacco smoke); the other measurement options (e.g., questionnaires) all relate to exogenous exposures.

Traditionally, exposure to many non-biological risk factors (e.g., cigarette smoking) has been measured with questionnaires, and this approach has a long history of successful use in epidemiology. Questionnaires may be self-administered (e.g., postal questionnaires) or interviewer-administered (e.g., in telephone or face-to-face interviews) and may be completed by the study subject or by a proxy (e.g., parental completion of questionnaires in a childhood asthma study). The validity of questionnaire data also depends on the structure, format, content, and wording of questionnaires, as well as methods of administration and selection and training of interviewers. Questionnaires may be combined with environmental exposure measurements (e.g., pollen counts, industrial hygiene surveys) to obtain a quantitative estimate of individual exposures. Questionnaires and environmental measurements have good validity and reproducibility with regard to current exposures and are likely to be superior to biological markers with respect to historical exposures (as described in the following).

Exposure can also be measured using molecular markers of internal dose. However, there are a number of major limitations of many available biomarkers of exposure (Armstrong et al. 1992), particularly with regard to historical exposures (Pearce et al. 1995) with even the best markers of exposures usually reflecting only the last few weeks or months of exposure. Thus, if the aim is to measure historical exposures, then historical information on exposure surrogates may be more valid than direct measurements of current exposure or dose levels. This situation has long been recognized in occupational epidemiology, where the use of work history records in combination with a job-exposure matrix (based on historical exposure measurements of work areas rather than individuals) is usually considered to be more valid than current exposure measurements (whether based on environmental measurements or biomarkers) if the aim is to estimate historical exposure levels (Checkoway et al. 2004). However, some biomarkers have potential value in validation of questionnaires which can then be used to estimate historical exposures. Furthermore, biomarkers of internal dose may have relatively good validity in studies involving an acute effect of exposure such as the triggering of specific asthma attacks.

A more fundamental problem of measuring internal dose with a biomarker is that it is not always clear whether one is measuring the exposure, the biological effect, or some stage of the disease process itself. Thus the findings may be uninterpretable in terms of the causal association between exposure and disease.

A further major problem with the use of biomarkers is that the resulting expense and complexity may drastically reduce the study size, even in a case-control study, and therefore greatly reduce the statistical power for detecting an association between exposure and disease.

Thus, questionnaires and environmental measurements will continue to play a major role in exposure assessment in asthma epidemiology, but biomarkers may be expected to become increasingly useful over time, as new techniques are developed. The emphasis should be on using “appropriate technology” to obtain the most practical and valid estimate of the etiologically relevant exposure.

The appropriate approach (questionnaires, environmental measurements, or biological measurements) will vary from study to study and from exposure to exposure within the same study (or within the same complex chemical mixture, e.g., in tobacco smoke).

56.4.3 Measuring Causal Mechanisms

The causal mechanisms of asthma are still poorly understood. The focus, until recently, was on atopic immune responses, and epidemiological studies therefore often involved measuring atopy. With the introduction of new techniques such as exhaled NO measurements, sputum induction testing, and exhaled breath condensate measurements, epidemiologists now have a wider range of tools available allowing both atopic and non-atopic immunological mechanisms to be studied more fully in population surveys (rather than in laboratory animals as has traditionally been the case).

56.4.3.1 Atopy

Atopy (as defined above) is both an associated condition and a risk factor for developing *allergic* asthma. In the latter context, atopy can often also be considered as an intermediate factor in the causal pathway leading from allergen exposure to allergic asthma. For example, it might be considered inappropriate to control for atopy in a study of dust mite allergen exposure in infancy and asthma at age 5 years, since the development of atopic sensitization might be considered to be an intermediate stage of the causal process leading from dust mite allergen exposure to asthma symptoms. However, atopy may also modify the effect of dust mite allergen exposure, that is, non-asthmatic atopic persons may be more likely to develop asthma symptoms than non-atopic persons at the same level of dust mite exposure. Also, atopics may be more sensitive to irritant exposures causing non-allergic asthma. Thus atopy may be an intermediate factor and/or a modifier of the effects of other exposures.

A positive response to the application of a specific allergen in skin prick testing reflects the production of specific IgE antibodies to the allergen. Skin prick testing therefore provides a convenient test for atopy in epidemiological studies. Although asthma and atopy are often strongly associated, they also occur independently of each other, and "only" one half of all asthma is attributable to atopy (see Sect. 56.3.1) (Pearce et al. 1999). Serum IgE measurements are another well-accepted and widely used measure to assess atopy or atopic sensitization and have the advantage that a larger panel of allergens can be tested. However, they require venipuncture, which may reduce response proportions. Both skin prick tests and serum IgE measurements provide additional information about the potential immunological mechanisms (atopic versus non-atopic), and in case of atopic asthma, they may provide an indication of the potential causal allergen involved.

56.4.3.2 Exhaled NO

Airway inflammation is often considered a hallmark of asthma, but it is difficult to measure, particularly on the scale required for large population studies. Bronchial biopsy, bronchoalveolar lavage, and induced sputum (see below) can be used, but these methodologies are invasive (with exception of suptum induction), time-consuming, and require highly specialized staff. The measurement of the fraction of nitric oxide in exhaled air (FE_{NO}) has been increasingly recognized as a convenient and cost-effective means of non-invasively assessing atopic airway inflammation in asthma, and several instruments are now available utilizing either chemiluminescent or electrochemical NO measurement technologies.

Increased FE_{NO} has been shown to be associated with disease severity, atopy, airway eosinophilia, and bronchial hyperresponsiveness in asthmatics (Alving et al. 1993; Jatakanon et al. 1998; Berry et al. 2005), and corticosteroid therapy has been shown to decrease FE_{NO} (Kharitonov et al. 1996). More recently, it has been suggested that FE_{NO} measurements can be used to optimize corticosteroid dose without negatively impacting upon asthma control (Pijnenburg et al. 2005). Although measuring FE_{NO} shows promise in the diagnosis and management of asthma, other factors not directly related to asthma such as smoking, atopy, height, and sex affect FE_{NO} levels (Kharitonov et al. 1995; Olin et al. 2006; Taylor et al. 2007; Dressel et al. 2008). Furthermore, increased FE_{NO} levels may only be associated with atopic or eosinophilic asthma, as patients with non-atopic or non-eosinophilic asthma appear to have normal FE_{NO} levels, regardless of disease severity (Porsbjerg et al. 2009). Thus, despite FE_{NO} being used in large population studies, it is a poor single diagnostic marker of asthma as has been demonstrated in community-based population studies (Travers et al. 2007). Nonetheless, FE_{NO} may be used to assess allergic or atopic airway inflammation and may therefore provide additional information on the mechanism underlying asthma.

56.4.3.3 Sputum Induction Testing and Exhaled Breath Condensate

Objective monitoring of a wide range of inflammation markers and mediators in asthmatic subjects can provide important information with regard to underlying mechanisms causing asthma symptoms. Exhaled NO (see above) measures only one aspect of airway inflammation which therefore does not provide a complete picture of the inflammatory responses underlying respiratory allergies and asthma. Initial studies on airway inflammation in asthmatics have relied upon bronchoalveolar lavage taken during bronchoscopy, but this technique is invasive and unsuitable for large-scale epidemiological studies. Sputum induction testing and exhaled breath condensate testing are methods involving non-invasive procedures that have the potential to be used in population-based studies.

Sputum induction involves subjects inhaling a 4.5% saline solution at increasing intervals typically starting at 30s to a total of up to 10 to 12 min (Gibson et al. 2000; Simpson et al. 2006). Lung function is measured in between each inhalation period and subjects given inhaled β_2-beta agonist if their FEV_1 drops below 15 to 20% of baseline. The subjects are asked to cough up any sputum after each dose of hypertonic saline and samples will be used to analyze cell types and inflammatory markers and mediators (e.g., IL4, IL5, IL8, ECP). These tests can be done in children from age 8 to 10 years and adults but given the laborious procedures involved the population sample size will necessarily be limited. An increasing number of population-based studies are being conducted using sputum induction testing, and these and previous studies have clearly shown that asthma consists of at least two inflammatory phenotypes (see Sect. 56.3.1). Further studies are currently in progress to assess the clinical and epidemiological importance of these findings.

Exhaled breath condensate (EBC) sampling is a technique that has been used to identify inflammatory markers and mediators in a number of respiratory conditions, including asthma, COPD, acute respiratory distress syndrome (ARDS), and cystic fibrosis (Hoffmeyer et al. 2009). EBC collection involves normal tidal breathing into a tube that is cooled by ice, the breath condensing against the tube's inner surface forming a condensate which can then be poured into vials and frozen for future analysis. Breath condensate volume is mainly determined by duration of ventilation, and it takes up to 10 to 20min to obtain 1 to 3mL of condensate which is sufficient for most analyses.

Most of the condensate consists of water vapor, including a number of volatiles that may serve as markers of airway inflammation. In addition, non-volatile substances (i.e., proteins including a number of cytokines) in the lower respiratory tract can be transported in the form of aerosols in exhaled breath. Successful collection of EBC has been reported using a variety of devices including teflon-lined tubing in an ice bath and specially designed double-wall glass condenser systems (Hoffmeyer et al. 2009). EBC has been shown to contain a range of inflammatory markers and mediators, including nitric oxide, hydrogen peroxide, nitrites, eicosanoids, and various cytokines (Kharitonov and Barnes 2006; Hoffmeyer et al. 2009). The significance of breath condensate analyses is that this technique is straightforward, non-invasive, and completely safe and could be widely used in population-based surveys of asthma (including young children in whom more invasive procedures are not possible). However, EBC results have been highly variable between and within laboratories, and further validation work is therefore required before the technique can "routinely" be used in epidemiological studies of respiratory allergies and asthma (Czebe et al. 2008).

56.5 The Global Burden of Respiratory Allergies and Asthma

56.5.1 Time Trends

It has long been suspected that the prevalence of asthma has been increasing not only in industrialized countries but also in developing countries (Pearce et al. 2000b). However, this has been a particularly difficult issue to resolve because of the lack of systematic standardized studies measuring changes in asthma prevalence over time, and some reviewers have argued that the increases in reported prevalence are largely due to increased awareness, labeling and diagnosis of asthma symptoms (Magnus and Jaakkola 1997). Nevertheless, most studies, which have determined the prevalence of asthma symptoms using the same methodology in the same community at different times, have reported that asthma prevalence has increased in recent decades and that the magnitude of the increase has in some cases been substantial (Table 56.2). Although methodological differences in these studies make it difficult to compare the magnitude of the differences in asthma prevalence between countries, the trend of increasing prevalence among populations in countries of widely differing lifestyles, and ethnic groups is generally consistent.

One of the most informative studies to date is that of Haahtela et al. (1990) who analyzed the medical examination reports of approximately 900,000 conscripts to the Finnish defence forces during 1966–1989, and a proportion of those examined in 1926–1961. During 1926–1961, the prevalence of asthma recorded at call up examinations was in the range of 0.02–0.08%. However, asthma prevalence increased from 0.29% in 1966 to 1.79% in 1989. The authors concluded that the increase was unlikely to be due to improved diagnostic methods and that much of the increase was likely to be real. This conclusion was strengthened by a concomitant rise (from 0.12% in 1966 to 0.75% in 1989) in exemptions and discharges due to asthma. This study is consistent with other evidence that the increases in asthma prevalence in industrialized countries appear to have commenced after the Second World War, particularly in the 1960s and 1970s.

Thus, until recently, most studies had reported that asthma prevalence has increased in recent decades and that the magnitude of the increase had in some cases been substantial.

However, several recent studies have reported either no increase or even a decrease in asthma prevalence over the last ten years. For instance, Bollag et al. (2005) examined time trends in consultations for asthma in primary care in Switzerland and found that overall consultation rates for asthma increased from 1989 to 1994, then stabilized and have declined since 2000. The observation that asthma incidence might be falling is in agreement with several other studies that showed similar time trends for asthma and hay fever (Pearce and Douwes 2005). The best indication of what is currently happening globally is provided by the Phase III of the International Study on Asthma and Allergies in Children (ISAAC); the results of which are discussed below.

The causes of the international time trends in the prevalence of asthma are unclear and are currently a major focus for asthma epidemiology worldwide. An important component of this research process involves standardized international prevalence comparisons (Pearce et al. 1998a). The key problem is to gain information on large numbers of people in random samples collected in a comparable manner across social groups, regions, and countries. Thus, comparisons of asthma prevalence are increasingly being based on a simple comparison of symptom prevalence in a questionnaire survey in a large number of people, followed by more intensive testing of factors related to asthma (e.g., BHR) and risk factors for asthma (skin prick test positivity, serum IgE, and environmental exposures) in a subsample, and a repeat of the prevalence survey over time. This approach has been used in the international

Table 56.2 Changes in asthma prevalence in children and young adults

		Asthma prevalence		
Country	Period	1st study	2nd study	Reference
Australia	1964–1990	19.1%	46.0%	Robertson et al. (1991)

[a] Men

[b] Women

[c] Prevalence per 10,000 subjects

[d] Incidence rates per 100,000 subjects

survey of asthma prevalence in adults (Burney et al. 1994) and in the International Study of Asthma and Allergies in Childhood (Pearce et al. 1993; Asher et al. 1995; Ellwood et al. 2005).

56.5.2 The European Community Respiratory Health Survey (ECRHS)

In the European Community Respiratory Health Survey (ECRHS), a representative sample of 3,000 adults in each center, aged 20 to 44 years, completed a Phase I screening questionnaire seeking information on asthma symptoms and medication use (Burney et al. 1994). Individuals answering “yes” to waking with an attack of shortness of breath, an attack of asthma, or current asthma medications were defined as “asthmatic.” A random subsample of 600 subjects and an additional sample of up to 150 “asthmatic” individuals in each center were then studied in more detail in Phase II, with measurements of skin prick tests to common allergens, serum total, and specific IgE and bronchial responsiveness to inhaled methacholine, as well as an additional questionnaire on asthma symptoms and medical history, occupation and social status, smoking, the home environment, and the use of medications and medical services. The Phase I results (Burney et al. 1996) included data from 48 centers, predominantly in Western Europe, with only 9 centers from 6 countries (Algeria, Iceland, India, New Zealand, Australia, USA) being from outside of Europe. Phase II was conducted in 37 centers in 16 countries (Burney et al. 1996).

56.5.3 The International Study of Asthma and Allergies in Childhood (ISAAC)

The International Study of Asthma and Allergies in Childhood (ISAAC) (Asher et al. 1995; Ellwood et al. 2005) had a similar study design compared to that of the ECRHS study, with a simple Phase I survey and a more in-depth Phase II survey. However, in order to obtain the maximum possible participation across the world, Phase I (which was conducted in 155 centers in 56 countries) was separated from Phase II (which was conducted in a smaller number of centers), and the Phase I questionnaire modules were designed to be simple and inexpensive to administer. In addition, a video presentation of clinical signs and symptoms of asthma was developed (Shaw et al. 1995) in order to minimize translation problems. The population of interest was school children aged 6 to 7 years and 13 to 14 years within specified geographical areas. The Phase I findings, involving more than 700,000 children, showed striking international differences in asthma symptom prevalence (Asher et al. 1998; Beasley et al. 1998). Figure 56.1 shows the international patterns of 12-month period prevalence of wheezing in 13 to 14-year-olds (based on the question “have you had wheezing or whistling in the chest *in the last 12 months*?”).

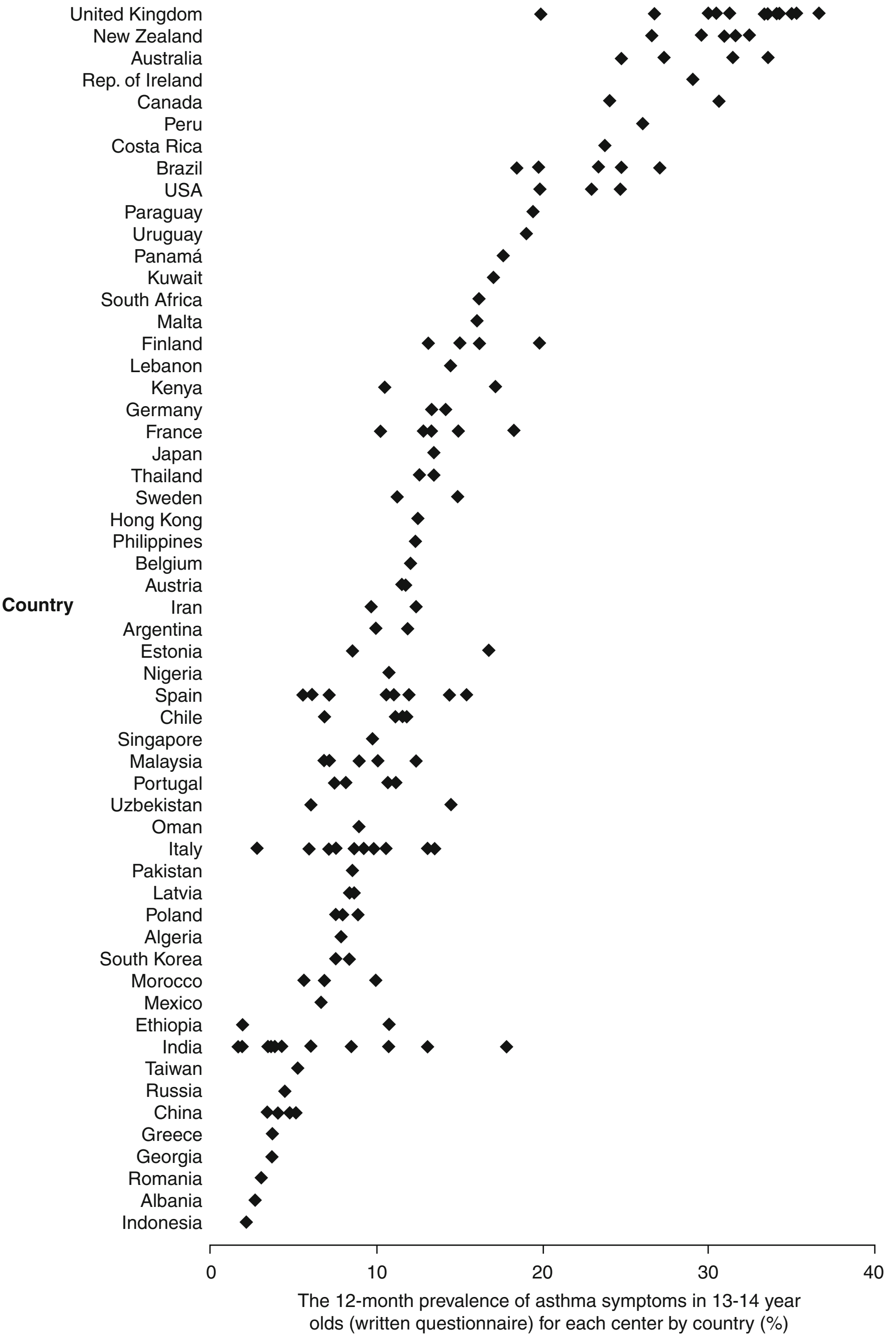

Fig. 56.1 Wheeze in the previous 12 months for each center by country ordered according to the mean prevalence for all centers in the country (Source: Beasley et al. 1998)

ISAAC Phase II was conducted in 30 centers in 22 countries and involved parental questionnaires ($n = 54{,}439$), skin prick tests ($n = 31{,}759$), and serum IgE measurements ($n = 8{,}951$). House dust samples to measure indoor allergens were also collected (Weinmayr et al. 2007).

Phase III involved a repeat of the Phase I survey after 5 to 10 years in 106 centers in 56 countries in children aged 13 to 14 years ($n = 304{,}679$) and in 66 centers in 37 countries in children aged 6 to 7 years ($n = 193{,}404$) (Asher et al. 2006; Pearce et al. 2007).

56.5.4 What Do the ECRHS and ISAAC Studies Show?

The ISAAC and ECRHS studies provide, for the first time, a picture of global patterns of asthma prevalence and identify the key phenomena which future research must address and attempt to explain.

Firstly, both studies show a particularly high prevalence of reported asthma symptoms in English-speaking countries (Fig. 56.1), that is, the British Isles, New Zealand, Australia, the United States, and Canada (Burney et al. 1996; Asher et al. 1998). This appears to be unlikely to be entirely due to translation problems, since the same pattern was observed with the ISAAC video questionnaire (Asher et al. 1998).

Secondly, the ISAAC survey showed that centers in Latin America also had particularly high symptom prevalence (Fig. 56.1). This finding is of particular interest in that the Spanish-speaking centers of Latin America showed higher prevalences than Spain itself, in contrast to the general tendency for more affluent countries to have higher prevalence.

Thirdly, among the non-English-speaking European countries, both studies show high asthma prevalence in Western Europe, with lower prevalences in Eastern and Southern Europe. For example, in the ISAAC survey, there is a clear northwest-southeast gradient within Europe, with the highest prevalence in the world being in the United Kingdom and some of the lowest prevalences in Albania and Greece (Asher et al. 1998). The west-east gradient was particularly strong; in particular, there was a significantly lower prevalence in the former East Germany than in the former West Germany.

Fourthly, Africa and Asia generally showed relatively low asthma prevalence (Fig. 56.1). In particular, prevalence was low in developing countries such as China and Indonesia, whereas more affluent Asian countries such as Singapore and Japan showed relatively high asthma prevalence. Perhaps the most striking contrast is between Hong Kong and Guangzhou which are close geographically and involve the same language and predominant ethnic group; Hong Kong (the more affluent city) had a 12-month period prevalence of wheeze of 10.1%, compared with 2.0% in Guangzhou (the less affluent city).

Fifthly, in contrast to the asthma findings, the highest prevalences of rhinitis symptoms were reported from centers scattered throughout most regions of the world, including Western Europe, Africa, North America, and Southeast Asia; the highest prevalences of eczema were generally in centers of high latitude, including Scandinavia and New Zealand, although there were some notable exceptions including some centers in South America and Africa (Ethiopia). Thus, although the prevalences of these conditions were correlated, the association was not particularly strong, and there were numerous centers which had high prevalence for asthma but not for rhinitis and/or eczema, and vice versa, suggesting that the major risk factors are different for these related disorders or that they involve different latency periods and time trends.

Sixthly, the ISAAC Phase II study showed that the link between atopic sensitization and asthma symptoms differed strongly between populations and increased with economic development (Weinmayr et al. 2007); the association between atopy and flexural eczema was also weak and positively linked to gross national income (Flohr et al. 2008).

Finally, asthma prevalence has peaked or even begun to decline in many affluent countries, whereas asthma symptom prevalence continues to rise in less affluent countries. In particular, ISAAC Phase III showed that international differences in asthma symptom prevalence have reduced, particularly in 13- to 14-year-olds, with decreases in prevalence in English-speaking countries and Western Europe and increases in prevalence in regions where prevalence was previously low including Africa, Latin America, and parts of Asia (Fig. 56.2) (Asher et al. 2006; Pearce et al. 2007). Similarly, Phase II of the European Respiratory Health Survey (ECRHS) found no further increase in current or severe asthma symptoms (Chinn et al. 2004). Nonetheless, a significant increase in diagnosed asthma was observed which most likely reflects changes in diagnostic labeling and/or medical treatment for mild and/or moderate asthma (Weiland and Pearce 2004). The asthma symptom prevalence increases in Africa, Latin America, and parts of Asia indicating that the global burden of asthma is continuing to rise, but the global prevalence differences are lessening.

56.6 Causes of Respiratory Allergies and Asthma

56.6.1 Risk Factors

56.6.1.1 Genetic Factors

Asthma is multifactorial in origin and influenced by multiple genes and environmental factors. Thus, it is not inherited in the simple Mendelian fashion that is characteristic of single-gene disorders. A particular genetic factor may affect one or more aspects of the complex etiological processes potentially involved in asthma including atopic sensitization, bronchial hyperresponsiveness (BHR), airway inflammation, innate immunity, etc. Whether this genetic potential is expressed will depend on various factors, including whether sufficient exposure to environmental factors occurs. Investigating possible genes for the individual etiological factors is also fraught with difficulties, since control of these factors (e.g., IgE production and BHR) are also multifactorial (Zamel et al. 1996).

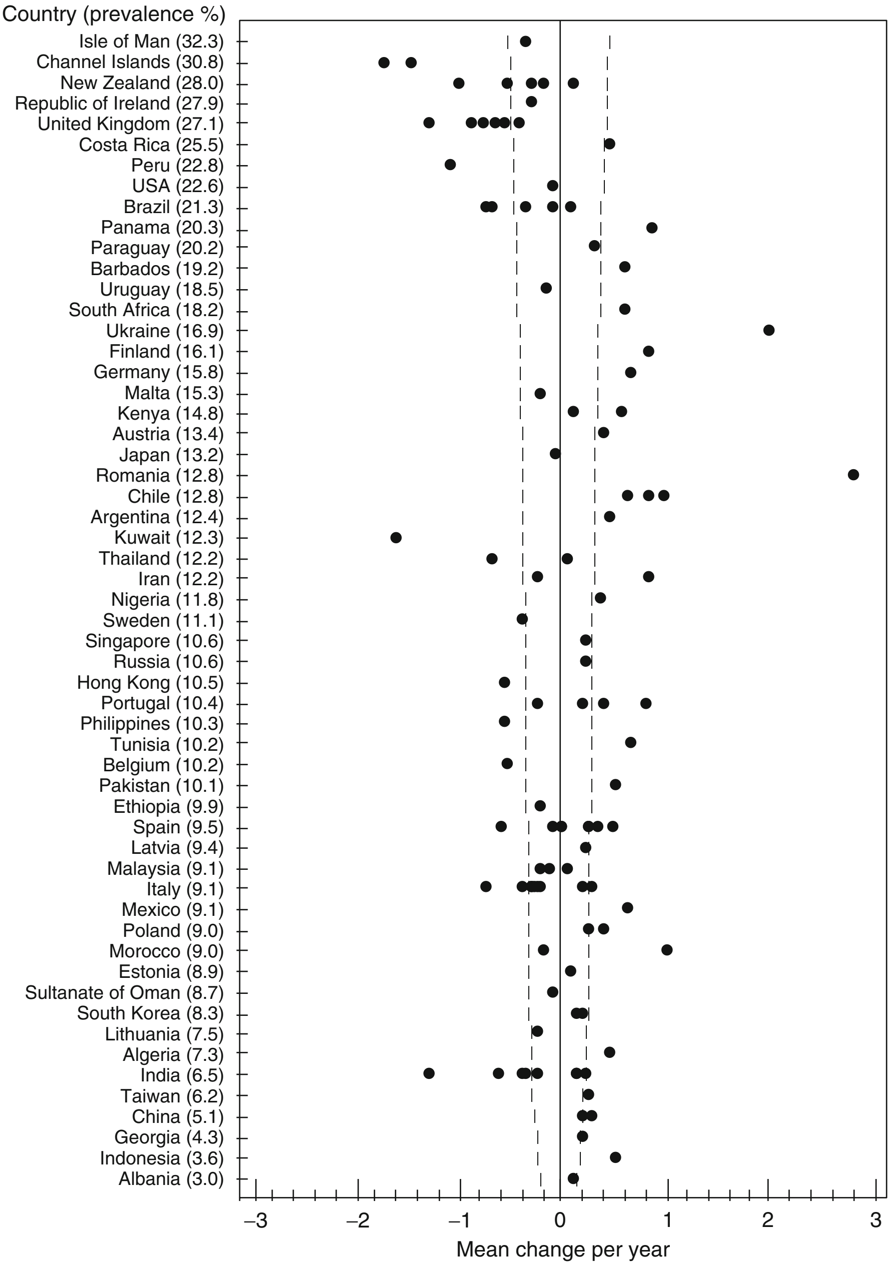

Fig. 56.2 Ranking plot showing the change per year in prevalence of current wheeze (wheeze in the last 12 months) in 13- to 14-year-old children for each center by country, with countries ordered by their average prevalence (for all centers combined) across Phase I and Phase III [the plot also shows the confidence interval about zero change for a given level of prevalence (i.e., the average prevalence across Phase I and Phase III) given a sample size of 3,000 and no cluster-sampling effect] (Source: Pearce et al. 2007)

Also, as noted earlier, asthma is an extremely heterogeneous disease including a variety of phenotypical and clinical manifestations which are likely to be associated with different (combinations of) genes. Another potential source of phenotypic variability is that asthma development, exacerbations, and progression may involve different environmental triggers and genetic factors.

Nonetheless, it is well established that people with a family history of asthma are more likely to develop asthma themselves, and parental asthma is a stronger predictor of asthma in the offspring than parental atopy. However, this association is not necessarily due only to genetic factors but could also reflect similar lifestyles and exposures in family members (Sandford et al. 1996).

Some indication of the possible contribution of genetic factors in asthma is given by studies of twins. For example, Edfors-Lubs (1971) analyzed data on 7,000 twin pairs from the Swedish Twin Registry and found that concordance of asthma in monozygotic twins was greater than in dizygotic twins. However, the concordance was still only 19%, and even this may in part be due to similar environmental exposures in monozygotic twins, including a common intrauterine environment (Godfrey et al. 1994). Other large population studies have yielded similar findings, but this may be because these studies have determined asthma on the basis of questionnaires or hospital and pharmacy records, whereas smaller studies with more intensive diagnostic methods have generally yielded higher concordance (Sandford et al. 1996).

Recent genome-wide association studies (GWAS) including two meta-analyses (GABRIEL and EVE consortia; Moffatt et al. 2010; Ober and Yao 2011) have shown a number of loci that were consistently associated with asthma. However, these associations were relatively weak and the genetic variants very common. As a result, despite these associations being highly statistically significant, the sensitivity and specificity for identifying asthmatics based on these genetic variants was poor (Ober and Yao 2011). Also, many "asthma genes" previously indentified in candidate gene association studies (using a hypothesis-driven approach) were not replicated in these large GWAS meta-analyses. This may be because GWAS studies are not able to detect some of the rarer variants (Michel et al. 2010), or, alternatively, the previously indentified candidates may be false-positive results. Whatever the reason, it is clear that our knowledge of the genetics of asthma is currently still very limited, but future GWAS for asthma on well-defined asthma phenotypes may shed some more light on the importance of genetics in the development of asthma.

56.6.1.2 Demographic Factors

There are a variety of demographic factors which are associated with asthma including age (Anderson et al. 1992), sex (Anderson et al. 1992), and ethnicity (Pattemore et al. 2004). Age is the demographic factor which is most strongly related to asthma symptom prevalence, with symptoms usually declining at or before the onset of puberty (Kimbell-Dunn et al. 1999).

Asthma incidence and prevalence are consistently lower in females than in males before age 12 years, whereas during adolescence and adulthood there is evidence of higher incidence and prevalence in females (Kimbell-Dunn et al. 1999). One possible explanation is that the average age of onset in childhood and adolescence may be later in females. Levels of cord blood IgE are lower at birth in girls than in boys (Weeke 1992), indicating a lower risk of the subsequent development of asthma. Some authors have noted that boys have smaller airways than girls, relative to lung size, and that this may explain the greater frequency and severity of lower respiratory tract illness in boys, even though infection rates are similar for both sexes (Martinez et al. 1988). Alternatively, it is possible that boys have more exposure to factors that increase asthma incidence or duration. The relatively higher prevalence (or smaller reduction in prevalence) in females than in males after puberty could be due to hormonal influences on allergic predisposition, airway size, inflammation, and smooth muscle vascular functions (Redline and Gold 1994). Premenstrual asthma may be especially relevant to the hormonal involvement of asthma since it may not only cause asthma exacerbations but may thereby affect the frequency and duration of asthma symptoms, resulting in an increase in the prevalence of "current asthma."

Studies in the 1960s and 1970s suggested that asthma is more common in children in the higher social classes. There has been less evidence of social class differences as the diagnosis of asthma has become more widespread (Littlejohns and Macdonald 1993), even though diagnostic labeling of wheezing in adults differs by social class (Littlejohns et al. 1989). However, severe asthma appears to be more common in children in the lower social classes (Stewart et al. 2001) and in some disadvantaged ethnic groups (Pattemore et al. 2004), and low socioeconomic status is associated with hospital admissions for asthma (Watson et al. 1996) and with reduced lung function in adults. This could represent either a greater prevalence of asthma in disadvantaged groups, or increased severity due to environmental factors (e.g., environmental tobacco smoke, nutrition, occupational exposures) (Eagan et al. 2002; Ellison-Loschmann et al. 2007), or inadequate disease management and poor access to health care (Ellison-Loschmann and Pearce 2006).

56.6.1.3 Obesity

The specific mechanisms linking body weight and asthma are unclear, but several have been proposed including (1) common etiologies, (2) comorbidities, (3) mechanical factors, and (4) adipokines, that is, cytokines secreted by adipose tissue (Shore 2007). Like asthma, the prevalence of overweight and obesity has increased dramatically in the past few decades in many regions of the world (Burney 2002). Studies have shown associations between body weight and asthma in both adults (Braback et al. 2005) and children (von Mutius et al. 2001). Prospective studies of children suggest that obesity precedes asthma signaling a causal link (Gilliland et al. 2003; Gold et al. 2003), as do studies showing associations between asthma and both weight gain and weight loss in adults (Hakala et al. 2000). Nonetheless, some studies have failed to show an association (Brenner et al. 2001), while others showed an association only in one sex (Mannino et al. 2006). Several reported an association only with respiratory symptoms (e.g., wheeze), but not BHR (Bustos et al. 2005), although this may merely indicate that obesity increases asthma risk through mechanisms other than BHR. Obesity may also increase severity in subjects with preexisting asthma (Akerman et al. 2004).

56.6.1.4 Diet

Many studies have investigated the effects of breast-feeding on allergies and asthma with some studies showing protective effects, some showing no effect, and others suggesting that breast-feeding is a risk factor (Friedman and Zeiger 2005). A recent longitudinal study found that exclusive breast-feeding was associated with a slightly reduced risk of asthma and atopy at age 7, but an increased risk at age 14 and 44 (Matheson et al. 2007). Another infant cohort study showed that breast-feeding did not protect against atopy and asthma but even increased the risk at age 9 to 26 years (Sears et al. 2002). A cluster randomized trial reported similar findings for allergies and asthma at age 6.5 years (Kramer et al. 2007).

Other nutritional factors may also play a role in the etiology of asthma. In particular, it has been speculated that the increase in asthma prevalence may be due to a change in dietary patterns in the past few decades, that is, as cultures have become more “westernized,” they have shifted from a tradition of growing and consuming locally grown foods to consuming more processed foods with an overall increase in the intake of refined sugars, fats, and additives, as well as a reduction in the intake of fresh fruits, vegetables, and fish. Several observational studies have shown protective effects of fruit and vegetables, whole grain products, and fish (Devereux 2007), and these findings are consistent with an ecological analysis of the ISAAC Phase I survey (Ellwood et al. 2001). Fruit, vegetables, and wholegrain products are rich in antioxidants and may reduce airway inflammation by protecting the airways against both endogenous and exogenous oxidants (Devereux 2007). Fish oils are rich in n-3 polyunsaturated fatty acids which may also protect against airway inflammation and subsequent symptoms of asthma (Devereux 2007). However, dietary supplement studies focusing on antioxidants and n-3 fatty acids have not shown convincing evidence of a protective effect on allergies and asthma (Reisman et al. 2006; Almqvist et al. 2007).

56.6.1.5 Outdoor Air Pollution

The role of outdoor air pollutants (particulate matter, ozone, nitrogen dioxide, and sulfur dioxide) in asthma and other diseases has been extensively studied and debated. An association between measures of distance to major roads or traffic density and asthma symptoms has been found in a number of European countries (WHO 2005). Also, a large number of studies have reported associations between direct measurements of air pollution levels and exacerbation of preexisting asthma, both in children and adults (Boezen et al. 1999; WHO 2005). Some studies, including a recent birth cohort study (Brauer et al. 2007), have also suggested that air pollution may cause *new onset* of asthma and allergic disease. In particular, several large prospective studies have suggested a role for ozone (McDonnell et al. 1999; McConnell et al. 2002), although significant associations with some asthma outcomes were also shown for PM2.5, soot, and NO_2 (Brauer et al. 2007). Nonetheless, although it is clear that air pollution can provoke exacerbations in preexisting asthma and a positive association between outdoor air pollution and asthma prevalence at the population level has been shown (Asher et al. 1998), the weight of evidence does not currently support a *major* role for outdoor air pollution as a cause of the initial development of asthma.

56.6.1.6 Indoor Air Pollution

Little is currently known about the contribution of indoor air pollutants (other than environmental tobacco smoke) to the incidence and prevalence of asthma. The range of potential pollutants is large, the determinants of ambient levels involve a complex interaction of lifestyle and building factors, and precise measurement of airborne concentrations is difficult. Nitrogen dioxide from burning fossil fuels has received by far the most attention, while sulfur dioxide from burning sulfur-containing coal or gas, mosquito coil smoke, and formaldehyde from wood preparation have also been considered. Particulates from open or closed wood and coal burning fires have received less attention in developed countries but have been studied in developing countries where very high indoor levels have been encountered.

Damp indoor environments and indoor fungal exposure may also play a role as demonstrated in a large number of studies conducted across many geographical regions (Douwes and Pearce 2003). However, although it has been concluded that the evidence for a causal association between dampness and respiratory morbidity is strong, it is not clear whether indoor dampness *causes* or “only” *exacerbates* preexisting respiratory conditions such as asthma (Douwes and Pearce 2003).

56.6.1.7 Tobacco

Similarly, the evidence for a role of tobacco smoke in asthma is strongest for increases in severity in children who already have asthma, whereas the evidence for the initial occurrence of asthma (incidence) is less conclusive. In particular, several recent reviews and meta-analyses differ in their conclusions about the role of second-hand tobacco smoke (SHS). The US Environmental Protection Agency (EPA) and Californian EPA concluded that SHS was causally associated with the development of asthma in children (EPA 1992; OEHHA 1997). The 2006 Surgeon General’s report on “health effects from involuntary exposure to tobacco smoke” (DHHS 2006) concluded that the evidence was suggestive, but not sufficient to infer a causal relationship. This analysis was based on a previous meta-analysis conducted by Strachan and Cook (1998) and did not include the most recent epidemiological studies. However, the more recent meta-analysis including studies published between 1970 and 2005 concluded that household SHS exposure was positively and consistently associated with the incidence or new onset asthma (Vork et al. 2007) not only in younger but also older children.

The evidence on active smoking as a risk factor is also conflicting with some studies reporting only exacerbations (Siroux et al. 2000), whereas others have also documented a dose-related risk of new-onset asthma in adolescents and adults (Eagan et al. 2002). Overall, it therefore appears that environmental tobacco smoke is a cause of asthma exacerbations and that in addition it may also be involved in the development of asthma itself.

56.6.1.8 Occupational Exposures

Occupational asthma (OA) is the most common occupational respiratory disease in developed countries. For example, asthma accounted for 28% of cases reported to the United Kingdom surveillance of work-related and occupational respiratory diseases (SWORD) project (Meredith et al. 1991). Estimates of the total proportion of adult asthma which is thought to be occupational in origin range from 2 to 15% in the United States (Chan-Yeung and Malo 1994), 15% in Japan (Chan-Yeung and Malo 1994), 5% in Spain (Kogevinas et al. 1996), 2% to 3% in New Zealand (Fishwick et al. 1997), and 2% to 6% in the United Kingdom (Meredith and Nordman 1996). However, much higher estimates have also been reported. For example, a study of the entire employed population of Finland from 1986 to 1998 estimated the attributable fraction of adult-onset asthma due to occupation to be 29% for men and 17% for women (Karjalainen et al. 2001). More than 250 agents have been identified as causes of OA (Department of Health and Senior Services, State of New Jersey 2006). Some of the most common occupational asthmagens include flour/grain dusts, wood dusts, latex allergens, and isocyanates.

56.6.1.9 Respiratory Viruses

Viral infections are common causes of exacerbations of asthma (Johnston et al. 1995). In fact, respiratory viral infections are detected in the majority of asthma exacerbations (80% to 85% in children and 75% to 80% in adults); of these, about 60% are rhinoviruses (Johnston 2007). There is also a strong association between viral infections and hospital admission for asthma in both children and adults.

Viral infections may also be involved in the development of asthma, but the evidence is less clear. Several long-term longitudinal studies have shown that respiratory syncytial virus (RSV) infections increase the risk of subsequent recurrent wheezing and asthma in early childhood (Stein et al. 1999; Sigurs et al. 2005). However, this risk may progressively decrease with increasing age (Stein et al. 1999). Other viruses have also been associated with asthma development including human rhinovirus (HRV) which may in fact be a more important risk factor than RSV (Lemanske et al. 2005). The mechanisms of viral-induced asthma are poorly understood, but it has been speculated that impaired innate immune responses may play a crucial role (Johnston 2007).

56.6.1.10 Medications

Antibiotics The "hygiene hypothesis" postulates that growing up in a more hygienic environment with less microbial exposure may increase the risk of allergies and allergic asthma (see Sect. 56.6.3). A corollary of the hygiene hypothesis is that antibiotic use may increase the risk of asthma by reducing the protective effect of bacterial infections and/or disruption of the normal gut bacterial flora (Farooqi and Hopkin 1998; Mendall and Kumar 1998). However, the epidemiological evidence of an association between exposure to antibiotics (as well as infection) and the development of asthma has been conflicting (Celedon et al. 2002; Cohet et al. 2004; Kummeling et al. 2007).

One of the first reports was that of Farooqi and Hopkin (1998) who found significant associations between treatment with oral antibiotics in the first two years of life and subsequent asthma, hay fever, and eczema at age 12 to 20 years in Oxfordshire. The association was stronger for infections treated with broad-spectrum antibiotics and increased with the number of antibiotic courses received. McKeever et al. (2002a) found that antibiotic exposure in early life was associated with an increased risk of asthma diagnosis, but the association was reduced when the data were adjusted for consulting behavior. They also reported that exposure to antibiotics in utero was associated with a dose-related increase in the child's risk of asthma, hay fever, and eczema (McKeever et al. 2002b). However, Celedon et al. (2004) found no significant association between antibiotic use in the first year of life and the subsequent development of asthma, allergic rhinitis, or eczema at age 5 years. Wjst et al. (2001) found a dose-dependent association of antibiotic use with asthma diagnosis in children aged 5 to 14 years. However, the authors suggested that their findings may be due to reverse causation.

More recently, Foliaki et al. (2009) analyzed the ISAAC Phase III data (see Sects. 56.5.3 and 56.5.4) and found that the reported use of antibiotics in the first year of life was associated with parental-reported symptoms of asthma in 6 to 7-year-old children, following adjustment for other asthma risk factors. The association was present in all major regions of the world (with the possible exception of Africa). Similar associations were observed between the use of antibiotics in the first year of life and the risk of severe asthma symptoms and "asthma ever." Weaker (but still statistically significant) associations were also observed for symptoms of rhinoconjunctivitis and eczema.

Paracetamol It has been reported that prenatal paracetamol (or acetaminophen) use during pregnancy was a risk factor for asthma, wheezing, and total IgE in the offspring at 6 to 7 years of age (Shaheen et al. 2002, 2005) which was unlikely to be confounded by unmeasured behavioral factors linked to paracetamol use (Shaheen et al. 2010). Similarly, several cross-sectional and longitudinal studies have reported that paracetamol use was associated in a dose-dependent manner with an increase in asthma in children and adults and also new-onset asthma in adults (Shaheen et al. 2000, 2008; Barr et al. 2004). Furthermore, national per capita consumption of acetaminophen was ecologically associated with the prevalence of wheeze, diagnosed asthma, and bronchial hyperresponsiveness in Western Europe (Newson et al. 2000).

In the ISAAC Phase III data (see Sects. 56.5.3 and 56.5.4), the reported use of paracetamol for fever in the first year of life was associated with an increased risk of current asthma symptoms (Beasley et al. 2008). There was a dose-dependent increased risk of current asthma symptoms. However, the association was weaker than that observed for antibiotic use in the same data set (see above; Foliaki et al. 2009), and the association reduced (from 1.77 to 1.46) when adjusted for antibiotic use and other asthma risk factors, indicating that the elevated risk was, at least in part, due to confounding. In particular, it has been suggested that the observed association is due to confounding by indication or reverse causation (Lowe et al. 2009).

However, confounding by indication or reverse causation are unlikely to fully explain the positive associations in birth cohort studies (Shaheen et al. 2002, 2005, 2010), and longitudinal studies in adults that focused on new-onset asthma (Barr et al. 2004). The underlying mechanisms are unclear, but it has been suggested that paracetamol decreases glutathione levels in the lung, which may predispose to oxidative injury, bronchospasm, and an increased Th_2 response (Shaheen et al. 2002). Interestingly the use of paracetamol has increased considerably (replacing aspirin) in the 1970s and 1980s (Varner et al. 1998) suggesting that the increased use of paracetamol may account for some of the increasing prevalence of childhood asthma.

56.6.1.11 Allergens

Indoor allergens, particularly house dust mite allergens, are perhaps the group of possible asthma risk factors that have received the greatest attention. It is well established that in sensitized asthmatics, allergen exposure can trigger asthma attacks and that prolonged exposure can lead to the prolongation and exacerbation of symptoms. However, most studies in children show only weak associations between allergen exposure and current asthma, even when the analyses are restricted to atopic patients and allergen avoidance has been accounted for (Pearce et al. 2000c). Also, secondary intervention trials have had mixed results (Gotzsche et al. 1998).

In fact, although there is good evidence for asthma exacerbations, the evidence for new onset asthma is much weaker (Pearce et al. 2000c). The key study linking allergen exposure in infancy to the subsequent development of asthma is that of Sporik et al. (1990) who followed 67 children with a family history of atopy. They found an association between dust mite allergen levels and mite sensitization and an association between exposure to more than 10ug/g in the first year of life and a history of wheezing, although this association was not statistically significant (odds ratio $(OR) = 2.3$, $\mathrm{p} = 0.17$). There were non-significant associations of dust mite levels with “active wheezing and BHR” ($p = 0.08$) and with “receiving medication” ($p = 0.10$).

More recent longitudinal birth cohort studies have found little or no association between early dust mite allergen exposure and asthma later in childhood (Burr et al. 1993; Corver et al. 2006; Tepas et al. 2006). For example, Burr et al. (1993) conducted a longitudinal study among 453 infants in South Wales with a family history of allergic diseases. Doctor diagnosed asthma and wheezing at age 7 years was neither associated with mite allergen exposure as determined in the first 12 months nor with dust mite levels measured at 7 years of age (odds ratios were not given). Similarly, in the German Multicentre Allergy Study, levels of mite and cat allergens in early life remained strongly related to specific sensitization at age 3 to 7 years, but no dose-response relationship between allergen exposure and any measure of asthma/wheeze at 7 years of age was found (Lau et al. 2000, 2002). Dust mite allergens are therefore unlikely to play a major role in the initial development of asthma.

There are several other indoor and outdoor allergens that have been suggested to be associated with the development of asthma including cat, dog, cockroach, and *Alternaria* allergens. However, the evidence for a causal relationship is even weaker than for house dust mite allergens (Pearce et al. 2000c). In fact, several studies have even reported that having a pet early in life protects against the development of asthma (see Sect. 56.6.3).

56.6.1.12 Emotional Stress

Until the second half of the twentieth century, the predominant view was that asthma was a psychosomatic disorder in which emotional stress was the key factor in its etiology; the condition was therefore commonly referred to as "asthma nervosa" (Salter 1860). With the recognition of causal environmental exposures such as pollen (Blackley 1873) and house dust (Osler 1892) in the latter half of the nineteenth century and the increased understanding of the inflammatory mechanisms underlying asthma in the second half of the twentieth century (Holgate 2004), the notion that asthma was caused by emotional stress slowly lost support. Thus, many asthma researchers currently regard emotional stress as predominantly a consequence of the disease or as an external factor which may trigger exacerbations in those with preexisting asthma. Associations between stress/anxiety and asthma in (cross-sectional) epidemiological studies are therefore generally dismissed as examples of reverse causation. However, several prospective studies in young children and adults suggest that this assumption may not be justified (Douwes et al. 2010, 2011).

A recent birth cohort in 5,810 children aged 7.5 years showed a strong association between prenatal maternal anxiety symptoms (as an indicator of stress during fetal life) and asthma prevalence at 7.5 years (Cookson et al. 2009). Children of mothers in the highest quartile of anxiety scores were 64% more likely to have asthma compared with those in the lowest quartile (*OR* = 1.64, 95% confidence interval (CI) = 1.25–2.17). Postnatal anxiety was not associated with asthma when adjusted for prenatal anxiety, suggesting that the prenatal period may be particularly critical.

The effects of stress/anxiety may not be limited only to early life events. For example, a 13-year follow-up study which assessed the associations between war-related stressors and new onset asthma in 2,066 elderly (50 to 69 years) Kuwaiti civilians following the Iraqi invasion in 1990 and the subsequent 7-month occupation found a dose-response relationship with asthma incidence (assessed as a self-reported doctor diagnosis of asthma), after adjusting for potential confounders including air pollution related to burning oil fires (Wright et al. 2010). The highest stress level more than doubled the risk of new onset asthma (*OR* = 2.3, 95% CI = 1.3–3.9).

The mechanisms underlying the association between stress and asthma remain far from clear. Several studies have suggested that stress acts principally through altered regulation of the hypothalamic-pituitary-adrenal (HPA) axis and sympathetic-adrenomedullary (SAM) nervous system (Vig et al. 2006). The subsequent change in levels of neurohormones (and in particular endogenous glucocorticoids) has considerable immunomodulatory effects, including an atopy (or Th_2)-biased response favoring allergic outcomes (von Hertzen 2002). In addition to neuroimmunomodulatory effects, it is plausible that direct neurogenic mechanisms may underlie at least part of the association between stress and asthma (Miller et al. 2009).

56.6.2 Can the Traditional Risk Factors Explain the International Patterns and Time Trends?

Although there is substantial evidence that various environmental risk factors can increase the risk of developing asthma, there is little evidence that the traditional risk factors can account for the global prevalence increases or the international prevalence patterns that have been observed. The increases in asthma prevalence cannot be due to genetic factors, since they are occurring too rapidly, and the rapidity of the increases indicates that genetic factors alone are unlikely to account for a substantial proportion of asthma cases (Douwes and Pearce 2002), although genetic susceptibility to changing environmental exposures may play an important role.

The global patterns of asthma prevalence are also inconsistent with the hypothesis that air pollution is a major risk factor for the development of asthma (Asher et al. 1998, 2006; Beasley et al. 1998). Regions such as China and Eastern Europe where there are some of the highest levels of traditional air pollution such as particulate matter and SO_2 generally have lower asthma prevalence than the countries of Western Europe, North America, Australia, and New Zealand which have lower levels of pollution. It also appears very unlikely that the international prevalence patterns can be explained by differences in smoking (Mitchell et al. 2002) or in occupational exposures.

Allergen exposure is the risk factor that has perhaps received the most attention as a possible cause of the global increases in prevalence of asthma and allergies. In particular, it has been suggested that increases in indoor allergen exposures, through changes in lifestyle such as wall-to-wall carpeting, cold water washing, greater time spent indoors watching television, etc., could account for the global increases in asthma prevalence (Sporik et al. 1990). However, the only study of English homes at two time points (1979 and 1989) did not find any change in house dust mite allergen levels (Butland et al. 1997), although marked increases have been observed in Australian studies (Peat et al. 1996).

The ISAAC (Asher et al. 1998) and ECRHS studies (Burney et al. 1996) have consistently found uniformly high levels of asthma prevalence in centers in English-speaking countries, even though there is a wide variation in house dust mite levels across these countries (Martinez 1997). In geographical areas in which dust mite exposure is very low or absent, including desert regions and mountainous regions, the prevalence of asthma is as high or even higher than that in other areas where house dust mite exposure is high (Martinez 1997).

Other available evidence on the association between allergen exposure and the subsequent risk of asthma at the population level is also less than persuasive. For example, Leung et al. (1997) reported that asthma prevalence was high in

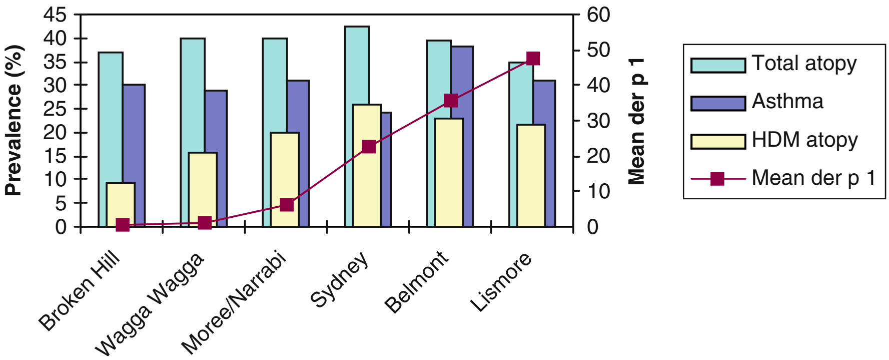

Fig. 56.3 Mean Der p 1 levels and prevalence (%) of house dust mite atopy, total atopy, and asthma in six areas of Australia

Hong Kong (6.6% for asthma ever) and low in San Bu, China (1.6%), but exposures to house dust mite allergen were similar in Hong Kong and San Bu. Similarly, Fig. 56.3 shows data from seven Australian surveys in centers with widely differing levels of mite allergen exposure; the overall prevalences of sensitization and asthma were both unrelated to the levels of house dust mite allergen (Der p 1) exposure in the six centers. The dominant allergen varied between regions, but there was little overall difference in the prevalence of sensitization or of asthma despite the major differences in mite allergen levels. Similarly, von Mutius et al. (1994) found that asthma was significantly higher in Munich, West Germany (5.9%) than in Leipzig, East Germany (3.9%), and this paralleled the pattern of skin prick test positivity (19.2% and 7.3%). However, house dust mite allergen levels were similar in the east and the west (Hirsch et al. 1998).

The other asthma risk factors (e.g., diet, obesity, paracetamol, emotional stress) may significantly contribute to the observed time trends and international patterns of asthma prevalence, but there is little evidence for this currently.

56.6.3 Protective Factors

Recent research has shifted attention from allergens that may cause sensitization and/or provoke asthma attacks, to factors that may "program" the initial susceptibility to asthma, through allergic or non-allergic mechanisms. This also in part involves a shift of attention from risk factors for asthma to protective factors and the possible role of the loss of protective factors in the global increases in asthma prevalence.

56.6.3.1 The Hygiene Hypothesis

The "hygiene hypothesis" postulates that growing up in a more microbiologically hygienic environment may increase the risk of developing respiratory allergies and has been prompted by evidence that overcrowding and unhygienic conditions were associated with a lower prevalence of atopy, eczema, hay fever, and asthma (Strachan 1989). Having a large number of siblings (especially older siblings) and attendance at day care centers were determined to be particularly protective (Ball et al. 2000). An increase in infections has been proposed as an explanation for these findings and several studies have in fact shown a direct association between infections (e.g., Hepatitis A, measles) or immunization with BCG (Bacillus Calmette-Guérin) against tuberculosis and a lower prevalence of atopy and allergies (Shaheen et al. 1996; Matricardi et al. 1997). However, the results for airborne viruses (measles, mumps, rubella, and chickenpox) and BCG vaccination were inconsistent (Alm et al. 1998; Matricardi et al. 2000).

Exposure to specific microbial agents with strong proinflammatory properties, such as bacterial endotoxin, has also been suggested to be protective (Douwes et al. 2002a). Studies in both rural and non-rural environments have reported a significant inverse association between indoor endotoxin levels and atopic sensitization (Gehring et al. 2001), hay fever, and atopic asthma (Braun-Fahrlander et al. 2002). In contrast, a birth cohort study conducted by the same researchers found that early endotoxin exposure was associated with an *increased* risk of atopy at the age of 2 years (Bolte et al. 2003). However, two similar birth cohort studies found a protective effect on atopy in 2-year-olds (Bottcher et al. 2003) and asthma symptoms in 4-year-olds (Douwes et al. 2006).

Thus, the evidence is currently mixed as to whether endotoxin exposures may protect against atopy and allergic asthma. If there is a causal association, most of the evidence points toward endotoxin, but other pathogen-associated molecular patterns (PAMPs) may be equally (or more) important. There is evidence that exposure to peptidoglycans, CpG-containing DNA, and certain viruses may also reduce the risk of atopic disease (Douwes et al. 2004). The evidence for these PAMPs is, however, scarce.

Although the specific immune mechanisms are not clear, it is believed that microbial exposure may affect T lymphocytes which have an important function in controlling immune responses, including help for B cell production of antibodies (IgE, IgG, IgA, IgM). T-helper-2 (Th_2) cells stimulate B cells to produce IgE upon allergen stimulation, whereas T-helper-1 cells (Th_1) inhibit this process. The initial interpretation was that growing up in a more hygienic environment with less microbial exposure may enhance atopic (Th_2) immune responses, whereas microbial pressure would drive the response of the immune system – which is known to be skewed in an atopic Th_2 direction during fetal and perinatal life – into a Th_1 direction and away from its tendency to develop atopic immune responses. More recently, an alternative interpretation has been offered which involves inadequate immunoregulation by T regulatory cells wich control both Th_1 and Th_2 immune responses. Active regulation through T regulatory cells is believed to be critical in maintaining tolerance to allergens through a balanced Th_1/Th_2 immune response. The hypothesis is that a lack of microbial exposure may result in reduced immune suppression of T regulatory cells allowing upregulation of both Th_1 and Th_2 immunity, thus rendering subjects more susceptible to developing allergies (as well as Th_1

conditions including autoimmune disease which has also increased in prevalence in the past few decades). However, the immunological mechanisms underlying the observed epidemiological associations remain largely unclear (Romagnani 2004).

56.6.3.2 Animal Contact

Several studies have shown that the presence of pets in the home early in life is inversely associated with atopy in children (Hesselmar et al. 1999). Other studies have also shown a protective effect of pet ownership and asthma, for example, de Meer et al. (2004b) showed that having had a cat before the age of 18 protected against atopy to outdoor allergens, airway hyperreactivity, current wheeze, and current asthma. These results should, however, be interpreted with caution, since avoidance behavior (removal of pets in the families with sensitized and/or symptomatic children) may have contributed to this inverse association. However, in a longitudinal study in which subjects with childhood asthma at enrolment were excluded from the analyses, the protective effects actually increased (de Meer et al. 2004b), whereas a decrease would be expected if selective avoidance was a major issue. There are also studies that have found no association, or a positive association, between pet exposure and asthma, despite showing an inverse association with atopy (Apelberg et al. 2001; Kerkhof et al. 2009). In other parts of the world (Guinea-Bissau and Nepal), it has been shown that pigs and cattle in the home are associated with less atopy (Shaheen et al. 1996; Melsom et al. 2001). Thus, although the evidence for a protective effect on atopy is reasonably consistent, currently, it is unclear whether pets can also protect against asthma.

At present it is not clear which specific exposures and immunological mechanisms underlie the observed protective effects on atopy of animal contact, but increased microbial exposure may play a role, which would be consistent with the hygiene hypothesis (see above).

56.6.3.3 Farming

A number of studies have found consistently low prevalences of allergies and asthma in farmers' children, both in high-income countries such as Canada, the US, Australia, New Zealand, and Europe (Braun-Fahrlander et al. 1999; Ernst and Cormier 2000; Riedler et al. 2000, 2001; von Ehrenstein et al. 2000; Downs et al. 2001; Klintberg et al. 2001; Horak et al. 2002; Remes et al. 2002, 2003; Wickens et al. 2002; Chrischilles et al. 2004; Alfven et al. 2006; Dimich-Ward et al. 2006; Perkin and Strachan 2006; Midodzi et al. 2007; Douwes et al. 2008), and in low-income countries including Mongolia and Southern Africa (Weinberg 2000; Viinanen et al. 2007). These protective effects for allergies and asthma have also been observed in adult farmers (Leynaert et al. 2001; Kauffmann et al. 2002; Kilpelainen et al. 2002; Portengen et al. 2002, 2005; Braback et al. 2004; Eduard et al. 2004a, b; Koskela et al. 2005; Radon et al. 2006; Chen et al. 2007; Douwes et al. 2007; Smit et al. 2007, 2008) despite the increased risks of other respiratory conditions such as COPD, reduced lung function, and farmers' lung (Schenker et al. 1998). The fact that similar effects are found in low-income countries

(Weinberg 2000; Viinanen et al. 2007), where people have less opportunity to move away from farming because of allergies and asthma, further suggests that selection effects are unlikely to explain the often substantial lower risk in farming communities (Douwes et al. 2009).

The observed protective effects of farming on allergies and asthma have been particularly strong for animal contact (Riedler et al. 2000; von Ehrenstein et al. 2000; Downs et al. 2001; Remes et al. 2002, 2003; Douwes et al. 2008). Farm animals are associated with high exposures to microorganisms, in particular bacterial endotoxin (Douwes et al. 2002b). Also, an upregulation of several innate immune receptors specific for microbial products (TLRs and CD14) has been shown in farmers' children (Ege et al. 2006) suggesting that microorganisms and microbial products may be involved. In fact, a recent study showed that exposure to a wide variety of environmental microorganisms as well as exposures to specific fungal and bacterial species explained a substantial fraction of the inverse association between farm upbringing and asthma (Ege et al. 2011). Exposures early in life including the prenatal period appear particularly protective, although continued exposure may be required to maintain optimal protection (Douwes et al. 2007).

Consumption of unpasteurized farm milk in farmers' and non-farmers' children has also been shown to be protective in several of the farmers studies (Riedler et al. 2000; Barnes et al. 2001; Wickens et al. 2002; Perkin and Strachan 2006; Waser et al. 2007). The etiological mechanisms are unclear, but probiotic bacteria or other currently unidentified non-microbial components in farm milk may play a role. Evidence from other populations with anthroposophic lifestyles which are characterized by (among other things) diets rich in (probiotic) microbes (Alm et al. 1999) suggests that this protective effect may not be limited only to the farming environment, although the findings of these studies have not always been consistent (Alfven et al. 2006). These observations are also consistent with the hygiene hypothesis.

56.6.4 Can Protective Factors Explain the International Patterns and Time Trends?

As noted above, the hygiene hypothesis, if it is correct, would explain an increase in atopic/allergic asthma. However, since about one-half of asthma cases involve non-atopic/allergic mechanisms (Pearce et al. 1999), it is questionable whether the hygiene hypothesis on its own can explain the large increases observed over the last decades or the global prevalence patterns, particularly since there is some evidence that non-atopic asthma may have increased more than atopic asthma (Thomsen et al. 2004). Also, although housing conditions are unlikely to have become more hygienic in United States inner city populations, asthma prevalence has increased significantly in those populations, particularly among African Americans living in poverty (Crater et al. 2001). Finally, the hygiene hypothesis is unlikely to explain why asthma prevalence is now apparently falling in affluent countries, as exposures to factors that have previously been identified as being "protective" (family size, endotoxin exposure, infectious diseases, pets) are likely to have decreased in more recent times rather than increased. These findings thus further emphasize the potential limitations of the current hygiene hypothesis (Douwes and Pearce 2008). Nevertheless, whatever mechanism is involved, it is becoming increasingly clear that the "package" of changes associated with westernization may be contributing to the global increases in asthma susceptibility and prevalence.

56.7 The Role of Epidemiology in Respiratory Allergy and Asthma Research

In this final section, we will make some more general observations on the role of epidemiology in respiratory allergy and asthma research. Until fairly recently and with some notable exceptions, most asthma epidemiology was done by clinicians rather than professional epidemiologists, and epidemiology was largely regarded as a means of "confirming" clinically based observations and theories (e.g., that allergens can cause asthma exacerbations and therefore "must" also cause asthma itself) (Pearce and Douwes 2009). The field was perhaps comparable to the situation in cardiovascular disease and cancer in the 1950s. For these diseases, the first epidemiological step in exploring the etiology of these conditions involved descriptive epidemiology ("person, place, and time"), particularly international prevalence or incidence comparisons such as the MONICA project (Tuomilehto et al. 1987) and Cancer Incidence in Five Continents (Doll et al. 1966). These naturally led to the development of hypotheses as to the possible explanations for the observed global patterns, which were investigated in analytical studies (cohort and case-control studies), eventually evolving into more complex studies involving the use of biomarkers and genetic testing.

Because asthma epidemiology has arrived on the scene relatively late, there has been a natural tendency to jump straight into the use of relatively high-tech methods (e.g., BHR testing, atopy testing, IgE, airway eosinophil measurements, and more recently, genetic testing) focusing on very specific etiological mechanisms (e.g., TH_1/TH_2, eosinophilia), without the "reality check" which large-scale population comparisons provide. As a result, we have developed theories of asthma etiology (e.g., the TH_1/TH_2 theory, and the associated "hygiene hypothesis") which work well in mice, but do not seem to work so well in Latin America or inner city populations in the US (see Sect. 56.6.4) (Pearce and Douwes 2006). In the last couple of decades, epidemiology has played the major role in rectifying this situation, for example, by mounting standardized international prevalence surveys to provide global asthma maps, and other population comparisons (see Sect. 56.5), as a starting point for the more careful and appropriate development of theories of asthma etiology which not only work in the laboratory but which have the potential to explain what is happening in the population context. Of course, such population comparisons are not the solution by themselves, but they are an essential first step in the process of identifying and understanding the causes and etiology of asthma.

Much of the confusion that has permeated asthma epidemiology has simply reflected confusion about what asthma is and how it should be defined. Ironically, most clinicians have little problem diagnosing and treating asthma, which is regarded simply as “variable airways obstruction” (e.g., “asthma is a disease characterized by wide variation over short periods of time in resistance to flow in the airways of the lung” (American Thoracic Society Committee on Diagnostic Standards 1962)) – a condition that is easily diagnosed on the basis of a clinical symptom history, perhaps supplemented by serial measurements of lung function (Pearce et al. 1998a). Despite some major therapeutic disasters (Pearce et al. 1998b), symptoms are relatively easy to control (at least for the eosinophilic phenotype; see Sect. 56.3.1). However, there has not been the same clarity in understanding the etiological mechanisms by which variable airways obstruction occurs, or in the methods used for measuring asthma in prevalence studies (Pekkanen and Pearce 1999). Epidemiology can make an important contribution in the development of a better understanding of the etiology of asthma and whether it constitutes several different conditions or a single condition. This in turn will help to redefine the best methods of defining asthma in clinical practice and in epidemiological surveys.

56.7.1 The Future of Allergy and Asthma Epidemiology

Although epidemiological research may not have yielded a target for asthma intervention (yet), it has made a major contribution in changing the focus from risk factors to protective factors and identifying populations with a “naturally” low prevalence of allergies and asthma. These observations provide interesting new avenues of research with a high likelihood of identifying novel targets for prevention and treatment.

So where could innovative new theories of the etiology of asthma come from? Global prevalence (and if possible, incidence) comparisons can play a major role in this process (Pearce 1999) as has been successfully demonstrated in asthma studies such as ISAAC (Asher et al. 1995) and ECRHS (Burney et al. 1994), but, clearly, they are just part of a larger scientific process, and these sorts of initiatives are now well established for many non-communicable diseases such as cancer (Doll et al. 1966) and coronary heart disease (WHO MONICA Project Principal Investigators 1988).

Perhaps the most promising new direction is the development of truly interdisciplinary research that integrates the usually separate worlds of epidemiology, social science and biomedical, and clinical research. Traditionally, these disciplines have been conducting research in relative isolation, a situation which has distinct disadvantages. In particular, (i) many animal models of disease are only partially applicable to human populations; (ii) clinical studies are generally not well equipped to determine the causal exposures of primary causation; and (iii) epidemiological studies often do not fully acknowledge the complexity of the biological responses involved.

Mice do not get asthma, and even after manipulation to produce an "asthma model," they do not exhibit the pathophysiology that is consistent with asthma in humans (Wenzel and Holgate 2006). Thus, although we have learnt a great deal about immunology in mice in the past few decades, these mouse models have provided only limited understanding of the underlying immunological mechanisms of human asthma. Nonetheless, most biomedical research on asthma continues to be conducted in mice. Similarly, the overemphasis of allergen exposure as the "causal" factor of asthma, as well as the lack of appreciation of the heterogeneity of asthma in many epidemiological studies, has guided biomedical and clinical research into studying (almost exclusively) allergic mechanisms and allergy-specific treatment options, with very little consideration of other potentially relevant mechanisms. In particular, there are now several studies suggesting that corticosteroid treatment is less or non-effective in asthma phenotypes that do not involve allergic mechanisms and subsequent non-eosinophilic airway inflammation (Berry et al. 2007), despite these phenotypes being very common (Douwes et al. 2002a; Simpson et al. 2007). Also, studies of asthma genetics continue to be based on populations of mixed phenotypes limiting the potential to find meaningful results. This "tunnel vision" has led to assumptions that findings in Western countries can be extrapolated to the rest of the world, and it has taken international collaborations such as the ISAAC study, to show that, for example, the strong associations between atopy and asthma symptoms that have been repeatedly observed in Western countries are not so evident in low- and middle-income countries (Weinmayr et al. 2007). Thus, considering the complex interplay between environmental exposures, genetic susceptibility, immunological mechanisms, as well as social and cultural factors involved in asthma development – and indeed most non-communicable diseases – an interdisciplinary approach bringing together expertise from each of these disciplines is most desirable, as it is likely to open up new avenues of cutting edge research, yielding greater explanatory power, more efficient use of research funding, and more efficient translation into disease prevention. Also, a closer link with biomedical research will ensure the development of more sensitive and valid methods that can be widely applied in population studies to improve both disease definition (including the assessment and recognition of disease phenotypes) and relevant exposures.

Epidemiologists have a major role to play in coordinating, integrating, and expanding these efforts, and that the "population perspective" (Pearce 1996, 1999) provides a valid reference point and "reality check" for such interdisciplinary work. However, although epidemiology is well placed to take the lead in developing interdisciplinary research, we also see a role for more "traditional" epidemiology. In particular, epidemiology has a strong tradition of generating new hypotheses or refuting old dogmas. Studies such as ISAAC (see Sect. 56.5.3) are an excellent example where the use of a one-page questionnaire conducted in more than one million children worldwide has made a major impact on how we think about asthma etiology (Enarson 2005).

56.8 Conclusions

Despite decades of intensive biomedical and epidemiological research, the etiology and pathogenesis of asthma is still poorly understood. In particular, a large number of potential risk factors for asthma have been identified including genetic factors, allergen exposure, demographic parameters, diet, obesity, indoor and outdoor pollution, passive and active tobacco smoking, occupational exposures, viral infections, stress/anxiety, and the use of paracetamol (acetaminophen). However, none of these risk factors on their own appears to explain the substantial global increases in asthma prevalence observed in the last few decades. They also cannot explain the significant differences in asthma prevalence between countries. Recent studies have shown that the increase in asthma prevalence appears to have leveled off in many high-income countries, with some even showing a decrease. The reasons for this are also unclear. As a consequence, a single target for intervention has not (yet) been identified.

Understanding why these changes in prevalence are occurring, and ascertaining which elements of the "package" of twentieth century economic development and lifestyle changes are responsible, is essential in order to develop effective intervention programs to halt the current global asthma epidemic. Recent epidemiological studies have provided innovative theories of the etiology of asthma, such as the hygiene hypothesis, which have considerable potential to guide the development of feasible primary (and secondary) prevention options. However, given the complex gene-environment interactions (Vercelli 2009) and diverse asthma phenotypes (Douwes et al. 2002a), any single type of intervention is unlikely to prevent all or even a substantial proportion of asthma cases – a "one size fits all" approach is unlikely to work. Epidemiology (alongside other disciplines) has a major role to play in developing new theories regarding asthma causation and the subsequent development and evaluation of effective prevention strategies. However, for these efforts to be maximally effective, they would need to be part of a multidisciplinary program that includes expertise (in addition to epidemiology) in biomedical, clinical, genetic, psychological, and other disciplines.

57.1 Introduction

Oral health means more than "good teeth" – it is integral to general health, is essential for well-being and is a determinant for quality of life.

Having good oral health allows us to speak, smile, kiss, touch, taste, chew, swallow, and even to cry or express ourselves. Conversely, oral diseases restrict activities and amount to significant time lost in school, at home, and in work. Further, it is the psychological impact of these diseases that can diminish the quality of life (Petersen 2003a). This wider definition of oral health should not detract from the importance of the two most important oral diseases – dental caries and periodontal disease, which will be the focus here, in addition to considering the general oral health measure of tooth loss. Other oral diseases and conditions including dental abscess, dental fluorosis, dental trauma, dental erosion, and dentofacial anomalies, in addition to oral mucosal conditions including oral cancer, are beyond the scope of this chapter.

Both dental caries and periodontal disease have the potential to be effectively prevented and treated, but have to be increasingly considered in the context of their strong relationship between socioeconomic factors. The incidence of oral disease is greatest in people from deprived areas and backgrounds (Sweeney et al. 1999; Selwitz et al. 2007; McMahon et al. 2010).

The integral interrelationship between oral health and general health is well documented, with oral disease and non-communicable chronic disease having many common risk factors (Sheiham and Watt 2000). Moreover, many general conditions have oral manifestations or can affect dental treatment.

Dental epidemiology is defined here to encapsulate epidemiology of oral diseases. Knowledge about the burden, trends, and causes of oral disease comes from the findings of dental epidemiology. Such understanding provides a basis for assessing and determining needs in populations, communities, and individuals. This, in turn, can support the planning and monitoring of the effectiveness of services and interventions designed to meet these oral health needs. Epidemiology provides the basis of preventive interventions and dental public health policies and interventions.

This chapter will discuss epidemiology in relation to describing the trends in dental caries, periodontal disease, and tooth loss and the analytical approaches to determining risk factors and the etiology of these diseases.

57.2 Definitions and Basic Concepts

57.2.1 Dental Caries

57.2.1.1 Pathogenesis

Dental caries or dental decay is a disease of the dental hard tissue. The pathogenesis of caries is a complex interaction between host factors (including teeth and saliva), oral bacteria, and fermentable carbohydrate in the form of sugars. Acid is produced as a by-product of the metabolism of dietary fermentable carbohydrate and oral bacteria within dental plaque. The resultant drop in pH at the tooth surface leads to the diffusion of calcium and phosphate ions from the enamel (demineralization); this process is reversed as the pH rises again (remineralization). Thus, caries is a dynamic disease process between periods of demineralization and remineralization, which progresses if demineralization predominates over time, and in turn will lead to loss of mineral content of enamel and eventually to carious cavitation. The disease develops in both the crowns and roots of teeth (Fejerskov 1997; Kidd 1987).

Enamel caries – is the early "white spot" lesion that appears on the surface of the tooth (the enamel). Within the enamel, this appearance is due to demineralization of the subsurface layer with the outer surface remaining more mineralized. With continued "acid attack" demineralization predominates and the outer surface changes from smooth to rough and can become stained, eventually becoming pitted or cavitated. In the early stages of demineralization, the process can be reversed through reuptake of calcium, phosphate, and fluoride ions (Selwitz et al. 2007).

Dentine (or dentinal) caries – is when caries reaches the dentine, which is the hard tissue surrounding the dental pulp and underneath the dental enamel. Caries is more severe by the time it has progressed to dentine. Dentinal caries is characterized by demineralization and subsequent bacterial invasion (Kidd and Fejerskov 2004).

Root-surface caries – appears when the root of the tooth becomes exposed due to recession of the gingival margins (the gums) from around the base of the crown of the tooth. This can result from poor oral hygiene, loss of periodontal attachment, and age; dental plaque can build up in these areas, and caries lesions can readily develop (Fejerskov and Kidd 2003).

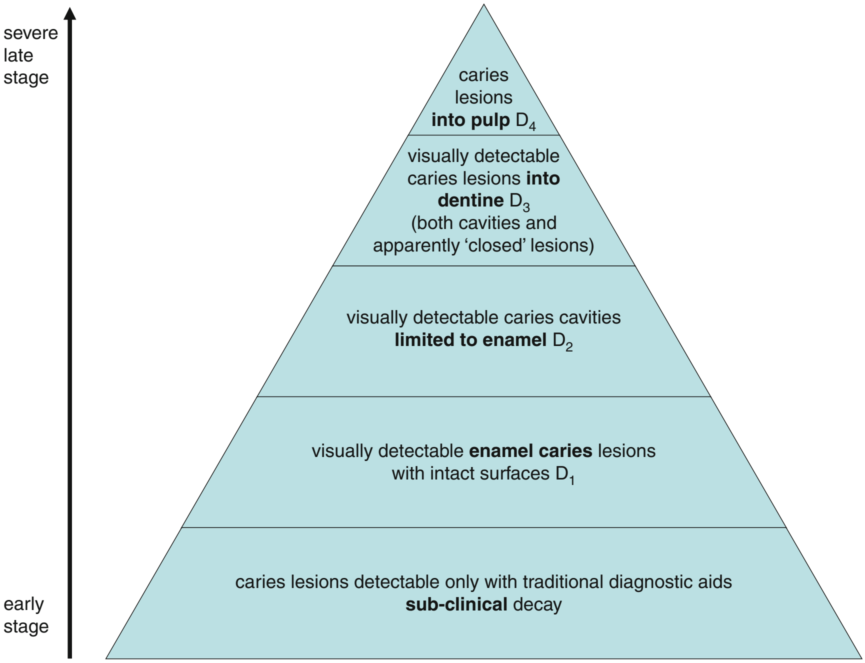
57.2.1.2 Clinical Diagnosis

Dental caries is a continuous progress of increasing severity in terms of tooth destruction – from molecular changes to obvious frank cavitation. Therefore, the assessment of the presence of dental caries depends on the diagnostic criteria employed. In the clinical setting, dental practitioners would usually undertake a visual inspection of all visible surfaces of the teeth using a good light source, a dental mirror, and a dental probe – although the use of a dental probe is controversial and discouraged (James et al. 2001). Dental radiographs or fiber optic transillumination (FOTI) are also used to identify caries which may not be readily visible, particularly caries on the "interproximal" surfaces between teeth. White spot lesions can also be identified by blowing air across the tooth surface to remove saliva and make the "white spot lesions" more visible (Pitts 1997). Newer and more sensitive research methods and emerging technologies for caries diagnosis include laser fluorescence, light fluorescence, digital imaging fiber optic transillumination, and ultrasound that are potentially able to detect even more subclinical initial lesions, which are in a state of dynamic progression and regression at the early stage of the disease process, before they are discernible by conventional clinical methods. This gives the potential for lesions to be detected and for the impact of preventive care to be assessed in order to ensure that cavitation is avoided (Stookey and González-Cabezas 2001).

57.2.1.3 Epidemiological Measurement

In dental epidemiology, dental caries is usually diagnosed as caries into dentine (dentinal caries). These dentinal caries lesions are recorded following visual clinical inspection – examination with the naked eye under standard lighting, without the use of a dental probe or radiographs (Ismail 2004). Due to the possibility of subclinical (not visually obvious decay) being present, the traditional term "caries free" is increasingly being replaced with "no obvious decay experience" (Selwitz et al. 2007). Figure 57.1 demonstrates the various thresholds of dental caries diagnosis.

Dental caries is measured via the D_3MF/d_3mf index (upper case letters (DMF) for permanent dentition/lower case (dmf) for deciduous teeth and where the subscript "3" indicates caries at the level into dentine). It is the sum of the number of decayed, missing, or filled teeth (D_3MFT) or decayed, missing, or filled (tooth) surfaces D_3MFS. It was first described by Klein and Palmer (1937). The advantages of the DMF index for measuring dental caries include global acceptance and widespread use for over 60 years, providing an accurate measure of dental caries prevalence. However, it is not without limitations, which include some differences in criteria for caries diagnosis across the globe (e.g., in the USA a sharp probe is used, while in Europe researchers use a blunt probe only to remove plaque prior to inspection



severe
late
stage
early
stage
caries lesions **into pulp** D_4
visually detectable caries lesions **into dentine** D_3 (both cavities and apparently 'closed' lesions)
visually detectable caries cavities **limited to enamel** D_2
visually detectable **enamel caries** lesions with intact surfaces D_1
caries lesions detectable only with traditional diagnostic aids **sub-clinical** decay

Fig. 57.1 Pyramid of thresholds of dental decay (Adapted from Pitts 2001)

of surface); the reason for missing teeth is not always due to caries (e.g., teeth can be lost due to periodontal disease, trauma, extracted as part of orthodontic treatment, or can be congenitally missing); the filled component is influenced by practitioners' decision to restore a tooth, and also new aesthetic restorations can be difficult to detect with a simple visual inspection (Whelton and O'Mullane 2007). The filled (FT) component as a proportion of DMF has been considered the care index – i.e., a measure of the amount of decay which has been treated by restorations ("fillings"). The prevalence of dental caries is usually presented as the mean DMF score or conversely as the proportion of subjects with "free of obvious dental decay experience."

Decay at the tooth surface level (D_3MFS) is a more precise measure of obvious dental caries experience than at the tooth level (D_3MFT) as, for example, a tooth with four or five surfaces affected by caries has the same contribution to the D_3MFT score as a tooth with only one surface decayed. Nevertheless, the D_3MFT remains a useful indicator of the number of teeth that are affected and require treatment. Another way in which caries data are analyzed is on the basis of the type of tooth surface that has been decayed. Thus, differences can be reported between coronal pit and fissure (the biting) surfaces of teeth and the proximal (between teeth) or smooth surface caries (McDonald and Sheiham 1992).

The mean D_3MFT or D_3MFS is usually reported. However, as a significant proportion of many populations have no obvious decay experience and the disease is skewed to a smaller proportion of the population having the majority of the disease, the mean D_3MFT in those with any decay (i.e., $D_3\text{MFT} > 0$) is also used to report caries prevalence.

In older age groups and adults, the use and validity of the D_3MFT is questionable (due to root surface caries in addition to exacerbation of the limitations described above). Other measures of oral health include number of natural teeth present, the absence of all natural teeth – edentulousness, and other measures of the impact of oral health on quality of life are increasingly recognized (Locker 2004).

New systems for recording caries at enamel and dentinal levels have been developed, e.g., the International Caries Detection and Assessment System (ICDAS) – which records decay at a range of levels of severity from early stage enamel to severely decayed lesions involving pulp (Pitts 2004). This system is more complex and requires compressed air to systematically dry the teeth prior to visual inspection. However, it is increasingly being used in epidemiological surveys and clinical trials.

57.2.2 Periodontal Disease

57.2.2.1 Pathogenesis

Periodontal disease is a range of conditions that can be inflammatory, infective, traumatic, metabolic, neoplastic, developmental, and genetic in origin. However, it usually refers to inflammatory disease of the tissues which support the teeth (the periodontium). There are two main conditions: gingivitis and periodontitis.

Table 57.1 Classification of periodontal conditions (Armitage 1999)

I. Gingival diseases
A. Dental plaque-induced gingival diseases
B. Non-plaque-induced gingival lesions
II. Chronic periodontitis
A. Localized
B. Generalized
III. Aggressive periodontitis
A. Localized
B. Generalized
IV. Periodontitis as a manifestation of systemic diseases
V. Necrotizing periodontal diseases
VI. Abscesses of the periodontium
VII. Periodontitis associated with endodontic lesions
VIII. Developmental or acquired deformities and conditions

There is an emerging consensus on the classification of the range of periodontal conditions (Table 57.1). The pathogenesis of periodontal disease is complex and involves the interaction between a pathogenic microflora within the dental biofilm (plaque) on the tooth surface and the host immuno-inflammatory response (Kornman 2008). Gingivitis is a highly prevalent condition, whereby the gingiva (gums) are inflamed. It is reversible by oral hygiene measures. Periodontitis is the more severe and serious condition, where the inflammation extends into the deeper tissues with the loss of supporting connective tissue and the dentoalveolar bone (i.e., the alveolar bone of the jaws that immediately surrounds the teeth). This is known as periodontal attachment loss, and it generally manifests as deepening of the crevice between the gingival tissue and root of the tooth – known as "pocketing." As these pockets deepen, the teeth can become loose, and mastication can be effected, which can lead to tooth loss. It is also possible that gingival recession accompanies the attachment loss and there is no obvious "pocketing."

57.2.2.2 Clinical Diagnosis

The symptoms of gingivitis are limited to mild bleeding gums on toothbrushing, while periodontitis, in its mildest forms, is largely similar. However, as periodontitis progresses, halitosis (i.e., malodors exhaled on breathing; colloquially known as "bad breath") is a common symptom, and when severe, teeth can loosen or even be lost. Both conditions are rarely painful although there is increasing evidence that periodontal disease can lead to a significant impact on oral-health-related quality of life measures (Bernabé and Marcenes 2010).

Diagnosis is based on a clinical examination and radiographs. Using a periodontal probe, clinical probing depths are recorded by measuring the distance from the gingival margin to the depth of the periodontal pocket (the pocket being the space between the tooth and gingivae) using a periodontal probe. The healthy depth is 2 mm; with periodontitis, this depth increases as the periodontium and bone are lost. Initially, a Basic Periodontal Examination (BPE) is undertaken. The full dentition is divided into sextants. The six sextants comprise of the four sets (upper and lower and left and right) of molars and premolars, and the two sets (upper and lower) of canines and incisors. The periodontium surrounding all teeth is probed gently using a ball-ended probe with a colored measurement area corresponding to 3.5–5.5 mm in clinical probing depth and each sextant is scored. Sextants are recorded as a "4" if there is at least one tooth with a pocket greater than 5.5 mm; score "3" for pockets 3.5–5.5 mm; score "2" for no pockets exceeding 3 mm, but calculus (i.e., a hardened form of dental plaque caused by continual accumulation of minerals from saliva on plaque; also known as "tartar") or plaque present; score "1" for no pockets but bleeding on gentle probing; and score "0" for no bleeding or pocketing (Ainamo et al. 1982; Dowell and Chapple 2002). Comprehensive periodontal examination includes measuring the loss of attachment from a fixed point on the tooth and the clinical probing depth at six points around each tooth. Bleeding on probing, the amount of dental plaque and dental calculus (hardened, mineralized dental plaque), horizontal bone loss between the roots, and mobility of the teeth are also recorded. Radiographs are required to demonstrate loss of alveolar bone. The American Academy of Periodontology classifies loss of attachment as mild (1–2 mm of attachment loss), moderate (3–4 mm of attachment loss), and severe (≥5 mm of attachment loss) (Armitage 1999).

57.2.2.3 Epidemiological Measurement

In epidemiology of periodontal disease, cross-sectional surveys are the norm, which usually aim to measure the prevalence and severity of gingivitis and periodontal disease. The epidemiology is complicated by the varying definitions of the disease. The historical perspective that periodontal disease was a single-disease continuum from gingivitis progressing to periodontal disease is now redundant. Separate clinical measures are now used to record gingivitis and periodontitis, although the varied use of different indices further complicates comparison across surveys and populations.

There are a number of indices for measuring gingivitis. The Gingival Index (GI) described by Löe and Silness (1963) gives a score of the level of inflammation from 0 to 3 for the gum at each surface of the teeth based on signs of inflammation. It does not include the pocket depth and therefore the health of the periodontium. More recently, the presence of gingival bleeding upon "gentle probing" has become the standard measure of gingivitis (Greenstein 1984), although the variation and subjectivity of how "gentle" probing is defined and carried out has been questioned (Polson and Caton 1985). Nevertheless, bleeding on probing (BOP) measures are increasingly used in epidemiology; however, there remains significant debate about the discriminatory power, as well as issues related to infection control, and the ethics justifying the inducement of bleeding for epidemiological (not treatment) purposes (Burt and Eklund 2005). A Modified Gingival Index (MGI) has been proposed which does not involve bleeding on probing – but it is recognized that further development of a valid objective measure is still needed (Lobene et al. 1989).

The Community Periodontal Index ofTreatment Needs (CPITN) is frequently used in epidemiological surveys to measure periodontal disease (Ainamo et al. 1982). However, it is increasingly used as a clinical assessment of treatment need or as a screening tool for further periodontal investigation – when it is known as Basic Periodontal Examination (BPE) (Dowell and Chapple 2002). The CPITN measures periodontal pocket depth from a sample of sites in the dentition (rather than measuring the pocket depth from all sites around each tooth in a more detailed periodontal examination). This sampled measure has the inherent problem of potentially underestimating disease prevalence and has been argued as not appropriate for measuring severity or prevalence of periodontal disease (American Academy of Periodontology 1996). Full-mouth recording of the clinical attachment loss and clinical periodontal probing depth are considered more appropriate for recording severity and prevalence of periodontitis. However, this is rarely done due to the fact that it is extremely time-consuming (Burt and Eklund 2005). All partial-mouth recording techniques can result in an underestimation in the prevalence, extent, and severity of disease (Susin et al. 2005). As with gingivitis measures, debate remains around probing force used, and computerized probes have been proposed, although there seems little difference with human scoring (Osborn et al. 1990). Biomarkers are increasingly being sought to measure periodontal disease but, at this stage, are largely experimental.

57.2.3 Tooth Loss

Tooth loss has been considered a form of “dental mortality” (Burt and Eklund 2005). It is a crude measure of general oral health – either as total tooth loss, also known as edentulism, or partially dentate. Furthermore, the World Health Organization defines a functional dentition as one which has at least 20 natural teeth in occlusion; it is also known as the shortened dental arch (Petersen 2003a). Total tooth loss has also been consistently shown to be related to poorer general health (Kandelman et al. 2008).

57.3 Descriptive Epidemiology

57.3.1 Trends in Dental Caries

Global comparisons of the prevalence of dental caries are complicated by variations in diagnostic criteria. Estimates of dental caries prevalence from a large number of countries are collated by the WHO Global Oral Health Database and the WHO Oral Health Country/Area Profile Programme (WHO 2010a). However, as some results are from national surveys with representative samples while others relate only to small local surveys, caution is required in making simplistic intercountry comparisons using the raw data. It is also necessary to understand the public health aims behind the WHO “basic methods” diagnostic criteria employed by most datasets in their databank, and these surveys are only intended to provide an overview of caries prevalence rather than detailed estimates of burden (Petersen 2003b). The prevalence of dental caries varies across the world. The disease is less common and severe in Asia and Latin America and even less common in Africa. Figure 57.2 presents the dental caries levels of 12-year-old children in six global regions as defined by the World Health Organization (WHO) at the turn of the twenty-first century (Petersen 2003b). The WHO also demonstrated that dental caries among 12-year-olds has declined in many developed countries from a high D_3MFT level of around 4.5 in 1980 to about 2.5 in 1998. Similar data across the same period for children in developing countries were lower across the same period, although they have been rising constantly from a D_3MFT of 1.5 to 2.5 (Petersen 2003b).

Marthaler (2004), in a comprehensive review of dental caries trends in industrialized countries from 1953 to 2003, described the emergence of robust dental epidemiological methods and surveys from 1960s. He identified a substantial decline in the prevalence of dental caries from the 1970s and through the 1980s documented over this period, which he related to the introduction of fluoridated toothpaste. However, by 1990, when low prevalence rates had been reached, this decline had begun to slow and had almost stopped. The disease had concentrated in specific teeth and surfaces in both primary and permanent teeth. In permanent teeth, dental caries had not declined on occlusal (biting) surfaces as it had on smooth surfaces (Brown and Selwitz 1995).

Figure 57.3 demonstrates the general trend of caries prevalence from cross-sectional surveys in developed and developing countries during the 1980s and 1990s. These trends can potentially be explained in the context of the risk factors for dental caries (specifically high-sugar diet) and the protective factors (specifically fluoride use). With developing countries shifting to adopt developed (Westernised) culture and diets, sugar consumption has increased, and this has an impact on increasing caries levels. Since the 1960s, affluent-income countries have increasingly adopted caries protective measures – particularly the use of fluoride toothpaste (and in some countries water fluoridation), which has had an effect of reducing caries levels overall. Sales of fluoride toothpaste in the United Kingdom were reported to be less than 5% of total sales in 1970 but had risen to more than 95% of sales by 1977 (Anderson et al. 1981). However, the flattening of the improvement in these countries is perhaps an indication of the limitations in the penetration or reach of fluoride and the underlying unequal distribution of the disease (see below), which may be holding further improvements back.

There are significant inequalities in the distribution of dental caries between and within countries. International data over time are available for 11- to 12-year-olds, which show trends in dental health during a period of nearly 30 years. Figure 57.4 compares the mean DMFT of several European countries for which data were

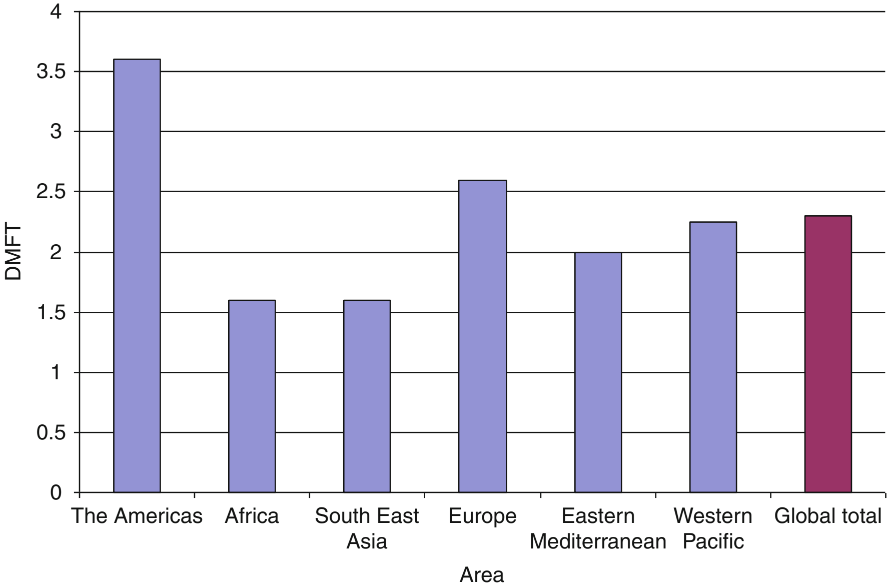


Fig. 57.2 Dental caries experience (D_3 MFT) of 12-year-old children by WHO defined regions, circa 2000 (Data from Petersen 2003b)

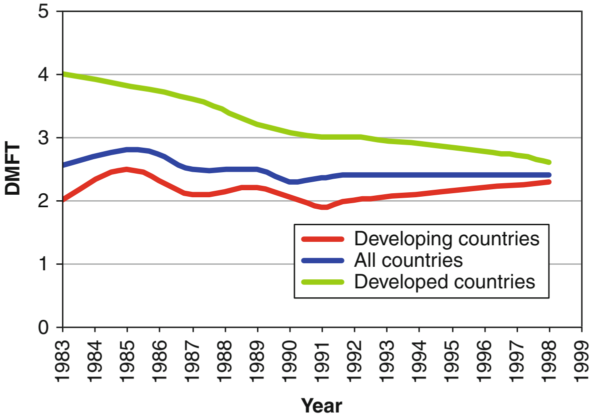

Fig. 57.3 Changing levels of dental caries experience (DMFT) among 12-year-olds in developed, developing, and all countries combined, 1983–1998 (Adapted from Petersen 2003b)

available. Countries in Eastern Europe have consistently higher levels of decay. Overall, it can be seen that for many countries, there was a steep decline in the prevalence of dental caries among 11- to 12-year-olds between 1983 and 1989. This rapid improvement has been followed by a far more gradual improvement since 1989. Marthaler (2004) puts the flatlining of the improvement down to the widening

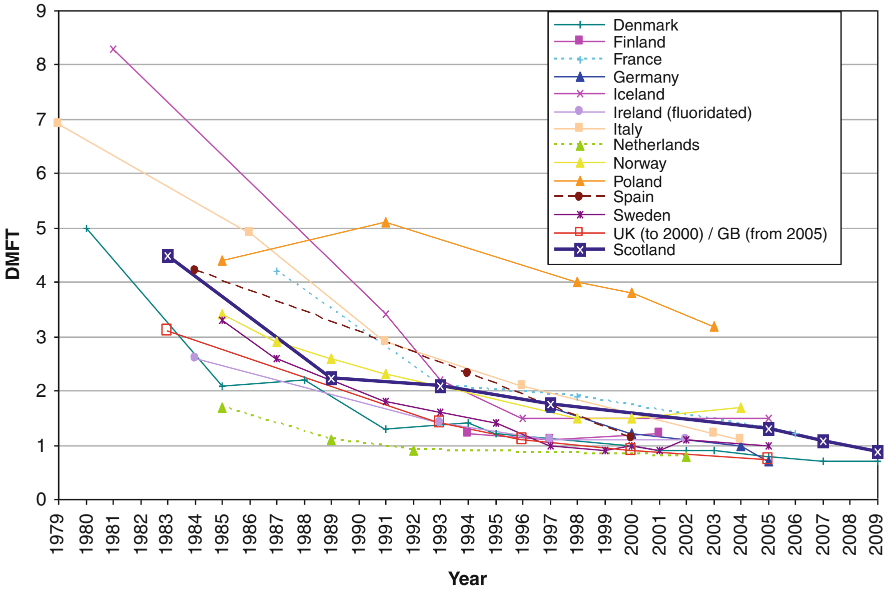

Fig. 57.4 Mean number of decayed, missing and filled teeth (DMFT) in 11- to 12-year-olds, by selected European countries, where data available, 1979–2009 (WHO 2010a)

socioeconomic inequalities which have seen oral health promotion and education approaches reaching the majority of the population but remain out of reach for low socioeconomic groups in society.

Surveys of 5-year-olds perhaps provide a more sensitive barometer of change in the oral health of children, as they include decay in the primary dentition only. Data presented here on the trends in the percentage of 5-year-olds in Scotland with no obvious decay are a typical (if not more comprehensive in terms of methodology and reporting) example of those from developed countries. Comparable data from the national child dental health surveys of the UK Office of Population Census Surveys (OPCS) undertaken in 1983 and 1993, the Scottish Health Boards' Dental Epidemiological Programme (SHBDEP) of surveys between 1987 and 2002, and the National Dental Inspection Programme (NDIP) from 2003 to present are presented in Fig. 57.5. Recent data from NDIP (Merrett et al. 2008; Macpherson et al. 2010a) show a continuation of the marked improvement in the oral health of 5-year-olds in Scotland from 44.6% in 2003 with no obvious decay to 54.1% in 2006 and 64.0% in 2010 – when the (somewhat modest) national target of 60% of children with no obvious decay experience was met. This improvement contrasts favorably with the fairly steady pattern seen over previous years in Scotland, and the considerable investment in child oral health improvement in recent years is a potential explanation.

There are some limited data showing that caries in the primary dentition of 5-year-olds can be used to predict the levels of decay in the permanent dentition

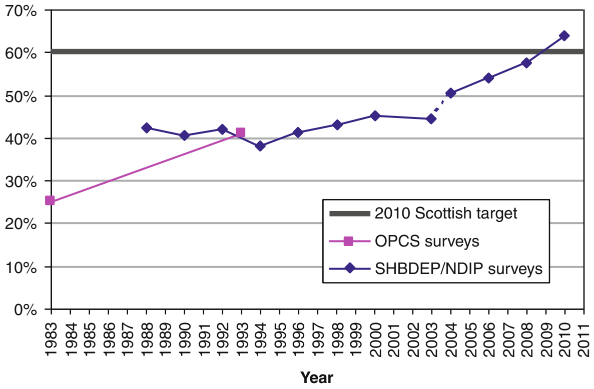

Fig. 57.5 Trends over time in the percentage of 5-year-old children with no obvious decay experience in Scotland, 1983–2010

at 10 years, and in turn caries levels in childhood go onto reflect caries experience in adulthood as reported in a small Norwegian cohort study (Skeie et al. 2006). Susceptibility to the disease continues through adulthood, where it is the major cause of dental pain and tooth loss. Nevertheless, it has been noted that the rate of progression of the disease slows with increasing age (Mejare et al. 2004). There is evidence that dental caries is increasing in prevalence among older adult populations. In the USA, older adults have been found to be getting new caries lesions (root caries) at the same rate as children (Griffin et al. 2004).

57.3.2 Inequalities in Dental Caries

As in childhood caries, adults in vulnerable, high-risk groups have also been identified as having increased dental caries levels. These groups include older adults who are frail (Petersen and Yamamoto 2005) or who live in a residential care home (Chalmers et al. 2005); homeless people (Conte et al. 2006); prisoners (Jones et al. 2004; Treadwell and Formicola 2005); those who are medically compromised (Wyatt and MacEntee 2008) – including those with HIV AIDS (Phelan et al. 2004); recent immigrants (Marthaler 2004); Black and ethnic minority groups (Verrips et al. 2006); and those who are socioeconomically disadvantaged determined by education (Nyyssonen et al. 1984), income (Fukuda et al. 2009), the level of deprivation of the area where they live (Petersen and Yamamoto 2005).

Variations or inequalities in health and disease determined by social or economic determinants have received much attention in terms of policy and research aimed at understanding and trying to tackle these inequalities – e.g., the World Health Organization (Commission on Social Determinants of Health 2008) and the UK government over the past few decades (Bambra et al. 2011). There has been less attention and detailed analysis aimed at understanding between and within country differences and variations in dental caries levels across population groups or areas.

Inequalities in dental caries are observed between different ethnic groups, children from rural and urban areas, and across different area-based socioeconomic circumstances. For example, children from some ethnic backgrounds can

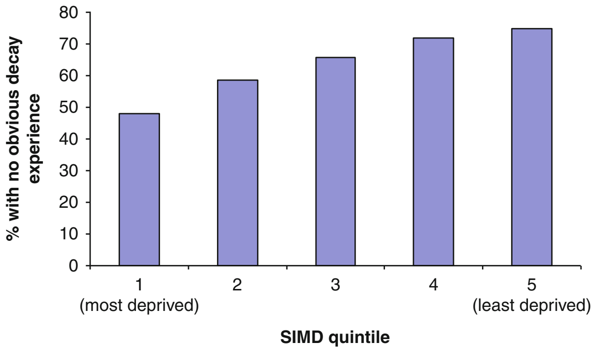

Fig. 57.6 Percentages of 11- to 12-year-old children with no obvious decay experience in permanent teeth by SIMD quintile in the year 2006 in Scotland

have higher caries prevalence than their white contemporaries over and above socioeconomic circumstances (Conway et al. 2007). Children in remote and rural areas of Scotland appear to have better dental health and a higher proportion of filled teeth when compared with those living in cities (Levin et al. 2010).

Figure 57.6 shows that dental decay is more prevalent among children from the most deprived areas in Scotland (Merrett et al. 2009). Area deprivation is measured here by the Scottish Index of Multiple Deprivation (SIMD). SIMD, created by the Scottish Government, for monitoring and planning purposes is calculated using data (from census and other population sources) including six domains of income, employment, housing, health, education, and geographical access to services/telecommunications – which are derived from 31 individual indicators of deprivation at the level of "data zones" neighborhoods. An SIMD score of "1" represents the most deprived areas, and "5" represents the most affluent areas (Scottish Government 2006). These findings are repeated across the developed world (Dye et al. 2010).

Simple measures of inequality like the absolute difference (i.e., the range) and ratio in percentages, from the most deprived to the least deprived, can be calculated from these figures. A range of techniques for quantifying inequalities in health has been developed as described by Kakwani et al. (1997). These analyses include the Gini coefficient, concentration index, slope index of inequalities, relative index of inequality, and population attributable risk. These measures have had limited application in dental data (Antunes et al. 2004; Cheng et al. 2008; Perara and Ekanayake 2008), and while they are not always explicit in terms of the socioeconomic distribution, they generally show a skewed distribution with a small portion of the population (usually the poorest) having the greatest levels of decay.

57.3.3 Trends in Periodontal Disease

Estimating periodontal disease prevalence is complicated by the multiple definitions of the disease and the limited consistency in reporting by age group. There is widely recognized global variation in the prevalence, severity, and rates of disease progression (Löe et al. 1986, 1978; Demmer and Papapanou 2010). According to the World Health Organization, the initial signs of periodontal diseases in adults are highly prevalent across countries, while severe periodontitis is observed in 5–15% of populations (Petersen 2003a).

Recent estimated global variations in reported severe periodontitis given by Demmer and Papapanou (2010) range from 1% among 20- to 29-year-olds in Northern Europe to 39% among those 65 and over in North America. The wide range in these estimates seems to be mainly due to the variation in age ranges of the surveys sampled. Periodontal disease is consistently observed to be more prevalent among men than women, among older than younger age groups, and in black and minority ethnic groups relative to white populations (Demmer and Papapanou 2010). Some studies report a greater prevalence in developing countries (Philstrom et al. 2005), although this is not a consistent finding (Albandar et al. 1999; Demmer and Papapanou 2010) nor is it the case among indigenous or isolated populations (Ronderos et al. 2001).

An earlier WHO report on periodontal health in Europe found that 10% of subjects between 35 and 44 years of age showed advanced periodontal destruction, while moderate disease affected 20–30% of this population. Using CPITN, the prevalence of advanced periodontal disease ranged from 7% to 18%, and moderate disease ranged from 31% to 62% across European countries. The prevalence of periodontitis increases with age, and up to 88% of teeth were affected in older groups (Reich 2001).

In the UK, a survey conducted in 1998 demonstrated that 54% of adults had periodontal disease and 5% had severe periodontitis; prevalence increased with age (Kelly et al. 2000). Oral hygiene was poor in the same population, with nearly three-quarters of dentate adults had visible dental plaque and 73% had calculus present. In the USA, a large survey estimated prevalence of mild periodontitis at 22% of adults and severe periodontitis at 13% (Albandar et al. 1999).

Periodontitis has generally been reported as being rare in younger age groups. The World Oral Health Report of 2003 (Petersen 2003a) reported that globally, while most children have been found to show signs of gingivitis, early onset periodontitis (now referred to as aggressive periodontitis) affected around 2% of children (Albander et al. 1997). In the UK, 35% of children aged 4–18 years had any level of gingivitis or periodontal disease; 40% of 15- to 18-year-olds had gingivitis – with 17% of them having evidence of periodontal disease, which was twice as likely in boys than girls (Gregory et al. 2000). In a cross-sectional study in the United States, more than 11,000 adolescents between 14 and 17 years old were examined; 0.53% had "localized aggressive," and 0.13% had "generalized aggressive" types of periodontal disease. In the same study, Black and Hispanic young people were shown to be at much higher risk for all forms of aggressive periodontitis than white people. Males were more likely to have generalized aggressive periodontitis than females. Moreover, the sex predisposition is different for localized aggressive periodontitis in young people, whereby it was more common in black males than in black females but was more common in white females than in white males (Löe and Brown 1991).

57.3.4 Trends in Tooth Loss (Adults)

As recently as the 1960s/1970s in the UK, loosing a tooth or eventually all teeth – total tooth loss or edentulism – was considered inevitable and dentistry was largely concerned mainly with dental extractions. Anecdotally, a cultural norm in parts of the UK was having all your teeth removed and replaced with shiny full dentures for a common 21st birthday present! (Taylor 1975). Both public expectations and restorative dentistry developed dramatically in the latter parts of the end of the twentieth century and tooth retention has increased particularly in developed countries. Edentulous rates are generally lower in developing countries, although intercountry comparisons are difficult because of the different age groupings employed in national surveys (Petersen 2003a).

Globally, dental caries is considered the principal cause for tooth loss for all ages combined (Oliver and Brown 1993). For those over the age of 45 years, periodontal disease is increasingly recognized as being an important cause of tooth loss (Chestnutt et al. 2000). Some studies suggest it is the main cause of tooth loss (Klock and Haugejordan 1991), while others reaffirm caries is still the most important cause (Chestnutt et al. 2000; Burt and Eklund 2005).

The most recently available data from the UK in 1998 showed that 13% of all adults had no natural teeth, which was projected to decline to 8% by 2008 (Steele et al. 2000). The levels of edentulousness were found to be higher in lower socioeconomic groups and in northern regions and countries of the UK.

The general trends from analysis of edentulous data from Scotland (presented below) are typical (albeit at a higher levels) of the trends observed in developed countries (Burt and Eklund 2005). It should be noted that despite the improvement, the oral health of people in Scotland still lags behind Western European norms (TNS Opinion and Social 2010). The main source of data on the oral health status of adults in Scotland is from the series of UK Adult Dental Health Surveys, which were conducted in 1972, 1978, 1988, and last conducted in 1998 (Kelly et al. 2000). More recently, the Scottish Health Survey (SHeS) from 2008 to 2009 has provided similar data for Scotland. The dental health of adults was poorer in Scotland than in the rest of the UK with recent data from England, Wales, and Northern Ireland showing that the proportion of the population with no natural teeth was 6% in 2009 (Scottish Government 2009; Steele and O'Sullivan 2011). Nevertheless, there has been considerable improvement since in Scotland in recent decades the proportion of adults with no natural teeth declined from 44% in 1972 to 12% in 2008 (Fig. 57.7).

Although Fig. 57.8 shows that as recently as 2008, more than 40% of all people aged over 65 in Scotland had lost all their teeth, there has been a substantial improvement in the oral health of adults since 1972. Moreover, Fig. 57.8 shows very strong cohort effects in the percentage of edentate people. In 1978, 27% of people aged 35–44 were edentate, and by 2008, some 41% of people in the same cohort were edentate. This suggests that there is persistence in oral health over time.

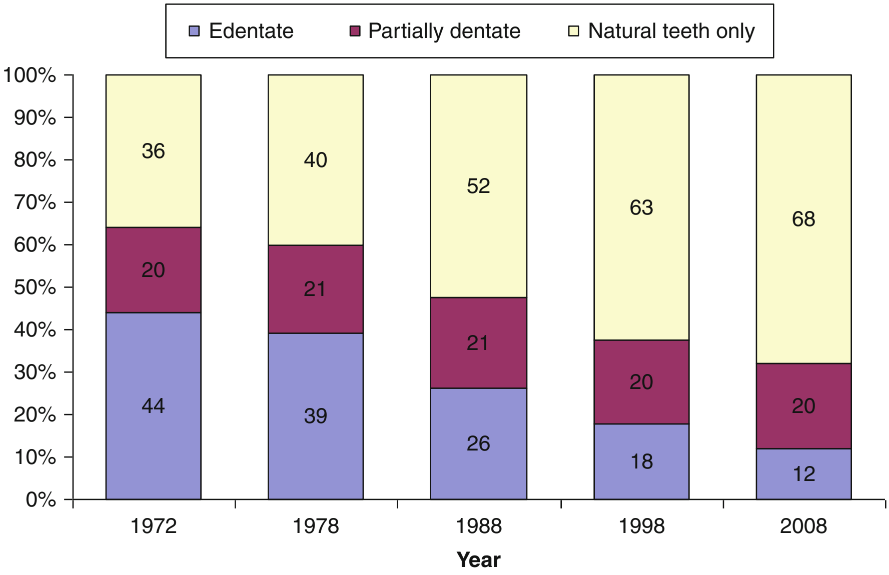

Fig. 57.7 Trends in oral health status of adults in Scotland (1972–2008)

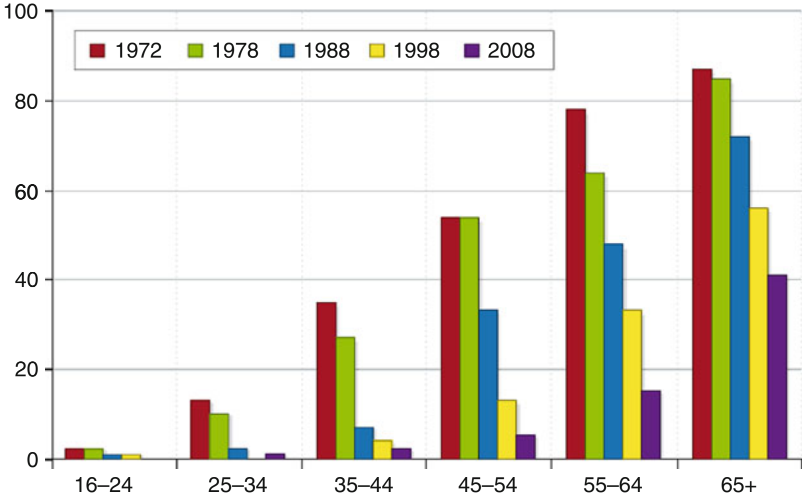

Fig. 57.8 Percentage edentate by age group in Scotland (1972–2008)

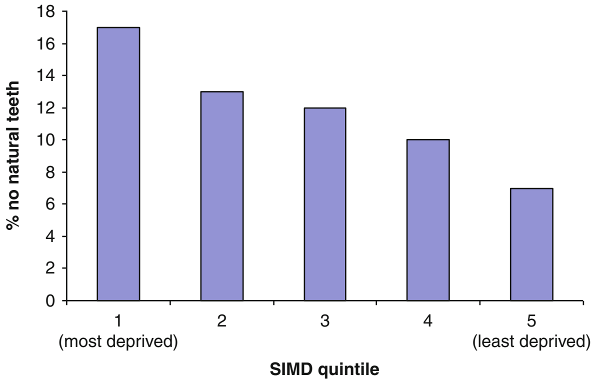
Fig. 57.9 Percentage of adults with no natural teeth by Scottish Index of Multiple Deprivation (SIMD) quintile (1998)



While there has been a substantial improvement in adults' oral health in Scotland since 1972, Fig. 57.9 shows that people from the most deprived backgrounds are more likely to be edentate.

Data from the recent Scottish Health Survey (Scottish Government 2009), in conjunction with previous work at the UK level using data from the Adult Dental Health Surveys (Kelly et al. 2000), indicate that the proportion of adults retaining their natural teeth has increased over time. Data from these surveys also suggest that attitudes to dental care have changed significantly during the past 20 years, and an increasing number of people are retaining teeth into old age.

Trends from SHeS and Scottish data from previous the Adult Dental Health Surveys can be applied alongside population projections (General Register Office for Scotland 2009) to predict future numbers of adults with certain dental characteristics. This will provide some insight into the potential demand for dental services. Figure 57.10 shows that the percentage of edentate adults in each age group decreased between 1972 and 2008. It is projected that by 2028, levels of edentulism in the under-55 age groups will have fallen to 1% or less.

57.4 Analytical Epidemiology

Figure 57.11 highlights the potential pathways from determinants to disease and demonstrates the "common risk factors" for oral health and disease (Sheiham and Watt 2000), which recognizes that risk factors are common to many chronic conditions and that there is much overlap between general health and oral health. It is also now widely accepted that poverty or low socioeconomic circumstances are strong determinants for ill health. Similarly, this relationship has regularly been shown in relation to oral diseases. How this relationship is mediated is less well established.

Oral diseases are determined by many of the same risk factors as other conditions (Sheiham and Watt 2000). In summary, (i) diets, particularly those high in sugar

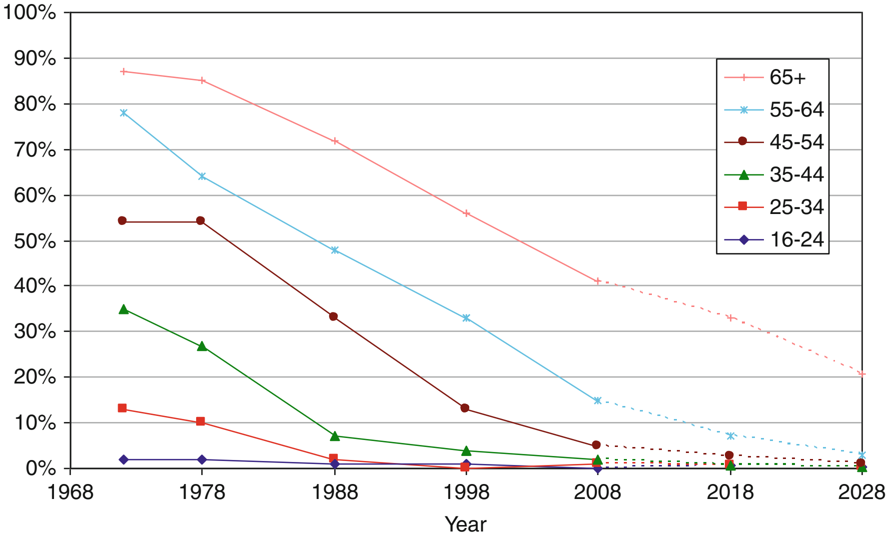


Fig. 57.10 Actual (solid lines) and projected (dotted lines) percentages of edentate adults in Scotland by age group (1972–2028)

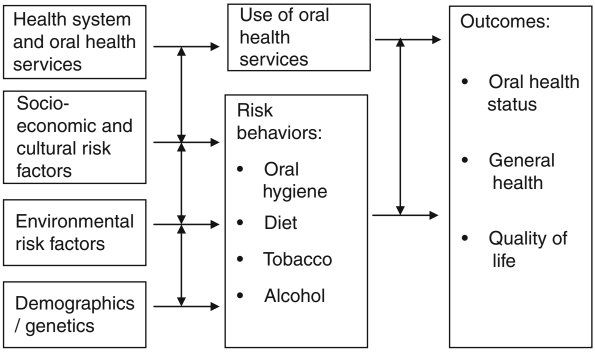

Fig. 57.11 Model of the common risk factor approach (Adapted from Sheiham and Watt 2000; Petersen 2003a)

and/or fat and/or low in fiber and essential vitamins are associated with conditions such as coronary heart disease, stroke, obesity, diabetes, cancers, and dental decay; (ii) smoking is implicated in many diseases, including cancers of the lung, throat, and mouth. In addition, smokers are more likely to have coronary heart disease, diabetes, and gum (periodontal) disease as well as other diseases of the soft tissues of the mouth; (iii) poor oral hygiene is the main cause of gum disease and is also implicated in dental decay, while low general personal hygiene is a factor in many conditions of the skin.

57.4.1 Risk Factors for Dental Caries

This section will outline the risk factors for dental caries. For more details, the reader is referred to comprehensive reviews (Fejerskov and Kidd 2003; Burt and Eklund 2005; Selwitz et al. 2007).

Risk factors for dental caries are multiple, complex, and interrelated; they include bacteria infection, host factors, socioeconomic factors, behavioral or lifestyle factors, and iatrogenic or dental factors. Selwitz and colleagues (2007) consider the behavioral or lifestyle, social, and dental or iatrogenic risk factors most important – however, comprehensive cohort studies have thus far not been undertaken which could unbundle their relative importance. Evidence for each of the key risk factors will be described briefly here.

57.4.1.1 Bacteria

It has long been considered that bacteria are necessary for caries to occur and that caries levels are associated with prevalence of cariogenic bacteria in dental plaque: principally mutans streptococci and lactobacilli (Emilson and Krasse 1985). A systematic review found a strong association between mutans streptococci levels and early childhood caries, although it noted a paucity of longitudinal studies investigating this relationship (Parisotto et al. 2010). The establishment of mutans streptococci colonies in infants has been proposed to be transmitted from mother to child (Berkowitz 2003). However, a direct causal temporal relationship between mutans streptococci and dental caries has yet to be proven – this is partly due to the complexity of the constituents of the oral microflora, with mutans streptococci and lactobacilli also present in healthy mouths. This has led some to propose an imbalance in the composition of the oral microflora (i.e., the interrelationships between the oral mircoorganisms and with their environment) rather than specific bacterial infection. This composition is disrupted and modified (to one with particularly high level of mutans streptococci) by a diet high in refined carbohydrate (Burt and Eklund 2005).

57.4.1.2 Host Factors

Host factors associated with dental caries include deficient salivary flow and quality, tooth morphology and dental enamel quality (determined by levels of mineral – particularly fluoride in the crystalline structure), immunological deficiencies in response to cariogenic bacteria, and genetic factors (Fejerskov and Kidd 2003). A systematic review found some but limited evidence for dental caries genetic variation of host factors including those related to the structure of dental enamel, immunological response to cariogenic bacteria, or the composition of saliva (Shuler 2001).

57.4.1.3 Behavioral or Lifestyle Factors

Behavioral or lifestyle factors include limited access to fluoride, poor oral hygiene, diet with frequent consumption of refined carbohydrates, poor infant feeding and weaning behaviors, and protracted use of sugar-containing oral medicines.

A series of systematic reviews have found that fluoride has a significant caries preventive effect. Risk of dental caries is reduced if fluoride is accessed via, for example, fluoridated toothpaste (Marinho et al. 2003), with increasing preventive effect with fluoride concentrations over 1,000 ppm (Walsh et al. 2010), although there is evidence of increased levels of mild fluorosis if commenced in very young children (Wong et al. 2010). Other clinical caries preventive measures include treatments such as fluoride varnish (Marinho et al. 2002), pit or fissure sealants (Ahovuo-Saloranta et al. 2008) or via fluoridated public drinking water (McDonagh et al. 2000). Similarly, good oral hygiene regimen have been found in a systematic review to be protective for dental caries in children (Harris et al. 2004), although whether this is related to the mechanical dental plaque/bacterial removal versus the fluoride delivery has yet to be fully disentangled.

Historically, in dental epidemiology, etiology and risk has been inferred from descriptive epidemiology studies (rather than analytical case-control and cohort studies). The general relationship between diet (sugars) and dental caries has been established via these methods, including the “causal” role of refined carbohydrates and in particular non-milk extrinsic sugars being widely accepted (Rugg-Gunn and Edgar 1984). This historical evidence has been built up over the past century and includes (i) a series of observational studies of sugar rationing in Norway during World War II (Toverud 1957); (ii) series of observations of the inhabitants of the isolated island of Tristan da Cunha in the South Atlantic as they progressively were exposed to modernized diets as their contact with England increased in the mid-twentieth century (Fisher 1968); (iii) observations of dental caries levels and diet in children in Hopewood House in the 1950s – a care home in Australia – in which children had a diet with restricted sucrose. Comparisons with those of similar age in local population demonstrated dramatic differences in caries prevalence (Sullivan and Harris 1958); and (iv) the infamous Vipehölm experimental study carried out in an institution for adults with learning disabilities and mental health problems in the 1940s and 1950s in Sweden, in which groups were given differing and very high amounts and frequencies of refined sugars in a sticky form. The main findings from this study were that caries risk increased with increased sugar consumption, consumption of sticky form of sugars, and between meal consumption of sticky sugars. They also found that caries risk decreased on removing sticky sugar from the diet and that caries risk is negligible in those with no refined sugar consumption in their diet (Gustafsson et al. 1954).

However, more recent studies have shown that the relationship between dental caries and total sugar consumption or frequency of sugar consumption is less strong than once suspected – particularly in low-caries populations where fluoride exposure is high. A systematic review of observational studies from 1980 to 2000, investigating this relationship, identified studies from countries mainly where fluoride exposure was high and found moderate evidence that sugar was an important risk factor. But the review concluded that limited fluoride exposure was the more important factor (Burt and Pai 2001).

The role of carbonated sugar-sweetened “soft” drinks in dental caries has received some attention not least because of the implication of these drinks in the epidemic of childhood obesity (Mann 2003). A systematic review and meta-analysis investigating the health effects of soft drinks found a small positive association from the two studies with available data (Vartanian et al. 2007). A further systematic review by Kantovitz et al. (2006) found some evidence of a correlation between dental caries and obesity.

A systematic review, albeit of the limited research available, provided inconclusive findings around the relationship between prolonged breast-feeding and early childhood caries, where the confounding effects of socioeconomic status could not be fully taken into account (Valaitis et al. 2000). However, nighttime bottle-feeding and early weaning onto solid foods have been found to increase infant caries risk (Douglass et al. 2001).

A review of the literature for the development of clinical prevention guidelines in Scotland concluded that there was some, albeit limited, evidence supporting increased risk of dental caries following long-term use of sugar-sweetened medicines (Scottish Intercollegiate Guidelines Network 2000).

57.4.1.4 Social Factors

Social factors associated with dental caries risk include individual low income or poverty, low educational attainment, low occupational social class, as well as deprivation associated with area of residence, and in some countries, lack of dental insurance coverage (Gratix and Holloway 1994; Sweeney et al. 1999). A recent life-course study analyzing social mobility over time from a birth cohort in New Zealand identified increased adult caries risk associated with low socioeconomic status in childhood into adulthood, compared to persistent high socioeconomic status and that downward social mobility increased risk, while upward social mobility decreased risk (Thomson et al. 2004). The effect of low socioeconomic status has been proposed as an independent risk factor beyond known explanatory behavioral factors in a Finnish analysis (Millen 1987). Understanding the pathway between low socioeconomic status and dental caries is yet to be fully explored.

57.4.1.5 Dental or Iatrogenic Factors

Dental or iatrogenic factors which can increase caries risk include poor dental restorations or fillings, poor partial dentures, orthodontic appliances, and limited use of (protective) fissure sealants (Fejerskov and Kidd 2003; Benson et al. 2005). A recent Cochrane review found that fissure sealants were effective at preventing dental caries particularly in children’s molar teeth (Ahovuo-Saloranta et al. 2008).

57.4.2 Risk Factors for Periodontal Disease

In this section, the current knowledge about risk factors for gingivitis and periodontal disease is briefly summarized. For more detail, the reader is referred to comprehensive reviews (Philstrom et al. 2005; Demmer and Papapanou 2010; Stabholz et al. 2010).

Poor oral hygiene and supragingival dental plaque have been shown in experimental studies to have a causal relationship with gingivitis (Löe et al. 1965). There does not seem to be any evidence of specific microorganisms responsible, and the condition is considered a non-specific infection (Philstrom et al. 2005).

There is strong evidence from observational epidemiology studies and systematic reviews of these studies that the risk factors associated with increased periodontal disease prevalence include (i) oral microorganisms – both nature and quantity of oral microflora, with a wide range of microorganisms implicated (Haffajee et al. 2004); (ii) dental plaque and calculus which harbor microorganisms, and (iii) poor oral hygiene (Lang et al. 1973; Philstrom et al. 2005). Furthermore, there is increasing evidence of increased periodontal risk associated with genetic factors – particularly variations in genes associated with the inflammatory response (Michalowicz et al. 2000; Stabholz et al. 2010); tobacco smoking (Klinge and Norlund 2005); diabetes mellitus (Ryan et al. 2003); HIV infection and AIDS – particularly in high incidence populations such as South Africa (Scheutz et al. 1997; Arendorf et al. 1998); conditions which impair immune response (Philstrom et al. 2005); low socioeconomic status (Sheiham and Nicolau 2005); psychosocial factors (Nicolau et al. 2007a); and obesity (Chaffee and Weston 2010).

Systematic reviews also reveal that there is more moderate level or limited evidence for periodontal disease risk being associated with the following factors: heavy alcohol consumption (Tezal et al. 2004), nutritional deficiencies (van der Putten et al. 2009), osteoporosis and hormone replacement therapy (Philstrom et al. 2005), and psychosocial stress (Peruzzo et al. 2007). Men are consistently at more risk than women for destructive periodontal disease, and sex hormones have been suggested as having a role, although gender differences in oral hygiene and attendance patterns are also possible explanatory variables (Kelly et al. 2000; Shiau and Reynolds 2010). Dental treatment that predisposes to plaque build-up or oral malocclusions may also be contributory factors (Bollen 2008).

Conversely, there is also moderate level evidence that periodontal diseases are implicated as risk factors in the etiological pathway of other diseases and conditions including adverse pregnancy outcomes – particularly preterm birth and low birth weight (Xiong et al. 2006), cardiovascular disease (Humphrey et al. 2008), stroke (Scannapieco et al. 2003a), pulmonary disease (Scannapieco et al. 2003b; Azarpazhooh and Leake 2006), and type 2 diabetes mellitus (Demmer et al. 2008). The cause and effect relationship between periodontal disease and diabetes is still not clear, and a bidirectional or two-way interrelationship has been proposed. It has been reported that periodontal disease can potentiate the development of diabetes and interfere with glycemic control through pro-inflammatory pathways; however, it has also been shown that periodontitis is itself a complication of diabetes (Iacopino 2001).

57.5 Prevention and Dental Public Health Approaches

As with all epidemiological study of disease, its ultimate aim is prevention.

The WHO Ottawa Charter for Health Promotion (WHO 1986) provides a useful structure with which dental caries can be prevented at a population level. The charter includes developing public health policy, reorientating health services, creating supportive environments, and working with communities, as well as personal skills for behavior change.

57.5.1 Dental Caries

There has been a raft of clinical guidelines on prevention for dental caries produced recently (e.g., Scottish Intercollegiate Guidelines Network 2000; Scottish Intercollegiate Guideline Network 2005; European Academy of Paediatric Dentistry 2009; Scottish Dental Clinical Effectiveness Programme 2010; American Dental Association 2011). These documents focus on grading and interpreting the epidemiology and clinical trial evidence into practical advice and recommendations for clinical practitioners. The role of health services to deliver prevention activities is important, but oral health promotion and improvement of activities in other settings and with other partners are also essential.

It is widely acknowledged that for the prevention of dental caries, these approaches need to focus on activities that will reduce the frequency and amount of sugars in the diet and on programs that will deliver fluoride and fissure sealants. Influencing diet remains a difficult challenge both at the population level and the individual patient level. At the population level, food consumption and choice are determined by many factors, not least access, affordability, culture, education, cooking skills, food regulation, and labeling. Changing dietary behavior at the population level requires concerted multidisciplinary working with a wide range of relevant organizations, agencies, policy makers, businesses, and professionals, as well as consumers. Professional dietary advice in dental practices is usually based on providing one-to-one dietary advice based on individualized health education models. However, there is evidence from a systematic review in a dental setting that this education approach is largely ineffective (Sprod et al. 1996).

Population programs involving the delivery of fluoride have been shown to be effective with a range of different interventions. These programs have included community water fluoridation, school water fluoridation, fluoridated salt, school supervised toothbrushing, professional topical fluoride varnish or gel application in schools, mouth rinsing in schools, provision of fluoride tablets in schools, and fissure sealant programs in school children (Selwitz et al. 2007). There is some concern expressed about the safety of fluoride. However, a systematic review in relation to water fluoridation by McDonagh and colleagues (2000) has shown that the only adverse effect is mild dental fluorosis (i.e., mottling) – although the quality of studies was described as poor. They also identified a need for more longitudinal follow-up studies at the tooth surface level including different socioeconomic subgroups.

57.5.2 Periodontal Disease

Prevention of chronic gingivitis and periodontitis is based on the control of the key risk factor, namely, the buildup of the oral biofilm (dental plaque) which forms on the teeth in the absence of effective oral hygiene (toothbrushing). However, it is also important to take into account the various additional risk factors including smoking, socioeconomic factors, and diabetes control in the prevention and treatment planning of periodontal diseases. It should be noted there are big differences in the potential for control and prevention between gingivitis, chronic periodontitis, and aggressive periodontitis. Gingivitis and chronic periodontitis can be prevented by both professional and personal good oral hygiene regimen. Patients who suffer from aggressive forms of the disease may be hyperresponsive to relatively little plaque. Periodontal susceptibility tests are not yet applicable to clinical practice, and therefore good oral hygiene is the only preventative measure available.

Löe and colleagues (1965) demonstrated that within 24 hours of cessation of toothbrushing, the oral biofilm begins to develop on the teeth leading to gingivitis in 2–3 weeks, which is reversed within 1 week if toothbrushing returns. While the destructive effects of chronic periodontitis cannot be reversed, it has also been shown that professionally administered oral hygiene (one-to-one in a clinical setting) can slow or stop periodontitis, and tooth loss can be avoided (Axelsson et al. 2004).

Community and school-based health education promotion programs have been found to be effective in reducing dental plaque and gingivitis levels in the short-term (6 months), but not in the long-term or in relation to periodontal disease (Watt and Marinho 2005). Moreover, school-based oral health education approaches have been found to widen oral health inequalities, with those from higher socioeconomic groups more able, or to take on health messages and behaviors (Schou and Wight 1994). Nevertheless, the WHO oral health promotion strategy proposed for low-income countries with high-prevalence periodontal disease and limited dental services and public health programs aimed at educating and promoting oral hygiene practices would be cost-effective (Petersen 2003a). They also suggested that oral health promotion in general needs to be integrated to the wider public health agenda and address the socioeconomic and environmental, as well as the behavioral, risk factors of oral disease. In this regard, tobacco control should be an important aspect of preventive programs for periodontal disease as part of a common risk factor approach to health – as smoking is a risk factor for many chronic diseases (Sheiham and Watt 2000).

57.5.3 Dental Public Health

Dental public health approaches are concerned with implementing interventions and activities aimed at preventing oral diseases. This work is often more positively framed as health improvement or health promotion, and it needs to be done via a strategic approach based on appropriate assessment of the population/community needs alongside the resources and assets available. Health promotion cannot be done within the boundaries of health services alone, rather by working in partnerships such as those between health services, local government organizations, education settings, private sector/business, local organizations, communities, and people.

An example of this approach is the *Childsmile* national (country-wide) child oral health improvement program for Scotland (which the authors of this chapter are heavily involved with). It is a comprehensive health promotion intervention, including community development activities and service redesign as major components (Macpherson et al. 2010b; Turner et al. 2010). It is not simply a dental health education program, whereby oral health advice is passively given – it includes "active" interventions such as nursery (kindergarten) and school toothbrushing alongside healthy snack policies; distribution of free toothbrushes and toothpaste from primary care health services and in nursery schools; referral to dental services from community public health nurses (health visitors) from birth; a targeted nursery school fluoride varnish program; and dental services reoriented to focus on prevention interventions in children such as fluoride varnish, toothbrush demonstration, and tailored dietary advice delivered by other members of the dental team including dental nurses – not only dentists. One of the key challenges this program faces is in tackling oral health inequalities (described via the epidemiology in Sect. 57.3.2 above) and in deciding whether this is best done in a targeted approach focusing efforts on those at greatest need from deprived backgrounds and communities or in a universal, population-wide approach. This has been debated at length for *Childsmile* and resolved, in terms of the strategy, via a combination of the two approaches (Shaw et al. 2009). This approach follows the "Marmot" strategy for tackling health inequalities globally (Marmot et al. 2008) and in England (Marmot et al. 2010) described as "proportionate universalism," which recognizes that inequalities are a gradient and not just extremes of health differences between rich and poor. A major evaluation program has been established to assess the effectiveness of *Childsmile* and its components (Turner et al. 2010). The national epidemiology program of surveys of dental caries in children will be central to the evaluation and will be used to assess the impact on oral health improvement in terms of reduced dental caries and on whether oral health inequalities in terms of the socioeconomic distribution of children's dental caries has reduced. The first paper has recently been published demonstrating a clear improvement in oral health in terms of reduction of caries in 5-year-olds in Scotland, following the introduction of a national supervised toothbrushing programme in nursery schools for 3- and 4-year-olds (Macpherson et al. 2013)

57.6 Conclusions

Dental epidemiology is focused on better understanding the burden and causes of oral diseases. It is increasingly used to evaluate the effectiveness of dental public health programs aimed at improving population oral health (e.g., Turner et al. 2010; McMahon et al. 2011).

The future of dental epidemiology has a number of outstanding issues. With regard to dental caries descriptive epidemiology, the epidemiological threshold for dental caries diagnosis is an important consideration in measuring the prevalence of disease, and there are strong arguments to begin to look at enamel level lesions or subclinical levels. Relatively recent proposals also include a new index, the Significant Caries Index (SiC), which aims to bring attention to the individuals with the highest caries values in each population under investigation. The SiC is calculated as follows: (i) individuals are ranked by their DMFT scores, (ii) the one-third of the population with the highest caries scores is selected and (iii) the mean DMFT for this group is calculated (Bratthall 2000). This index focuses attention on children with the greatest amount of dental caries, and the WHO has begun to adopt the SiC as part of their country level targets for 12-year-olds; thus, countries should aim to have a DMFT of 3 or less for the whole population, and then they should aim to have a SiC of 3 or less DMFT for the one-third of children with the highest levels of caries (WHO 2010b).

The limited understanding of the nature and extent of inequalities in dental caries demonstrates a need to undertake detailed analysis of the trends associated with inequalities in distribution from survey data. These descriptive approaches need to be complemented with analytical epidemiology involving new, large cohort studies to investigate fresh the risk factors for dental caries from the social determinants to the microbiological and genetic levels but also including better quantification of diet and fluoride use. This could include social epidemiology approaches set out in Berkman and Kawachi (2000), life-course epidemiology (Kuh and Ben-Shlomo 2004; Nicolau et al. 2007a), and genetic epidemiology (Burton et al. 2005).

Descriptive epidemiology of periodontal disease needs to be developed conforming to standard definitions and classifications of disease. As with dental caries, the etiological analytical epidemiology literature is somewhat limited in terms of the quantity and quality of longitudinal studies which could temporally determine causal risk factors in the etiology of periodontal disease. Nicolau et al. (2007b) propose the use of life-course epidemiological approaches to investigate oral disease etiology. This approach has the potential to better elucidating the social, ecological, temporal, behavioral, and biological or genetic disease pathways and mechanisms.

58.1 Introduction

The most obvious characteristic of digestive disease epidemiology is diversity. Most other clinical specialties deal with one or a limited number of organs each, and within these specialties, certain diseases feature much more prominently than others. In contrast, the digestive system comprises all parts of the alimentary canal from the esophagus to the anus, several solid organs (liver and pancreas), the biliary tree, and the intra-abdominal fascial structures (mesentery, peritoneum) (Fig. 58.1). As the organs are manifold, so are the ways in which they may be affected by disease – structural, inflammatory, cancerous, functional, psychosomatic, endocrine, toxic/drug induced – the list is non-exhaustive. None of the digestive diseases are so prevalent as to dominate the specialty. Rather, the most common 10 diseases taken together represent only 20% of the total prevalence of the digestive diseases (Everhart and Ruhl 2009a). The remaining 80% are spread out over a large number of less frequent diseases.

Similarly, in digestive disease epidemiology, most epidemiological methods may be applicable. Infection and vaccination, genetic epidemiology, cancer and screening, public health and prevention, nutrition, environment, clinical epidemiology including diagnosis, prognosis and therapy, health economics, pharmacoepidemiology all are relevant issues in gastroenterology. In short, digestive disease epidemiology offers a particularly wide scope of diseases and methods.

Conferences and textbooks of epidemiology rarely feature explicit sections on digestive disease epidemiology. More often, selected topics emerge in other contexts, such as risk factors for colorectal cancer in cancer epidemiology, *H. pylori* transmission in infectious disease epidemiology, and diarrhea prevention

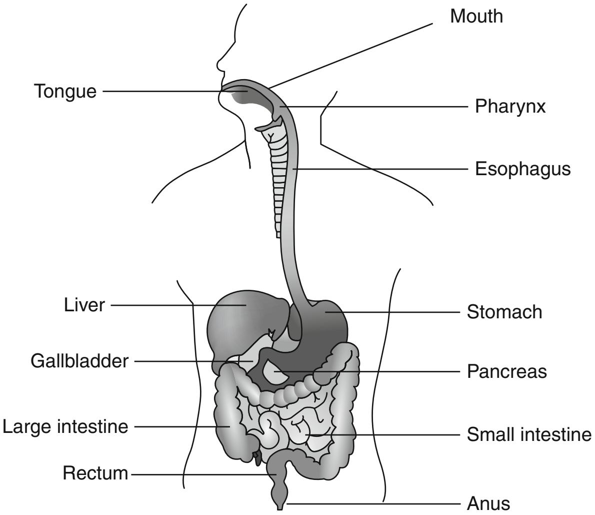

Fig. 58.1 Organs of the digestive system. Courtesy of David Darling, http://www.daviddarling.info/encyclopedia/D/digestive_system.html

and control in developing countries epidemiology. A substantial body of the digestive disease epidemiology literature is generated by clinical or bench-based researchers who have never attended an epidemiology course or conference. Putting this together in a comprehensive way is beyond the scope of a single chapter. Rather, we will highlight a few topics we feel are interesting or of prominent public health relevance. Others are chosen because they hide pitfalls which may evade the epidemiologist not familiar with the clinical aspects of these diseases. For a more comprehensive approach, we refer the interested reader to a book on gastrointestinal epidemiology (Talley et al. 2007).

Following an introduction into the scope and approaches used in digestive disease epidemiology, we will first discuss the relative frequency and burden of digestive diseases, including trends over time (Sect. 58.3). We will move from a global perspective to the descriptive epidemiology of several specific problems representing the main organ groups within the digestive tract. Care has been taken to focus on exemplary, common problems, such as viral Hepatitis and related liver disease, the more common gastrointestinal cancer sites, the inflamed bowel, and functional diseases.

In the fourth section, etiological aspects will be described, covering genetics, poverty-related factors, and behavioral risk factors. *H. pylori* infection will be discussed, as this is maybe the most important discovery in gastroenterology in the last century.

A special section will be devoted to clinical epidemiology, as this field features particularly strong in digestive disease epidemiology. All sections will be illustrated by a number of examples. We will start with an overview on the descriptive epidemiology of digestive diseases.

58.2 Scope and Approaches

Epidemiology of digestive diseases deals with the frequency, distribution, risk factors, clinical behavior, and management of diseases of the digestive tract. Internationally, concepts of what belongs to the corresponding clinical specialty of gastroenterology vary. The main categories as listed in ICD 10 (World Health Organization 2007; http://www.who.int/classifications/icd/en/) are shown in Table 58.1. For this chapter, we will include aspects of the epidemiology of the liver (hepatology) along with diseases of the upper gastrointestinal tract, bowel, and pancreas but exclude metabolic disease, in particular diabetes, and disorders of the oral cavity.

As there is no tradition of digestive disease epidemiology which might have driven specific methods, we will focus on the descriptive epidemiology of several of the more common disorders, risk factor associations, and some observations on the success of preventive measures. For more detailed methodological aspects, we refer the readers to other chapters of this handbook.

Table 58.1 Diseases of the digestive system

ICD 10	Disease
A00–A09	Intestinal infectious diseases
B15–B19	Viral Hepatitis
C15–C26	Malignant neoplasms of the digestive organs
D00, D01, D12, D13, D27	In situ neoplasms, benign neoplasms, unknown behavior of oral cavity and digestive organs
C15–C26	Malignant neoplasms of the digestive organs
K20–K31	Diseases of esophagus, stomach, and duodenum
K35–K38	Diseases of appendix
K40–K46	Hernia
K50–K52	Non-infective enteritis and colitis
K55–K63	Other diseases of intestines
K65–K67	Diseases of peritoneum
K70–K77	Diseases of liver
K80–K87	Disorders of gallbladder, biliary tract, and pancreas
K90–K93	Other diseases of the digestive system

58.3 Global Burden of Digestive Diseases

58.3.1 Overview

The burden of digestive diseases varies worldwide. In the developing world, infectious diseases, including diarrhea and viral Hepatitis, as well as cancer of the liver, are major problems. In the West, functional diseases are more prevalent. With the exception of infectious diseases and cancers of the digestive tract, there are few valid data on population prevalences. As many diseases are non-fatal, ranks based on mortality rates give another picture than figures derived from hospital discharge diagnoses, and the distribution in ambulatory care is again quite different, as are the health economical consequences (Table 58.2).

About one in three citizens attends a physician for digestive complaints each year in the Western world (Everhart and Ruhl 2009b). Gastrointestinal disease is the third most common cause of death, the leading cause of cancer death, and the most common cause of hospital admission in the UK (Williams et al. 2007).

The major causes of death from gastrointestinal disease in high-income countries, excluding cancer, are liver cirrhosis, peptic ulcer, ischemic bowel disease, diverticular disease, and gastrointestinal hemorrhage. Many other, non-fatal diseases of the digestive tract rank relatively low in vital statistics and hospital admission rates but impact substantially on the quality of life of those affected. Typical examples include gastroesophageal reflux disease, dyspepsia, irritable bowel syndrome, and

Table 58.2 Top ten prevalent digestive diseases (USA 2004; Everhart and Ruhl 2009b)

	Ambulatory care	Hospital discharges	Deaths	Total costs
1	Gastroesophageal reflux disease	Gastroesophageal reflux disease	Colorectal cancer	Chronic liver disease/cirrhosis
2	Chronic constipation	Diverticular disease	Liver disease/cirrhosis	Gastroesophageal reflux disease
3	Abdominal wall hernia	Chronic liver disease/cirrhosis	Pancreatic cancer	Colorectal cancer
4	Hemorrhoids	Chronic constipation	Esophageal cancer	Gallstones
5	Diverticular disease	Gallstones	Gastric cancer	Abdominal wall hernia
6	Irritable bowel syndrome	Peptic ulcer disease	Primary liver cancer	Pancreatic cancer
7	Hepatitis C	Pancreatitis	Bile duct cancer	Diverticular disease
8	Colorectal cancer	Gastrointestinal infections	Hepatitis C	Pancreatitis
9	Chronic liver disease/cirrhosis	Hepatitis C	Gastrointestinal infections	Peptic ulcer disease
10	Gastrointestinal infections	Abdominal wall hernia	Peptic ulcer disease	Hepatitis C

anorectal disorders (e.g., hemorrhoids or fecal incontinence). Symptoms of gastrointestinal disease tend to be unspecific, such as abdominal discomfort, loss of appetite, bloating, heartburn, fatigue, or constipation. Many patients never present to a physician, and in many instances, gastrointestinal conditions remain untreated or in patient self-management. There is an increasing body of research on the determinants of health-care-seeking behavior, in particular in functional diseases.

For most diseases, there is no single test or key symptom to prove the diagnosis. This may pose problems in studying these diseases on a population level. Use of administrative data can also be a challenge as many gastrointestinal conditions occur in the presence of other morbidity. As an example, elderly patients on multiple drugs are of particularly high risk to suffer from gastrointestinal hemorrhage, for example, as a consequence of gastric ulcer related to the use of non-steroidal anti-inflammatory drugs (NSAID). Obviously, the accuracy of, for example, hospital discharge or mortality data depends on the number of diagnoses available for analysis per case.

58.3.2 Examples

58.3.2.1 Infectious Diseases: Hepatitis C Still on the Rise

Methodological approaches to infectious disease epidemiology are covered in chapter ▶Infectious Disease Epidemiology of this handbook. Three infectious entities seem particularly important and interesting from an epidemiological and public health view. Besides acute infectious diarrhea and *H. pylori*, which will be discussed below, these are viral hepatic infections, specifically chronic Hepatitis C.

Viral Hepatitis may be caused by a number of viruses, most prominently Hepatitis A, B, or C (HAV, HBV, and HCV). The main differences of these are described in Table 58.3. In summary, HAV infection is a food-borne and self-limiting acute infection. HBV and HCV are blood-borne and may run a chronic course. It is estimated that about one third of the world's population has been exposed to either HBV or HCV, although only about a third of those affected are aware of the infection (Lancet Editorial 2008).

HAV and HBV are, as so many infectious diseases, associated with poverty-related risks, namely poor sanitation (HAV, HBV), unsafe sex, and vertical transmission from infected mothers during delivery (HBV). Both HAV and HBV are endemic in certain low- and middle-income countries and currently on the decrease thanks to successful interventions, including vaccination programs and screening of pregnant women. In high-income countries, HAV and HBV are now mainly restricted to specific risk groups: HAV in international travelers and HBV in immigrants, inmates, and i.v. drug abusers.

Quite in contrast, the burden from HCV is still expected to rise. In most high-income countries, HCV is now the most common cause of chronic liver disease, in others, second only to alcohol. In the USA, the current prevalence of chronic HCV is 1.3% (RNA positive), as compared to 0.4% for chronic HBV (Liangpunsakul and

Table 58.3 Viral Hepatitis – differences A, B, C

Characteristics	HAV	HBV	HCV
Main mode of transmission	Feco-oral: Contaminated food and water Close personal contact	Blood-borne, mucosal: perinatal Sexual intercourse/unsafe sex i.v. drug abuse, needle sharing	Blood-borne: i.v. drug abuse, needle sharing blood products before 1992 Other iatrogenic (contaminated needles)
Other ways of transmission	Homosexual activity i.v. drug abuse	Hemodialysis Blood products in unsafe health care settings Household sharing	Hemodialysis Professional (needle stick injury) Controversial: sexual intercourse (multiple partners) Rare: tattooing, acupuncture, piercing, household sharing, perinatal
Diagnosis	Anti-HAV IgM/IgG – acute or past exposure; Immunity	HBs Ag = acute or chronic infection Anti-HBs = past exposure; immunity	Anti-HCV = past exposure or chronic infection HCV-RNA = confirmatory test (acute or chronic infection)
Vaccination	Available since 1995	Recommended since 1992	Not available
Acute infection	Mostly symptomatic in adults, often no symptoms in children	Mostly symptomatic (jaundice), Rare: fulminant (liver failure)	Rarely symptomatic
Proportion resulting in chronic infection	<1%	<10% (more if perinatally acquired)	55–90%, depending on age and sex
High-prevalence regions	Developing world (>90% exposed during childhood); occasional outbreaks in middle-/high-income countries	Far East, Southeast Asia (up to 16% chronic HBV), sub-Saharan Africa, Amazon area, Eastern Europe	More evenly distributed including North America and Europe (world wide 2.2%)
Number of persons currently infected (worldwide)	Incidence 1.4 million/year (acute)	Prevalence >350 million (chronic)	Prevalence 170 million (estimated) (chronic)
Preventive strategies	Vaccination (children, international travel, high-risk persons) Improve sanitation	Vaccinations (infants and high-risk persons) Screening of pregnant women Immunoprophylaxis to avoid perinatal transmission Screening of donors/inactivation of blood products Safer sex	Screening and testing of blood donors Risk reduction counseling of persons at risk, e.g., avoid needle sharing, safer sex

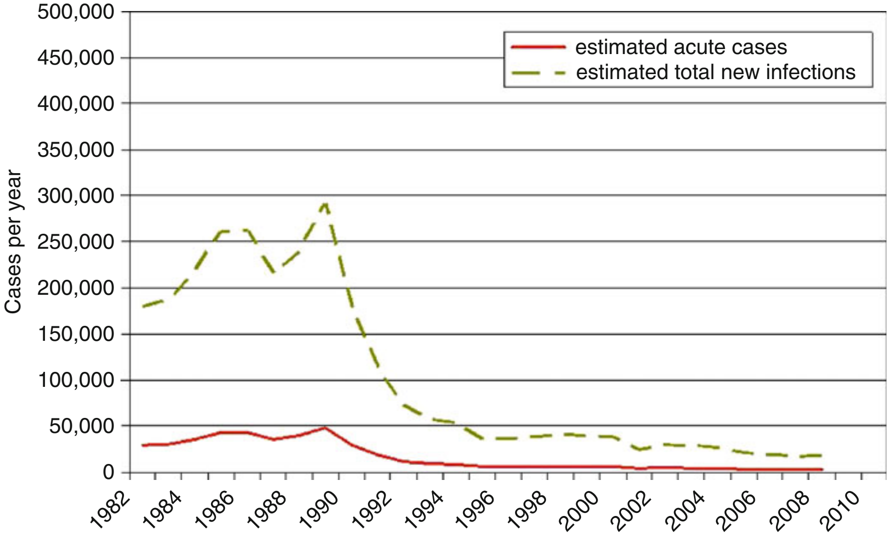

Fig. 58.2 HCV infection – number of cases per year (USA, CDC data). Source: http://www.cdc.gov/hepatitis/Statistics/index.htm (with kind permission)

Chalasani 2005). In Western Europe, HCV accounts for 70% of all cases of chronic Hepatitis, 40% of all liver cirrhosis, and 60% of hepatocellular carcinoma (Williams et al. 2007).

Acute HCV infection is rarely symptomatic and mostly goes unnoticed (World Health Organization 2007). Diagnosis is usually delayed until routine lab examinations unveil raised liver enzymes or until complications of liver disease manifest. In consequence, there are hardly any empirical data on the incidence of HCV. Estimations have been based on mathematical modeling (Davis et al. 2010). These indicate a steep fall in the incidence from the first description of the virus in 1989 to recent times. The decrease has been linked to the introduction of blood donor testing in 1989, improved diagnostic tests in 1992, and the promotion of safer needle using techniques in i.v. drug users (Fig. 58.2).

For the natural history of the disease, several natural experiments are available. In Germany, several thousand women were infected with HCV when immunoglobulin from donors with acute non-A and non-B Hepatitis (as this viral Hepatitis was known before the description of HCV) was used for rhesus incompatibility prophylaxis. Two thousand four hundred and sixty four affected women were acknowledged as vaccination victims and received compensation from the Eastern German Government from 1979 and later from the Federal Republic of Germany. In Ireland, a regional analysis of blood donors in 1991 discovered a strong association of chronic Hepatitis C with rhesus-negativity. In a subsequent national investigation, more than 62,000 of women were tested who had received anti-D immune globulin between 1970 and 1994, confirming that quantities used in 1977 and 1978 had been contaminated. All infections could be traced back to a single donor, and 1,042 successful claims were made by infected women (Akehurst 1999). More diverse claimant cohorts are available for follow-up from other countries, such as the UK, Canada, and Japan (Harris et al. 2002; Pokorski 2001; Thein et al. 2009). Male sex, older age at infection, use of alcohol, and coinfection with HIV or HBV are the most important risk factors for HCV-related morbidity (Poynard et al. 1997).

A prognostic study using complex Markov modeling took into account the different prognosis by age and sex and arrived at the following estimations (Davis et al. 2010): Following acute infection in women under the age of 30, 55% will run a chronic course. Of these 4.2% will have end-stage liver disease (cirrhosis) after 30 years, 0.02% will have hepatocellular carcinoma (HCC), and 0.9% will have died from liver-related death. In contrast, infected male persons aged 31–50 have a risk of 80% for chronic HCV and, if chronic, will suffer from cirrhosis in 38.1%, HCC in 0.5%, and liver death in 11.1%.

Of those currently infected, most contracted the virus between 1970 and 1990 and are now entering the stages of complicated liver disease. According to the Markov model, the prevalence of cirrhosis within those currently infected will continue to increase from currently 25 to 45% in 2030, before, eventually, the burden will decrease. The most important message is: despite the major advances in reducing the incidence of this infection since it was first described, the peak of the HCV epidemic is still to come.

58.3.2.2 Cancer of the Gastrointestinal Tract: Subsite Matters

Cancer epidemiology is covered by chapter ▸Cancer Epidemiology of this handbook. A few aspects specific to gastrointestinal cancers seem worth noting in the context of digestive disease epidemiology. Digestive cancers account for about 18% of all cancers in the Western world. Most prominently, these are the primary malignancies of the esophagus, stomach, large bowel, liver, and pancreas. Less commonly, the biliary tract, the small bowel, or the peritoneal cavity is affected.

For most entities, men are affected more often than women. The average age at onset is relatively high as compared to cancers at other sites. Most malignancies in the gastrointestinal tract are solid, and of these, most are adenomas, although other entities, for example, lymphoma or neuroendocrine tumors, do occur. The majority of gastrointestinal cancers still have a very poor prognosis. For example, less than 5% of those diagnosed with cancer of the pancreas survive 5 years following the diagnosis; mortality rates still equal incidence. The decrease of both incidence and mortality in colorectal cancer (see chapter ▸Cancer Epidemiology of this handbook) is one of the rare successes in gastrointestinal cancer epidemiology and so far mainly restricted to Western countries, specifically those where screening takes place.

Quite in contrast to colorectal cancer, primary cancer of the liver (hepatocellular carcinoma, HCC) is endemic in Africa, where prevalence rates may be as high as 20% (Hainaut and Boyle 2008). This is a direct consequence of a high prevalence of chronic HBV. HCC almost exclusively develops in the presence of cirrhosis of the liver, and in low-income countries, chronic HBV infection is the most common cause of cirrhosis of the liver. Vertical transmission of HBV to newborns of infected mothers carries the highest risk of both running a chronic course of HBV infection as well as of resulting in cancer. HBV is amenable to preventive measures, most importantly childhood vaccination programs, screening of pregnant women, and perinatal active-passive immunization of babies of infected mothers. Consequently, HCC may be expected to decrease in these countries, while it is currently on the rise in the Western world due to the epidemic of HCV-associated morbidity, as discussed above.

Divergent trends in incidence are observed in esophageal cancer. So far, the dominant histological type of cancer of the esophagus has been squamous, but adenomatous cancer is on the rise and is now more frequent in several Western European countries (Bosetti et al. 2008). Squamous carcinoma of the esophagus is closely associated with smoking and alcohol (see below). These risk factors are estimated to account for more than 80% of this highly fatal malignancy (Danaei et al. 2005). In contrast, adenocarcinoma of the esophagus, arising from the lower part of the esophagus, is related to acid reflux and obesity.

Cancer of the upper (cardiac) part of the stomach and the gastroesophageal junction is in its risk profile similar to lower esophageal cancer. The distinction may sometimes be difficult to make. Other than cancer of the lower (non-cardiac) part of the stomach, infection with *H. pylori* does not play a role in cancer of the cardiac region or may even be protective. Whereas the elimination of *H. pylori* will result in a decreased risk for non-cardiac gastric cancer, this is not the case for cancer of the cardiac region. There is even some controversy whether *H. pylori* might be protective for this type of cancer.

This may appear confusing. However, these examples underline the importance of thoroughly defining subtypes of a given cancer in terms of site and histology in order not to blur any risk associations or time trends.

58.3.2.3 The Inflamed Bowel: Inflammatory Bowel Disease, Appendicitis, and Diverticulitis

About every part of the digestive system may be affected by chronic inflammation and autoimmune reactions. Examples include autoimmune pancreatitis, pernicious anemia (arising from autoimmune gastritis), autoimmune Hepatitis, primary biliary cirrhosis, and celiac disease. With the exception of celiac disease (gluten-sensitive enteropathy, 1% of the population), these conditions are relatively rare, and few data are available from larger cohorts regarding risk factors and incidence. For some conditions, viral triggers are suspected. The epidemiological literature is scarce.

In contrast, innumerable descriptive and case-control studies have been published on the incidence and possible etiological factors of the inflammatory bowel diseases (IBD), Crohn's disease, and ulcerative colitis. Typically, these diseases manifest in early adulthood and run a chronic, relapsing course. Complications may include growth failure in the young, bowel obstruction, and fistulization in Crohn's disease frequently necessitating surgery and colorectal cancer in ulcerative colitis. Although life expectancy is now close to normal, morbidity is high. In consequence, these patients constitute a relevant fraction in the daily practice of a gastroenterologist. Inflammatory bowel diseases are also an attractive target for biological therapy, as well as genetic studies, and feature highly in the clinical trial literature. The prevalence in the population is relatively low and is currently estimated to be about 0.4% in North America and Western Europe (Loftus Jr. 2004). These diseases have been linked to a Western lifestyle. They were very uncommon before World War II and have increased since.

Quite in contrast, other inflammatory bowel disorders are more common but receive less research attention. In particular, these are acute appendicitis, which may affect up to 10% of persons in the Western world during a lifetime, mostly at young age, and diverticulitis, a common condition in the elderly. While IBD is a disease of the second half of the twentieth century, appendicitis incidence peaked in the first half of the last century and has been declining since then. Not only do these diseases show divergent time trends in correlational studies, there is also a strong negative association between ulcerative colitis and appendicitis in individual level analyses: the odds ratio (OR) of getting ulcerative colitis in appendectomized persons is about one third of those not appendectomized (Frisch et al. 2009). This finding is so far unexplained. Overall, there has been remarkably little research on appendicitis, although it is such a common surgical condition. Most of the descriptive and etiological literature stems from the 1970s and 1980s (Heaton 1987).

Diverticular disease is another common but relatively understudied condition. Up to 70% of the elderly are estimated to have diverticulosis of the large bowel, little pouches in the colon wall arising from increased intraluminal pressure, associated with a sedentary lifestyle and low-fiber diets. Only a minority of these become symptomatic, but still so many as to make this one of the ten most common digestive diseases (Everhart and Ruhl 2009b). Diverticula of the large bowel are also the most frequent cause of lower gastrointestinal bleeding. In the case of inflammation (diverticulitis), if complicated by abscess, peritonitis, or recurring, the affected part of the bowel will be removed surgically. Thus, as appendicitis, diverticulitis can be cured by surgery. Other than IBD, it is usually not associated with lifelong morbidity.

58.3.2.4 Hepatobiliary and Pancreatic Diseases: Gall Stones, Pancreatitis, and Cirrhosis of the Liver

Gallstones are among the most common gastrointestinal conditions. They are easily diagnosed using ultrasonography, so valid cross-sectional evaluation of representative populations is possible. Ultrasonography-based prevalence data are very variable even within the same country (Kratzer et al. 1999). For example, figures within Germany ranged from 8% to 21% (Völzke et al. 2005; Walcher et al. 2005). This is not yet sufficiently explained.

Risk factors for gallstone disease include age, female sex (parity), obesity, fast weight loss, and some digestive diseases interfering with intestinal resorption, for example, inflammatory bowel disease. There is also a strong genetic component. Gallstones are particularly common in North American natives, where up to two thirds of the female population are affected.

The presence of gallstones does not indicate disease. Most gallstones are asymptomatic and not in need of therapy. It is estimated that only 1% to 2% of persons with gallstones will develop complications per year. Most commonly, these are colics from biliary obstruction or inflammation of the gallbladder (cholecystitis). Usually, treatment is by cholecystectomy.

Gallstones are also the most common cause of acute pancreatitis, as obstruction of the biliary tract may lead to this condition. We will discuss this disease entity in the context of alcohol-related diseases.

Chronic liver disease, in particular cirrhosis of the liver, is among the most expensive disease groups in gastroenterology and among the most deadly (Everhart and Ruhl 2009c). This is the more tragic in that this condition is to a large extent preventable. We have touched on this before: in the developing world, cirrhosis is usually due to chronic HBV infection. In contrast, in high- and middle-income countries, cirrhosis of the liver is most commonly due to HCV infection, followed by alcoholic and non-alcoholic fatty liver disease. There are many other causes including autoimmune and metabolic disorders, but these non-preventable conditions taken together cause less than 20% of all cases of cirrhosis.

About 1% of the population is estimated to have histological evidence of cirrhosis, that is, scarring of the liver resulting from chronic liver injury. Hepatic tissue is replaced by connective tissue as part of the wound healing process; the liver slowly becomes fibrotic. The end stage is characterized, on the one hand, by loss of liver function and on the other hand by increased hepatic resistance resulting in hypertension within the portal vein and circulatory deregulation. Patients with end-stage liver disease may suffer from diverse life-threatening complications, including hepatic coma, bleeding from esophageal varicose veins, peritonitis, and kidney failure. These account for the substantial burden chronic liver diseases pose to society. Mortality is high, and liver transplantation is the only treatment option in advanced liver disease. The pattern of the global burden of liver disease and its causes is expected to change substantially over the coming decades.

58.3.2.5 Functional Diseases: Definitions Matter

Functional diseases of the digestive tract are among the most common disorders in the population, affecting about a third of the population in Western countries (Koloski et al. 2002). Irritable bowel syndrome alone is estimated to constitute up to 50% of the workload of a gastroenterologist working in ambulatory care (Williams et al. 2007). Prevalence rates are mostly unreliable and vary depending on the definitions used (Vandvik et al. 2004). Only a minority of those affected seeks medical care and ever gets a diagnosis, and of those who do see a general practitioner, many are never referred to a specialist.

In general, functional disease is assumed in the presence of symptoms without underlying organic disease. This is overly simplistic. Insufficiently understood gut motility abnormalities seem to arise from disordered interaction between the central nervous system and the gut nervous system (Cremonini and Talley 2004). Learned illness behavior and emotional factors may play a role in how the individual copes with these common symptoms and whether medical help is sought (Levy et al. 2000). Although not usually associated with increased mortality or hospitalization, quality of life is known to be decreased, and substantial loss of work productivity has been shown.

Quite a few functional entities are defined in gastroenterology: globus pharyngis (feeling a lump in the throat), non-cardiac chest pain, functional (or non-ulcer) dyspepsia, functional abdominal pain, functional constipation, and irritable bowel syndrome. Of these, dyspepsia, constipation, and irritable bowel syndrome are the most common. Substantial overlap may exist in the symptoms reported, both between the different functional disorders, as between functional and organic disorders. This makes the definition of diagnostic criteria such a challenge. Dyspepsia, for example, refers to abdominal discomfort, which may or may not be associated with peptic ulcer, gastritis, or esophagitis. In about 50%, there is no structural correlate, and, thus, functional or non-ulcer dyspepsia is assumed (Vakil and Talley 2007). Clinical symptoms are not sufficient to differentiate between these entities (Moayyedi et al. 2006).

Chronic constipation is endemic in certain subpopulations, in particular the elderly. It may constitute a major management problem in nursing homes. In a minority of patients, slow bowel transit or defecatory dysfunction is identified. These patients form a specific subgroup. Constipation is also a side effect of many medications, most notably opioids. Furthermore, it is associated with a variety of neurological and psychiatric conditions such as Parkinson's disease, multiple sclerosis, or depression. The average prevalence in the normal population in North America is 15% if stringent diagnostic criteria are used but may be up to 27% when studies rely on self-reporting (Higgins and Johanson 2004).

Thus, functional disorders pose specific problems for epidemiological research. Not only do diagnosis and symptom severity require careful definitions, the choice of outcome criteria for clinical trials is also a challenge. Most commonly, the Rome criteria are used in research and practice, currently in their 2nd revision (Rome III) (Drossman 2006). The Rome group differentiates 28 adult and 17 pediatric functional gastrointestinal disorders and has developed consensus criteria for those more frequent. Symptom questionnaires are also available, although mostly not validated for use in epidemiological research. The key publications on the diagnostic criteria by disease as well as diagnostic questionnaires and scoring codes are available from the Rome Foundation website (www.romecriteria.org).

58.4 Risk Factors and Determinants, Prevention and Control

58.4.1 Overview

There is a high potential for public health interventions in digestive disease. Hand washing to prevent the spread of acute diarrhea is a prominent example. Many diseases of the alimentary tract are strongly associated with risk behavior, for example, alcohol and i.v. drug abuse in chronic liver disease. Some are amenable to prevention by eradication of precursor conditions, such as adenomas in colorectal cancer or *H. pylori* infection in peptic ulcer disease and gastric cancer. Vaccination programs are also in place, apt to substantially changing the prevalence of several infectious diseases. Examples include Hepatitis B or rotavirus infection.

In this section, we describe some of the major risk factors in gastrointestinal disease by the example of selected entities. Besides poverty in the context of infant mortality, alcohol is probably the most important modifiable risk factor for digestive diseases. It contributes to the majority of cases of esophageal cancer, pancreatitis, and cirrhosis of the liver in affluent societies. A comprehensive analysis of published data calculated population attributable fractions for several common cancers due to nine common environmental and behavioral risk factors (Table 58.4) (Danaei et al. 2005).

Most of the current research in digestive disease etiology seems to focus on genetics.

58.4.2 Examples

58.4.2.1 Genetic Factors: Crohn's Disease as a Prominent Example of Complex Heritability

Several digestive diseases, or multiorgan diseases affecting the digestive system, display a monogenic heritability. Examples include hemochromatosis (affecting the liver, pancreas, and brain), cystic fibrosis (affecting the lung and pancreas), alpha-1-antitrypsin deficiency (affecting the lung and liver), several types of hereditary pancreatitis, hereditary non-polyposis cancer of the colon, and familial adenomatosis coli (FAP). These relatively rare conditions have, in the clinical context, important implications for surveillance programs, as some are precancerous, and others are associated with severe non-malignant, sometimes avoidable morbidity. Counseling of affected families is necessary.

More commonly, complex heritability is present, posing considerable challenges to the effective collaboration between epidemiologists and geneticists. For methodological issues, please refer to chapter ▸Statistical Methods in Genetic Epidemiology of this handbook. Crohn's disease may be taken to illustrate quite a few of the techniques presented there (Gaya et al. 2006; Cho 2008). Observations of increased prevalence in families of affected persons, higher concordance in monozygotics in several twin studies, segregational analysis pointing at an autosomal recessive gene, and mapping of a first susceptibility locus (IBD1) preceded the concurrent identification of the NOD2 gene using positional cloning on the one (Hugot et al. 2001) and candidate gene assessment on the other hand (Ogura et al. 2001) in 2001. This was just a start: as of today (July 2010), a PubMed search using the phrase "inflammatory bowel disease AND genetic" returns 3,268 hits – to go into detail is beyond the scope of this chapter. The many mutations discovered so far explain only a minority of cases.

Epigenetic approaches may help elucidate the pathogenesis not only of Crohn's disease but of gastrointestinal development in general (Waterland 2006). Differentiation of the colonic gut flora taking place in early infancy is suspected by some

Table 58.4 Risk factors for gastrointestinal cancer mortality with population attributable fractions (*PAF*), global (high-/low- and middle-income countries) (Danaei et al. 2005)

	High body mass index (BMI)	Low fruit/vegetable consumption	Physical inactivity	Smoking	Alcohol	Intravenous injection in health-care settings	Risk factors combined
Esophagus (combined)	–	18 (12/19)%	–	42 (71/37)%	26 (41/24)%	–	62 (85/58)%
Stomach (combined)	–	18 (17/19)%	–	13 (25/11)%	–	–	28 (34/27)%
Colorectum	11 (14/9)%	2 (1/2)%	15 (14/15)%	–	–	–	13 (15/11)%
Liver (HCC)	–	–	–	14 (29/11)%	25 (32/23)%	18 (3/21)%	47 (52/45)%
Pancreas	–	–	–	22 (30/15)%	–	–	22 (30/15)%

to play a major role in many diseases, including diabetes and obesity (Frank and Pace 2008; Peterson et al. 2009). Research in this has only just started and may bring the gut much more to the forefront of research, including epidemiology, than previously anticipated.

58.4.2.2 Poor Sanitation, Unsafe Water, and Contaminated Food: Acute Infectious Diarrhea

Several of the digestive diseases are poverty related and occur endemically in countries with crowded housing conditions as well as contaminated food and water supplies. Most of these are infectious (for methods, see chapter ▸Infectious Disease Epidemiology of this handbook). We have already mentioned viral Hepatitis, of which HBV and HAV are amenable to effective preventive measures, including vaccination and screening of pregnant women. *H. pylori* is another example, which we will discuss below. Here we would like to concentrate on an issue of primary importance in global public health: acute infectious diarrhea.

Acute diarrhea is still, besides pneumonia, the leading cause of death in children under the age of five. It accounts for 17% of the infant deaths worldwide (World Health Organization 2007). Diarrhea is common all over the world, in particular in children. Fatality from diarrhea is closely related to the traditional risk factors associated with poverty – the combined risks of underweight, insufficient breastfeeding, and vitamin deficiencies are estimated to account for 73% of infant mortality from diarrhea, and 99% of deaths from diarrhea occur in low-income countries (World Health Organization 2007).

A short summary (not comprehensive) of common causative organisms is presented in Table 58.5 (O'Brian and Halder 2007). Good advances have been made in the prevention and treatment of bacterial and parasitic organisms. Previously common enteric infections such as typhoid fever, cholera, and amoebic colitis are on the decline. Today, most intestinal infections are viral. Of these, norovirus is ubiquitous and regularly causes outbreaks all around the world, affecting persons of any age. In children under the age of five, rotavirus is more common. Besides watery diarrhea, fever and vomiting are also typical, aggravating the risks for the underprivileged. In high-income countries, the disease will subside within a few days. In low-income countries, many children die from dehydration. The relative contribution of rotavirus infection to infant deaths from diarrhea has been increasing and may currently be as high as 40% (Parashar et al. 2009).

The high mortality from acute diarrhea including rotavirus infection is the more tragic as cheap and effective measures are available for treating this condition. WHO oral rehydration solution (ORS) works via the sodium channel glucose transport system in the bowel mucosa. It is superior to i.v. fluids or any other therapy in watery diarrhea (Hartling et al. 2006; Gregorio et al. 2009). Diarrhea prevention programs have been in place from 1978 and have led to dramatic falls in the infant death rate from diarrhea in the following years (Santosham et al. 2010). Unfortunately, in the 1990s, the specific diarrhea programs were merged into integrated health programs. Diarrhea as a distinct entity lost priority, as did the promotion of ORS, formerly named the major medical advance of the twentieth century (Santosham et al. 2010).

Table 58.5 Common risk factors for specific antigens causing infectious diarrhea (Modified from O‘Brian and Halder (2007))

Antigens	Risk factors
E. coli O157:H7	Undercooked beef, unpasteurized milk, apple cider, visits to animal farms, petting zoos
Shigella	Contaminated water and vegetables, day-care centers, custodial institutions
Clostridium difficile	Antibiotics, hospitalized patients
Campylobacter	Undercooked poultry, contaminated milk, tuna salad
Salmonella	Raw eggs, undercooked poultry, unrefrigerated dressing, reptiles as a pet, family members with Salmonella
Non-cholera vibrio	Raw/undercooked seafood
Giardia	Contaminated water, recreational exposure in lakes, rivers, or swimming pools, day-care centers
Cryptosporidium	International travel, contact with cattle, freshwater swimming
Rotavirus	Cold season, infancy
Norovirus	Cold season, raw oyster consumption, cruise ships, health institutions

Since 1995, there has not been much progress in the acceptance of this easy and effective therapy. Currently, only about a third of children with watery diarrhea receive ORS; many health workers still prefer antibiotics for watery diarrhea. If the millennium goal of reducing infant mortality worldwide by two thirds by 2015 is to be met, the prevention and treatment of acute diarrhea need to get back in focus.

A seven-point plan set up for comprehensive diarrhea control includes rotavirus vaccination, promotion of early and exclusive breastfeeding, vitamin A supplementation, promotion of hand washing with soap, improvement of water quantity and quality, promotion of community-wide sanitation, and, for treatment, fluid replacement and zinc supplements (Wardlaw et al. 2010). Two vaccines against rotavirus are now available in developed countries but need to be evaluated in endemic countries as soon as possible. Introduction to low-income countries will depend on priority setting by governments and WHO (Rose et al. 2009).

58.4.2.3 Peptic Ulcer Disease and *H. Pylori*: A Success Story?

One of the most exciting milestones in gastroenterology in the twentieth century was the discovery that peptic ulcer disease was caused by a bacterial agent, *Helicobacter pylori* – rightly awarded the Nobel Prize in Medicine in 2005 (Lang 2005). This major success story of clinical medicine was, quite in contrast, prominently discussed as one famous example where epidemiology failed (Davey-Smith and Ebrahim 2001).

For most of the twentieth century, peptic ulcer disease was a common problem with high morbidity and mortality. Severe complications occurred frequently, such as life-threatening bleeding or perforation into the abdominal cavity. If not fatal, recurrence was almost inevitable. Many patients ended up having major surgery, such as total or, more often, subtotal gastrectomy or vagotomy. These procedures are themselves associated with high perioperative morbidity and subsequent decreased quality of life.

There have been numerous epidemiological studies into the etiology of peptic ulcer disease (Davey-Smith and Ebrahim 2001). This was sparkled, among other things, by so far unparalleled patterns in the incidence and prevalence of these diseases, similar as, more than 50 years later, the inflammatory bowel diseases. Comparable to coronary heart disease, lung cancer, and appendicitis, the incidence of both gastric and duodenal ulcer increased during the first half of the twentieth century. From the 1950s on, however, the incidence of peptic ulcer decreased for unknown reasons. Strong birth cohort effects were discovered as early as 40 years ago, pointing at the relevance of events occurring early in life (Susser 1982; Sonnenberg 2007). Persons born between 1870 and 1920 had the highest risk. For each subsequent generation, the risk for peptic ulcer incidence and mortality successively decreased.

Similar observations for, for example, tuberculosis incidence could have raised the suspicion of an infectious etiology in peptic ulcer disease. It did not. Up until the 1970s, diet, alcohol, emotional stress, and personality had been identified as risk factors for peptic ulcer disease – none of them would have explained the birth cohort effect. Davey-Smith in his critical essay on our discipline points out that the epidemiological transition from infectious to non-infectious diseases may have had, in this case, clouded the view of epidemiologists in favor of non-infectious factors (Davey-Smith and Ebrahim 2001). Improved sanitary conditions and less domestic crowding resulting in lower infection rates would have been a plausible explanation of the birth cohort phenomenon. Still, etiological hypotheses focused on nutrition and psychosomatics.

Epidemiology was not the only discipline led astray in this case. The notion that peptic ulcer disease was caused by microbes colonizing the gastric mucosa was revolutionary in clinical medicine, pathology, and microbiology as well. Until then, the stomach had been assumed to be sterile, due to its high acidity.

It was a junior gastroenterology fellow who performed a simple cross-sectional study in 100 patients referred to endoscopy after a pathologist had described a curved bacterium, later called *Helicobacter pylori*, in the gastric mucosa of patients with gastritis (Marshall and Warren 1984). He found a strong association between the presence of the microbe and active chronic gastritis, duodenal ulcer, or gastric ulcer. Later, he demonstrated acute gastritis in himself after ingestion of *H. pylori*.

H. pylori gastritis is a chronic inflammation as a reaction to *H. pylori* colonization, playing a pivotal role in the development of several gastric disorders. Carriers of *H. pylori* have a 10% to 20% lifetime risk of peptic ulcer disease and a 1% to 2% life time risk of gastric cancer. Taking another perspective, more than 70% of all gastric cancer is attributable to *H. pylori* (Goodwin et al. 1997). Eradication of *H. pylori* with combination of antibiotic therapy effectively cures peptic ulcer disease. It is also expected to decrease the risk for gastric cancer.

Naturally, the question now arises whether screening for and treatment of *H. pylori* are useful from a public health perspective. Several issues play a role in this ongoing discussion – the prevalence of the infection in a population, the availability of tests and their performance, costs, acceptance, and rates of microbial resistance to antibiotic agents.

On average, about 50% of a population carries *H. pylori*. This varies by age and region. In developing countries, prevalence rates may be as high as 80%. In industrial countries, the rate is, on average, 40%, but with a marked generational gradient. Infection seems to occur in the first years of life, primarily from close family contacts. In adults, new infection is very rare, as is spontaneous seroconversion. This means that the observed differences by age group are almost completely caused by generation (birth cohort) effects. Crowding during industrialization and decreasing hygiene has been suggested to explain the effect (Sonnenberg 1995). The prevalence in children is a good indicator for the future burden. German school children now have prevalence rates as low as around 10% (Rothenbacher et al. 1999).

58.4.2.4 Behavioral Risk Factors: Alcohol and Smoking

Four entities in particular are strongly associated with high alcohol intake: esophageal cancer, acute and chronic pancreatitis, and cirrhosis of the liver.

As pointed out above, in esophageal cancer, the type of cancer needs to be defined in order to correctly interpret risk data. For example, in a recent prospective cohort study, the relative risk for squamous esophageal cancer in persons with high alcohol intake ($\geq$30 g/d) was 4.6 (95% confidence interval (CI) 2.2–9.5) as compared to abstainers, but no association was found for adenocarcinoma of the esophagus (Steevens et al. 2010).

Alcohol plays the major role in the pathogenesis of acute pancreatitis, ahead of biliary causes (obstruction by gall stones). The exact mechanism by which alcohol exerts this effect is unclear. Several hypotheses have been discussed, including direct toxic effects of acetaldehyde on acinar cells, sensitization of the pancreas to injury, or mediation via alcohol-induced duodenitis (Chowdhury and Gupta 2006). A genetic predisposition to pancreatic injury from alcohol seems to be essential. Only a minority of heavy drinkers develops pancreatitis.

In acute pancreatitis of any etiology, systemic reactions are common, including multiorgan failure. Case fatality is now about 10%. Acute pancreatitis is also a relevant side effect of some drugs (e.g., occurs in about 3% of those on the immunosuppressive azathioprine) or diagnostic procedures involving the pancreatic duct (endoscopic retrograde cholangiopancreatoscopy (ERCP), occurs in up to 5% of procedures), but these account for only a small part of the overall burden. Other rare causes are viral, traumatic, autoimmune, or hereditary. What makes some people's pancreas susceptible to damage by alcohol is still subject of research. Both genetic and environmental factors seem to play a role (Haber et al. 1995; Yadav and Whitcomb 2010).

Chronic pancreatitis is probably not a consequence of recurrent or intractable acute pancreatitis but due to different yet unclear mechanisms. Up to 80% of cases are estimated to be due to chronic abuse of alcohol. Pancreatic tissue is replaced by scarring; characteristic features are chronic pain and loss of weight, in advanced cases diabetes due to destruction of islet cells (endocrine function) and maldigestion due to loss of exocrine function. Chronic pancreatitis is a major risk factor for pancreatic carcinoma making the latter another mediate, potential consequence of alcoholism.

In the liver, different pathologies may occur following alcoholic injury. Alcoholic fatty liver is the earliest stage, in which lipids are deposited in hepatic cells, and is found in 90% to 100% of liver biopsies in heavy drinkers (Dufour 2007). Alcoholic Hepatitis affects about 10% to 35% of drinkers at some time. It may present very acutely and may result in acute liver failure. Recurrent hepatitic episodes and progression of fatty deposits will result in fibrosis and eventually cirrhosis, in up to 20% of heavy drinkers or 70% of drinkers who have had alcoholic Hepatitis (Mandayam et al. 2004). Alcohol is also an important cofactor for liver damage from other causes, such as chronic viral Hepatitis, where it exerts synergistic effects. Ultimately, cancer may occur in the cirrhotic liver, as in cirrhosis of other etiologies.

As compared to alcohol, smoking is less important in gastrointestinal disease. Several disorders show elevated risks, but for most, the associations are moderate (Steevens et al. 2010). Smoking is, however, an important cofactor of alcohol in several entities – both in esophageal squamous carcinoma as well as in acute pancreatitis, smoking increases the deleterious effect of alcohol.

In inflammatory bowel disease, contrasting roles for smoking have been demonstrated by type of disease. Smoking is the only established external risk factor for Crohn's disease and is, in addition, associated with a poor prognosis (Calkins 1989; Birrenbach and Bocker 2004). In contrast, in ulcerative colitis, smoking seems to be protective. Typically, the disease begins in former smokers, following smoking cessation (Corrao et al. 1998). Attempts to use nicotine (gums, patches) in the treatment of ulcerative colitis have been unsuccessful, partly due to incompliance as side effects are common with nicotine. Although these divergent associations have been known since the 1980s, the underlying mechanisms remain obscure.

58.4.2.5 Risk Factors in Affluent Societies: Sedentary Lifestyle, Nutrition, and a Sheltered Childhood

Colorectal cancer is commonly perceived as a malignant disorder particularly closely associated with the sedentary Western lifestyle. High-calorie food intake low in fruits, vegetables, and fibers and high in processed meats has been confirmed as risk factors (Bingham et al. 2003; Norat et al. 2005; Friedenreich et al. 2006; van Duijnhoven et al. 2009). However, the joint behavioral risk factor attributable fraction is relatively low in colorectal cancer as compared to the other common digestive tract cancers (Table 58.4). It constituted only 13% in a cumulative analysis based on published data and results from the WHO Comparative Risk Assessment Project (http://www.who.int/whr/2002/en/) (Danaei et al. 2005).

In contrast, non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis are increasingly recognized as sequelae of overnutrition in affluent societies. They are now considered the digestive disease manifestation of the metabolic syndrome. Exact mechanisms are still unclear. On biopsy, features resemble those of alcoholic liver disease. Prevalence data depend on the method used for detection (ultrasonography, magnetic resonance imaging (MRI), or liver biopsy). Prevalence has been reported as up to 30% of the US population (Browning et al. 2004). NAFLD may progress and is expected to become the most common cause of cirrhosis and HCC in Western societies once HCV-related complications have peaked and started to regress (Davis et al. 2010). Currently, a lot of research, bench based, as well as clinical, is addressing this relatively newly discovered phenomenon. New diagnostic tools, in particular the elasticity liver scan, may make this disease easier to examine in large-scale population-based studies.

For data on the importance of nutrition on digestive cancers, we refer to chapter ▶Cancer Epidemiology of this handbook and Table 58.4.

In inflammatory bowel disease, a lot of effort has been devoted to the identification of nutritional risk factors, compromised by recall bias and problems of reverse causation. Due to the relative scarcity of the diseases, most investigators relied on retrospective studies. Since long time periods may elapse between the onset of symptoms and first diagnosis, eating patterns are usually already altered once patients become available for interview. There are now a few prospective studies looking into risk factors for IBD as secondary research aims, in particular EPIC (Hart et al. 2008). Unfortunately, as this cohort is conceptionalized for the investigation of causes of cancer, the population is rather old, and only an atypical subgroup of IBD patients presenting late is available.

More interestingly, in analogy to findings for atopic diseases, IBD seem to be associated with a “sheltered childhood,” that is, improved hygienic conditions in infancy (Timmer 2003). Most likely, in genetically predisposed persons, insufficient priming results in an inappropriate immunological response to antigens, probably within the normal gut flora later in life (Baumgart and Carding 2007).

58.5 Clinical Epidemiology of Digestive Diseases

58.5.1 Overview

Clinical epidemiology and, as its application in clinical medicine, evidence-based medicine have a relatively long and successful history in the treatment of digestive diseases. This is reflected by a growing number of clinical practice guidelines taking into account the results of clinical research. Mega-trials, as encountered in cardiovascular diseases, are uncommon, making meta-analyses more important. Quality of life issues are particularly important in functional disorders, and there has been substantial work to develop validated instruments to measure patient-related outcomes of health interventions. However, there are still many underdeveloped areas in clinical epidemiology research.

Diagnostic and therapeutic options available to highly skilled endoscopists and ultrasonographers advance rapidly, and so must be the rigor in assessing the benefit of these procedures. Prognosis and surveillance in high-risk populations are prominent issues, in particular the prevention or early detection of complications in chronic diseases. The clinical strategies to deal with these risks are often insufficiently corroborated by epidemiological data.

Lastly, pharmacoepidemiology in clinical digestive disease epidemiology is very important. Side effects on the digestive tract are the most common side effects of drugs, ranging from slight nausea to life-threatening gastrointestinal bleeding.

58.5.2 Examples

58.5.2.1 Therapy: Randomized Controlled Trials and the Cochrane Collaboration

The evidence base for therapy in digestive diseases varies substantially by entity. There is extensive clinical trial activity for IBD, HCV, and cancer. In contrast, for some of the more common conditions, the evidence base is surprisingly small. As an example, a PubMed search for randomized clinical trials (publication type) renders 1,104 trials for inflammatory bowel disease, but only 55 for diverticulitis (July 2010). For the latter, potential treatment options are relatively cheap. For example, a diet rich in fiber is commonly recommended to prevent recurrence despite absence of evidence of efficacy. In contrast, immunomodulating drugs as applicable in IBD, the duration of interferon therapy in viral Hepatitis, or individualized (antibody) therapy in colorectal cancer have severe commercial as well as health economical consequences.

For the treatment of HCV, combination therapy with interferon and ribavirin is effective (Brok et al. 2010). The virus can now be eliminated in about 50%, depending on viral genotype, age, sex, and coinfections, for example, with HBV or HIV. Very complex treatment recommendations tailor length of treatment to the various clinical situations (Mangia and Andriulli 2010), mostly supported by evidence from clinical trials and observational prognostic studies. Stepping back from the clinical context to a population perspective, the situation is sobering. In the Markow model cited above, treatment of Hepatitis C by combination of antiviral therapy was estimated to reduce the future risk of late complications (cirrhosis, death, HCC) in those infected today by just 1% (World Health Organization 2007). The problem is that an estimated 70% of infections remain undetected and only 25% of all detected cases are offered treatment. The effect of antiviral therapy on the prevalence on HCV-related morbidity will remain small unless awareness both of the infection and of the treatment options is improved along with the advances in efficacy.

Inflammatory bowel diseases are a good example for difficulties encountered when choosing appropriate endpoints for clinical trials in non-fatal diseases. There is considerable interindividual diversity of symptoms and signs which may indicate relapse or a severe disease course. No single phenomenon has been identified which might function as a useful outcome criterion in clinical trials on inflammatory bowel disease, in particular in Crohn's disease. Instead, a number of composite indices have been developed to allow for standard assessment across patients with varying symptoms. The combination of time in or to remission, based on predefined thresholds of well-validated composite clinical activity scores, and the additional assessment of quality of life have been recommended for use in clinical trials (Sandborn et al. 2002; D'Haens et al. 2007). Unfortunately, at this time, there seems to be some falling back on a preference for surrogate measures of (so far) unproven prognostic relevance. They are not even easily assessable nor without risk for the patient. We allude to "mucosal healing," which requires endoscopy for visualization and is poorly correlated with patient symptoms (Rutgeerts et al. 2007).

Clinical trials are even more challenging in the functional diseases. In these disorders, not just the outcome criteria but also diagnosis and inclusion criteria require thoughtful definitions in order to avoid misclassification and advance generalizability.

Of specific concern are the new invasive procedures, such as endoscopic mucosal resection for early cancers of the esophagus and stomach or natural orifice transluminal endoscopic surgery (NOTES) for intra-abdominal operations. These emerging techniques require highly skilled interventional gastroenterologists or abdominal surgeons proficient in endoscopic techniques. Slow learning curves and restriction to highly specialized centers make these techniques difficult to evaluate, even more so than was previously the case for laparoscopic techniques (Sauerland et al. 2004; Keus et al. 2006).

As mega-trials are rare in digestive disease due to the relative rarity of most conditions, meta-analysis strongly features in gastroenterology and hepatology. Inflammatory bowel diseases were the first digestive diseases to be represented by a Cochrane review group. A Cochrane review group is a team within the Cochrane Collaboration which serves as an editorial basis for systematic reviews prepared for a specific group of diseases (see chapter ▶Clinical Epidemiology and Evidence-Based Health Care of this handbook). Currently, there are 52 of these groups worldwide. Four of them are devoted to digestive tract diseases (Table 58.6). Some disorders may be covered by other groups, such as acute diarrhea by the Infectious Diseases Group and fecal incontinence and rectal prolapse by the Incontinence Group. All groups keep specialized registries of clinical trials in the respective area, including hand search activities, screening conference abstracts, and journals not currently indexed in Medline, representing a useful resource for clinical researchers.

58.5.2.2 Diagnosis: Endoscopy and Symptom Scores

Many gastrointestinal diseases depend on invasive procedures for a definite diagnosis, making these diseases difficult to study in epidemiology. For example, in gastroesophageal reflux disease (GERD), there are structural correlates (esophagitis, acid reflux) to define the diagnosis, but these require upper endoscopy and, possibly, pH-metry.

In functional disease, such as non-ulcer dyspepsia and irritable bowel syndrome, there are no diagnostic signs. These are rather syndromes, requiring thoughtful definitions as discussed above. Even where internationally agreed on definitions are

Table 58.6 Cochrane groups covering digestive disease therapy and diagnosis

Name (year founded)	Location, web address	Scope
Inflammatory Bowel Diseases (1995) and Functional Bowel Disorders Group (renamed 2005)	London, Ontario, Canada http://www.cochrane.uottawa.ca/ibd/	Ulcerative colitis Crohn's disease Since 2005: other intestinal disorders including microscopic colitis, collagenous colitis, lymphocytic colitis, irritable bowel syndrome, chronic constipation, and diarrhea
Hepatobiliary Diseases Group (1996)	Copenhagen, Denmark http://ctu.rh.dk/chbg	Hepatic diseases, including alcoholic liver disease, Hepatitis B and C, cirrhosis of the liver, hepatic malignancies Biliary diseases, including gallstone diseases, infections, malignancies
Colorectal Cancer Group (1998)	Copenhagen, Denmark http://cccg.cochrane.org/	Colorectal, anal, and small bowel cancer Benign proctologic diseases Benign peritoneal diseases Surgical treatment for inflammatory bowel diseases Surgical anal diseases Abdominal hernias Appendiceal diseases Diverticulitis Peritonitis
Upper Gastrointestinal and Pancreatic Diseases Group (1998)	Hamilton, Ontario, Canada http://fhs.mcmaster.ca/ugpd/index.html	Disorders of the esophagus, stomach, duodenum, and pancreas

in place such as the Rome III criteria, these have a tendency to undergo frequent revisions and are subject to severe interrater disagreement (Vandvik et al. 2004).

Advanced diagnostic techniques develop rapidly in gastroenterology at this time. More and more new modifications become available, posing new challenges both with respect to the manual skills of the investigators, as to the technical equipment. Examples include contrast-enforced ultrasonography, the endoscopic capsule, virtual colonoscopy, endoscopic ultrasonography, chromo-endoscopy, virtual chromo-endoscopy, magnetic resonance imaging (MRI) of the small bowel or biliary-pancreatic ducts, and so forth. There is some risk that the technical and manual advances are not accompanied by thoughtful evaluation of diagnostic test accuracy, not to speak of the critical assessment of whether the procedure has an effect on outcome. At times, the ultimate goal of diagnosis (or any clinical maneuver) – make the patient better! – gets out of focus when enthused clinicians formulate clinical guidelines. More input from clinical epidemiologists would be desirable to help researchers adhere to good standards as set out in chapter ▶Clinical Epidemiology and Evidence-Based Health Care of this handbook.

58.5.2.3 Prognosis: Early Detection of Long-Term Complications of Gastrointestinal Disease

Gastroenterology and hepatology comprise many conditions associated with severe, potentially avoidable long-term consequences, some of them malignant. Generally in these conditions, the question arises if and how surveillance is appropriate to prevent or alleviate these complications.

Few conditions will inevitably result in cancer if untreated. An example is familial adenomatous polyposis (FAP) – all affected will develop colorectal cancer at an early age, and total proctocolectomy is recommended in the teenage years. More often, the risks are less well defined.

Long-standing extensive ulcerative colitis is associated with an increased risk of colon cancer. Data are conflicting, but cancer rates of up to 30% after 20 years have been reported (Eaden et al. 2001). Most clinical guidelines recommend regular surveillance colonoscopy from about 10 years after the diagnosis, depending on the extent of the inflammation in the bowel. More recent data have given rise to some controversy whether the risk is really that high.

There is a biliary condition associated with ulcerative colitis, primary sclerosing cholangitis, which is itself strongly associated with cholangiocarcinoma, but surveillance is more difficult. Visualization of the biliary system by endoscopic retrograde cholangiography (ERC) or the MRI equivalent (magnetic resonance cholangiography (MRC)) is required, with unproven, maybe improvable, effectiveness.

As pointed out before, cirrhosis of the liver may result in hepatocellular carcinoma (HCC); in fact, very few HCC develop in a non-cirrhotic liver. Tumor markers (alpha-fetoprotein, AFP) and ultrasonography used to be recommended for follow-up. More recently, AFP has been found of insufficient specificity and sensitivity and has been replaced by imaging techniques only (once yearly). The effectiveness of these schemes is still unclear.

Other examples include Barrett's esophagus, which corresponds to displaced gastric mucosa in the low esophagus. From Barrett's metaplasia, adenocarcinoma of the gastroesophageal junction or lower esophagus may develop. Most endoscopists would probably recommend regular follow-up of patients with Barrett's esophagus diagnosed via upper endoscopy, in particular if a longer segment is involved. However, this has, so far, not been shown to be effective. Most cases of Barrett's are undetected, as this condition, as GERD, correlates poorly with symptoms. As Barrett's metaplastic areas can now be removed by endoscopic resection, the role of screening by upper endoscopy might be reconsidered. So far, population screening for upper gastrointestinal disease is not recommended, and individual surveillance is only contemplated when Barrett's mucosa was detected by endoscopy performed for symptoms.

There are several conditions with markedly raised incidence ratios but low absolute risks of lymphoma or other malignancies. These include small bowel malignancy in celiac disease or Crohn's disease. Surveillance is not recommended in these cases. Similarly, screening for pancreatic cancer in chronic pancreatitis (which is a risk factor for pancreatic cancer) or new onset diabetes (which may be a symptom of advanced pancreatic cancer) is not helpful to improve survival in pancreatic cancer. And lastly, there is the unanswered question on how to proceed following a diagnosis of an *H. pylori* infection in asymptomatic patients, as discussed above. So far, most gastroenterology societies do not recommend eradication to prevent gastric cancer, but the issue is still controversial.

In short, many conditions await critical assessment to help decide on the usefulness of surveillance programs. At this moment, for most cases, patients and clinicians are left with considerable uncertainty.

58.5.2.4 Assessment of Quality of Life in Persons with Digestive Diseases

Several of the more prevalent chronic gastrointestinal diseases have mortality rates close to those of the normal population but impact heavily on persons' daily functioning and life satisfaction. Quality of life research aims at assessing this impact, preferably from the patient's view (chapter ▶Health Services Research of this handbook). Health-related quality of life (HRQL) assessment is now firmly established in gastroenterological research (Glise and Wiklund 2002). In functional diseases, the impact of symptoms on HRQL may be the only measure that defines disease status. In chronic inflammatory disease and cancer, HRQL is now routinely used as an adjunct outcome measure in therapeutic trials. A good example is the inflammatory bowel disease questionnaire (IBDQ), developed by Guyatt et al. (1989). HRQL assessment is also important for health economical analyses and pharmacoeconomical evaluations.

Many instruments are available for use in digestive disease epidemiology, some of them well validated and translated to various languages (Borgaonkar and Irvine 2000). Most are multi-item instruments, appreciating aspects of physical well-being and functioning as well as emotional and social consequences of health. Generally, they can be classified as generic or disease specific, symptom or function oriented, and treatment specific (Wiklund 2007).

Generic instruments help to compare quality of life across various diseases or to the general population (Coons et al. 2000). With respect to physical symptoms, generic instruments tend to focus on issues of self-care and mobility – aspects that may be particularly important in joint disease or cancer, but would be expected of limited relevance in most gastrointestinal diseases. Even so, several of these instruments have been shown to work remarkably well in gastroenterology. Most often, the SF-36 and various modifications of this score have been used (Ware Jr. and Sherbourne 1992; Ware Jr. et al. 1996; Bernklev et al. 2005; Billingsley et al. 2007). Also, the 5-item EuroQol has been successfully validated in patients with various bowel and liver diseases (König et al. 2002; Spiegel et al. 2009). This instrument is particularly helpful in that it facilitates the calculation of health utilities (Stark et al. 2010).

Disease-specific quality of life instruments in gastroenterology are numerous. The Patient-Reported Outcome and Quality of Life Instruments Database (ProQolid, http://www.proqolid.org/) currently lists 30 different instruments for digestive diseases excluding cancer. A detailed overview on available instruments has been published a few years ago and is recommended for reference (Borgaonkar and Irvine 2000). The European Organization for Treatment of Cancer (EORTC) promotes a modular approach to assessing quality of life in clinical trials. The core instrument QLQ-C30 assesses quality of life in cancer patients in general and is available in 81 languages (Aaronson et al. 1993). Additional modules have been developed for specific cancer entities, including many gastrointestinal sites (Sprangers et al. 1993). These can be found at the official EORTC website (http://groups.eortc.be/qol/index.htm).

58.5.2.5 Adverse Events, Pharmacoepidemiology, and Health Economics

Some of the most frequent side effects of drugs relate to the digestive system: nausea and vomiting, diarrhea, and constipation. All of these may have grave consequences for the management of patients, in particular in the elderly and in patients with cancer. Here we would like to focus on two other problems: NSAID-induced gastrointestinal bleeding and the various forms of hepatotoxicity.

Following the introduction of successful treatment schemes for *H. pylori*-associated associated peptic ulcer disease, drug related gastric lesions are now the most frequent reason for ulcer bleeding. The risk is particularly high with aspirin, followed by conventional NSAID’s (Hawkey 2009). As often the elderly and the multimorbid are affected, mortality from gastrointestinal hemorrhage is substantial. The prevention of cardiovascular events by antiplatelet therapy on the one hand and the risk of gastrointestinal bleeding on the other hand need thoughtfully balanced consideration. The issue is further complicated by suspected interactions between antiplatelet (clopidogrel) and antiulcer treatment (proton pump inhibitors).

The short history of selective COX-2 inhibitors is an interesting example on how perspectives differ by clinical specialty. These drugs were expected to alleviate the substantial problem of severe gastrointestinal bleeding in patients depending on NSAID therapy. Most of these are patients with joint disease, often elderly. The drugs decreased ulcer bleeding but increased cardiac events.

Critics have noted the paradoxon that

> “COX-2 inhibitors and NSAIDs were found to increase risks of myocardial infarction and liver failure, while NSAIDs additionally caused hundreds of thousands of deaths from ulcer complications worldwide, (but) it were COX-2 inhibitors rather than NSAIDs that fell from favour” (Steinfeld and Bjorke 2002; Hawkey 2009).

As a side note, there are interesting methodological issues relating to these associations. For example, pharmacovigilance studies came to different conclusions as compared to randomized clinical trials with respect to the bleeding potential of selective COX-2 inhibitors due to insufficient control for confounding. This clinical problem has been used to illustrate the usefulness of propensity scores (Schneeweiss et al. 2006).

Drug-related liver toxicity is an interesting field in pharmacoepidemiology and a somewhat complex one. Different mechanisms apply: cell injury, cholestatic patterns or enzyme induction, and hypersensitivity. The clinical relevance may range from asymptomatic, transient liver enzyme elevation to acute life-threatening situations requiring urgent liver transplantation. Most cases are not reported, so the true incidence is unknown. In the USA, hepatotoxicity is the most frequent reason for the Food and Drug Administration to take regulatory action (Navarro and Senior 2006). A recent example is troglitazone used for glycemic control in patients with diabetes, which was withdrawn in 2000 because of an increased risk of acute liver failure.

With respect to costs of medication, proton pump inhibitors are high up the list. Indications include heartburn and GERD, peptic ulcer disease, gastritis, and ulcer protection with antiplatelet therapy. Many patients use this medication lifelong.

There are quite a few situations where cost-oriented decision analyses have the potential to guide treatment recommendations. Besides lifelong drug treatment of GERD as opposed to surgical interventions (fundoplicatio), these concern, for example, screening and treating of *H. pylori*-positive persons in the absence of symptoms or inflammation, the treatment of viral Hepatitis in subgroups of patients with low chances of virus elimination, and the introduction of vaccines. Most of these issues have not been resolved.

58.6 Conclusions

In this chapter, we have highlighted the burden of various digestive diseases and some of the most important risk factors. Some previously important disorders are currently on the decline, some for unknown reasons, some due to improved living conditions, and some due to successful public health interventions. The retreat of peptic ulcer disease is most likely to fall in the category of hygiene-related diseases; the infectious agent has been identified (*H. pylori*). For appendicitis, the etiology is still unclear, and remarkably little research has been published although this is such a common condition. Good examples for successful public health interventions include screening for colorectal cancer and vaccination to prevent Hepatitis B virus infection. Squamous esophageal cancer is also on the decline, due to the decreasing prevalence of smoking and alcohol abuse in Western populations.

For other diseases, the burden is still expected to increase. These are, for example, the long-term sequelae of chronic Hepatitis C infection, non-alcoholic fatty liver disease as a previously undescribed manifestation of the metabolic syndrome, adenocarcinoma of the esophagus and gastroesophageal junction, and, possibly, functional disorders as well as those conditions associated with old age – NSAID-induced gastrointestinal hemorrhage, diverticulitis, and constipation, to name just a few.

A large proportion of the presented problems are preventable. There are strong associations with modifiable risk factors. Specifically, these include alcohol and i.v. drug abuse in the economically advanced societies and infections for which vaccinations and simple sanitary measures are available (Hepatitis B, rotavirus) in the developing world.

Digestive disease epidemiology seems to be difficult to grasp as an entity, as the conditions are so diverse. Also, there are no epidemiological methods specific to gastroenterology. However, we hope that the gastroenterologists' perspective is helpful to bring some issues back into focus that may have run the risk of losing priority. Most urgently, this refers to acute diarrhea in low-income countries.

With the gut flora as the major part of the human microbiom increasingly acknowledged as potentially crucial in the pathogenesis of various disorders, both gastrointestinal as well as others, the digestive system may become more prominent in the study of health in the future. More input from methodologically advanced epidemiology would certainly be of help in many clinical decisions, such as surveillance of clinical populations at high risk for malignancy.

59.1 Introduction

59.1.1 History of Psychiatric Epidemiology

The history of epidemiological approaches to the study of mental illness spans over 150 years. A classic paper by Dohrenwend and Dohrenwend (1982) proposed the division of psychiatric epidemiological studies into three time periods: first generation, second generation, and third generation. First-generation studies were those conducted from the end of the nineteenth century through the first half of the twentieth century. These studies relied mainly on official records and key informants to identify persons with mental disorders and, accordingly, were limited by a lack of clear operational criteria for the classification and assessment of psychiatric conditions. Although the Dohrenwends were mainly discussing prevalence studies, the historical division into these three generations is used here to describe a broader range of studies.

The first study that attempted to quantify mental illness for public health purposes was conducted in Massachusetts in 1855 by Edward Jarvis (1971). Jarvis located cases with mental disorders through the use of key informants, for instance, general practitioners and hospital records. He identified 2,632 "lunatics" and 1,087 "idiots" and analyzed the data according to demographic variables such as sex, place of birth, and economic status. A more comprehensive study was done by Arthur Mitchell in Scotland later in the nineteenth century (Susser et al. 2010).

Later in this "first generation," a landmark series of studies were led by Goldberger and Sydenstricker in the 1920s. These studies demonstrated the association between nutritional deficiency and the presence of psychosis secondary to pellagra and, moreover, went on to describe how the ecology and social inequalities of mill towns in Southern states fostered this type of nutritional deficiency (Terris 1964). In a subsequent major study of this time period, Faris and Dunham examined the geographical distribution of psychiatric patient hospitalizations in Chicago from 1922 to 1934. They found that admissions for schizophrenia were related to the ecology of urban and suburban areas, typically with higher rates reported in urban areas (Faris 1939).

During this initial period, there was also growing interest in the role of social factors in the etiology of psychiatric disorders. This idea was first introduced in the foundational work of the French scientist Émile Durkheim. In the classic text *"Le Suicide,"* published in 1897, Durkheim sought to explore the social correlates of suicide (Durkheim 1951). He explored the roles of social isolation and control among different groups and concluded that the higher rates of suicide observed among Protestants compared to Catholics and Jews and among single persons as compared to married, resulted from social isolation and deficits in social control.

In regard to prevalence, in the Dohrenwends' review of first-generation studies, they found a median prevalence rate for any psychiatric disorder of around 3.6%. These low rates, as compared to future studies, are likely due to major changes in nomenclature following World War II that broadened the definition of mental disorders, resulting in higher prevalence rates (Dohrenwend and Dohrenwend 1982).

The second generation of psychiatric epidemiological studies occurred after World War II. The community became the focus of renewed attention for both the field of psychiatry and policy makers. Several factors occurred before, during and after the war that played a role in the development of a new complement of epidemiological studies. In World War II, the diagnosis of a psychiatric disorder was the leading cause of men being rejected from military service, and after the war, more than half of all hospital beds were occupied by patients with mental conditions (Tohen et al. 2000). The National Mental Health Act of 1946 initiated a cascade of funding for psychiatric education and research that resulted in the establishment of the National Institute of Mental Health (NIMH) in 1949 and financial support for epidemiological research in service of community psychiatry.

Major improvements occurred in the second-generation psychiatric epidemiological studies: mainly (1) that study participants were interviewed directly and (2) that well-defined, large populations were studied. However, these studies continued to be limited by some of the challenges of the first-generation studies, specifically, the lack of structured diagnostic instruments and an often unclear definition of diagnostic criteria (Tohen et al. 2000). Several well-known population-based studies were conducted during this period – most notably the Midtown Manhattan (Srole et al. 1962) and Stirling County (Leighton et al. 1963) studies. Both of these used highly trained non-professional interviewers to conduct standardized interviews with study participants. This second generation of studies also began to utilize more objective measures of psychopathology as opposed to clinical judgments. The measure most often used was a 22-item questionnaire called the Langner Index developed in connection with the Midtown Manhattan Study (Langner 1962). It is widely regarded as an index of psychophysiological symptomatology and general malaise (Seiler 1973). For purposes of epidemiological studies, the questionnaire is a non-specific measure of psychological distress (Dohrenwend and Dohrenwend 1982) and did not generate psychiatric diagnoses. The Midtown Manhattan Study, initiated in 1954, had three primary objectives: to canvass the community for variations in mental health, to examine sociocultural determinants of mental health, and to establish the need for psychiatric services in the community. The Midtown Manhattan Study examined mental health in 1,660 adults culled from 1,911 Midtown dwellings, selected as a probability sample. Investigators, comprising psychiatrists and social scientists, devised a composite classification of mental health, which they called the Global Judgment of Mental Health. By and large, the same approach and set of methods employed by the Midtown Manhattan Study were used in the non-urban context of Stirling County, Nova Scotia, conducted in 1952.

These two studies reflected the recognition that the local context influenced the occurrence, expression and distribution of psychopathology – a hallmark of early epidemiological studies informing community psychiatry. The results of the Midtown Manhattan Study estimated that over 80% of those surveyed had some form of current psychopathology. However, only a quarter (23.4%) were classified as impaired, signifying the presence of marked, severe, or incapacitating symptoms – mostly anxiety. Moreover, about three quarters of those who were impaired had never sought help for their symptoms (Srole et al. 1962). In Stirling County, lifetime prevalence of any DSM-I (first edition of Diagnostic and Statistical Manual: Mental Disorders) mental disorder was about 20% (Leighton et al. 1963).

Clinical studies were also conducted during this second generation of epidemiological research. Unlike population-based studies, which surveyed community participants, these studies investigated treated populations. For example, one classic clinical study (Hollingshead and Redlich 1958) investigated the association between social class and mental illness among patients in New Haven, Connecticut, and reported higher rates of psychopathology among patients of lower social class and differences in the type of treatment received by social class. A landmark clinical study by Tsuang and Dempsey (1979) used a historical cohort design to compare patients with a diagnosed mental disorder to a surgical control group on various outcomes including patients, marital, residential, occupational, and psychiatric status. They found that, after a 30- to 40-year follow-up, patients with psychiatric disorders had worse outcomes, specifically those with schizophrenia.

The first- and second-generation studies had an important impact on the field of psychiatric epidemiology. They showed that mental illness was a substantial public health problem, that treatment service availability was lacking, and that the prevalence of psychiatric disorders varied consistently by gender, socioeconomic status, and locale (urban vs. rural) (Dohrenwend 1997). However, these studies suffered from design limitations, most notably the lack of reliable and valid assessment tools to identify cases, which impeded the quest for data on the distribution of mental disorders and potential causal factors (Tohen et al. 2000).

The third generation of epidemiological studies was marked by the development of standardized measures of mental disorders. In the late 1980s the NIMH Diagnostic Interview Schedule (DIS), a lay-administered, standardized diagnostic interview, was developed for use in the Epidemiological Catchment Area (ECA) Study (discussed in more detail below). Subsequently, a similar instrument, the Composite International Diagnostic Interview (CIDI), was used in the National Comorbidity Study (NCS) (discussed in more detail below). The creation of structured diagnostic interview instruments allowed for the reliable estimation of the prevalence of mental disorders (Tohen et al. 2000). This was the single most important contribution of the third-generation studies and resulted in the two largest population-based studies on psychiatric disorders conducted in the USA, the ECA and NCS. (Similar developments outside of the United States are discussed below.) In addition to estimates of the current prevalence of mental disorders, these instruments also collected data on lifetime prevalence and risk factors. Short-term follow-up interviews of samples from the ECA have subsequently been conducted to provide estimates of incidence (Dohrenwend 1997). These studies also examined utilization of health services, confirming prior reports that the majority of persons with mental disorders do not receive adequate treatment. The development of more accurate diagnostic instruments and symptom scales in the third generation has also resulted in better research into the natural history of psychiatric disorders (Tohen et al. 2000). For instance, the Suffolk County Study (Bromet et al. 1992) provided new insights on the time of onset of schizophrenia. And the NIMH Collaborative Depression Study focused on recovery and relapse in major depressive disorder and bipolar disorder (Keller et al. 1992, 1993).

While the above focuses on epidemiological studies in North America, similar studies have been conducted in other regions of the world. Examples include those conducted in Taiwan (Hwu et al. 1989), Brazil (Almeida-Filho et al. 1997), and India (Mehta et al. 1985). In the 1960s, the International Pilot Study of Schizophrenia (IPSS), sponsored by the World Health Organization (WHO), set out to determine if it was feasible to engage in large-scale epidemiological research of psychiatric disorders, specifically schizophrenia, with comparable methods across different contexts, and to determine what, if any, differences existed in the incidence of schizophrenia across contexts (Sartorius et al. 1974). Indeed, the IPSS, which included 1,202 participants in its initial assessment, showed that this type of study was feasible. The IPSS also demonstrated that when schizophrenia was defined as a construct with extensively tested instruments, rates were fairly consistent across contexts and nations (Sartorius et al. 1974).

Later, the WHO sponsored the Determinants of Severe Mental Disorders (DOSMeD), also known as the Ten-Country Study, which built on the work of the IPSS to study the variation in incidence and course of severe mental illness, particularly schizophrenia, across countries and cultures. The DOSMeD included sites in Denmark, India, Colombia, Ireland, the USA, Nigeria, the USSR, Japan, the United Kingdom, and the Czech Republic. The study showed that the prevalence of schizophrenia was fairly constant across countries and that schizophrenia had a better course in developing versus developed countries over a period of 2 years (Jablensky et al. 1992), which gave rise to a long debate over potential factual and artifactual explanations for these findings (Hopper and Wanderling 2000).

With recent advances in neuroscience, brain imaging, genetics, and other related fields, it is fair to say that the field of psychiatric epidemiology has, in the past decade or so, entered a new fourth generation of discovery. This includes new study designs (including family, sibling, high-risk designs, and others), new statistical methods, new diagnostic assessment techniques, and an array of new approaches to assess exposures that may reflect potential causes and mechanisms resulting in mental disorder.

59.1.2 Overview of the Chapter

In this chapter, we summarize in considerable detail what we view as both some of the major achievements of the generation of epidemiological research recently completed (e.g., the third generation of community prevalence studies) and highlight some of the exciting new approaches currently under investigation with the present generation of research. We start with a general description of the major classes of psychiatric disorders, the major classification systems used to diagnose these conditions, and summary statements regarding the global burden of mental illness. We then summarize major work in the USA and abroad on the prevalence and distribution of major psychiatric disorders and highlight two particular conditions (autism and schizophrenia) to demonstrate some of the approaches and discoveries from the current era of psychiatric epidemiology.

59.2 Overview of Major Mental Disorders

While there has been considerable change and refinement in the taxonomy and nosology of mental disorders, there is general consensus on the major categories of conditions studied in psychiatric epidemiology.

Psychotic Disorders are among the most debilitating and persistent diseases in humans. These disorders include schizophrenia, schizoaffective disorder, psychotic depression, bipolar disorder with psychotic features, and delusional disorder. Schizophrenia is the most common of the psychotic disorders and is characterized by a breakdown of thought processes and by poor emotional responsiveness. It commonly manifests as auditory hallucinations, paranoid or bizarre delusions, disorganized speech and thinking, and is accompanied by significant social or occupational dysfunction.

Mood Disorders are characterized by a disturbance in the regulation of mood, behavior, and affect. Major mood disorders include depressive disorders and bipolar disorder. One of the more common mood disorders is major depression, defined as a persistent period of dysphoric mood or loss of interest or pleasure, along with other symptoms. Bipolar disorder (also known as manic depressive illness) is a cyclical mood disorder in which episodes of major depression are interspersed with episodes of mania or hypomania.

Anxiety Disorders are disorders characterized by abnormal and pathological fear and anxiety. Anxiety disorders include generalized anxiety disorder, phobic disorders, and panic disorder. Generalized anxiety disorder is characterized by unrealistic or excessive anxiety and worry. A phobia is defined as an irrational fear that produces a conscious avoidance of the feared subject, activity, or situation. And panic disorder is a type of anxiety disorder characterized by recurring, unexpected panic attacks.

Personality Disorders are defined as inflexible and maladaptive personality traits that cause either substantial functional impairment or subjective distress. They are conceptualized as long-term characteristics of individuals that are likely to be evident by adolescence and continue throughout adulthood.

59.2.1 Refinements in the Definition and Classification of Mental Disorders: Growth of the Diagnostic and Statistical Manual of Mental Disorders (DSM) and International Classification of Diseases (ICD)

The goal of psychiatric epidemiology is to systematically study the distribution and determinants of psychiatric disorders in the population. This goal can only be obtained if there is a classification system that allows for a standardized method of collecting data on psychiatric disorders. This goal was advanced when the World Health Organization (WHO) published the sixth edition of *International Classification of Diseases* (ICD) in 1949, which included mental disorders for the first time. The American Psychiatric Association Committee on Nomenclature and Statistics developed a variant of the ICD-6 that was published in 1952, the first edition of the *Diagnostic and Statistical Manual: Mental Disorders* (DSM-I). The purpose of DSM-I was to create a common nomenclature based on a consensus of the contemporary knowledge about psychiatric disorders. These developments came in the post-World War II era (or "second generation" of psychiatric epidemiology research) to better incorporate the outpatient presentations of servicemen and veterans. DSM-I included three categories of psychopathology and was the first official manual of mental disorders to focus on clinical utility. The manual was developed to be both useful to those who diagnose and treat patients with mental illness and to provide a statistical classification to facilitate the collection of statistics on mental disorders. DSM-II was published in 1968 and had 11 major diagnostic categories and 185 diagnoses. DSM-I and DSM-II included only brief definitions of disorders which were not sufficiently operationalized to allow for reliable diagnostic judgments.

DSM-III, published in 1980, improved on previous editions by applying a descriptive approach and including diagnostic criteria. It included 265 diagnoses. The explicit diagnostic criteria in DSM-III provided the foundation for measurement of mental disorders at the population level (Eaton 2012). The emphasis on descriptive features of disorders, generally without regard for presumed etiology, allowed DSM-III to be largely embraced across disciplines. DSM-IV was published in 1994 and included 365 diagnoses. A major revision from previous versions was the inclusion of a clinical significance criterion to many of the categories, which required that symptoms cause "clinically significant distress or impairment in social, occupational, or other important areas of functioning."

A major component of psychiatric epidemiology studies is accurate psychiatric diagnosis of a clearly defined study population. Determining the prevalence of mental illness in a population requires reliable well-operationalized definitions of the disorders. There are three aspects of the DSM that have proved most valuable in the field of psychiatric epidemiology. First is the widespread acceptance of the DSM across psychiatry and related fields. This has enabled a common language for classifying mental disorders allowing for comparisons of data across studies. Second is the use of symptomatic descriptions in the DSM rather than hypothesized etiological assumptions. And third is the provision of operationalized definitions.

The introduction of DSM-III in 1980 and the subsequent development of a fully structured diagnostic interview based on it, the Diagnostic Interview Schedule (Robins et al. 1981), were critical to major population-level epidemiological studies.

One of the main questions in psychiatric epidemiology is whether the prevalence of mental disorders has been increasing over time. We have seen a clear increase in the number of persons meeting criteria for mental disorders, but this does not prove that the prevalence is increasing, as this may be due to changes in diagnostic criteria. Specifically, the DSM has expanded and the number of disorders has increased over time, which may result in an increased number of persons meeting criteria for psychiatric disorders. Researchers have questioned whether the DSM criteria are too inclusive such that we are diagnosing people with mild severity, which may not have clinical utility. This is one of the reasons that DSM-IV requires the presence of clinically significant distress or impairment to qualify for a diagnosis. As we move into the current, fourth generation of psychiatric epidemiology, there are plans for dramatic modifications to prior classification systems – both dimensional approaches based on presumed neurocognitive substrates which may cut across current diagnoses, as well as new categorical diagnoses based more on empirical data than clinical consensus.

59.2.2 Public Health Burden of Mental Disorders

Research has shown that mental disorders have a high public health burden. A global study by the World Health Organization (WHO), the so-called World Mental Health (WMH) Survey, estimated the prevalence, severity, and treatment of DSM-IV mental disorders in 14 countries (Demyttenaere et al. 2004). The findings showed a consistently high overall prevalence of mental disorders across the globe. The Global Burden of Disease (GBD) Study (Murray and Lopez 1996) found that mental disorders were responsible for 21% of the total disease burden in the world. Mental disorders ranked almost as high as cardiovascular diseases and respiratory diseases, and surpassed all different types of cancer and HIV, in Disability Adjusted Life Years (DALYs) (Ustun 1999). Specifically, depression was the fourth leading cause of disease burden, accounting for 4.4% of total DALYs (Ustun et al. 2004). Depression was reported to cause the largest amount of non-fatal burden, accounting for almost 12% of all total years lived with disability worldwide. Furthermore, WHO has projected that depression will be the second leading cause of disability by the year 2020. The DALYs are particularly high for mental disorders in part because these are non-fatal conditions of long duration, most of which have their onsets in childhood or young adulthood (Eaton 2012).

The European Study of the Epidemiology of Mental Disorders (ESEMeD) examined the impact of mental and physical disorders on work role disability and quality of life in six European countries (Alonso et al. 2004). The study showed that in each country, mental disorders resulted in loss of work and loss of quality of life.

The results suggested that mental disorders are important determinants of work role disability and quality of life, often having a greater impact than chronic physical disorders.

Studies have also shown the high cost of mental illness to individuals and society. Kessler and colleagues (2008) found that respondents with a serious mental illness in the past 12 months had earnings averaging $16,306 less than those without a mental illness, for a societal-level total of $193.2 billion. The authors used statistical modeling to show that the mean expected annual earnings of respondents with a serious mental illness in the absence of that illness were estimated at $38,851 compared to the mean observed earnings of $22,545. This difference, of approximately $16,000 (or 42%), is the estimated mean impact of serious mental illness on earnings. This study provides evidence that mental disorders are associated with substantial societal-level impairments that should be taken into consideration when making decisions about the allocation of treatment and research resources.

59.3 Summary of Findings from Major Population-Based Studies of Mental Illness

59.3.1 Major Epidemiological Studies of Psychiatric Disorder Among Adults

A number of major psychiatric epidemiological studies from the late twentieth century have helped establish methods for contemporary psychiatric epidemiology. Two classic studies in the USA include the Epidemiological Catchment Area (ECA) study and the National Comorbidity Survey (NCS). The ECA and NCS, discussed in more detail below, used reliable lay-administered structured diagnostic assessments to obtain standardized diagnostic criteria based on the DSM. The studies also compared clinical interviews with lay interviews to evaluate diagnostic validity and used advanced sampling strategies to identify nationally representative samples.

The Epidemiological Catchment Area (ECA) Study was initiated in response to the 1977 Report of the President's Commission on Mental Health, which described the state of American mental health research and services (Grob 2005). NIMH needed to provide descriptive psychiatric epidemiological data to the President's Commission, since the clinical picture of community mental health was incomplete (Regier et al 1978; Robins 1978). The ECA, therefore, sought to address the gaps identified in the President's commission report (Robins and Regier 1991).

The ECA, which commenced in 1980, was a collaborative effort between NIMH and a group of established psychiatric epidemiologists that surveyed the prevalence of mental disorders and service need and use in five US communities that had been designated Community Mental Health Center catchment areas – Baltimore, New Haven, St. Louis, Durham, and Los Angeles. Each site collected data on a common set of core questions and sample characteristics and sampled over 3,000 community residents and 500 institutionalized residents. Together, the 5-site ECA collected diagnostic service need and use data on 20,861 adults, aged 18 and over. An important innovation of the ECA was the use of a fully structured research diagnostic interview known as the Diagnostic Interview Schedule (DIS), which was shown to yield reliable and valid diagnoses of mental disorders (Helzer et al. 1985).

The ECA was the first study to document the prevalence of DSM-III disorders. While the ECA determined the epidemiological burden and service use patterns in these five communities, it also provided the indices of success of community-based treatment programs for mental illness. The ECA was critical in determining the prevalence of specific psychiatric disorders, as well as service needs and use patterns in the five communities studied. The rich information provided by the study once again supported the notion that services were inadequate relative to need; under 20% of respondents with recent mental disorders accessed services in the year prior to study participation (Robins and Regier 1991; Regier et al. 1993a). However, because the samples in the ECA were not collected to be nationally representative, there was an imperative to address epidemiological gaps regarding the prevalence and distribution of psychiatric disorders throughout the United States. Moreover, the ECA could only provide basic information regarding the comorbidity of psychiatric disorders; it was therefore necessary to determine patterns of comorbidity and the complexities of the affiliated need for services and their use.

Some of the limitations of the ECA influenced considerably the origins of the *National Comorbidity Survey (NCS)*, a truly national study of the prevalence, causes, and consequences of comorbidity between psychiatric and substance use disorders (Kessler 1994). The NCS, which began in 1990, was the first nationally representative survey of mental and substance use disorders in the United States. This study developed a new measure, the Composite International Diagnostic Interview (CIDI), to determine the prevalence and correlates of DSM-III-R (Diagnostic and Statistical Manual of Mental Disorders, third and revised edition) disorders in a nationally representative sample of 8,098 individuals, aged 18–54. The NCS was a face-to-face household survey.

The NCS found that DSM-III-R disorders are more prevalent than previously thought. The prevalence estimates of lay-administered CIDI-diagnosed psychiatric disorders were higher than those reported by the ECA, with the exception of psychotic disorders and lifetime anxiety disorders. Like the ECA, the NCS reported underuse of mental health services – about 13% of respondents accessed outpatient services in the prior 12 months. One of the most striking findings of the NCS indicated a problem with "met unneed" – that is, people with low levels of need had a higher probability of accessing treatment (Kessler et al. 1997; Mojtabai et al. 2002), with implications for policies affecting the distribution of community-based mental health services.

Similar prevalences of DSM-IV disorders and service use patterns were observed in the *NCS Replication Study (NCS-R)*, conducted about a decade later in 2001–2002 with a nationally representative sample of 9,282 respondents, aged 18–54 (Kessler et al. 2005a, b). Harkening to the results of the Midtown Manhattan Study, 26.2% of respondents reported a past-year psychiatric disorder; nearly a quarter of those with a past-year psychiatric disorder were classified as serious (Kessler et al. 2005b).

Significant unmet need for services was observed in the NCS-R; nearly 60% of those endorsing a serious past-year psychiatric disorder remained untreated (Kessler et al. 2001).

Among other large-scale epidemiological efforts, *The National Epidemiological Survey on Alcohol and Related Conditions (NESARC)* was a nationally representative United States sample of 43,093 adults aged 18 or older conducted in 2001–2002 by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) (Grant et al. 2004). This face-to-face household survey demonstrated a high degree of comorbidity between DSM-IV substance use disorders and mood and anxiety disorders.

The National Longitudinal Alcohol Epidemiological Survey (NLAES) was a nationally representative household study conducted in the United States in 1992 sponsored by NIAAA (Grant and Harford 1995). The survey consisted of face-to-face interviews with 42,862 respondents aged 18 or older. DSM-IV diagnoses were made using the Alcohol Use Disorders and Associated Disabilities Interview Schedule (AUDADIS), a fully structured psychiatric interview administered by lay interviewers. The AUDADIS was designed to determine diagnoses of alcohol abuse and dependence over the course of the previous year or over a person's lifetime, other drug use and associated disorders, and the incidence of major depression.

The Christchurch Psychiatric Epidemiology Study (Oakley-Browne et al. 1989) was conducted in 1986 as a random survey of 1,498 adults aged 18–64 years living in the Christchurch area of New Zealand. The Diagnostic Interview Schedule (DIS) was used to make DSM-III diagnoses through in-person interviews. The study used similar methods as the NIMH ECA study to allow for comparisons.

A well-known prospective, longitudinal study is the *Dunedin Multidisciplinary Health and Development Study* which has followed 1,037 babies born in Dunedin, New Zealand, between 1972 and 1973 from birth until age 38 (Silva 1990). The study has very high retention rates (96%) and has collected a wealth of information on physical and mental health across the life span, including estimates of the prevalence and incidence of psychiatric disorders from childhood through adulthood (Newman et al. 1996).

These epidemiological studies provided valuable information on the occurrence of mental disorders. All of the studies revealed that psychiatric disorders are highly prevalent in the general population, with onset often beginning in early life and with subsequent high rates of comorbidity (Insel and Fenton 2005). There is also evidence that prevalence rates may be considerably higher than reported in many prior studies. Specifically, lifetime prevalence rates have been shown to be much greater in prospective versus retrospective studies, suggesting that asking participants to recall if they have ever experienced mental disorder symptoms leads to an under-reporting (Moffitt et al. 2010). Given that most of the information about lifetime prevalence of psychiatric disorders comes from retrospective surveys, mental disorders may be far more common than previously thought (Susser and Shrout 2010).

Importantly, the high prevalence of mental disorders found in these studies led to questions about the severity of the conditions diagnosed. More recent studies have attempted to address this concern by examining the severity of diagnosed conditions.

Table 59.1 Prevalence estimates from major psychiatric epidemiology surveys in adult populations

	Study							
	ECA	NCS	NCS-R	Christchurch	NESARC	NLAES	Dunedin	World Mental Health Surveys

Abbreviations: ECA, Epidemiological Catchment Area Study; NCS, National Comorbidity Survey; NCS-R, National Comorbidity Replication Survey; Christchurch, Christchurch Psychiatric Epidemiology Study; NESARC, National Epidemiological Survey on Alcohol and Related Conditions; NLAES, National Longitudinal Alcohol Epidemiological Survey; Dunedin, Dunedin Multidisciplinary Health and Development Study.

Notes: NLAES mood disorder includes major depression only; Dunedin mood disorder includes depression only. ECA and Christchurch psychotic disorders refer to schizophrenia/schizophreniform disorders only.

The values presented for the World Mental Health Surveys represent the range of prevalence estimates across the 14 countries studied.

For example, findings from the NCS-R showed that 22.3% of individuals with a disorder in the past 12 months were reported to be “serious,” 37.3% were reported to be “moderate,” and 40.4% mild (Kessler et al. 2005b). These results suggest that over half of diagnosed cases of mental illness are moderate or severe, but a substantial portion are mild.

59.3.2 Prevalence and Incidence of Major Adult Psychiatric Disorders

The major epidemiological studies discussed above have provided a wealth of information on the prevalence and incidence of psychiatric disorders in the general adult population. While recent developments in the field have moved far ahead in insights regarding risk factors, causes, and mechanisms related to the etiology of these disorders, it is valuable to summarize some of these foundational elements of the field of psychiatric epidemiology. Table 59.1 provides a summary of the prevalence estimates described below – some of the major products of the "third generation" of psychiatric epidemiology research.

Any Disorder The prevalence of any psychiatric disorder provides information on the overall burden of mental disease in the population. Prevalence estimates have been consistently high across studies. The ECA reported a 12-month prevalence of 28.1%. The NCS and NCS-R reported similar 12-month estimates at 29.5% and 26.2%, respectively. The Christchurch study reported somewhat higher rates with 31.3% of the respondents having any disorder in the past 12 months. Lifetime prevalence of any disorder is also high, with approximately half of the respondents reporting a lifetime disorder (48% in the NCS, 46.4% in the NCS-R, and 50.7% in the Christchurch study). The NCS-R also found that psychiatric disorders generally had an early onset with half of all cases reporting onset by age 14 and three quarters by age 24.

Anxiety Disorders Anxiety disorders are the most common group of disorders to occur in the general population. The ECA, NCS, and NCS-R all showed anxiety disorders to be more prevalent than mood disorders. The ECA found that 11.8% of the respondents had an anxiety disorder diagnosis in the past 12 months. Estimates in the NCS and NCS-R were similar with 12-month rates of 17.2% and 18.1%, respectively. The Christchurch study reported somewhat lower estimates of 9.1% for past 12-month diagnoses, and the NESARC found that 11.1% of the respondents had an anxiety disorder in the past 12 months. The lifetime prevalence of anxiety disorders is around one quarter. The ECA found that lifetime diagnoses of anxiety disorders occurred in 19.2% of the respondents, the NCS found a lifetime rate of 24.9%, and the NCS-R 28.8%. The Christchurch study reported a lower estimated rate of 10.5%.

Phobias have been found to be the most common anxiety disorder. The NCS-R reported that 8.7% of the respondents reported a phobia in the past 12 months with social phobia being the most common type. The NCS-R also reported on the prevalence of panic attacks, a subtype of anxiety disorder, with a lifetime prevalence of 28.3% and 12-month prevalence of 11.2% (Kessler et al. 2006). This rate is somewhat higher than that of the NCS (7.3%).

Mood Disorders Mood disorders are the second most prevalent class of disorders. The ECA found that 10.1% of the respondents had a mood disorder diagnosis in the past 12 months. Estimates in the NCS, NCS-R, and Christchurch study were comparable at 11.3%, 9.5%, and 10.4%, respectively. The NESARC found that 9.2% of the respondents had a mood disorder in the past 12 months, while the NLAES found a considerably lower prevalence of 3.3% (which is likely due to the fact that they only measured major depression).

The ECA found that lifetime diagnoses of mood disorders occurred in 14.9% of the respondents, while estimates in the NCS and NCS-R were higher at 19.3% and 20.8%, respectively. The Christchurch study found a prevalence of 14.7% for lifetime diagnosis, and the NLAES reported that 9.9% of the respondents had a lifetime diagnosis.

Psychotic Disorders Psychotic disorders are less common than mood and anxiety disorders and are less often studied in epidemiological surveys of the general population. The ECA found a lifetime prevalence of psychotic disorders of 1.4%, while the NCS reported lower estimates at 0.7% lifetime and 0.5% in the past 12 months. The Christchurch estimates were even lower at 0.2% lifetime and 0.4% past 12 months (which is likely explained by the fact that only schizophrenia/schizophreniform disorders were diagnosed).

Comorbidity of Psychiatric Disorders The ECA was among the first studies to show how common psychiatric comorbidity of psychiatric disorders is in the general population. Over 54% of the ECA respondents with a lifetime history of a disorder were found to have a second diagnosis. Similarly the NCS found that over 50% of all lifetime disorders occurred in a small proportion of the respondents with a history of three or more comorbid psychiatric disorders (Kessler et al. 1994). And the NCS-R also found high rates of psychiatric comorbidity; nearly 30% of the people surveyed had two disorders, and almost 20% had three (Kessler et al. 2005a, b).

Sociodemographic Risk Factors for Adult Psychiatric Disorders Studies have consistently shown that women have higher rates of mood and anxiety disorders, while men have higher rates of substance use disorders (Wells et al. 1989; Kessler et al. 1994). The prevalence of most disorders has been shown to decline with age and higher socioeconomic status (Regier et al. 1993b; Kessler et al. 1994). A family history of mental illness consistently elevates the risk for psychiatric disorder (Kendler et al. 1997).

Prior studies have also shown that persons who are separated or divorced are more likely to have a psychiatric disorder than those who are married (Regier et al. 1993b; Bjorkenstam et al. 2012). For instance, the National Survey of Mental Health and Wellbeing of Adults, a random sample of adults in Australia, found that married people were the least likely to suffer from a mental disorder, while divorced and separated adults were the most prone to mood and anxiety disorders and never-married adults were the most at risk for drug and alcohol disorders (Andrews et al. 1999). The nature of this association is complicated and may vary by sex and type of mental disorder (Fox 1980). It remains unclear whether the protective effect of marriage is due to the social role of being married (social causation) or characteristics of the individuals who get married (social selection). Persons with mental disorders may be less likely to marry and more likely to divorce; and separation and divorce or the death of a spouse may adversely affect a person's mental health. A study by Bjorkenstam et al. (2012) supported both the selection hypothesis, linking healthy individuals to long and stable marriages, and the social causation hypothesis, linking the stress of recent divorce to increased psychiatric disorder for both women and men. In a study of women, Afifi et al. (2006) found that never-married mothers from the NCS were similar to married mothers in lifetime prevalence rates of mental disorders. However, separated/divorced mothers had increased odds of various disorders such as depression and anxiety, as compared to married mothers.

59.3.3 Major Epidemiological Studies of Children and Adolescents

There has also been substantial epidemiological research on the occurrence of mental disorders among children and adolescents. The global burden of mental illness in young people is significant; the WHO predicts that by 2020, childhood neuropsychiatric disorders will become one of the leading causes of morbidity, mortality, and disability among children worldwide (USDHHS 1999). This age group is also important in light of the findings that many psychiatric disorders have their onset in early life (Kessler et al. 2007). Most major epidemiological studies, such as the National Comorbidity Survey Replication (NCS-R), indicate that many individuals with mental illness report onset of their disorders in adolescence or early adulthood. Mental disorders, particularly if left untreated, are likely to persist into adulthood. According to the 2001 Surgeon General's Conference on Children's Mental Health, approximately 74% of 21-year olds with mental disorders had prior mental health problems. Furthermore, researchers are interested in examining early risk and protective factors for psychiatric disorders in the hopes that early intervention can reduce the burden of disease in children, adolescents, and adults. Considerable scientific ground has been covered regarding the epidemiological study of child and adolescent psychopathology in the past 30 years. Most notably, much more is now known about the measurement, community study, prevalence, and risk factors for psychiatric disorders, particularly those of older children and adolescents. Epidemiological data suggests that roughly 20% of children aged 1–18 years are in need of mental health services (Burns et al. 1995; Shaffer et al. 1996).

A number of important epidemiological studies have been conducted in child and adolescent populations. One of the first major studies was the *Isle of Wight/Inner London Borough Study* (Rutter et al. 1975). The study reported on the prevalence of psychiatric disorders, measured by parent interviews, in a sample of 10-year-old children from inner city London ($n = 1{,}689$) and the Isle of Wight ($n = 1,279$). *The Ontario Children's Study* (Offord et al. 1987) studied the 6-month prevalence of four child psychiatric disorders (conduct disorder, hyperactivity, emotional disorder, and somatization) among approximately 2,670 children 4–16 years of age residing in Ontario, Canada.

The Great Smoky Mountains Study (GSMS) was a population-based study of 1,420 children aged 9–13 years in North Carolina that began in 1992 (Costello et al. 2003). The study was a longitudinal design in which three cohorts of children were examined at age 9, 11, and 13 years at intake. The children were assessed annually through age 16 years for DSM-IV disorders using the Child and Adolescent Psychiatric Assessment (CAPA), an in-person diagnostic interview. Both parents and children were interviewed, leading to one of the major methodological challenges in the field of child psychiatric epidemiology – namely, how to treat the large number of families in which child and parent diagnostic reports are inconsistent. *The Puerto Rico Community Study* examined DSM-IV disorder in 1,886 children aged 4–17 years using the Diagnostic Interview Schedule for Children (DISC) (Canino et al. 2004).

The National Comorbidity Survey Adolescent Supplement (NCS-A) (Merikangas et al. 2009b) was a nationally representative face-to-face survey of 10,148 adolescents aged 13–18 years in the United States conducted from 2001 to 2004. The purpose of the survey was to provide the first nationally representative estimates of the prevalence, correlates, and risk and protective factors of mental disorders in US adolescents. DSM-IV diagnoses were made based on a modified version of the Composite International Diagnostic Interview (CIDI), a fully structured research diagnostic in-person interview designed for use by trained lay interviewers. In addition to in-person interviews with adolescents, there was also a parent self-report questionnaire.

59.3.4 Prevalence and Incidence of Major Child and Adolescent Psychiatric Disorders

As discussed previously, psychiatric disorders among children and adolescents are widespread. Previous summaries of the prevalence of mental disorders in population surveys of US youth conclude that about one out of every four youth meet criteria for a DSM disorder (Costello et al. 2004). A review by Merikangas et al. (2009a) found that about one third of youth experience a mental disorder in their lifetime; and fewer than half with a current disorder receive mental health treatment (Merikangas et al. 2009a). Angold and Costello (1995) summarized findings from previous studies and found that the 6-month prevalence rate for any psychiatric disorder ranged from 17% to 27%. The most common forms of psychopathology were anxiety disorders, behavior disorders, and mood disorders, in that order.

In a review of 52 studies of psychopathology in children and adolescents, Roberts et al. (1998) found that prevalence estimates of psychopathology ranged from 1% to nearly 51%, with a mean prevalence of any mental disorder of 15.8%. In a similar review by Costello et al. (2005), the median prevalence estimate of psychiatric disorders was 12%. Importantly, the authors noted that disorders that often appear first in childhood or adolescence are among those ranked highest in the World Health Organization's estimates of the global burden of disease.

The Ontario Children's Study found that among children 4–16 years of age, the 6-month prevalence rate of any disorder was 18.1%. The Quebec Child Mental Health Survey (QCMHS) was conducted in 1992 on a representative sample of 2,400 children and adolescents aged 6–14 years in Quebec (Breton et al. 1999). The 6-month prevalence of any disorder was 19.9% according to parent report and 15.8% according child report. The rates of one or more anxiety disorders ranged from 58% to 17.5%, while rates of depressive disorders ranged from 1.1% to 3.5%.

The GSMS found a 3-month prevalence of any disorder of 13.3%; but by age 16 years, 36.7% (lifetime prevalence) of children had met DSM-IV criteria for one or more disorders. The authors concluded that while the proportion of children with a diagnosis at a given time was small, almost three times this number had one or more disorders over the entire study period suggesting that cross-sectional studies may underestimate the prevalence of psychiatric disorders among children.

Furthermore, 25.5% of children with a mental disorder diagnosis had two or more conditions. There was significant comorbidity among the behavioral disorders and between anxiety and depression. In particular, there was a strong association between oppositional defiant disorder and depression, and depression and anxiety.

The Puerto Rico Community Study found that 16.4% of children aged 4–17 years had a DSM-IV diagnosis in the past year. The most prevalent disorder was attention deficit/hyperactivity disorder (ADHD) occurring in 8% of children. They also found that 6.9% of children had an anxiety disorder and 3.4% of children had a depressive disorder.

The NCS-A showed high rates of mental disorders among adolescents; 40% of adolescents had a DSM-IV disorder in the past year (Kessler et al. 2012) and approximately one in every 4–5 youth met criteria for a mental disorder with severe impairment across their lifetime (Merikangas et al. 2010). Anxiety disorders were found to be the most prevalent mental disorder (24.9% 12-month prevalence and 31.9% lifetime prevalence), followed by behavior disorders (16.3% 12-month prevalence and 19% lifetime prevalence) and mood disorders (10% 12-month prevalence and 14.3% lifetime prevalence). Comorbidity was common with approximately 40% of those with one class of disorder also meeting criteria for another disorder. The median age of onset was earliest for anxiety disorders (6 years), followed by 11 years for behavior disorders, and 13 years for mood disorders.

Table 59.2 provides a summary of the prevalence estimates described above.

Risk Factors for Child and Adolescent Psychiatric Disorders A number of risk factors for child and adolescent psychiatric disorders have been identified. Findings from twin and adoption studies have firmly established the contribution of genetics to the occurrence of disorders in children. However, the mechanism of inheritance is complex (State and Dykens 2000) and the heritability estimate of each childhood psychiatric disorder is typically considerably less than 100%. Psychopathology in parents has also consistently been shown to be associated with mental disorders in offspring (Angold and Costello 1995).

Variation in rates of mental disorders by sex has been observed in child and adolescent populations. Most studies have found that behavior disorders are more common in boys and depressive and anxiety disorders are more common in girls (Offord et al. 1987; Costello et al. 2003; Canino et al. 2004; Merikangas et al. 2010; Kessler et al. 2012). The GSMS found that overall psychiatric disorders were more prevalent in boys aged 9–16 years than in girls as a result of the much higher rate of conduct disorder and attention deficit-hyperactivity disorder (ADHD) in boys.

Sex differences in developmental trajectories for mental disorders have also been observed. For example, the Ontario Children's Study found that rates of emotional disorders in boys and girls were similar in the 4- to 11-year-old age group at around 10%. However, by ages 12–16 the rate had dropped to 4.9% in males but increased to 13.6% in females. With regard to depression, among preadolescents, studies have shown either no sex differences in rates of depression or even higher rates in preadolescent boys (Merikangas and Avenevoli 2002). During adolescence,

In the QCHMS, 'child' refers to diagnosis based on child report and 'parent' refers to diagnosis based on parent report.

however, rates of depression are higher among girls than boys (Cohen et al. 1993; Kessler and Walters 1998).

Overall psychiatric disorders have been shown to become more prevalent as children age. The NCS-A found that the lifetime prevalence was 8.4% in those 13–14 years versus 15.4% in those 17–18 years. However, there is variation in age-related rates by specific disorder. For example, prevalence rates of depressive disorders and anxiety disorders have been shown to increase with age, while prevalence rates of ADHD decrease with age (Breton et al. 1999; Canino et al. 2004).

Higher prevalence rates of child mental disorders have been found in urban versus rural areas (Offord et al. 1987; Costello et al. 1996; Canino et al. 2004). This was shown in the Isle of Wight/Inner London Borough Study in which the prevalence of any psychiatric disorder was higher in the London borough (25.4%), an urban area, than the Isle of Wight (12%), a rural area. Other risk factors for psychiatric disorders include lower socioeconomic status (SES) (Rutter et al. 1975; Costello et al. 1996; Merikangas et al. 2010), having unmarried parents (Canino et al. 2004; Merikangas et al. 2010), and a variety of exposures and complications during the prenatal period (Buka et al. 1993).

59.4 The Fourth Generation of Psychiatric Epidemiology: Examples of Specific Disorders

The material described thus far summarizes some of the major accomplishments of what we characterize as the “third generation” of psychiatric epidemiology research – largely conducted between 1980 and 2000. These large-scale community studies have solidified epidemiological knowledge of the prevalence, incidence, risks, and course of major disorders of children, youth, and adults. Since the turn of the century, there has been rapid expansion in the number and variety of epidemiological investigations pursued worldwide. With recent advances in neuroscience, brain imaging, genetics, and other related fields, the field of psychiatric epidemiology has entered a new fourth generation of research. This includes more extensive and sophisticated use of certain study designs (including family, sibling, high-risk designs, nested case-control studies, and others), new statistical methods, new diagnostic assessment techniques, and an array of new approaches to assess exposures that may reflect potential causes and mechanisms resulting in mental disorder. While space does not permit us to describe the full array of exciting work conducted over the past 10–20 years, we highlight two specific disorders to give some sense of these recent developments. We highlight two of the more severe and persistent mental disorders – autism and schizophrenia.

59.4.1 Autism Spectrum Disorders

Autism spectrum disorders (ASD) are a heterogeneous group of neurodevelopmental disorders characterized by deficits in social interaction and communication and the presence of restricted and repetitive behavior (Diagnostic and Statistical Manual of Mental Disorders, fourth edition, text revision). These core characteristics are frequently accompanied by impairments in cognition, learning, attention, and sensory processing. ASDs include three main conditions classified as pervasive developmental disorders in the DSM: autistic disorder, Asperger syndrome, and pervasive developmental disorder not otherwise specified (PDD-NOS). ASDs are typically diagnosed in early childhood and remain lifelong conditions. Symptoms are usually present before 3 years of age, but most individuals are now diagnosed between 3 and 4 years of age, with boys being diagnosed, on average, earlier than girls (Chakrabarti and Fombonne 2001; Yeargin-Allsopp et al. 2003).

Autism was first described in the US and European medical literature in the 1940s. Through the 1980s, it was believed to be rare, with an estimated prevalence of 5 per 10,000 persons. The estimated prevalence has increased dramatically over the past 30 years, and at the present ASDs are estimated to occur in 110 in 10,000 children in the United States (Kogan et al. 2009; Principal Investigators 2012). Prevalence estimates in Europe are similar to the USA (Baron-Cohen et al. 2009), while prevalence rates in other parts of the world are somewhat lower. For example, a study conducted in Japan found a prevalence of 27.2 per 10,000 individuals (Honda et al. 2005).

A steady increase in ASD prevalence has been consistently shown in the USA and globally. In the USA, the prevalence of ASD in 8-year-old children increased by 78% between 2002 and 2008, with larger increases seen in children of borderline and average or above-average intellectual functioning (Principal Investigators 2012). A study of time trends in ASD diagnoses among children aged 36 months and younger in Massachusetts found that ASD incidence increased from 56 per 10,000 among the 2001 birth cohort to 93 per 10,000 in 2005 (Manning et al. 2011).

A little less than half of the considerable increase in the prevalence of ASD is best explained by broadening diagnostic criteria and increased awareness. Significant changes occurred in the diagnostic criteria from the DSM-III to DSM-IV, during which time increases in prevalence were observed (King and Bearman 2009). Furthermore, studies have shown that diagnostic substitution, which occurs when children with another diagnosis have their diagnosis changed to ASD, also explains some of the rise in ASD prevalence. One study found that 26.4% of the increased autism caseload in California was associated with diagnostic change (specifically, children previously diagnosed with only intellectual disability) (King and Bearman 2009). A large part of the increase remains unexplained, however, by any of these factors. Therefore, we must leave open the possibility that there has actually been an increase in prevalence due to a true increase in incidence.

There has been a particularly large increase in children meeting criteria for ASD who do not have cognitive delay. The inclusion of Asperger disorder in DSM-IV is likely to have contributed to the increased prevalence of ASDs by encouraging identification of high-functioning children with social problems but no language delay (McPartland et al. 2012). Furthermore, DSM-III applied a monothetic approach (i.e., an individual must meet all diagnostic criteria), while DSM-III-R used a set of polythetic criteria (i.e., individuals must meet only a subset of a range of criteria), which also broadened the diagnostic concept. A recent study revisited a sample of children diagnosed with ASD by DSM-III-R to determine how many would meet criteria under DSM-IV (Miller et al. 2013). The results showed that 91% of participants met both criteria and a large number of participants who did not meet criteria under DSM-III (59%) did meet DSM-IV-TR criteria. Similar retrospective studies that have applied current ASD diagnostic criteria to samples diagnosed in the past show that prior studies may have underestimated prevalence

(Heussler et al. 2001; Charman et al. 2009). Finally, recommendations from the American Academy Pediatrics to screen all children for ASD, and increased public awareness, have helped to improve diagnosis and treatment and may explain increases in prevalence (Duchan and Patel 2012).

Innovative epidemiological methods have been used in the field of autism epidemiology in recent years to better understand the distribution and determinants of ASD. Researchers have used new study designs and methods to obtain more accurate prevalence estimates and to attempt to explain increases in prevalence over time. Various epidemiological studies have been conducted to examine time trends in the prevalence of ASD. To study trends, repeated surveys in defined geographical areas at different points in time can be used, provided that methods are kept relatively constant (Fombonne 2009). These studies have generally shown increases in prevalence over time (Gillberg 1984; Kawamura et al. 2008). Also, age-period-cohort analyses of time trends in California have established that the increased prevalence of ASD in that state is primarily a birth cohort effect, which limits the possible explanations to some degree (Keyes et al. 2012).

Many studies have relied on public records (medical and educational) to obtain prevalence estimates in large population-based samples (Croen et al. 2002; Principal Investigators 2012). The most prominent ongoing population-based surveillance program is the Autism and Developmental Disabilities Monitoring (ADDM) Network conducted in the United States by the Centers for Disease Control (CDC) (Principal Investigators 2012). The ADDM uses a standardized protocol across various study sites in the USA to examine medical and educational records of 8-year-old children to diagnose ASD. The ADDM studies have been valuable in providing data on the prevalence of ASDs, describing the population of children with ASD, and identifying changes in prevalence over time.

Recent studies have challenged the diagnostic criteria for ASD outlined in the DSM. For example, Lord and colleagues (2012) found that clinical distinctions among categorical diagnostic subtypes of ASD (autistic disorder, Asperger disorder, and pervasive developmental disorder not otherwise specified) were not reliable across multiple study sites and concluded that dimensional descriptions of core features, along with language and cognitive function, would be more useful. Studies like this one provide support for the diagnostic changes proposed for DSM-V, which will eliminate subgroups in favor of one overall diagnosis – autism spectrum disorder.

A consistently shown risk factor for ASD is male sex. Studies show that the odds of having ASD are approximately four times greater for boys than girls (Kogan et al. 2009). However, when females are affected, they generally have lower functioning (Rivet and Matson 2011). Comorbid conditions are common in individuals with ASD. Kogan et al. (2009) found that 87.3% of children with ASD also had attention deficit disorder or attention deficit/hyperactivity disorder (ADHD), anxiety problems, behavioral or conduct problems, depression, or developmental delay. Among these conditions, the most common was ADHD, with an estimated prevalence of 47.2 per 100 among individuals with ASD. Psychiatric disorders in family members are also more frequent in individuals with ASD (Duchan and Patel 2012). Recent studies have shown that schizophrenia coaggregates with ASD in many families (Sullivan et al. 2012).

Another common condition associated with ASD is intellectual disability (ID), defined as IQ at or below 70. Current estimates are that around 40% of children with ASDs have ID (Principal Investigators 2012). Epilepsy is also known to be comorbid with ASD and occurs in approximately 14% to 16% of individuals with ASD (Tuchman et al. 1991; Levy et al. 2010), a greater proportion of whom also have ID. Longitudinal studies that follow persons with ASD into adulthood have reported higher epilepsy rates (Danielsson et al. 2005). Genetic and medical problems are also common; one study found that 15% of individuals with pervasive developmental disorder had a known genetic disorder (Chudley et al. 1998).

Outcomes in persons with ASD vary greatly depending on the type of ASD, severity of symptoms, and presence of comorbid conditions. Individuals with ASD have higher mortality rates as compared to the general population (Gillberg et al. 2010), in particular persons with ASD and epilepsy (Pickett et al. 2011). While ASD can improve through treatment, in particular through behavioral therapies implemented in early childhood (Smith et al. 2000; Dawson et al. 2010), for most individuals the condition remains a significant lifelong impairment. Much of the epidemiological research on autism has focused on children. Very little is known about adults with ASD. However, it is critical to know more about this population because, at present, many adults with ASD were misdiagnosed or undiagnosed as children and there is a large number of children with autism who will soon become adults (Bresnahan et al. 2009). Furthermore, addressing the needs of adults with autism is a major public health concern. As the number of adults with ASD increases, there is a growing need for expanded services and an improved understanding of the types of services and treatment needed for adults. Epidemiologists must employ a life course approach to autism, which will improve our understanding of the disorder (Bresnahan et al. 2009).

The use of new study designs has moved the field of autism epidemiology forward. Infant sibling studies have played an important role in ASD research over the past decade. These studies have provided important new knowledge about the early signs of ASD, have improved our understanding of the developmental course of autism, and are useful methods to identify risk factors for autism. The use of infant sibling designs is effective because of the increased recurrence rate of autism in siblings and the opportunity to observe early behavioral markers of autism (Newschaffer et al. 2012). Furthermore, the enrollment of participants during pregnancy allows for prospective research on risk factors occurring during the perinatal period. This type of study has been labeled as an enriched-risk pregnancy cohort study and has been applied in studies such as the Early Autism Risk Longitudinal Investigation (EARLI) (Newschaffer et al. 2012). Large birth cohorts have also been employed in the research of ASD. For example, the Autism Birth Cohort (ABC) identifies cases of autism through population screening of participants from the Norwegian Mother and Child Cohort, a large, randomly selected birth cohort in Norway (Stoltenberg et al. 2010). More than 107,000 children have been screened for autism. Cases are compared to controls from the same cohort in a nested case-control design to identify genetic and environmental risk factors for autism.

There is a clear genetic risk for ASD as evidenced by twin and family studies. The relative risk of ASD is 22 times greater in individuals who have a sibling with ASD autism (Lauritsen et al. 2005), and there is a higher concordance rate in monozygotic (MZ) than dizygotic (DZ) twins (Lichtenstein et al. 2010). Based on twin studies, the heritability of ASD is estimated to be between 60% and 90%, making autism one of the most genetic of all developmental neuropsychiatric disorders (Kumar and Christian 2009). While prior studies showed significantly higher concordance rates in MZ twins (Steffenburg et al. 1989; Bailey et al. 1995), more recent studies have provided evidence of a greater role for environmental factors. Rosenberg and colleagues (2009) found a higher concordance rate in DZ twins than previously reported (31%), and Hallmayer et al. (2011) found a rate of concordance in DZ twins of 31% to 36%, concluding that environmental factors explain about 55% of the liability to autism. These studies have increased interest in research on environmental risk factors for ASD, in particular those occurring during the prenatal period. Environmental risk factors that have been identified include perinatal complications (Hultman et al. 2002; Gardener et al. 2009) and increased maternal (Manning et al. 2011) and paternal age (Durkin et al. 2008). In a meta-analysis, Gardener and colleagues (2009) reported that advanced parental age at birth, maternal prenatal medication use, bleeding, gestational diabetes, being firstborn, and having a mother born abroad were associated with increased risk of autism. Durkin et al. (2008) showed that both maternal and paternal age were independently associated with autism.

The recent interest in environmental risk factors for ASD has resulted in the identification of potential protective factors that reduce ASD risk. For example, in a Norwegian cohort of mothers and children, maternal use of folic acid supplements in early pregnancy was associated with a reduced risk of severe language delay, a condition associated with ASD, in children at age 3 years (Roth et al. 2011). And Schmidt and colleagues (2011) found that mothers of children with autism were less likely than those of typically developing children to report having taken prenatal vitamins before or in early pregnancy. The use of folic acid supplements and prenatal vitamins may reduce the risk of having a child with autism.

Exciting research investigating genetic risk factors for ASD has also been conducted in recent years. The advent of microarray technology has led to a revolution in the discovery of copy number variants (CNVs) in autism. A number of CNVs have been identified that occur more frequently in persons with ASD than controls (Morrow 2010). Curiously, many of these same CNVs are also related to other psychiatric disorders, such as schizophrenia (Sanders et al. 2012). Recently, genome-wide association studies (GWAS) of autism have been conducted that have found chromosomal deletions (Kumar et al. 2008) and copy number variants (Marshall et al. 2008) associated with autism. Currently ongoing are “next-generation” genomic studies, which use approaches such as whole genome sequencing that are far more comprehensive than GWAS approaches. One of the earliest to be published showed that paternal age is associated with increased risk of de novo SNP mutations (not just CNVs) and suggested that some of these mutations were related to autism and/or schizophrenia (Kong et al. 2012). While these studies have yielded important findings, they have also underscored the complexity of autism inheritance.

Finally, recent advances in neuroscience and brain imaging have resulted in a better understanding of the brain development of persons with ASD. For example, a longitudinal study of brain growth by Schumann and colleagues (2010) found an abnormal growth rate of multiple areas of the brain among children with autism. The widespread use of standardized diagnostic instruments in the autism epidemiology field, in particular the Autism Diagnostic Interview Revised (ADI-R) (Rutter et al. 2003) and the Autism Diagnostic Observation Schedule (ADOS) (Lord et al. 2000) has allowed for better ascertainment of cases and the ability to make comparisons across studies. As DSM criteria for ASD continue to change (Wing et al. 2011), there will remain challenges in studying the incidence, prevalence, and risks for the disorder. While several risk factors have been identified, the exact cause or causes of ASD are still unknown. Further research on risk factors for ASD is needed, in particular those that occur during the perinatal period or which may be involved in the interplay of genes and environment. There also continues to be a need for studies examining the diagnostic criteria for ASD to better refine case identification.

59.4.2 Schizophrenia

Schizophrenia is a psychotic disorder characterized by a breakdown of thought processes and poor emotional responsiveness. The essential features are the presence of specific psychotic symptoms (delusions, hallucinations, etc.), social or occupational dysfunction, and a 6-month duration of illness (Tsuang and Tohen 2002).

In a review of 188 studies, McGrath et al. (2008) found a median point prevalence of schizophrenia of 4.6 per 1,000 and lifetime prevalence of 7.2 per 1,000. The risk of developing the illness over the life course was 0.7%. The Dutch national morbidity survey reported a lifetime prevalence of 3.7 per 1,000 (van Os et al. 2001).

Several studies have estimated the incidence of schizophrenia. A systematic review of 158 incidence studies reported a median annual incidence of 15.2 per 100,000 (McGrath et al. 2008). In a global study (WHO ten-country study, Jablensky et al. 1992), the estimated annual incidence of schizophrenia ranged from 16 to 40 per 100,000 using broad diagnostic criteria and 7 to 14 per 100,000 using narrow criteria. Eaton et al. (1998) reviewed incidence studies and reported a median annual incidence rate of 0.20 per 1,000. Currently many investigators question whether narrowly diagnosed schizophrenia is clearly separable from other psychotic disorders, at least in terms of genetic and early environmental causes. The overall incidence of psychoses varies, of course, but most studies suggest that the proportion of people who develop psychoses in high-income countries is similar to the proportion who develop ASD. Studies of incidence and prevalence for autism and schizophrenia from low-and middle-income countries (LMIC) are not yet sufficient to draw general conclusions that pertain beyond high-income countries, although LMIC represent ~90% of the world's population. With the growth of research capacity in LMIC, recent pioneering studies of incidence (Menezes et al. 2007) and prevalence (Kebede et al. 2003; Kim et al. 2011; Phillips et al. 2004) are now emerging for both ASD and schizophrenia, and we should soon have enough data to paint a broader, global picture for these disorders.

Although schizophrenia has been studied over the past century, its causes remain largely unknown. Among the reasons are the inherent etiological heterogeneity of schizophrenia as a "syndrome" defined by a confluence of symptoms, and the related historical practice of assigning a different diagnosis than schizophrenia once a specific cause of the syndrome is identified (e.g., pellagra, syphilis, drug-induced psychosis). There are clearly both environmental and genetic causes, and the interplay among these causes is likely to be important.

Schizophrenia has been shown to run in families (Jones and Cannon 1998; Gottesman and Shields 1982); heritability estimates range widely with an upper bound of ~80% (Sullivan et al. 2003; Gottesman and Shields 1982). Individuals are at higher risk if a biological parent or sibling had the disease, and intriguingly, the increased risks related to parents and siblings are somewhat different despite the fact that parents and siblings share about 50% of their genes with an index individual (Heston 1966; Jones and Cannon 1998; Gottesman and Shields 1982). Twin studies show a substantially greater concordance in monozygotic as compared to dizygotic twins (Cannon et al. 1998; Sullivan et al. 2003).

In recent years, major advances have been made in identifying specific genetic mutations related to schizophrenia. About 5 years ago, we argued that individually rare mutations would turn out to be important causes (McClellan et al. 2007), and since then, a large number of studies have been published that identify rare mutations as strong causes (e.g., Gilman et al. 2012). However, it is still not known whether these individually rare mutations will be related to a very large proportion of cases. Thus, the counterargument that schizophrenia is related to multiple common genetic variants, each with a weak effect, could also be true for a proportion of cases (Owen et al. 2009). A very large number of common polymorphisms have been related to schizophrenia in GWAS studies (with weak effects as would be expected). Overall, with a few notable exceptions (e.g., 22q deletions), results across studies are not yet consistent enough to draw definitive conclusions about specific genes or gene regions, but do suggest that both rare mutations and common variants within pathways relating to neuronal (especially synaptic) development play a role. An intriguing recent paper reports that genes within these pathways are important for both ASD and schizophrenia and that there is substantial overlap for these two disorders (Xu et al. 2012). Finally, we note that genetic studies of both rare and common genetic variants are frequently subject to potential bias due to overlooking basic epidemiological precepts (e.g., Schwartz and Susser 2010), although we do not think such potential bias has altered the overall pattern of results described here.

A number of environmental risk factors for schizophrenia have also been identified. With regard to demographic factors, one of the most consistent findings is the lower socioeconomic level of persons with schizophrenia compared to unaffected individuals A large body of research has addressed various hypotheses for this association, ranging from theories of social selection/social drift in which individuals who have or are prone to schizophrenia "drift" progressively downwards in social class as a result of the disorder and/or are prevented from attaining higher social class levels, to theories of social causation involving environmental conditions occurring among persons of lower SES. Both earlier (Dohrenwend et al. 1992) and recent cohort studies tend (Corcoran et al. 2009) to support the social selection view, with only children of the lowest social classes at elevated risk to develop schizophrenia. By contrast, there has been a large recent body of work indicating that ethnic minorities migrating to developed countries are at increased risk for developing schizophrenia and psychotic symptomatology, due to presumed (and yet unexplained) mechanisms of social causation (Morgan and Fearon 2007; Veling et al. 2011). There is also evidence that schizophrenia is more common among males than females (McGrath et al. 2004). McGrath et al. (2008) reported a relative risk in males versus females of 1.4. Higher rates of schizophrenia are also seen among persons who are unmarried (Eaton et al. 1998). It has been hypothesized that this may be due to reverse causation, such that individuals at risk for schizophrenia are less likely to become married or more likely to divorce. The evidence is mixed; van Os et al. (2000) found that the incidence of schizophrenia was higher in single people than married people.

There is also strong evidence for a role of perinatal risk factors in the etiology of schizophrenia. In a meta-analysis of 18 studies, the risk for schizophrenia approximately doubled (odds ratio of 2) for infants born with obstetric complications of all kinds (Geddes and Lawrie 1995). Susser and Lin (1992) showed that nutrition deprivation during pregnancy was associated with increased risk of schizophrenia in offspring. Other risk factors include being born in the winter (Torrey et al. 1993), urbanicity (McGrath et al. 2004), and older paternal age (Byrne et al. 2003). With regard to course and prognosis, many studies find that younger patients, males, and those with a family history have worse outcomes (Tsuang and Tohen 2002).

Current epidemiological investigations regarding the etiology of schizophrenia, as reflected by the work of two of the current authors, demonstrate the range of interdisciplinary approaches used in contemporary psychiatric epidemiology. A series of cohort studies dating back to a paper by Susser and Lin (1992), conducted first in the Netherlands (Susser et al. 2012) and later in China (St Clair et al. 2005) have identified periconceptional maternal nutritional deprivation (approximately 4 weeks before to 8 weeks after conception) as a risk factor for subsequent schizophrenia. Susser and colleagues are pursuing a program of epigenetic research linking maternal prenatal nutrition, DNA methylation and schizophrenia (Kirkbride et al. 2012). Several studies in humans now suggest that prenatal nutritional exposures can influence DNA methylation, in offspring, although the evidence is considerably more scant than that provided by animal studies. A follow-up study of persons exposed and unexposed to famine during the Dutch Hunger Winter of 1944–1945 (not focused on schizophrenia) reported epigenetic changes among the offspring of women exposed to periconceptional starvation. The “sensitive” period for these epigenetic changes was very similar to the “sensitive” period identified in the schizophrenia studies described above (Heijmans et al. 2008). At approximately 60 years old, these offspring exhibited less methylation of the IGF2 locus in whole-blood samples than offspring of women who were unexposed or exposed later in gestation. IGF2 is an imprinted gene that plays a crucial role in early development and continues to play a role in cognitive and other brain processes over the life course (Chen et al. 2011). If genuine, it suggests that periconceptional maternal famine exposure can have a lasting effect on offspring DNA methylation over the life course. More recent analysis of global methylation patterns in this cohort have demonstrated no discernible difference in global DNA methylation patterns between offspring of exposed and unexposed mothers (Lumey et al. 2012), perhaps highlighting the complexity and potentially target-specific nature of prenatal exposures upon the fetal epigenome. A further important question now being examined is whether or not the effects of prenatal nutritional deficiency are transmitted across generations (Susser et al. 2012).

Buka and colleagues (1999) are also engaged in a wide array of epidemiological studies investigating the direct and interactive effects of conditions during pregnancy and familial and genetic risks in the etiology of schizophrenia. These involve a number of study designs, high-dimensional measurement, and statistical approaches. Study designs include basic cohort, nested case-control, sibling, high-risk, and multistage approaches where participants receive greater or lesser intensity of assessment based upon their risk profiles. Study measures reflect the influence of previous generations of epidemiological research (e.g., sociodemographic factors) as well as influences from related disciplines including neuropsychology, neuroscience, genetics, and immunology. Assessments include traditional diagnostic procedures, but also more fine-grained assessments of presumed related endophenotypes, including neuropsychological testing, functional and structural brain imaging, molecular genetics, and immune function. Following decades of research suggesting prenatal risks for schizophrenia, these and other investigators have used archived maternal serum samples from long-running pregnancy cohort studies to confirm the association between maternal infections, exposure to inflammatory cytokines during pregnancy, and subsequent schizophrenia (Buka et al. 2001a, b; Brown et al. 2004a, b). Subsequent work has incorporated molecular genetic methods, investigating the combined influences of prenatal complications, prenatal neurotrophic factors which are stimulated as part of a neuroprotective response to fetal distress (e.g., brain-derived neurotrophic factor), and related polymorphisms which have been associated with schizophrenia (Cannon et al. 2008). Other work motivated by this combined neurodevelopmental, neuroscience, and epidemiological orientation has focused on established gender differences in the phenomenology of schizophrenia and fetal brain development (Goldstein et al. 2011). New analyses move beyond traditional diagnostic classifications of psychotic disorders to dimensional approaches characterized by level and severity of dysfunction in multiple domains (Goldstein et al. 2001; Seidman et al. 2006, 2012). This is in line with recent developments at the National Institute of Mental Health calling for new Research Domain Criteria (RDoC) with efforts to integrate genetic, neurobiological, imaging, behavioral, and clinical data. Modern epidemiological approaches require such integration of new disciplines, designs, and analyses to continue to advance understanding of the epidemiology of schizophrenia.

Prevention Although preventive interventions are beyond the scope of this chapter, we believe it important to note that there are already examples of successful public health prevention efforts for mental disorders, and promising initiatives that may lead to discovery of others. To illustrate, we use the example of nutritional interventions.

We offer two examples of nutritional interventions already implemented and proven effective. Pellagra was once a major cause of mental disorder, especially psychosis (Susser et al. 2006). After public health programs addressed the micronutrient deficiency underlying pellagra, it became a rare cause, almost nonexistent in high-income countries. Similarly, and equally dramatic, prenatal iodine deficiency was shown to be a cause of intellectual disability, mild cognitive impairment, and behavioral problems (Zimmermann 2012). Public health interventions such as iodized salt have dramatically reduced mental impairments related to iodine deficiency, in most though unfortunately still not all parts of the globe.

With regard to promising initiatives, we offer an example that follows on the studies linking periconceptional starvation and schizophrenia described above. Since neural tube defects are related to periconceptional folic acid intake and peaked in the same birth cohort as schizophrenia in the Dutch Famine studies, it is natural to consider whether folic acid deficiency also played a role in schizophrenia. This hypothesis is being explored in a variety of ways, one of which is the ongoing follow-up of a large Norwegian cohort comprising more than 100,000 pregnancies (Magnus et al. 2006; Stoltenberg et al. 2010). Studies from the Norwegian cohort have found that maternal use of periconceptional folic acid supplements (from 4 weeks before to 8 weeks after the last menstrual period) is associated with a reduced risk of child neurodevelopmental disorders such as autism and severe language delay (Surén et al. 2013). Moreover, as noted earlier, converging lines of evidence suggest substantial overlap in the causes of autism and schizophrenia. Within the next decade, the ongoing follow-up of this Norwegian cohort will make it possible to directly test whether these supplements are related to reduced risk of schizophrenia and, if so, to examine potential mechanisms (Kirkbride et al. 2012). We only consider this a promising initiative because we do not yet know whether periconceptional folic acid supplements will ultimately be proven to reduce the risk of autism, schizophrenia, and/or other neurodevelopmental disorders after birth (they are already proven to reduce the risk of neural tube defects at birth). Thus far, however, the evidence for this hypothesis is promising, and if it is ultimately proven true, it will add substantially to examples of successful prevention efforts achieved through public health initiatives.

59.5 Conclusions

Based on generations of studies, it is quite clear that the burden of mental disorders is very high across the globe, in LMIC as well as in high-income countries. Indeed, for several reasons, the burden is likely to increase substantially in the coming decades. For example, as we continue recent progress in reducing child mortality in LMIC, a large population of "child survivors" emerges, who often have neurodevelopmental delays and disabilities (Scherzer et al. 2012). Yet the resources devoted to research and treatment of mental disorders remains minimal in comparison with the resources devoted to other disorders, which make a smaller contribution to burden of disease (Prince et al. 2007; Saxena et al. 2007). The reasons for this discrepancy are not fully understood, but surely one is the stigma associated with mental illness. Since the shortage of resources is most pronounced in LMIC, a current focus of WHO, NIMH, and other leading organizations is to identify strategies to "close the treatment gap" in LMIC (Collins et al. 2011). A related problem is that services that do exist are not well distributed within countries; at times, those with no diagnosis of a mental disorder are more likely to access psychiatric treatment than those with severe mental illness.

We propose that we are now at a critical moment of transformation in psychiatric epidemiology. In recent years, epidemiological investigations of the causes of mental disorders have grown exponentially, and the nature of these investigations has changed. We are now studying specific genetic and epigenetic causes and their relationship to environmental exposures, using large population registries that provide data over long time periods, employing new technologies to examine neighborhood and societal-level effects, and transforming the use of high-risk and other designs that previously existed but could not be applied with the same sophistication. This kind of research entails interdisciplinary collaboration (and training to facilitate this), refined assessment of potential etiological factors, and more attention to potential mechanisms. It also entails the acknowledgement that factors at multiple levels, from cell to society, contribute to these disorders. This broader framework is important for the design of all studies; even though a single study will likely address questions at only one or two levels, the framework helps in the selection of the appropriate level and the understanding of the limitations inherent in studying only one level (Susser and Susser 1996; Susser et al. 2006).

The recognition that mental disorders should be a priority in all populations has also grown exponentially. Although the United Nations in 2011 did not include mental disorders among non-communicable disease priorities, there was considerable controversy about this exclusion, and soon afterward many international funding agencies added mental disorders to their list of priorities. The 2011 decision by the UN is already being seen as a mistake by many leaders in public health. We think it highly unlikely that by the end of this decade, the exclusion of mental disorders will still be considered acceptable in any broad public health initiative.

The magnitude of the global public health burden associated with mental disorders also highlights the need for additional applied research related to the organization, financing, and delivery of mental health services. Throughout the past 100 years of research, there has been consistent evidence of the sizable proportion of persons with diagnosable mental disorders who receive no or limited treatment. At the same time, more recent epidemiological surveys reflect a high level of "met unneed" where individuals with low levels of need had a higher probability of accessing treatment than those with more severe conditions (Kessler et al. 1997; Mojtabai et al. 2002). There is an urgent need to increase both research and mental health services throughout the continuum of prevention and treatment, to increase availability in LMIC, and to better align service receipt with treatment need. As highlighted in this chapter, the field of epidemiology has advanced our knowledge of the forms and prevalence of major psychiatric conditions and is contributing to new discoveries regarding etiology. Parallel emphasis is needed on the applied side of psychiatric epidemiology, around the distribution and evaluation of population-level resources to reduce the burden of these highly prevalent and debilitating set of disorders.

60.1 Introduction

Diabetes is a heterogeneous group of metabolic diseases which share a common characteristic: hyperglycemia. Hyperglycemia develops as a result of various defects in insulin secretion by pancreatic beta-cells or from changes in insulin action. Either defect jeopardizes the delicate interplay between insulin secretion and insulin action which is essential for the maintenance of normoglycemia. Normal pancreatic beta-cells can adapt to changes in insulin action. For example, under regular circumstances, a decrease in insulin sensitivity in target organs such as muscle is compensated by upregulation of insulin secretion and, alternatively, a decrease in secretory function of beta-cells can be counterbalanced by increases in insulin sensitivity. This hyperbolic relationship between insulin secretion and insulin action is deteriorated in patients with diabetes, resulting in chronically higher than normal levels of glycemia (Stumvoll et al. 2005). Type 2 diabetes, the most common form of diabetes, is characterized by a relative loss of beta-cell function which leads to insufficient compensation for increased insulin resistance. Type 1 diabetes is characterized by an absolute deficiency of insulin secretion resulting from autoimmune destruction of pancreatic beta-cells. Due to the different pathophysiology and causative factors involved, a detailed description of the epidemiology of type 1 diabetes is beyond this chapter. Interested readers should refer to previous reviews (Ekoé et al. 2008; Maahs et al. 2010).

Knowledge about the possible causes of type 2 diabetes has greatly advanced over the past few decades largely due to findings from experimental and observational prospective studies in diabetes epidemiology. Unhealthy diet and lifestyle are the most important modifiable factors for type 2 diabetes, and observational studies and randomized clinical trials have demonstrated that diabetes is largely preventable through lifestyle interventions. Accordingly, several countries have responded by implementing national diabetes programs (Colagiuri et al. 2010) and developing guidelines for diabetes prevention (Paulweber et al. 2010). However, despite our improved understanding of the determinants for type 2 diabetes, obesity and physical inactivity have continued to grow in most parts of the world. Particularly in developing countries that are experiencing an economic transition, the current diabetes trend is exceedingly alarming and deserves immediate attention.

The following section describes criteria for diagnosing diabetes and the rationale behind diagnostic cut-offs; the third section discusses current estimates of prevalence and incidence; the fourth section lays out common methodological approaches in diabetes epidemiology; the fifth section presents evidence for different lifestyle risk factors; biochemical and genetic biomarkers as risk factors for type 2 diabetes are discussed in Sects. 60.6 and 60.7, respectively; Sect. 60.8 summarizes evidence from observational and experimental studies on the preventability of type 2 diabetes; Sect. 60.9 discusses approaches for screening to detect undiagnosed cases and high-risk individuals; and the final section draws some conclusions from the chapter.

60.2 Diagnostic Criteria of Diabetes

Classic symptoms of diabetes are polyuria, dehydration, and increased thirst due to glycosuria. Glycosuria occurs if the glucose concentration in the blood is raised beyond the renal threshold, which may vary substantially between individuals (Butterfield et al. 1967). The diagnostic criteria applied today with regard to fasting plasma glucose concentrations are considerably lower than the renal threshold (about 162–180 mg/dL/[9–10 mmol/L]) for most patients (Table 60.1).

All diagnostic criteria for diabetes are dependent on a threshold value that is not clearly linked to symptoms but instead are based on a continuous distribution of blood glucose values. Justification of the diagnostic thresholds has been a long-standing matter of debate. The original approach defined abnormal glucose values as those greater than the mean + 2 SD in a given population. This approach has not been found to correlate well with symptoms (Siperstein 1975). An alternative statistical approach, to be used if the distributions of glucose values follow a bimodal distribution with clear separation of diabetes patients and diabetes-free individuals, is the use of the anti-mode (McCance et al. 1994). This approach, however, is dependent upon population characteristics and is, therefore, unlikely to yield generalizable thresholds (Barr et al. 2002). The clinical approach widely used today is based on the assumption that there exists a threshold above which diabetic complications occur at an increased rate. Chronic exposure to hyperglycemia as a result of diabetes is associated with long-term damage, dysfunction, and failure of different organs, particularly the eyes, kidneys, nerves, heart, and blood vessels. However, diagnosing diabetes based on the relation of glucose values to diabetes complications remains problematic. Although patients with diabetes are at a two- to

Table 60.1 Diagnostic criteria of diabetes and prediabetes from the American Diabetes Association and the world Health Organization

	American Diabetes Association (2011)		World Health Organization/ International Diabetes Federation (2006, 2011)	
	Diabetes	Prediabetes	Diabetes	Prediabetes
Fasting plasma glucose	≥126 mg/dL (7.0 mmol/L)	100–125 mg/dL (5.6–6.9 mmol/L)	≥126 mg/dL (7.0 mmol/L)	110–125 mg/dL (6.1–6.9 mmol/L)
2h plasma glucose after ingestion of a 75-g glucose load	≥200 mg/dL (11.1 mmol/L)	140–199 mg/dL (7.8–11.0 mmol/L)	≥200 mg/dL (11.1 mmol/L)	140–199 mg/dL (7.8–11.0 mmol/L)
Hemoglobin A1c	≥6.5%	5.7–6.4%	≥6.5%	–

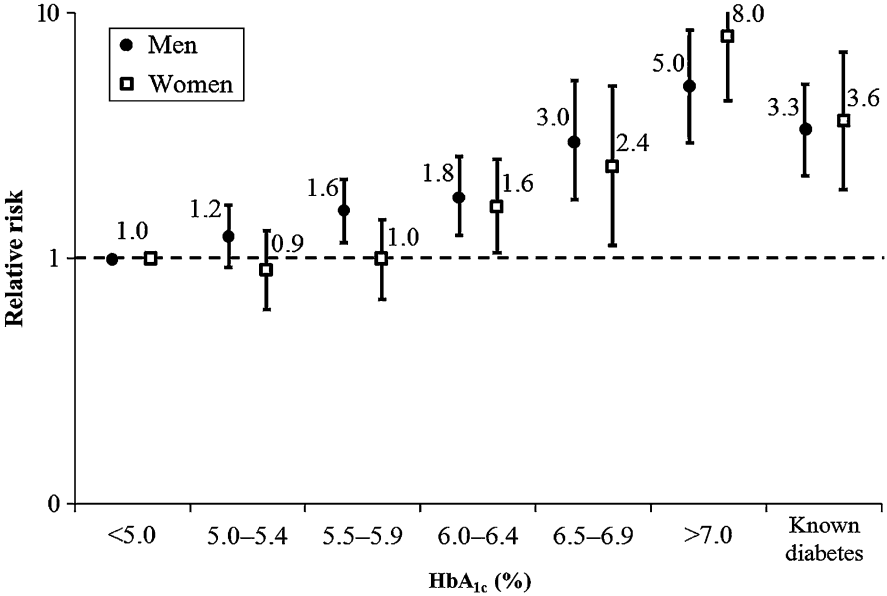

Fig. 60.1 Age-adjusted relative risk of cardiovascular disease events by categories of HbA_{1c} concentrations and known diabetes, EPIC-Norfolk Study (Khaw et al. 2004)

four-fold increased risk of coronary heart disease (Haffner and Cassells 2003; Hu 2002), there appears to be a relationship between glycemia and cardiovascular risk that extends well into the area that is clinically considered non-diabetic (Levitan et al. 2004; Sarwar et al. 2010). This association appears to be more evident when using hemoglobin A_{1c} (HbA_{1c}) compared to 2h plasma glucose (2hPG) during an oral glucose tolerance test or fasting plasma glucose (FPG) values (Sarwar et al. 2010). In the EPIC-Norfolk Study (Khaw et al. 2004), the largest prospective study which evaluated HbA_{1c}, there was a stepwise increase in risk for CVD with higher HbA_{1c} values over a follow-up period of 8 years. A 60–80% increase in risk was shown for HbA_{1c} values between 6.0% and 6.4% compared to participants with HbA_{1c} <5% (Fig. 60.1). Thus, the relationship between glycemia and cardiovascular risk does not provide evidence to substantiate a diagnostic threshold for diabetes.

In contrast to macrovascular complications, the associations between different measures of glycemia and the prevalence of microvascular complications are markedly non-linear (Barr et al. 2002). Still, defining optimal diagnostic thresholds from the shape of the associations has been challenging. For example, recent data from the DETECT-2 study (Fig. 60.2), a consortium of several studies with ~45,000 participants, suggest that the risk of diabetes-specific retinopathy increases around an HbA_{1c} of 6.5% and a 2hPG in the range of 10.1–11.2 mmol/L. These findings support current diagnostic thresholds (Colagiuri et al. 2011). However, the optimal

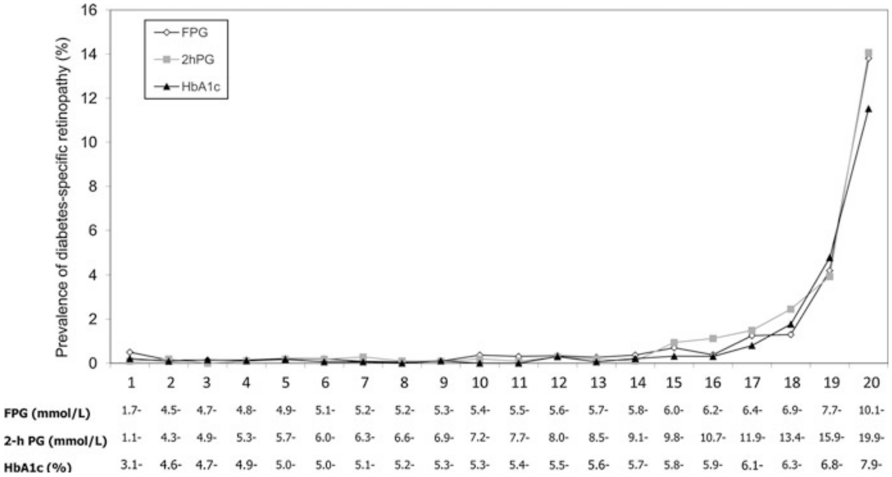

Fig. 60.2 Prevalence of diabetes-specific retinopathy (moderate or more severe retinopathy) by vigintiles of the distribution of FPG, 2hPG, and HbA$_{1c}$ (Colagiuri et al. 2011)

cut-off for FPG in the DETECT-2 study was found to be around 6.5 mmol/dL (117 mg/dL), which is considerably lower than the current diagnostic cut-off of 7.0 mmol/dL (126 mg/dL).

60.3 Prevalence and Incidence of Diabetes Across the World

According to estimations of the International Diabetes Federation, the global prevalence of diabetes in 2010 was 6.4% for adults between 20 and 79 years of age (International Diabetes Federation 2009). In absolute terms, approximately 285 million people in this age range are estimated to have diabetes. There are substantial regional differences in diabetes prevalence. The highest age-adjusted prevalence has been observed in the North American and Caribbean region (10.2%) and the Middle East and North African region (9.3%) (Table 60.2). Global projections predict that the total number of affected individuals will continue to increase over the coming years. The International Diabetes Federation estimates that by the year 2030, 438 million people will have diabetes, accounting for 7.7% of the total population in this age range. These projections probably underestimate the impact of the diabetes epidemic as they are only based on the expected population growth and age-specific demographic changes as determinants of disease prevalence, without taking changes in the prevalence of behavioral and lifestyle risk factors into account. Large differences in diabetes prevalence exist when people from rural and urban geographical areas (with the same or similar ethnicity) are compared. This indicates that the ongoing transition in behavioral, environmental, economic, and social risk factors (urbanization, unhealthy diets, physical inactivity, obesity) will most likely

Table 60.2 Worldwide prevalence of diabetes in 2010 and 2030 among adults (20–79 years) (International Diabetes Federation 2009)

	2010		2030

[a] Prevalence adjusted to world population in 2010 and 2030

result in accelerated growth in diabetes prevalence in many parts of the world, particularly in developing countries.

Representative data on type 2 diabetes incidence rates are lacking from most parts of the world. Many prospective cohort studies collect diabetes incidence data; however, participants are usually selected based on specific geographical regions, age ranges, or individual characteristics. Thus, prospective cohort studies are frequently conducted in populations that are not nationally representative. Countries with nationally representative studies generally draw from cross-sectional survey data, medical records, registries, or health administration data to reflect the current incidence of diagnosed diabetes. For example, estimates of diabetes incidence in the US are based on the representative National Health Interview Survey. The survey data are continuously available; however, the survey does not distinguish whether increases in diabetes incidence rates are due to an actual increase in the number of cases or to improved case ascertainment or a combination of these factors. Based on this survey, the incidence of diagnosed diabetes has increased in the USA from 4.9 to 6.9 per 1,000 adults (18–79 years) between 1997 and 2003 (Geiss et al. 2006). These data, in combination with trend data on the ratio of diagnosed and undiagnosed diabetes (Gregg et al. 2004), provide strong evidence that diabetes incidence has substantially increased during recent years in the USA, likely due to increased obesity and changes in behavioral risk factor prevalence.

There are several methodological difficulties in the assessment of diabetes prevalence and incidence which hinder the comparability of country- or region-specific estimates (Table 60.3). For example, the data sources used by the International Diabetes Federation in determining the country-specific prevalence rates draw from considerably heterogeneous study populations and diabetes assessment techniques (International Diabetes Federation 2009). While representative studies are likely to produce reliable prevalence estimates, such studies are not available for many

Table 60.3 Methodological problems in estimation of diabetes prevalence and incidence (Schulze et al. 2010a)

Problem	Comment
Unknown diabetes	• Clinical diagnosis is made frequently by chance • Considerable proportion of cases are likely unknown • Proportion of unknown cases depends on the availability and acceptability of population-wide screening
Diagnostic parameters	• Guidelines offer a variety of alternative parameters with changes over time (e.g., recent inclusion of HbA_{1c}) • Different parameters do not identify similar case groups • Prevalence of known diabetes in a population depends on the parameters commonly used in clinical practice
Diagnostic thresholds	• Changes in diagnostic thresholds affect prevalence estimates (e.g., increasing prevalence after lowering the threshold for FPG from 140 to 126 mg/dL)
Reliability of measures	• Clinical diagnosis requires confirmatory measurement • Reproducibility of elevated glycemia levels: ~50% • Reproducibility is different for different parameters (e.g., higher for FPG than for 2hPG) and depending on time

countries. Frequently, data from selected study populations are not generalizable to the national level. For countries where representative studies have been conducted, a difference in time intervals or diagnostic parameters makes cross-country comparisons challenging.

Universal glucose screening has not been common practice in most countries, and insurance coverage of screening programs is frequently low. Thus, individuals meeting diagnostic criteria may remain undetected in the general population at any point in time. For example, in a representative study in a region of southern Germany, the prevalence of undetected diabetes has been estimated to be as high as the prevalence of diagnosed diabetes (Meisinger et al. 2010; Rathmann et al. 2003). In the USA, undiagnosed diabetes cases account for about 1/5 of all diabetes cases in NHANES 2003–2006 (overall prevalence among adults $\geq$20 years of age is 9.6%) (Cowie et al. 2010). To estimate the total population level of prevalence and incidence, representative studies would need to identify all individuals previously diagnosed with diabetes as well as those currently meeting the diagnostic criteria. Data from the US-based NHANES 2005–2006 indicate that there is limited overlap across the three diagnostic parameters FPG, 2hPG, and HbA_{1c} (Cowie et al. 2010). Of the three diagnostics, 2hPG results in the highest prevalence of undiagnosed diabetes (4.9%), followed by FPG (2.5%) and HbA_{1c} (1.6%).

The actual proportion of undiagnosed diabetes in a population is a function of the true total prevalence and the extent to which diabetes cases are identified within the health care system through screening programs. In most cases, survey estimates for the prevalence of undiagnosed diabetes rely on a single diagnostic measurement. Studies have suggested that about half of the cases detected through screening utilizing 2hPG as the diagnostic criterion will be confirmed in a second measurement (Brohall et al. 2006; Eschwege et al. 2001). The results from the 2hPG diagnostic are less reproducible than the results from FPG or HbA_{1c} screening. Thus, diabetes prevalence is overestimated when glucose parameters are measured only once. To increase accuracy, repeated measurements that confirm screen-detected cases are necessary. Logistically, this clearly presents a challenge.

60.4 Approaches in Analytical Diabetes Epidemiology

While descriptive diabetes epidemiology describes the distribution, prevalence, and incidence of diabetes in populations, analytical epidemiology investigates the determinants of diabetes development. Observational prospective cohort studies have been widely used in diabetes epidemiology to investigate the determinants of disease (for a detailed description of cohort studies see chapter ▸Cohort Studies of this handbook). In addition, several randomized controlled trials have been conducted to evaluate the efficacy of lifestyle interventions and drug treatments in the prevention of diabetes. Prospective cohort studies are less prone to reverse causation and information bias (e.g., recall bias) than case-control or cross-sectional studies. Therefore, prospective cohort studies are considered the strongest study design among observational studies. Nested case-control studies and case-cohort studies (see chapter ▸Modern Epidemiological Study Designs of this handbook) can benefit from the efficient use of existing biological samples collected through prospective cohort studies. Although randomized clinical trials can provide the strongest evidence for causal inference, such trials are often infeasible for individual dietary and lifestyle factors due to high cost and lack of long-term compliance.

Lifestyle factors play an important role in the etiology of type 2 diabetes (see Sect. 60.5). Thus, methodological developments in assessment tools are essential to diabetes epidemiology. Optimal methods for collecting data on diet and physical activity have been a longstanding source of debate (see chapters ▸Nutritional Epidemiology and ▸Physical Activity Epidemiology of this handbook). Semiquantitative food frequency questionnaires are the most commonly used method to assess diet in nutritional epidemiological studies, but the validity of this method varies across different populations. To account for the correlations between intakes of energy and nutrients, adjustment of dietary data requires sophisticated statistical modeling (see chapter ▸Nutritional Epidemiology of this handbook). In addition, anthropometric measures such as weight, height, and waist and hip circumferences have been commonly used to assess body fat and fat distribution in epidemiological studies. These measures tend to have a high degree of intercorrelations, and simultaneous modeling of these variables is subject to various interpretations (see Sect. 60.5.1). Complex modeling of risk factors typically employs logistic (see chapter ▸Regression Methods for Epidemiological Analysis of this handbook) or Cox (see chapter ▸Survival Analysis of this handbook) regression models.

60.5 Major Lifestyle Risk Factors

60.5.1 Overweight and Obesity

Excessive body fat is the single largest risk factor for type 2 diabetes. For a detailed review on potential mechanisms by which obesity leads to insulin resistance and type 2 diabetes, the reader should refer to Kahn et al. (2006). The diabetes risk associated with excessive body fat, measured by the body mass index (BMI, the ratio of body weight in kg to squared height in meter) or anthropometric indicators such as waist circumference or skinfold thickness, increases in a continuous fashion. Clinical risk categories for BMI (normal weight 18.5–24.9 kg/m^2, overweight 25–29 kg/m^2, and obesity $\geq$30 kg/m^2) are associated with a stepwise increase in diabetes risk. However, studies have clearly shown that diabetes risk increases already within the normal body weight range (Hu et al. 2001a). Existing evidence from randomized controlled trials has convincingly demonstrated the benefits of weight reduction on diabetes incidence, but these studies were limited to high-risk individuals who were overweight (Knowler et al. 2002; Ramachandran et al. 2006; Tuomilehto et al. 2001).

Whether anthropometric measures that reflect body fat distribution are superior to measures of total or percent body fat has been a matter of debate. A meta-analysis of prospective observational studies suggests that the relative risk associated with higher waist circumference is slightly stronger than that associated with higher BMI (Vazquez et al. 2007). These findings suggest that waist circumference is a valid alternative to BMI when assessing type 2 diabetes risk in a clinical setting or at the population level, although the combination of BMI and waist circumference can be more predictive of diabetes risk. Waist-height ratio has also been investigated in a number of studies, although the added value beyond waist circumference alone remains unclear (Browning et al. 2010; Schulze et al. 2006; Taylor et al. 2010). Determining whether abdominal adiposity predicts type 2 diabetes independently of general adiposity has become a research priority. Numerous studies have used multivariable modeling to examine the role of body fat indices, but the colinearity of anthropometric measures is analytically challenging, and the interpretation of mutually adjusted body fat measurements is not straightforward (Table 60.4).

While BMI is the most frequently used clinical and epidemiological measure of body fat and is generally thought to be uncorrelated with height, studies indicate that BMI is slightly correlated with height in many populations, particularly among women (Diverse Populations Collaborative Group 2005). Height and diabetes risk have an inverse relationship (Schulze et al. 2006; Weitzman et al. 2010). Similarly, waist and hip circumferences are correlated with height (Heymsfield et al. 2011). These correlations have implications not only for defining clinical cut-offs for waist and hip circumferences but also for estimating the strength of the association between body fat measures and diabetes risk. Waist-hip circumference measures reflect fat accumulation in the abdominal region more accurately than BMI, but these measures are still imprecise as they are not specific enough to assess the

Table 60.4 Conceptual meanings of statistical models using various anthropometric variables to predict type 2 diabetes risk (Hu 2008)

Models	Interpretations
1. $Y =$ height + weight	Coefficient for weight can be interpreted as the association between overall body fatness and disease risk; the interpretation of height is unclear as, to some degree, it becomes a surrogate for lean body mass
2. $Y =$ height + BMI	BMI and height are uncorrelated. BMI is a measure of overall adiposity, while height can be interpreted as a surrogate of childhood and adolescent nutritional status
3. $Y =$ height + weight adjusted for height	The correlation between height and weight adjusted for height (residuals) from a regression model is zero. Weight adjusted for height is a marker of overall adiposity, while height is a surrogate of childhood and adolescent nutritional status
4. $Y =$ BMI + WC (or WHR)	BMI and WC (or WHR) are highly correlated. While WC is a measure of central obesity, the interpretation of BMI (holding WC constant) is complicated, as it largely reflects the effects of muscularity rather than body fatness, especially in the elderly
5. $Y =$ BMI + WC adjusted for BMI	BMI and WC adjusted for BMI (residuals) in a regression model is zero. WC residuals represent the effects of central obesity adjusted for overall adiposity, while BMI represents the effect of overall adiposity
6. $Y =$ WC + hip circumference	Waist and hip circumferences are moderately correlated. While WC is a measure of central obesity or abdominal fat, hip circumference (holding WC constant) largely represents the effects of gluteal muscularity and bone structure
7. $Y =$ baseline weight + current weight	After adjusting for baseline weight, current weight largely reflects the effects of change in body weight on disease risk
8. $Y =$ change in weight + change in WC	change in WC represents the effects of changes in body fat distribution on disease risk, while change in weight (holding change in WC constant) largely reflects changes in lean body mass (e.g., in the elderly, weight loss is largely due to muscle loss)

Y disease outcome (e.g., type 2 diabetes), *BMI* body mass index, *WC* waist circumference, *WHR* waist-to-hip circumference ratio

amount of visceral and subcutaneous fat. Studies have shown that visceral adipose tissue is metabolically more active than subcutaneous adipose tissue (Jain et al. 2009).

60.5.2 Physical Activity

The notion that physical activity is a central element in diabetes prevention is supported by evidence from multiple major lifestyle intervention trials (Knowler et al. 2002; Ramachandran et al. 2006; Tuomilehto et al. 2001), although it is difficult to disentangle the independent roles of physical activity and dietary interventions in these trials. In the Da Qing Study, a group-randomized trial of high-risk individuals with impaired glucose tolerance conducted in China, physical activity intervention alone had a significant, beneficial impact on diabetes incidence in comparison with the standard intervention (Pan et al. 1997).

A large body of observational studies further supports the beneficial role of physical activity in diabetes prevention (Wareham 2007). Physical activity is a cornerstone of weight maintenance, and it is associated with increased insulin sensitivity (Maarbjerg et al. 2011). Several prospective studies have demonstrated a reduction in diabetes risk with higher levels of physical activity (reviewed in Gill and Cooper (2008) and Wareham (2007)). In most studies, a significant inverse association between physical activity and diabetes remained after adjusting for BMI, suggesting that the benefits of physical activity on diabetes are not entirely mediated through body weight.

Measuring physical activity by questionnaires is prone to measurement errors in epidemiological studies (see chapter ▸Physical Activity Epidemiology of this handbook), likely resulting in an underestimation of the true effect size. Thus, the amount of physical activity required to prevent diabetes remains unresolved. New technologies of activity assessment, e.g. heart rate monitoring and accelerometers, provide more accurate estimates of physical activity levels, although the applications of these technologies in large populations are expensive and logistically difficult. Nonetheless, the combination of self-reported and objectively measured physical activity data will provide further insights on the beneficial role of different amounts and intensities of physical activity in the development of diabetes.

The type of activity most strongly related to a reduction in diabetes risk remains unclear. Moderate to vigorous activity, including brisk walking, has consistently been related to lower diabetes incidence (Jeon et al. 2007). However, no study has examined the role of resistance training such as weight lifting versus aerobic exercise in diabetes risk. Sedentary behaviors, such as prolonged television watching, are associated with an increased risk of diabetes. This relationship is not explained by unhealthy eating patterns associated with television watching (Grøntved and Hu 2011). Appropriate control for different physical activities in analyses of a specific activity as exposure can be performed using isotemporal substitution models reflecting the displacement of time spent on different activities (Mekary et al. 2009). However, the multidimensional nature of physical activity (or inactivity) makes it hard to conclude whether the benefits are due to increased total energy expenditure (i.e., that any form of activity is advisable) or the fitness-producing effect of activities (i.e., that prevention efforts need to focus primarily on fitness-promoting recreational activities). Although several studies have suggested that higher fitness is associated with lower diabetes risk independently of body fatness (Carnethon et al. 2009; Lee et al. 2009a), the benefits of physical activity are likely due to the combination of both increased energy expenditure and improved physical fitness.

60.5.3 Smoking

Active cigarette smoking has consistently been associated with increased diabetes incidence (for a systematic review the reader can refer to Willi et al. (2007)).

Although the relative risk for active smokers compared to never smokers is moderate (∼1.5), smoking accounts for a considerable proportion of diabetes cases due to its high prevalence in many populations. In the USA, where smoking prevalence is declining, smoking has been estimated to account for about 12% of all diabetes cases (Ding and Hu 2007).

Smoking cessation is associated with a modest increase in weight. There is a dose-response relationship among former smokers with weight gain being proportional to the number of cigarettes formerly smoked daily (Filozof et al. 2004). However, this weight gain typically occurs in the shortterm. While diabetes risk is particularly high among individuals who recently quit smoking (Yeh et al. 2010), the beneficial effects of smoking cessation outweigh the adverse effects of associated weight gain in the longterm, leading to a reduction of diabetes risk (Wannamethee et al. 2001; Will et al. 2001).

60.5.4 Alcohol Consumption

Moderate alcohol consumption (1–3 drinks/day) has consistently been associated with lower diabetes incidence. Most studies have observed a u-shaped association, where an increased risk of adverse health outcomes is observed for abstainers and for heavy alcohol consumers. The large number of prospective observational studies that addressed alcohol consumption and diabetes risk has been summarized by several meta-analyses (Baliunas et al. 2009; Carlsson et al. 2005; Koppes et al. 2005). In most studies, the increased risk among alcohol abstainers compared to moderate drinkers should be interpreted cautiously because of heterogeneity in the abstainer population (e.g., life-long abstainers, sickquitters, underreporters). Nonetheless, the benefits of moderate alcohol consumption on diabetes still persisted even when light drinkers (e.g., half a drink or less per day) were used as the reference group.

For moderate alcohol consumers, the reduced risk of type 2 diabetes could be due to increased insulin sensitivity (Davies et al. 2002; Joosten et al. 2008) and adiponectin concentrations (Beulens et al. 2008a). However, results from randomized controlled trials are not entirely consistent, particularly for male participants (Beulens et al. 2006, 2007, 2008b; Sierksma et al. 2004; Zilkens et al. 2003). Although some studies observed different associations depending on the type of alcoholic beverage consumed, randomized trials suggest that the underlying biological mechanism is most likely to be explained by the consumption of alcohol, regardless of the type (Beulens et al. 2006, 2007, 2008b; Davies et al. 2002).

60.5.5 Dietary Factors

It has been hypothesized that higher total fat intake contributes to diabetes, directly by inducing insulin resistance and indirectly by promoting weight gain. Results from metabolic studies in humans, however, are inconsistent and generally do not support the idea that high-fat diets have a detrimental effect on insulin sensitivity (Lichtenstein and Schwab 2000; Riserus et al. 2009). Additionally, changing the dietary fat and carbohydrate composition in intervention studies generally had no effect on subsequent weight change over a long-term period (Howard et al. 2006). In most observational prospective studies, total fat or carbohydrate intake was not associated with diabetes risk (for an overview of the literature, the reader should refer to reviews on this topic (Hu et al. 2001b; Melanson et al. 2009; Schulze and Hu 2005)). This point is further supported by the Women's Health Initiative, a large randomized trial in which women who consumed a low-fat diet had similar diabetes incidence rates compared with women who consumed a standard USA diet (Tinker et al. 2008). The specific type of fat and carbohydrate may be more important than the total intake. Prospective studies suggest that diets that favor plant fats over animal fats (Hu et al. 2001b; Melanson et al. 2009) and that are rich in fiber, particularly from cereals (Schulze et al. 2007), are advantageous.

Carbohydrate quality can be determined by evaluating the physiologic response to carbohydrate-rich foods. The glycemic index reflects the quality of carbohydrates by ranking the ability of specific foods to raise postprandial blood glucose levels (Jenkins et al. 1981), whereas the glycemic load, a crossproduct of the glycemic index of a specific food and the amount of carbohydrates, reflects both quality and quantity of the carbohydrates. The relationship between glycemic index or load and risk of diabetes has been evaluated by a number of prospective studies, which showed that diets with low average glycemic index and glycemic load might be associated with lower risk for diabetes compared with high glycemic index/load diets (Dong et al. 2011a; Liu and Chou 2010). These associations appear to be independent of the amount of dietary fiber.

Though data are limited with regard to dietary protein, higher intake of animal protein has been observed to be associated with higher diabetes risk (Schulze et al. 2008; Sluijs et al. 2010; Song et al. 2004). In addition, cohort studies suggest that higher magnesium intake (Dong et al. 2011b; Larsson and Wolk 2007; Schulze et al. 2007) decreases diabetes risk, whereas higher iron intake – particularly from animal sources (iron bound to heme in oxygen-binding proteins myoglobin and hemoglobin) – increases diabetes risk (Rajpathak et al. 2009a). The relationship between antioxidative nutrients and diabetes risk has been evaluated in post hoc analyses of several randomized clinical trials. Generally, no benefits from vitamin C, vitamin E, or beta-carotene supplementation were found (Song et al. 2009), but supplementation with selenium was associated with increased risk of diabetes in one trial (Stranges et al. 2007).

A growing number of studies have evaluated the role of specific foods with regard to diabetes risk. Coffee consumption has been associated with lower diabetes risk in a large number of studies (Huxley et al. 2009; van Dam and Hu 2005). Residual confounding is unlikely to explain these results because regular coffee consumption is generally associated with unfavorable lifestyle habits in most populations. Whole grains have consistently been associated with lower diabetes risk in prospective studies (de Munter et al. 2007; Priebe et al. 2008). Similarly, dairy consumption is associated with lower diabetes risk (Tong et al. 2011), although this benefit may be restricted to low-fat dairy products. Consumption of nuts has also been associated with lower risk of diabetes, although to date, very few prospective studies have directly evaluated this hypothesis (Kendall et al. 2010). In contrast, frequent consumption of red and processed meats has consistently been related to higher diabetes risk in prospective cohort studies (Aune et al. 2009; Micha et al. 2010; Pan et al. 2011). Prospective studies also suggest that consuming sugar-sweetened beverages increases the risk of developing type 2 diabetes (Malik et al. 2010). A meta-analysis indicates that higher consumption of fruits and vegetables is not significantly associated with diabetes risk (Carter et al. 2010), although green leafy vegetables were found to be protective. It should be noted that observational studies may not be able to capture the true effect of diet on disease risk due to measurement errors inherent in the use of questionnaires, which could potentially lead to an underestimation of the effect (Harding et al. 2008).

To capture an individual's exposure to overall diet, several methods have been developed to derive dietary patterns. For details on food pattern evaluation methods and studies that evaluate the relationship between dietary patterns and diabetes risk, the reader should refer to published reviews (Esposito et al. 2010; Kastorini and Panagiotakos 2009; Michels and Schulze 2005; Schulze and Hu 2002; Schulze and Hoffmann 2006). Studies that evaluate major eating patterns through the use of exploratory patterning methods (e.g., factor and cluster analysis) suggest that "Western" diets rich in red and processed meats, sugary drinks, and refined grains are related to higher diabetes risk (Fung et al. 2004; van Dam et al. 2002). Several authors have used the reduced rank regression technique, which allows the use of intermediate risk markers in pattern recognition to identify diabetes-related patterns (Heidemann et al. 2005; Imamura et al. 2009; Liese et al. 2009; McNaughton et al. 2008; Schulze et al. 2005). Most studies support the notion that dietary patterns that favor fruits, vegetables, whole grains, and vegetable fats at the expenses of red meats, refined grains, and sugared soft drinks reduce the risk of type 2 diabetes. While this evidence is observational, additional support for the beneficial effects of similar diet patterns (e.g., the Mediterranean diet) comes from intervention studies (Salas-Salvado et al. 2011).

Measuring dietary intake in observational studies has been a major focus of research in nutritional epidemiology (see chapter ▶Nutritional Epidemiology of this handbook). Semiquantitative food frequency questionnaires are the most commonly used method to assess diet in large-scale studies to date. Food frequency questionnaires can be self-administered by participants, are relatively easy to complete, can be processed by computer, and are inexpensive – features that make them particularly feasible for use in large epidemiological studies. However, the validity of this method may vary with different populations and cultures. In addition, because food frequency questionnaires lack the detail and specificity of diet records or recalls, they may not provide accurate estimates of absolute intake of some nutrients. As a consequence, food frequency questionnaires provide very useful information on relative ranking of usual nutrient and food intakes rather than precise amounts of intakes. While more quantitative methods (food records, 24h-recalls) are available, they are short-term assessment instruments unlikely to reflect long-term usual intake and put considerable burden on study participants and investigators. New methodological developments focus on the combination of different assessment methods. For example, data from food frequency questionnaires can be used in combination with few repeated 24-h recalls to increase the validity of collected dietary data (Souverein et al. 2011).

In epidemiological studies on diet and diabetes, the regression calibration approach can be used to correct measures of association for random and systematic errors inevitable in all dietary assessments (Qiu and Rosner 2010). However, this approach requires a validation study in a subsample of the study. Also, random measurement errors can also be reduced by repeated dietary assessment over the course of a study (Hu et al. 1999). For example, correction for measurement error by the regression calibration approach and by using repeated dietary assessments in comparison to baseline diet only yielded stronger associations between red and processed meat intake and type 2 diabetes risk (Pan et al. 2011).

Due to the multidimensional nature of dietary intake, observational studies on dietary risk factors and diabetes require careful statistical model building. Given that several dietary exposures have been observed to be related to diabetes risk, confounder adjustment is a central requirement. Besides control of confounding, adjustment for total energy intake also mimics differences in dietary composition under isocaloric situations. In the case that the effect of specific energy-providing macronutrients on disease outcome is modeled, effect estimates then reflect macronutrient substitutions. For example, adjustment of carbohydrate density (percentage of total energy) for total energy intake and specific other macronutrient densities allows to evaluate associations with diabetes risk for an isocaloric substitution of carbohydrates for fat or for protein (Schulze et al. 2008). Multivariable modeling can also be used to investigate the effect of a substitution of a serving of one food for another (Halton et al. 2006; Pan et al. 2011).

60.5.6 Emotional Stress and Sleeping Problems

Findings from prospective cohort studies suggest that different forms of emotional stress increase the risk of type 2 diabetes. Here, emotional stress refers to consequences of the failure to respond appropriately to emotional threats, with signs of stress defined at a cognitive, emotional, physical, or behavioral level (Pouwer et al. 2010). Depression has consistently been associated with higher diabetes incidence (Knol et al. 2006; Mezuk et al. 2008). Also, general emotional stress has been found to increase diabetes risk, although the data are not conclusive (Pouwer et al. 2010). There is some evidence that psychosocial stress at work is also associated with increased diabetes risk (Agardh et al. 2003; Heraclides et al. 2009). Emotional stress can affect sleep duration and sleep quality. Conversely, sleeping problems may not only be a consequence of emotional stress but are often experienced as a significant source of stress (Pouwer et al. 2010).

Prospective studies have consistently observed higher diabetes risk with short sleep duration ($\leq$5–6 h/night) and long sleep duration ($>$8–9 h/night). There is also strong evidence that reduced sleep quality, e.g., difficulties in initiating or maintaining sleep, increases diabetes risk (Cappuccio et al. 2010). Potential mechanisms relating short sleep duration to increased risk include changes in circulating levels of leptin and ghrelin as well as cortisol metabolism and inflammation. While BMI is an important potential confounder because it can contribute to snoring problems and sleep apnea (and thus to sleeping problems), short sleep duration has generally been found to increase diabetes risk independently of body fatness. There is less clear indication of possible mechanisms mediating the risk-increasing effect of long sleep duration, although confounding by depressive symptoms, low socioeconomic status, unhealthy lifestyle patterns, and prevalent health conditions may be potential explanations (Pouwer et al. 2010).

60.6 Biochemical Predictors

In light of the increasing prevalence of diabetes worldwide, interest in identifying "novel" predictors is mounting. A growing number of studies have evaluated biochemical markers for associations with diabetes risk in recent years. Such research has mainly been targeted at improving our understanding of the pathogenesis of diabetes. Biochemical markers have also been increasingly used to evaluate potential mechanisms by which conventional risk factors might be related to diabetes risk. These investigations focus on etiology and can be separated from the debate on whether biomarkers have value as a screening tool for predicting future diabetes cases. The latter point is discussed later in this chapter.

The evaluation of biochemical markers in epidemiological studies involves a number of challenges which are often not sufficiently addressed (see chapter ►Molecular Epidemiology of this handbook). These complex problems include: residual confounding, inappropriate adjustment for intermediate variables, and analytical measurement error and biological variation. For a more detailed discussion, the reader might refer to Sattar et al. (2008). While biochemical markers of diabetes risk may generally be measureable in different body tissues, the overwhelming majority of studies have focused on peptides, proteins, and metabolites measureable in peripheral blood. Parameters of glucose metabolism have been of particular interest because these are either directly relevant as diagnostic parameters (FPG, 2hPG, HbA_{1c}) or they reflect the primary underlying mechanisms of insulin resistance (reflected by different indices, e.g., HOMA insulin resistance index) and impaired β-cell function (reflected by fasting insulin, proinsulin, or HOMA β-cell function index). Additional biomarkers that have been found to predict diabetes incidence include blood lipids (i.e., triglycerides and HDL-cholesterol (Fagot-Campagna et al. 1997; Montonen et al. 2011; Schmidt et al. 2005; Stern et al. 2002; Wilson et al. 2007)), liver enzymes (alanine aminotransferase and gamma-glutamyltransferase (Fraser et al. 2009)) and other hepatic-derived predictors (sex hormone-binding globulin (Ding et al. 2006)), the adipokine adiponectin (Li et al. 2009), and markers of subclinical inflammation, in particular CRP (Lee et al. 2009b). There is also emerging evidence that novel markers related to inflammation and endothelial dysfunction (e.g., IL-6, cellular adhesion molecules, white cell count (Goldberg 2009)), body iron stores (Forouhi et al. 2007; Jehn et al. 2007; Rajpathak et al. 2009b), hepatokine fetuin-A (Ix et al. 2008; Stefan et al. 2008), or PAI-1 (Festa et al. 2002; Kanaya et al. 2006) are associated with diabetes risk. For a detailed review of the literature, the reader may refer to published reviews (Herder et al. 2011; Sattar et al. 2008).

Current approaches focus on complementing candidate-based biomarker studies with hypothesis-free approaches. In particular, metabolomics has gained more interest because metabolites are considered to be the most proximal biomarkers of pathophysiological processes. The number of different metabolites (including lipids, sugars, nucleotides, amino acids, organic acids), their substantial chemical diversity in terms of polarity and water/lipid solubility, and their wide range of concentration levels across different human tissues make the application of metabolomics in large-scale epidemiological studies particularly challenging (see chapter ▸Molecular Epidemiology of this handbook). A recent prospective study using a targeted metabolomics approach indicated that branched-chain and aromatic amino acids in plasma could be used as predictors of risk of type 2 diabetes (Wang et al. 2011).

60.7 Genetic Predictors

In addition to biochemical markers, there has been a growing interest in genetic markers as predictors of diabetes. Several loci were identified in candidate association studies (PPARG, KCNJ11, TCF7L2, WFS1, and HNF1B), but the majority of the known susceptibility loci for type 2 diabetes have been identified by genome-wide association studies (GWAS) based on case-control studies (e.g., FTO, SLC30A8, HHEX-IDE-KIF11, CDKAL1, IGF2BP2, CDKN2A-CDKN2B, TSPAN8, ADAMTS9, NOTCH2, CDC123-CAMK1D, THADA, JAZF, KCNQ1, IRS1, DUSP9, ZFAND6, PRC1, CENTD2, TP53INP1, KLF14, ZBED3, BCL11A, HNF1A, CHCHD9, HMGA2, UBE2E2, C2CD4A-C2CD4B, and RBMS1-ITGB6) or by evaluating associations with diabetes-related quantitative traits, e.g., FPG, 2hPG, HbA_{1c}, and indices of insulin resistance and β-cell function (MTNR1B, DGKB-TMEM195, GCKR, GCK, PROX1, and ADCY5) (for a detailed description of genome-wide association studies see chapter ▸Statistical Methods in Genetic Epidemiology of this handbook). GWAS have resulted in a major paradigm shift in epidemiological research from hypothesis-driven investigations toward exploratory analyses and decision-making based on the presence or absence of statistical significance. The pooling of study populations has led to increased statistical power and the discovery of many new loci. These loci are typically associated with a small to moderate effect on diabetes risk, with most variants carrying an odds ratio of

Table 60.5 Genetic variants evaluated to predict type 2 diabetes in prospective cohort studies considering multiple loci simultaneously

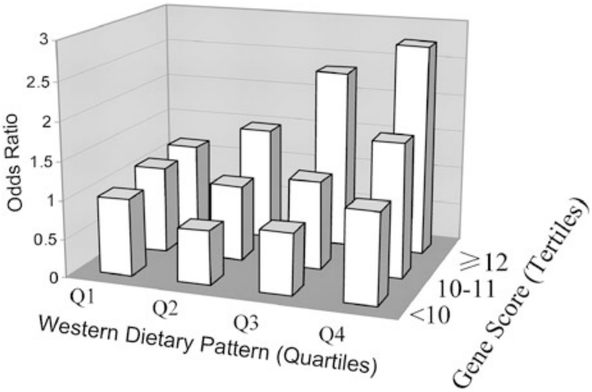
Study	Number of genetic variants	Comparison	Relative risk (95% CI)
Rotterdam Study (van Hoek et al. 2008)	18	Per risk allele	1.04 (1.02–1.07)
Framingham offspring Study (Meigs et al. 2008) (de Miguel-Yanes et al. 2011)	18 40	Per risk allele	1.12 (1.07–1.17) <50 years: 1.24 (1.13–1.36) ≥50 years: 1.11 (1.03–1.19)
Malmö preventive project (Lyssenko et al. 2008)	11	Per risk allele	1.12 (1.08–1.15)
Botnia Study (Lyssenko et al. 2008)	11	Per risk allele	0.94 (0.84–1.04)
Health professionals follow-up Study (Cornelis et al. 2009a)	10	Per risk allele	1.19 (1.14–1.24)
Nurses' health Study (Cornelis et al. 2009a)	10	Per risk allele	1.16 (1.12–1.20)
EPIC-Potsdam Study (Schulze et al. 2009)	20	≥22 vs. <17 risk alleles	1.47 (1.12–1.93)
Whitehall II Study (Talmud et al. 2010)	20	Per risk allele	1.7 (0.9–2.5)

1.1–1.2 per risk allele. In addition, these risk alleles are usually common, often exceeding 25% prevalence in most populations (Herder et al. 2011). Interestingly, the majority of risk loci reflect variation in genes involved in β-cell function rather than insulin resistance (Florez 2008).

Several recent prospective studies have used genetic risk scores or risk allele scores to capture genetic risk at multiple loci simultaneously (Table 60.5) (Cornelis et al. 2009a; de Miguel-Yanes et al. 2011; Lyssenko et al. 2008; Meigs et al. 2008; Schulze et al. 2009; Talmud et al. 2010; van Hoek et al. 2008). Such scores can generally be calculated by either assuming equal contribution of each risk allele or weighting the risk alleles. The latter technique has been applied by assigning study-specific or literature-based weights. Given that most genetic variants are associated with a modest increase in risk of diabetes and that study-specific associations are frequently inconsistent with associations reported from large pooling projects for single loci, the use of study-specific weights is likely to introduce overoptimism in risk prediction when evaluating genetic risk scores (de Miguel-Yanes et al. 2011). Also, because there is very little difference in effect sizes between most variants, weighted genetic risk scores may not be substantially different in their associated risk compared to that for unweighted scores (Cornelis et al. 2009a; Talmud et al. 2010).

The risk variants identified to date only account for ~10% of observed familial clustering of type 2 diabetes (Voight et al. 2010). Thus far, the identified variants

Fig. 60.3 Diabetes risk according to joint classification of a “Western” dietary pattern and genetic risk (Qi et al. 2009)



are common alleles (frequency >5%), and it remains unclear whether less common variants would have a stronger genetic effect on diabetes. Potentially, the combined effects of common and less common variants may explain a greater degree of heritability of diabetes, although rare variants with large effects are yet to be identified.

Current research is also focused on investigating the interplay between environmental risk factors and genetic susceptibility. For an overview of the literature, the reader should refer to reviews on this topic (Franks et al. 2007; Qi et al. 2008; Qi and Liang 2010). There is some evidence that the effectiveness of lifestyle interventions is dependent upon genetic variants (Florez et al. 2007). For example, prospective studies have observed that the beneficial effects of fiber-rich diets or diets with high carbohydrate quality (low glycemic index) may depend upon genetic variation in TCF7L2 (Cornelis et al. 2009b; Fisher et al. 2009). Additionally, the detrimental effects of adhering to a “Western” dietary pattern were stronger among individuals carrying a relatively large number of diabetes risk alleles compared to those with relatively few (Fig. 60.3) (Qi et al. 2009). Interactions between physical activity and genetic variants have also been found (Brito et al. 2009). Still, intensive lifestyle modification reduced diabetes risk irrespective of genetic susceptibility to diabetes in the Diabetes Prevention Program (Hivert et al. 2011). Although genetic predictors of diabetes have been identified by large consortia of cross-sectional and case-control studies in recent years, these studies are generally not suitable for evaluating gene-environment interactions because most of the studies did not collect exposure information on environmental factors, especially diet and lifestyle. Also, diet and lifestyle information assessed in case-control or cross-sectional studies is prone to recall bias and reverse causation. Analyses on gene-environment interactions require large prospective population-based studies with sufficient statistical power, detailed information on diet and lifestyle, and replication of the findings in various populations.

60.8 Prevention of Diabetes

60.8.1 Healthy Lifestyles and Preventability of Type 2 Diabetes

Epidemiological evidence strongly indicates that diabetes is associated with Western dietary and lifestyle habits. People who migrate to Western countries generally have more sedentary lifestyles and consume “Western” diets and, therefore, have a greater risk of developing type 2 diabetes compared with their counterparts who remain in their native countries (Manson and Spelsberg 1994). Populations undergoing westernization in the absence of migration have also experienced dramatic rises in obesity and type 2 diabetes (Gohdes et al. 1993; Collins et al. 1994; Hodge et al. 1994).

Although a large body of evidence from epidemiological studies has implicated individual dietary and lifestyle factors in the development of type 2 diabetes, only a few studies have examined multiple risk factors simultaneously (Ford et al. 2009; Gopinath et al. 2010; Hu et al. 2001a; Mozaffarian et al. 2009; Reis et al. 2011). All of these studies considered physical activity, diet, smoking, and overweight or obesity as modifiable risk factors (Table 60.6). Alcohol consumption was considered by three of the five studies as an additional risk factor (Hu et al. 2001a; Mozaffarian et al. 2009; Reis et al. 2011). Overall, participants who adhered to all of the low-risk behaviors had a dramatically lower risk of developing type 2 diabetes. The studies also observed that only a small fraction of participants fulfilled all low-risk behavior criteria and that the population attributable risk of not adhering to healthy lifestyles is very high.

In these studies, the definition of a healthy diet based on population percentiles is somewhat arbitrary, thus making the translation of findings into public health practice challenging. The categorization of continuous risk factors is also subjective as different cut-offs for BMI and waist circumference were used in different studies. Despite these limitations, the data provide strong epidemiological evidence that the majority of type 2 diabetes cases could be prevented by the adoption of a healthier lifestyle.

Several randomized trials have also demonstrated the preventability of diabetes through lifestyle modification (Table 60.7). In a group-randomized trial in China, intervention with diet alone, exercise alone, and diet-plus-exercise was associated with a 31%, 46%, and 42% reduction in the risk of developing diabetes compared to the control group (Pan et al. 1997). In the Finnish Diabetes Prevention Study, reduction in weight through dietary modification and increasing physical activity resulted in an overall diabetes risk reduction of 58% over 3 years (Tuomilehto et al. 2001). Similarly, in the US-based Diabetes Prevention Program, a lifestyle-modification program with the minimum goal of a 7% weight reduction and a minimum of 150 min of physical activity per week reduced diabetes incidence by 58% over 3 years (Knowler et al. 2002). In all of these studies, the effect was maintained several years beyond the active intervention period (Li et al. 2008; Lindstrom et al. 2006; Knowler et al. 2009). Similar effects of lifestyle modification on diabetes incidence have been observed in the Indian Diabetes Prevention

Table 60.6 Classification of low-risk, relative risk, and population attributable risk of type 2 diabetes mellitus in prospective studies for groups defined by combinations of modifiable risk factors

Lifestyle risk factors	Nurses' Health Study (Hu et al. 2001a)	Cardiovascular Health Study (Mozaffarian et al. 2009)	EPIC-Potsdam Study (Ford et al. 2009)	Blue Mountains Eye Study (Gopinath et al. 2010)	National Institutes of Health (NIH)–AARP Diet and Health Study (Reis et al. 2011)
Physical activity	Moderate-to vigorous exercise ≥30 min/day	≥median	≥3.5 h/week	≥3 times/week	20 min ≥ 3 times/week
Diet	Upper 2 quintiles of diet score	Upper 2 quintiles of diet score	>median of diet score	>median of diet score	Upper 2 quintiles of diet score
Smoking	No current	Never	Never	Never	Never or quit smoking >10 years ago
Overweight/obesity	BMI < 25 kg/m^2	BMI < 25 kg/m^{2}or waist circumference <88/92 cm	BMI < 30 kg/m^2	BMI < 30 kg/m^2	BMI 18.5–25 kg/m^2
Alcohol consumption	≥half a drink/day	Yes			Moderate
Percentage of population adhering to all factors	3.4%	3.4%	9.1%	11.4%	Men: 4.0% Women: 2.3%
Relative risk (95% CI)	5 factors vs. rest: 0.09 (0.05–0.17)	5 factors vs. rest: 0.11 (0.01–0.76)	4 factors vs. 0: 0.07 (0.05–0.12)	4 factors vs. 0: 0.17 (0.07–0.42)	5 factors vs. rest: Men: 0.28 (0.23–0.34) Women: 0.16 (0.10–0.24)

Program (Ramachandran et al. 2006) and in a Japanese trial (Kosaka et al. 2005). These trials share the limitation that study participants were preselected based on their risk profile with prevalent impaired glucose tolerance being a prerequisite. Consequently, diabetes incidence – even with lifestyle intervention – was very high, and thus, these results may not be easily generalizable to other risk groups.

60.8.2 Drugs in the Prevention of Type 2 Diabetes

Several trials have evaluated the efficacy of drugs in the prevention or delay of type 2 diabetes (Table 60.8). Metformin treatment resulted in a diabetes risk reduction in the diabetes prevention program (Knowler et al. 2002) and in the Indian Diabetes Prevention Program (Ramachandran et al. 2006). Metformin improves hyperglycemia primarily by suppressing hepatic gluconeogenesis. In the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM) (Chiasson et al. 2002), the acarbose intervention group experienced a 25% diabetes risk reduction compared with the placebo group. Treatment with voglibose resulted in a risk reduction in a Japanese study (Kawamori et al. 2009). Both acarbose and voglibose are alpha-glucosidase inhibitors that decrease the absorption of carbohydrates from the intestine, resulting in a slower and lower rise in blood glucose, particularly after meals. Thiazolidinediones were used as drug intervention in several studies. Both troglitazone (Buchanan et al. 2002; Knowler et al. 2005) and rosiglitazone (Gerstein et al. 2006) reduced the risk of incident diabetes by at least 50% over 3 years compared to placebo. Furthermore, a low-dose combination therapy with rosiglitazone and metformin reduced the risk of type 2 diabetes in patients with impaired glucose tolerance (Zinman et al. 2010). The primary mechanism of action of thiazolidinediones involves binding to the peroxisome proliferator-activated receptor gamma, a transcription factor that regulates the expression and release of mediators of insulin resistance originating in adipose tissue. Treatment with orlistat, a potent inhibitor of pancreatic lipases that prevents the absorption of fats from the human diet, reduced diabetes risk by about 40% in two intervention studies (Heymsfield et al. 2000; Torgerson et al. 2004). A diabetes risk reduction was also observed for valsartan, an angiotensin receptor blocker (McMurray et al. 2010). In contrast, nateglinide, which stimulates insulin secretion, (Holman et al. 2010) and ramipril, an angiotensin-converting enzyme inhibitor (Bosch et al. 2006), were not found to significantly reduce diabetes risk in randomized controlled trials.

While these trials provide evidence that type 2 diabetes can be prevented through pharmacological interventions in high-risk populations, lifestyle modifications are more efficacious than drug interventions (Knowler et al. 2002; Ramachandran et al. 2006), and they do not cause side effects that are common in drug treatments. In particular, troglitazone was withdrawn from the market in 2000 due to liver toxicity, and rosiglitazone has been found to increase risk of cardiovascular disease. In addition, the beneficial effects of drugs on diabetes were lost shortly after the drugs were stopped (i.e., a few weeks), whereas lifestyle interventions had sustained benefits on diabetes prevention even after the active intervention discontinued for

Table 60.8 Major drug trials for prevention of type 2 diabetes

Study (author)	Population	Intervention	Relative risk (95% CI) of intervention compared with placebo
Diabetes Prevention Program (Knowler et al. 2002, 2005)	$n = 3{,}234$ with impaired glucose tolerance, aged ≥ 25 years	850 mg metformin or placebo twice daily, mean 2.8 years	0.69 (0.57–0.83)
		400 mg troglitazone or placebo daily, mean 0.9 years	0.25 ($p < 0.001$)
Indian Diabetes Prevention Program (Ramachandran et al. 2006)	$n = 269$ native Asian Indians with impaired glucose tolerance, aged 35–55 years	250 mg metformin or placebo twice daily, median 30 months	0.74 (0.65–0.81)
Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM) (Chiasson et al. 2002)	$n = 1{,}429$ with impaired glucose tolerance, aged 40–70 years	100 mg acarbose or placebo three times daily, mean 3.3 years	0.75 (0.63–0.90)
Japanese Study (Kawamori et al. 2009)	$n = 1{,}780$ with impaired glucose tolerance, aged 30–70 years	0.2 mg voglibose or placebo three times daily, mean 48 weeks	0.60 (0.43–0.82)
Three trials (Heymsfield et al. 2000)	$n = 675$ with BMI ≥ 30, aged > 18 years	120 mg orlistat or placebo three times daily, 582 days	0.39 ($p = 0.04$) among participants with impaired glucose tolerance at baseline
XENDOS (Torgerson et al. 2004)	$n = 3{,}305$ with BMI ≥ 30, aged 30–60 years	120 mg orlistat or placebo three times daily, 4 years	0.63 (0.46–0.86)
TRIPOD (Buchanan et al. 2002)	$n = 266$ hispanic women with previous gestational diabetes, aged ≥ 18 years	400 mg troglitazone or placebo once a day, mean 30 months	0.45 (0.25–0.83)
DREAM (Gerstein et al. 2006)	$n = 5{,}269$ with impaired fasting glucose or impaired glucose tolerance, aged ≥ 30 years	8 mg rosiglitazone or placebo daily	0.40 (0.35–0.46)
CANOE (Zinman et al. 2010)	$n = 207$ with impaired glucose tolerance, aged 30–75 years	2 mg rosiglitazone and 500 mg metformin or placebo twice daily, median 3.9 years	0.34 (0.20–0.59)
NAVIGATOR (Holman et al. 2010; McMurray et al. 2010)	$n = 9{,}306$ with impaired glucose tolerance, mean age 64 years	160 mg valsartan or placebo daily, median 5.0 years	0.86 (0.80–0.92)
		60 mg nateglinide or placebo three times daily, median 5.0 years	1.07 (1.00–1.15)
HOPE (Bosch et al. 2006)	$n = 5{,}269$ with impaired fasting glucose or impaired glucose tolerance, aged ≥ 30 years	15 mg ramipril or placebo daily, median 3 years	0.91 (0.81–1.03)

several years. Moreover, healthy diet and lifestyle modification is effective not only in preventing diabetes, but also in reducing the risk of other chronic diseases such as coronary heart disease (Ford et al. 2009; Stampfer et al. 2000).

Although lifestyle and drug interventions have been found to reduce the risk of diabetes among individuals at high risk, the benefits of these interventions for the prevention of cardiovascular events, death, or other long-term adverse health outcomes are yet to be demonstrated. For example, no difference in cardiovascular event rates was observed in the US Diabetes Prevention Program (Ratner et al. 2005); however, the study was not powered to examine cardiovascular outcomes. Treatment with acarbose reduced the risk of cardiovascular events in a post hoc analysis (Chiasson et al. 2003), but treatment groups had high attrition rates (33%). In the DREAM trial, cardiovascular event rates did not significantly differ between the rosiglitazone and placebo groups (Gerstein et al. 2006). Other studies among diabetic patients found that rosiglitazone treatment was associated with increased risk of myocardial infarction despite its glucose lowering effect (Nissen and Wolski 2007). On the other hand, lifestyle interventions, assuming a high adherence, are not only effective at reducing the risk of diabetes but also cost-effective at the population level. For a detailed discussion, the reader should refer to reviews on this topic (Waugh et al. 2007; Echouffo-Tcheugui et al. 2011; Norris et al. 2008).

60.9 Screening for Diabetes and Prediabetes

The benefits of early diabetes detection and treatment through screening programs compared to delayed treatment once cases become clinically diagnosed remains unclear because, to date, no randomized study has examined the effectiveness of screening programs. Results from the ADDITION study suggest that for screen-detected diabetes cases, intensive diabetes control did not significantly decrease the number of cardiovascular events beyond what has been achieved with standard care (Griffin et al. 2011). However, improvements in standard care over the study period may have resulted in small differences in patient care between the study groups. Notably, intensive glycemic control did not result in increased mortality risk – an effect that had been observed among patients with more advanced diabetes (Gerstein et al. 2008). As previously mentioned, thus far no randomized studies have compared screened and unscreened individuals with regard to long-term health benefits. The ongoing ADDITION-Cambridge study (Echouffo-Tcheugui et al. 2009) may shed more light on this question.

Despite uncertainties regarding the effectiveness of screening programs, a large body of literature has been published on screening techniques for undiagnosed diabetes. For an overview of the literature, the reader should refer to reviews on this topic (Echouffo-Tcheugui et al. 2009; Waugh et al. 2007). Point-of-care testing for FPG or HbA_{1c} is simple and convenient, but – as was discussed earlier in this chapter – they are unlikely to detect all prevalent diabetes cases. The 2hPG value is considered more reliable for diagnosing diabetes, but it requires an 8-h fast, commitment from the patient and the nursing staff, and has lower test-retest reproducibility compared with other tests. There is also a growing body of literature on risk scores that do not require blood sampling (Echouffo-Tcheugui et al. 2011). Although none of these tools are optimal in detecting undiagnosed diabetes, they have acceptable validity and are particularly useful tools to screen populations for further glucose screening.

Screening for diabetes cases at baseline and during follow-up has also been common practice in many analytical epidemiological studies. However, as pointed out earlier, screening at a single time point can produce a substantial number of false-positive screens, particularly when 2hPG is used. Because the diagnosis of diabetes requires confirmation in a subsequent assessment, screen-positive study participants should be considered to be potential cases but not necessarily true cases. While this approach allows to include undiagnosed cases, particularly the subgroup with isolated elevated 2hPG levels, the misclassification might in fact bias relative risk calculations and might lead to an overestimation of absolute risk. In contrast, other studies used only self-reported clinical cases. This approach will miss undiagnosed cases which can only be detected through screening and who can be expected to be on average younger than clinical cases. Also, clinical cases will frequently exclude asymptomatic diabetes cases with isolated elevated 2hPG levels since this criterion is not commonly used in clinical practice. Thus, studies based only on self-reported diabetes are likely to underestimate absolute risk and may not represent specific subgroups of cases adequately. While both approaches have pros and cons, the prevalence of undiagnosed diabetes cases in studies based on verified self-reports will not bias estimates of relative risk if this misclassification is non-differential with regard to exposure status (Greenland and Lash 2008). In general, it is, therefore, more relevant to invest in increasing the specificity of the case definition (by verification) than its sensitivity (by additional screening). Still, if studies are also required to accurately reflect absolute risks and to represent all patient subgroups, screening based on all diagnostic parameters and confirmation of screen-detected cases would need to be included.

There is a growing interest in developing prediction models for incident diabetes. Glucose screening could be used as a method to detect individuals at high risk with intermediate states of abnormal glucose regulation that precede overt type 2 diabetes. Impaired fasting glucose (FPG 100 or 110–125 mg/dL/5.6 or 6.1–6.9 mmol/L), impaired glucose tolerance (2hPG 140–199 mg/dL/7.8–11.0 mmol/L), or elevated HbA_{1c} (5.7–6.4%) have been used widely in this context to define a "prediabetic" status (Table 60.1). A meta-analysis of prospective studies conducted in different populations estimated that the relative risk for diabetes compared to normoglycemic individuals was 6.35 in people with impaired glucose tolerance, 5.52 in people with isolated impaired glucose tolerance, 4.66 in people with impaired fasting glucose, 7.54 in people with isolated impaired fasting glucose, and 12.13 in people with both impaired fasting glucose and impaired glucose tolerance (Gerstein et al. 2007). Despite demonstrating a clear increase in risk, dichotomizing glucose values as either "normal" or "prediabetic" neglects the continuum of risk associated with higher values. For example, a steady increase in diabetes risk has been observed for FPG values well within the range considered normal (Schulze et al. 2010b; Tirosh et al. 2005). Although current guidelines still include categories of prediabetes (Table 60.1), it is well established that risk is continuous, extending below the lower limit of the range for prediabetes and becoming disproportionately greater at the upper end of the range (American Diabetes Association 2011).

As an alternative to individual measures of blood glucose or HbA$_{1c}$, prediction models involving several diabetes risk factors hold significant promise for identifying those at high risk of developing type 2 diabetes. While several, moderately accurate diabetes prediction models have been developed based on risk factor information, there is evidence to suggest that these models could be improved with the addition of biochemical markers, in particular those reflecting hyperglycemia (Schmidt et al. 2005; Schulze et al. 2009). However, adding more complex markers of glucose and insulin metabolism, novel diabetes risk markers (such as CRP or adiponectin), or genetic information does not seem to further improve diabetes prediction. For a detailed review of prediction models, the reader should refer to Buijsse et al. (2011).

60.10 Conclusions

Similar to cardiovascular disease, overweight and obesity, diet, and lifestyle are predominant risk factors for type 2 diabetes. Diabetes epidemiology, therefore, shares important characteristics with other chronic disease epidemiology fields. Methodological developments to reduce misclassification in assessing dietary and lifestyle risk factors are of central interest to all fields of chronic disease epidemiology. Meanwhile, it is important to minimize confounding through improved study design and statistical analysis. Existing prospective cohort studies have increasingly been used for diabetes epidemiology although they may have initially been started as cancer epidemiology studies, e.g., the Nurses' Health Study or the European Prospective Investigation into Cancer (EPIC) study. The case-cohort study design for the evaluation of biochemical and genetic markers has increasingly been used to investigate type 2 diabetes and cardiovascular endpoints simultaneously to improve cost-efficiency. Recent advances in molecular and genetic epidemiology are of relevance to diabetes epidemiology, as they are to other fields.

Diabetes epidemiology also faces specific challenges. The definition of endpoints is heterogeneous across studies due to different diagnostic parameters and study-specific follow-up procedures. Based on current methodology, the misclassification of endpoints is almost unavoidable in diabetes epidemiology. This issue has also substantial implications for the estimation of population-level diabetes prevalence and incidence rates.

Diabetes epidemiology has played an essential role in demonstrating the importance of risk factors and the potential for prevention. The role of overweight and obesity in the etiology of type 2 diabetes has been demonstrated by numerous observational studies, and this link has also been causally established by intervention studies that focus on weight reduction among high-risk individuals. Physical activity, specific components of the diet, smoking, and other lifestyle factors have also been implicated in the development of diabetes. Overall, the majority of type 2 diabetes cases in the general population is attributable to modifiable diet and lifestyle factors.

These findings have had important implications for public health initiatives. For example, the International Diabetes Federation prevention plan for type 2 diabetes is based on controlling modifiable lifestyle risk factors. The plan divides the population into two groups that should be targeted simultaneously: people at high risk of developing type 2 diabetes (high-risk approach of prevention) and the remaining population (population-wide approach of prevention) (Alberti et al. 2007). Similarly, European guidelines for the prevention of type 2 diabetes have highlighted lifestyle modifications as key elements, both in high-risk and population-wide prevention approaches (Paulweber et al. 2010).

Accurate tools used to quantify absolute risk are essential for establishing programs that target high-risk individuals. The field of diabetes epidemiology has developed a number of tools that frequently outperform similar prediction tools used in the fields of cardiovascular or cancer epidemiology. Therefore, identifying high-risk groups seems a feasible task for diabetes interventions. However, the changes required to reduce the risk of diabetes at the population level are unlikely to be achieved without major environmental changes to facilitate appropriate choices by individuals.
