Confounding occurs when the exposed and non-exposed subpopulations of the source population have different background disease risks. When we make a comparison of the frequency of disease in the exposed and non-exposed groups, we would ideally wish to be able to assume that the disease frequency in the non-exposed group provides a valid estimate of what the disease frequency would have been in the exposed group if it had not been exposed. If this assumption is incorrect, that is, if the exposed and non-exposed groups would have had different disease frequencies in the counterfactual situation in which the exposed group had not been exposed, then we say that the comparison of the exposed and non-exposed groups is confounded. A related concept is that the exposed and non-exposed group are not "exchangeable," in that the estimated effects would have been different if the exposed group had not been exposed and the non-exposed group had been exposed (i.e., if the exposure status of the subjects had been exchanged).

Interaction usually means that the exposure effect on disease risk varies by some other factor. In other words, in order to estimate the effect of exposure, we must first know whether or not another factor is present (or the level of this other factor). This idea turns out to subsume two separate concepts: *effect-measure modification* (statistical interaction) and *biological interaction*. When considering an exposure that has an effect, all other causal factors will modify either the rate ratio or the rate difference, and uniformity over one measure implies non-uniformity over the other, for example, an apparent additive joint effect implies a departure from a multiplicative model. Effect-measure modification is algebraically equivalent to the definition of "interaction" used in most statistics books and programs; it refers to variation in a population measure of effect and corresponds to the need for a product term in a model. In contrast, biological interaction refers to effects in individuals; for purely causal factors, its absence implies absence of risk-difference modification, for example, if there is no biological interaction between causal factors A and B, then the risk difference due to factor A will be independent of whether or not factor B is present or absent, and vice versa.

In the simple case of a dichotomous main exposure (e.g., asbestos exposure), a dichotomous health outcome (e.g., lung cancer), and another categorized exposure (e.g., smoking vs. non-smoking), assessment of confounding involves stratifying on the potential confounder and assessing whether the stratum-specific effect estimates are similar to the (crude) overall effect estimate. For example, we may ask "how close are the relative risks in smokers and non-smokers (or a summary of these stratum-specific effect estimates) to the relative risk estimated when smoking is ignored?" In contrast, assessment of effect-measure modification involves assessment of how the stratum-specific effect estimates compare with each other, for example, how does the relative risk in smokers compare with the relative risk in non-smokers? Effect-measure modification is thus often confused with confounding because in this simple situation they are both assessed by stratification. However, confounding and interaction are completely different concepts. A factor may be a source of confounding or effect-measure modification, or both, or neither.

19.1 Introduction

Over recent decades recognition has grown that the conventional statistical models used to analyze epidemiological data cannot be reasonably claimed to be correct in the way most textbooks treat them to be. In particular, conventional models for epidemiological data-generating processes cannot be credibly taken to represent targets of primary scientific interest. For example, a logistic model for the regression of an observed disease indicator on covariate measurements would only rarely correspond closely to the causal effects on disease of the risk factors represented by the measurements. The discrepancies between the statistical model parameters and the underlying target effects are often called systematic errors, biases, or bias sources. Large biases undermine the interpretation of both frequentist statistics (such as confidence intervals) and Bayesian statistics (such as posterior intervals).

The present chapter provides an overview of one useful family of approaches to analyzing and adjusting for bias that cannot be controlled by familiar stratification or regression adjustments on measured variables. It provides basic descriptions of familiar bias problems in the case of binary variables in 2 × 2 tables, with some simple illustrations. It then provides discussions of the bias problem in terms of statistical theory, compares ordinary sensitivity analysis to probabilistic bias analysis, and concludes by considering when these analyses might be helpful or essential.

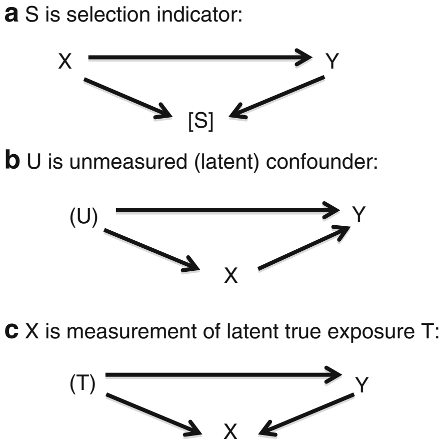
An introduction to basic Bayesian concepts (e.g., Greenland 2008 and chapter ▶Bayesian Methods in Epidemiology of this handbook) is helpful in understanding concepts of bias analysis before reading the present chapter. More extensive coverage and examples of basics including computational details can be found in Fox et al. (2005), Greenland and Lash (2008), Greenland (2009a), and Lash et al. (2009), with software implementations in Steenland and Greenland (2004, appendices), Fox et al. (2005), Orsini et al. (2008), and Lash et al. (2009), while general theories can be found in Vansteelandt et al. (2006) and Greenland (2005, 2009b), among others. Throughout, variables will be denoted by capital letters, while unspecified values for a variable will be denoted by lowercase letters; for example, X may represent an exposure variable in which case x will represent a possible but unspecified value for X.

19.2 Fundamentals of Methodological Biases in 2 × 2 Table Analysis

Table 19.1 displays data on mother's report of antibiotic use during pregnancy (coded $X = 1$ yes, 0 no) and subsequent sudden infant death syndrome (SIDS, coded $Y = 1$ yes, 0 no) from a multicenter case-control study (Kraus et al. 1989); a plus sign ("+") in a subscript indicates summation over that subscript. Given the rarity of SIDS, the population risk ratio (relative risk) comparing newborns exposed to antibiotics in utero to those unexposed is approximated by the corresponding

Table 19.1 Data from case-control study of SIDS (Kraus et al. 1989). X indicates maternal recall of antibiotic use during pregnancy, and Y indicates SIDS ($Y = 1$ for cases, $Y = 0$ for controls). A plus sign ("+") in a subscript indicates summation over that subscript

	$X = 1$	$X = 0$	Totals
$Y = 1$	$A_{+11} = 173$	$A_{+01} = 602$	$A_{++1} = 775$
$Y = 0$	$A_{+10} = 134$	$A_{+00} = 663$	$A_{++0} = 797$



a S is selection indicator:
X
Y
[S]
b U is unmeasured (latent) confounder:
(U)
Y
X
c X is measurement of latent true exposure T:
(T)
Y
X

Fig. 19.1 Causal diagrams for three basic bias structures; *parentheses* indicate variable is unmeasured (unobserved), and *brackets* indicate observations are conditional on the variable

population odds ratio. If there were no bias, we could take this odds ratio OR_{XY} or its log, $\beta_{XY} = \ln(OR_{XY})$, as the target parameter.

The usual maximum-likelihood estimate (MLE) of $OR_{XY} = \exp(\beta_{XY})$ is the sample odds ratio $\widehat{OR}_{XY} = 173(663)/134(602) = 1.422$, with standard error for $\widehat{\beta}_{XY} = \ln(\widehat{OR}_{XY})$ of $(1/173+1/602+1/134+1/663)^{1/2} = 0.128$ and 95% confidence limits (CL) for $OR_{XY} = \exp(\beta_{XY})$ of $\exp\{\ln(1.422) \pm 1.96 \cdot 0.128\} = 1.11, 1.83$. Were there no bias, such results might be interpreted as providing an inference that OR_{XY} is above 1 but below 2. Nonetheless, experienced epidemiologists know better than to make this interpretation without cautions about common sources of bias: selection bias, uncontrolled confounding, and misclassification. As is traditional, the term "selection bias" will refer to non-random (differential or systematic) non-response and loss as well as non-random selection into the analysis.

Figure 19.1 shows the simplest representations of these three bias sources using causal directed acyclic graphs (causal diagrams), in which the arrows represent direct effects of one variable on another. With S denoting the selection indicator, the selection-bias problem (Fig. 19.1a) can be described by saying that we see the relation of X to Y conditional on $S = 1$ but we want to see that relation unconditionally (without regard to S). The confounding problem (Fig. 19.1b) can be described by saying that we see the unconditional relation of X to Y but we want to see that relation conditional on U. The misclassification problem (Fig. 19.1c) can be described by saying that we see the relation of X to Y but

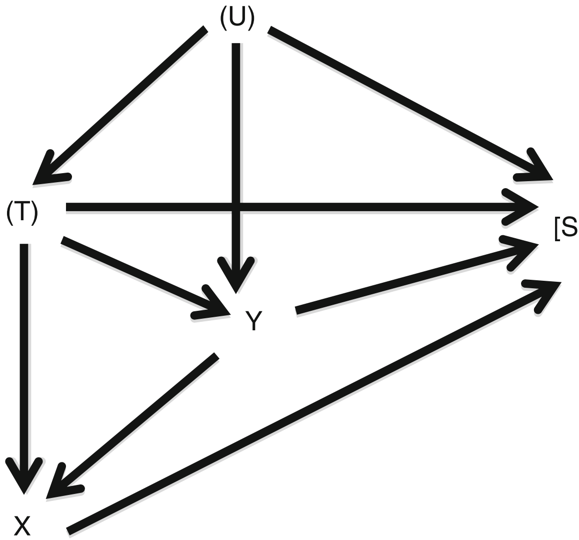


Fig. 19.2 Causal diagram combining selection, confounding, and measurement

Table 19.2 Imputed complete-population data table from SIDS study when S indicates selection into study, N_{xy} = population total with $X = x, Y = y$, and $\pi_{sxy} = \Pr(S = s|X = x, Y = y)$. Column totals form the target table

	$X = 1$		$X = 0$	
	$Y = 1$	$Y = 0$	$Y = 1$	$Y = 0$
$S = 1$	$173 = N_{11}\pi_{111}$	$134 = N_{10}\pi_{110}$	$602 = N_{01}\pi_{101}$	$663 = N_{00}\pi_{100}$
$S = 0$	$N_{11}\pi_{011}$	$N_{10}\pi_{010}$	$N_{01}\pi_{001}$	$N_{00}\pi_{000}$
Totals	$N_{11} = 173/\pi_{111}$	$N_{10} = 134/\pi_{110}$	$N_{01} = 602/\pi_{101}$	$N_{00} = 663/\pi_{100}$

we want the relation of T to Y unconditionally (without regard to X). More realistic situations involving combinations of these biases can also be represented, as in Fig. 19.2, which combines all three problems. Such diagrams are recommend as a preliminary to algebraic and statistical analyses, for they can reveal biases and assumption violations that might otherwise go undetected (Glymour and Greenland 2008; Pearl 2009; see also chapter ▶Directed Acyclic Graphs of this handbook).

Tables 19.2–19.4 display the corresponding data representations of these problems when the variables are binary, using count tables to show the target table (i.e., the unobserved structure of the target population). From these tables we can draw parallels and highlight differences among the three bias situations in Fig. 19.1:

(a) For selection bias (Fig. 19.1a and Table 19.2), we are interested in the unconditional relation of X to Y unconditional on selection S. But because we see only the relation of X to Y conditional on selection ($S = 1$), we must impute the unconditional relation of X to Y using probabilities of selection given what we do see (X and Y given $S = 1$).

(b) For confounding (Fig. 19.1b and Table 19.3), we are interested in the relation of X to Y conditional on U. But because we do not see U, we must impute its values using probabilities (bets) about the values of U given what we do see (again, X and Y).

(c) For misclassification (Fig. 19.1c and Table 19.4), we are interested in the unconditional relation of the true exposure T to the outcome Y so that if we saw T, we could discard X and just look at the TY association. But because we do not see T, we must impute its values using probabilities (bets) about the values of T given what we do see (again, X and Y).

In all three cases, we need a set of four probabilities to complete the three-way table of the three variables in the graph. These probabilities are denoted by π_{1xy} in Tables 19.2–19.4, where they correspond to probabilities of $S = 1$, $U = 1$, or $T = 1$ given the observed X and Y. We need only these four probabilities because the corresponding probabilities of $S = 0$, $U = 0$, or $T = 0$ are $\pi_{0xy} = 1 - \pi_{1xy}$. Using these probabilities, Table 19.2 displays the complete distribution of those unselected as well as those selected, while Tables 19.3 and 19.4 display the complete distribution of the observed subjects under confounding and misclassification.

Were these complete distributions known, we could compute our target parameter directly from them. But they are not known with certainty, and the best we can do

Table 19.3 Imputed complete-data table from SIDS study when U is an unmeasured confounder and $\pi_{uxy} = \Pr(U = u|X = x, Y = y)$. This table is the target table

	$X = 1$		$X = 0$	
	$Y = 1$	$Y = 0$	$Y = 1$	$Y = 0$
$U = 1$	$A_{111} = 173\pi_{111}$	$A_{110} = 134\pi_{110}$	$A_{101} = 602\pi_{101}$	$A_{100} = 663\pi_{100}$
$U = 0$	$A_{011} = 173\pi_{011}$ $= 173 - A_{111}$	$A_{010} = 134\pi_{010}$ $= 134 - A_{110}$	$A_{001} = 602\pi_{001}$ $= 602 - A_{101}$	$A_{000} = 663\pi_{000}$ $= 663 - A_{100}$
Totals	173	134	602	663

Table 19.4 Imputed complete-data and target tables from SIDS study when T indicates actual antibiotic use during pregnancy and $\pi_{txy} = \Pr(T = t|X = x, Y = y)$

(a) Complete data

	$X = 1$		$X = 0$	
	$Y = 1$	$Y = 0$	$Y = 1$	$Y = 0$
$T = 1$	$A_{111} = 173\pi_{111}$	$A_{110} = 134\pi_{110}$	$A_{101} = 602\pi_{101}$	$A_{100} = 663\pi_{100}$
$T = 0$	$A_{011} = 173\pi_{011}$ $= 173 - A_{111}$	$A_{010} = 134\pi_{010}$ $= 134 - A_{110}$	$A_{001} = 602\pi_{001}$ $= 602 - A_{101}$	$A_{000} = 663\pi_{000}$ $= 663 - A_{100}$
Totals	173	134	602	663

(b) Target table (complete data collapsed over X):

	$Y = 1$	$Y = 0$
$T = 1$	$A_{1+1} = 173\pi_{111} + 602\pi_{101}$	$A_{1+0} = 134\pi_{110} + 663\pi_{100}$
$T = 0$	$A_{0+1} = 173\pi_{011} + 602\pi_{001}$ $= 775 - A_{1+1}$	$A_{0+0} = 134\pi_{010} + 663\pi_{000}$ $= 797 - A_{1+0}$
Totals	$A_{++1} = 173 + 602 = 775$	$A_{++0} = 134 + 663 = 797$

is try to adjust our inferences using any relevant background information, such as information about the π_{1xy}, their combinations, or their components. This process is sometimes called *external* or *indirect* adjustment and is a core component of bias analysis.

19.2.1 Formulas for Selection Bias

Simplifications may arise depending on the available information, assumptions, and the target parameter. For example, in the selection-bias problem, the usual case-control target would be the population XY odds ratio OR_{XY} (the odds ratio unconditional on S), but the observed sample odds ratio, $\widehat{OR}_{XY|S=\mathit{1}}$, only estimates the odds ratio among those selected, $OR_{XY|S=1}$. The selection bias in $\widehat{OR}_{XY|S=\mathit{1}}$ relative to the population OR_{XY} is thus $\text{Bias}_{S=\mathit{1}} = \pi_{111}\pi_{100}/\pi_{110}\pi_{101} = OR_{XY|S=\mathit{1}}\big/OR_{XY}$. This bias equation suggests the following approximate estimating equation to adjust $\widehat{OR}_{XY|S=\mathit{1}}$ for selection bias:

$$\begin{aligned} OR_{XY} = N_{11}N_{00}/N_{10}N_{01} &\approx [(173/\pi_{111})(663/\pi_{100})]/[(134/\pi_{110})(602/\pi_{101})] \\ &= (173 \cdot 663)/(134 \cdot 602)/(\pi_{111}\pi_{100}/\pi_{110}\pi_{101}) \\ &= \widehat{OR}_{XY|S=\mathit{1}}/\text{Bias}_{S=1}. \end{aligned}$$

The approximation of chief statistical concern arises from substituting sample numbers for population numbers.

The equation shows that we need information on only one number, $\text{Bias}_{S=1}$, rather than all four selection probabilities π_{1xy}. $\text{Bias}_{S=1}$ might be estimated as the ratio of estimates without and with information from initial non-responders on whom data was later obtained ("call-back survey" information) from studies reporting such information (e.g., Hatch et al. 2000). Even with such information, however, concerns about generalization across studies must be addressed by considering how differences between the study populations may have affected response and selection.

19.2.2 Formulas for Confounding

Suppose there is no selection bias (so that $OR_{XY|S=1} = OR_{XY}$). Consider first the odds ratio $OR_{XY|U=1}$ in the $U = 1$ stratum (which is free of confounding by U). The bias in $\widehat{OR}_{XY}$ relative to $OR_{XY|U=1}$ is $\text{Bias}_{U=1} = \pi_{110}\pi_{101}/\pi_{111}\pi_{100} = OR_{XY}/OR_{XY|U=1}$. Table 19.3 then suggests the following approximate estimating equation to adjust $\widehat{OR}_{XY}$ for confounding by U:

$$\begin{aligned} OR_{XY|U=1} &\approx [A_{111}A_{100}]/[A_{110}A_{101}] \\ &= [(173\pi_{111})(663\pi_{100})]/[(134\pi_{110})(602\pi_{101})] \\ &= (173 \cdot 663)/(134 \cdot 602)/(\pi_{110}\pi_{101}/\pi_{111}\pi_{100}) \\ &= \widehat{OR}_{XY}/\text{Bias}_{U=1} \end{aligned}$$

A parallel formula can be written for $OR_{XY|U=0}$. To simplify analysis, however, it is usually assumed that the odds ratio is a constant $OR_{XY|U}$ across U ($OR_{XY|U=0} = OR_{XY|U=1} = OR_{XY|U}$, called the odds-ratio *homogeneity* assumption). In that case, $\text{Bias}_{U=1}$ is also the bias in $\widehat{OR}_{XY}$ relative to $OR_{XY|U=0}$, $\text{Bias}_{U=0} = \pi_{010}\pi_{001}/\pi_{011}\pi_{000} = OR_{XY}/OR_{XY|U=0}$, and both can be written as $\text{Bias}_U = OR_{XY}/OR_{XY|U} \approx \widehat{OR}_{XY}/OR_{XY|U}$. Thus, to adjust $\widehat{OR}_{XY}$ toward the constant U-specific odds ratio $OR_{XY|U}$, we need only information on one number, Bias_U, rather than all four confounder-prevalence probabilities π_{1xy}.

Suppose now that the target parameter what the effect of exposure would be on the entire population (often called the total-population or *marginal* effect of exposure). Evidence suggests that estimation of $OR_{XY|U}$ is not sensitive to heterogeneity (violations of homogeneity) in typical epidemiological settings in which the disease is uncommon and neither the XY effect nor the heterogeneity is large (Greenland and Maldonado 1994). Nonetheless, the assumption should be considered critically in any application, especially if the target parameter is the effect in a subpopulation (such as the exposed). Given the assumption, we still must estimate Bias_U. The relation $\text{Bias}_U = OR_{XY}/OR_{XY|U}$ suggests using the ratio of estimates without and with U adjustment from studies reporting such estimates; again however concerns about generalization across studies must be addressed.

The above formulation was derived for only one binary confounder U and an unadjusted $\widehat{OR}_{XY}$. Nonetheless, it extends directly to multiple confounders of any form and to situations involving a partially adjusted initial estimate (e.g., an initial estimate adjusted for age and sex but not smoking habits). This can be done by allowing $\widehat{OR}_{XY}$ to represent the partially adjusted estimate and Bias_U to represent the ratio $OR_{XY|partial}/OR_{XY|full}$ between a partially adjusted measure $OR_{XY|partial}$ and a fully adjusted measure $OR_{XY|full}$; this ratio can be estimated from reports or data providing estimates with both degrees of adjustment.

19.2.3 Sensitivity Analysis and Probabilistic Bias Analysis

The process of seeing how results change under different choices for a bias parameter (such as Bias_S or Bias_U) is often called a *sensitivity analysis*. When the focus is on the degree of bias implied by each parameter choice, the process is sometimes called *bias analysis*. The term "sensitivity analysis" is also used more broadly to include examination of the impact of any change in the statistical model, such as varying the model for the regression or random error; such model-sensitivity analysis is a large topic in econometrics and engineering (Leamer 1978, 1985; Saltelli et al. 2000) but is not covered here.

For selection bias or confounding, a sensitivity analysis might comprise nothing more than noting that, based on other data, the bias factor seems likely to fall in range, e.g., 0.80–1.33, and then displaying the adjusted point estimates for bias factors in this range. But it is not clear how to gauge or combine the uncertainty this range represents with the conventional statistics. One naïve approach would expand the confidence limits of 1.11, 1.83 in the SIDS example using the extremes of the bias range, to produce limits of 1.11/1.33 = 0.83 and 1.83/0.80 = 2.29. As shown below, this approach tends to overstate the uncertainty because it combines only the extremes of bias and random error, ignoring that in the majority of possible combinations at least one of bias and random error is small or that in half the cases the two would be in opposite directions. For example, random error is just as likely to partially counterbalance bias as add to it.

These preceding observations suggest that more modest combinations of bias and random error are more probable than extremes, an intuition that is captured mathematically in *probabilistic bias analysis*, and which is also treated under related topics such as uncertainty assessment and risk analysis (Eddy et al. 1992; Lash and Fink 2003; Phillips 2003; Steenland and Greenland 2004; Greenland 2001, 2003, 2005; Greenland and Lash 2008; Lash et al. 2009; Turner et al. 2009). As a simple example, one might specify a *prior probability* that the bias factor Bias_U for confounding by U falls in a stated range like 0.80, 1.33, typically 95%. The term "prior" signals that the assigned probability may be nothing more than an educated bet based on available relevant literature, although it could be based on detailed analysis of other studies. Regardless, one can use standard lognormal formulas to combine the bias uncertainty seen in this interval and the uncertainty from random error represented by the standard error or confidence interval.

Specifically, suppose the range 0.80, 1.33 were taken to represent the 2.5th and 97.5th percentiles of a lognormal prior-probability distribution ("prior") for Bias_U. Uncertainty about $\ln(\mathrm{Bias}_U)$ would then follow a normal distribution, with mean m_U the average of the log limits: $\mathrm{m}_U = [\ln(1.33) + \ln(0.80)]/2 = 0.0310$. We can subtract this mean bias m_U from the log odds-ratio estimate $\hat{\beta}_{XY} = \ln(\widehat{OR}_{XY})$ to get a bias-adjusted estimate of

$$\hat{\beta}_{XY} - m_U = \ln(1.422) - 0.0310 = 0.320.$$

The prior standard deviation would be the width of the log-bias interval $\ln(1.33) - \ln(0.80) = 0.508$ divided by the number of standard deviations in its width, which is $2 \cdot 1.96 = 3.92$ for a normal 95% interval. We then square this ratio to get the prior log-bias variance: $v_U = (0.508/3.92)^2 = 0.0168$. This bias variance is then added to the estimated random variance $v_R = 0.128^2 = 0.0164$ of $\ln(\widehat{OR}_{XY})$ to get a total variance $v_+ = v_R + v_U = 0.0164 + 0.0168 = 0.0332$. Finally, we compute an approximate bias-adjusted 95% *posterior probability* interval

$$\exp\{0.320 \mp 1.96(0.0332)^{1/2}\} = [0.96, 1.97].$$

This interval is more narrow than in the extreme-adjusted interval of [0.83, 2.29] but is still noticeably wider than the original confidence interval [1.11, 1.83] (as well as being shifted downward by a small amount).

To adjust for selection bias in addition to confounding, we could repeat the above process by specifying a selection-bias interval, converting that to a prior mean m_S

and variance v_S for $\ln(\text{Bias}_{S=1})$, then computing the posterior interval from the adjusted estimate $\hat{\beta}_{XY} - m_S - m_U$ and the total variance $v_R + v_S + v_U$. This extension assumes that the confounding and selection bias are independent, which would not be the case in the situation depicted in Fig. 19.2, where everything including U directly affects selection S.

The above log-linear approach to selection bias and confounding appears simple in concept but raises the question of how one can justify assigning a particular prior distribution to the bias factors. One way is to base the interval estimate for $\text{Bias}_U = OR_{XY}/OR_{XY|U}$ or $\text{Bias}_{S=1} = OR_{XY}/OR_{XY|S=1}$ seen upon adjustment in a past study, then use that interval for the current adjustment (Greenland and Mickey 1988; Greenland 2003). More often however such direct bias information is not readily available or is not considered generalizable from its source.

19.2.4 Confounding Parameters

The confounding bias factor Bias_U can be expressed as a function of the confounder distribution along with measures of the association of the confounder with exposure and disease (Kitagawa 1955; Cornfield et al. 1959; Bross 1966, 1967; Schlesselman 1978; Breslow and Day 1980, Sect. 3.4; Yanagawa 1984; Gail et al. 1988; Flanders and Khoury 1990; Schneeweiss 2006; VanderWeele and Arah 2011). For example, under homogeneity the odds-ratio bias Bias_U can be written

$$\text{Bias}_U = (1 + \theta \cdot OR_{UX|Y} \cdot OR_{UY|X})(1 + \theta)/(1 + \theta \cdot OR_{UX|Y})(1 + \theta \cdot OR_{UY|X})$$

where $\theta = \pi_{100}/\pi_{000} = \pi_{100}/(1 - \pi_{100})$ is the odds of $U = 1$ when $X = Y = 0$, $OR_{UX|Y}$ is the constant UX odds ratio given Y, and $OR_{UY|X}$ is the constant UY odds ratio given X (Yanagawa 1984). It can happen that there is some generalizable background information to place priors on these three bias parameters even though there is no direct information about Bias_U. For example, if the exposure ($X = 1$) and disease ($Y = 1$) are uncommon in the general population, then the prevalence π_{100} can be estimated from population survey data on U. If the exposure is rare or its effect on Y is "weak" ($0.5 < OR_{XY|U} < 2$), then we may expect $OR_{UY|X}$ to be similar to OR_{UY}, and OR_{UY} may be available from earlier studies.

The preceding approach assumes that U is a known confounder (e.g., a smoking indicator) that was unmeasured in the study in question but has been previously identified and subject to study in relation to disease if not exposure. If instead U represents an unspecified, unknown confounder, then the entire sensitivity exercise will remain far more speculative. Nonetheless, decomposition of the bias factor can still be successful in demonstrating that only implausibly strong confounder or selection effects can account for a strong observed association. Cornfield et al. (1959) is considered a landmark study in which such an approach was used to examine claims that the smoking-lung cancer relation might be attributable to confounding.

One approach to expanding intervals to account for uncertainties about multiple bias parameters is *Monte Carlo sensitivity analysis* (MCSA, also known as Monte Carlo risk analysis) which is based on taking random draws for each component parameter in the bias adjustment. There are many ways to proceed. One simple approach assigns prior distributions to $\text{Bias}_{S=1}$, θ, $OR_{UX|Y}$, and $OR_{UY|X}$ (which may be dependent) and a normal sampling distribution to the unadjusted log odds ratio $\hat{\beta}_{XY}$ with mean equal to the point estimate ln(1.422) and standard deviation equal to $v_R^{1/2} = 0.128$. We then cyclically generate thousands of draws from each of these distributions. Let $\text{Bias}^*_{S=1}$, θ^*, $OR^*_{UX|Y}$, $OR^*_{UY|X}$, $\hat{\beta}^*_{XY}$ be the values drawn in one such cycle. At each draw we compute a Bias^*_U from θ^*, $OR^*_{UX|Y}$, and $OR^*_{UY|X}$ and then compute $\hat{\beta}^*_{adj} = \hat{\beta}^*_{XY} - \ln(\text{Bias}^*_{S=1}) - \ln(\text{Bias}^*_U)$. We may then create a histogram of the adjusted estimates from this simulation and take the 2.5th and 97.5th percentiles of the distribution of $\hat{\beta}^*_{adj}$ so generated as a simulated 95% posterior interval for the *XY* log odds ratio β_{XY}.

An alternative "bootstrap" approach to incorporating random error is to resample (with replacement) the entire data set at each cycle and recompute $\hat{\beta}^*_{XY}$ from the resampled data. This can work well with large cell counts but may slow computation considerably and may require complex corrections in small or sparse data sets in order to account for zero cells and other problems (Efron and Tibshirani 1994).

The posterior-interval interpretations given above are approximate and assume implicitly that there is no prior information on any parameter other than the bias parameters $\text{Bias}_{S=1}$, θ, $OR_{UX|Y}$, and $OR_{UY|X}$. This assumption is not realistic in practice because (apart from genes) few studies are the first to examine a given association. As a consequence, some authors call the resulting interval a "simulation interval" without specifying a statistical meaning for the interval (e.g., Lash et al. 2009). Nonetheless, a much more severe criticism applies to the conventional 95% confidence interval: It is routinely interpreted as a posterior interval for the target parameter $OR_{XY|U}$, yet this interpretation is based on the same assumption of no prior information about this target, along with the extremely unrealistic assumption that there is no bias at all (which would be represented by priors for $\text{Bias}_{S=1}$ and Bias_U that are point masses at 1).

If one wishes to employ informative priors for parameters other than the bias parameters, it will be necessary to switch to a penalized-likelihood or explicitly Bayesian analysis format in order to correctly interpret the resulting intervals as posterior probability intervals (Joseph et al. 1995; Graham 2000; Gustafson et al. 2001, 2010; Scharfstein et al. 2003; Steenland and Greenland 2004; Gustafson 2003, 2005; Chu et al. 2006; McCandless et al. 2007, 2012; Greenland 2005, 2009a, b; Molitor et al. 2009; Turner et al. 2009; Welton et al. 2009). The traditional alternative, ordinary sensitivity analysis, avoids this complication by simply displaying results for various choices of bias parameters (Copas and Li 1997; Rosenbaum 2002; Brumback et al. 2004), but can become unwieldy if the number of bias parameters is more than three (as will happen when misclassification is addressed).

For those seeking to avoid explicit prior distributions, the dimensionality problem may be addressed by estimating regions of compatibility between the data and the parameters of interest given the random-error model and sharp bounds for the bias parameters (Vansteelandt et al. 2006). These regions generalize confidence intervals to account for the bias parameters. Nonetheless, sharp bounds for the bias parameters are needed to construct the regions, and it is not clear why they provide a less arbitrary solution to the problem than do prior distributions, since the results are just as sensitive to choice of bounds as to choice of priors (Greenland 2009b).

19.3 Bias Formulas for Misclassification

Misclassification adjustment is usually much more difficult than others, in part because the target parameter is the association (such as the odds ratio OR_{TY}) between the completely unobserved true exposure indicator T and Y, not X and Y. Its complexity is sometimes overlooked, in part because it appears that the problem can be solved by simply dividing $\widehat{OR}_{XY}$ by the bias factor $\text{Bias}_M = OR_{XY}/OR_{TY}$ to adjust for the misclassification.

Unfortunately, unlike with selection bias and confounding, the bias-factor approach is not widely useful for misclassification adjustment. First, although the bias factor could be estimated as the ratio of estimates of OR_{XY} and OR_{TY} from studies reporting both estimates, such reports are very uncommon. Second, even when an estimate of Bias_M is available, there are exceptional concerns about generalization across studies: Bias_M can be highly sensitive to the prevalence of true exposure ($T = 1$), this prevalence may vary greatly across populations, and the extent of variation may be highly uncertain because exposure prevalence may have never been reported without misclassification.

19.3.1 Formulas Based on Sensitivity and Specificity

The aforementioned problems have led the misclassification literature to focus on quantities that are more often published and more transportable (generalizable) than bias factors. Let $\phi_{xty} = \Pr(X = x|T = t, Y = y)$. The *sensitivities* of X for T are then the ϕ_{11y} and the *specificities* are ϕ_{00y}, which are sometimes studied in themselves to inform later uses of X as a measurement of T. For example, patient recall of medical events or treatments (X) is often compared to medical record information (T). The latter information is of course imperfect and is quite subject to error regarding, for example, use of drugs but may be accurate enough for other exposures (e.g., implanted devices or drug *prescriptions*) to be cautiously treated as the truth or "gold standard" for those exposures. The non-differentiality assumption (independence of X and Y given T) then corresponds to $\phi_{xty} = \Pr(X = x|T = t, Y = y) = \Pr(X = x|T = t)$ so that sensitivities and specificities remain constant across Y ($\phi_{111} = \phi_{110}$ and $\phi_{001} = \phi_{000}$).

Sensitivities and specificities are often called “true positive rates” and “true negative rates,” respectively. In parallel, the complements of sensitivities and specificities,

$$\Pr(X = 0|T = 1, Y = y) = \phi_{01y} = 1 - \phi_{11y} \text{ and}$$
$$\Pr(X = 1|T = 0, Y = y) = \phi_{10y} = 1 - \phi_{00y}$$

are often called the “false-negative rates” and “false-positive rates,” respectively. Note that X being a perfect measurement of T ($X = T$) corresponds to perfect sensitivity and specificity ($\phi_{11y} = \phi_{00y} = 1$) as well as to perfect T prediction ($\pi_{11y} = \pi_{00y} = 1$).

Given a set of values for the ϕ_{xty}, we can estimate the four desired TY counts A_{t+y} from the observed XY counts A_{+xy} by solving a system of four equations (one for each X, Y combination) giving each observed XY count A_{+xy} as the sum of those with $T = 1$ and those with $T = 0$ who contribute to the count:

$$\begin{aligned} \text{observed count} = A_{+xy} &\approx \phi_{x1y}A_{1+y} + \phi_{x0y}A_{0+y} \\ &= \phi_{x1y}A_{1+y} + \phi_{x0y}(A_{++y} - A_{1+y}) \\ &= (\phi_{x1y} - \phi_{x0y})A_{1+y} + \phi_{x0y}A_{++y} \end{aligned}$$

provided all the solutions are positive. The solutions are $A_{1+y} = (A_{+xy} - \phi_{x0y}A_{++y})/(\phi_{x1y} - \phi_{x0y})$, which lead to an adjusted TY odds ratio collapsed (summed) over X:

$$\begin{aligned} \widehat{OR}_{TY} = &[(A_{+11} - \phi_{101}A_{++1})(A_{+00} - \phi_{010}A_{++0})]/ \\ &[(A_{+01} - \phi_{011}A_{++1})\ (A_{+10} - \phi_{100}A_{++0})]. \end{aligned}$$

This formula does not simplify to a simple direct adjustment to $\widehat{OR}_{XY}$ and shows that without further assumptions, we need to know four parameters to adjust for the misclassification.

Background information on the four classification parameters may sometimes be found in *validation studies*, which examine the accuracy of X as a measure of T. If the validation study is a substudy of the study under analysis (internal validation), one can and should analyze its TXY data together with the main XY data using special methods. Those methods may be viewed as missing-data techniques because with a validation substudy T becomes a partially missing variable (Little and Rubin 2002; Carroll et al. 2006), and thus may be handled by methods as simple as multiple imputation (Cole et al. 2006). A key assumption for these techniques however is that T is missing at random (MAR), which is satisfied if subjects with T measurement are a random sample of subjects within each level of the observed variables.

If the validation data are from outside the study under analysis (external validation), uncertainty about generalizability must be considered, although the validation data can help one specify a prior distribution for the classification parameters (which are bias parameters). Again, it appears that estimates of sensitivities and specificities (ϕ_{11y} and ϕ_{00y}) are more safely generalized than estimates of T-predictive probabilities (π_{1xy}) because the latter depend directly on the T distribution, which is unobserved in the analysis data and thus has unknown discrepancy from the T distribution in the validation data. An alternative approach is to use background information on sensitivities and specificities to help specify components of the π_{1xy}. This approach will be illustrated below.

19.3.2 Probabilistic Analysis Based on Sensitivity and Specificity Priors

One may parallel the earlier simulation analysis by setting priors on the sensitivities and specificities and sampling from these priors and the random errors to generate a simulation histogram of $\widehat{OR}_{TY}$ (Lash and Fink 2003; Lash et al. 2009; Fox et al. 2005; Greenland and Lash 2008). Unfortunately there are several complications that arise due to the more complex structure of misclassification adjustments. First, some combinations of ϕ_{1ty} allowed by the priors may lead to negative (and thus impossible) values for the imputed TXY counts. Such combinations are said to be *inadmissible*. If the priors chosen for the ϕ_{1ty} allow a non-negligible probability for inadmissible combinations, the resulting simulation intervals will no longer agree well with the correct Bayesian posterior intervals, whether or not the inadmissible values are discarded (Greenland 2005; MacLehose and Gustafson 2012).

Second, independent priors for the ϕ_{1ty} are grossly unrealistic. A large source of negative correlation between sensitivity and specificity is the stringency of criteria used to declare $X = 1$ (as an indicator of $T = 1$), with more stringency leading to lower sensitivity and higher specificity, and less stringency leading to higher sensitivity and lower specificity. A source of positive correlation is that use of more accurate measurement methods to create X (e.g., direct measurements) can increase both sensitivity and specificity compared to less accurate methods (e.g., self-reports). These sources of correlation need not balance to zero.

Of even greater concern, case and non-case sensitivity and specificity will be very highly positively correlated. If as usual the same method is used for measurement of cases and non-cases, the proper "null" reference point is not independence, but is instead its positive opposite, non-differentiality ($\phi_{\mathrm{xt1}} = \phi_{xt0}$). Non-differentiality implies complete dependence (and thus 100% correlation) between case and non-case sensitivity and specificity (although complete dependence is not sufficient to produce non-differentiality). For the same reasons, realistic priors for the T-predictive probabilities π_{txy} will also be highly correlated.

It is possible to construct dependent priors to account for such correlation sources, although specifying the correlations can be difficult. See Fox et al. (2005) and Greenland and Lash (2008) for details and examples.

19.3.3 Probabilistic Analysis Based on Predictive-Value Components

The predictive approach is familiar in validation-study analysis (Lyles 2002) but is also a useful alternative to using direct priors for sensitivity and specificity, because it can use instead parameters that have no admissibility restrictions and for which prior independence may not be such a severely distortive assumption (Greenland 2009a). To this end, we recast the T-predictive probabilities π_{1xy} in terms of a logistic model:

$$\pi_{1xy} = \Pr(T = 1|X = x, Y = y) = \text{expit}(\beta_T + \beta_{TX}x + \beta_{TY}y + \beta_{TXY}xy)$$

where $\text{expit}(z) = e^z/(1 + e^z)$, which can be rewritten as the odds model:

$$\begin{aligned}\pi_{1xy}/\pi_{0xy} &= \Pr(T = 1|X = x, Y = y)/\Pr(T = 0|X = x, Y = y)\\ &= \exp(\beta_T + \beta_{TX}x + \beta_{TY}y + \beta_{\mathrm{TXY}}\mathrm{xy}).\end{aligned}$$

The odds ratio relating T and X when $Y = y$ is then seen to be

$$\begin{aligned}OR_{TX|Y=y} &= (\pi_{11y}\pi_{00y})/(\pi_{10y}\pi_{01y}) = (\pi_{11y}/\pi_{01y})/(\pi_{10y}/\pi_{00y})\\ &= \exp(\beta_{TX} + \beta_{TXY}y).\end{aligned}$$

Some algebra shows that (by the usual symmetry property of odds ratios), $OR_{TX|Y=y}$ also equals $\phi_{11y}\phi_{00y}/\phi_{10y}\phi_{01y}$, which is the product of sensitivity and specificity divided by the product of false-positive and false-negative rates. This ratio is the *receiver-operating characteristic* (ROC) odds ratio; it measures the quality of X as an indicator of T, being infinite when X is perfect and 1 when X is completely worthless.

Assuming a rare disease (so that the odds ratio among non-cases $OR_{TX|Y=0}$ approximates the odds ratio OR_{TX}), a prior for $\beta_{TX} = \ln(OR_{TX|Y=0})$ can be based on expectations for the population sensitivity and specificity via the relation $OR_{TX|Y=0} = \phi_{110}\phi_{000}/\phi_{100}\phi_{010}$. For X to be a high-quality indicator of T, this ROC odds ratio must be very large (Pepe et al. 2004). For example with sensitivity 0.6 and specificity 0.8 among non-cases, $OR_{TX0} = \exp(\beta_{TX}) = (0.6/0.4)/(0.2/0.8) = 6$; 0.6 and 0.9 yield (0.6/0.4)/(0.1/0.9) = 13.5; 0.8 and 0.8 yield (0.8/0.2)/(0.2/0.8) = 16; and 0.8 and 0.9 yield (0.8/0.2)/(0.1/0.9) = 36. Thus, even for a mediocre measurement (with sensitivity of only 0.6 and specificity of only 0.8) the *TX* odds ratio among non-cases, $OR_{TX0} = \exp(\beta_{TX})$ is 6 indicating that a prior for β_{TX} should be distributed well above zero. The preceding numeric examples would be encompassed by a lognormal prior for OR_{TX0} with median 13.5 (in the center of the examples) and 95% limits of 5 and 36, which translates to a normal prior with mean ln(13.5) and variance 0.25 for β_{TX}

Table 19.5 A set of independent normal prior distributions for the coefficients in the logistic regression of T on X and Y in the antibiotic-SIDS example

	Mean	Variance	95% prior limits for
β_T	logit(0.1)	0.16	$\pi_{100} = \text{expit}(\beta_T)$: 0.05, 0.20
β_{TX}	ln(13.5)	0.25	$\exp(\beta_{TX})$: 5, 36
β_{TY}	0	0.50	$\exp(\beta_{TY})$: 0.25, 4
β_{TXY}	0	0.125	$\exp(\beta_{TXY})$: 0.5, 2

The ratio of ROC odds ratios is $\text{ROR}_{TX} = OR_{TX|Y=1}/OR_{TX|Y=0} = \exp(\beta_{TXY})$, which is a summary measure of how much better (if over 1) or worse (if under 1) X is as a T indicator among cases compared to non-cases. Under non-differential misclassification, β_{TXY} is 0 and $\exp(\beta_{TY})$ equals the target parameter OR_{TY} (although $\beta_{TXY} = 0$ is not sufficient to produce non-differentiality or $\exp(\beta_{TY}) = OR_{TY}$). Thus, unless severe non-differentiality is expected, it is reasonable to use a prior for β_{TXY} that is concentrated near zero, for example, a normal prior with mean 0 and variance 0.125, which produces 95% prior limits for ROR_{TX} of 0.5 and 2. Likewise, it would be reasonable to use a prior for β_{TY} that is similar to but somewhat wider than what would be considered a reasonable prior for the target log odds ratio $\ln(\text{OR}_{TY})$, for example, a normal prior with mean zero and variance 0.5, which produces 95% prior limits for $\exp(\beta_{TY})$ of 0.25 and 4.

In settings where recall bias is expected (differences in case and non-case recall), it is important to not be deceived into thinking such bias alone implies that ROR_{TX} is above or below 1 (β_{TXY} above or below 0). In the example in Table 19.1, the traumatic event of SIDS may trigger both true and false recall, increasing sensitivity (which increases ROR_{TX}) as well as decreasing specificity (which decreases ROR_{TX}). The net result is that uncertainty about β_{TXY} should be more symmetrically distributed around 0 than naïve reasoning might suggest.

Finally, note that $\text{expit}(\beta_T) = \pi_{100} = \Pr(T = 1|X = 0, Y = 0)$ is the probability that a "test negative" ($X = 0$) in a non-case is erroneous. For an exposure with an expected prevalence well below 50% (as was antibiotic use in unselected pregnancies during the study period) and a reasonably sensitive measure X of T, we should concentrate our prior distribution for π_{100} well below 0.5, which forces the prior for $\beta_T = \text{logit}(\pi_{100})$ to be well below 0. An example would be a normal prior with mean for β_T with mean $\text{logit}(0.1) = -2.20$ and variance 0.16, which produces 95% prior limits for π_{100} of 0.05 and 0.20.

Table 19.5 summarizes the independent normal priors suggested above for the logistic predictive-value coefficients β_T, β_{TX}, β_{TY}, β_{TXY}, which are also consistent with the limited background information about the antibiotic-SIDS relation at the time (Kraus et al. 1989). These can be used in a Monte Carlo sensitivity analysis in which at each cycle:

1. All counts are resampled from Table 19.1.
2. β^*_T, β^*_{TX}, β^*_{TY}, and β^*_{TXY} are drawn from their priors and used to compute the π^*_{txy}.
3. These π^*_{txy} are multiplied against the resampled counts to get a simulated TXY table, as in Table 19.4a.

4. The TXY table is collapsed over X, and $\widehat{OR}^*_{TY}$ is computed from the resulting TY table (Table 19.4b).

After 250,000 repetitions of sampling cycle 1–4, the 2.5th and 97.5th percentiles of the resulting $\widehat{OR}^*_{TY}$ distribution are 0.37 and 3.4, with a median of 1.2. Various Bayesian calculations with non-informative priors on all parameters besides β_T, β_{TX}, β_{TY}, and β_{TXY} yield similar results (Greenland 2009a, b). These results show that the precision of the conventional 95% confidence limits of 1.1, 1.8, if interpreted as an interval for OR_{TY}, is due to its assumption that X is a perfect measurement of $T(X = T$, i.e., $\pi_{11y} = \pi_{00y} = 1$ or $\phi_{11y} = \phi_{00y} = 1)$. The expansion of the 95% interval for OR_{TY} to [0.37, 3.4] further suggests that the data add little information about OR_{TY} beyond that conveyed by the priors.

The simple simulation analysis just described can be extended to allow for selection bias and confounder adjustment (both measured and unmeasured) as well as for misclassification, although it can become quite unwieldy due the number of bias parameters and data cells involved (Greenland 2005). Unfortunately, it does not extend easily to situations in which all parameters (not just bias parameters) are given priors, whereas Bayesian computation has no such difficulty.

19.4 Pointwise Versus Probabilistic Analysis

While basic sensitivity or bias analyses are widely accepted and even promoted, there are difficulties if not objections to arbitrary elements in the priors are needed for probabilistic extensions (such as prior shape, e.g., normal vs. beta vs. trapezoidal). These difficulties are understandable given the lack of neutral and accepted conventions for these elements.

To address these elements, the analysis may be repeated using different identifying distributions and the results from different choices tabulated and contrasted. This process is called *prior sensitivity analysis*. Sensitivity analyses that instead directly vary bias parameters (*pointwise analyses* or deterministic analyses) are the special case of prior sensitivity analysis in which the varied priors are limited to point-mass priors (which assign 100% probability to just one value for the parameter).

From this viewpoint, pointwise analyses are of limited value compared to full probabilistic sensitivity analysis. Their main limitation is that they provide no explicit accounting for uncertainty about the bias parameters (Greenland 1998, 2005; Gustafson et al. 2001). The point-mass priors implicit in these analyses have no scientific justification given the uncertainty inherent in the parameters and do not escape the arbitrariness problem because they are based on a range of bias-parameter variation that is itself arbitrary. Too broad a range will lead to inclusion of values that would be recognized by subject experts as misleadingly absurd (e.g., a smoking prevalence of 90% in a general population), while too narrow a range will exclude important possibilities that cannot be ruled out. It is thus worthwhile to use genuine background information to create credible or plausible priors, or at least to specify the values used in a pointwise analysis.

In accounting for background information, there is a need to avoid giving that information more weight than it is worth, in recognition of the generalization problems touched on earlier. In particular, prior distributions should not be too narrow (incautious), lest our results remain overconfident. Of special note is that confidence intervals from other studies do not account for generalization problems and thus are too narrow to be used directly as prior intervals; at the very least, their probability percentage would need to be reduced below the original confidence percentage. For example, a 95% confidence interval for an effect from one study (even a perfect trial) should not be accorded 95% probability of containing the effect in another study, since generalization should reduce our confidence that the interval contains the latter effect.

Even with attention to such details, what appear to be cautious priors to one analyst may appear incautious to another. An ideal solution would allow each analyst to plug in their own priors and repeat the procedure, thus making the audience an active participant in sensitivity analysis. Macros and spreadsheets allowing such a solution have been offered (Steenland and Greenland 2004; Fox et al. 2005; Orsini et al. 2008; Lash et al. 2009); in principle these do not require audience access to the data, so confidentiality can be assured. Similar extensions to model-sensitivity analysis and influence analysis are also possible (e.g., by re-specifying external constraints on inclusion and exclusion criteria).

19.5 Some Theoretical Considerations for General Bias Analysis

This section concerns general formulations that come into play in analyzing more complex data and in multiple-bias modeling (Greenland 2005, 2009b; Vansteelandt et al. 2006; Molitor et al. 2009). It presumes some familiarity with mathematical statistics and may be skipped by less theoretical readers.

For the purposes of basic bias analysis of a single data set, the following definitions can be useful. A parameter in a data-generating model is *fully identified* by a system of estimating equations for the model parameters if the parameter is constant over the set of solutions to the system. More generally, a function of the model parameters is *fully identified* by the equations for the model parameters if the function maps the solution set to a unique value. At the opposite extreme, the function is *not identified* by the equations if it maps the solutions onto its entire range. Thus, in the confounding example (Table 19.3), the target parameter is not identified by its estimating equation $OR_{XY|U} \approx \exp(\widehat{\beta}_{XY})/\text{Bias}_U$, because given XY data with a finite $\widehat{\beta}_{XY}$ (and no further constraint), there is a solution for every possible value r of $OR_{XY|U}$; one merely chooses the bias parameters to make $\text{Bias}_U = \exp(\widehat{\beta}_{XY})/r$.

Between the extremes of full and no identification, a function is *partially identified* by the equations if it maps solutions to a proper subset of its range but not to a unique value. In bias settings this usually means the solutions are mapped into a subset of the range of reduced but positive dimension, although it may also or instead mean that the image of the solutions is sharply bounded inside the function range. The entire model is *non-identified* if some function of its parameters is only partially identified. An *identification problem* exists if the target parameter is not fully identified, for that means multiple possible values for that parameter arise from solutions to the estimating equations.

These are data-dependent definitions and so oriented toward likelihood and Bayesian analysis; they are modified for asymptotic sampling theory since non-identification whose probability goes to zero with increasing sample size can be ignored in that theory. Regardless, identification problems are traditionally solved by introducing artificial, arbitrary constraints (such as no bias for the target parameter) that at most have justification in a very narrow range of real circumstances (e.g., randomized trials with perfect compliance and no loss) and may be generalized only in very limited ways (e.g., to generalized linear semi-parametric models like Cox proportional hazards regression).

A common example is the assumption of *no residual selection bias or confounding* (often referred to as "no uncontrolled selection bias or confounding" although the terminology varies considerably). This condition corresponds to an ignorability condition that selection for analysis and treatment assignment are randomized conditional on the regression covariates, making selection and assignment independent of the potential outcomes that compose the target effect parameter (the ignorability being *strong* or *weak* according to whether it refers to joint or component-wise independence of potential outcomes and treatment assignment). Coupled with the assumption that the regression model is correct, the regression model for Y then coincides with the structural equation for Y (the Y-potential-outcome function), and further confounding concerns are obviated; unbiased conditional-effect estimation then reduces to the familiar problem of unbiased estimation of the regression of Y on treatment and the covariates. Alternatively, assuming instead correct models for selection and treatment-assignment probabilities, the fitted models for these probabilities can be used to estimate marginal effects (as in inverse-probability-weighting methods).

A problem with this traditional approach (of forcing identification through no-residual bias assumptions) is that it generates highly overconfident inferences: Confidence intervals so derived fail to cover the target near the nominal rate, and posterior intervals are far too narrow given the actual amount of external information available. This overconfidence follows from forcing unknown bias parameters to equal unique values, which takes no account of the huge uncertainty surrounding those parameters.

To reflect this uncertainty properly, Leamer (1974, 1978) and many others recommended instead one begin with non-identified models, and then examine the impact of augmenting the estimating functions with contextually based parameter constraints (Graham 2000; Gustafson et al. 2001; Greenland 2003, 2005, 2009a, b; Gustafson 2003, 2005). Those constraints are in turn derived from a *prior distribution* or *penalty function* for some or all of the parameters. If one allows for the fallibility of these contextual inputs, bias analysis then serves chiefly as an antidote or diagnostic to counterbalance the overconfident results from the conditionally randomized model. The conditionally randomized model remains a simple if doubtful reference point, arguably a necessary convention given the enormous number of prior distributions that would identify the target parameter.

Randomization assumptions correspond to prior distributions that assign positive probability to only a proper subspace of the non-identified parameters (making the priors degenerate with respect to the bias-parameter space). In the selection-bias example, random sampling corresponds to no association of X with S, which occurs in the subspace defined by $\pi_{s1y} = \pi_{s0y}$; in the confounding example, randomization induces no association of U with X, which occurs in the subspace defined by $\pi_{u1y} = \pi_{u0y}$. More generally, no net bias ($\text{Bias}_{S=1} * \text{Bias}_U * \text{Bias}_M = 1$ in the example) constrains all bias parameters to a manifold of much lower dimension than the entire bias-parameter space. Realistic priors rarely entail any such dimension reduction, even when they concentrate near lower-dimensional manifolds, and thus reveal the source of overconfidence from traditional identifying assumptions.

19.6 Conclusions

The present chapter has addressed settings in which a "correct" model for the data generation can never be known or approximated, and hence the data cannot tell us whether we are close to or far from the target, even probabilistically. In these settings, we cannot guarantee that inferences from a posterior distribution will be superior to inferences from our prior alone (Neath and Samaniego 1997). Thus, the importance of specific models and priors is de-emphasized in favor of providing a framework for sensitivity analysis across plausible models and priors. This framework need not be all-encompassing, because often just a few plausible specifications can usefully illustrate the illusory nature of an apparently conclusive conventional analysis.

When inference is mandated in these settings (as in pooled analyses to advise policy), we must admit we can only propose models that incorporate or are at least consistent with facts as we know them and that all inferences are completely dependent on these modeling choices (including non-parametric or semi-parametric inferences). There will be an infinite number of such models, and they will not all yield similar inferences, necessitating some sort of sensitivity analysis to provide a picture of the problem unless the effects in question are so large as to be obvious (as is typically the case in disease outbreaks).

In this task statistical modeling provides only inferential possibilities rather than inferences. Any analysis should thus be viewed as part of a sensitivity analysis which depends on external plausibility considerations to reach conclusions (Greenland 2005, 2009b; Vansteelandt et al. 2006). Results from single models are merely examples of what might be plausibly inferred, although just one plausible inference may suffice to demonstrate inherent limitations of the data.

Whatever their value for summarization, conventional models treat unknown parameters as if known and thus do not satisfy plausibility considerations. These unknowns include many bias parameters that can be forced to their null by successful design strategies but are probably not null in most observational settings. The use of prior distributions can provide more plausible inferences by allowing expansion of conventional models to include bias parameters as unknowns.

In any given observational context, progress beyond prior-based analyses can be made only by obtaining data from a study design that pins down a previously unknown bias parameter. Examples of such designs include studies with successful randomization, highly accurate measurement, or that have isolated a controversial effect in a setting where the effect is so large as to exceed plausible bias magnitudes. Because such designs are often infeasible (e.g., in the electromagnetic field-childhood cancer controversy), proper construction and use of prior distributions should become a component of statistical training for observational research.

Despite these considerations, there is no basis for mandating a bias analysis of every study or even most studies. For example, bias analysis is superfluous when conventional intervals show that no useful conclusion could be drawn from the study even if it were perfect apart from random error. More generally, rather than providing a bias analysis, a study may provide greater service by refraining from inference; instead it can focus on carefully reporting its design, conduct, and data in great detail to facilitate pooling and meta-analysis (Greenland et al. 2004). Inferences are best based on a more complete account of evidence than can be provided in a single study report, and thus the effort of bias analysis is more justifiable in research synthesis (Turner et al. 2009; Welton et al. 2009). Even there, bias analysis becomes essential only when doing risk assessment or when authors claim to offer near-definitive conclusions.

20.1 Introduction

Routine data are data collected continuously or at least repeatedly with some time intervals. They are collected in various ways, e.g., registration by the health services or by interviews with patients or population groups. The data could then be stored and administered in register format. Health registers contain data on persons with diseases or health-related events. The coverage can vary from a total registration to a population sample and from national to regional or local coverage. Data can be routinely collected for various reasons, from economic and administrative purposes to more strict epidemiological purposes.

We have limited our review to registers that allow individuals to be followed up. Such registers are routinely available in the Nordic countries, but also increasingly elsewhere. Most data in such registers contain event-based records, but registration of events with personal identification numbers or other identifiers allows observation of the health event sequences for each individual by using record linkage. Identifiers also make it possible to remove duplicate reports on the same events as well as add subsequent follow-up data later on. Anonymous data and statistical information have some value especially for descriptive epidemiological purposes, but the real value of register-based information systems depends on the possibility for record linkages.

This chapter is outlined in the following way. First, a presentation of registers will be made including types of registers, organization, contents, and variables in the registers as well as the quality of registers. Second, analytical options for register-based studies will be presented followed by examples of the usefulness and discussions on potentials and limitations of different designs. The ethical questions of privacy, autonomy, and confidentiality will also briefly be discussed.

20.2 Types of Registers

Most health registers can be classified into four basic categories: administrative registers, disease registers, reimbursement registers, and quality registers. Administrative registers record events that are needed for administrative, typically statistical purposes, and they cover, e.g., causes of death, births, hospital discharges, and population characteristics. Disease registers contain data related to some specific disorder, such as cancer or diabetes. Reimbursement registers compile monetary records such as health insurance claims, health-related social benefits, or reimbursable purchases of prescription drugs. Quality registers are collected in order to audit or to follow up treatment procedures and outcomes of care. An early example of quality register is the registry for total hip replacement surgery in Sweden which started in 1979 (Kärrholm 2010).

The most widespread and well-known registers are the causes of death and cancer registers. Most countries in the world have causes of death registers, mostly based on total registration, but in some cases on a sample of deaths, e.g., covering only deaths occurring in hospitals. Cancer registers are also frequently used around the world. In several countries, it is mandatory for the physician and other health care personnel to report all patients with diagnosed malignant neoplasms.

Medical birth registers are common in many countries, though not as widespread as the causes of death and cancer registers. All Nordic countries have introduced a separate medical birth register for detailed collection of parturients, deliveries, and newborns (Gissler et al. 1997; Gissler 2010). The registration covers both hospital births and planned or unplanned births outside hospitals. The follow-up extends usually until the child is discharged from the hospital or latest until the end of perinatal period, i.e., the first week of living. Information on deaths, however, can cover the whole infant period until 1 year of age. In addition, the register on congenital anomalies and birth defects is usually closely linked to the medical birth register, either as a separate register or as a part of the medical birth register.

Discharge registers are also common and typically contain data on inpatient hospitalizations with diagnoses and treatments of the patient. From an epidemiological point of view, these registers may be more difficult to interpret since traditionally they have captured only those patients who require inpatient admission. Currently, also outpatient hospital visits are increasingly recorded in many countries, but different care practices and strategies heavily affect whether patients with the same disease or medical condition are hospitalized or treated in outpatient settings in primary care.

Several countries have also introduced a national database to register prescription drugs (Furu et al. 2010). National prescription registers contain data on drugs dispensed at pharmacies to people receiving ambulatory care. Nordic countries include all prescribed and dispensed medication, excluding Finland, which registers only medication covered by the national health insurance system (currently 99% of prescribed medications). Over-the-counter (OTC) drugs and drugs dispensed elsewhere than in pharmacists, e.g., hospitals and outpatient clinics, are excluded in all prescription registers. The largest limitation with the Nordic prescription registers is the lack of information on the indication or diagnosis for the use of medicine. Finally, the data are based on purchases of medication, and there is no information if the medicine was actually taken or not. Also, information on the use of old drugs, other people's drug, or use of drugs purchased in other countries remains unregistered.

Besides these main types of health registers, there are also many local research registers covering other disease groups like cardiovascular and psychiatric diseases. An increasing phenomenon is the development of quality registers. In Sweden, there are up to 100 national quality registers covering treatment procedures and outcomes for different disease groups or medical interventions (Swedish Local Authorities and Regions 2011). New data sets or registers have also been created by record linkages, the most common ones being linkages between the population censuses and other available health registers to gather information on special disease, such as diabetes (Sund and Koski 2009; Carstensen et al. 2011). Registers can also be used to follow a cohort for a long time, and these ad hoc registers are administered by research groups. But these research registers cannot usually be considered as routinely collected or permanent registers, as the national health registers kept by the authorities. The purposes and epidemiological applications for these linkages will be presented later on in this chapter.

Countries with lacking disease registers can use data from health insurance systems as a basis for epidemiological research. These data can cover routinely collected notifications on sickness absence of employees or health outcomes of the insured population. One problem is that insurance systems and insured populations usually vary in many aspects, which may create bias and limit their comparability. Validity may also be impaired due to the fact that these data are generated for administrative purposes. Diagnoses and treatments may be influenced by aspects related to payments and accounting. Another problem is that the insurance registers are not always accessible because of strict interpretation of confidentiality legislation and rules.

In the following, we have mainly restricted our presentation to the five most common registers, i.e., causes of death, cancer, birth, prescription, and hospital discharge registers.

20.3 Organization of Registries

According to the IEA dictionary of epidemiology (Last 1988), the term "register" is applied to the file of data that can be related to a population base, i.e., the actual document, while the registry is the system of ongoing registrations. The organization of registries and collection of data differ from country to country, but they have always some basic governmental or other public funding. In most countries, the registries are organized within a governmental body such as national statistical offices, national boards of health, or public health institutes. Many disease registers, such as cancer registries, have more or less close links to disease-related societies from where they also can get a part of their funding.

The Nordic countries have a long tradition of collecting data in health registers (Table 20.1). They employ epidemiological registers of high quality covering the whole population. The causes of death have been registered in Sweden since 1751 (computerized from 1952), while the oldest cancer register in Denmark dates back to 1943. The registers of congenital malformations were established in Finland and Sweden in 1963–1964 as an early warning system and as a direct response to the thalidomide catastrophe. Norway was the first to start a nationwide medical birth

Table 20.1 Starting years for computerized nationwide health register data in Nordic countries

Register	Denmark	Finland	Iceland	Norway	Sweden
Hospital discharges/inpatient care	1977	1967	2001	2007	1987
Outpatient hospital/ambulatory care	1995	1998	2005	2007	2001
Birth	1973	1987	1982	1967	1973
Cancer	1943	1953	1955	1952	1958
Prescription	1994	1994	2006	2004	2005
Causes of death	1970	1971	1981	1951	1952

register in 1967. It includes information on mothers and children, e.g., diagnoses, birth weight and height, operations as well as maternal tobacco and drug use during pregnancy. In Finland, all hospital discharges have been recorded since 1967 and outpatient care in public hospitals since 1998. In Denmark, inpatient care has been recorded since 1977 and ambulatory care since 1995. The National Hospital Discharge Register covers all publicly run inpatient care in Sweden from 1987, and data on hospital outpatient care has been collected from 2001. The value of these registers grows continuously as time passes.

The routine registers may not always be optimal for research purposes. If the register is run by a statistical authority, there may be strict limitations, as to whether or how much register personnel are allowed to use their time in scientific research. It has proven useful to dedicate scientifically qualified staff to run the register (Jensen and Whelan 1991), since these people have a research interest in the data. When the register data are good enough for scientific research, they normally also are guaranteed to be very good for routine statistical production. Moreover, the dedicated personnel are very useful in helping other researchers with the data use by knowing the strengths and weaknesses and the most relevant method issues. In many countries, e.g., in Finland, the existence of such personnel has been guaranteed, e.g., for cancer research (Finnish Cancer Registry 2011). The Finnish Cancer Registry is a research organization specialized in statistics and studies, making use of the nationwide cancer register in Finland. In Sweden, the National Board of Health and Welfare is responsible for several other health registers in addition to the cancer register (EpC 2003). These research organizations have a multidisciplinary scientific staff consisting of epidemiologists, statisticians, physicians, social scientists, computer scientists, etc.

It is necessary to have legislation on the registration. In the Nordic countries, the existence of the health registers and the way they are run with responsibilities, rights, and obligations is based on laws. It is also important to have secured funding and the core scientific and clerical staff on permanent funding. The knowledge required for register keeping and the scientific work cannot possibly be maintained on short-term project funding contracts only.

In countries with numerous registers, it may be difficult for researchers to find all the data and get access to them. Therefore, infrastructure supporting and promoting register-based research has been established: The National Center for Register-based Research in Denmark was established in 2000, the Finnish Information Center for Register Research (ReTki) in 2003, and the European Center for Register-Based Health-Related Population Research (ECREPH) in Denmark in 2008.

20.4 Personal Identification Number and Other Variables in the Registers

A necessity in registers with data on individuals is a unique identity, usually in forms of a personal identification number (PIN) or a social security number (SSN). If the same PIN system is used in all data sources, it is possible to make deterministic record linkages within and between data from different registers and other sources of

Table 20.2 Common variables in health data registers in the Nordic countries

Register	Variables
Causes of Death Register	PIN (personal identification number), age, sex, place of residence, date and place of death, underlying cause of death, nature of the injury, contributing causes of death, autopsy (clinical or forensic)
Cancer Register	Name, PIN, age, sex, place of residence, site of tumor, histological type, basis of diagnosis, date of diagnosis, reporting hospital and department, and reporting pathology/cytology department
Medical Birth Register	Mothers' and live-born children's PINs, maternal sociodemographic background, previous pregnancies and deliveries, maternal diagnoses, care and interventions during pregnancy and delivery, and information on newborn health, diagnoses, care and interventions
Hospital Discharge Register/Patient Register	PIN, sex, age, place of residence, date of admission, date of discharge, acute/planned admission, main and secondary diagnoses, external cause of injury and poisoning, surgical procedures, and hospital/department These registers are in some countries enlarged to also include outpatient visits at hospitals.
Prescription Register	PIN, age, sex, and place of residence, prescriber, prescribing and dispensing date of the drug, Anatomical Therapeutic Chemical classification (ATC) code, amount in defined daily doses (DDD), and pharmacy details

relevant data. Some countries have to rely only on names, birth dates, and addresses as the identifier which can cause some bias and creates practical problems for follow-up as only probabilistic linkages can be performed.

The use of PINs in Nordic systems has created large data banks that are invaluable to the research community, since the data do not have to be collected from scratch but can be linked with PINs. For example, an (fictional) example of a Finnish personal identity code (PIC) is 131052-308T, where six first digits correspond to date of birth (day, month, and two last digits of the year), separator shows the century (+ for 1800, – for 1900, and A for 2000), number consisting of three next numbers distinguish persons with the same date of birth from each other and is even for women and odd for men, and the last digit is check digit calculated by modulo-31 algorithm (PRC 2011). The Finnish PIC was introduced and appointed to all living residents during 1960s and has a smart and informative structure adopted from the Swedish version (Ludvigsson et al. 2009) but improved with the excellent check digit algorithm. Virtually, everyone knows their own date of birth which means that they also remember their PIC without extra efforts and check digit as well as odd/even sex rule help to accept only valid PICs during registration.

Other common variables usually collected in the Nordic health registers are sex, age, and residential area of the individual (Table 20.2). The cause of death register usually includes data on underlying and contributory causes of death, place and date of death, and basis of cause certification. For the cancer registers, data on tumors, date of diagnosis, histological type, reporting department, hospital and pathology/cytology department, etc., are available. Medical birth registers generally include data on sex, weight, length, size of head, analgesia, birth conditions and operations of the children, but also data on the mother's previous gestation, smoking habits, and, in Sweden, also drugs taken during pregnancy. Hospital discharge registers include data on main and secondary diagnoses, external cause of injury and poisoning, surgical procedures, date of admittance and discharge, length of stay, and hospital and clinical department. Except operations, there are in general few or no data on type of interventions during hospital stay.

20.5 The Quality of Data in Registers

Register data have not been collected primarily for certain specific research design or study questions, and the quality and validity of routinely collected data can hardly be as consistent as for those obtained in clinical trials where predefined criteria for data collection are used. In fact, the validity of the data obviously depends on the intended use (Sørensen et al. 1996).

Most of the numerous validity studies of health registers have evaluated the quality from the epidemiological perspective and in general detected relatively good completeness of registration and validity of variables in the registers. For example, cancer registration in the Nordic countries is based on compulsory reports from all physicians and all pathologists, in both public and private administration. One Swedish study from the 1980s estimated the deficit in cancer registration to be 4.5% and less than 2% when the diagnosis had been histologically verified (Mattsson 1984). A Finnish study showed good coverage for solid tumors, but a roughly 10% underregistration for benign neoplasms of the central nervous system, chronic lymphatic leukemia, and multiple myeloma (Teppo et al. 1994). Technical quality control procedures are usually applied by cancer registries, e.g., the computers are programmed to detect invalid codes, inconsistent combinations of codes, duplicate registrations, and illogical time sequences. Examples of inconsistent combination of codes are testis cancer in a female and distant metastasis associated with carcinoma in situ. This kind of quality control reduces some types of errors but cannot deal with missing data or false primary diagnoses. Some cancers will never be diagnosed during the lifetime of individuals but may occur on the death certificate after an autopsy. Thus, changes and differences in autopsy rates between time periods and regions may affect the validity of cancer registration. The increase in incidence of prostate cancer during the last decade is to a large extent due to extensive PSA tests rather than a real increase in incidence (Tretli et al. 1996; Walsh 2002).

The accuracy of diagnoses in the causes of death registers varies considerably depending on the age of the deceased, underlying and contributing diseases and depending on practice variations among physicians and coders. In general, fatal diseases where the deceased has been treated for some time before death have good accuracy of diagnoses, e.g., most cancers and ischemic heart disease. The autopsy rates are usually higher for younger people and accidents, which makes this group of diagnoses quite reliable. A general problem in many cause of death registers are, however, the declining autopsy proportions (Lindström et al. 1997). In Sweden, the overall autopsy proportion was about 41% in 1980 and about 13% in 2009. In addition, it is known that there are variations in classification procedures by country (Percy and Muir 1989), and also regional variations within a country should be interpreted with caution due to potential practice variations.

Most of the variables in the Nordic Medical Birth Registers have been reported to have good or at least satisfactory validity (Gissler et al. 1997), and a systematic reviews of validity studies of Finnish and Swedish inpatient registers concluded that validity is high for many but not all diagnoses (Ludvigsson et al. 2011; Sund 2012). For example, about 6% of those with a diagnosis of acute myocardial infarction in the Swedish inpatient register had a false positive diagnosis, while 3% were false negative, i.e., should have had an acute myocardial infarction as the main diagnosis but had some other diagnosis in the register (Rosén et al. 2000). The underreporting in Swedish inpatient register has been estimated to be less than 2% for somatic short-term care. In 2001, personal identification numbers were missing in 0.4% of number of stays, and the main diagnosis was missing in 0.9% of the stays reported from Swedish hospitals. Such biases can be considered minor in epidemiological studies that contain hundreds of thousands of cases.

If validity needs to be evaluated for other than basic epidemiological purposes, it may require a much more complicated approach. For example, if there is not any obvious definition for the good quality of variable, several substantially different values can be considered technically equally good, or the quality requirements may be conditional on other available information, it is typically a good idea to prepare a conceptual model mapping the available variables explicitly to their theoretical counterparts and use such a model as a framework for the actual validity analyses (Sund et al. 2007).

In addition to specific validation studies, a reasonable criterion of quality of a register is also the common use of its data in scientific studies as each properly performed study should have been critical in the use of register-based data. Nordic health registers seem to fulfil this criterion as there are, in addition to specific validation studies for each register, thousands of published scientific articles based on data from these registers.

20.6 Methodological Approaches to Register-Based Data Analysis

If register-based study is compared to a standard scientific inquiry, the most important difference is that register data are of secondary nature, i.e., collected for other purpose(s) than the specific research question in hand (Cartwright and Armknecht 1980). This changes the nature of traditional empirical research process so that measurement and related data collection cannot be tailored to meet the exact needs or best practices available for certain well-defined research question, but one needs to opportunistically use the available data. The limitations of secondary data are determined by the choices made while producing data, such as a decision to collect only easily available data and using fixed classifications in the data production

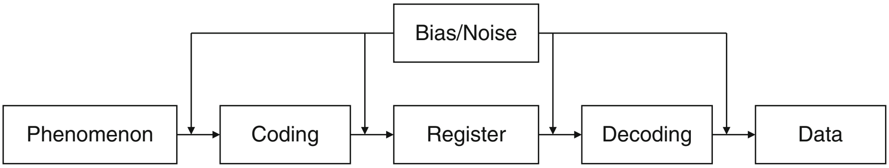

Fig. 20.1 Schematic diagram of information communication via administrative registers

with potentially varying local production practices. For example, imagine that your observational world is all that you see, hear, smell, taste, and feel. Would you trade your observational world for an old black-and-white photo when you could trade it for a high-quality three-dimensional digital movie with full color scale, including infrared (Sund 2003)?

Figure 20.1 is a schematic diagram illustrating information communication via registers. We may assume that some observable phenomenon exists, but it is impossible to make exact measurements for most phenomena. Some kind of simplified coding, however, can be used to describe most relevant things systematically. This measurement of phenomenon in terms of coded signal will then be stored in a database (or register). The noise and bias reflect the unavoidable measurement compromises, possible inconsistencies, or coding errors and coding practices existing in the stored signal. In order to utilize this signal (data in register), it must be decoded into suitable form for the current utilization purpose. This phase is also subject to noise and bias caused by incompatibility of choices and interpretations made by the data producer and the data user. Even the decoded signal (research data) is not a final phase in the research process, because further analysis and processing is needed in order to transform this data into actual information. Even though this is a very simple and technical representation of communication, it seems to capture the essential elements needed in the commonsense understanding of secondary data (Sund 2003).

It is particularly important to notice that it cannot be assumed that secondary data contain information, but information is something that has to be created from the data and pre-knowledge. This idea has been presented more formally in terms of infological equation

$$I = i(D, S, t),$$

which states that the information I is produced from the data D and the pre-knowledge S by the interpretation process i during time t (Langefors 1993). From this perspective, it becomes understandable that any sharing of data can only be a proxy for the sharing of information, because the unbiased communication would require the background knowledge S to be identical with the producer and the users of data. The problem can be dealt with by increasing the common pre-knowledge by offering descriptive data about data, i.e., metadata (Sundgren 1996). The key problem in using secondary register data in research is to find some shared perspective between the original and intended data utilization purposes in terms of available data and (more or less tacit) metadata (Sund 2007).

In practice, there are three options to utilize secondary data. First option is to use data that require no special pre-knowledge and are directly compatible with the current research problem. For example, data on dates of death are typically easily interpretable and can be used as such in most research problems. The second option is data abstraction, i.e., *enrichment* of data with special pre-knowledge (Shahar 1997). For example, there are no acute myocardial infarctions (AMIs) in hospital discharge or causes of death registers, but relevant information on them can be extracted by searching certain diagnoses from the registers by knowing that severe AMIs lead to hospital admission or death. Another example is a complication after surgical operation. That is a medical concept consisting of generalizations that apply across patients, but from individual-level hospital discharge data complications must be abstracted by using certain systematic rules, such as a list of particular diagnosis codes with appropriate time stamps recorded in the data. The third option is to slightly modify the original research problem to be more compatible with the available data. For example, it is difficult to identify reliably all hip fractures in risk population, needed for the calculation of hip fracture incidence, from the hospital discharge data, as there may be several readmissions and reoperations in addition to new fractures for each individual. In terms of data, the solution is to identify only the first hip fracture of each person. That is not the complete solution, because the standard incidence interpretation is not valid for such data, but also a justified epidemiological interpretation for the incidence of first hip fractures only is required (Sund 2007). Virtually, any use of register data requires data-sensitive preprocessing of data, and this preprocessing is typically the most important and time-consuming part of register-based data analysis.

Most data in health registers describe situation in the proximity of certain time stamped event such as cancer diagnosis, death, birth, hospital discharge, or drug purchase. Such observable events can be assembled to describe the history of an individual just as the basic idea of record linkage assumed (Dunn 1946). Such event history of an individual – event sequence – can also be interpreted as a sample path of a marked point process, which also makes it clear that a very general family of statistical hazard-rate models and other well-known methods in event-history framework suit well for the analysis of register-based data (Sund 2003). That framework contains also virtually all standard epidemiological methods. For example, health registers can be used to measure incidence, prevalence, mortality, and survival of different diseases over time and for different geographical areas and population groups. This is an important task for descriptive epidemiology (cf. see chapter ▸Descriptive Studies of this handbook), but the main advantage of registers for analytical purposes is that data from several sources can be linked together.

Record linkage of two or more national registers is one option. Another common application is that researchers use their own collected cohort as a baseline and then make follow-up in the national health data registers. The "Study of men born in 1913" is one such example of a cohort study where subjects with local registration of risk factors for cardiovascular disease were followed up for decades with health data registers (Tibblin et al. 1975). In addition to cohort studies, case-control as well as case-cohort studies are common study designs with register-based data. Also intergenerational studies have become feasible with register-based data as there is long history of data and typically population or birth registers contain identifiers for parent-child relationships. In fact, the possibility to link data allows creative construction of exposures and outcomes. For instance, long-term pregnancy outcomes of individuals who suffered major adverse events (such as the death of a child) can be followed (Li et al. 2009). Especially in Nordic countries with possibilities to deterministic record linkages and universal health systems, the health registers allow totally novel approaches to study many issues – only imagination is the limit. Some examples of studies are given in Sect. 20.8.

20.7 Potentials and Limitations of Register-Based Studies

In general, the advantages of using routine collected health registers as a main source for data are that they are already available, the number of observations is large, data are often nationwide and cover a whole population, and long follow-up periods as well as creative study designs become feasible via record linkages. By using large nationwide registers, on the one hand, a common critique of many studies to focus on men, on a limited age-group or on a specific geographical area can be avoided, and, on the other hand, it becomes feasible to study also rare outcomes. Registers also allow an assessment of outcomes in a real world situation that is not the case with randomized controlled trials with specific inclusion and exclusion criteria. Use of register data is also typically relatively cheap, especially compared to large surveys.

There are, of course, also shortcomings in national health registers. Some commonly mentioned problems are related to privacy and confidentiality issues, limited data availability, limited number of collected variables, poor population coverage, short registration period, limited record-linkage possibilities, lack of clinically relevant data, variation in data format, coding systems and coding practices, poor completeness of registration, limited accuracy of registered data, data processing issues, large size of data, possibility to discover chance occurrences, and changes in time in any of the above mentioned (Potvin and Champagne 1986; Connell et al. 1987; Bright et al. 1989; McDonald and Hui 1991). Many of the problems are, however, related to particular study designs or properties of certain known data sets, and therefore, their relevance should be evaluated separately for each study (Motheral et al. 2003). Quality of data can differ, but as described above, they are usually manageable for epidemiological research.

A more general problem is that the effective use of register-based data presumes skills in at least four fields: in computer science, statistics, the principles of measurement, and the theory of subject matter (David 1980). One can seldom be an expert on all of them, which makes collaboration the key to obtaining the best results.

Without doubt, accessibility to individual-based data in register research has a tremendous advantage when it comes to causal inferences. There are two fundamental pitfalls in this regard: Since all the data are typically available at the same time in register-based studies, it is easy to forget the direction in which time moves leading to temptation to organize the data analysis as prospective while conditioning on a future event. Another approach that is strictly against conservative causal reasoning is to "fish" or to "shop" interesting patterns from the data without any well-defined hypotheses.

In the following, some examples of the usefulness of register-based studies will be demonstrated, mainly when individual data are a necessity.

20.8 Examples of the Usefulness of Health Registers

Most of the Nordic registers are nationwide and cover the whole population. It may, however, be questioned, particularly in larger countries, whether it is not sufficient to do periodic surveys or geographically limited registration for the assessment of the disease occurrence in a country. The answer may depend on the disease or medical condition and on the desired goals of the registration or study. For rare outcomes, it is important to have large samples in order to come to conclusive answers. In environmental studies, it is an advantage to have data covering different areas. This will be illustrated later in this section. If epidemiological data are used for planning purposes like identifying needs of preventive actions, studies of equity in access to care or allocating health care resources, it is also important to have data from all parts of a country.

Thousands of scientific articles have been published based on data from national registers around the world and particularly from the Nordic countries. In many cases, the studies have added knowledge to the existing state of the art or later been replicated with other kinds of epidemiological studies, in others it has been nearly impossible for economic reasons to conduct studies without utilizing the existing registers. In general, register-based studies are very cost-effective due to the fact that data have already been collected for a long time period. Illustrations of the usefulness of register-based studies will be presented under headings: Environmental Epidemiology, Social Epidemiology, Pharmacoepidemiology, and Other Examples. For more examples in psychiatric epidemiology, see Miettunen et al. (2011).

20.8.1 Environmental Epidemiology

If the goal is to give answers related to environmental exposures, it is useful to have the registration in the whole country and over a longer period of time. For example, by using data from cancer register, it is possible to count the observed number of cancer cases in the area of interest and to compare them to expected numbers on the basis of suitable reference populations (e.g., neighbors or the cancer control region). It is also possible to evaluate the historical development in the area itself and in the other comparable areas. All these evaluations can be done really quickly when the historical database and the software are in an appropriate condition. The cancer register has been an important source, e.g., for analyzing the association between residential radon exposure and lung cancer in Sweden (Pershagen et al. 1994) and the potential effects of magnetic fields (Feychting and Ahlbom 1993).

Also the adverse effects of radioactive fallout following the Chernobyl accident in 1986 have been studied with registers. In Finland, the exposure level varied strongly between areas that were quite irregular in shape and did not coincide with health districts, but with data from the cancer registry, it was possible to reconstruct historical trends in childhood leukemia incidence in each of these different irregular areas and to study whether any changes in these trends could be related to the exposure level in the area. The answer was negative for the periods of 1986–1988 and 1989–1992 (Auvinen et al. 1994). The Swedish medical birth register was used to show that there was no significant adverse pregnancy outcome in Sweden after the Chernobyl accident (Ericson and Källén 1994).

More than 500,000 cleanup workers from the former Soviet Union were forced to clean the accident site in Chernobyl and its environment. The majority of the 500,000 cleanup workers came from different parts of the former Soviet Union where no reliable cancer registration existed (IPHECA 1996). For the almost 5,000 Estonian workers, however, it was possible to estimate whether the cancer risk of the workers had been affected, since cancer cases had been reliably registered in Estonia since 1978, and registration continued also after the accident and the return of the cleanup workers. The result has been negative for the period of 1986–1993 (Rahu et al. 1997). However, the former workers had an increased risk of dying through suicide, as shown by the causes of death register. Biological dosimetry done on the workers has also indicted that the range of doses the workers received was not likely to cause markedly increased cancer risks (Bigbee et al. 1997).

Cancer registration also revealed excess cancer risks related to the Chernobyl accident: children having lived in the nearby areas of Chernobyl experienced an epidemic of thyroid cancer (Kazakov et al. 1992). This was totally unexpected given the scientific knowledge available at the time of the accident.

Another example on routine register use is provided by a much smaller local exposure. In 1987, increased concentrations of chlorophenol were detected in the drinking water source of Järvelä, the center of Kärkölä municipality in Southern Finland (Lampi et al. 1992). According to the International Agency for Research on Cancer, exposure was related to possible increased risks at eight sites of cancer. The cancer registration in Finland covered Kärkölä, the other municipalities in the same local health care district and all the municipalities in the corresponding cancer control region. It was therefore very easy to quantify whether the population in the exposed municipality had faced any increased risks since 1953 related to the suspected eight forms of cancer or related to any other cancer. The results showed an increased risk of non-Hodgkin lymphoma and of soft-tissue tumors during the most recent 15 years, but not before that time. Subsequent case-control studies in the local health care district based on the material from the cancer registry confirmed that only these two cancers were concerned and the excess risk could be related to chlorophenol exposure. The exposure had come from a saw mill in Järvelä and was related to antifungal treatment of timber. Subsequent sediment analyses revealed that the exposure had been there for decades.

For a more detailed discussion of environmental epidemiology in general, we refer to chapter ▸Environmental Epidemiology of this handbook.

20.8.2 Social Epidemiology

Occupations at high risk for cancer and premature mortality have been followed and analyzed using record linkages of population censuses with the cancer register or the causes of death register. For example, up to 45 years of cancer incidence data by occupational category have been collected for the 15 million working aged persons in the 1960–1990 censuses in the Nordic countries (Pukkala et al. 2009). The study was undertaken as a cohort study with linkage of individual records based on the personal identity codes used in all the Nordic countries, and it was able to repeat most of the confirmed associations between occupations and cancers. Overall cancer risk was lowest in domestic assistants, seafarers, farmers, gardeners, and teachers, and highest in waiters, tobacco workers, seamen, and chimney sweepers. Almost all mesotheliomas are associated with asbestos exposure, and plumbers, seamen, and mechanics were the occupations with the highest risk to such neoplasm. Outdoor workers such as fishermen, gardeners, and farmers had the highest risk of lip cancer, while the lowest risk was found among indoor workers such as physicians and artistic workers. Increased nasal cancer risk, associated with exposure to wood dust, was found among woodworkers. Waiters and tobacco workers had a high risk of lung cancer, probably attributable to active and passive smoking. Miners and quarry workers also had a high lung cancer risk, which might be related to their exposure to silica dust and radon daughters. For more comprehensive view on occupational epidemiology see chapter ▸Occupational Epidemiology of this handbook.

The national registers have also been used continuously to study social inequalities, in healthcare and in mortality by record-linking health data registers with population censuses (Hallqvist et al. 1998; Manderbacka et al. 2009; Henriksson et al. 2010; Mortensen et al. 2011; Tarkiainen et al. 2012) and to examine the adverse health outcomes for vulnerable groups, e.g., psychiatric patients, immigrants, and single mothers (Ringbäck Weitoft et al. 1998, 2000; Wahlbeck et al. 2011).

Many studies of the health and social outcomes of single parents and their children have been conducted by linking several registers, i.e., population census, total enumeration income survey, hospital discharge register, and the causes of death register. The studies show increased premature mortality and morbidity both for single parents and their children, even after adjustments for socioeconomic factors and previous somatic and psychiatric inpatient history (Ringbäck Weitoft et al. 2000, 2003). Socioeconomic factors, especially a lack of economic resources, explained some of the disadvantages. Still, the results indicated an independent excess risk for single parents irrespective of socioeconomic factors and health selection into single parenthood. Similar results have been received in the long-term follow-up of women with alcohol or drug abuse during pregnancy and their children (Kahila et al. 2010; Sarkola et al. 2011).

Other aspects related to social epidemiology are discussed in chapter ▸Social Epidemiology of this handbook.

20.8.3 Pharmacoepidemiology

The study of vitamin K and childhood cancer well illustrates the advantages of large national health registers. A case-control study by Golding et al. (1992) indicated that intramuscular vitamin K administration doubled the risk of childhood cancer compared to oral administration. This result created much concern especially in Sweden, because intramuscular administration was recommended by the National Board of Health and Welfare. A study based on the medical birth and cancer registers was initiated immediately, and it showed no increased risk of childhood cancer (Ekelund et al. 1993). Later studies have confirmed the Swedish results. There were several differences between the British case-control study and the Swedish register-based study. One was sample size: the case-control study included 195 cases and 558 controls, while the register-based study included more than 2,300 childhood cancers and 1.3 million controls. In the register-based study, data were already available in the registers, and data from the medical birth and cancer register were merged by linking individual records. Supplemented with data on maternity hospital routines for vitamin K administration, the study was complete within a few months.

Another example is the possibly evaluated cancer risk associated with insulin glargine use. A large observational study suggested that use of insulin glargine is, after adjustment for dose, associated with a possible increase in tumor risk in humans (Hemkens et al. 2009). According to the editorial in the same issue, interpretation of the analysis proved controversial, but the implications were serious (Smith and Gale 2009). A special advisory group convened by the European Association for the Study of Diabetes agreed that the findings should not be published in isolation, and therefore three other large observational analyses were commissioned to investigate the safety of insulin glargine (Jonasson et al. 2009; Colhoun et al. 2009; Currie et al. 2009), and several other studies from many countries have been published since then. The evidence remains still somewhat inconclusive, but this case is an excellent example of how several countries could rapidly react and produce more information on the issue that would not have been feasible to study without good registers that already include the necessary data.

Since all the Nordic countries have initiated a prescription register between 1994 and 2006, Nordic studies on drug exposure have become feasible. For example, a study covering more than 1.6 million births showed that the use of selective serotonin-reuptake inhibitors (SSRI-antidepressants) in late pregnancy increased risks of persistent pulmonary hypertension of the newborn (Kieler et al. 2012).

A Finnish register-based study showed that long-term treatment with antipsychotic drugs of patients with schizophrenia was associated with lower mortality than no drug use and that clozapine seems to be associated with a substantially lower mortality than any other antipsychotics (Tiihonen et al. 2009). Studies have also shown inequity in access to drugs, e.g., immigrants from outside the European Union did not get all the recommended medication after myocardial infarction to the same extent as the Swedish citizens (Ringbäck Weitoft et al. 2008).

For more details on pharmacoepidemiological studies, refer to chapter ▶Pharmacoepidemiology of this handbook.

20.8.4 Other Examples

The medical birth registers have been used extensively in reproductive epidemiology, e.g., to analyze the short- and long-term risks of smoking during pregnancy (Ericson et al. 1991; Cnattingius and Haglund 1997; Ekblad et al. 2010), teenage pregnancy outcomes (Otterblad Olausson et al. 1999), and effects on children born after in vitro fertilization (Bergh et al. 1999; Klemetti et al. 2005). Since the registration of births has continued for decades in the Nordic countries, long-term follow-up (Paananen and Gissler 2011) and intergenerational studies (Nordtveit et al. 2008) have become feasible. As an example of Nordic collaboration is the study in which a cohort of 100,000 Nordic children born after in vitro fertilization treatment was built up to follow the children from conception until childhood and early adulthood (Henningsen et al. 2011).

A family-cancer database has been constructed in Sweden by linking population registers and the national cancer register in order to study familial cancer risks (Hemminki and Vaittinen 1998). The database includes approximately six million persons and more than 30,000 cancers in offspring diagnosed at ages 15–51 years and their parents. Numerous studies have been published based only on this database (Hemminki and Vaittinen 1998; Hemminki and Li 2001).

Survival analysis of cancer patients is a common application where registers have been used as extensive sources. Linking the date of cancer incidence in cancer registers with the date of death in the cause of death register create opportunities for survival analysis. Many large survival analyses have been published based on registers (Stenbeck and Rosén 1995; Dickman et al. 1999; Storm et al. 2010). The EUROCARE-4 study included follow-up of nearly 2.7 million cancer cases (Capocaccia et al. 2009). The social dimension of cancer survival has also been investigated in some studies by linking population census and cancer register (Vågerö and Persson 1987; Dickman et al. 1997). One methodological problem in survival analysis is that survival analysis by definition must be based on historical data, thus, assessing the effects of old treatment strategies. This problem is universal irrespective if the study is based on registers or not. However, one way to reduce this problem is to conduct period analysis using the latest information available (Brenner and Hakulinen 2002). Further methodological aspects are discussed in chapter ▶Survival Analysis of this handbook.

20.9 Quality Control in Medical Care Using Registers

There has also been a general trend worldwide to improve systems for effectiveness and quality control in medical care (OECD 2002). Outcomes of care have often been assessed by a mortality analysis. One famous example is the coronary bypass mortality study in New York State (Hannan et al. 1994, 1995) where they gathered clinical data whereby results could be adjusted for risks or patient mix. During the study period, mortality declined by 41% in the study area while it went down by only 18% in the rest of the country. The improvement was claimed to partly be due to the fact that less successful teams abandoned the market and partly to quality improvements by the other teams.

In Sweden, the Federation of Municipalities and County Councils (currently Swedish Local Authorities and Regions) and the National Board of Health and Welfare collaborate at the national level in providing financial and other kinds of support for creation and development of the national quality registers that routinely collect data on treatment procedures and outcomes of care (Garpenby and Carlsson 1994). Similar developments can be seen internationally, both in the Nordic and in other European countries. The hip fracture register in Sweden started in 1988 but expanded to a larger project where data are compared and analyzed between several European countries (Parker et al. 1998).

In Finland, a comprehensive performance monitoring system for several disease groups based entirely on existing nationwide registers has been constructed (Häkkinen 2011). A microeconomic disease-based strategy, in which the episodes of care and related costs are (re)constructed using record-linkable register data from several registers, has turned out to be a fruitful approach to assess the performance of health care systems (Peltola et al. 2011). In fact, the use of routinely collected registers is a very cost-effective way to produce useful information on performance, effectiveness, and quality of treatment without need for extra data collection. For example, it seems that some of the indicators that are typically calculated from the data collected with separate hip fracture audits can be derived directly from the routine Finnish registers (Sund 2008; Sund et al. 2011). Also this performance monitoring approach based on routine registers only has been extended to several European countries with individual-level linkable data (Häkkinen et al. 2011). Probably the best results could be obtained by combining the collection of separate quality registers (collection of important clinical data on selected disease events) and routine registers (common registration for all diseases).

20.10 Ethics, Confidentiality, and Legislation

The principles of autonomy, doing good, doing no harm, justice, and solidarity must guide decisions on how to administer national registers. The decision is a trade-off between benefits and risks (Allebeck 2002). The registers and their use are governed by national legislation.

There is one main difference between research based on health registers and other research projects where it is necessary to collect data on individuals. In the latter, there is a need for informed consent from all participants. This is not feasible for routinely collected national health registers. For these kinds of routinely collected national data banks, it would be practically and economically impossible to apply the informed-consent rule for data collection and for secondary use of register data in scientific research. To do so would substantially hamper clinical work and take resources from other important health service tasks. One may say that the national parliaments and governments in the Nordic countries have given informed consent on behalf of the population by national legislation. This exception from the rule of informed consent is based on the judgment that the benefits far outweigh the negative consequences. Here principles of doing good and justice or solidarity outweigh that of autonomy. This solution also follows the EU Directive on Data Protection (95/46), which states that Member States may, for reasons of substantial public interest, by national law or by decision of the supervisory authority, lay down exemption for the requirement for informed consent of each registered person (European Union 1995).

Another important topic is the risk of violating individual integrity. This risk of doing harm may be twofold: the risk of unlawful trespass/encroachment of data on individual diseases and medical conditions and the perceived uneasiness/discomfort at just being registered. No system could guarantee 100% security, but after more than five decades of administering health data registers in the Nordic countries, there is no known case of misuse or data leakage to unauthorized persons. Also the register keepers do their best in preventing any threat to data protection. In most cases, register-based studies can be performed by using anonymous or pseudonymized data sets without direct identifiers. The remote use of ad hoc research data located on the server of the register keeping organization prevents the problems related to delivering the data set with discs or memory sticks.

That some people feel discomfort at just being registered is a negative aspect we must consider seriously. Public confidence in health data registers is influenced by mass media debate and knowledge of how the registers are being handled. This confidence could vary from country to country. The Directorate-General Justice, Freedom, and Security at European Union regularly studies citizens' opinions on data protection. In the Eurobarometer survey in 2008 (Eurostat 2008), two out of three respondents in the European Union (64%) were very or fairly concerned on data protection issues. In general, older people and more educated were the most concerned population groups. By country, Finland had one of the lowest percentages (35%), while Sweden (75%) and Denmark (72%) were countries with relatively high proportion of people with data protection concerns. Also the percentage of citizens who are very concerned on data protection varies substantially between Sweden and Denmark (45–46%) and Finland (less than 5%). Dissemination of the purposes and the usefulness, and the careful administration, of these registers are therefore important and never-ending responsibilities for administrators and users.

It may well be concluded that it is worth having routine registers and registries also for giving a good basis for scientific research. Thus, scientific research should not primarily be seen as a secondary user of registers created mainly for other purposes. The only justification of registration is that the registered data are used. The use has to be guaranteed by securing the manpower and resources and by finding a correct balance between the individual's right to privacy and its protection and the right of the individual and the mankind to benefit from research knowledge based on data registers (International Association for Cancer Registries 1992).

For a broad discussion of ethical aspects in epidemiological research, refer to see chapter ▶Ethical Aspects of Epidemiological Research of this handbook.

20.11 Conclusions

The short summary of conducted studies presented in Sect. 20.8 shows clearly both the present and the future benefits of register-based epidemiological research. A small selection of studies using routine data and health registers presented here could also have been conducted by collecting new data sets. In that case, however, one would have to accept the use of much greater resources and more time before answers to the research questions were available. In some cases, it is not even feasible to conduct a study without national registers.

So far, the nationwide health registers with data linkable at individual level have mainly been a privilege of the Nordic countries. Smart choices to start routine collection of data and to introduce personal identity codes during the 1950s and 1960s have resulted in an invaluable gold mine for health research and in a laboratory environment for developing methodology for register-based data analysis. From this perspective, one may question why the utilization has not been as intensive as it could have been, especially after the argument that it would be unethical not to use available data to improve health in the population. A simple answer would be to state that the resources have been limited and should not be used for data with unknown quality. This may be partly true at least in terms of attitudes.

It is, of course, crucial that the quality of data in the health registers is good enough for research purposes. Many validity studies of the registers have been conducted indicating mostly good data quality and reliable results provided that the data are analyzed with care. In fact, the main challenge in the register-based research is the fact that there is not any simple solution to transform raw secondary register data into useful information, but a wide variety of expertise is required for innovative results. However, regardless of such pragmatic problems, only the imagination defines the limits of register-based data analyses, and every new study conducted with register-based data provides evidence on the usefulness of the registers.

In the future, the amount of register data will increase. For example, hospital discharge registers have been transformed to hospital patient registers where all visits to hospitals are included, and even information on primary health care visits are to be collected to central registers. As also the electronic health records can be seen a kind of health register, there will be more countries with register data and closer correspondence between clinical work and register-based surveillance systems in the future.

In the Nordic countries, the value of health registers increases all the time as longer and longer follow-up times and intergenerational studies become feasible. As the examples in Sect. 20.8 showed, there have been collaboration projects in which data from several Nordic countries have been pooled to provide larger data sets. This kind of collaboration is likely to be increasing in the future. It will also be essential to confirm that other data, such as biobanks or health surveys, will remain linkable to health register data as that will open novel perspectives for many issues.

21.1 Introduction

During crises that threaten public health, as during more ordinary circumstances, surveillance is a fundamental part of public health practice and is used to measure the impact of disease, detect changes in trends, guide immediate and long-term actions, and prioritize the use of public health resources. Surveillance is especially critical during times of crises such as epidemics, natural disasters, famines, and conflicts. During events that rise to the level of becoming humanitarian emergencies, the highest rates of mortality and morbidity occur during the early phases when resources are scarce, healthcare and other service delivery systems are disrupted, and the health, safety, security, and well-being of populations are at risk (Toole and Waldman 1990). Compared with routine surveillance, surveillance during major emergencies is abbreviated in order to focus on those diseases or conditions with epidemic potential or with the highest risk of severe morbidity or mortality. During other urgent but less severe public health events, such as outbreaks or disasters that have lesser impacts, surveillance is needed to characterize health threats, track the health of affected populations throughout the course of events, and complement more targeted epidemiological and laboratory investigations. Absent clearly imminent threats to public health, certain surveillance methods can be employed on an ongoing basis to provide early indication or rapid characterization of disease outbreaks, should they occur, enabling prompt investigations and responses. Across this spectrum of scenarios, a common theme is the importance of the timeliness of surveillance, including the need to collect, manage, analyze, interpret, and report surveillance information quickly in order to be useful in urgent and rapidly evolving situations. This premium on timeliness may constrain the ability of epidemiologists to maximize other desirable attributes of surveillance, such as detailed information, completeness, or specificity.

As Dr. William Foege stated over 35 years ago, “The reason for collecting, analyzing and disseminating information on a disease is to control that disease. Collection and analysis should not be allowed to consume resources if action does not follow. Appropriate action, therefore, becomes the ultimate response goal and the final assessment of the earlier steps of a surveillance system” (Foege et al. 1976). Besides detecting and responding to epidemics, additional objectives of public health in disasters and emergencies, as in routine times, are to determine the healthcare priorities requiring intervention, target the available resources, evaluate the effectiveness of programs that are existing or newly established to determine if they are meeting those priorities, and reassess the priorities over time.

This chapter provides an overview of the current field of disease surveillance during emergencies, disasters, and other urgent population health crises and of surveillance approaches used to detect or rapidly characterize outbreaks. After defining terms, the chapter examines different mechanisms for collecting surveillance data and for communicating that information during urgent situations. The chapter will contrast surveillance methods used in developed and developing countries and give current examples where they have been deployed. Disaster planning and emergency preparedness efforts should take into account the full spectrum of potential threats that communities might face and the attendant surveillance information needs of public health emergency and humanitarian relief responders. For a more general overview of the principles of public health surveillance, (see chapter ▶Infectious Disease Epidemiology of this handbook).

21.2 Definitions of Events

21.2.1 Disease Outbreaks

Outbreaks represent an increase beyond expected in cases of disease within a given geographical area or group of people over a particular period of time. The terms "outbreak" and "epidemic" are often used interchangeably, although "epidemic" is often reserved to describe events that affect relatively large numbers of people (Centers for Disease Control and Prevention 2004). The term "epidemic" may be used to describe public health problems that evolve over periods of years, e.g., the "obesity epidemic," but such use is beyond the scope of this chapter. Outbreaks are rarely triggered intentionally, but increasing concerns about the threat of bioterrorism since the early 2000s have heightened investments in surveillance systems aimed at the early detection and prompt characterization of outbreaks arising from intentional acts. The earlier disease outbreaks are recognized, the more quickly investigations can be conducted and control measures initiated, with the attendant benefits of minimizing morbidity or mortality. Outbreaks may arise from exposures to infectious agents, toxins, or other environmental hazards. Humanitarian emergencies, natural disasters, and mass gatherings might give rise to circumstances associated with increased risks for disease outbreaks, although vulnerabilities and potential impacts are highly variable across different situations.

21.2.2 Mass Gatherings

High-profile events, such as sporting championships, political conventions or demonstrations, religious gatherings, or other events that attract large numbers of people, may stress public health infrastructures in ways that increase the vulnerability for a disease outbreak. These events might also be targets for a bioterrorist attack. Mass gatherings may necessitate efforts to bolster existing public health surveillance capacity or initiate special surveillance activities for a time-limited period before, during, and after the event. In these situations, surveillance planning needs to take into account the potential for threats to public health, which may or may not arise. Surveillance planning should consider the unique challenges posed by the influx of large numbers of people who are not normally residents of an area, including plans for the delivery of healthcare services during the event and associated impacts on the ability of healthcare facilities to provide surveillance data during periods when staff and other resources might be stressed. During mass gatherings at high-profile forums, multiple governmental agencies and non-governmental organizations (NGOs) are likely to be engaged to address public safety and health needs, including agencies and organizations that would not normally be convened in a particular locality. As a result, procedures for reporting and use of surveillance information should be established as part of larger advance planning activities (Stergarchis and Tsouros 2007). These mass gatherings are usually defined as having more than 25,000 participants (Lombardo et al. 2008) and often include international sporting games.

21.2.3 Natural Disasters and Humanitarian Emergencies

Although often used interchangeably, the terms "natural disaster" and "humanitarian emergency" (or "complex emergency") represent events with different causes and consequences, with the former resulting from ecological events and the latter from the breakdown of governance and authority. The Pan American Health Organization (PAHO) defines natural disasters as overwhelming ecological disruptions of sufficient magnitude that assistance is usually required from outside agencies and organizations (Pan American Health Organization 1981). The United Nations Disaster Reduction Secretariat declared 2010 as the deadliest year in the past two decades based on data compiled by the Centre for Research on the Epidemiology of Disasters. In 2010, there were over 370 natural disasters, 300,000 people killed, and nearly 208 million persons affected, with the top two lethal disasters being the Haiti earthquake and the Russian heat wave (United Nations Radio 2010). Natural disasters can occur with varying degrees of advance warning and can be of atmospheric or geologic origin, including severe weather in the form of floods, droughts, heat waves, ice storms, and hurricanes/cyclones or geological events, such as earthquakes, tsunamis, volcanic eruptions, avalanches, and landslides. They usually occur quickly (droughts being an exception) and have the greatest impact on lives in the first few days following the event.

The Inter-Agency Standing Committee (IASC) was formed in 1992 to strengthen coordination, policy development, and decision-making among United Nations agencies and partner organizations in responding to complex humanitarian emergencies (Inter-Agency Standing Committee 2009). The IASC defines a complex emergency as a "a humanitarian crisis in a country, region or society where there is total or considerable breakdown of authority resulting from internal or external conflict and which requires an international response that goes beyond the mandate or capacity of any single and/or ongoing UN country program" (World Health Organization 2011a). Commonly used mortality thresholds in defining humanitarian emergencies include a crude mortality rate of one death or more per 10,000 total population per day or two or more deaths per 10,000 children under 5 years of age per day (Checchi and Roberts 2005). In areas where the baseline mortality rates are known, the threshold for humanitarian emergencies is a doubling of those rates. These indicators also are useful for monitoring the extent to which relief services are meeting the needs of the affected population and, thus, the overall impact of the relief response.

Natural disasters and humanitarian emergencies typically result in different patterns of morbidity and mortality. In natural disasters, injuries are the leading cause of death, including deaths due to blunt trauma or crushes, drowning, or hyper- or hypothermia, while deaths due to infectious disease are less common (Watson et al. 2007). In contrast, infectious disease epidemics are common during complex emergencies. For example, in the 10-year period of 1995–2004, infectious disease epidemics occurred during 63% of the 30 largest complex emergencies versus 23% of the 30 largest natural disasters (Spiegel et al. 2007). Contributors to epidemics during complex emergencies include the lack of authority, security, healthcare infrastructure, basic services, and access to and for the population because of security issues, as well as vulnerabilities arising from human rights violations; marginalization of specific ethnic, religious, social, or political groups; and mass displacements. Mass displacements following from natural disasters can also lead to outbreaks depending on the size of displaced populations, access to potable water, and sanitation (Spiegel et al. 2007), as seen in the occurrence of outbreaks of gastrointestinal illness within days in Muzaffarabad following the 2005 Pakistan earthquake (United Nations Country Team in Pakistan 2005). Because they were homeless from the earthquake, about 10,000 people set up spontaneous camps with an unsafe water supply and poor sanitation facilities. Without separate latrines for those with acute watery diarrhea and with a water system damaged by the earthquake, further contamination of the water supply resulted. The international humanitarian community responded by supporting the Pakistan Government with water supply repair, adequate sanitation facility construction, and provision of emergency health care to those with diarrhea and dehydration.

21.3 Formal Surveillance

Surveillance in the context of disasters or other urgent situations may depend on enhancements to routine surveillance systems not specifically designed to serve emergency preparedness and response activities, ongoing surveillance systems specifically designed to provide very timely information for outbreak detection or characterization, event-prompted activation of a previously developed emergency surveillance or assessment utility, or ad hoc implementation of an event-specific surveillance system. In crises, as in more routine surveillance practice, surveillance may draw on information generated when people use healthcare services, such as hospital emergency departments or emergency field clinics, or on population surveys conducted to assess health status. A spectrum of surveillance methods may be employed, geared to the information needs of a specific situation and the resources available to conduct surveillance.

21.3.1 Uses of Surveillance

Among questions that surveillance systems might be tasked to address, three essential questions regarding disease outbreaks include the following:

Is an outbreak occurring? Outbreaks are detected in a variety of ways, depending on a mix of disease-specific, epidemiological, population, and other factors (Buehler et al. 2003). If sufficient numbers of cases of disease are manifest within a community, the outbreak will be apparent to clinicians as an unusual increase in patients with a particular pattern of disease. Many outbreaks are detected in this way, including outbreaks associated with previously unknown diseases as well as with familiar causes of food- or waterborne disease. However, in emergencies or disasters with mass migration, an increase in case numbers might be caused by an increase in the population size due to population movement. In these situations, knowing migration patterns and receiving or obtaining periodic counts of the affected population are critical to understanding changes in disease surveillance case numbers and determining if true outbreaks are occurring. In other instances, the emergence of disease might be too geographically diffuse or unfold too slowly to be recognizable by individual clinicians. In these instances, different types of disease surveillance systems might provide the initial indication of an outbreak. This surveillance includes traditional systems based on mandated reporting of diagnosed cases of "notifiable" diseases; automated systems that monitor trends in the manifestations of disease – "syndromic surveillance" systems that monitor respiratory, gastrointestinal, and other syndrome-based categories of disease (Buehler et al. 2003; Mandl et al. 2004); or laboratory-based systems that track particular attributes of microbiologic agents, such as bacteriological serotypes or DNA "fingerprints" (Swaminathan et al. 2001). Selected notifiable diseases are aggregated weekly from the 50 US states and the 5 US territories and reported by the Centers for Disease Control and Prevention (US CDC). These include both infrequently reported diseases such as anthrax, measles, and congenital syphilis and more frequent diseases such as chlamydia, Lyme disease, and varicella. Regular examination of surveillance data, including examination of alerts generated by statistical algorithms used to detect aberrant temporal or temporal/geographical trends, might signify the emergence of an outbreak. The most common use of syndromic surveillance data by US health departments is to detect the beginning and end of the annual influenza season (Buehler et al. 2008).

In yet other instances, the diagnosis of a single case of a rare disease might be an indication of a potential disease outbreak, such as the original recognition of inhalation anthrax infection in an employee of a media company in 2001 in the United States (Traeger et al. 2002) or a single case of measles, regardless of location. In settings where clinical laboratory testing is not routinely available, targeted laboratory testing of clinical specimens can support the recognition of epidemics, as in the detection of shigellosis in Sudan in 2004 (Musani et al. 2004). Any such indication should prompt an examination of data from existing surveillance systems to confirm or exclude the presence of an outbreak. Depending on the situation, the review of surveillance data combined with outreach to local healthcare providers can improve their awareness of possible unusual trends in illness. Conversely, surveillance can be useful to determine that an outbreak is not occurring, either to provide assurance that suspect case reports are not harbingers of a more widespread problem or to quell rumors during a crisis.

What are the characteristics of recognized outbreaks? Regardless of how outbreaks are detected, once they are recognized, there is a need for timely monitoring to track their course from beginning to end, often requiring enhancements to routine surveillance procedures or special ad hoc surveillance efforts. Surveillance may be coupled with targeted epidemiological and laboratory investigations to characterize the extent of exposures to infectious or toxic agents, the extent and severity of disease and accompanying needs for healthcare services, the impact and effectiveness of interventions, the need for immunization (e.g., determine if available vaccine protects against serotype of meningococcal outbreak), or the potential adverse effects of medications or vaccines provided to mitigate the impact of an outbreak. The need for information often evolves over the course of an event. Intensive efforts to identify and characterize individual cases of disease might be appropriate at the initial stage of an event, but such efforts might not be feasible or necessary at later stages of an event. If very large numbers of cases are occurring, information priorities are likely to shift to tracking the broader sweep of an epidemic, requiring less detailed or specific information. For example, following initial recognition of illness due to H1N1 influenza A in the United States in 2009, initial surveillance efforts focused on reporting individual cases and were accompanied by investigations to characterize the clinical, laboratory, and epidemiological features of the disease (Swerdlow et al. 2011). As familiarity with the new pandemic strain of influenza increased and as infections became widespread, less specific measures were employed to monitor the sweep of the pandemic across the country, drawing on procedures developed over many prior influenza seasons to monitor "influenza-like illness" (Brammer et al. 2011).

Are anticipated health complications occurring following disasters? Experience with prior disasters can be used to anticipate possible health consequences, such as injuries associated with exposure to physical forces or cleanup efforts, carbon monoxide exposures associated with inappropriate venting of gasoline-powered generators in situations where electricity service is disrupted, or infectious diseases in situations where there is mass displacement, where sanitation services are strained, or where water and supplies are contaminated or compromised. Disruption in access to routine healthcare services can lead to an increase in complications of chronic diseases, such as diabetes or cardiovascular diseases, or infectious diseases requiring long-term treatment, such as tuberculosis or HIV infection (Mokdad et al. 2005). Large-scale disasters with substantial morbidity and mortality or with environmental impacts that affect the economic or social well-being of communities can have substantial impacts on mental health, which may manifest both as symptoms of psychiatric illness and as somatic disease (Gerrity and Flynn 1997; Green et al. 2006; Thienkrua et al. 2006; van Griensven et al. 2006). Surveillance systems aimed at tracking various categories of illness may be complemented by rapid community needs assessment surveys that aim to provide a more comprehensive assessment of the health needs of populations affected by disasters, such as the Community Assessment for Public Health Emergency Response (CASPER) toolkit developed by the US CDC (Centers for Disease

Table 21.1 Sectors evaluated in the Initial Rapid Assessment

Control and Prevention 2009) for developed countries and the IASC Initial Rapid Assessment tool for global use (Inter-Agency Standing Committee 2009). The Initial Rapid Assessment (IRA) looks at six sectors (Table 21.1) that need evaluation following a humanitarian emergency or large-scale disaster. The four subsections for the health facility/outreach site sector that are assessed include (1) general information of the facility such as location, contact person, type of facility (hospital, center, post, outreach), level of damage and patient access, and financial requirement of patients; (2) resources such as staffing types and numbers and essential drugs, vaccine, and simple supply availability; (3) any additional information and (4) type of care provided such as community outreach; primary care including feeding program, HIV, mental health; and secondary care with surgery, laboratory, X-ray, and blood bank services.

21.3.2 Enhanced Notifiable Disease Surveillance

In some instances, there may be a premium on ensuring that all cases of a highly critical disease are identified during an outbreak, such as a situation when there is a need to contact every affected person to interrupt transmission of a transmissible infection associated with severe morbidity. One approach would be to enhance routine procedures for notifiable disease surveillance (i.e., surveillance for conditions where healthcare providers are mandated to report cases to public health authorities). This occurred in 2001 in the United States when cases of inhalational and cutaneous anthrax occurred in several communities as a result of intentional contamination of mail with anthrax spores. For example, in the Trenton, New Jersey, region, where contaminated letters entered the postal system and where anthrax infections were detected, an extremely active approach to surveillance for possible anthrax cases was implemented. This involved daily outreach to area hospitals to identify patients who met a relatively broad definition for possible inhalational anthrax, followed by case reviews, and, when indicated, laboratory testing for anthrax infection. This labor-intensive approach to surveillance led to assurances that the outbreak had ended and was shortly discontinued since such intensive efforts on the part of hospital and public health personnel were no longer necessary or sustainable (Tan et al. 2002).

21.3.3 Syndromic Surveillance

Surveillance of disease syndromes – constellations of symptoms or other manifestations of disease – is a long-standing element of public health surveillance, especially when the etiology of a newly recognized disease is unknown and surveillance definitions must depend on syndromic criteria, when resources are not available to routinely diagnose disease or the ability of the public health laboratory system is inadequate, or when definitive diagnostic testing is not routinely necessary or used in practice for common illnesses. Nonetheless, the term "syndromic surveillance" has been applied to relatively new surveillance systems specifically geared to rapid monitoring on a daily or more frequent basis of syndromic categories of disease, prompted in large part by concerns about the threat of bioterrorism since 2001. While investments in "syndromic surveillance" in developed countries has incorporated the use of electronic health records and automation of key steps in the surveillance process, syndromic surveillance can also involve surveillance that depends on manual data collection. When automated healthcare information systems are available and accessible, the application of informatics tools to tap and extract selected routinely recorded data from these systems obviates the need for clinicians or healthcare staff to modify their activities for surveillance purposes. Automated information management tools can be further applied to collect such information from multiple facilities; compile the data into a common data store; scan recorded descriptions of patients' symptoms or diagnoses and collate these into counts of patients with various categories of disease, such as respiratory illness, upper or lower gastrointestinal illness, or influenza-like illness; perform statistical tests for aberrant temporal or temporal/geographical trends; and automatically display the results for review by epidemiologists. Such systems can be used to scan for possible disease outbreaks, characterize community illness patterns when outbreaks are suspected for any reason, track the course of relatively large outbreaks, and monitor expected seasonal illness due to influenza, other respiratory viruses, and common viral gastrointestinal infections, such as norovirus or rotavirus (Heffernan et al. 2004; Mandl et al. 2004). In the event of a disaster, syndrome categories might be modified or attention honed to track potential infectious and non-infectious complications or injuries.

A common approach to syndromic surveillance is to monitor patient visits to hospital emergency departments, although a large mix of sources have been applied, including outpatient clinics, calls to ambulance dispatch systems, calls to services that provide telephone guidance to patients, and calls to poison control centers (Heffernan et al. 2004; Mandl et al. 2004; Buehler et al. 2008). One such example was the monitoring of patient emergency department visits in Georgia by residents from Louisiana and Mississippi following Hurricane Katrina (Cookson et al. 2008). Of residents who visited participating emergency departments, 174 visited during the 8 months before and 151 visited during the 1 month after Hurricane Katrina, reflecting a sevenfold increase in monthly visits. Cardiopulmonary complaints significantly increased ($p = 0.03$) after Hurricane Katrina. Examining emergency department data as they are received can help assess needs among disaster victims.

Syndrome categories may be based on algorithms that scan the recorded text of patients' self-description of their symptoms, i.e., the "chief complaint"; recorded diagnoses, including diagnoses coded using the International Classification of Diseases (ICD); or both. Other approaches depend on the use of services, such as the purchase of over-the-counter medications, or other manifestations of illness, such as school or workplace absenteeism.

A wide variety of statistical techniques have been developed to detect aberrant trends – an increase beyond expected in the number of patients falling into a particular syndrome category, with varying levels of complexity being incorporated to account for underlying patterns in the use of healthcare services, such as variations in the use of care by day of the week, and to consider geographical as well as temporal clustering of disease (Buckeridge et al. 2005). In practice, relatively simple approaches not requiring extensive historical data are commonly used, such as the Early Aberration Reporting System, based on the cumulative sum or CUSUM statistical method (Centers for Disease Control and Prevention 2010a). CUSUM uses a running baseline or denominator that consists of the average number of counts for the selected syndrome from a previous 7-day period. This denominator is compared with the numerator of current syndrome counts. Traditionally, three different CUSUM methods are performed using different numerator and denominator counts. If the result of one of these three CUSUM methods is significantly greater than the expected rate, a signal is generated.

When syndromic surveillance is conducted for a short period of time, as might be necessary during an urgent response to a crisis or for a time-limited period shortly before, during, and after a high-profile public event or mass gathering, the term "drop-in" surveillance might be used to describe the work of a team mobilized to implement and support a surveillance system for the duration of the event. "Drop-in" surveillance may depend on hospital or emergency department staff or surveillance team members to record the necessary surveillance data manually if automated methods cannot be applied, although dependence on such manual effort is not likely to be sustainable beyond the period of the urgent situation (Centers for Disease Control and Prevention 2002a).

21.4 Communication

Surveillance systems are often based on the roles and relationships among healthcare providers and public health officials within communities and the ability to use lines of communication arising from these relationships is essential during crises. Formal surveillance systems may be complemented by enhanced outreach by public health staff to key contacts at clinical facilities or by specially convened in-person, teleconference, or web-enabled meetings during crises. These engagements can foster the exchanges that enhance insights into the status of an outbreak or a population's health that can be more nuanced than insights available from surveillance data alone. During emergencies, such communication among response participants, either formal or informal, is critical, and various formats for communication may be used in different situations.

21.4.1 Formal Systems: Inter-Agency Standing Committee, Cluster Approach

After the December 2004 Indonesian tsunami, humanitarian organizations and agencies cited the need to improve the leadership and coordination of aid responses in large disasters or complex emergencies. In response, the IASC developed the "cluster approach" to clarify roles, responsibilities, and lines of authority and delegation, with the aim of strengthening partnerships among host ministry of health NGOs, international organizations, the International Federation of the Red Cross/Red Crescent (IFRC), and United Nations agencies (World Health Organization 2006). The cluster approach was established to address gaps found in the effectiveness of humanitarian response through building partnerships. Its purpose is to ensure predictability and accountability of the international responses to humanitarian emergencies by clarifying the division of labor among organizations, defining the roles and responsibilities of the different sectors of the response, and making the international humanitarian response more structured and accountable to the need of the partner host governments, local authorities, and local civil society. At the global level, the objective of the cluster approach is to strengthen system-wide preparedness and technical capacity, while at the country level it is to improve predictability of leadership and accountability among partners across all "sectors" of response activities. During a large-scale natural disaster or complex emergency, for countries with designated humanitarian coordinators (Table 21.2), the cluster approach is to be activated. These countries have been appointed a humanitarian coordinator because they can and do face sudden major emergencies requiring a multisectoral response with the participation of a wide range of international humanitarian responders. At the daily to weekly health cluster meetings occurring once the emergency has arisen and the cluster has been activated, information is shared by the partner host ministry of health, different participating NGOs, international organizations, IFRC, and United Nations agencies. At the meetings, such information as standardized case definitions and surveillance forms, methods and routes for specimen collections, and increases in cases of outbreak potential syndromes or diseases are shared.

Among the cluster approach response sectors, three – water, sanitation, and hygiene (WASH); nutrition; and health – involve public health directly, while other sectors address capacities or services that can affect health, such as emergency shelter and protection for displaced people and telecommunications. Websites, such as ReliefWeb (2013) (http://www.reliefweb.int) and Humanitarian Response (2013) (http://www.humanitarianresponse.info) (formerly OneResponse), have been created to be a source of information and to improve coordination during humanitarian responses. Preliminary assessments of responses to the 2010 earthquake and subsequent cholera epidemic in Haiti illustrated the opportunities available in communication by implementing the cluster approach (Pan American Health Organization 2010). In Haiti, health and WASH cluster meetings provided a venue for in-person sharing of information among representatives of organizations participating in the response, including NGOs providing healthcare services in camps for displaced people, and for coordinating surveillance efforts, including the establishment of a

surveillance system for monitoring health in the camps and subsequently tracking cholera cases. In addition, the Haitian Ministry of Public Health and Population in collaboration with PAHO and US CDC created an Internet-based forum to share information, such as disease case definitions for surveillance, surveillance forms, and information on observed disease trends, including cholera (Centers for Disease Control and Prevention 2010b, c). Because of high turnover of NGO staff and because partners cannot always attend cluster meetings as clinics are located across a wide geographical area and to obtain definitions and forms, these types of publicly accessible Internet forum (ReliefWeb, Humanitarian Response, or Haiti Internet-based forum) allow for the exchange of messages and materials either with the entire group or a specific staff member. Electronic files can be posted or downloaded by any member. The Haiti Internet-based forum was effective in encouraging timely and reciprocal communication between surveillance coordinators and NGOs; weekly feedback reports were available to NGOs that included analysis of trends of proportions of each reportable condition. This probably led to the high response rate from the large clinics seen across the weeks; from epidemiological week 5–16, a mean and median of 35 clinics were reporting weekly (range: 12–48).

21.4.2 Incident Command Structures

Increasingly, public health agencies in the United States are implementing the use of formal systems of "incident command" or "incident management" to manage public health activities during crises and to facilitate communications with public health colleagues in neighboring jurisdictions or different levels of government (local, state, or national), healthcare providers, and other responder agencies and organizations. Systems of incident command have a longer history of use by public safety and emergency management agencies. By training and acquiring skills in the use of incident management protocols, public health agencies are better prepared to interact with these agencies, which typically have lead responsibility for managing multiagency emergency response activities. For example, the National Incident Management System provides standardized approaches for organizing, leading, and managing emergency response activities and for channeling information, such as data from surveillance systems (Federal Emergency Management Agency 2007). One such structure for leadership and management used by the US CDC for their support to the Haitian government following the 2010 earthquake is illustrated below (Fig. 21.1). Pre-event, multiagency participation in exercises that use this approach can minimize confusion when participants from different agencies and disciplines, each with different cultures and jargon, collaborate during crises. For example, the term "surveillance" itself describes very different activities when used by epidemiologists and law enforcement investigators who may be collaborating in responding to a possible bioterrorist threat.

21.5 Additional Tools for Public Health Response

In responding to large-scale disasters or humanitarian emergencies, multiple surveillance approaches and other tools that complement public health surveillance might be used at different stages of the response, including initial rapid assessments, facility-based health surveillance, and surveys for specific diseases or conditions (Table 21.3). To quickly assess basic needs for shelter, water, food, sanitation, and health care immediately after an event, the first tool used is often a rapid assessment of the extent of destruction or disruption of essential services. Ad hoc response without a formal needs assessment can lead to inappropriate and ineffective humanitarian responses. To support rapid assessments, the IASC and global leads for the WASH, health, and nutrition clusters have developed and continue to refine the IASC Initial Rapid Assessment tool (Inter-Agency Standing Committee 2009). In 2010, this was used following the earthquake in Haiti and during the monsoon floods in Pakistan. For the Pakistani floods, its purpose was to provide a rapid overview of the emergency situation, identify the immediate impacts of the floods, estimate needs of the affected population for assistance, and define the humanitarian response priorities (and needed funding) in the early weeks of the crisis (World Health Organization 2010a). A total of 515 councils in eight

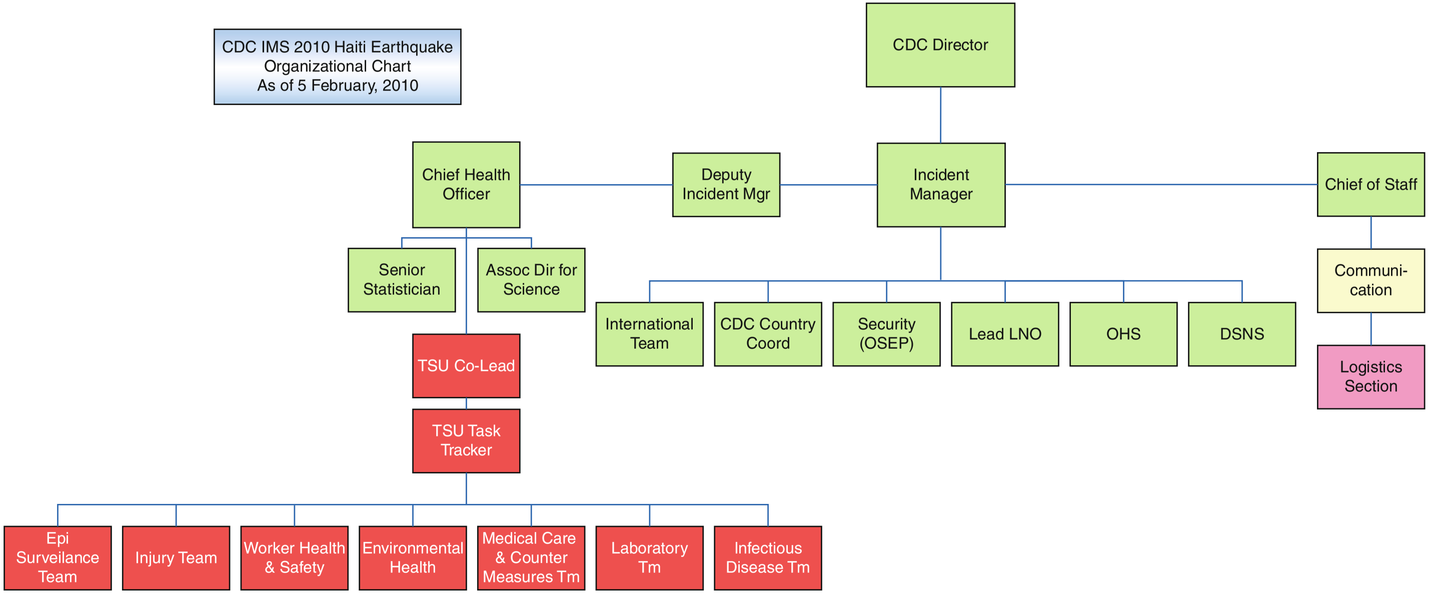

Fig. 21.1 Centers of Disease Control and Prevention (CDC), Incidence Management Structure (IMS) for support and response to 2010 Haiti earthquake organizational chart, 5 February 2010. Legend: *TSU* Technical Support Unit, provides scientific expertise for response in areas of epidemiology, laboratory, and other disease-specific expertise, *OSEP* Office of Security and Emergency Preparedness, coordinates security with other local law enforcement for CDC personnel at an event site and coordinates personal (security clearance) and the physical security of CDC campus, *LNO* Liaison Officer, coordinates with other agencies in providing emergency assistance, *OHS* Office of Health and Safety, ensures that personnel have preventive health measures and assesses resiliency of those deployed, *DSNS* Division of Strategic National Stockpile, provides medical counter measures, if needed

Table 21.3 Types of tools, their characteristics, and methods for public health response to large disaster or complex emergency

	Tool		
Characteristics	Rapid assessment	Survey	Surveillance
Purpose	Preliminary overview	Cross-sectional in-depth appraisal	Detect outbreaks and monitor trends in diseases or conditions of public health importance
Data quantity	Wide variety	Wide variety if sound methods are not followed	May be limited due to constraints and service demands affecting healthcare providers
Source	Observations, often convenience based	Sample of population	Case reports from all or subset of care providers (selected to be as representative as possible)
Time frame	Rapid, single time	Medium term, single time after other tools are completed or established	Ongoing over course of event
Data method and type	Qualitative/review of secondary sources	Quantitative/cross-sectional view/ numerator and denominator based on sample design	Quantitative/numerator and (if possible) denominator (usually proportional rate, using total number of cases)

flood-affected districts in Punjab were assessed. The assessment teams were without any specialized technical expertise and were of both gender, with female assessors conducting group discussions with women and children. Health staff was assigned the role of monitoring and supervising of the teams during data collection by providing on-the-spot assistance to each assessment team. The data were collected and reported in 24–48 h per council, and data for all eight districts were completed in eight days. Rapid assessments should be performed as quickly as possible to identify the affected region and population, set immediate response priorities, determine resource needs and identify essential health information needs. Rapid assessment findings should enable governments, the United Nations agencies, and NGOs to gauge their in-country capacities relative to observed needs, as well as inform aid donors. These rapid needs assessments should combine available information on services and health status to define the pre-event context of the disaster with observations of the post-event situation. Interviews with key informants, such as village or religious leaders; informal focus group discussions with affected persons, and visits to a convenience sample of households are additional methods that can be used. While theoretically desirable, efforts to collect representative data based on statistically valid sampling methods might not be practical or implemented quickly and can waste valuable time (Garfield et al. 2011).

A major challenge in rapid assessments is defining the size of affected persons since individuals and families may be constantly moving to escape violence or to fill needs. One of the best conducted rapid assessments was during the Pakistan 2010 floods. In spite of that, capturing population data are still difficult. Of the eight assessment districts, only 27% had a registration process in their communities to track the affected populations. In Haiti, the International Organization for Migration developed a Displacement Tracking Matrix (DTM) to create a comprehensive list of all known and assessed settlements (Camp Coordination Camp Management Cluster in Haiti 2011). As these types of registrations become more used, the quality of affected-population data will continue to improve. These population figures are needed both to assess whether mortality rates reach emergency thresholds and to determine needs for food, water, shelter, and non-food items, such as cooking items, water storage containers, and soap. Frequent constraints in performing rapid assessments include difficulties in reaching affected areas because of security concerns, problems with logistical support, and transportation barriers. Because of potential biases in available data and differences in perspective of key informants, including the potential for the intentional introduction of misinformation, it is important to consider and synthesize information from as many sources and perspectives as possible. To be useful, the findings of the rapid assessment must be reported promptly to be relevant, given the potential for postdisaster events to unfold rapidly; the recommendations should be concise and specific to the roles of responsible partners and agencies; and the limitations should be clear.

After initial rapid assessments, population health surveys are a tool that is often used during emergencies. For health status measures and conditions that are not readily amenable to accurate assessment through healthcare facility-based surveillance, such as mortality, malnutrition, and gender-based violence, surveys using a representative sample design might be the method of choice to obtain population-based estimates. Systematic random sampling is the preferred method for conducting surveys; however, organized lists of the population or well-organized layout of the camps are not often the reality. Therefore, multistage cluster design sampling is the method often used for conducting these surveys, although this relatively complex method is susceptible to measurement errors if not done correctly. An assessment of 67 surveys performed over 15 months in relation to the famine in Ethiopia in 1999–2000 found that major methodical errors occurred with the vast majority of the surveys, resulting in the possibility that unreliable findings might have influenced policy and resource allocation decisions (Spiegel et al. 2004). Of the 125 surveys evaluated, only 52% used the accepted at the time standard cluster design of 30 clusters × 30 households per cluster. Of these 52%, over 80% used non-random sampling, and almost 10% used sample sizes less than 500 children. Because of the potential for such errors, in 2002, an interagency initiative, the Standardized Monitoring and Assessment of Relief and Transitions (SMART) project, was begun to improve survey methods for three key indicators of the severity of humanitarian crises: the nutritional status of children under 5 years of age and mortality rates for the total affected population and children under 5 years of age. A survey manual and accompanying analytical software were developed.

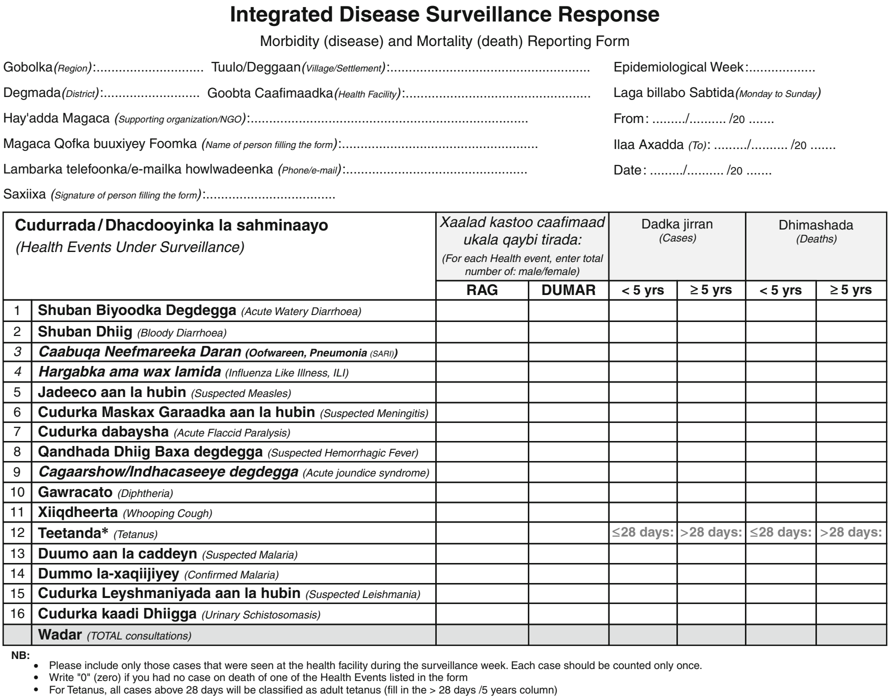
The survey manual was designed to be used by field staff, persons who may have limited understanding and knowledge of epidemiology and statistics. SMART was initiated to improve the technical capacity of agencies to systematically conduct, analyze, interpret, and report survey findings in a standardized and reliable manner. Training sessions have been conducted throughout the world with field staff before and when crises are unfolding such as the 2011 famine in the Horn of Africa. The goal of SMART is to "make the survey process as easy as possible for the field staff and as reliable as possible for the decision-makers" (Standardized Monitoring and Assessment of Relief and Transitions 2009). The software used for SMART can be found on the SMART website (http://www.smartmethodology.org).

21.6 Surveillance in Less-Developed Countries

Surveillance systems are established to detect outbreaks and monitor trends in specific diseases or conditions of public health importance (Médecins Sans Frontières 1997), even though the risk of epidemics is lower in disasters compared with complex emergencies (Spiegel et al. 2007). Rumors of outbreaks and unconfirmed reports occur frequently following disasters and during humanitarian emergencies or mass gatherings. A well-functioning surveillance system can reassure the public and health authorities that these rumors are just that, that no large-scale outbreak has occurred. However, resources for public health are often limited in developing or resource-limited countries. As a result, surveillance systems are sometimes not well developed and do not provide timely or useful data. To provide a common strategy for improving surveillance capacity, the World Health Organization (WHO) and other United Nations agencies have developed standardized approaches for ongoing, routine surveillance. One such system is the Integrated Disease Surveillance and Response strategy, another is the United Nations High Commissioner for Refugees Health Information System, and a third is the Early Warning and Response Network. The latter two can be activated following or during a disaster or humanitarian emergency.

21.6.1 Integrated Disease Surveillance and Response (IDSR)

In 1998, member states of the WHO African Regional Office adopted the Integrated Disease Surveillance and Response (IDSR) strategy to improve the availability and use of surveillance and laboratory data for control of communicable diseases of public health importance, reflecting their importance as leading contributors to mortality, morbidity, and disability in the African region. By 2009, 43 of the 46 countries in the region were participants in the program, which involves policy and technical support to member nations, defining minimum core capacities, training, facilitating information exchange, and improving laboratory capacity to confirm the diagnosis of priority diseases, with the final product being that of an integrated national surveillance system (World Health Organization Regional Office for Africa 2009).



Integrated Disease Surveillance Response

Morbidity (disease) and Mortality (death) Reporting Form

Gobolka *(Region)*:............................ Tuulo/Deggaan *(Village/Settlement)*:.. Epidemiological Week:..................

Degmada *(District)*:.......................... Goobta Caafimaadka *(Health Facility)*:... Laga billabo Sabtida *(Monday to Sunday)*

Hay'adda Magaca *(Supporting organization/NGO)*:... From: ..../.......... /20 ....

Lambarka telefoonka/e-mailka howlwadeenka *(Phone/e-mail)*:.. Date: ..../.......... /20 ....

Saxiixa *(Signature of person filling the form)*:...................................

	Cudurrada / Dhacdooyinka la sahminaayo *(Health Events Under Surveillance)*	*Xaalad kastoo caafimaad ukala qaybi tirada:* *(For each Health event, enter total number of: male/female)*		Dadka jirran *(Cases)*		Dhimashada *(Deaths)*	
		RAG	**DUMAR**	**< 5 yrs**	**≥ 5 yrs**	**< 5 yrs**	**≥ 5 yrs**
1	**Shuban Biyoodka Degdegga** *(Acute Watery Diarrhoea)*						
2	**Shuban Dhiig** *(Bloody Diarrhoea)*						
3	***Caabuqa Neefmareeka Daran*** ***(Oofwareen, Pneumonia*** *(SARI)****)***						
4	***Hargabka ama wax lamida*** *(Influenza Like Illness, ILI)*						
5	**Jadeeco aan la hubin** *(Suspected Measles)*						
6	**Cudurka Maskax Garaadka aan la hubin** *(Suspected Meningitis)*						
7	**Cudurka dabaysha** *(Acute Flaccid Paralysis)*						
8	**Qandhada Dhiig Baxa degdegga** *(Suspected Hemorrhagic Fever)*						
9	***Cagaarshow/Indhacaseeye degdegga*** *(Acute joundice syndrome)*						
10	**Gawracato** *(Diphtheria)*						
11	**Xiiqdheerta** *(Whooping Cough)*						
12	**Teetanda*** *(Tetanus)*			≤28 days:	>28 days:	≤28 days:	>28 days:
13	**Duumo aan la caddeyn** *(Suspected Malaria)*						
14	**Dummo la-xaqiijiyey** *(Confirmed Malaria)*						
15	**Cudurka Leyshmaniyada aan la hubin** *(Suspected Leishmania)*						
16	**Cudurka kaadi Dhiigga** *(Urinary Schistosomasis)*						
	Wadar *(TOTAL consultations)*						

NB:

- Please include only those cases that were seen at the health facility during the surveillance week. Each case should be counted only once.
- Write "0" (zero) if you had no case on death of one of the Health Events listed in the form
- For Tetanus, all cases above 28 days will be classified as adult tetanus (fill in the > 28 days /5 years column)

Fig. 21.2 Weekly integrated diseases surveillance and response reporting form used in Somalia

For example, the July 2010 IDSR Epidemiological Report provides country-specific information on trends for polio, influenza, and yellow fever and on outbreaks of cholera, meningitis, and dengue (World Health Organization Regional Office for Africa 2010). The overall objective is to identify communicable diseases and thereby reduce their burden. Data are collected at healthcare facilities on a weekly basis, the number of variables is usually less than 20. One sample form for IDSR that was used briefly in Somalia can be found in Fig. 21.2.

However, many challenges still exist for the member nations, including a national coverage, integration of the 2005 International Health Regulations, and mobilizing resources and staff, including laboratory capacity to mention a few. As with many of these surveillance systems, high staff turnover and attrition at all levels of the healthcare system impact on the quality of the data and usefulness of the system.

21.6.2 United Nations High Commissioner for Refugees Health Information System

In protracted refugee camp settings, a mix of factors contribute to disrupted collection and flow of health information, including evolving operational environments, uncertain access to the camps, uncertain communications, and staff turnover.

In addition, multiple organizations might be involved in providing camp health services and may simultaneously operate independent information systems to meet the reporting requirements of their respective organizations, donors, and host ministries of health. The result is fragmented and often incomplete and inaccurate reporting and a lack of comparability of health data across camps. To address these problems, from 1999 through 2005, the US CDC collaborated with the Office of the United Nations High Commissioner for Refugees (UNHCR) to develop a Health Information System (HIS) for refugee camps in Pakistan and Tanzania. Since 2005, the HIS has been implemented in 17 NGO operations covering 1.5 million refugees in 85 camps in Africa, Asia, and the Middle East. Its purpose was to design, monitor, and evaluate healthcare programs and thereby improve the health status of refugees under the protection of UNHCR through use of evidence to base policy formation and changes and manage the healthcare programs. Despite the use of common HIS tools and guidelines, initial evaluations demonstrated weaknesses in implementing the system and disparities in the ability of users to interpret and apply the data to improve camp health services (Haskew et al. 2010).

21.6.3 World Health Organization Early Warning and Response Network (EWARN)

During crises, preexisting disease surveillance systems may be insufficient to provide early warning of outbreaks and provide ongoing situational awareness, and special surveillance efforts might be required. Such surveillance should cover as much of the affected population as security and logistic limitations allow, and it should provide quantitative and qualitative information related to diseases with high mortality and, depending on the type of event, injuries. While involving as many stakeholders as possible, it should have a single lead agency, such as the Ministry of Health in the countries where the crisis has occurred or, if the Ministry is unable to take the leadership role, the WHO. The Early Warning and Response Network (EWARN) of the WHO's Health Action in Crises program provides guidance for surveillance during crises (World Health Organization 2011c). EWARN guidance recommends that:

- A monitoring team be established at the managerial level of the overall emergency relief operation.
- A limited number of diseases and indicators of the functionality of healthcare services be targeted for monitoring, based on priorities identified by a rapid assessment (see Sect. 21.5).
- Only experienced epidemiologists and public health officials take the lead in choosing these diseases and other indicators.
- Syndrome-based case definitions be used for surveillance, presuming that routine access to laboratory testing to confirm diagnoses is unavailable. To the extent that diagnostic tests are available at reference laboratories, syndrome-based surveillance should be supplemented by laboratory testing to confirm diagnoses in a sample of affected people, where possible.

Table 21.4 Ten communicable diseases/syndromes under surveillance, Darfur 2004 (Centers of Disease Control and Prevention, field observation, October 2009)

Disease/syndrome	Threshold to respond[a]
Acute watery diarrhea	5 cases in aged 5 or more years
Bloody diarrhea	5 cases
Acute flaccid paralysis	1 case
Suspected measles	1 case
Acute jaundice syndrome	5 cases or 1.5 times baseline
Suspected meningitis	5 cases or 1.5 times baseline
Suspected malaria	1.5 times baseline
Acute unknown fever	1.5 times baseline
Acute respiratory infection	Not defined
Neonatal tetanus	1 case

[a] Adapted from World Health Organization. Communicable disease control in emergencies: a field manual (Connolly 2005)

The EWARN approach has been used since 2004 in the Darfur crisis in Sudan, where it tracks ten communicable diseases or syndromes (Table 21.4) and where it supported detection of two disease outbreaks, one of shigellosis and another of Hepatitis E virus, and helped confirm a decline in measles incidence after a measles vaccination campaign (Musani et al. 2004). Although the EWARN approach has shown its worth, there remains a need to improve data quality, determine standard performance indicators, and improve training (World Health Organization 2010b). The threshold levels are used to initiate a response to the area where the notification was generated, which can be as little as a telephone call to verify that the report was real to as extensive as a team to investigate the potential case, determine an outbreak is occurring, and establish interventions, such as setting up cholera treatment centers or supplemental immunization activities for measles. Although EWARN was designed for crisis situations, it was recently implemented nationally in Macedonia, where communicable disease laws mandate reporting for 47 pathogens or diseases based on laboratory confirmation but where resources are lacking to provide laboratory confirmation for all diseases/pathogens on this list. Following a pilot in three cities, the country implemented the EWARN approach to monitoring eight syndrome categories of disease (Kisman et al. 2010).

21.6.4 Examples of Specific Developing-Country Uses: Haiti 2010

National Sentinel Site Surveillance Following the earthquake in Haiti in January 2010, two surveillance systems were established through a joint effort of the Haitian Ministry of Public Health and Population, PAHO, and US CDC (Centers for Disease Control and Prevention 2010d). The first, the National Sentinel

Site Surveillance (NSSS) system, was established within 2 weeks of the earthquake because there was no existing surveillance system that could provide timely data on disease trends, detect outbreaks, or characterize the affected population to target relief efforts (Centers for Disease Control and Prevention 2010d). NSSS engaged 51 hospital and clinic sites that had previously been affiliated with the US President's Emergency Plan for AIDS Relief (PEPFAR) and involved daily reporting by e-mail or telephone for 25 specified reportable conditions. During the first 3 months, surveillance data were accumulated for over 42,000 persons with reportable conditions. Nationally, the four most frequently reported conditions were acute respiratory infection (16%), injuries (12%), suspected malaria (10%), and fever of unknown cause (10%).

Internally Displaced Persons Surveillance System In just over 1 month following the earthquake, the Internally Displaced Persons Surveillance System (IDPSS) was instituted because of the increased risk of outbreaks among the more than one million displaced persons living in the hundreds of camps that spontaneously sprang up in and around Port-au-Prince (Centers for Disease Control and Prevention 2010b). This system allowed sharing and tracking of illness data among the NGOs that supported the camps and involved monitoring of six immediately notifiable conditions (suspected cases of acute hemorrhagic fever, measles, rabies, meningococcal meningitis, acute flaccid paralysis, or diphtheria), suspected cases of ten additional communicable diseases with less risk of outbreak potential or mortality, and persons with either of the three conditions considered as "programmatic indicators" (tuberculosis with interrupted treatment, HIV/AIDS with interrupted antiretroviral therapy, and pregnancy in any trimester with complications or third trimester pregnancy in a woman who had not received prenatal care).

At the time the IDPSS was established, the risk of cholera was believed to be low since cholera outbreaks had not been seen in Haiti for at least a century (Centers for Disease Control and Prevention 2010c). For the first 5 weeks of the camp surveillance, 31 NGOs reported over 96,000 new clinic visits of which 23,000 were by persons with one of the 19 reportable conditions. The three most common conditions were acute respiratory infection (9%), suspected malaria (5%), and watery diarrhea/not suspected cholera (5%) (Centers for Disease Control and Prevention 2010b).

Many previously documented challenges of postdisaster public health surveillance were experienced in Haiti, including logistical constraints, absence of baseline information on disease trends, unavailable population data to define disease rates, underreporting, lack of clarity or consistency in using surveillance case definitions, and limited laboratory capacity. Despite these challenges, both systems were valuable elements of the public health response, providing daily or weekly reports to public health partners in Haiti during the emergency response and serving as tools to respond to rumors or concerns of increases in disease (Centers for Disease Control and Prevention 2010b, d).

21.7 Disaster and Crisis Surveillance in Developed Countries

Although natural and other disasters can affect developed countries with devastating consequences, for a comparable geologic or atmospheric event, the human health impact is likely to be less severe in developed than less developed countries for multiple reasons, including a greater likelihood that homes or buildings can withstand physical stresses, stronger infrastructures to support essential services, more stable governments, and greater healthcare capacity. Moreover, developed countries have not been directly affected by large-scale complex humanitarian emergencies, such as those described elsewhere in this chapter. While the questions likely to be asked of surveillance systems during emergency or urgent situations are comparable in developed and less developed countries, preexisting surveillance capacities are generally greater in developed countries. This difference affects the relative dependence on enhancements or modifications to existing surveillance systems versus establishing event-specific surveillance systems. Despite multiple advantages of developed countries, experience with recent disasters highlights vulnerabilities in their surveillance capacity. This section presents examples of event-specific and disaster-directed surveillance in the United States and Europe as well as steps taken in the United States following Hurricane Katrina to improve uniformity of disaster surveillance tools.

21.7.1 Examples of Event- and Disaster-Related Surveillance Uses: United States

Role of Automated Syndromic Surveillance Investments in the United States in automated surveillance systems aimed at the early detection and prompt characterization of outbreaks were prompted largely by concerns in the early 2000s about the threat of potential large-scale bioterrorist attacks, and the threat of bioterrorism persists (National Intelligence Council 2004). However, in the absence of bioterrorist attacks, epidemiologists have found additional uses for these new surveillance systems and have embraced an "all-hazards" approach in their use (Buehler et al. 2008, 2009). Their ability to provide early detection of a potentially devastating bioterrorist attack has not been tested in practice, but their performance in detecting more common types of disease outbreaks has been mixed, depending on the nature of outbreaks, the type of healthcare services that affected people use, and the approach employed to conduct surveillance in specific localities. Based on observations from actual outbreaks and mathematical models, in general, the larger the outbreak and the more rapid the upswing in numbers of affected people, the more likely that syndromic approaches will provide an early indication of the presence of an outbreak (Buckeridge et al. 2005). Reflecting on the substantial impacts of influenza on seasonal patterns of respiratory disease, monitoring the impact of influenza-like illness has proved to be one of the most common uses of syndromic surveillance (Olson et al. 2007; Buehler et al. 2008), and syndromic surveillance systems became part of the mosaic of approaches used to monitor the emergence and course of H1N1 pandemic influenza in 2009–2010. In situations where environmental exposures to airborne irritants are widespread, such as exposures to smoke arising from massive wildfires or airborne particulates arising from a volcanic eruption, syndromic surveillance has proved useful in assessing the population-level impact on respiratory disease (Johnson et al. 2005; Elliot et al. 2010). Although it is difficult to define the capacity of syndromic surveillance to exclude the presence of an outbreak, when combined with other sources of information, it can provide an important "piece of the puzzle" in providing assurance that outbreaks are not occurring when the questions about threats to public health are raised (Buehler et al. 2009).

Hurricane Katrina In August 2005, Hurricane Katrina not only affected coastal regions of the United States along the Gulf of Mexico but also resulted in large numbers of evacuees migrating to other states. Because of the disruption of public health services in the New Orleans region, an ad hoc surveillance system was established that depended largely on manual data collection for a limited number of infectious diseases, non-infectious conditions, and injuries, based on reporting from selected healthcare facilities in the area for a time-limited period. Reporting from these sites was supplemented by event-specific reporting from evacuation centers and coroners. Despite the extensive structural damage and flooding in affected coastal areas and the large number of displaced persons, no major outbreaks of disease or hazardous environmental exposures were detected (Centers for Disease Control and Prevention 2005). In Georgia, where a substantial number of evacuees migrated, preexisting automated syndromic surveillance was used during the event to track emergency department use and retrospectively to inform planning for future hurricanes (Cookson et al. 2008). More broadly, US CDC sought to compile surveillance data from twelve states that were either directly affected by the hurricane or were the destination for evacuees from coastal areas. However, the ability to compile a multistate profile of the health impacts of the hurricane, especially among displaced people temporarily residing in evacuation centers, was limited by variations in surveillance methods and approaches among states (Centers for Disease Control and Prevention 2006). Following Hurricane Katrina, recognition of this variability prompted the US CDC to work with state and local public health authorities to develop, revise, and pilot tools for shelter health assessments and for morbidity and mortality surveillance after natural disasters (Schnall et al. 2011). These tools are now available on the US CDC website (Centers for Disease Control and Prevention 2011). They include a shelter assessment tool to assist environmental health practitioners to conduct a rapid assessment of shelter conditions and make recommendations for improvements, a mortality surveillance form to identify number and cause of deaths related to disasters, an individual morbidity surveillance form to capture individual-level medical conditions treated in shelters or potentially hospitals during a disaster, a morbidity surveillance line list form to summarize or collect less detailed data on medical conditions of multiple individuals seen in shelters or hospitals, and tally and summarize sheets to aggregate morbidity data from individual or line list forms.

Population Health Surveys Mental health impacts of disasters are well recognized, mental, and physical effects of disasters may be interactive, and needs for mental health services may be substantial. Following the September 2001 terrorist attacks on the World Trade Center in New York City, a telephone survey using a random-digit dialing sample design targeting households in the borough where the World Trade Center was located. Questions addressed respondents' demographic characteristics, measures of exposure to the event (e.g., directly witnessing the event, having a friend or relative killed in the attack), measures of social support or resiliency (e.g., social support networks), and mental health status (e.g., sets of questions that reflect the presence of post-traumatic stress disorder (PTSD) or depression symptoms). Survey findings demonstrated a "substantial burden" of PTSD and depression symptoms, even though the post-event approach to implementing the survey precluded clear pre- and post-event comparisons (Galea et al. 2002). In addition to ongoing monitoring of trends in health-related behaviors that might be affected by emotional distress, health departments of New York and two neighboring states supplemented an existing state-based population health survey, the Behavioral Risk Factor Surveillance System, to assess psychological and emotional effects of the attacks, such as anger, nervousness, and sleep problems (Centers for Disease Control and Prevention 2002b). Multiple surveys examining the affected populations of disasters and conflicts have also been performed with persons in less developed countries and similar results are found (Sabin et al. 2003; Cardozo et al. 2004; Thienkrua et al. 2006; van Griensven et al. 2006). The majority of these surveys use population-based sampling and standardized instruments, such as the Hopkins Symptom Checklist-25 (Mollica et al. 1987) that identifies elevated levels of symptoms of anxiety and depression and the Harvard Trauma Questionnaire (Mollica et al. 1992) that measures trauma events and PTSD symptoms.

21.8 Conclusions

Globally, there is an increasing threat of disasters and accompanying health impacts due to multiple factors: population growth, the increasing concentration of populations in urban areas due to migration, the location of many large urban centers in coastal areas, and the impact of climate change on rising sea levels and the increasing threat of extreme weather events (Freeman et al. 2003; James et al. 2008). The health impacts of natural disasters on affected populations are likely to differ in developed and less developed countries, where high concentrations of poverty and lack of infrastructure in the latter will result in heightened vulnerability to the adverse effects of disasters and where weak governance and marginalized population conditions are more likely to prompt humanitarian crises. Despite these differences between developed and less developed countries, when disasters and humanitarian emergencies occur, effective surveillance systems will be needed by public health response agencies to detect and track outbreaks, identify and monitor health status and urgent healthcare needs, and inform efforts to minimize adverse health effects.

The key components and requirements of surveillance systems in disasters and humanitarian emergencies are to only capture those conditions or diseases that have the greatest potential of causing high morbidity and mortality, that if not controlled can lead to epidemics and further morbidity and mortality, and for which an intervention exists in the area affected or through advocacy can be brought into the area. Therefore, the system needs to be simple, capturing as few conditions or diseases as possible; flexible to allow for addition of diseases if new pathogens are identified, such as cholera in October 2010 in Haiti; and acceptable to all partners so participation is high and completeness of reporting maintained; the data flow must be well characterized and understood so data can be collected, reported, and analyzed in a timely fashion. Finally, the information must be valid (requiring continuous training and frequent monitoring), useful, and result in action – data should be collected for the sole purpose of detecting and responding to diseases among the affected population.

22.1 Introduction

22.1.1 General Principles of Screening

Screening, sometimes termed “secondary prevention,” is one of the major components of disease control, the others comprising primary prevention, diagnosis, treatment, rehabilitation after treatment or disability, and palliative care. Ideally, the control of a disease should be achievable, either by preventing the disease from occurring or, if it does occur, by curing those who develop it by appropriate treatment. Complete success from prevention would make treatment obsolete. Complete success from treatment, however, would not make prevention obsolete, as there are costs and undesirable sequelae from the disease and treatment that patients and society would like to avoid if at all possible, especially from diseases such as cancer, diabetes, and hypertension. At present, neither is completely successful for most diseases; they will continue to complement each other for a number of conditions, while screening can be regarded as complementary to one or both of the other approaches.

Because of the deep-rooted belief among physicians that “early diagnosis” of disease is beneficial, many regard screening as bound to be effective. However, for a number of reasons discussed below, this is not necessarily so, as shown by the failure of screening for lung cancer using sputum cytology or chest X-rays to reduce mortality from the disease (e.g., Prorok et al. 1984). It is the purpose of this chapter to attempt to define some of the fundamental issues that are relevant to the consideration of screening in disease control. The approach taken will be from the epidemiology, or public health viewpoint, rather from the clinical standpoint.

Although it is often assumed that screening tests must involve some sort of technological procedure, such as an X-ray or laboratory test, screening can involve simple clinical examinations, such as assessment of blood pressure or a clinical breast examination. However, it is the advent of expensive technologically based screening tests in the last few decades which has focused attention on the need for critical evaluation of screening and the importance of soundly based screening programs.

22.1.2 Definition

Screening was defined by the United States Commission on Chronic Illness (1957) as: “the presumptive identification of unrecognized disease or defect by the application of tests, examinations or other procedures that can be applied rapidly.” A screening test is not intended to be diagnostic. Rather a positive finding will have to be confirmed by special diagnostic procedures.

By definition, screening is offered to those who do not suspect that they may have a disease. This is subtly different from being asymptomatic. Symptoms may be revealed by careful questioning related to the organ of interest, not regarded by the individual attending for screening as being related to a possible disease. Further, in a public health program, open to all comers, it may not be possible to determine that all subjects who enroll are truly asymptomatic. Indeed, many may enroll because they have a suspicion that they have the disease of interest, in the hope that their suspicion will not be confirmed. Thus, although it is usual to make the assumption that participants in screening programs are asymptomatic, this is not a necessary nor an absolute prerequisite for participation in public health-based screening programs.

22.2 General Principles Governing the Introduction of Screening

The principles that should govern the introduction of screening programs were first enunciated by Wilson and Junger (1968) and refined since (e.g., by Miller 1978, 1996; Cuckle and Wald 1984; Strong et al. 2005). These will now be considered:

1. *The disease should be an important health problem*. In practical terms, this means that the disease prevalence should be high and the disease should be the cause of substantial mortality and/or morbidity. However, it is important to recognize that the life expectancy of a screened population may be changed little even if the program is successful. In most technically advanced countries, for example, even if all cancer were to be eradicated, the effect of other competing causes of death is such that life expectancy would be increased only by about 2 1/2 years. The benefits of cholesterol screening to prevent heart disease are measured, at the population level, in days. It is not possible to provide a precise estimate for the level of burden necessary to mount a screening program. The level of morbidity and mortality considered to be important will depend on a combination of factors such as the age distribution of the population affected or the severity of the illness. There may be certain circumstances when the major benefit from screening follows, not from reduction in mortality but from reduction of morbidity consequent upon the diagnosis of the disease in a more treatable phase in its natural history. This could mean that the extent of treatment required and the possibility that treatment may be debilitating or mutilating would be much less. Such advantages may be difficult to quantify; however, as they may be considerable in psychological terms to individuals, and to communities in the lowering in the requirements for extensive rehabilitation services, they should not be overlooked.
2. *The disease should have a detectable preclinical phase (DPCP)*. It is important to recognize that this principle is not as follows: "The natural history of the disease should include a phase with a detectable precursor." For example for many cancers, including breast and prostate cancer, the DPCP is largely asymptomatic invasive cancer (Fig. 22.1). For cervix cancer, on the other hand, the DPCP probably includes the whole range from dysplasia (Cervical Intraepithelial Neoplasia (CIN) 1 or Low grade Squamous Intra-epithelial Lesion (LSIL)) through to occult invasive cancer (Fig. 22.2). An alternative name given to the

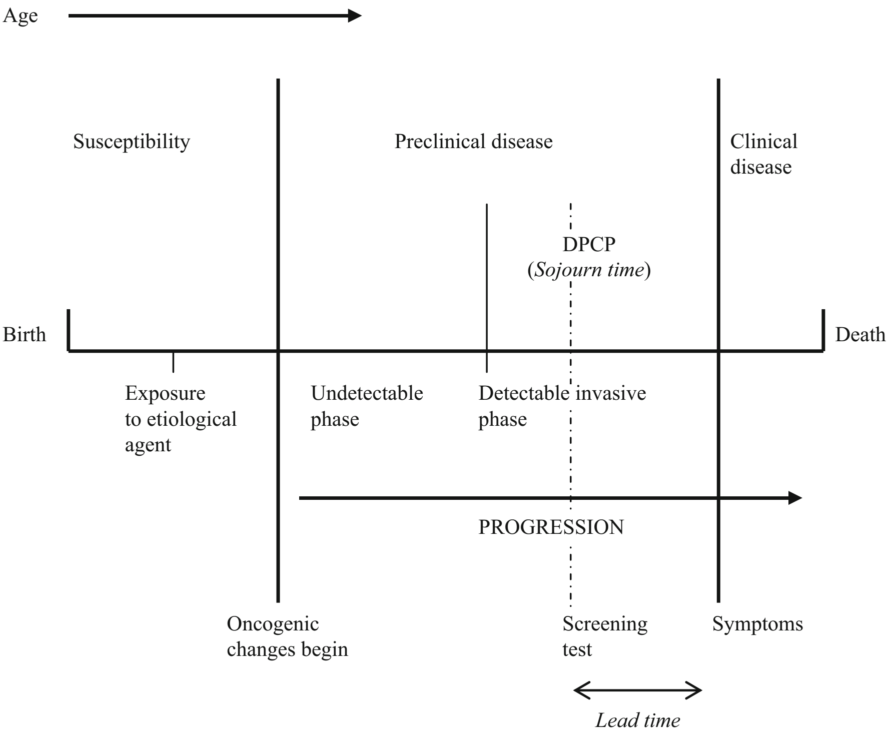

Fig. 22.1 The natural history of a cancer when the detectable preclinical phase is asymptomatic invasive disease

DPCP is sojourn time, meant to indicate the period during which a detectable lesion "sojourns" in the organ. In screening for cardiovascular disease with cholesterol or hypertension, physiological markers of risk are being identified rather than detectable precursors. Nevertheless, such a marker can be considered as synonymous to a preclinical phase.

3. *The natural history of the condition should be known*. Ideally such a requirement implies that it is known at what stage in the disease process progression, disability, and/or death can no longer be prevented. If such information was available and the stage that the development of the disease had reached in individuals was determinable, it would be possible to decide precisely when a screening test should be applied in order to achieve maximum benefit and minimal overutilization of resources. In a disease such as cervix cancer, it is now recognized that the majority of the preclinical abnormalities detected by the cytology test are not destined to progress and that the majority will regress, as depicted in Fig. 22.2 (Boyes et al. 1982; Holowaty et al. 1999). This makes it imperative that screening is planned to ensure that gross overtreatment of the majority does not occur. The same requirement may be even more necessary for

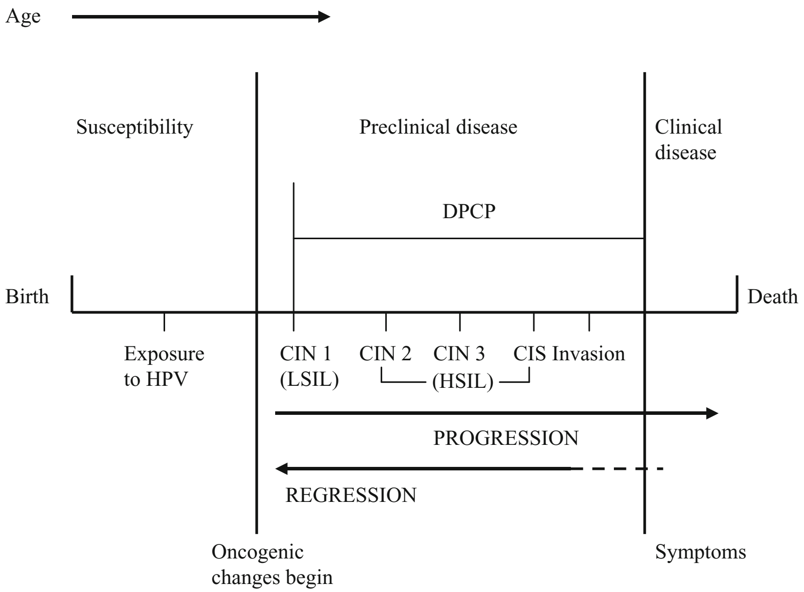

Fig. 22.2 The natural history of cancer of the cervix

the test for the primary etiological agent of the disease and the test for evidence of infection with high-risk types of the human papilloma virus (Miller 2004). Such conclusions have substantial implications with regard to the optimum frequency of screening examinations. Designing a program directed to those lesions that, in the absence of screening, will progress and more rapidly escape curability, if they can be identified, will be the appropriate approach. Designing a program which maximizes the detection of all cases, the majority with a good prognosis but which in the absence of screening may be unlikely to progress, will waste resources. Such knowledge can be applied to the population in planning screening programs, but unfortunately, it seems unlikely that knowledge will be accumulated to make it possible to determine the natural history of disease in individuals within the population sufficiently precisely. It is recognized that the rate of progression of clinically detected disease from the point of diagnosis to cure or to death varies substantially in different individuals. The distribution of rates of progression of preclinically detectable disease that might be identified by screening is likely to be equally wide. Thus, although an objective for research on screening has to determine the extent of the distribution of the sojourn times of the DPCP, in considering the introduction of screening programs and the scheduling of tests within programs, it is necessary to balance benefits with costs. This means that the schedule will have to be determined that will enable the detection of the maximal number of still curable cases compatible with the longest interval between tests, principles which unfortunately are often anathema to clinicians.

4. *The disease should be treatable, and there should be a recognized treatment for lesions identified following screening*. This principle can be elaborated as follows:

   There should be evidence of the effectiveness of treatment of lesions discovered as a result of screening in reducing disease incidence and/or mortality and the level of improvement expected should be stated,

   and secondly:

   There should be a reasonable expectation that recommendations for the appropriate management of the lesions discovered from a screening program will be complied with both by the individual with the lesion and by the physician responsible for his (or her) health care.

   Screening programs should only be set up when there are adequate facilities for treating lesions discovered as a result of screening and functioning referral systems for securing such treatment. There is obviously no point in establishing a screening program and identifying lesions that should be treated if the facilities, or the infrastructure, are not available for referral, confirmation of diagnosis, and treatment. In general, this is not a problem for technically advanced countries, but it can be for developing countries. Unfortunately problems allied to these have occurred. Thus, on occasions, it has not been certain whether or not lesions identified as a result of screening should be regarded as true disease precursors. When lesions are first identified in a screening program, information may not be available as to their appropriate treatment, and special studies may be required. Otherwise, errors in terms of observation rather than treatment on the one hand or too extensive treatment on the other are possible. In prostate cancer screening, for example, if too radical treatment is applied in the elderly to the latent or good prognosis prostate cancers that may be identified in a screening program, the morbidity in terms of incontinence and impotence, and even the mortality from treatment, could offset any benefit from the earlier detection of lesions with truly malignant potential (Chodak and Schoenberg 1989; Miller 1991; Krahn et al. 1994; Andriole et al. 2009).

   A different sort of difficulty could arise when, as a result of screening, lesions are diagnosed earlier in their natural history, but in spite of this, death is still inevitable. For example, if the available screening methods will not succeed in diagnosing disease before it is outside the range of current therapy, then screening to detect such disease is not worthwhile. The early studies of screening for lung cancer suggested this was not a condition amenable to screening, probably for this reason (Prorok et al. 1984). Recently, evidence has accrued from uncontrolled studies that low-dose helical (spiral) computerized tomography of the lung is capable of detecting approximately four times as many small stage 1 lung cancers as chest X-rays and that these appear likely to have a good prognosis (e.g., Henschke et al. 1999). However, these are peripheral cancers and are largely adenocarcinomas or related cancers so that the technique may not be capable of detecting early either the majority of squamous cell or of small cell cancers and thus may be selectively detecting only those cancers with a good prognosis. If, after spiral CT scanning, the majority of the lung cancers with a poor prognosis continue to occur at about the same time in their natural history as at the present, there could be little overall effect upon lung cancer mortality in the spiral CT screened group (Bach et al. 2007). Yet considerable costs will be incurred in treating the peripheral lesions not destined to progress. It is for this reason that large-scale trials of this approach are under way in the United States and Europe.

5. *The screening test to be used should be acceptable and safe*.
   In general, this implies a non-invasive test with high validity. Other criteria of a good screening test include ease of use and relatively low cost. These principles and approaches to assessing validity will now be discussed.

22.2.1 The Validity of a Screening Test

Two measures suffice to describe the validity of screening tests: sensitivity and specificity.

Sensitivity is defined as the ability of a test to detect all those with the disease in the screened population. This is expressed as the proportion of those with the disease in whom a screening test give a positive result.

Specificity is defined as the ability of a test to correctly identify those free of the disease in the screened population. This is expressed as the proportion of people free of the disease in whom the screening test give a negative result.

These two terms may be further expressed in terms of test results as follows: sensitivity is calculated as the true positives divided by the sum of the true positives and false negatives and may be expressed as a proportion or a percentage; specificity is calculated as the true negatives divided by the sum of the true negatives and the false positives and may be expressed as a proportion or a percentage (Fig. 22.3). In practice, difficulties with these measures arise over defining a positive result from the test as well as distinguishing the true positives from the false positives among those who test positive and the true negatives from the false negatives among those who test negative. A relatively imperfect test of a quantitative, continuously distributed measurement can be artificially given a very high sensitivity by setting the boundary between negative and positive to incorporate a high proportion of those who are eventually found to have the disease in the positive category, but at a substantial cost in terms of low specificity. Conversely the same test can be made to appear highly specific, but will then become insensitive, if the boundary between positive and negative is shifted in the opposite direction.

If the test result is expressed in a quantitative form so that the boundaries between what is defined as positive and negative can be varied at will, it is possible to plot a receiver operating characteristic (ROC) curve (Swets 1979). What is plotted is the sensitivity in the vertical axis and 1-specificity (the false-positive rate) in the horizontal axis (Fig. 22.4). The point on the curve that is chosen as optimal is often that furthest from the 45° diagonal, labeled “Chance” in Fig. 22.4, as this represents

	Disease status	
Test result	Present	Absent
Positive	True positive (*TP*)	False Positive (*FP*)
Negative	False negative (*FN*)	True negative (*TN*)

Then:

$$\text{Sensitivity} = \frac{TP}{TP + FN} \text{ x } 100\%$$

$$\text{Specificity} = \frac{TN}{TN + FP} \text{ x } 100\%$$

$$\text{Predictive value positive} = \frac{TP}{TP + FP} \text{ x } 100\%$$

$$\text{Predictive value negative} = \frac{TN}{TN + FN} \text{ x } 100\%$$

Fig. 22.3 The relationship between sensitivity, specificity, and predictive value positive and negative

a test with no better sensitivity or specificity than could be expected by chance. In Fig. 22.4, this point is between 70% and 80% sensitivity, the corresponding 1-specificity being 25%, i.e., a specificity of 75%. This is about the level expected with cervical cytology and represents rather a poor test. We would hope that even at greater sensitivity, the specificity would be at least 90% to avoid too many health-care costs investigating the false positives. ROC curves are most easily derived for blood tests, but have also been applied to mammography, by varying the extent to which different mammographic abnormalities were regarded as an indication of suspicion of malignancy (Goin and Haberman 1982). Such curves cannot be applied to a test with a dichotomous outcome if the boundaries defining positive and negative are invariant. Further they imply a similar weight to sensitivity and specificity, which, as discussed below, may not be ideal.

The position of the boundaries that are set between what is regarded as disease and non-(or benign) disease can also considerably influence the numerical values placed on sensitivity and specificity. This arises because of uncertainty as to what

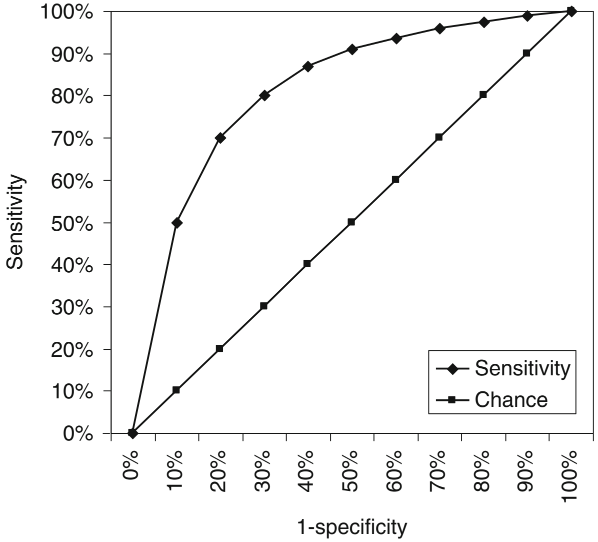

Fig. 22.4 Example of a ROC curve

truly constitutes an abnormality in the context of a screening program. In order to come to such a decision, it is essential that the conditions identified as a result of screening should have a known natural history. However, as has already been pointed out, such knowledge may not be available at the initiation of a screening program and may only be obtained as a result of careful study of findings from screening programs.

Nevertheless, the definition as to what constitutes disease is crucial in order to determine sensitivity and specificity. Most people have a clear idea as to what they regard as disease in terms of that which surfaces in standard medical practice. By definition, screening is conducted on asymptomatic individuals so that many conditions that are identified through screening are likely to be at an early stage and may not have the generally recognized clinical characteristics of relatively advanced disease. This difficulty should theoretically be overcome by having clearly defined definitions of disease. However, for cancer, diagnosis is usually made on histology, and histology only imperfectly characterizes behavior, especially for lesions within the DPCP. For cancer, one hope for the future is that some of the markers for prognosis currently being evaluated such as markers of oncogene expression or other markers of DNA change may serve to identify those precancerous or in situ components of the DPCP that are likely to progress.

A common error in evaluating potential screening tests is to determine the sensitivity by utilizing the experience of the test in relation to people who have clinical disease. A test that may appear to be highly sensitive under these circumstances may later be found to be much less sensitive when its ability to detect the DPCP is evaluated. A similar error is substituting an intermediate marker as the gold standard for calculating sensitivity and specificity. For example, the test characteristics for a thyroid assay may be compared to a more accurate assay, rather than the presence of the condition in the individual tested. In the screening context, therefore, sensitivity and specificity may vary according to whether they are estimated for early disease or preclinical lesions, and sensitivity for both should be determined in active screening programs. To do so for specificity is very much easier than for sensitivity. This is because the diagnostic process put in train by a positive screening test generally fairly rapidly identifies those who have the disease and thus distinguishes the true from the false positives. As under most circumstances, the proportion of those who have the disease in relation to the total population screened is low, a very good approximation to specificity is obtained by calculating the proportion of all those who tested negative of the sum of the test negatives and false positives. Including the unidentified false negatives in the numerator and denominator of this expression will in practice introduce little error.

Sensitivity is however a difficult measure to determine initially in a screening program. The reason for this is that the false negatives are not immediately apparent, as there is no justification to retest all the test negatives just to identify a few false negatives. Only by following the total population who screened negative is it eventually possible to identify those who had the disease at the time the test was administered but were not so identified at the time of screening. This is facilitated if test materials are retained, for example, cervical smears or mammograms originally classed negative can be reassessed for those who are found to have disease at the next scheduled screen or who develop disease during the interval between screens. Such reassessments should preferably be made blind to avoid bias. Such an approach was used in the assessment of the sensitivity of the "reader error" for cervical cancer screening (Boyes et al. 1982) and in the assessment of the sensitivity of mammography in a trial of breast cancer screening (Baines et al. 1988).

When test materials cannot be retained, however, such as in the assessment of the sensitivity of physical examination as a screening test for breast cancer, and for what we have called the "taker error and the biological component" of false negatives in cervical cytology, i.e., disease that was indeed present but was not incorporated in the smear or for some reason did not exfoliate (Boyes et al. 1982), a direct identification of false negatives will not be possible. A usual approach is to assume that disease occurring within a certain period are false negatives, an approach we used in estimating the sensitivity of physical examination of the breasts (Baines et al. 1989). However, a possibly more satisfactory approach is to assess the expected detection rate of disease on screening after repeated screens, assuming that most of the false negatives had by then been identified, and to regard the excess disease above this level at the second screen as a measure of the false negatives at the first screen. As a result of such an approach, it was determined that the taker and biological component of false negatives was approximately equal to the directly measured reader error so that the level of sensitivity for cervical cytology approximated to 78% (Miller 1981).

It is generally accepted that:

- The sensitivity and specificity of the screening test to be used should have been evaluated and their expected values stated.
- There should be an acceptable program of quality control to ensure that the stated levels of sensitivity and specificity are attained and maintained.

Quality control involves issues that concern not only the validity of the screening test but also its safety. There is, for example, the need to ensure that radiation exposure does not drift upward in a mammography screening program. Quality control encumbers the training of those who will actually administer and read screening tests, their supervision, and the introduction of procedures to check actively on the extent to which those positive or negative are misclassified.

Quality may suffer because of overwork and boredom. One of the reasons why a recommendation was made to change the frequency of examination for most women in cervical cytology screening programs in Canada was to avoid repetitive rescreening of normal women, with the flooding of laboratories with unnecessary and unrewarding work (Task Force 1976). The Task Force described the mechanisms for ensuring appropriate quality control. It is relevant that these requirements had to be reemphasized more than a decade later (Miller et al. 1991b).

That such issues are not simple was underlined by consideration of observer variation in mammography reading (Boyd et al. 1982). Relevant to all screening programs is not only the accuracy with which abnormalities are identified but, if identified, the extent to which appropriate recommendations are made on their management. Our experience suggested that including a category of "probably benign" in a screening mammography report increases the extent of observer variation. Readers differ substantially in the extent they use this category, the extent to which they recommend special observation of individuals placed in this category, and the extent to which they recommend biopsy. Dual reading helps to increase specificity, without much, if any, loss of sensitivity. This permits the simplification of recommendations into two groups, "suspicious of malignancy" and "satisfactory (normal)" examination, and results in far greater consistency. Further, it is compatible with the appropriate separation of findings from screening tests into the probably abnormal (test positive) and probably normal (test negative) dichotomy. The probably abnormal group is subjected to diagnostic tests in the normal way. This approach to use of screening mammography was accepted with difficulty in North America due to an initial tendency for most radiologists to regard mammography as a diagnostic rather than a screening test. This resulted in greater use of biopsy as a diagnostic test in North America than that reported from Europe (McLelland and Pisano 1992), where more use was made of diagnostic mammography subsequent to screening mammography (often called by European radiologists "complete" mammography) with a consequent reduction in biopsies and a much lower benign to malignant ratio.

Most commentators in the past, when considering the relative weight to be placed on sensitivity and specificity, tended to encourage high sensitivity at the cost of relatively low specificity, as it was felt important to attempt to avoid missing individuals who truly had disease. One vigorous exponent of this view for breast cancer screening was Moskowitz, who coined the term "aggressive screening," as only by such an approach did he feel that the "minimal" breast cancers with an excellent prognosis would be identified (Moskowitz et al. 1976). However, there continues to be little evidence that such cancers are really responsible for the mortality reduction following breast cancer screening. Rather, there is much evidence that the early diagnosis of more advanced disease results in the benefit (Miller 1987, 1994; Miller et al. 2000b, 2002). A disadvantage of aggressive screening was a high benign to malignant ratio and low specificity of the screen. Although the objective of screening is to identify disease in the DPCP before it gets to the stage of escaping from curability, if a test is made so sensitive that it picks up lesions that would never have progressed in that individuals lifetime, there will be substantial additional costs for diagnosis and treatment (this is one consequence of the "overdiagnosis" bias, which is more fully discussed in relation to survival of cases following screen detection in a later section of this chapter). There is no point in identifying through screening disease which would never have presented clinically and little point (other than less radical therapy) in identifying early disease that would have been cured anyway if it had presented clinically. Similarly, identifying disease that results in death, even following screen identification and subsequent treatment, only results in greater observation time and no benefit to the screenee. It is only disease that results in death in the absence of screening, but which is cured following treatment after screen detection, from which the real benefit of a screening program derives. Hence, if high "sensitivity" is largely based on finding more good prognosis disease, but results in lowering specificity, the program will incur much greater costs without corresponding benefit.

The process measure, as distinct from a measure of validity, that most clearly expresses this difficulty is the predictive value of a positive screen. This is defined as the proportion of those who test positive who truly have the disease (Fig. 22.3). This measure is influenced not only by the sensitivity and specificity of the test, especially the latter, but by the prevalence of disease in the population, whereas sensitivity and specificity are invariant with regard to disease prevalence. If tests are administered under circumstances that incur a low predictive value positive, then not only may costs be high in terms of correctly identifying those who are falsely positive but also the potential hazard may be high, as an individual classified as positive falsely derives no benefit and potentially a substantial risk from the associated diagnostic procedures. A test with a low positive predictive value rapidly enters into disrepute. The predictive value positive will be very much higher when people at high risk for the disease are screened, as distinct from the general population. This is the main reason why in screening programs, those eligible are defined by age.

This is sometimes misunderstood by those responsible for organizing screening, especially if their experience to date has been largely related to the treatment of the disease for which it is now intended to screen. As an example, because of the different age pyramid in most developing countries, those who treat breast cancer in such countries often believe that the cancer they see is different from technically advanced countries, as it occurs a decade earlier. The error has been to look at the age distribution of cases and not relate that to the age distribution of the population from which the cases are drawn. So that often, such clinicians will demand screening to begin in women in their thirties, rather than in their forties or fifties as in developed countries, as a much higher proportion of the cases they see are young than in developed countries. What they have failed to understand is that the age-specific incidence of breast cancer in women in their thirties is no higher than in technically advanced countries and is often lower. So that, to take an example from one country in the Eastern Mediterranean region of the World Health Organization, if they were to attempt to screen women at, say, age 35–39, they would on average have to examine over 3,500 women to detect one case of breast cancer, whereas the burden would be much less if they were to screen older women. This relationship between prevalence and positive predictive value is causing concern as we begin to contemplate the requirement for continued screening of women vaccinated to prevent cancer of the cervix, given that the available vaccines do not provide protection against all high-risk HPV types (Howlett et al. 2009). Although screening will be needed in such women, the positive predictive value will be much lower than in unvaccinated, even normal risk women.

To complete discussion of process measures, the predictive value negative should be defined. This is the proportion of those who test negative who are truly free of the disease. This measure, like sensitivity, is dependent on identifying the false negatives and therefore is rarely determined while being of little operational value. In practice, however, it is usually high. However, it has, in theory, become important in relation to cervical screening, where one of the major benefits of using primary HPV screening is likely to be its higher negative predictive value than cytology, thus permitting longer intervals between repeat screens (Dillner et al. 2008).

As Day (1985) has pointed out, because of the difficulty in identifying false negatives, and because of the overdiagnosis bias, the usual approach to defining sensitivity is not ideal nor particularly biologically meaningful. He suggested an alternative measure of sensitivity which can be derived if the expected incidence of disease in the absence of screening can be determined, ideally from the control group in a randomized trial but sometimes in population-based programs from historical data or data from comparable unscreened populations. The method basically computes the extent a program is successful in reducing the expected incidence of disease in the absence of screening. The lower the proportion of expected incidence occurring after screening, the greater the sensitivity. The use of this approach, and other measures relevant to sensitivity, such as test, episode, and program sensitivity, is fully discussed by Hakama et al. (2007).

22.2.2 The Acceptability of the Test

One of the desirable attributes of a good screening test is that it should be acceptable to the population to which screening is offered and acceptable to those who will administer the test. In general, cervical cytology screening programs have found acceptance with women and their physicians. Although those who tend to be at highest risk of the disease do not comply as well as those with lower risk, this is not strictly related to acceptability of the test, but rather the fact that such individuals tend to have so many pressing health and social problems, that taking action to reduce an uncertain risk in the future does not have priority with them. Nevertheless, this results in lower effectiveness of programs than would be the case if all women were to be included. This lack of acceptance is largely related to lower socioeconomic status, accompanied by high parity, and often multiple sexual partners.

Breast cancer screening has encountered different problems over acceptability, though this varies substantially in different countries, ranging from the 90% acceptance with screening invitations in the Swedish Two-County Trial (Tabar et al. 1985) to the difficulties with both physician and women compliance in the early stages of mammography utilization for breast screening in the United States (Howard 1987). In Europe, a median uptake of 74% has been reported for mammography offered in the population (European Society for Mastology 1993). Perhaps fortunately, those who tend to comply with invitations to attend breast screening programs tend to be those at higher risk. An exception relates to the misperception of many older women that they are not at risk for the disease, whereas the older they become, the greater is their risk.

Another example is screening for colorectal cancer because of the inevitable distaste of individuals for a procedure that involves manipulation of feces. In a number of pilot programs, therefore, the return rates for hemoccult slides have been low, though they have been better in well-organized studies (Chamberlain and Miller 1988), and achieved approximately 75% in the Minnesota Colon Cancer Screening Trial (Mandel et al. 1999).

A screening test, therefore, has to be acceptable to the population in its widest sense. The test should be simple and as far as possible easily administered. It should involve procedures that are not unacceptable, and its use should not have unpleasant or potentially hazardous implications. There are also economic advantages in a test being administered or read by allied health professionals, such as use of technologists in screening cervical cytology slides (Anderson 1985) or the use of nurses to perform breast examinations (Bassett 1985; Miller et al. 1991a).

22.3 The Ethics of Screening

In general medical practice, the special nature of the relationship between a patient and her or his physician has dictated the need to build up a core of ethical principles that govern this relationship. Further, it is generally accepted that additional issues arise when a patient becomes the subject of a research investigation that is superimposed upon his or her search for and receipt of appropriate medical care. It was not initially appreciated, however, that screening opened up a completely new spectrum of issues, possibly requiring more restrictive boundaries of ethical behavior than those applied in usual medical care. For example, when a patient goes to see a physician for relief of a symptom or treatment of an established condition, the physician is required to exercise his or her skills only to the extent that knowledge is currently available, while doing what is possible with available expertise and appropriate assistance to help the patient. Treatment may be offered without any implied guarantee that it is necessarily efficacious or will do more than just temporarily relieve the symptoms of which the patient complains. Thus, the physician promises to do his or her best for the patient; there is no implied promise that the patient will be cured.

In screening, however, those who are approached to participate are not patients, and most of them do not become patients. The screener believes that as a result of screening, the health of the community will be better. He or she does not necessarily intend to imply that the condition of every individual will be better. However, screening is often promoted as if it implies a benefit to everyone who is screened. In fact, in some circumstances, individuals included in a screening program may be placed at a disadvantage, as discussed above. Furthermore, the harm from a screening test is not only related to the risk of being false positive or negative. Those that are screened may also incur psychological consequences, sometimes merely from being labeled as being at risk of disease. At the very least, therefore, those planning to introduce a screening program should be in a position to guarantee overall benefit to the community and a minimum of risk that certain individuals may be disadvantaged by the program. It was the inability to guarantee overall benefit and lack of disadvantage for those screened that led to the proscription of mammography in women under the age of 50 in the Breast Cancer Detection Demonstration Projects in the United States (Beahrs et al. 1979).

A second ethical issue, which is directed more to the obligations for appropriate care in the community than toward individuals, concerns how limited resources are equitably distributed across the whole community to obtain maximum benefit. Under certain circumstances, the offer of screening could diminish the total level of health in a community. This may be a particular problem for developing countries by diverting resources intended for routine health care into screening. Thus, resources diverted to a screening project, which might be regarded as prestigious, especially if involving high technology, could lower the resources available for other more pressing but also more mundane health problems. Although several screening programs have been proposed for developing countries, there is a particular need for caution and care in order to ensure that they do not overbalance the health-care system in the area in which they are introduced.

A final ethical dilemma for screening programs is how to implement informed consent. Information about risks and benefits of tests and treatments is expected to be provided in usual clinical practice. For screening, providing information about the test alone is not sufficient. Information about the consequences of the test, the diagnostic assessment process, and the diseases to be detected and their treatments should also be presented, if a truly informed decision is to be made. Presenting such a large amount of information is obviously difficult, particularly in a primary care setting where several screening tests may be done at the same time. Furthermore, presenting such information becomes even more cumbersome when the evidence base for a screening test is limited, such as in the case with prostate screening with the prostate-specific antigen (PSA) test.

Those in charge of screening programs, therefore, carry an ethical responsibility at least as great as that for medical practice in that approaches to participate are made to ostensibly healthy people. Indeed, the burden of proof for efficacy of the procedures and the necessity to avoid harm are greater than may be required for diagnostic or therapeutic procedures carried out when a patient presents with symptoms to a physician. In screening, the physician or public health worker initiates the process, and he or she bears the onus of responsibility to be certain that benefit will follow.

22.4 The Population to be Included in Screening Programs

For a screening program to be successful, the population to be included should be one in which it is known that the disease has a high prevalence. This will not only encourage a high predictive value for a positive test; it will tend to promote higher quality of performance and assessment of results of screening tests and will result in lower costs per case detected. Thus, in all screening programs, it is desirable to attempt to include only those who are at risk of the disease and to concentrate particularly on those who are at high risk of the disease. This approach was recognized by the Canadian Task Force on Cervical Cytology Screening Programs (Task Force 1976) who carefully defined those whom it believed were at such low risk for the disease that they need not be included in cervical cytology screening programs, thus defining the remaining "at-risk" population on whom major efforts should be concentrated to bring them into screening. In the case of cardiovascular disease, family history and factors such as smoking have been used by some to define populations to be screened.

For other diseases, however, the known risk factors, apart from age, may not suffice to adequately distinguish between those who should be considered for inclusion in screening programs compared to those who should not. For breast screening, for example, although some discrimination using risk factors has been achieved (Schechter et al. 1986), this has not been sufficient to justify selection on this basis alone. However, age is an important predictor of risk, and for breast cancer in technically advanced countries, all women in the appropriate age group can be regarded as at high risk. Thus, for breast cancer currently, it seems unlikely that any program could justify routine screening of women under the age of 40, while several trials only found a delayed effect of screening women in this age group, and our trial in Canada, the only so far specifically designed to evaluate breast screening at age 40–49, could not find evidence that screening women at these ages with mammography is effective (Miller et al. 2002). The other trial designed to evaluate screening at these ages had an innovative design, women entering their forties were randomized 1:2 to annual mammography screening for 7 years compared to no screening, followed without screening until they reached the age of 50, and then all were invited to participate in the UK screening program of 3-yearly mammography also found no significant benefit from screening at these ages (Moss et al. 2006). As a result, the organized programs in most European countries and in Canada do not attempt to recruit women under the age of 50 into screening.

One possible approach to concentrating on the relevant segment of the population for screening might be to administer a prescreening test, especially for a marker for a factor necessary in the causation of the disease. The test for human papilloma virus infection could be used as a prescreen for cancer of the cervix (Miller et al. 2000a), as the test does not identify the presence of disease – other tests such as cytology of colposcopy have to be used in those found positive to the test. A difficulty here is the high proportion of infections that are self-limiting without the development of high-grade cervical intraepithelial neoplasia. This means that the test is too non-specific if used among women under the age of 30. However, in older women, if found to be negative to a test for oncogenic HPV strains, they can be deemed at low risk for the disease and screened far less frequently than women who are HPV positive (Dillner et al. 2008).

The development of genetic susceptibility testing opens up the possibility in the future of prescreening for a range of diseases. Unfortunately, the tests that indicate high risks so far only identify individuals in the population responsible for a low proportion of disease. It seems possible that it will be necessary to screen for a combination of genetic polymorphisms each responsible for relatively low relative risks in the population, but with high attributable risk, in order to adequately discriminate at risk from low-risk individuals. This will increase the complexity, and costs, of the process considerably.

Nevertheless, in programs that attempt to select for screening on the basis of risk factors, there will almost invariably be cases occurring in the unscreened group. A consequence of such programs, however, will be reduced numbers of false positives (in absolute terms) which with the increased prevalence of the disease will result in a higher positive predictive value of the screen. Hakama (1984) coined the terms program sensitivity and program specificity which help in understanding the effects of screening concentrating on “high-risk” subjects. The more a program concentrates on high-risk groups, the lower the program sensitivity, as more and more cases will occur in unscreened people. Conversely, however, the program specificity will increase because of the increase in healthy people unscreened with a reduction in the costs of screening. However, because the reduction in program sensitivity will result in a reduction in the overall effectiveness of the program, the overall result of such an approach could be unacceptable.

One other approach to using risk factors is to help determine the optimal periodicity of rescreening. Those judged at high risk could be screened more frequently, as in the example of HPV tests for cervix screening given above. Once again, however, much of the necessary research is incomplete, and we do not know how appropriate such an approach may be. It will probably be necessary to calculate the marginal cost-effectiveness of extending screening from high- to low-risk groups (i.e., the additional cost for such an extension of screening related to the increase in effectiveness of the screening) in order to make the necessary policy decisions.

22.5 Diagnosis and Treatment of the Discovered Lesions

As a screening test is not diagnostic, inevitably the success of the program will ultimately depend upon the extent those identified as having a positive test accept the procedures offered to them for further evaluation and the effectiveness of the therapy offered.

A number of difficulties may arise. For example, in the initial phases of many breast cancer screening programs, it was necessary to demonstrate to the general community of medical practitioners that the abnormalities identified were indeed of importance and that they required care and expertise to biopsy. Indeed in the absence of skills in diagnosis and management, there can be unnecessary biopsy (potentially reducible by the use of diagnostic mammography and fine needle aspiration biopsies) as well as failure to excise the lesion when biopsy is performed. This is part of the spectrum of problems that arise over the fact that lesions may be identified in screening programs whose biological features, natural history, and other characteristics may be in doubt. The screening participants may require special education programs so that they understand the diagnostic process to reduce as far as possible one of the major adverse consequences of screening, the anxiety accompanying the identification of an abnormality, as well as ensuring that they comply with the recommendations for management. There may even be major disagreements over the histological interpretation of the excised lesions, with uncertainties over the borderline between benign and malignant. Thus, the public and the professionals at all levels in a screening program may require education and/or retraining dependent on their responsibilities. One mechanism to reduce difficulties in the professional area that should be encouraged is the provision of special diagnostic and treatment centers where the necessary expertise in diagnosis and management can be concentrated and where the necessary facilities are available (Miller and Tsechkovski 1987). Such diagnosis centers could be regionally based, serving a number of screening centers.

22.6 Evaluation of the Efficacy of Screening

A number of issues have to be noted when evaluating the efficacy of screening. Almost invariably individuals with disease identified as a result of screening will have a longer survival time than those diagnosed in the normal way. Four biases associated with screening explain this (see Box 22.1). The first is “lead time,” defined as the interval between the time of detection by screening and the time at which

Box 22.1. The biases associated with survival

Lead time: the period by which screening advances the diagnosis of the disease.

Length bias: less rapidly progressive cases are likely to be detected by screening.

Selection bias: volunteers for screening are likely to have a better outcome from their disease than those who decline screening.

Overdiagnosis bias: lesions identified by screening which would not have progressed to clinical disease in the absence of screening.

the disease would have been diagnosed in the absence of screening (depicted in Fig. 22.1). In other words, it is the period by which screening advances the diagnosis of the disease. For example, if, as a result of screening, the average point of diagnosis is advanced by 1 year, then inevitably cases diagnosed by screening will survive 1 year longer even if there is no long-term benefit. It is important to recognize that the lead time for different cases will vary, depending in part on the timing of the screening test in relation to the duration of the DPCP in that case, as well as the rapidity of progression of the DPCP in that individual. Thus, there will be a distribution of lead times (Morrison 1985). The lead time for fatal cases will be fairly short, but in one study, some fatal cases have been identified as having a lead time of one or more years following mammography screening (Miller et al. 1992).

The determination of lead time is complex, but models have been developed that do so providing there are control data that permit comparison of screen detection with that expected (Walter and Day 1983).

Differential lead time can be an important factor in comparing the outcome among cases detected by different screening modalities, making it almost impossible to make a comparison based on survival, unless it is possible to estimate and correct for differential lead time (Walter and Stitt 1987).

The second bias that accounts for improved survival of screen-detected cases is "length-biased sampling," or more simply, length bias. This relates to the fact that individuals who have rapidly progressive disease will tend to develop symptoms that cause them to consult physicians directly. Thus, only less rapidly progressive cases are likely to remain to be detected by screening. Yet the former have a poorer and the latter a better prognosis, hence the improved survival of screen-detected cases, over and above lead time. A representation of this bias is in Fig. 22.5. It is obvious that if the screening test were to be administered just before clinical symptoms occur, nearly all cases would be detected, but by them, some of them would probably have a poorer prognosis. So it is important to try and detect cases earlier in the DPCP, but if one is successful, many of the rapidly progressive cases will be missed. What is more, what is depicted is just at one point in time, rapidly progressive cases that were present at the time the slowly progressive cases become detectable, would have

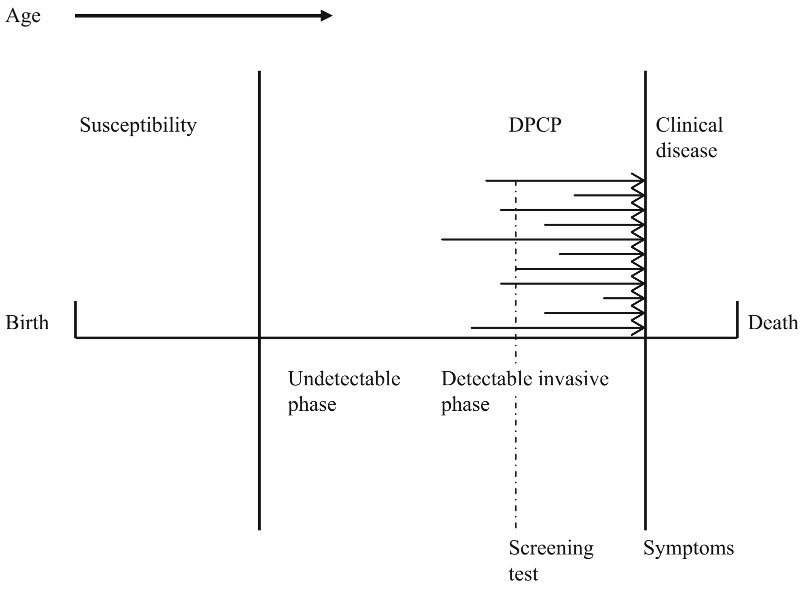

Fig. 22.5 The impact of a screening test when the detectable preclinical phase varies in duration – length bias

presented with symptoms before the screening test was administered. This bias is most obvious at the initiation of a screening program, at the first or prevalent screen. However, length bias will also affect the type of cases detected at rescreening, with the more rapidly progressive cancers diagnosed in the intervals between screens. Hence, in evaluating the total impact of programs, the interval cases must be identified and taken into consideration as well as the screen-detected cases.

The third bias which can artifactually improve survival is selection bias, i.e., participants in screening are likely to have a better outcome from their disease than those who decline screening. This is because those who enter screening programs are volunteers and almost invariably more health conscious than those who decline to enter. This means that they are likely, even in the absence of screening, to have a better outcome from their disease than the overall rates in the general population.

The fourth bias is overdiagnosis bias. Simply it means that some lesions identified and counted as disease would not have progressed to present clinically in those individuals during their lifetimes in the absence of screening. It is, in practice, an extreme example of length bias. It is difficult to obtain absolute confirmation of the existence of this bias, though it seems likely that it is at least in part an explanation for the substantial excess of cancers detected by PSA screening for prostate cancer (Draisma et al. 2003), and it has also been strongly suspected for breast cancer (Miller et al. 2000b, 2002).

The only design that effectively eliminates the effect of all these biases is the randomized controlled trial (Prorok et al. 1984), but only if mortality from the disease (i.e., deaths related to the person-years of observation) is used as the endpoint, rather than survival. Survival could be used in a randomized controlled screening trial only under special circumstances. These are that there is good evidence because of the equivalence in cumulative numbers of cases during the relevant period of observation that there is no overdiagnosis bias and providing that the start of the period of observation of the cases is taken as the date of randomization, as that will eliminate differential lead time. This is the approach that was planned to be used in a study of breast self-examination in Russia, where it will not be possible to follow all entrants to determine their alive and dead status at the end of the trial (Semiglazov et al. 1993). Length bias and selection bias are not issues, the latter having been equally distributed by the randomization and the former by having started at the same point in time and by including all cases that occur during follow-up in the evaluation. However, to date, it has not been possible to perform a definitive analysis of the results of this trial, as the collapse of the Soviet Union resulted in too much disruption to permit the collection of the data deemed necessary to adjust for the cluster (as distinct from individual) randomization performed in the trial.

Outside a randomized trial, if the screening test detects a precursor, reduction in incidence of the clinically detected disease can be expected and evaluated. This effect has been well demonstrated in the Nordic countries in relation to screening for cancer of the cervix (Hakama 1982). It is also anticipated from endoscopy screening for colorectal cancer, with the detection and removal of adenomas, and was demonstrated in the randomized Minnesota trial of colorectal screening using the fecal occult blood test with colonoscopy extensively used for diagnosis (Mandel et al. 2000). If the screening test does not detect a precursor, or even if it does but the main yield is invasive cancer, then incidence can be expected to increase initially following the introduction of screening and remain elevated while screening continues, though there may be some reduction toward the baseline after continued screening, if the application of the test results in most at-risk subjects being included, and the subsequent screening tests are largely used for rescreening. This seems to have happened with the major rise and then fall, but not to the original levels, of prostate cancer incidence following the opportunistic introduction of the PSA test in North America. Under such circumstances, when further reduction in incidence cannot be anticipated, and improvement in survival cannot be relied upon because of the biases already discussed, the only valid outcome for assessment of results of a screening program is mortality from the disease in the total population offered screening in comparison with the mortality that would be expected in the same population if screening had not been offered.

As already emphasized, the design of choice for evaluation of changes in mortality is the randomized controlled trial. This can either be an efficacy trial or an effectiveness trial. Efficacy trials are based on randomization of the screening test, which answers the biologically relevant question as to whether mortality is reduced in those screened. An effectiveness trial is based on the randomization of invitations to attend for screening and more nearly replicates the circumstances that may eventually pertain in practice in a population. Both those who accept the invitation as well as those who refuse will have to be included in the assessment of outcome. Thus, it tests the impact of introducing screening in a population. Some trials of this type involve randomization by cluster. However, cluster randomization can lead to difficulties in determining whether the trial results are valid, especially if it cannot be confirmed that the randomized groups were balanced, or if there is evidence that they were not. Such problems led to difficulties in determining the validity of some cluster randomized trials of breast screening (IARC 2002).

If for some reason randomization is believed inappropriate, a second-best method is the quasi-experimental study in which screening is offered in some areas, and unscreened areas as comparable as possible are used for comparison purposes. However, this design is not a cheap and easy way out but demands the same methodological accuracy as required for randomized trials. Further, in view of the substantially larger populations that may have to be studied than in randomized trials, it may prove to be more expensive than the preferred design. Critically, difficulties in analysis may ensue if the baseline mortality in the comparison areas differs (UK Trial of Early Detection of Breast Cancer Group 1988).

Nevertheless, ethical issues may preclude the utilization of randomized trials, particularly for programs that were introduced before the necessity of utilizing trials as far as possible for evaluation was appreciated. This has been the case for screening for cancer of the cervix, for example. One approach under these circumstances is to compare the mortality in defined populations before and after the introduction of screening programs, preferably with data available on the trends in acceptance of screening so that changes in mortality can be correlated with the mortality trends. Such a correlation study will be strengthened if other data that could be related to changes in the outcome variable are entered into a multivariate analysis (Miller et al. 1976).

A case-control study of screening is another approach that can be used to evaluate programs that were introduced sufficiently long before the study that an effect can be expected to have occurred. Case-control studies depend on comparing the screen histories of the cases with the histories of comparable controls drawn from the population from which the cases arose. Individuals with early stage disease if sampled would be eligible as a control, providing the date of diagnosis was not earlier than that of the case, as diagnosis of disease truncates the screening history. However, a bias would arise if advanced disease is compared only with early stage disease, as the latter is likely to be screen-detected, though this is just a function of the screening process, not its efficacy (Weiss 1983). Cases have to reflect the endpoints used to evaluate screening, i.e., those that would be expected to be reduced by screening. Thus, cases are often deaths from the disease or advanced disease as a surrogate for deaths or, if a precursor of the disease is detected through screening, incident cases in the population. If incident cases are screen-detected, the controls should be drawn from those screened in the same program; if the cases are not screen-detected, the controls should be population-based (Sasco et al. 1986).

One difficulty with case-control studies of screening is that they may be affected by selection bias as the health conscious may select themselves for screening. This may be difficult to correct in the analysis, though such a correction should be attempted if the relevant data on risk factors for the disease (confounders) are available. This was possible in a case-control study of breast self-examination nested within the Canadian National Breast Screening Study, in which data on risk factors for breast cancer were collected from all on enrollment (Harvey et al. 1997). Such a bias may not be a problem, however, in other circumstances, if it can be demonstrated that the incidence of cancer in those who declined the invitation to the screening program is similar to that expected in an unscreened population.

However, even if data are available on risk factors for disease, adjusting for them may not result in avoiding the effect of selection bias. For breast cancer, for example, experience in studies in Sweden and the UK, where case-control studies were performed within trials, shows that although those who refused invitations for screening had similar breast cancer incidence to the unscreened controls in the trial, their breast cancer mortality experience was worse than that of those controls. This meant that the estimate of the effect of screening in such case-control studies was greater than could have been expected in the total population (Miller et al. 1990; Moss 1991).

In addition to assessing effectiveness of screening, case-control studies may also be of use to assess other aspects of screening programs. For example, a method has been proposed for estimation of the natural history of preclinical disease from screening data based on case-control methodology (Brookmeyer et al. 1986).

The cohort study design may also provide an estimate of the effect of screening, an approach in which the mortality from the cancer of interest in an individually identified and followed screened group (the cohort) is compared to the mortality experience in a control population, often derived from the general population. This approach has been used to evaluate the mortality experience in the US Breast Cancer Detection Demonstration Project (Morrison et al. 1988) and in a cohort of women in Finland included in a breast self-examination program (Gastrin et al. 1994). In these studies, it has to be recognized that those recruited into a screening program are initially free of the disease of interest so that it is not appropriate to apply population mortality rates for the disease to the person-years experience of the study cohort. Rather, as is required in estimating the sample size required for a controlled trial of screening, it is first necessary to determine the expected incidence of the cases of interest, then apply to that expectation the expected case-fatality rate from the disease to derive the expectation for the deaths (Moss et al. 1987). In practice, a cohort study of screening suffers from the same problem of selection bias as for case-control studies, so the results have to be interpreted with caution.

Indirect indicators of effectiveness are often desired in evaluating screening programs, especially one that would predict subsequent mortality. Compliance with screening, and rate of screen detection, as well as the ratio of prevalence and incidence can be indicators of potentially effective screens (Day et al. 1989). The cumulative prevalence (not the percentage distribution) of advanced disease is one such measure (Prorok et al. 1984). For example, reduction in advanced disease predicted subsequent breast cancer mortality reduction in a trial of mammography screening versus no screening in Sweden (Tabar et al. 1989). However, case detection frequency, numbers of small tumors, and stage shift in percentages of the total should not be used as indicators of effectiveness as they potentially reflect all four screening biases.

In evaluating whether screening programs are effective in a population, different methods have generally to be used. They are considered in the Sect. 22.11, later in this chapter.

22.7 Organized Screening Programs

There are a number of features of effective screening programs that are largely related to good organization. Indeed, there is good evidence, at least for cancer of the cervix, that unorganized or opportunistic screening programs, which depend on the willingness of individuals to volunteer for screening, and the extent to which their physicians offer screening, often to low-risk women, are far less successful (Hakama et al. 1985).

Hakama et al. (1985) defined certain essential elements of organized programs. These are:

- The target population has been identified.
- The individual women are identifiable.
- Measures are available to guarantee high coverage and attendance such as a personal letter of invitation.
- There are adequate field facilities for performing the screening tests.
- There is an organized quality control program on performing and reading the tests.
- Adequate facilities exist for diagnosis and for appropriate treatment of confirmed abnormalities.
- There is a carefully designed and agreed referral system, an agreed link between the participant, the screening center, and the clinical facility for diagnosis of an abnormal screening test, for management of any abnormalities found and for providing information about normal screening tests.
- Evaluation and monitoring of the total program is organized in terms of incidence and mortality rates among those attending, among those not attending, at the level of the total target population.
- Quality control of the epidemiological data should be established.

Although these elements are present in many European cancer screening programs, especially in the Nordic countries, and contribute greatly to their success, several elements are missing from programs elsewhere, especially those largely based on the private medical care system in North America. In Canada, there are opportunities for introducing some of them, such as the first three, and these were recommended by the two Canadian Task Forces on cervical cancer screening

(Task Force 1976, 1982). Unfortunately, only three of the provincial health-care authorities (Ontario, Manitoba, and British Columbia (the latter having accepted from the beginning the need for centralized laboratory services)) have taken the initiative to establish such programs. All provinces in Canada that introduced breast screening programs, however, accepted from the outset the necessity for them to be organized (Workshop Group 1989), thus attempting to replicate the organization of breast cancer screening in some of the Nordic countries, the Netherlands, and in the United Kingdom.

There has been some debate as to whether organized as distinct from opportunistic screening is most efficacious in reducing the incidence of cancer of the cervix. Nieminen et al. (1999) produced evidence that in Finland, the organized program is far more effective than opportunistic screening.

22.8 Health-Related Quality of Life and Screening

An important evaluation measure for screening is the extent overall quality of life is improved or impaired by screening compared to usual care. Decision making for health-care policy is only possible if information is available on quality of life as well as health costs of screened and unscreened participants as well as mortality reduction from screening. For example, it requires an “optimistic” estimate of screening effectiveness to derive an overall benefit from screening for prostate cancer (Krahn et al. 1994). Issues concerning health-related quality of life (HRQL) may well vary with different cultural value systems and different health-care systems.

Because of lead time, HRQL events will tend to occur earlier in life than similar events associated with usual care. Given that the adverse quality of life associated with false-positive screening tests, and those associated with treatment will tend to occur relatively early, it could be easy to convince oneself (as it has convinced some commentators for prostate cancer screening already) that the HRQL issues are overwhelming and that screening should not be conducted. It will require prolonged follow-up, probably more than 10 years, for the detriments associated with advanced disease late in life that may be prevented from occurring in the screened group to appear in the non-screened group (Miller et al. 2001).

If the outcome of screening were to be a major benefit in terms of mortality reduction, the issues related to HRQL would be overwhelmed. It is only if the outcome is a moderate to small mortality reduction that these issues become critical, and paradoxically then it would be necessary for them to have been measured with as much precision as was possible during screening, as, particularly for HRQL, the decrements could not be measured retrospectively with precision. For this reason, in screening trials where adverse HRQL can be anticipated, it is important for such events to be identified and quantified.

22.9 Economics of Screening

Space does not permit a detailed evaluation of the various principles that have to be considered in assessing the economics of screening. In brief, it is necessary to determine the costs of the test and the subsequent diagnostic tests. Also should be included are the costs associated with any hazard of the test as well as the costs of overtreatment. Balancing these costs may be reduced costs of therapy of the primary condition, reduced costs associated with less expenditure on the treatment of advanced disease, and the economic value of the additional years of life gained. This can become quite complex when the value of treatment of disease in years of life gained, transfers such as pensions, and economic productivity are considered. The latter is often disputed, if not regarded with some distaste, so that often what is computed is the cost per year of life saved. Critical may be the marginal costs of additional tests in relation to the benefit, especially when considerations of the frequency of rescreening arise.

Part of the difficulty in economic assessment is that costs are often incurred early, while benefits flow later, so that for proper comparisons of such costs, they have to be discounted to the present day. Additional complexity ensues if attempts are made to assess quality of life in economic terms, while the calculations rarely attempt an economic assessment of the fact that if a death is prevented by screening, the relevant individual will inevitably die of some other condition and that death could be more costly.

It is likely that economic assessments will increasingly guide policy decisions in the future, so it behooves those interested in evaluation of screening to collect the necessary data. Although some economic assessments have suggested that cost-effective programs are achievable, for example, programs of breast cancer screening using single-view mammography in Sweden (Jonsson et al. 1988), others have suggested that programs may not be cost-effective, for example, breast cancer screening programs for younger women in the US (Eddy et al. 1988). Economic analysis is particularly important for making decisions *within* screening programs, for example around screening intervals or method of follow-up. Economic analyses have also facilitated the planning of national breast screening programs (IARC 2002).

22.10 Genetic Susceptibility Testing

The completion of mapping of the human genome holds great promise for disease control. This presages the advent of genetic susceptibility testing. However, the availability of a range of markers for disease susceptibility will lead to increasing controversies about the use of screening tests. While the general principles of screening outlined above will still apply, they will need to be modified. Genetic screening will identify individuals at risk of disease, rather than those with precursors or early stage disease. Although this could lead to focused application of screening tests on those at higher risk, ideally, primary prevention strategies will be available. Nevertheless, for many conditions, the preventive strategies will be the application of other screening tests implying that diagnostic assessment and treatment strategies will still be required.

22.11 Surveillance

Surveillance of a program is performed to assess its performance and to ensure that it is being as effective as possible. This requires adopting the principles of program evaluation.

Program evaluation is "the systematic assessment of the operation and/or outcomes of a program or policy compared to a set of explicit or implicit standards, as a means of contributing to the improvement of the program or policy" (Weiss 1998). Continuous evaluation of processes and outcomes of a screening program is an essential tool for assessing its organizational progress and enhancing its effectiveness.

Monitoring is the process of ongoing evaluation to determine whether a program is achieving its intermediate objectives. Monitoring uses "process measures," that are designed to indicate whether the program is on course to achieve its objectives. Of themselves, these process measures are not indicators of the success of the program. Rather they indicate whether or not the program is on the route to ultimate success, as unless they are achieved, the program is unlikely to be successful. These process measures cover a number of different aspects of the program. If the targets, as outlined below, are not met, it should be obvious which aspects of the program require urgent attention by the program managers to rectify the situation. Monitoring should be an ongoing activity, carried out as an integral part of the program, by the program's own staff.

Evaluation is a process whereby the success of the program in reaching the targets set for the intermediate outcome and outcome measures is carefully reviewed and analyzed. When carried out during the early phases of the program, it will indicate whether the program is likely to be successful. When carried out at certain defined time points after the initiation of the program, it will indicate whether the program has been successful, and, whether in the light of the degree of that success, it should be continued. Evaluation is an intermittent activity. It can be carried out by the program staff, but it can also be performed by an external consultant to the program, providing the information system is fully functional and successful in obtaining the data required.

Surveillance and evaluation are essential for all programs to ensure that the resources used achieve the benefit expected. Process measures such as the numbers of screens performed, the numbers of positive tests reported, the number (and proportion) of those screened referred for diagnosis and therapy, the numbers of cases of disease diagnosed, and the numbers of precursor and benign lesions detected should be derivable providing the data are collected from the screening centers and the treating institutions and collated. Such data must be analyzed by age to confirm that those in the target age group are being screened and receive appropriate subsequent management. However, such data cannot evaluate the effectiveness in terms of the likely prevention of occurrence of disease or of deaths from the disease, unless the data can be related to that derived from the total population on an ongoing basis, which requires linkage to a preexisting disease register or vital statistics system, or to a register of cases of the relevant disease established for this purpose.

Depending on the endpoint that should be affected by screening, e.g., deaths from the cancer of interest for cancer screening programs, the simplest form of surveillance and evaluation that will provide measures of the effectiveness of the program in the population is to be able to demonstrate a change in the slope of the trend in mortality from the disease in the population. More detailed evaluation requires the identification of all who develop the disease and die from it in the target population and documentation of their screening history. Such documentation could be done by comparing incident cases of disease in the target population with a register of those from the same population who have been screened. This will permit an estimate of the risk in those who have been screened and in those who failed to attend screening, and the combined effect can then be compared with the prescreening period. Where such registers have not been established, a screening history should be obtained from subjects with the disease, though this may not be reliable as many are unable to recall whether a screening test has been taken in the past. Efficient surveillance requires a system of linked records. A population register (or available substitute) allows periodic call-back for rescreening at appropriate intervals. The screening program register, when linked with a disease register, permits the active surveillance of those detected with abnormalities to ensure recall for diagnosis and therapy. Evaluation of the program can then be performed with regard to assessment of:

- Management of those screened with positive tests
- Disease diagnosed between the screening interval
- Groups missed in the target population

22.12 Responsibility for Screening

Responsibility for the efficient management of screening in a country (or region) should preferably be placed on a designated official within a relevant organization. If disease control has been designated to a special agency in a country, this official should have an appointment within that agency. Alternatively, it would be appropriate to designate an official within the Ministry of Health.

In general, it is not appropriate for the director of the department or laboratory performing the tests to be given responsibility for the overall direction of the whole program. This is because the responsibilities for direction of the program are far wider than reading the screening test, but cover aspects from the identification of the target group, through their recruitment, screening, and management of abnormalities found to evaluation of the impact of the program.

The director should recognize that successful screening programs:

- Are organized as public health disease control programs, and not simply as services for providing clinical investigation
- Target the age groups at greatest and most immediate risk, concentrating on those who have never had a test
- Use population registers
- Have someone in charge who is named, has a telephone number, and can be held to account

The skills necessary to encompass the responsibility for running a successful program include epidemiology, public health, and management.

22.13 Programs

The principles that underlie the evaluation of screening programs are that they should be compatible with the program objectives; there should be standardization of nomenclature, procedures, and measurements to facilitate evaluation; and that the programs should facilitate relevant research.

The *general objectives* of screening programs are:

- To reduce the incidence of the disease (if a disease precursor is detected)
- To reduce mortality from the disease

The *specific objectives* to achieve the general objectives are:

- To provision accessible and acceptable screening services
- To recruit eligible subjects, ensuring that those at high risk are screened
- To ensure adherence to recommended screening schedules
- To ensure quality in taking the test and reading it
- To effectively communicate of results
- To appropriately follow-up if there is an abnormal test
- To provide efficient and effective treatment services

The *components* of program evaluation should be designed to be compatible with these objectives. They should include:

- Population based information systems
- Quality control systems, both internal and external

In the absence of population-based information systems, specific surveys may provide some of the needed information. They could include surveys of awareness of the need for screening in eligible and especially high-risk subjects and of the practice of screening by the target group and the advice rendered by their physicians.

Specially designed epidemiological studies, most economically of the case-control type, can also be used for program evaluation, but should in general be part of a specific research project and subject to peer review.

The data requirements for efficient program evaluation include data on the target population, and a register of all screening tests performed, with identification as to first or repeat (these records must be capable of being linked to provide a longitudinal screening history of each screenee. This requires capturing information on all changes of name and preferably using unique personal identifying numbers).

Other requirements include:

- A separate register of all abnormal tests, with data on follow-up, management, and outcome
- Data on all preclinical lesions diagnosed, classified by the recommended terminology
- Data on all cases of the disease diagnosed
- Data on all deaths from the disease
- Information on cost/manpower items, relevant to every aspect of screening

For evaluation and monitoring purposes, the data in information systems must be maintained in individually identifiable and linkable form, and the system should be so designed that it is accessible for evaluation and monitoring purposes and research as well as for the requirements of routine functioning of the program. The information on the target population should be provided by age, geographical area, and if possible the family physician of those eligible for screening. This will permit the identification of those in the population who are not being screened, who are likely to include those at highest risk, for whom special efforts will be needed to bring them into the program. Such linkages will enable the success of the measures taken to recruit eligible subjects to be determined.

The *criteria* for success or failure of screening programs relate to the objectives of the program. These include:

- Increase in awareness of the need for screening in the at-risk population
- Increase in participation rates for screening
- Reach members of the target group who have never been screened
- Improve the performance of test centers or laboratories
- Reduce the utilization of unnecessary medical procedures
- Reduce the incidence of and mortality from the disease

Thus, evaluation should include not only outcome measures, most importantly incidence and mortality from the disease, but also process measures so that if a program is not effective, the corrective actions needed can be taken.

There has to be some designated authority who will accept responsibility for program evaluation, assess the success in achieving the program objectives, and ensure corrective action is taken as necessary. Although this may vary by program and country, the primary responsibility should usually be assumed by government, though government may seek the assistance of non-government organizations in reaching the objectives. It would be desirable for government to appoint a broadly based advisory committee, with expert members drawn from a variety of disciplines. Acting on the advice of this committee, government may be able to delegate to various organizations responsible for different program components the responsibility for any corrective action necessary.

22.14 Information Systems for Screening Programs

A population-based information system is the basic building block of organized screening programs. Such information systems must be capable of supporting a diversity of goals and objectives (see below) including individual information retrieval and sophisticated aggregate and comparative data analyzes.

The range of goals and objectives to which information systems can contribute attest to their importance in assisting screening programs to achieve positive health outcomes. Information systems for screening programs should be designed to:

(a) Identify the target population
(b) Identify individuals in the target population
(c) Permit the individuals in the target population to be sent letters to:
    1. Remind her/him to attend for screening once she/he reaches the recommended age
    2. Remind her/him to reattend for screening at the recommended intervals
    3. Remind her/him to attend the local diagnosis center if an abnormality is discovered on self-examination or physician examination
(d) Monitor that action has been taken following the discovery of an abnormality
(e) Provide long-term follow-up for patients who have received treatment following the diagnosis of disease
(f) Permit linkage of individual screens at the individual level
(g) Permit evaluation and monitoring of the total system

Development of information systems will be facilitated by the introduction of permanent individual health-care identifiers. However, establishment of data bases to support screening programs need not be dependent upon unique individual identifiers and should not be delayed where such identifiers are not yet in use.

22.14.1 Goals and Objectives of Information Systems

The *goals* of an information system are:

- To facilitate enrolling the at-risk population
  For a screening program, it is essential that the data base incorporate data on the entire target population.
- To maintain information
  Information on the screening history of each screenee must be maintained on the data base; in addition, information must be organized and the data elements defined to facilitate analysis and planning.
- To provide the means for follow-up
  The information system must support communication with individuals concerning test results, the need for screening, rescreening or medical follow-up.
- To support evaluation of quality assurance

Design of the information system must incorporate the capacity for qualitative assessment of the program as a whole.

- To track utilization of screening by the target population
  A critical measure of the value of the program's information system will be its utility to follow patterns of use to determine levels of utilization.
- To monitor compliance
  Compliance with recommended screening and appropriate follow-up must be monitored by the information system to assist in evaluating the success of the overall program.

The information system developed to support the screening program must be designed to meet the following *objectives (action list)*:

- To locate the unscreened and underscreened
- To provide data to aid programs to reach special targeted groups such as the elderly
- To record detected abnormalities
- To assist in follow-up and treatment
- To assist in follow-up communications to the target population
- To support a schedule of testing
- To evaluate compliance
- To define high-risk groups
- To facilitate evaluation and planning
- To determine the cost-effectiveness of the screening program

22.14.2 Information System Design

Information system design should not be regarded as simply a technical exercise involving systems experts but must incorporate the views and data requirements of all groups involved in the program. In other words, wide-ranging consultation and participatory planning is essential. Design of information systems requires collaboration between many disciplines, the clinicians concerned with administering and interpreting screening tests, and the specialists in computer systems that can ensure that the data required to monitor and evaluate a screening program are collected, coded, collated, and made available for analysis. This process is often very difficult in developing countries. A proposal for a cervical screening information system for developing countries has been published (Marrett et al. 2002).

Without appropriate interaction on system design, opportunities may be overlooked to structure systems in ways which can serve ongoing program needs. For example, data concerning screening facilities (location, hours, wheelchair accessibility) might be identified as necessary by consumer advocates.

Participatory systems planning and development should include all stakeholders in the success of a screening program. The process of developing an information system should be sensitive to the needs of diverse interest groups. Among the groups which should be included are:

- Consumers – including representatives of health groups and all minority groups (ethnic minorities, the disabled);
- Professional colleges and associations
- The relevant non-governmental organization and the non-communicable disease (NCD) control committee
- Government including representation from public health units, health agencies, and health promotion agencies
- The research communities – including epidemiologists and academic researchers in health-care and public policy.

22.14.3 Policy Issues and Data Use

Policymakers should understand the need for the information system. In brief, the system is justified because it enables the program to be run on a daily basis, permits its performance to be assessed, and enables any necessary improvements to be made while the system can be used for evaluation and other scientific purposes, i.e., in research. The uses to which data are put are of just as much concern as is the design of the systems from which information is derived. A central concern of custodians of health-care data bases is the question of access to information and the protection of individual privacy. Extensive consultation is necessary to ensure that personal privacy is protected and that appropriate protocols are developed for the use of linked and aggregated data. In addition, other policy issues will arise that will require similar consultation and review.

22.14.4 Components of Information Systems

Information systems developed in support of health programs usually contain a number of common elements and frequently include the target population file, a registration file, data linkage capabilities (e.g., for linkage to disease registries, vital statistics systems), and mechanisms for monitoring and evaluation. Despite the likelihood of a substantial commonality of data elements when similar programs are developed in different jurisdictions, opportunities to improve program evaluation and delivery may be lost if efforts are not made to coordinate data definitions and standards.

To obtain maximum benefit from the introduction of a screening program, it is important that common definition of data elements be achieved, through appropriate consultation.

22.14.5 Conclusion on Information Systems

As part of the process of consultation needed to set up information systems for screening, a range of information management issues will have to be addressed. It is anticipated that the consultative policy and planning process advocated will provide the mechanism for addressing them.

Implementation of well-designed and monitored information systems can enhance the benefits of an organized nationwide screening program. They can help to ensure quality control by linking testing and treatment with outcomes, increase efficiency, identify underscreening of some risk groups (e.g., the elderly), support program evaluation, and help in answering research questions. These and other results can be fed back to yield further program improvement.

22.15 Conclusions

There are a number of fundamental issues that have to be resolved when considering disease control by screening. The general principles that govern the introduction of screening programs include:

- The disease should be an important health problem.
- The disease should have a detectable preclinical phase.
- The natural history of the lesions identified by screening should be known.
- There should be an effective treatment for such lesions.
- The screening test should be acceptable and safe.

The other issues range from ethics to economics. Critical issues include the population to be included in screening programs and whether or not it is possible to introduce an organized screening program. It cannot necessarily be assumed that a screening program will benefit the population to which it is applied. Not only do ethics demand that only programs with proven effectiveness be widely disseminated, it is also necessary to ensure that the program is continually monitored to confirm that effectiveness is maintained. Further, the benefits derived from the program must be clearly shown to exceed the costs, both in terms of ill health induced by the test and accompanying procedures and in economic terms. This requires that all programs are evaluated to ensure that they do meet their objectives.

In spite of these caveats, screening carries the potential for a fairly rapid and important impact on mortality from the disease, often exceeding what can currently be anticipated from other approaches to disease control, hence the continuing interest in and expectation from existing and potential programs.

23.1 Introduction

Modern epidemiology can boast of a precise definition, clearly formulated basic concepts, and well-elaborated methods, all of them described elsewhere in this handbook. They are in principle the same in developing and in developed countries. What is different is the *framework*, the choice of *topics* and *applications* to be treated given local necessities, but also the battery of *tools* adapted to typical tasks and available under local conditions, and finally, the type of *difficulties* that epidemiological work is facing.

This chapter attempts to outline these differences. Still, both developing and developed countries vary enormously also between themselves. Moreover, many countries belong to one of the two categories when applying certain criteria like income but to the other one regarding other aspects like education. We will therefore not adhere throughout to a fixed definition of a developing or a developed country.

In Sect. 23.2, after a short description of essential features that are specific to health systems in developing countries, we review the main needs of these countries in the realm of epidemiology. The last four sections are devoted to the methods of acquiring and applying epidemiological knowledge. Of these, global health information systems are a particularly striking specific component of the health structures in developing countries because they practically exist only there. Sample surveys also play a more important role than in developed countries, whereas the opposite is true for more advanced epidemiological studies.

Public health and health systems in India can be used as an illustrative example of the challenges and achievements of epidemiological investigations in designing public health interventions in India. India is the second most populous country in the world with a population of over 1.2 billion in 2010 and an annual birth cohort of approximately 25 million in 2001 (Census of India 2001). This gigantic population is distributed through diverse geographical terrains and shows a wide spectrum of socioeconomic development, cultural heterogeneity, and linguistic diversity. The phenomenon of health planning is relatively recent, initiated after independence, a little over 60 years ago. The historic evolution of the health sector has witnessed the development of both public and private health sectors. There is currently no mechanism to capture health data from the private medical sector. Adding to this complexity is the fact that India has plural systems of medicine, namely, Indian systems of medicine such as ayurveda, unani, siddha, naturopathy, as well as allopathy and homeopathy. These different streams of medical practice, with different methods of diagnosis and categorization of disease, enhance the challenge of collecting accurate, reliable, and up-to-date morbidity and mortality data.

In Sect. 23.3, we first describe the organization of the health system, pointing out the huge outreach and the well-defined Health Management Information System (HMIS) that exists for regular collection of health data. We next point out the caveat to this data collection system, caused by the presence of a colossal private health sector from where there is no mechanism to capture morbidity data. We then move to the specific example of tuberculosis, firstly showing how epidemiological research, done outside the health system, has helped in shaping the tuberculosis control program. We show the impact of international "vertical" funding in strengthening the health information system and the continued role of repeated research in contributing to the understanding of the efficiency of the control program in case detection. We complete the circle of the discussion by reiterating that despite the best efforts of establishing a HMIS, accurate data for basing health interventions will be lacking in India unless the country tackles the formidable task of designing an integrated data collecting system that includes health information from both public and private health sectors.

23.2 General (by K. Krickeberg)

23.2.1 The Framework: Health in Developing Countries

The specific form of epidemiological research and applications in a given country is conditioned to a large extent by the way health care is organized and functioning. Here, we encounter many differences between developed and developing countries. The former are generally richer and can spend more money on health in absolute terms but usually also in relative terms as measured in relation to national income.

More specifically, the way curative care is organized differs substantially between the two groups. This is especially true for primary health care in the classical sense of health care that begins at the time of the first encounter between a patient and a provider of health service. In developed countries it rests essentially with the general practitioner who is a trained physician and to a lesser extent with doctors in hospitals and policlinics. In developing countries it is mostly offered by *communal health centers* (CHCs) or comparable health facilities that are mainly staffed with health workers like nurses and midwives who are less trained but sometimes more efficient than physicians. Regarding secondary health care, hospitals in the least developed countries tend to be concentrated in large cities, especially in the capital, to the detriment of the rest of the country.

General hygiene and specific preventive measures in developing countries suffer particularly from the lack of material means and knowledge. Bureaucratic weak administrative structures and lack of management training and experience also have much bearing on public health and so do insufficient civil registries and other records, especially demographic ones. It is in this environment that, for instance, the burden of AIDS has been incommensurably heavier than in developed regions of the world.

The main reason next to poverty for which the health system in developing countries has taken such a different path from that of developed ones is founded in their historical evolution and in particular in the role of contributions from outside. These were twofold.

Firstly, health care in colonies was initially built up to a large extent by missionaries and then by the colonial masters, the latter adapting it mainly to their own needs, sometimes to the detriment of indigenous medicine. This building up continued later in the form of bilateral cooperation with developed countries, especially training, and also embraced developing countries that had never been colonized like Thailand or Turkey, often in synergy with national efforts. In general it emphasized individual health care and often suffered from the concentration of hospitals in urban centers. Again, there were exceptions, some developing countries like Vietnam succeeding in making substantial progress in public health, too, and in creating networks of CHCs and small hospitals that covered the entire country.

Secondly, international programs have been a very important source of contributions from outside. They were mostly designed by WHO but implemented by organizations like UNICEF, international or national non-governmental organizations, and national health authorities or institutes like ministries of health or national hygiene institutes. They are installed and run *vertically*, from their respective top administrations down to the basic providers of health care. They tend to strengthen public health and are sometimes curative, sometimes preventive, and sometimes both. They have shaped large sectors of the health system of developing countries. Since they usually involve a lot of epidemiological work, we will list some of them here. For details, see the relevant publications of WHO.

The first major international programs after World War II concerned tuberculosis and malaria. Other programs directed against particular diseases followed, for example, against smallpox, which lead to its eradication, poliomyelitis, goiter, cataract, and finally HIV. There were some programs of more regional importance like leprosy, schistosomiasis, onchocerciasis (river blindness), meningitis, and arthropod-borne virus diseases, especially yellow fever and dengue fever.

In addition, WHO programs of a different type appeared which were not meant to prevent or cure a specific disease but to prevent death caused by certain unspecific manifestations of any of a whole group of acute ailments: CDD and ARI. The core of CDD (Control of Diarrheal Diseases) consisted in preventing death from dehydration of children under the age of 5 who suffered from acute diarrhea. The main method was *oral rehydration* regardless of the cause of the diarrhea. Hygienic measures to prevent diarrheas were included but not the main objective. The philosophy of ARI (Acute Respiratory Infections) was similar, namely, to prevent, by a non-specific antibiotic standard treatment, the death of children under 5 who had caught an acute respiratory infection like pneumonia. Preventive action against the infections themselves was a side issue.

Essential drugs is a WHO program of still a different nature, and so is reproductive health, which often boils down to plain family planning.

The most beneficial WHO program is probably EPI (Extended Program on Immunization) by which a high number of cases of severe diseases and deaths have been prevented. Its objective is the systematic vaccination of all children under 1 or 2 years of age against measles, poliomyelitis, diphtheria, tetanus, and pertussis (whooping cough), plus a dose of BCG that is, however, controversial and no longer generally recommended. Moreover, the program includes a vaccination of all women in childbearing age against neonatal tetanus. The vaccination of children against Hepatitis B was added later.

Many other international programs of varying importance exist or have existed, above all MCH (Mother and Child Care), reproductive health, but also nutrition, vitamin A deficiency, rehabilitation of war victims, etc.

In many developing countries, a plethora of international organizations is running a health program, mostly of the vertical type. These programs have unfortunately been very little coordinated with each other. Often they draw many of the resources of the health system to themselves, to the detriment of other activities, detracting in particular from the normal routine. In particular, EPI was sometimes overly stressed. The conceptual and operational bases of an integration of the various aspects of primary health care have been expounded long ago (Krickeberg 1989). A program IMCI (Integrated Management for Childhood Diseases) was launched by WHO around 1990.

We are now going to outline the role that epidemiological work plays and, more importantly, ought to play within this framework.

23.2.2 Epidemiological Needs of Developing Countries

In the area of *descriptive* epidemiology in the classical sense, that is, *health statistics*, the needs of developing countries are in principle hardly different from those of developed ones: incidence or prevalence of major diseases by sex, age, time, and place of residence plus disease-specific mortality, infant mortality, maternal mortality, etc. (cf. chapter ▸Descriptive Studies of this handbook). These statistics are one of the pillars of the *management* of the health system, especially yearly budgeting. They ought to be used also for rational planning and implementing *global health strategies*, but this aspect still leaves much to be desired apart from international vertical programs. They are often presented in official health statistics publications, for example, health yearbooks that sometimes appear to be their main justification.

The actual differences between the needs for descriptive epidemiology within the two groups of countries result from the different weight that the various categories of disease have or that health authorities attribute to them. Infectious diseases certainly weigh much more in developing countries than in developed ones in spite of their resurgence in the latter (cf. chapter ▸Infectious Disease Epidemiology of this handbook). Incidence or prevalence figures should be available regularly. Classical *epidemic surveillance* is of course of utmost importance.

Health authorities in developing countries still tend to neglect non-infectious ailments like cancer, cardiovascular diseases, diabetes, chronic respiratory diseases, and osteoarthritis. Their incidence, prevalence, and mortality are now in some of these countries of the same order of magnitude as that of the main infectious diseases. This “epidemiological transition” is partly due to the so-called demographic transition, that is, longer life, because the incidence of most of these non-infectious diseases is increasing with increasing age. It is also due to changing life-style, for example, less healthy food and increasing air pollution. Obesity is becoming prominent both as a risk factor and as a disease of its own. Hence reliable figures on the frequency of these diseases, too, are required.

Very few indicators are known on *nicotine addiction*, one of the most menacing epidemics in developing countries.

There are two more areas where the emphasis that is placed on knowing the basic indicators is different in developing countries on the one hand and developed on the other, namely, Mother and Child Care (MCH) and reproductive health.

The most *specific* requirements regarding incidence or prevalence usually emanate from the managers of special programs, mainly international vertical ones, who need them for planning, running, monitoring, and evaluating their programs.

In the domain of *analytical (observational) epidemiology*, that is, the study of risk factors, the needs of developing countries have been less well formulated than in that of health statistics. There has been a tendency to rely on results obtained in developed countries or by teams from there who found interesting study objects in a developing country but often contributed little to furthering the epidemiological capacities of their hosts. However, there is an obvious need of knowing the essential risk factors of diseases such as tuberculosis, AIDS, malaria, dengue fever, nicotine addiction, cancer, cardiovascular diseases, and diabetes in order to plan and implement preventive measures. Even when studies of such risk factors are made, rules on how to implement practical conclusions from them, especially about prevention, are not always derived in a satisfactory way.

Regarding observational epidemiology of non-infectious diseases, specific to developing countries, there is obviously an urgent need regarding, above all, the investigation of new nutritional risk factors and of environmental exposures in large cities, but also of infections, for example, viral infections as causes of cancer. Risk factors for cardiovascular diseases under the conditions of a developing country ought to be known better.

For infectious diseases, the principal risk factor being the infective agent, there has been less motivation to investigate contributing factors like genetic, social, and environmental ones. Studies have mainly centered on the pathways of the pathogen and their effect on infections including mathematical modeling. Their practical conclusions regarding, for example, hygiene are more or less known. For concrete illustrations, it suffices to think of diarrhea and AIDS. However, studies of general risk factors of the type mentioned above are indeed direly needed in developing countries. For example, in the realm of the program ARI, what is the effect of smoke in dwellings on acute respiratory diseases? Which factors influence the malaria cycle, and how?

Preventive measures are determined by the knowledge of risk factors. The principal classical preventive measures in developing countries have been on the one hand person-based *interventions* of the type treated in chapter ▸Intervention Trials of this handbook, especially *immunizations* in the framework of EPI, and, on the other hand, community-based *health promotion* as described both in chapters ▸Intervention Trials and ▸Community-Based Health Promotion of this handbook, often connected with vertical programs. As examples we can quote classical hygiene, treating bednets against anopheles, and urging the community to cooperate in a given program. Campaigns for healthier nutrition or against smoking are still in their infancy and so are screening programs along the lines of those presented in chapter ▶Screening of this handbook for developed countries. There is a need to evaluate the effect of such activities in a more precise way.

Regarding *immunizations*, there is again a tendency to make do with the results about their efficacy obtained in developed countries. Sometimes, however, the situation may be different. A case in point is the problem of the optimal period for vaccinating against *measles*, the so-called window. In developed countries, this vaccination can wait until the maternal antibodies still present in the infant's blood can no longer interfere with its immunizing action. In developing countries, however, the infectious potential around a child is often very high from the beginning. The child's maternal antibodies do not provide sufficient protection, hence early vaccination is called for. To overcome this dilemma, WHO decided to advocate the use of a higher-titer vaccine of the "Edmonston-Zagreb" type in spite of the existence of epidemiological studies, which gave rise to the fear that this might lead to a higher overall-mortality among vaccinated female children. This was indeed observed in later studies, and the vaccine had to be withdrawn (Das Gupta et al. 1997; in particular the article Aaby 1997).

Community-based interventions in developing countries of which we have mentioned above some examples are obviously much needed. The objectives are often very different from those in developed ones. Their evaluation is in principle the same, but like the actions themselves, it is often much more poorly designed and executed. Similarly, rigorous person-based intervention trials are largely lacking.

Up to now, we have dealt with *global* epidemiological needs in the sense that they concern a whole country. It is health authorities at the top of the hierarchy who ought to be aware of them. In contrast, there is what WHO once called "epidemiology at the basis," not to be confused with "field epidemiology." This is *local* epidemiology, which is tied to a smaller geographical or administrative entity, usually a commune. For example, knowing the so-called disease spectrum, that is, the relative frequencies of the various diseases including traumata which appear at a CHC, has not only a practical value for managing the center but also an educative one. It may be a motivation for the health worker as well. The same holds for other simple activities in local observational epidemiology like linking an incidence to a social factor or a geographical one, for example, stagnant waters to shigellosis. While nurses often design ingenious charts, maps, and other devices to monitor certain epidemiological features of their community including rules how to apply them, a general and systematic approach is wanting.

In *experimental* epidemiology including intervention activities, the needs of developing countries are manifold. They arise in all branches of that area. There is *clinical* epidemiology both in the form of studies in diagnostics and of clinical trials of curative treatments, and there are trials to evaluate preventive actions. All of them play a particular role in vertical programs. Let us elaborate a bit and look at a few examples.

As said above, diagnostics and curative treatment in developing countries are often very different from what is customary in the developed world. To a large extent they take place in CHCs and are performed by only partly trained health workers under poor material conditions, in particular in the absence of laboratory equipment. Therefore, simplified and *standardized decision rules* for case management have been designed.

For example, diagnoses have usually to be made on the basis of only some clinical symptoms without any laboratory analysis. In regions of Cambodia where malaria is endemic, the symptoms "fever" and "headache" used to entail the preliminary diagnosis "malaria." Similarly, a differential diagnosis of amoebic and bacterial dysentery (shigellosis) must often be founded on the clinical symptoms "headache," "fever," "blood in the stool," and "mucus in the stool." In both cases, a more reliable diagnosis may take time because a blood or stool analysis can only be done in a laboratory that is far away, or it may not be possible at all. However, it is usually both necessary and common to treat the patient at once, having only a preliminary diagnosis at one's disposal. If one wants to judge the merits and dangers of this strategy, one needs to know the epidemiological characteristics of the underlying preliminary diagnostic decision rule, that is, its *sensitivity*, *specificity*, and *prognostic values*. One may also wish to compare this clinical decision rule with alternatives of the same type in order to select the best one.

The program CDD is another example. Here, the result of the diagnosis is not expressed in the form of a particular disease but as a degree of dehydration, either 0, I, II, or III, determined as a simple function of a few easily recognizable clinical symptoms. The treatment, too, has a standardized form and depends only on this degree, in particular oral rehydration in case II. Again, the epidemiological characteristics of the diagnostic rule need to be known in order to evaluate the usefulness of the entire strategy. ARI works analogously.

The preceding discussion of diagnosis applies in a similar way to simple standardized *curative treatments* that are being used widely in developing countries. Their efficacy ought to be estimated by appropriate clinical trials.

Traditional medicine, too, is an area where the epidemiological necessities of developing and developed countries obviously differ. In order to bridge the gap between traditional curative treatments and those taught in medical schools at universities and to integrate the useful part of the former into the health system of developing countries, clinical trials including meta-analyses are required. There is in principle no difference between the two curative systems. After all, much of the "Western" pharmacopoeia had its origin in traditional medicinal plants, for example, quinine, aspirin, digoxin, and, more recently, viagra. Unfortunately, until not long ago, medical herbs and animals that were known for centuries if not millennia have been studied only from a purely pharmacological and chemical point of view, to extract the "active principle," without raising the question of their actual efficacy. It is only recently that traditional cures of any kind have been subjected to epidemiological scrutiny, first in India and China, and then in developed countries, too.

Many of the deficiencies mentioned before result from poor training of physicians and health officials. Good *teaching* in the area of epidemiology is indeed one of the most basic needs of developing countries. Many courses on particular subjects are being organized by international organizations, often under the heading "field epidemiology," but the usual epidemiological curricula in universities both for medical students and for future public health specialists are usually very weak. They do not convey a global view on the fundamental ideas.

For example, few physicians and health officials will realize that there is a fundamental difference between the epidemiology of infectious and non-infectious diseases in addition to the obvious ones such as the role of the infectious agents and of epidemic surveillance. It consists in the *indirect* effect of not only preventive but also of curative measures against infectious diseases; the latter is absent for non-infectious ones. Treatment of cases of an infectious disease usually reduces the number of sources of infection and thereby contributes to lower the incidence. Analyzing and predicting this indirect effect requires mathematical modeling (chapter ▸Infectious Disease Epidemiology of this handbook). In developing countries this was done for various diseases and recently also attempted for AIDS. However, the lack of theoretically well-trained epidemiologist in developing countries rarely permits to organize such analyses that take into account the specific situation there.

We now turn to the question of how and to which extent the epidemiological needs of developing countries can be satisfied in theory and practice. We will first describe the most important tool, namely, health information systems and its role in epidemiology. This role is fundamental but is often not clearly recognized; it is therefore treated in some detail. In the last two sections, we examine the contributions of the two other tools that exist, namely, health surveys and epidemiological studies.

23.2.3 Health Information Systems in Developing Countries

A health information system (HIS) links different institutions that are concerned with health between each other. It consists of mechanisms to *collect*, *transmit*, *analyze*, and *exploit* information on health in the widest sense. This is mostly done regularly, in a *routine* fashion, but may be supplemented by an ad hoc exchange of information. For example, most hospitals have their own, sometimes computerized, system by which information flows between its various wards and administrative units.

Here, we will be dealing only with HISs which go beyond a single institution and where information is transmitted between CHCs, policlinics, hospitals, and public health institutions and administrations. For instance, a central disease register as described in chapter ▸Use of Health Registers of this handbook amounts to a HIS where reports from physicians, hospitals, and laboratories are directed to the office where the data are stored and handled.

We are now going to restrict our scope further by focusing on much larger HISs that may deal with many sorts of information and link institutions of very different nature. In the extreme case, such a system may be founded on *regular reports* on *all* major events and activities from *all* health institutions of a *whole country* to higher health authorities, culminating in the Ministry of Health. The bulk of information emanates from the basic health institutions that are in direct contact with the population for curative or preventive activities: private practitioners, health centers, policlinics, small hospitals, individual wards of large hospitals, hygiene teams, etc.

Developing countries have, as a rule, started very early to build HISs, sometimes rudimentary, sometimes quite elaborate. They were motivated by the need to manage scarce resources efficiently, including traditional budgeting, and to control the functioning of the various components of the health system. Epidemiological information for planning and implementing health strategies played originally a secondary role apart from simple health statistics based on statistics of treatments, but over the years HISs have become an essential and often the main source of epidemiological knowledge.

In spite of the necessity felt by health planners to be equipped with a reliable HIS, the systems actually constructed have almost consistently been suffering from serious deficiencies. In some countries, for example, in Africa and Central America, they did not reach far enough into the countryside nor did they cover the essential subject matter well enough. In others, on the contrary, especially in socialist countries, they were usually too heavy and bureaucratic, attempting to cover everything and containing many redundant or superfluous elements that impeded their functioning. Neither the former nor the latter were designed following clear ideas and guidelines including a rational logical structure.

In the beginning, HISs were installed by the central health authorities, usually the Ministry of Health. They tried to build a more or less centralized HIS under which basic health institutions had to send routine reports on their general activities following a hierarchical path, for example, from CHCs to district health administrations, from there to provincial health authorities, and ending up in the Ministry. Unfortunately, given the deficiencies of such systems mentioned above, in some countries other central institutions had to build their own HIS that ran parallel to that of the Ministry. For example, a national hygiene institute would set up a separate reporting system on *infectious diseases* including *epidemic surveillance*. Central tuberculosis or malaria institutes would establish similar systems of their own. All of this caused a lot of extra work in basic institutions, especially in CHSs.

The worst confusion, however, resulted from the management of international programs. As said above, managers usually felt the need for a centralized and *vertical* approach, working from the top to the bottom. This involved specific systems for providing the required information in the form of basic demographic, epidemiological, sociological and economic indicators, and of indicators to be updated all the time, for instance, on the logistics of drugs or on vaccination coverage. Thus a plethora of information systems emerged for the various programs. As a rule these manifold HISs were coordinated neither with each other nor with the system of the Ministry and other existing systems. The burden of writing and filing all the required reports rested mainly with the local health workers who were naturally more interested in their purely medical activities. It became frequently unbearable. The situation in Vietnam as described in a report (Krickeberg 1999) is a good example though there are great differences between countries.

The question of how to design a *single* information system that could be handled efficiently and at the same time serve all the essential needs of health care, that is, a so-called *integrated* HIS, has therefore been discussed occasionally. Although some developing countries have in fact set up reasonable HISs, for example, Cuba, the principles on which such systems should rest have been investigated only recently in a systematic way (Krickeberg 1994, 2007; Lippeveld et al. 2000). The remaining part of this section will be devoted to a short presentation of these principles, starting with the functions of HISs, passing on to the properties which they should have in order to do what we want them to do, and finally looking at their structure. More details can be found in the three references just quoted.

Regarding functions, *budgeting* and all *health management* that go beyond the smallest entities of the health system require a good HIS. This holds for the general standing health system as well as for special vertical programs that rely, for instance, on an efficient logistics for drugs or vaccines. *Health insurance* could in principle get from an integrated HIS all the information it needs for planning and running. An example of an application would be to estimate the average cost caused by a case of a particular disease. In the context of this handbook, though, we are only dealing with the epidemiological functions of a HIS, to be described in the following section.

Regarding desirable properties, they are largely dictated by experience. The system should be *integrated*, that is, cover all health institutions and all kind of numerical information. In particular, the medical and epidemiological aspects must not be separated from the economic and managerial components. So-called Health Management Information Systems usually cover *some* clinical and epidemiological information but not enough. They are inadequate in most cases, and the term is misleading.

The HIS ought to have a *transparent*, *logical structure*. This is not only indispensable for designing and running the system efficiently but also constitutes, as again many experiences have shown, a powerful motivation for the health workers who handle it. Moreover, only a well-structured HIS can be computerized although there have been quite a few, always futile, attempts at saving a bad system by using computers.

The system needs to be shaped in view of *well-defined objectives* and incorporate rules how to analyze and exploit the information obtained in order to reach these objectives.

Given its objectives, it has to be *minimal*, free of superfluous elements and in particular of redundancies, and has to function at minimal cost. This has, in particular, an implication regarding the *flow of information* between institutions: routine reports must be filed only from and to institutions as really needed and following clear operational priorities.

The system should be *flexible* so it can be adapted to changes of all kind, in particular to varying epidemiological situations, but also to alterations of the structure of the health system or of health strategies and medical knowledge and techniques, economic and social changes of the country, and new information technology.

The information obtained must be as *reliable* as one can realistically hope for.

There have to be clearly defined rules indicating what to do about *wrong* or *missing information*, and there have to exist *error-correcting* procedures along the lines of chapters ▸Measurement Error and ▸Missing Data of this handbook; they must of course be sufficiently simple to be applied to every single report. We will come back to this at the end of the present section and in the next one.

Moving on to the underlying structural and technical principles, we have to recall first a few elementary definitions because there is no general agreement about them. As always in statistics when talking about information in a concrete context, we need to specify first a *population* (set) of *units* (elements). It is sometimes called the "target population" and need of course not consist of humans. Examples might be all children under 5 living at a given moment in a given village, or all consultations done during a certain month in a certain health center.

Information has either the form of *data* or of *indicators*. Data are the values of a *variable*, which is a function defined on a population, like the function *age* which assigns, to each child, his or her age or the function *diagnosis* that attributes to every consultation the diagnosis made, properly coded. A *register* is a concrete, explicit representation of the data of one or several variables as described in chapter ▸Use of Health Registers of this handbook, usually on paper or on a computer disk. We will not enter into technical details like sub-registers or linked registers.

An *indicator*, in contrast to data, concerns a population as a whole but not individual units. It depends on one or several variables defined on the same population. Two examples, concerning our first and second example of a variable above: the mean age of the children and the number of "diarrhea" cases recorded. An example of an indicator depending on two variables, again for consultations as units: the mean age of the children under 5 who consulted for "diarrhea." In practice, an indicator is computed from *all* the values of the underlying variables as given in a register. Let us note in passing that WHO has given a completely different definition of an indicator, which is at variance with the definition employed by statisticians.

Registers are *the* fundamental, and often neglected, components of a HIS. They need to obey the following "golden" rule: in any basic institution, there is *only one register for a given population*, that is, for a given type of unit. For example, it is compulsory that there exist, in a health center or a ward of a hospital, only one register of consultations, not a "general" one for the Ministry, and one more for each vertical program and for other special purposes. One reason is simplicity, which in turn is a strong motivation for the health worker to use the system conscientiously. The main reason, however, is epidemiological and will be discussed in the following section.

Well-designed registers are in the first place the main tools for the *local use* of the HIS, both clinical and epidemiological as defined in the preceding section and to be taken up again in the following one. Their multiple functions demand a clear definition of the variables involved.

The second function of a register, namely, to serve as the basis for the routine reports to be filed, should be determined by rigorous structural rules as well. This applies both to paper-based and computer-based HISs. We note first that most information contained in routine reports is in the form of *indicators*, be they epidemiological, economic, or others. The transmission of *data* on individual units, for example, on cases, is indeed rare and mainly restricted to epidemic surveillance and registers of special diseases. For indicators resulting from clinical activities which are the most prominent ones, the structural rule in question looks like this: the clinical act giving rise to the data, the immediate use of these data in the act, the filling in of the relevant register, and the drawing up of the reports based on these data have to be *integrated conceptually* and *technically*. In particular, the *layout* of the register and that of the reporting forms need to be closely coordinated so as to allow calculating the indicators and writing the report in a single, transparent, and almost automatic operation.

In this way, many indicators of quite a different nature can be easily computed and transmitted to various institutions and according to needs that may change, all based on the *same* registers and on the *same* variables. However, on no account should there exist a register that is not tied operationally to some function within the health system and whose only purpose is to calculate and report indicators.

There have been attempts, for example, by WHO, at designing HISs by starting with a list of the indicators to be covered in view of the goals of the system. This idea may be tempting at first sight but is in fact naïve. Such lists have always been long and very much subject to debate, they leave no room for flexibility, and they are at variance with the basic structural principles as outlined above. What we have to fix in the beginning are the *variables* needed; to do this well is crucial. The second step will then be the design of the *registers*.

Reliability of the information is a particularly difficult problem in the context of a developing country. Standard procedures to assure quality such as those described in the chapters ▶Epidemiological Field Work in Population-Based Studies and ▶Quality Control and Good Epidemiological Practice of this handbook can only be applied to a rather limited extent. Motivation of the health worker is a more efficient measure, but gaps and errors will remain. The topic of what to do when confronted with them has many facets. Chapters ▶Measurement Error and ▶Missing Data of this handbook concern errors and missing data in a *single* epidemiological study. In the realm of HISs, however, we have to handle them *routinely*, for example, for every monthly report of a district health administration to its superiors. To this end, simple rules and algorithms need to be developed which can function under the specific conditions (Krickeberg 1994, 2007).

Let us now try to elucidate to which extent, and how, HISs can fulfill the epidemiological functions enumerated in Sect. 23.2.4.

23.2.4 Epidemiological Insights from Health Information Systems

It is a truism that, *potentially*, epidemiological needs can be satisfied via a HIS to the extent, and only to the extent, that the necessary data or combinations of data are recorded in the system. The practice is a bit different, but let us look at the mechanisms anyway.

The traditional basic need is classical health statistics. It amounts to obtaining regularly indicators on incidence, prevalence, and mortality for, in principle, all diseases including traumata. In developing countries, these are usually derived from a HIS. This system may contain special components in the form of "disease registries" for particular diseases such as a cancer registry; they have been set up in several countries with varying degrees of completeness. Health statistics published by Ministries of Health and WHO are essentially based on national HISs. Let us look at the mechanisms.

Existing HISs have usually been built in view of establishing health statistics and of managing health activities albeit in a rudimentary fashion, for example, yearly budgeting. We have sketched the principles for reforming older HISs or building new ones. In any case, we are facing the following questions: What kind of registers are there? Which variables are being recorded and how? How is information extracted from the registers and transmitted to its destinations?

As stated in the preceding section, a register is tied in a natural way to a particular operation that is routinely executed in the health system, above all a clinical one. Thus, the main register in a CHC is the register of *consultations*. Next to the date of the consultation and data to identify the patient, it features variables like symptoms or syndrome, sometimes a tentative diagnosis, and treatment. Recording of the relevant data serves, in the first place, the clinical act "consultation" itself. Clearly defined variables may indeed help the health worker to decide about his diagnosis and treatment as explained in Sect. 23.2.3 for CDD and ARI cases.

The main traditional epidemiological function of the register of consultations is to calculate the incidence of symptoms like injury, stomachache, diarrhea, or acute respiratory infection, but also of tentative diagnoses that can be regarded as more or less satisfactory surrogates for a correct diagnosis of certain ailments, especially of frequent infectious diseases like measles and dengue fever. This is obviously conditional on the training of the health worker whom the patient is consulting.

Registers in policlinics, hospitals, specialized malaria or tuberculosis stations, and the like concern mainly the units "outpatient consultation," "hospitalization," "discharge," and various "laboratory tests." Rare are the hospitals in developing countries that have a so-called *Central Register* whose unit is a "patient." Most of the more elaborate incidence and prevalence statistics which appear, for example, in health yearbooks originate from hospitals where diagnoses are on the whole more precise. Many of the cases treated only in CHCs are lost in this way, though. The old problem of linking records in primary, secondary, and eventually tertiary health care usually does not get sufficient attention.

In particular, the case reports based on consultations and treatments in hospitals may still be quite incomplete. For instance, in Vietnam the cancer incidences reported within that system and published in the Health Yearbook are very much lower than the figures obtained from the Central Cancer Registry that has been operating for some time in a few regions (Krickeberg 1999).

As said in the preceding section, calculating and filing of the corresponding reports ought to be integrated with the data entry into the registers. The details depend of course on whether the register is on paper or on a computer disk. In any case, the report should display the epidemiological situation reported also immediately to the health worker himself in a vivid fashion in the spirit of the "epidemiology at the basis." This brings us back to the "local mastership" over information alluded to above which is one of the main roles of a good HIS, in contrast to the old bureaucratic idea that such a system exists mainly to produce indicators for higher-up administrations. This local mastership must not be taken away from the basic health institutions. It allows them to plan in particular preventive measures on their level. The often advocated "feedback" is useful but after all a poor substitute for local use of information.

Incidences calculated and reported may sometimes be *corrected* later, that is, replaced by *estimates* that will generally be closer to the true incidences and should therefore be used in health statistics and for health planning (Krickeberg 1994). A very rough procedure actually in use is the multiplication of every indicator obtained from the records by a constant "correcting factor" that had been estimated beforehand. An interesting application concerns maternal mortality (Ministerio de Salud Pública y Asistencia Social 2002) where the factor 1.58 is being used. Slightly more elaborate but still elementary estimations could use simple extrapolations or Bayesian methods (Krickeberg 2007).

A HIS fulfills other functions in addition to normal health statistics. Let us mention some of them here. When well organized, the register of consultations in a CHC can serve the *epidemiological surveillance* of infectious diseases as well. Moreover, by defining the values of the variable "symptoms" or "syndrome" appropriately so as to identify the consultations that belong to a program like CDD, ARI, malaria, or tuberculosis, a separate register of consultations for these programs becomes superfluous at the level of the commune without making the general register of consultations any more complicated. The latter will furnish all the incidences required.

The register of consultations of a CHC may also allow some rough but illuminating *experimental epidemiology*. In some CHCs this register contains an additional variable "outcome" which can take the value "cured" or "deceased" among others. Strictly speaking, this variable concerns the larger unit "case" and not a "consultation," but in the absence of a register of cases, it can easily be recorded in a paper-based register of consultations by going back to the first consultation for a case, provided that the outcome becomes known not too late, for example, for acute diseases. When using computers, recording an outcome which may occur much later, or even deriving a register of cases from that of consultations, is fairly easy. The variables "treatment" and "outcome" now permit both the local health workers and health administrators, in particular those of vertical programs, to monitor standard treatments. To this end, they can peruse the complete register during a certain period or, usually more efficiently, employ *sampling from records*, that is, random sampling from the units of a register, an unfortunately fairly neglected method although classical in hospitals of developed countries.

Sampling from records in CHCs also enables health authorities to estimate some of the epidemiological characteristics of the preliminary clinical diagnoses described in Sect. 23.2.3. If the true diagnosis will *eventually* be known for most cases as it happens with malaria, it suffices to retrieve this diagnosis for the subjects included in the sample from the relevant records of district or provincial malaria stations, hospitals, etc. In the opposite case, for example, for dysentery, a laboratory-based diagnosis for the sampled subjects needs to be done.

In addition to the register of consultations, CHCs frequently have a register for the program MCH whose underlying unit is not always well defined. In principle, it should serve the needs of EPI, too, making an EPI register superfluous.

Some CHCs have also set up a register of all *families* or *households* of the commune which can furnish certain epidemiological insights, for example, on infectious diseases or the role of socioeconomic factors in health.

Finally, HISs can be used for epidemiological studies. It is in this context that the "golden rule" formulated in the preceding section plays its main role. If we want to study the influence of a risk factor on an outcome variable, it is necessary to record their values in the *same* register for every unit of the target population. Let us look again at MCH. It is customary to record data on pregnancies in one register and those on the health of the newborn up to a certain age in a different one. This makes it impossible to use the registers, for example, for an investigation of the influence of prenatal care on the development of the child. A natural unit for an MCH register would be "a child from the moment of its conception until the age of 5 years, say." Registers of this kind have been designed by ingenious district health officials in Laos. We will not pursue the issue of epidemiological studies based on registers further; cf. Krickeberg (2007).

23.2.5 Epidemiological Sample Surveys

Let us start again with a truism that does not have much weight in practice either: sample surveys should be done and *only* be done if the results are not readily available from registers. For example, in developing countries many cases of measles do not lead to a contact of the patient with the health system and are therefore registered nowhere, not even with a tentative diagnosis. This is the so-called iceberg phenomenon. In such a situation, to get an idea of measles incidence, sample surveys are required. Another example of a different nature: the causes of death of children under 5. These causes are often not indicated in any register because it is impossible to perform routinely the necessary diagnoses.

We will also discuss situations where sample surveys are *not* required but often still being done.

In the present section, we will restrict ourselves to sample surveys whose purpose is to estimate indicators that depend on a *single* variable, for example, the incidence or prevalence of a disease, or mortality. Epidemiological studies to investigate the *association* between several variables like those between a risk factor and a disease, or between a treatment and the outcome, will be taken up in the last section although the borderline is not everywhere well traced; cross sectional studies, in particular, usually have outwardly the form of a classical sample survey.

The most frequent *units* of a sample survey, that is, elements of the "target population," are a person, a family (household), or a community, for example, a hamlet or a commune, but a unit like a CHC may also occur if one wishes to evaluate the performance of such centers.

It is customary that for every new vertical program, a sample survey is launched in order to estimate the so-called baseline indicators, and often this survey is repeated later to monitor changes that may reflect the impact of the program. Such indicators are, for instance, incidences or prevalences of the diseases; case fatalities; infant, child, or maternal mortalities; indicators describing the nutritional status of children; vaccination coverages; or sometimes plain demographic indicators.

Surveys outside of any vertical program that include an epidemiological component have mostly been organized in the form of a large international project. An early model was the "World Fertility Survey" of the International Statistical Institute (Cleland and Scott 1987) that had been conducted between 1974 and 1982 in 42 developing and a few developed countries. Its methods including software were subsequently incorporated into the baseline surveys of some family planning programs. UNFPA (United Nations Fund for Population Activities) organized "Demographic Health Surveys" (DHSs) in many countries, often repeatedly, and these were later also conducted by private firms. Household surveys done by the United Nations have been a similar global venture (United Nations 1984).

Unfortunately, in a given developing country, these multitudinous surveys have practically never been coordinated with each other regarding their purpose, choice and definition of variables and indicators, methodology, and availability of the results. Therefore they cannot be compared with each other and exploited only with difficulty or not at all. Often, they duplicate existing knowledge, or the results are buried in the files of the relevant program office, or both. By contrast, the World Fertility Survey is an early model of good quality and availability of its results, usually published locally.

Moreover, the definition of variables and indicators employed by most sample surveys is often not compatible with that of existing HISs. The fundamental question to which extent an information system could have furnished the same result is rarely asked. For example, in a country like Vietnam that, although economically poor, provides well-structured primary health-care, most cases of severe diarrhea lead to a consultation in a basic health care institution where the syndrome is recorded. Hence, a large if not the largest part of the CDD surveys that have been conducted were actually superfluous and could have been replaced by "register-based" studies, that is, sampling from records. The opportunity to compare indicators obtained from a survey with those extracted from the HIS is mostly lost although recently there have been notable exceptions, for example, the survey from Guatemala on maternal mortality already quoted (Ministerio de Salud Pública y Asistencia Social 2002).

The sample surveys we are discussing are simple cross-sectional studies that concern in principle only the state of affairs at the moment the data are recorded. If, for instance, we are interested in the incidence of an acute disease or the mortality by it as it happens in the framework of EPI, the diagnosis for a case or the cause of a death has to be recorded for a *period of the past* and can therefore only be determined by asking questions about the past, that is, by an *a posteriori diagnosis* or an *verbal autopsy*, respectively. These questions are addressed to persons in the surroundings of the patient, mostly members of his family.

Sometimes, this may not be very reliable. The average errors committed depend of course on the particular context and can be estimated by elementary studies. In any case, the survey should be confronted with the HIS if there is one. In particular, the questionnaire of the survey ought to contain a question about whether the patient had consulted his or her CHC or another health facility or not. Comparing the answers with the entries in the relevant register of consultations would then tell us a lot about the functioning of the HIS and the health system itself.

There is a related problem in the case of indicators defined with respect to *cohorts* that start at birth like infant mortality, child mortality, or vaccination coverage. In their definition, a cohort of children is to be followed from birth on to the age of 1, 2, or 5 years, respectively. They can be estimated directly by a register-based study. By contrast, a sample survey is done at a fixed moment. It either estimates a different indicator that concerns the state of a group of children at this moment as it happens with the usual EPI-coverage surveys or needs to resort to questions about the past. If the latter strategy is adopted as it is, for instance, being done within the Demographic Health Surveys (DHSs) when estimating child mortality, care must be taken to analyze possible bias resulting from censuring the 5-year period of the past within which a child was to be followed.

To look at the interplay between sample surveys and register-based studies is also most illuminating when dealing with chronic diseases, especially non-infectious ones. Sample surveys done in Vietnam by an association of cardiologists have shown a recent dramatic increase of the prevalence of hypertension, most of it hitherto hidden. Linking such surveys to the HIS could have provided much useful knowledge.

Sample surveys, like HISs, can play an educative and training role, too, as it happened with the World Fertility Survey that largely relied on local staff. The organizers of a survey who often come from an international organization should always take great care to explain to the local health personnel involved its rationale including both the objectives and the methodology. They do not do it every time, partly because not all of them understand the underlying principles of the methods. They also tend to apply ready-made recipes that do not take into account the local administrative structures. Worse, existing know-how is often not exploited; in some countries certain local personnel is in fact better qualified than the foreign "experts" who direct a survey.

For instance, the so-called 30-cluster-sampling plan has been widely used in developing countries (Henderson and Sundaresan 1982). Its first stage is a Madow sampling design (Cochran 1977, p. 265). Its second stage is tailor-made for countries that may not have lists of all households nor suitable maps of hamlets or villages. It has been very useful in many situations because it provides a standard method. Although it is not always self-weighting, it has been treated as if it were which implies a simple form of the estimators. However, it has also been much applied in contexts where other sampling plans would have been easier and cheaper to implement and more efficient. This author has seen the Madow design used by a foreign CDD specialist to select a sample of 30 administrative units from a list of only 32 or 33 such units. The local staff would simply have taken all of these units! Nowadays, suitable maps of houses can be cheaply and rapidly drawn by the geographical positioning system even for very remote and poor villages.

Another example: in a developing country that operates a high-level research institute for demography and family planning, a baseline survey for a reproductive health program was conducted by a person from abroad using the above-mentioned World Fertility Survey software although surveys providing a large part of the results had already been done by that institute and although the institute could very well have done the entire survey itself in a much cheaper and more imaginative manner, profiting at the same time from the training and insights (and money) that go with it.

As said above, baseline surveys of vertical programs and other surveys are sometimes repeated to monitor changes. To this end, samples are taken repeatedly in an independent fashion. There always exists a splendid opportunity to retain part of the sample and to use it for *longitudinal studies* that are most informative, for example, household-based ones, but this opportunity is usually missed as it happened in the family planning survey just mentioned.

The need for longitudinal studies was also one of the motivations for creating the concept of a sentinel network. This is a hybrid between a HIS and a sample survey. Since basic health facilities are all too often ill-equipped for making reliable diagnoses, do not have sufficient staff to keep registers and file reports, and cannot rely on good postal or other services to transmit information, the idea arose to select a fixed sample of such institutions, for example, CHCs. Their capabilities were to be enhanced substantially by furnishing some laboratory equipment, paying additional trained staff, and ensuring better communications. These fixed "sentinels" were to monitor demographic and epidemiological indicators over time including the impact of interventions. Sentinel networks may, however, give biased information because the measures taken to upgrade the selected sites alter the health situation there. More people might be attracted to use these facilities, better treatment can influence the dynamics of the transmission of infectious diseases, and better health education will reduce the incidence of many ailments including injuries.

Originally, sentinel networks were discussed mainly in the context of single vertical programs but occasionally also for larger components of primary health care. There was no general scheme and no coordination. More recently, Demographic Surveillance Systems (DSSs) have been installed in various "field sites," that is, geographically defined populations, in order to monitor their health and demographic status. Let us look at two examples. The first one is the DSS established in the early 1980s by an already existing institution, namely, the Nouna Health Research Center in the northwest of Burkina Faso. It covers about 55,000 people (Yé et al. 2002). The second one is a DSS created during the years 1997–1999 in the context of a Vietnamese-Swedish collaborate research project in the district of Ba

Vi of the province of Ha Tay in the North of Vietnam which counts around 235,000 inhabitants. It is combined with a field laboratory for epidemiological research. First results concern among others mortality, death reporting, theory and practice of verbal autopsies, knowledge of people about tuberculosis, and cardiovascular diseases (Ngyuyen and Diwan 2003).

Starting in 1998, an "International Network of field sites with continuous Demographic Evaluation of Populations and Their Health in developing countries" (INDEPTH) has been built up in order to link existing field sites and in particular to strengthen them and to enhance their visibility and use (INDEPTH 2002). In 2010, it comprised 38 field sites from 18 countries, among them the DSSs at Nouna and Ba Vi.

23.2.6 Epidemiological Studies

We will now take a quick look at how epidemiological studies, other than register-based studies or straight sample surveys, can satisfy the specific epidemiological needs of developing countries. We will thus be dealing with studies of the kind treated in chapters ►Descriptive Studies, ►Cohort Studies, ►Case-Control Studies, ►Modern Epidemiological Study Designs, ►Intervention Trials, and ►Design and Planning of Epidemiological Studies of this handbook.

The practical problems that a research team might face are summarized in Wawer (2001). Let us look at an example that illustrates one of the worst obstacles, namely, loss to follow-up. This study, the Bloemfontein vitamin A trial (Chikobvu and Joubert 2003), had in fact a dual purpose: firstly, to investigate the effect of vitamin A on the transmission of HIV from mother to child and secondly, to assess the extent of loss to follow-up in the presence of AIDS for the planning and analysis of other cohort studies on HIV/AIDS including clinical trials. A total of 303 HIV-positive pregnant women were recruited with 152 randomly allotted to the vitamin A group and 151 to the placebo group, to be followed until their baby was 18 months old. The tracing procedure of these women was precisely defined, the observed loss to follow-up was analyzed in detail, and the kind of bias that may have resulted was discussed. This trial and ten other cohort studies on HIV/AIDS quoted for comparison had losses to follow-up in the order of 10–48%. One of the main conclusions was that published studies must adequately discuss the tracing methods used.

Many sample surveys, especially large ones like the World Fertility Surveys or the Demographic Health Surveys, collect data both on risk factors, for example, social ones, and on outcome variables, for instance, morbidity. They can therefore be exploited in the form of cross-sectional studies on the influence of these factors on such outcomes. A good example is the study from Guatemala already quoted (Ministerio de Salud Pública y Asistencia Social 2002). This involves the shortcomings of cross-sectional studies in general which arise from the fact that many variables concern the past of a cohort and not the moment of the survey; we have sketched these problems in the preceding section.

Sample surveys and cross-sectional studies account for the majority of epidemiological investigations in developing countries. Pure case-control or cohort studies, to be conducted in accordance with a rigid protocol fixed in advance, are still relatively rare. In some developing countries, their number is increasing, though; they are often conducted by a mixed team of local and foreign epidemiologists. It would be futile to enter into details here since the methodology is the same as in developed countries.

The choice of the subject of a study is of course often dictated by local problems that were already mentioned in Sect. 23.2.3. We note that developing countries have been a fertile ground for research in *genetic* epidemiology. For instance, studies on thalassemia have a long history in Southeast Asia. Genetic susceptibility to infectious diseases has been studied intensively. An early example was the evidence for genetic susceptibility to leprosy obtained by a linkage analysis in a closed population, namely, on a Caribbean island (Abel et al. 1989). In the realm of parasitic diseases, the role of genetic factors in resistance to malaria had already been established in 1982 (Mims 1982). More recent work done in Sudan concerns schistosomiasis (Dessein et al. 1999) and visceral leishmaniasis (kala-azar) (Bucheton et al. 2003).

There have also been *clinical trials*, centering in particular around HIV, for example, on the prevention of mother-to-child transmission.

Much epidemiological work in developing countries has the form of *ecological* studies that are treated in chapter ▶Descriptive Studies of this handbook. A good example is the large descriptive ecological study in China (Chen et al. 1991). A community-based intervention trial, the Gambia Hepatitis Study, is mentioned in chapter ▶Intervention Trials of this handbooks, and a few other intervention studies of various sorts are quoted in Wawer (2001). Community-based intervention studies are often a useful and feasible type of investigation given the needs and conditions of developing countries, especially in the context of infectious diseases. They suffer from the same basic difficulties as in developed countries, though. Since there are usually only few communities involved, it is very difficult to exclude confounding factors when evaluating such a study by comparing communities "with intervention" with other, control, communities where no intervention had taken place.

The most typical, illuminating, and useful type of study looks different in practice. It is more informal, and *prospective*, usually lasting for many years or even decades. Often it starts small and expands later regarding objectives, study type, and basic population. It may concern anything connected with health: general or reproductive health of a community as time proceeds; nutrition; etiological factors, especially from the environment or social ones; results of person-based or community-based interventions; and often several of these together. The diseases involved are those already mentioned in the present chapter but rarely non-infectious ones.

An excellent summary of 34 such surveys plus a detailed presentation of 12 among them was published in 1997 (Das Gupta et al. 1997). It starts with pioneer studies done in China in the early thirties, it is organized by continents: Asia, Latin America, and Africa, and it provides fascinating reading. A good example is the malaria study in the Garki district in Nigeria, a savannah region. It took place from 1969 to 1976, involved 22 villages with a total population of 7,423, and has also been the subject of a separate monograph (Molineaux and Gramiccia 1980). The topics studied were manifold: demographic and epidemiological, in particular intervention evaluation. The epidemiology of malaria included all aspects: immunology, serology, parasitology, entomology, clinical manifestations, and the influence of various factors like weather and nutrition. The interventions consisted in pesticide spraying and mass prophylaxis. Let us quote some of the many results. No significant difference in mortality between mass-treated and untreated villages was found except for infant mortality. Malaria antibodies existed in people in sprayed as well as in unsprayed environments, and their level was uncorrelated with that of parasitemia except in infants. The intervention reduced, but did not eliminate, the prevalence of the plasmodia involved. Malaria transmission and vector capacity, which had existed on a high level, persisted.

23.2.7 Conclusions

Summarizing finally the respective roles of the three sources of epidemiological knowledge in developing countries, we may say that, roughly, HISs have their roots in the daily work of the health workers, especially in their clinical activities; sample surveys are mostly tied to particular projects or programs and concern mainly the state of affairs at a particular moment; analytical and experimental epidemiological studies provide the deeper knowledge that is indispensable for all useful planning of health strategies.

23.3 The Example India (by A. Kar, A.K. Chakraborty)

23.3.1 Health Information System for Public Health Interventions

23.3.1.1 Organization of Government Health Services

The historical, cultural, economic, and geographical contexts of a developing country like India influence the development of its health system and the ability of this system to accurately capture data and use them for health interventions. The health system in India is a little over 60 years old. In 1947, when the country achieved independence, health infrastructure was practically non-existent and infectious diseases periodically swept through the population, traumatized by food deprivation. The Report of Health Survey and Development Committee (1946) stated that the death rate in the year 1937 was 22.4 per 100,000/year while expectancy of life at birth was 27 years (Table 23.1). Mortality records of British India estimated a maternal mortality rate of 20/1,000 live births. Table 23.2 presents a comparison of mortality in infants and children in British India as compared to the United Kingdom and Wales. Cholera, smallpox, and plague accounted for 2.4%, 1.1%, and 0.5% of all deaths in the year 1932. Tuberculosis mortality rates in cities

ranged between 200 and 450 per 100,000 population. Only 2% of the population had access to potable water, while sanitary facilities were available for 4.5% of the populace. Trained health personnel and infrastructure were practically non-existent. This was more pronounced in the rural population, where, for example, one institution was available for the 105,626 inhabitants of 224 villages (Report of Health Survey and Development Committee 1946). From 1948, the evolution of the Indian health system occurred, wherein development of the government health

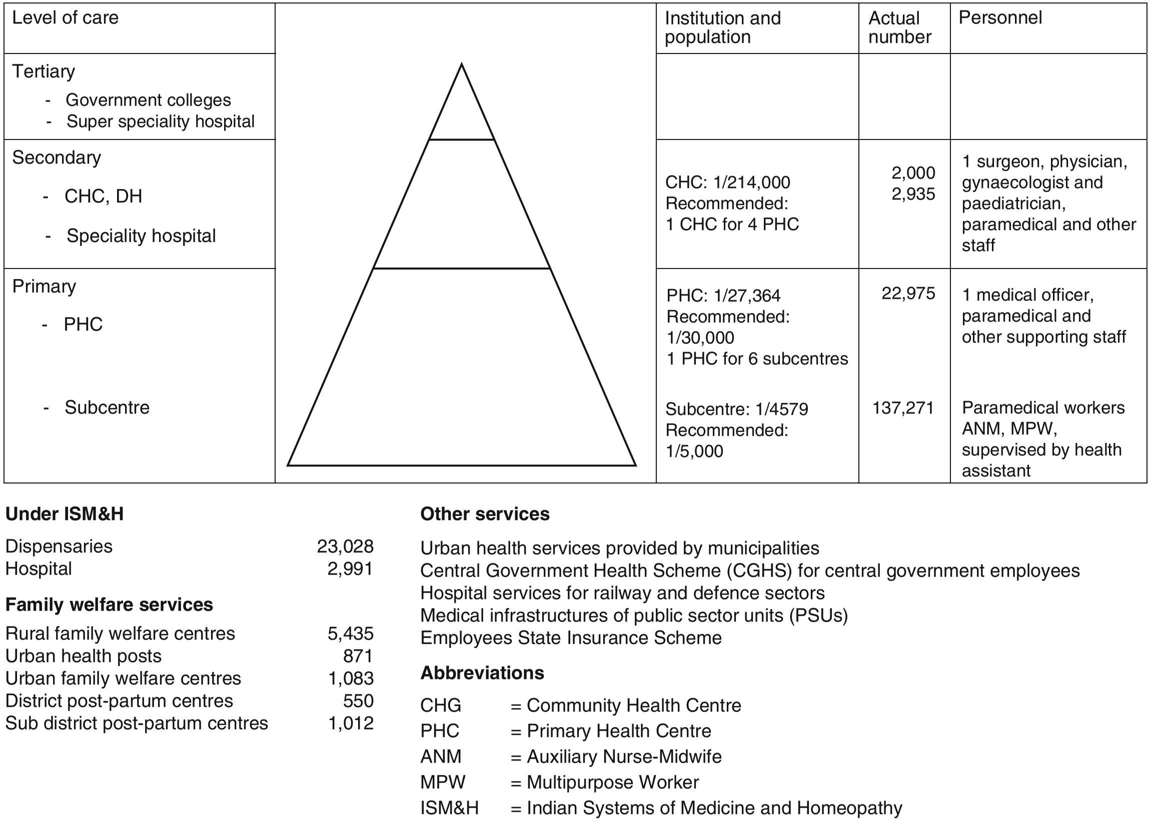
services was matched by a parallel proliferation of the private heath sector. Between 1948 and now, health of the population has improved as demonstrated by significant improvements in a number of health indicators (Tables 23.1 and 23.2). Smallpox and guinea worm have been eradicated, and polio is on the verge of extinction (National Polio Surveillance Project 2011). There has been a substantial drop in the total fertility rate and infant mortality rate while life expectancy has increased significantly (Planning Commission Government of India 2002).

The government health system has the mandate of developing and maintaining the health information system and for using this data for prevention and control of diseases, for health promotion activities, for decision making on provision of basic health services at minimal or no cost, and for outbreak investigation and control. The government health system has a definite organization through which health information is collected and transmitted (Fig. 23.1). The first contact between the population and the government health system occurs through the most peripheral health institution termed the subcenter. As mentioned earlier in the chapter, in a developing country like India, the subcenter is manned by paramedical staff, one auxiliary nurse-midwife (ANM) and one multipurpose worker (MPW). These health workers, supervised by a health assistant, have the responsibility of providing basic health-care services to a population of 5,000 residents in about four to six villages. The subcenter level activities include treatment for minor ailments and injuries, collection of blood smears from all fever (suspected malaria) cases, and referring patients and suspects to the Primary Health Center (PHC). Deliveries and antenatal care services are also done from the subcenters. The PHC is the referral unit for six subcenters and represents the next level of the health-care system. All PHCs have at least one qualified medical officer in charge. A majority of PHCs have four to six inpatient beds. One PHC is available for every 30,000 population. The PHC is the hub for compiling health data collected at the subcenters. The Community Health Center (CHC, also termed the First Referral Unit) is a 30-bed hospital that is the First Referral Unit for four PHCs. One CHC is available for every 200,000 population. The secondary health-care infrastructure consists of the district hospitals and other specialty hospitals, while the tertiary health-care infrastructure consists of government hospitals. The structure of the health system is described in Fig. 23.1. Starting from the subcenter level, morbidity and health data are collated and forwarded through district health officers to the Directorate of Health Services of each state. The national level data are collated from 28 states and 7 union



Level of care		Institution and population	Actual number	Personnel
Tertiary - Government colleges - Super speciality hospital				
Secondary - CHC, DH - Speciality hospital		CHC: 1/214,000 Recommended: 1 CHC for 4 PHC	2,000 2,935	1 surgeon, physician, gynaecologist and paediatrician, paramedical and other staff
Primary - PHC		PHC: 1/27,364 Recommended: 1/30,000 1 PHC for 6 subcentres	22,975	1 medical officer, paramedical and other supporting staff

territories of the country. The magnitude of the health information system can be conceived from the fact that government health services extend beyond urban areas to populations living in the nearly 668,000 villages in the country. The Rural Health Statistics 2009 lists 145,894 subcenters, 23,391 primary health centers (PHCs), and 4,510 community health centers (CHCs) functioning in the country (National Rural Health Statistics 2009).

23.3.1.2 Private Health Services and Traditional Medical Providers

The challenge to the HMIS in India comes from the fact that in addition to the government health services, India has a large private health sector. This private health sector consists of general and specialist medical practitioners, either in independent practice or working from hospitals. The exact number of practicing private practitioners in the country is unknown. Estimates of private practitioners are usually made from the number of students graduating from medical colleges each year. The majority of graduating physicians work in the private sector. The role of the private sector is to provide curative services for a fee. The infrastructure and quality of services present an outstanding range. The majority of the private sector institutions are single doctor dispensaries with very little infrastructure or paramedical support. Specialty care accounts for only 1–2% of the total number of institutions, while corporate hospitals (i.e., hospitals funded by large business organizations) constitute less than 1% of this infrastructure (Report of the Steering Committee on Health for the Xth Five Year Plan (2002–2007), 2002). The latter cater to people from the higher socioeconomic strata and offer their services to medical tourists from other countries. There are no mechanisms for collecting, integrating, and utilizing information on disease, infrastructure, or manpower from the private sector. In addition to the private health sector, it is estimated that there are more than 7,000 voluntary agencies (NGO, non-governmental organization) are involved in health related activities, mostly in the rural areas Report of the Steering Committee on Health for the Xth Five Year Plan (2002–2007) (2002).

Data of the National Sample Survey Organization show that there are significant interstate differences in the distribution of private sector hospitals and beds. Private sector hospitals are present in more prosperous districts and states, while in the poorer districts where health infrastructure is most needed, health services are provided by the public health sector (National Sample Survey Organisation 1998). The vulnerability of the HMIS is increased by the presence of multiple systems of medical practice in India. In addition to allopathic practitioners, licensed practitioners of traditional Indian systems of medicine (ayurveda, unani, siddha), Tibetan medicine and homeopathy are widely used by people in all parts of the country. A new Department of Ayurveda, Yoga, Unani, Siddha and Homeopathy (AYUSH) has been created (Anonymous 2008) with the objective of promotion and propagation of these systems of medicine in India and globally. There is a vast network of governmental institutions practicing and promoting the Indian Systems of Medicine and Homeopathy (ISM&H). There are 3,004 hospitals with 60,666 beds and over 23,000 dispensaries providing primary health care (Report of the Steering Committee on Health for the Xth Five Year Plan (2002–2007), 2002).

Over 16,000 practitioners from 405 colleges qualify every year. There is no estimate of the utilization of this sector, although ISM&H practitioners are extremely popular throughout the country. Inclusion of morbidity data from these practitioners into a disease database would be greatly limited since the rationale for diagnosis and disease classification is entirely different from the allopathic system of medicine.

23.3.1.3 Health and Morbidity Data: Disease Surveillance

Data on reproductive and child health, vector-borne diseases, tuberculosis, leprosy, blindness control, iodine deficiency disorders as well as health infrastructure, district level health plans for different states, community monitoring, etc., can be obtained through the portal of the National Rural Health Mission. Some selected sources of data are listed in Table 23.3. Data collection formats from subcenter to national level can be viewed at http://nrhm-mis.nic.in/Downloads_HMIS.aspx. The records reflect the health priorities of the country: maternal health (primarily deliveries and outcome), maternal and child immunizations, endemic communicable diseases, health infrastructure, and health manpower (the latter necessary for delivering services through the 1.2 billion population). Information is also collected on deaths and probable causes of death. Morbidity statistics on major infectious diseases are collected by the "vertical" disease control programs (described in part A) from both rural and urban health institutions. Again, the magnitude of the HMIS becomes apparent from the example of the tuberculosis control program in the state of Maharashtra. Data are collected from 29 district tuberculosis centers and 1995 peripheral health institutions, and 7 tuberculosis hospitals and sanatoria (Health

Status Report Maharashtra 2009). Each center is responsible for recording and reporting clinical data on cases, treatment outcome, case holding, and management. Each parameter is strictly defined and follows the guidelines from the global program. It is pertinent to recall that the HMIS is based on health data from the government system, since there is no mechanism to incorporate data from private practitioners, used by the large majority of the population.

The Integrated Disease Surveillance Project is a surveillance program for early warning of impending outbreaks. Although the private sector provides over 75% of curative care for common illnesses, the disease surveillance system does not have representation in the private health sector. Usually, diseases which are considered to be serious menaces to public health, like measles, whooping cough, and diphtheria, are included in the list of notifiable diseases. In India, there is a conspicuous lack of uniformity in the lists of diseases which are notifiable among the 28 states and 7 union territories of the country. Cholera, yellow fever, and plague which are internationally quarantinable diseases are notifiable throughout the country as required under international health regulation. Other than these three diseases, most of the important infectious diseases are not uniformly notifiable throughout the country.

23.3.1.4 Sources of Population Data

Denominator data for epidemiological studies can be obtained from a number of sources, such as the vital registration system, Sample Registration System, and from the census data. Although vital registration is required under law, there is significant under-registration especially in rural areas. Monitoring of vital events is also difficult considering the magnitude of the task. In Maharashtra, the second largest state in the country, for example, vital statistics data are obtained from 40,448 villages, 230 municipal councils, 15 corporations, 7 cantonment boards, and 4 ordnance factories. It is estimated that in Maharashtra, about 80% of births and about 62% of deaths are registered under the civil registration system (Health Status Report Maharashtra 2003). Computerization of vital events is present in only a handful of municipalities in the country. Vital registration is likely to be better in urban areas, since death certificate is compulsory for obtaining permission for cremation or burial. This rule is rendered ineffective in rural areas where regulated cremation areas are often not used (Health Status Report Maharashtra 2003).

A more reliable estimate of vital rates is obtained from the Sample Registration System (SRS). The objective of the SRS is to provide reliable annual birth and death rates at the state and national level for urban and rural areas. The SRS is a dual system of registration involving continuous enumeration of births/deaths in sample villages/urban blocks and matching these data with that of a 6-monthly retrospective survey. The data obtained through these two sources are verified by matching. Unmatched data are reverified. This method not only results in unduplicated reporting of events but also has an inbuilt system of quantifying the disparity between the two data sets. The details of sample design and sample size are given on the SRS website (Sample Registration System (SRS) Bulletin 2001) (http://censusindia.gov.in/Vital_Statistics/SRS/Sample_Registration_System.aspx).

The census forms one of the more authentic sources of demographic data in India. The first population census was initiated between 1865 and 1872 and has subsequently been undertaken uninterruptedly once every 10 years. Post enumeration surveys (PES) form an integral part of the census operation, aimed at estimating coverage and content error. Error tables for under-coverage of census houses and population are available through periodic publications from the Office of the Registrar General and Census Commissioner. Content error is estimated from a 10% sample of households enumerated in the census and reverifying certain specific data in the questionnaire. The 15th Census 2011 will lead to the formation of a National Population Register (NPR). The NPR will contain identification data of the population, which is to be linked to a Unique Identity Number. This system, once operational, would be of great relevance to epidemiologists. Currently, since health care is out of pocket, mechanisms for tracking patients, eliminating duplicate data, etc., form a formidable challenge to epidemiologists working in the country.

A series of Demographic Health Surveys (the National Family Health Surveys) have yielded accurate and valuable information. The primary purpose of these National Family Health Surveys was to collect data on key indicators for assisting in policy decisions pertaining to the national population policy. The utility of these surveys is demonstrated by the last survey (NFHS-3) where HIV testing was done for over 100,000 men and women aged between 15 and 49 years. HIV estimates in India were previously being made from sentinel surveillance of infection rate among pregnant women attending antenatal clinics (ANC) and from sentinel sites that were not completely representative of the Indian population due to the convenient nature by which the sites were selected. Using this far from accurate surveillance system, the National AIDS Control Organization and international agencies had estimated the adult prevalence of HIV to be 0.91%. The NFHS-3 survey reported one third of the estimate of the earlier surveillance system at 0.36% (NFHS-3 2007), leading to downward estimates of not only the Indian but also global HIV prevalence estimates.

23.3.1.5 HMIS Data and Their Limitations

Despite the existence of this extensive health collection system, there are two major reasons contributing to the incompleteness of the existing HMIS. As previously mentioned, the first reason is the lack of a mechanism to collect data from the health-care providers in the private sector. Various surveys have shown that people from all socioeconomic strata access the private sector for outpatient services. For inpatient services, 60% of individuals living below the poverty line (26% of the Indian population fall into this category) utilize the public health sector facilities. An equal number of people above the poverty line access the private health sector (National Sample Survey Organisation 1998, 52nd Round 1998). Other surveys have shown that 65% of households go to private hospitals or doctors for treatment when a family member is ill. Only 29% usually approach the public medical sector. Even among poor households, only 34% normally use the public medical sector during illness (NFHS-2 2000). A more recent survey of a nationally representative sample of 109,041 households found that nearly two thirds (65%) of households use the private medical sector for health care (NFHS-3 2007). The second reason contributing to the incompleteness of the data is that unlike rural health services, urban health services do not have the planned and organized primary, secondary, and tertiary services in geographically delineated areas. Usually, private practitioners, municipal dispensaries, and tertiary care institutions cater to an enormous patient population from both the urban and rural areas. There is no population identifier, and since nearly all health-care expenditure is out-of-pocket, there is no estimate of duplications of data. Thus, the enormous population, the mixed health system, and the lack of initiatives to integrate data from the government and private health-care sectors make the task of information management and using this data for planning health interventions an intimidating task.

23.3.2 Epidemiological Research in Shaping Public Health Programs: Tuberculosis Control

In this section, we demonstrate how epidemiological research from major research institutions together with the public HMIS have helped shape disease control programs, using the specific example of tuberculosis. India is listed first among the 22 high-burden countries that account for 80% of new tuberculosis cases in the world (World Health Organization Report 2009). Although the incidence of tuberculosis has decreased, in absolute numbers the country still has the largest number of prevalent cases of tuberculosis globally. Some seminal epidemiological investigations conducted by Indian research institutions led to defining tuberculosis control policies in the country. Tuberculosis is a long-standing, chronic epidemic which has existed for centuries in India, being recorded in the ancient ayurvedic texts. The first national survey aimed at estimating disease burden was undertaken shortly after independence when a national sample survey for tuberculosis was conducted in the country (Indian Council of Medical Research 1959). This survey measured the prevalence of tuberculosis using a sample of 300,000 individuals drawn from 150 villages, 6 cities, and 30 towns (Chadha et al. 2005). The survey showed that tuberculosis was a significant public health problem in the country, which required an increase in treatment facilities and a public policy for control of the disease. The manner by which treatment for tuberculosis patients could be delivered in an affordable manner in a resource poor country like India in the 1950s and 1960s was defined by a number of other key research studies. In 1956, the so-called Madras study demonstrated that ambulatory tuberculosis treatment was effective and that it did not increase the risk of tuberculosis amongst family contacts (Tuberculosis Chemotherapy Centre, Madras 1959). The implications of this study were enormous, since tuberculosis patients did not require admission for the duration of their treatment. In 1963, it was demonstrated that most tuberculosis cases approached treatment facilities due to persistence of symptoms (Bannerji and Andersen 1963). This significant study implied that there was no need for active case finding for tuberculosis. The feasibility of passive case finding using sputum smear microscopy for presence of acid-fast bacilli (AFB) opened the way for establishing relatively low-cost tuberculosis diagnosis and treatment facilities in Primary Health

Centers throughout the country (Baily et al. 1967). Based on these and other studies, the National Tuberculosis Program (NTP) was initiated in 1962, having as its core, case detection through sputum microscopy of chest symptomatics attending government health facilities on their own (supplemented by X-ray when needed) and ambulatory treatment of 12–18 months duration. The NTP was reviewed in the 1990s, and the Revised National Tuberculosis Control Program (RNTCP) having components of the global tuberculosis control initiative was launched from 1992. Key to RNTCP was supervised treatment of patients, directly observed treatment, and short course (DOTS) (World Health Organization 1994). Research conducted in 1958 and in the 1980s in India had shown the impact of treatment supervision on improving cure rates and that intermittent treatment was as efficacious as a daily treatment regimen (Tuberculosis Chemotherapy Centre, Madras 1959; Tuberculosis Research Centre Madras and National Tuberculosis Institute Bangalore 1986). More extensive reviews on tuberculosis control in India are available from some key articles and references quoted therein (Chakraborty 1997; Narayanan et al. 2003; Chadha et al. 2005).

23.3.2.1 Limitations of the Tuberculosis Register and Role of Research

The RNTCP is the example of a vertical program, having its own structure, manpower, precise case definitions, patient categorization guidelines, treatment guidelines, and data-reporting formats. Details can be viewed at http://www.tbcindia.org/documents.asp#. These extensive data serve to guide the governmental tuberculosis control program. As described earlier, tuberculosis case notifications in this disease register is from the public health program only and therefore does not represent the true prevalence and incidence of tuberculosis. The number of cases detected by the government program is expressed as the case detection rate, calculated as the number of annual new smear positive (infectious cases) notifications from the RNTCP to the estimated new smear positive incidence. The estimates of tuberculosis incidence (and prevalence) come from repeated studies conducted in different Indian institutes. India now has a case detection rate of 68% indicating that a large number of patients remain unnotified, probably accessing tuberculosis treatment from private medical practitioners (World Health Organization 2009).

23.3.2.2 Estimation of Burden of Disease Through Surveys

Tuberculosis infection is estimated through tuberculin surveys. Tuberculin test results in an induration which is measured between 48 and 96 hours of tuberculin challenge. The size of the induration is plotted on a histogram. It is possible to identify tuberculin reactors from non-reactors, since the induration measures cluster around two modes, separated by an antimode. For estimation of burden of disease, examination of sputum smears for presence of acid-fast bacilli (AFB) and radiography have been the standard epidemiological survey tools. The specificity of microscopy of sputum is high, ranging between 98% and 99%. However, the sensitivity is relatively poor ranging between 50% and 70% or even lower. Repeated sputum examinations are known to improve the sensitivity of microscopy

(Nair et al. 1976). For example, when two specimens are studied, case detection improves from 58% to 72%. Only 6% additional cases are however detected if 8 specimens are examined. Culture of concentrated bacilli from processed sputum on standard culture medium is more sensitive than microscopy, since culture detects approximately 100 bacilli per milliliter of sample. Although culture is considered to be the gold standard, expense has been a major limitation in the use of sputum culture in epidemiological studies in India. Transportation of samples from remote areas to the laboratory is another major problem that has challenged tuberculosis surveys. Although radiography has also been one of the major tools in epidemiological investigations, X-ray is considered to be a non-specific tool since considerable subjectivity exists in the reading of X-radiographs (Gothi et al. 1974). A list of major surveys and their outcomes have been summarized in Chakraborty (1997). Two major methodologies have been used in prevalence studies. In the "X-ray screening" approach, mass miniature radiography (MMR) of the entire population is used to identify individuals with abnormal chest shadows for sputum tests. In the "symptom-screening" method, chest symptomatics in the community have been identified through questioning individuals for the cardinal signs of tuberculosis (i.e., persistent cough, chest pain, low-grade fever, and hemoptysis). Individuals screened positive by this method are offered sputum examination and chest radiography.

Although prevalence estimates of pulmonary tuberculosis have been computed from different surveys that have been conducted from time to time in the country, the surveys lack in uniformity since the objectives and methodologies have varied (Chakraborty 1997). Moreover, the surveys have been conducted in certain specified and restricted areas of the country covering different populations. Thus, the available information is neither uniform in its content nor representative of the country as a whole. A global exercise has been conducted by Dye et al. (1999) directed toward providing an average estimate for the country. An updated summary of the tuberculosis situation in the country as measured through various surveys is summarized in Chadha et al. (2005). Prevalence estimates from surveys have been used for developing control strategies and for estimating the resources that will be required for the control program. However, such average calculations cannot be used to evaluate changes in the tuberculosis epidemic in the country, for which precise rates, such as those obtained through Annual Risk of Infection (*ARTI*) surveys described below are necessary.

The *ARTI* gives the proportion of the population which will be primarily infected or re-infected with tubercle bacilli in the course of 1 year (Styblo et al. 1969). It is usually expressed as a percentage or cumulative rate. *ARTI* is estimated through the following formula (Cauthen et al. 1988):

$$\widehat{ARTI} = 1 - (1 - P)^{1/A},$$

where A = average age studied and P = prevalence of infection. The method of calculating average age (A) is described in Cauthen et al. (1988). The estimated *ARTI* is actually demonstrated to be the same as the incidence of infection, worked out by repeat testing of the same population under Indian conditions, and represents the only observational evidence ever reported (Chakraborty et al. 1992). *ARTI* studies from different parts of India have demonstrated an infection rate of 1.5–2% per year, but regional differences in infection rates exist within the country (Chadha et al. 2005).

23.3.2.3 Evaluation of Epidemiological Changes Through Time

Assisting the HMIS in understanding tuberculosis in the population, longitudinal studies, conducted in a few areas of the country, has provided an insight into tuberculosis trends. One of the first longitudinal studies, conducted over a period of 23 years, was initiated in a rural population residing in 119 randomly selected villages of Bangalore district. All persons above 5 years of age were X-rayed, and those with radiological abnormality were bacteriologically investigated (Gothi et al. 1979; Chakraborty et al. 1982). The results of this study gave one of the first opportunities to observe the time trend of tuberculosis in a rural community in India. Prevalence and incidence of culture-positive and radiologic cases revealed no change during the period of 12 years for which information was available. The mean age of cases was higher at later surveys. *ARTI* had declined from 1.1% to 0.65% in 23 years. Incidence of smear positive cases had declined for the area from about 65 to 23 per 100,000 in the same period, parallel to the falling *ARTI*. The above data were used to estimate future case rates with the help of a mathematical model which projected that even in 50 years, tuberculosis case rates expressed in terms of prevalence of culture positive cases would come down minimally (Balasangameshwara et al. 1992). It also showed that more energetic and efficient tuberculosis control measures as defined in the model could, however, result in a verifiable change in case rates. The epidemic situation in India is probably on a slow downward curve as indicated by declining mortality and case fatality rates, decline in meningeal and miliary forms of the disease, relatively high prevalence of cases in higher age with a low rate of positive cases in children, higher prevalence of cases in males, especially adult males, and equal prevalence rates across the urban-rural divide. However, even if on a downward trend, the decline could be minimal, as witnessed from high *ARTI* of 1–2% (Chadha et al. 2005 and references cited therein) and an annual decline of around 0–3% reported from the Bangalore rural and Chennai areas (Chakraborty 2004).

23.3.3 Conclusions

The discussion serves to highlight some of the challenges of establishing a HMIS in a developing country. For India, demographic and geographical features of the country determine the magnitude of the HMIS and also challenge timely, complete, and accurate collection of health data. Despite the formidable nature of the task, an extensive governmental reporting system has been put in place in India. These systems use precise definitions, structured data-reporting formats, in many cases developed and shared with global disease control programs, and involve repeated training of staff at all levels of the health system in the method of collecting and reporting data. Despite these efforts, the mixed health system consisting of an unregulated private health-care sector undermines government efforts at collecting health information. For India at least, the HMIS at best reflects disease trends among those utilizing public health resources. In the second half of this section we show the role of epidemiological research in supporting decision making in public health programs through research studies. Thus, the limitation of absence of a disease data capture system from the private sector is supplemented through research that provides data for decision making. We conclude by noting that infrequent and isolated surveys are not the long-term solution to acquiring incidence and prevalence data (Dye et al. 2003). Rather, the ultimate solution would be the same approach currently used in low incidence countries, namely, comprehensive routine disease surveillance. Daunting as the task may appear, it is obvious that strengthening disease surveillance and HMIS systems need to be given a high priority in developing countries like India. A cohesive research thrust is needed to determine the mechanisms by which the existing HMIS can be extended so as to also include health information from the private health sector of the country.

24.1 Introduction

After a brief introduction into the general field of health services research, a large section deals with the specific issues arising when epidemiological or statistical methods are used to study health services. This is followed by sections describing the main fields of investigation which are usually thought of as pertaining to the wider realm of health services research. These are studies of demand, need, utilization, and access to health services which have the interface between the patient and health services in common. The next section describes the importance of financial resources, structure, and organization for the delivery of effective and efficient health care. This is followed by a description of the processes and outcomes of health care, including concepts such as effectiveness and appropriateness of care and their use, for example, in physician profiling or in hospital rankings. In the section on outcomes, special emphasis is put on health status measurement and the evaluation of health systems in international comparisons. Important health economic concepts, such as cost-effectiveness and efficiency, are covered in various sections. This chapter concludes with describing common pitfalls and caveats in interpreting health services research.

24.1.1 Health Services Research Defined

Health services research (HSR) attempts to answer questions about the best medical treatment or preventive course of action, the quality of care provided by a hospital or a physician, the efficient delivery of services to all populations, and their costs. The Institute of Medicine (1994) defines HSR as “A multi-disciplinary field of inquiry, both basic and applied, that examines access to, and the use, costs, quality, delivery, organization, financing, and outcomes of health-care services to produce new knowledge about the structure, processes, and effects of health services for individuals and populations.” The three basic dimensions of care studied are (1) the process of deciding what care to provide, (2) the process of providing care in the best possible manner, and (3) the outcomes that result from care (Scott and Campbell 2002). Many HSR projects study aspects of care that span all three dimensions under the rubric “quality of care” (Brook and Lohr 1985). As Scott and Campbell (2002) pointed out, this frequently used but rarely defined phrase encompasses notions of effectiveness, efficiency, safety, access, and consumer satisfaction and is thus not a very precise title for scientific investigation (Scott and Campbell 2002). HSR challenges the dominant biomedical model in which disease occurs, leading to illness, which is then treated (Black 1997). In contrast to the clinical view focusing on individual patients, it adopts a population perspective and considers other determinants of the use of health care (Black 1997), such as socioeconomic status, local availability or acceptability of health services. HSR thus often challenges medical claims about the value of specific interventions.

HSR cannot be defined as a methodological discipline. It draws upon and uses multiple methodologies and is multidisciplinary in nature. The majority of quantitative research in the field is done using epidemiological methods, and epidemiologists increasingly work in this field of research.

This multidisciplinary approach is seen by many authors as characteristic of this field of investigation, which is reflected in Last's definition of HSR as "The integration of epidemiological, sociological, economic, and other analytical sciences in the study of health services. HSR is usually concerned with relationships between need, demand, supply, use, and outcome of health services. The aim is evaluation, particularly in terms of structure, process, output, and outcome" (Last 2001).

The ultimate goal of HSR, however, is to provide unbiased, scientific evidence to influence health services policy at all levels so as to improve the health of the public (Black 1997).

24.1.2 The Input-Output Model of Health Care

Different models have been proposed for the study of health services. These include operational models, for example, the patient-flow model or the social sciences model. The patient-flow model starts with the assumption of a healthy population, where a patient's way through the different health-care institutions is followed once a disease manifests itself (Bennett 1978). The social sciences model attempts to consider the main social and political influences, causal relationships, and environmental conditions on the process of service delivery in a health-care system. Social experiences, values, priorities, importance of societal resources and structures are the focus of the analysis (Weinermann 1971). A causal or epidemiological model is also possible, which analyses care along known or supposed hypothetical causal biosocial links (de Miguel 1971). The drawback of such a model is its complexity.

For many analyses, simpler models are more adequate. We prefer a model adapted from engineering sciences in which some components of the other models have been integrated – the input-output model (Fig. 24.1) – which takes structure, processes, outputs, and outcomes into account (Schwartz and Busse 2003).

In this model, statistical data can be structured in an easy and transparent manner. Political debates on health services also often follow this structure.

The input of the health-care system is divided into (Schwartz and Busse 2003):

- Patient-side input, that is, the health status of the population as well as its access to care
- Resource oriented input, that is, the input in terms of financial and non-financial resources, such as human resources and infrastructure, as well as organizational structures, responsibilities, and interdependencies between actors and organizations

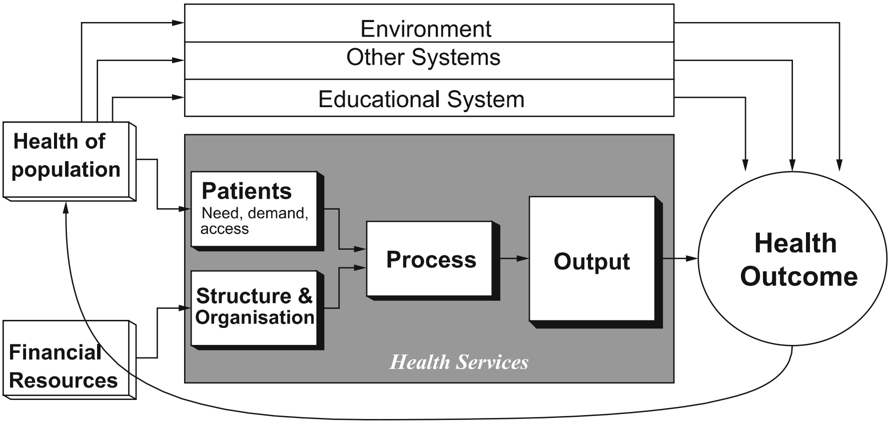

Fig. 24.1 The input-output model (Busse and Wismar 2002)

Throughput forms the center of the model – encompassing all processes of care in a health-care system.

The output of the health-care system is divided into two sequential elements (Schwartz and Busse 2003):

- Direct results of the processes, that is, output measures in the classical sense, also termed intermediary outcomes, for example, the number of cardiac catheterizations performed
- Outcomes in terms of changes in health status, which are often only measurable in the long-term, for example, the mortality avoided by a specific intervention

Common to all models deployed is the problem of causal inference. Although some problems are also encountered by epidemiological research, like the establishment of precedence in time in case-control studies or in historical cohorts (Hill 1965), these problems are much more important in health services research and thus make the latter more prone to biased or confounded results. The main problem is the complexity of the system with multiple interdependencies which result in the dilemma of "before the intervention is after the intervention." A good example is the evaluation of health-care reforms, which often come in a piece-meal fashion and which are only half-way executed before the next reform measures start. Assigning observed changes in an evaluation study to one particular reform package then becomes difficult, and as with all uncontrolled before-and-after studies, the results of such studies have to be interpreted with great caution (Grimshaw et al. 2001). However, in particular, for the evaluation of health reforms, such before-and-after studies are often the only possible research method, as conducting controlled studies is often not feasible.

24.1.3 Level of Analysis

A complementary approach to the one described is the analysis of the level at which processes of care take place (Schwartz and Busse 2003):

- The macro level – consisting of the health system as a whole and national health policy
- The meso level – research focusing on interorganizational structures and processes, for example, between health-care payers and providers, or the relationships between providers in a specific region
- The micro level – analysis of individual care services and technologies

Aday et al. (1998) attempted to match research methods to the level of analysis, illustrated in Table 24.1. In their model, the macro level refers to a population perspective on the determinants of the health of communities as a whole ("health of population" in the model), and the micro level represents a clinical perspective on the factors that contribute to the health of individuals at the system, institution, or patient level (Aday et al. 1998). Their intermediary system level encompasses both the macro and meso level in our model. It refers to the resources (money, people, physical infrastructure, and technology) and the organizational configurations used to transform these resources into health-care services either for the country as a whole (macro level) or within a specific region (meso level).

Table 24.1 Levels of analysis in health services research (Adapted from Aday et al. (1998))

	Level of analysis			
Data sources	Population	System	Institution	Patient
Census	x			
Public health surveillance systems	x			
Vital statistics	x

24.2 Methodological Considerations

Generally all types of data can be analyzed for the purposes of HSR. We find experimental data from randomized controlled trials as well as observational data from case-control or cohort studies, registers, or surveys. But many analyses in HSR make use of data from large administrative databases that are abstracted from medical or hospital discharge records, prescriptions, and bills of payments for delivered health services.

24.2.1 Study Designs

24.2.1.1 Randomized Controlled Trials

When alternative approaches to the delivery of health care have to be evaluated, a randomized controlled trial (RCT) is considered the gold standard, that is, the most rigorous method available. RCTs are performed in order to avoid bias and confounding. It is the effect of randomization that provides equality of study and control group in all relevant characteristics except the intervention being tested.

Regardless of this advantage, one has to keep in mind some critical issues when considering the RCT methodology. First, the recruitment of participants (or other experimental units like communities or schools, etc.), who meet all eligibility criteria, may be difficult and expensive. Furthermore, a randomized assignment of treatments to patients may not be feasible by ethical reasons (for instance, if you want to compare a treatment that is widely believed to be efficacious with "no treatment" or with a placebo). The study population is frequently not representative of the target population. Thus, it is true that an RCT has a high level of "internal" validity, as study group and control group are really comparable, but this tends to be connected with a low level of "external" validity which is an important consideration in HSR as it aims to examine effects under actual conditions and not under trial conditions. The results of an RCT refer solely to efficacy (a treatment is called efficacious if the desired effect is obtained under optimal conditions) but not necessarily to effectiveness (a treatment is called effective if the desired effect is obtained under everyday conditions).

Accordingly, the role of RCTs in HSR is more limited than in other areas of health research, and RCTs have only been carried out in certain areas of HSR. For example, the efficacy of cholesterol-lowering treatment in the prevention of coronary heart disease in men with high cholesterol was demonstrated by a multicenter, randomized, double-blind clinical trial, the *Lipid Research Clinics Coronary Primary Prevention Trial* (Lipid Research Clinics Program 1984). As Kelsey et al. (1998) report, the most expensive research study ever sponsored by the US National Institutes of Health – the Women's Health Initiative (Buring and Hennekens 1992) – consists of a series of RCTs to test the hypotheses, whether a low-fat dietary pattern protects against breast cancer and colon cancer, whether hormone replacement therapy reduces risk for coronary heart disease, and whether calcium and vitamin D supplementation protects against hip fractures. Even in the context of evaluating organizational change, RCTs had been carried out. The so-called *Health Insurance Experiment* (Newhouse 1974) was designed as an RCT to evaluate the effect of different levels of cost sharing in health insurance on utilization, expenditures, and health status (for more details, see Sect. 24.3.2). But regardless of such examples, the majority of RCTs are designed to evaluate a new (drug) therapy and are performed in clinical settings (randomized *clinical* trials).

24.2.1.2 Observational Studies

An overwhelming part of HSR is based on observational studies. In a pure epidemiological setting, case-control and cohort studies are used to estimate and evaluate the association between a specific exposure and a specific disease. In addition, exposure and outcome are frequently mapped into binary variables. In HSR, exposures and outcomes have a higher degree of variety than in chronic disease epidemiology.

Typical exposures are

- Conditions that may lead to inequalities in access to care, for example, low-income status, rural area of residence
- Health states that define certain needs for care, for example, mental illness
- Medical interventions, for example, stent implants versus bypass surgery to prevent heart attacks
- Different health-care delivery systems, for example, Health Maintenance Organizations (HMO) versus capitated Preferred Provider Organizations (PPO) versus a traditional indemnity plan with fee for service (FFS) payments
- Programs that aim to improve the quality of care, for example, disease management programs
- Programs to contain the costs of care, for example, drug formularies

Typical study outcomes are

- Access to care, for example, preventive services (vaccination), therapeutics
- Health status, for example, incidence of prespecified (tracer) diagnoses
- Life years gained, that is, reduction of mortality
- Patient reported outcomes, for example, health-related quality of life
- Quality of care scores, for example, measures of the Health Plan Employer Data and Information Set (HEDIS)
- Appropriateness of care measures, for example, an appropriateness evaluation protocol (AEP)
- Cost of care, for example, increases (additional costs or losses) or decreases (savings)

The general limitations of observational studies are dealt with among others in chapters ▸Cohort Studies, ▸Case-Control Studies, ▸Modern Epidemiological Study Designs, ▸Confounding and Interaction and ▸Design and Planning of Epidemiological Studies of this handbook. The absence of randomization gives reason for special concerns, that is, a special type of selection bias, when the goal of the study is to evaluate interventions. Persons who choose a particular intervention – or are advised by a physician to undergo it – are often on a different level of risk for the outcome of interest compared with persons who are not assigned to or did not choose to use this intervention (Selby 1994). Particularly in the case of an open intervention program, persons who pay attention to their health may be more likely to participate and comply with a recommendation (e.g., to undergo a screening examination) than persons who do not (Kelsey et al. 1998).

Case-Control Studies The methodology of case-control studies is treated in great detail in chapter ►Case-Control Studies of this handbook. Because of its obvious merits (a case-control study can be carried out at relatively low cost and comparably quickly), it is used with increasing frequency in HSR, especially in order to asses the adverse effects of drugs and other therapies and to evaluate the efficacy of preventive interventions (Kelsey et al. 1998).

Examples for the application of the case-control approach in HSR are numerous. This includes evaluations of vaccine efficacy and vaccination effectiveness, assessments of medical therapies, of screening programs for cervical, breast, and colon cancers, and of a number of programmatic activities in the community (Armenian 1998).

Cohort Studies Primary data collection for classical epidemiological cohort studies (cf. chapter ►Cohort Studies of this handbook) is relatively rare in HSR compared to chronic disease epidemiology. One reason might be that health systems change fast in small scales, that is, in trends in coding diagnoses, and in large scales as, for example, completely new reimbursement structures like diagnosis-related groups (DRGs) so that information from long-lasting follow-up studies may often be outdated and not worth the expense.

The majority of cohort studies in HSR is based on administrative data collected for purposes other than research and is focused on the outcomes of a medical treatment or a preventive intervention. The outcomes vary and may include mortality, morbidity, functional status, quality of life, costs, and satisfaction with care. The studies frequently use historical cohorts. For example, the investigation of short-term (30-day) and long-term (5-year) mortality in a cohort of members of a large HMO with hip fractures was a historical study that used computer-stored hospital discharge data linked with computer-stored data from death certificates (Petitti and Sidney 1989). A different type of cohort analysis in HSR focuses on the description of changes in symptoms, functional status, or quality of life in patients who undergo a treatment or are the subject of a preventive intervention (Petitti 1998a).

Cross-Sectional Studies If the goal of data analysis is related to health planning or the assessment of needs for services, prevalence rates are often more useful than incidence rates. Cross-sectional studies therefore represent an important tool for health planning and evaluation. In outcome research, the common methodological approach of *variance in practice* (e.g., to assess the quality of medical care or the outcome of the health system of a county) is tightly connected to a cross-sectional design, mostly based on administrative data, with organizations (e.g., hospitals), providers (e.g., surgeons), counties, states, or even countries as the units of analysis.

Cross-sectional studies are also used to establish research priorities based on consideration of the burden of disease (Kelsey et al. 1998). In a study on the prevalence of chronic gynecologic conditions among US women of reproductive age, for example, it was found that the most common conditions were menstrual disorders, adnexal conditions, and uterine fibroids. The results stressed the need for more effective treatments for these disorders and moreover, suggested that more research on their etiology would be highly desirable (Kjerulff et al. 1996).

Cross-sectional studies are of course less useful to examine hypotheses on causal effects mainly because of the lack of knowledge on the temporal sequence of hypothetical causes and potential effects but also because cross-sectional studies include both new and old cases. This results in a case group which has more than its fair share of individuals with disease of long duration because those who die or recover quickly will be underrepresented (Kelsey et al. 1998).

24.2.2 Complex Models for Data Analysis

In several health systems, available claims data are characterized by a longitudinal structure with long strings of repeated measures of health services for individual patients. Such data structures demand analytical designs. To make full use of them, complex longitudinal data analysis techniques must be applied that can handle time-varying exposures, repeated outcomes, and intra-person correlations.

The lack of detailed information on the severity of disease in claims data sometimes is a reason to use case-based study designs, as for instance, case-crossover studies to allow cases to be their own controls (cf. chapter ▶Intervention Trials of this handbook).

Another complicating factor is that observations in health-care delivery systems are often not independent. For many observational studies, the level of observation is a patient (characterized by a vector of patient attributes). A cluster of patients will be seen by the same physician (characterized by a vector of physician attributes) and will therefore experience similar treatment patterns so that their outcomes cannot be expected to be completely independent. Physicians often practice in groups sharing similar practice styles. These groups may practice in a larger health-care delivery system that imposes constraints to treatment choices, for example, drug formularies or payment by capitation (a lump sum per patient), which will make practice styles of groups within a health plan more similar than groups outside the plan. This clustering of observations on multiple levels has led to the adoption of multilevel regression models as standard tools of HSR.

24.2.3 Data Sources

Primary data collection in a randomized controlled trial, a case-control or a cohort study, is certainly an important, although unusual, data source of HSR. Primary data, when used in HSR, are more frequently collected from the general population (or subgroups) by questionnaire. The majority of data that are analyzed in HSR stem from large administrative data bases, as pointed out before.

24.2.3.1 Surveys

Survey research is frequent in HSR. For a detailed description of survey methods, see chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook. On the one hand, it can be used to provide snapshots of the current state of a health-care delivery system. On the other hand, survey subjects often become re-interviewed in regular intervals to form a longitudinal data structure or a panel. Further possibilities to classify surveys are given by the

- Unit of observation (patients, patient-provider contacts or providers)
- Target population (total population or subgroups)
- Type of data collected (interview data, data of medical examination, or both)
- Access to information (personal interview, mail survey, or telephone interview)

A well-known German survey – the *EVaS-Study* (*Study among office-based ambulatory care physicians in the Federal Republic of Germany*, Schwartz and Schach 1989) – was a cross-sectional survey with patient-physician (or patient-office) contacts as units of observation. The concept followed the US *National Ambulatory Medical Care Survey* (*NAMCS*, Tenney et al. 1974) to some extent. The target population was defined by a number of selected regions in Germany, a fixed study period, and the exclusion of a few medical specialties concerning the involved physicians. The data were collected by mail using an induction interview questionnaire, a reporting form, and a final questionnaire. The final data record covers data of the patient as well as data provided by the physician's office (including, e.g., the diagnosis corresponding to the patient's major reason for encounter, the assessment of the severity of the problem, the services delivered, and the duration of the encounter).

The *German National Health Interview and Examination Survey (GHS)*, however, (carried out from October 1997 to March 1999) targeted the general population aged between 18 and 79 years (Bellach et al. 1998).[1] The units of observation had been residents who were interviewed and medically examined. The data are available for research as a public use file. One of the results of this survey, for example, concerned the utilization of medical services available in Germany under statutory sickness fund facilities. About 90% of all Germans had seen their doctor at least once a year. Half of the population had consulted a doctor during the past 4 weeks and, on average, a medical practitioner was consulted 11 times a year (Bergmann and Kamtsiuris 1999). The Robert Koch Institute continued the GHS with the *German Health Interview and Examination Survey for Adults*. The recruitment period for this survey is November 2008 until November 2011 involving a total of 180 cities and municipalities all over Germany (Robert Koch Institute 2008a).

[1] This survey had three predecessors in the years 1984–1986, 1987–1989, and 1990–1991 and was supplemented by the *German National Health Interview and Examination Survey for Children and Adolescents (KiGGS),* carried out from May 2003 to May 2006. The target population were children and adolescents aged between 0 and 17 and living in Germany (Kurth 2007). The Robert Koch Institute continued the KiGGS study by carrying out telephone-based health interviews (Robert Koch Institute 2010).

Another frequently cited German survey is based on a representative, regionally stratified sample of 0.4% of all prescription forms, which are completed by office-based physicians for members of statutory sickness funds. This survey is supported in cooperation by the federal associations of the office-based physicians, the statutory sickness funds, and the free-standing pharmacies. It is carried out each year. The annually published results include an analysis of the sales increase with respect to its components referring to prices, volumes, and structural composition (Schwabe and Paffrath 2010).

The US *Medicare Current Beneficiary Survey (MCBS)* is an example of a survey that is designed as a panel. MCBS began in 1991 as a continuous panel in order to provide a more complete picture of the use of health services, expenditures, and sources of payment for the Medicare population. It is an ongoing computer-assisted personal survey of Medicare beneficiaries residing in the United States and Puerto Rico. Each person is interviewed three times per year over 4 years (regardless of whether he or she resides in the community or a long-term care facility), following a 4-year rotating panel design. The MCBS thus contains four overlapping panels of Medicare beneficiaries. Each year, one panel is dropped from the survey, and a new one is added. This design produces three calendar years of medical utilization data for each sample person. The data are collected over a 4-year period in which sample persons are interviewed 12 times. The first interview collects baseline information on the beneficiary. The next 11 interviews are used to collect three complete years of utilization data. Included are medical expenditure data as well as detailed data on health conditions, health status, use of medical care services, charges and payments, access to care, satisfaction with care, health insurance coverage, income, and employment (Adler 1994). The data are used to produce calendar year public use files on access to care, and cost and use. The nationwide MCBS data are released – as usual for public use files – only under a data use agreement. In addition, requests for regional or supplementing data must include a study protocol with specific justification for the additional data required, along with an identifiable data use agreement (see http://cms.gov/mcbs).

Another excellent population-based US panel, created by the (former) Agency for Health Care Policy and Research and the National Center for Health Statistics, is the *Medical Expenditures Panel Survey (MEPS)* which collects data from several sources to provide a complete picture of the health status and health-care utilization of a random sample of citizens (Cohen 1997).

In addition to other sampling methods, computer-assisted telephone interviews have become more frequently used in HSR. This method has comparatively low costs and guarantees an approximate full coverage of the general resident population in developed countries which have high rates of telephone access. Even unlisted households can be covered by means of random digit dialing.[2] Data are checked for correctness, completeness, and plausibility and stored continuously in the

[2] But the increased use of cellular phones poses a problem, and there is need for research to broaden the approach beyond the restrictions of the conventional telephone network.

course of the interview. Separate steps for data input and examination are not necessary. Germany, for example, started the first *National Telephone Health Survey* in September 2002. About 8,000 German speaking residents aged 18 years and older had been questioned on diseases, health-related behavior, and utilization of the health-care system (Ziese et al. 2003). This survey was supplemented by a regional one in Bavaria (Meyer et al. 2002). The recent telephone survey carried out by the Robert Koch Institute, the *German Health Update*, began in July 2008 and ended in April 2009. Twenty-five thousand people aged 18 and older were selected for an interview. The German Health Update was supplemented by regional surveys in Brandenburg and Saarland (Robert Koch Institute 2008b).

24.2.3.2 Official Statistics

Official mortality and other health or demographic statistics, especially vital statistics (births, marriages, deaths, etc.), have been extensively used in HSR. An early well-known and frequently cited example in the context of equity research is the study on differential mortality in the United States (Kitagawa and Hauser 1973). The comparison of mortality rates and the proportions of money from the national accounts that are spent on health is a popular starting point for health economists in analyzing the efficiency of a particular health system. But official statistics – mostly based on law – resemble routine registries and share their limitations (cf. chapter ►Use of Health Registers of this handbook and Sörensen 2001). The validity of mortality statistics in particular is strongly dependent on the rate of autopsies in a country. In a German survey of institutes of pathology within universities and in community hospitals in the year 2000, a median value of 23.3% and 13.3% of autopsies among hospital deaths was found, respectively. This was considered clearly below the recommended value of 30% (Schwarze and Pawlitschko 2003).

24.2.3.3 Administrative Databases

Administrative data are abstracted from medical or hospital discharge records, prescriptions, and bills of payments. Thus they have several advantages. They are routinely collected data representing the reality of health-care delivery. They need no additional time and money to gain access to large patient populations over long periods of time with repeated recordings of most health-care encounters of each subject. But the advantage of quick and easy access to large and representative populations is counterbalanced by data that may be incomplete and suffer from voluntary and involuntary miscoding. Although the quality of these data appears to improve over time, it has to be kept in mind that the primary reason for creating them was to document medical diagnoses and interventions obtained from medical records and manage the flow of payments for delivered health services obtained from claims data.

Since the advantages, particularly of electronic claims data, are so obvious, researchers try to better understand the consequences of the data limitations and develop analytical methods to adjust for them. Say, for example, the approach of Newhouse and McClellan (1998) used to overcome the typical selection problem, they were confronted with in analyzing the data of catheterization of patients with acute myocardial infarction. As data limitations are unique to each administrative database, a very good understanding of how data were generated is crucial for interpreting analytical findings.

Examples of administrative databases in the USA include the national Medicare and Medicaid databases as well as claims files for privately insured patients or members of a particular health facility. Data from the Medicare program, run by the *Centers for Medicare & Medicaid Services (CMS)*, are confidentiality-protected, longitudinally linked, person-level records that track virtually all elderly US citizens from their 65th birthday onward until death, through geographical moves and changes in providers.[3] The data sets include the types and amounts of health services used (e.g., hospitalizations, office visits, home health care, surgeries, and diagnostic tests), the medical problems being treated (diagnoses), provider characteristics (site of service and physician training), and charges. Information on long-term care services and outpatient prescription drugs, not covered by CMS, is not included (Diehr et al. 1999).

In Germany, administrative databases which do not find their ways into the official statistics or any kind of survey are scattered across the statutory sickness funds or other agencies of social security. Due to comparably strict data protection rules, record linkage is not a common practice in Germany.

From 2004 onward however, the associations of sickness fund physicians have been obliged by law to transfer beneficiary-related billing data, including diagnoses, to the statutory sickness funds.[4] Since then, anonymized/pseudonymized beneficiary-related databases from different research institutes were established, which encompass the data of several insurance companies and are used for purposes of drug safety and health service research (cf. Grobe et al. 2006, 2011; Ihle et al. 2008; Pigeot and Ahrens 2008; Glaeske and Schicktanz 2010; Bitzer et al. 2010; Sauer et al. 2010; Rothgang et al. 2010; Schäfer et al. 2011). In addition, the Federal Insurance Office governs a sample, which is annually drawn from all statutory insured persons, used for the calculations on risk structure equalization.

The abundance of information in claims databases in various states is often overwhelming. Many redundant measures are recorded, and researchers must identify the underlying variables that represent the concepts they want to evaluate. Since researchers on the other side, hate to discard already recorded information, *data reduction techniques* including comorbidity scores or propensity scores are increasingly applied to condense data while preserving information. For a detailed discussion of pharmacoepidemiological databases, we refer to chapter ▸Screening of this handbook.

[3] About 10% of Medicare enrollees are younger, disabled persons, who are tracked from their time of certification.

[4] The hospitals and the pharmacies had started to transfer their beneficiary-related data to the sickness funds long before.

24.2.4 Measurement Error (Misclassification)

In HSR, measurement errors (non-differential and differential as well; cf. chapter ►Measurement Error of this handbook) for all variables of interest are considered to be higher than in a traditional epidemiological setting for several reasons:

- Some data that are collected and stored but are not directly used for reimbursement or other administrative purposes (e.g., job or social status of an enrolled person) are likely to be not up-to-date.
- Diagnostic information on claims is documented to justify reimbursement; a bill for tests to rule out cancer, for example, may contain a diagnostic code for “cancer” even if the tests were negative.
- The information on clinical conditions in administrative data is in the form of diagnoses coded using the International Classification of Diseases (ICD) which is revised from time to time. Currently, ICD-10 (the tenth revision) is in use. Several countries (e.g., the USA) prefer ICD-10-CM, a clinical modification of the ICD. Some diseases such as arthritic or psychiatric disorders are difficult to classify because of lack of clearly defined diagnostic criteria. Less serious or vague conditions have a high probability of inconsistent coding. Regional and temporal variations of coding patterns may additionally reduce the reliability of coded diagnostic information.
- Especially the reliability of ambulatory diagnoses is a major concern. An analysis by the Medicare Payment Advisory Commission – MedPAC (1998) – demonstrated the inaccuracy of outpatient diagnosis coding. For the purposes of the study, MedPAC selected beneficiaries whose Medicare Part B claims in 1994 showed a diagnosis of 1 of 11 serious diseases, then checked for claims for the same diagnosis in 1995. As shown in Table 24.2, the likelihood of a claim in 1995 was only about 50–60% for each of the 11 diagnoses (cf. Newhouse et al. 1997). Part B Medicare covers the costs for medical service by general practitioners,

Table 24.2 Persistence in diagnostic coding of those identified in 1994 (Source: Medicare Payment Advisory Commission 1998, p. 17, Note: Excludes those who died in 1994 or 1995)

Diagnosis on 1994 Part B claim	Percent with Part B claim in 1995
Hypertension	59
Coronary artery disease	53
COPD	62
Congestive heart failure	61
Stroke	51
Dementia	59
Rheumatoid arthritis	55
High-cost diabetes	58
Renal failure	56
Quadriplegia/paraplegia	52
Dialysis	59

for a small selection of pharmaceuticals, for ambulatory treatments in hospitals, and other therapeutic and care services that are not covered by Part A Medicare.

- Moreover, administrative data used to reimburse hospitals or physicians are subject to some problems that are not familiar to epidemiologists, called "upcoding," "coding proliferation," and "gaming." Upcoding of diagnoses to more serious conditions is the process of assigning a diagnosis code or codes to a patient that may maximize the provider's reimbursement (e.g., ischemia to myocardial infarction) as it has occurred with some DRG payment systems (Dunn et al. 1996). Coding proliferation means the increase in the coding of all related conditions affecting treatment. Both types of distortion are relevant sources of measurement errors in HSR. Gaming is a serious problem that is dealt with in Sect. 24.5.2.3 because it cannot be subsumed under the term "misclassification" seamlessly.

In summary, the quality of claims data may be adequate for some purposes, but it is important to remember that claims are generated to justify reimbursement rather than to facilitate research.

24.2.5 Sampling Issues

A considerable part of data analyzed in HSR is based on samples from the population of interest (this is called the "target population" or the "population being sampled"). Sampling can help to save time and money. Sampling may also result in an increase of accuracy of measurement since more effort can be spent on this issue if only a manageable number of units of observation is included. Scientifically sound sampling methods are indispensable tools for designing an efficient sample and to provide consistent and unbiased projections from complex samples. Scientific sampling means *probability sampling*, that is, the probabilities of selection must be under control. Non-random samples based on volunteers or on the judgment of the sampler are not covered by this concept and are not recommended for use in HSR.

The sampling procedure is called *simple random sampling* if each of the possible samples of a given size has an equal chance to be selected. It follows that every one of the sampling units in the population has the same chance of being included in the sample. This is occasionally offered as the definition of simple random sampling (e.g., Kelsey et al. 1998) without realizing that there are other sampling procedures (e.g., systematic sampling, see below), which also have this property (Sukhatme and Sukhatme 1970). Simple random sampling is simple in theory but less so in practice because one needs a complete list of the population to draw the sample.[5] In many instances, it may not be the most efficient method of sampling. Therefore – apart from telephone sampling – it is not much used in practice.

[5] Random digit dialing in order to sample for computer-assisted telephone interviews is considered as a way to handle this problem if the existing lists are not complete and the target population can be accessed by conventional telephone network.

Systematic sampling is a common type of sampling based on selecting every *k*th individual from a list or a file after choosing a random number from 1 to k as starting point. It is based on a fixed rule and is not limited to selection from an actual file. Thus, selection of all those born on the (randomly chosen) third day of any month or of everyone whose social security number ends in (the randomly chosen digits) 17, 48, or 76 is similar to systematic sampling procedures yielding approximately 3% samples.[6] Because of these properties, systematic sampling is often simpler to administer under field conditions than simple random sampling. But systematic sampling has a severe handicap: differently from other sample designs, it is impossible to estimate the variance from one single sample. For an unbiased estimate, you need repeated sampling. Several (biased) approximations are used in practice to estimate the variance. One of these consists in treating the systematic sample as if it was a random sample of *n* units (Sukhatme and Sukhatme 1970).

When the population can be divided into *strata* in such a way that each stratum is more homogenous than the population as a whole, one can reduce the sampling error compared to a simple random error. Examples of variables that are often used for stratification are region, age, sex, race, and socioeconomic status. Following a *stratified sampling* design, a separate sample is drawn from each stratum, and the results are then appropriately combined in the analysis.

Cluster sampling has contrasting properties compared to stratified sampling. It is a simple random sample applied to groups of population members (*clusters*) that usually leads to a substantial loss of precision. But because of operational improvements of access to the units to be selected, one often achieves a heavy decrease of collecting costs and thereby an increase in precision per unit of cost. Examples of clusters that could be sampled are hospital wards, villages, schools, families, etc. If clusters are positively correlated within themselves, that is, they have a high positive *intraclass-correlation coefficient (ICC)*, indicating more homogeneity than would result from chance alone, cluster-sampling variance will be larger than simple random sampling variance. This is a situation frequently observed in real life. As ICCs are positive in most cases, simple sampling variance can grossly underestimate the true cluster-sampling variance. The ratio of the latter to the first-mentioned variance is called the *cluster effect*.

In a *multistage sampling design*, stratification and clustering may be combined on several stages of the sampling procedure forming a complex random sample. Stratified sampling, for example, may be used to ensure that schools are represented in the sample according to different socioeconomic areas in a large city, and cluster sampling of classrooms within the selected schools might then be employed for efficiency.

The analysis of data from a complex sample procedure that includes cluster sampling requires a sound knowledge of sampling theory or statistical advice. There

[6] Of course, the choice of the sampling scheme has to be relevant to the population being sampled. A population that is not completely covered by social security would be unsuitable for sampling by means of social security number.

are a series of textbooks on sampling theory (e.g., Hansen et al. 1953; Kish 1965; Stuart 1968; Sukhatme and Sukhatme 1970; Cochran 1968; Levy and Lemesshow 1991), and many handbooks or textbooks on statistics contain at least a chapter on sampling theory (e.g., Kendall and Stuart 1958; Kahn and Sempos 1989; Krishnaiah and Rao 1994; Voß 2003). The use of a special software (e.g., Sudaan) or a special module of one of the common large statistical packages (e.g., SAS, Stata or SPSS) is inevitable. They allow for variance weighting in the statistical procedures to adjust for the specific sampling design. Otherwise, as cluster-sampling variance may be many times larger than the variance calculated by assuming a simple random sample (Abraham 1986), and the analysis can result in severely misleading conclusions about the significance of the study findings.

24.2.6 Confounding and Risk Adjustment

For general principles of control for confounding, see chapter ►Confounding and Interaction of this handbook. Health services researchers tend to summarize methods to adjust for confounding under the term "risk adjustment." With respect to the large databases analyzed, standardization and multivariate modeling are more frequently used to control for confounding than the traditional approach of stratification.

Any level of comparison can be affected by confounding. This includes the mapping of health-care needs, the evaluation of clinical strategies and programs, studies of the effectiveness of quality improvement initiatives, or the evaluation of cost containment measures. Typical confounders are age, sex, ethnicity, income, smoking, or other risk variables. In outcome studies, confounding is a major concern because of differences in severity of illness and comorbidity.

The most frequent approach to control for confounding in HSR is to include the potential set of confounders as predictors in the regression model (cf. chapter ►Regression Methods for Epidemiological Analysis of this handbook) to predict the outcome of interest:

- Ordinary least squares (OLS) regression when the outcome has a continuous distribution (ideally a normal distribution) as, for example, the logarithm of costs
- Poisson (or negative binomial) regression when the outcome is described by counts (as, e.g., the number of hospital admissions in a specified year)
- Binomial (logistic) regression when the outcome variable is binary, indicating, for example, the occurrence of disease or death

When a large database is used for the analysis, comorbidity is often taken into account by including a lot of so-called dummy, that is, binary 0/1 variables in the regression model that indicate the presence (or absence, respectively) of each out of a list of classified comorbidities. When using samples of small or moderate size, this approach may not be possible. In this case, a premodeled aggregated index of comorbidity can be included in the analysis (Schneeweiss et al. 2001).

Including a potential confounder variable in the analysis requires its storage in the database. This is crucial whenever "secondhand" data are analyzed. Especially in a country like Germany where record linkage is not a common practice, one cannot expect to have full control over all relevant confounders, and many socioeconomic characteristics are available only in survey research.

Omission of one or several confounders usually leads to a violation of the assumptions underlying the estimation procedure in the OLS regression model

$$Y_i = \beta_1 x_{i1} + \beta_1 x_{i2} + \ldots\ldots.. + \beta_k x_{ik} + \varepsilon_i, \quad i = 1, \ldots., n,$$

as the k predictors x_{ij}, $j = 1, \ldots, k$, and the random errors ε_{i}, $i = 1, \ldots, n$, are no longer uncorrelated where n denotes the number of subjects, Y_i the response variables, and β_j the regression coefficients.

In this situation, the introduction of one or more of so-called *instrumental variables* can help to establish a consistent estimation of the interesting effects (that is, β_j). This has been a well-known technique of econometric analysis (IV-technique) for over half a century which is described in almost every econometric textbook (e.g., Greene 2003). But it is very rarely applied to HSR problems because a sound econometrical or statistical background is needed. Instrumental variables should be correlated with the predictor variable as much as possible, and at the same time, they should be (at least asymptotically) uncorrelated with the random errors. The skill of the technique consists in finding such variables which are already in the database or could be added to it at a tolerable cost.

An illuminating example of the usefulness of IV-technique is presented by Newhouse and McClellan (1998) who explain the instrumental variable convincingly as a device that achieves a pseudo-randomization. The authors analyzed the effect of catheterization and associated revascularization of acute myocardial infarction on mortality in the years following treatment. For IV-estimation of this effect, they used the differential distances of the patients' place of residence to the (nearest) catheterization, revascularization, and high-volume hospital as instrumental variables.

24.3 Demand, Need, Utilization, and Access to Health Care

A main focus of HSR is the assessment of demand, need, utilization, and access to health services, which represent closely related but distinct fields of investigation. In the input-output model, they represent the endogenous, risk-related input, which is, among others, determined by population health – representing the exogenous risk-related input in the model.

Demand is a general economic concept, which can be defined as the "quantity of a good buyers wish to buy at a conceivable price" (Begg et al. 1997a). Demand for health and health care is in many respects different from demand for other goods and services. The demand for health care is a derived demand as health care is not sought in itself but as a means to improve one's health or to prevent its deterioration. Health care itself is indeed often rather unpleasant (McPake et al. 2002). Health is not something that can be traded, and both health and health care are surrounded by uncertainty. What people want in essence from health care is to buy access to care in case they need it, that is, insurance (McPake et al. 2002). Another aspect is that health is both a consumption good and a capital good (McPake et al. 2002). Especially politicians and health-care funders often focus on the consumption side and neglect the potential of investing in health as a durable good which is an important prerequisite for economic growth.

The notions of need, utilization, access, and the relationships between them will be discussed in more detail in the following sections.

24.3.1 Assessing Health Needs

The concept of "need" for health and health care links directly to population health. Initially it appears simple and is often used by politicians in health policy discussions but quickly becomes complicated and is therefore avoided by many analysts (Kindig 1997). Instead many policy analysts, in particular, in the United States, prefer to use the economic demand and supply framework, where it is assumed that if someone "needs" something, he or she will express this desire by purchasing the item that is needed in the marketplaces, and as a consequence, supply will increase (Kindig 1997).

An alternative concept of need as the "capacity to benefit" has been proposed by Williams (1974) and Culyer (1993). Their concept also goes beyond the perspective of an initial baseline level of health because unhealthy individuals and populations cannot be said to need more health care without regard to their potential for improving their health status (Kindig 1997). Capacity to benefit also rules out health services which might be desired by individuals or providers but which do not make a positive contribution to health-adjusted life expectancy (Kindig 1997). It also goes beyond a mere epidemiological description of health needs in terms of ill-health or shortcomings in care in a specified population as it incorporates the notion of effectiveness of the intervention. Some authors use the terms "felt need," "normative need," and "expressed need." The "felt need" reported by patients is often substantially different from the "normative need" as judged by health professionals. "Expressed need" represents the need expressed by action, for example, visiting a doctor (Wright 2001).

Three main approaches to health needs assessment exist (Wright 2001):

- Epidemiologically based needs assessment – combining epidemiological approaches, such as specific health status assessments, with assessment of the effectiveness and possibly cost-effectiveness of interventions
- Comparative needs assessment – comparing levels of service receipt between different populations
- Corporate needs assessment – canvassing the demands and wishes of professionals, patients, politicians, and other stakeholders

In practice, comprehensive health needs assessments often combine all three approaches. Practical applications are manifold, such as to highlight areas of unmet need and to provide a clear set of objectives to meet these needs, to decide how to use resources to improve the local population's health, and to influence policy, interagency collaboration, or research and development priority setting (Wright 2001).

A good example for a health needs assessment is a study contrasting the epidemiological need for carotid endarterectomy with actual service provision in an English region (Ferris et al. 1998). The authors estimated the need for a carotid endarterectomy on the basis of demographic and epidemiological data, assuming that the rate of endarterectomies in their region should match the rate of patients with symptomatic carotid disease – the patient group for whom carotid endarterectomy is proven to prevent strokes. Based on estimates of the incidence of transient ischemic attacks ($77/10^6$ population/year) and minor strokes ($76/10^6$/year), they calculated that the need for endarterectomy was $153/10^6$/year, which contrasted with operation rates of $35/10^6$/year in 1991–1992 and $89/10^6$/year in 1995–1996. The ratio of use to need was 0.47 (95% confidence interval (CI) from 0.4 to 0.54), which was far from being satisfactory. Furthermore, they noted a disconcerting variation in the use to need ratios between districts, ranging from 0.28 (95% CI: 0.19–0.38) to 0.81 (95% CI: 0.62–1.06), and lower use to need ratios in elderly and female patients – indicative of inequity in access in relation to need. The epidemiological needs assessment was supplemented with a corporate needs assessment comprising interviews with vascular surgeons and a joint purchaser-provider workshop. These indicated that the low operation rates were primarily due to low rates of referral for diagnostic assessment by general practitioners. The variation between districts partly reflected the concentration of services – districts with a high use to need ratio tended to have one of the main provider sites. This study clearly demonstrates the usefulness of such research in identifying the main levers for improvement of current service provision – in this case, raising awareness for the clinical indications for carotid endarterectomy in general practitioners, in particular, those located in rural areas without access to a local vascular surgical service.

24.3.2 Assessing Utilization and Access to Services

Studies assessing the utilization of services attempt to improve our understanding of who uses health-care services and why (Black 1997). In the previous sections, it has already become clear that many factors determine whether a patient utilizes a health-care service, among them whether the patient suffers from a condition for which an effective intervention is available and whether he or she demands that service. Three other common determinants of utilization have become apparent in the example of the health needs assessment for carotid endarterectomy in England – clinician's judgment, distance from facilities, and sex. If a general practitioner does not consider that referral to a specialist is necessary, it is unlikely that the patient will end up having the procedure nonetheless – resulting in unmet need and underutilization of health services. Other important factors influencing utilization and access are patients' knowledge and the cost of services to the patient.

A well-recognized example for the influence of sex on utilization is higher rates of appendectomy in women than in men (Black 1997). After the primary assertion that appendicitis is more frequent in women was not supported by evidence, the more likely explanations were as follows: Appendicitis-like symptoms are more common in women, probably arising from ovarian dysfunction; in some cultures, young women prove their independence by undergoing an operation; operation rates are dependent on the availability of services – the more surgical services are available, the higher the sex difference in operation rates (Black 1997).

The influence of clinicians' judgment on health service delivery has been investigated in a series of studies comparing hospital care and related costs between Boston and New Haven in the United States – two cities with similar demographics where most hospital care is provided by university hospitals (Wennberg et al. 1987, 1989). However, in 1982, expenditures per head for inpatient care in Boston were about twice as high as in New Haven ($889 vs. $451) (Wennberg et al. 1987). The excess utilization in Boston compared to New Haven totaled $300 million and 739 hospital beds per year. In a subsequent study in 1985, Wennberg and colleagues showed that the variation in operation rates between the two areas did not result in statistically significant differences in mortality between the two cities (Wennberg et al. 1989). The authors concluded that the lower rate of hospital use in New Haven was not associated with a higher overall mortality rate in the populations concerned and consequently that hospital care was overutilized in Boston and not underutilized in New Haven.

The influence of geographical and financial barriers to access is also well documented. Black and colleagues (Black et al. 1995) attempted to identify the reasons for geographical variation in the use of coronary revascularization in the United Kingdom in a cross-sectional study. They found considerable variation in revascularization rates between districts, which arose from differences in supply factors, notably the distance to a regional revascularization center and the existence of a local cardiologist. The level of coronary heart disease mortality in the population and the lack of use of alternative treatments not only failed to explain the observed variation but was inversely associated with the rate of revascularization (Black et al. 1995). This inverse relationship between need and provision of care has been observed in many settings and has been termed the "inverse care law" by Julian Tudor-Hart (Tudor-Hart 1971, 2000). It has to be kept in mind that in measuring the utilization of health-care facilities, only those patients are counted, who have surmounted barriers to access – be it long distances, fear of an operation, lack of public transport, waiting lists – and are thus biased (Schwartz and Busse 2003). These barriers to access also exist in countries which grant a legal right to health care to every citizen, in particular, among socially disadvantaged groups in society. These differences in access to care are even more pronounced in countries without such a right to health care and where direct financial barriers to care exist on top of other barriers to access.

The effect of financial barriers to accessing health services has been studied in many countries at different levels of development. The most famous study is the RAND Health Insurance Study (see also Sect. 24.2.1.1) on the effect of cost-sharing measures on utilization (Newhouse 1974; Newhouse et al. 1981; Brook et al. 1983). Between 1974 and 1977, about 2,000 non-elderly families were randomly assigned to different insurance plans. Participants were assigned to either prepaid group practices or to one of 14 fee-for-service insurance plans, which varied in their coinsurance rates and in maximum spending per family and year (Newhouse 1993). The authors found that the more families had to pay out of pocket, the fewer health-care services they used. Families on the plan with the highest coinsurance (95%) up to a $1,000 limit on annual family expenditure reduced expenditure by 25–30% compared to a plan which was free to the family (Newhouse 1993). Interestingly, the use of all types of services, whether physicians, hospitals, pharmaceuticals, dental, or mental health services, fell with cost-sharing to a similar degree, except hospital admissions of children which did not respond to plan (Newhouse 1993). While the reduced utilization had no negative effect on the health for the average person, health among the "sick poor" – the most disadvantaged 6% of the population – was adversely affected (Newhouse 1993). Especially the poor who began the experiment with elevated blood pressure had their blood pressures lowered more on the free care plan than on the cost-sharing plans, and mortality rates predicted on the presence of major risk factors were 10% lower among those insured on the free plan (Newhouse 1993). Free care at the point of delivery also improved both near and far corrected vision, increased the likelihood that a decayed tooth would be filled, and the prevalence of anemia among poor children was lower (Newhouse 1993). All observed adverse health effects of cost-sharing hit the poor and less educated disproportionately more.

A number of other factors can limit access to services, in particular, gender, age, professional status, race, and religion (Schwartz and Busse 2003). The discrepancy between need in terms of ill-health and capacity to benefit from intervention and utilization is a commonly used measure of equity.

24.4 Financial Resources, Structure, and Organization of Health Services

Health-care financing can be described from different perspectives:

- The first one looks for the ultimate sources of funding. Here, intermediary sources of financing (government, social security funds, private social insurance, and private households above all) have to be tracked back to their origin.
- The second one, commonly used in National Health Accounts, aims at a breakdown of expenditure on health into the complex network of third-party payments plus the direct payments by households or direct funders (OECD 2000).
- The third one focuses on the allocation of the available resources. Health planning and management of health care among others includes the continuous task of distributing the financial resources, for example, to distinct segments in the natural history of disease (as reflected in prevention, cure, rehabilitation, and care), to alternative treatments for a specific disease, to different regions, to various groups of providers, or simultaneously with respect to some of these categories.

When comparing the developed countries with respect to financing from the first perspective, we can find two marked types of health services systems: systems that are funded by taxes and typically have a National Health Service (NHS) – so-called NHS-type or Beveridge-type systems – and systems that are predominantly financed by contributions of employees and employers (so-called Bismarck-type systems). In the real world, we find, of course, mixed systems including all the common forms of public and private financing. The UK is generally considered to be the classic example of an NHS-type health service system, and the German health system, as established by Bismarck in the late nineteenth century, naturally acts as the model of all Bismarck-type systems.

Health service systems also vary considerably in the overall health insurance coverage rates. In all EU member states, nearly 100% of the population has coverage of some type of public or private health insurance, whereas in the USA, 46.3 million persons (corresponding to 15.4% of the population) had no coverage at all during the entire year 2008 (U.S. Census Bureau 2009), which constitutes an important barrier to access as seen above.

International comparisons of health-care spending are hampered by a variety of definitions and classifications, used by the national statistical agencies, resembling the different organizational structures of health-care delivery (van Mosseveld 2003). To improve comparability of health, accounting data Eurostat, the statistical office of the European Union (EU), and the Organization for Economic Co-operation and Development (OECD) jointly developed a conceptual basis of rules for the statistical reporting of health accounts together with EU member states (OECD 2000). This so-called *System of Health Accounts (SHA)* corresponds to the new German health expenditure data system which was developed simultaneously (Brückner 1997; Statistisches Bundesamt 2000a, b). The SHA includes expenditures of private households, is consistent with the System of National Accounts (SNA) methodology (OECD 1993), and covers three dimensions: functions of health care, providers of health care, and sources of funding. Core of the SHA is a newly developed *International Classification for Health Accounts (ICHA)* that is based on a three-digit code.

The ICHA reflects the potential variations among health systems in structure and organization of health care and the share of work between the various providers. One remarkable distinction between health services systems, when looking at the organization, refers to outpatient care. In many countries, patient-physician contacts take place only in offices of general practice. Contacts with medical specialists are limited to hospital visits no matter whether the patient has been admitted to the hospital or not. But there are other countries, among them Germany, where outpatient specialized curative care is predominantly provided by office-based specialists.

There are many additional differences in the structure and organization of health services systems in spite of the fact that in all developed countries, patients with a specific health condition receive more or less the same treatment, provided that quality standards are observed. The package of activities in health care seems to be stable over the health systems, while the providers are different. International studies of health-care systems based on comparable data sets are rare. One of the outstanding examples is the WHO/International Collaborative Study of Medical Care Utilization – WHO/ICS-MCU (Kohn and White 1976). The data collection process of this carefully designed and methodically ambitious study included a cross-national multilingual household survey (by personal interviews) and standardized forms relating to health services resources and organizational factors. The study included almost 48,000 respondents representing over 15 million persons in 12 study areas scattered over Europe and America. One of the striking results of the WHO/ICS-MCU study was that study areas with the highest estimates of societal interest in health were also the areas with the lowest totals for per capita health expenditure and for health expenditure as a percentage of national income.

24.4.1 Allocation of Resources

Health-related decision makers in government, regional authorities, insurance companies, or other institutions are faced with the task of allocating resources. Examples are allocating research funds to different areas of HSR, Medicaid funds to treatments, Medicare funds to HMOs, or global funds to local authorities. Regional allocation is a main concern of all NHS-type health-care systems. Risk-adjusted capitation payments to insurers or to providers is a related topic that has been discussed extensively in several non-NHS-type countries (e.g., the USA, the Netherlands, and Germany).

There is no unique method for resource allocation analysis. Different levels and variable purposes of resource allocation analysis require different methods:

- For economic evaluation, for example, of drugs, surgical procedures, other types of clinical interventions, or of community intervention programs, limits on health-care resources mandates resource-allocation decisions guided by considerations of cost in relation to expected benefits (Weinstein and Stason 1977).
- The UK approach of weighted capitation has become the principal method of allocating health-care finance to regions (Rice and Smith 1999).
- Risk-adjusted capitation, whereby capitated payments are adjusted to reflect the expected cost of individual enrollees, is commonly based on multivariate regression models to predict health-care expenditure (Van de Ven and Ellis 2000).

While economic evaluation are mostly based on RCTs and observational studies (mainly on effectiveness and costs), risk-adjusted capitated payments and formulas of weighted capitation are generally based on official statistics (e.g., census or mortality statistics) or large samples from administrative databases. For an example, see Sect. 24.4.1.2.

24.4.1.1 Economic Evaluation, Especially Cost-Effectiveness Analysis

Economic evaluation can be defined as the comparative analysis of alternative courses of action in terms of both their costs and consequences (Drummond et al. 1997). There are four main types of economic evaluation (see Table 24.3).

Table 24.3 Types of health economic evaluations (Source: Epstein and Sherwood (1996))

Type of analysis	Assumption/question addressed
Cost-minimization	The effectiveness (or outcome) of two or more interventions is the same. Which intervention is the least costly?
Cost-effectiveness	The effectiveness of two or more interventions differs. What is the comparative cost per unit of outcome for the intervention?
Cost-utility	The question is the same as for cost-effectiveness analysis. The outcome is a preference measure that reflects the value patients or society places on the outcome.
Cost-benefit	The effectiveness (or outcome) of two or more interventions differs. What is the economic trade-off between interventions when all of the costs and benefits of the intervention and its outcome are measured in monetary terms?

But in practice, most of the health economic evaluations apply the cost-effectiveness methodology. *Cost-benefit analysis* is rarely used in public health and health-care settings because of methodological difficulties to measure the value of human life and low acceptability of its results on the side of health policy decision-makers and health professionals. *Cost-utility analysis (CUA)* is considered by many to be a subtype of *cost-effectiveness analysis (CEA)* where the effectiveness measure includes societal or individual preferences for the outcomes – a customary effectiveness measure in CUA is the quality-adjusted life year (QALY) (cf. Sect. 24.6.1.2 and chapter ▶Descriptive Studies of this handbook) – compared to natural units as effectiveness measure in CEA, for example, life years gained or mmHg blood pressure reduction. Most of the important methods and concepts applicable to cost-effectiveness studies are also applicable to cost-utility and cost-minimization studies. Cost-of-illness studies may be identified as a fifth type of economic study in HSR. Their goal is to estimate the total societal costs of caring for persons with a specific illness compared to persons without this illness, irrespective of any intervention. Such studies are carried out to demonstrate the (relative) burden of illness. They are not full economic evaluations because alternatives are not compared (Drummond et al. 1997).

One limitation that is common to all types of economic evaluation arises from the difficulty in obtaining a true estimate of costs, particularly in a health-care or public health setting where high proportions of fixed costs and little flexibility in changing the labor pool are typically found (Petitti 1998b).

A common understanding of cost-effectiveness claims that one of the three criteria has to be met (Doubilet et al. 1986). First, an intervention is cost-effective when it is less costly and at least as effective as its alternative. Second, an intervention is cost-effective when it is more effective and more costly, but the added benefit is "worth" the added cost. Third, an intervention is cost-effective when it is less effective and less costly, and the added benefit of the alternative is not "worth" the added cost.

Cost-effectiveness is measured as a ratio of cost to effectiveness. Two concepts to calculate this ratio should be distinguished (Detsky and Naglie 1990): An average cost-effectiveness ratio is estimated by dividing the cost of the intervention by a measure of effectiveness. An incremental cost-effectiveness ratio is an estimate of the cost per unit of effectiveness of switching from one intervention to another. In estimating an incremental cost-effectiveness ratio, both the numerator and denominator of the ratio represent differences between alternative interventions (Weinstein and Stason 1977). Often the terms "marginal" and "incremental" are used interchangeably in the literature, although *marginal costs* are strictly speaking the costs of producing one extra unit of output, whereas *incremental costs* usually refer to the difference, in cost or effect, between the two or more programs being compared in the economic evaluation (Drummond et al. 1997).

Estimating *average cost-effectiveness ratios* can be useful for service planning and for resource allocation decisions between very different health programs, for example, an influenza vaccination program and liver transplantations. However, for resource allocation decisions between interventions for the same disease, for example, two different antihypertensive drugs, *incremental cost-effectiveness ratios* should be used. The importance of using incremental cost-effectiveness ratios for decision making in some settings is best illustrated with the example of the sixth Guaiac stool test to screen for colorectal cancer, which had been endorsed by the American Cancer Society and which has later been shown to have an incremental cost of $47 million per case detected compared to an average cost of $2,451 per case detected (Neuhauser and Lewicki 1975).

The unspecified implicit alternative to an intervention is usually doing nothing. But doing nothing has costs and effects that should be taken into account in the analysis (Detsky and Naglie 1990). Furthermore, explicit declaration of "doing nothing" as the alternative intervention helps to frame discussions of the desirability of the intervention (Petitti 1998b).

Costs seem to be a straightforward notion, well understood by everybody. But actually, it is a rather complex term that consists of various components: direct costs, indirect costs, and intangible costs. Costs that are directly related to an intervention (and to side effects and other consequences) are summed up to the total of *direct costs*. By *indirect costs,* health economists understand the monetary value of lost wages and productivity due to morbidity and death of a person affected. *Intangible costs* refer to consequences that are difficult to measure and value, such as the value of improved health or the pain and suffering associated with illness or treatment (Drummond et al. 1997). The rationale of economic evaluation is based on the concept of *opportunity cost*, that is, the benefits forgone by not deploying resources for the next best alternative use.

As costs are seen differently from different *perspectives* (e.g., perspectives of health insurers, corporations, hospitals, physicians, and patients), it is also important to define a cost perspective in CEA and state it explicitly (Petitti 1998b). A common goal in CEA is the societal perspective so that the total costs of the intervention to all payers for all persons are included in the analysis.

Costs and benefits, after all, must be discounted before comparing them by calculating the ratio of cost to effectiveness. *Discounting* is the usual procedure in economics used to determine the present value of future money. This analysis gives a greater weight to costs and benefits the earlier they occur. High positive discount rates favor alternatives with costs that occur later or benefits that occur earlier. This clearly favors curative versus preventive health programs. In the business world, there is no fixed rate of return on investment, and the use of a private sector return rate for public sector program cost may not be correct (Sudgen and Williams 1990). Most published CEA in developed countries use discount rates between 3% and 5%. An expert panel commissioned by the US Public Health Service, based on the "shadow price of capital," recommended using a discount rate of 3% for economic evaluation in the public health sector (Gold et al. 1996). Whether benefits should also be discounted, and if so at what rate, is highly controversial.

Estimates of benefits and costs in a CEA may be uncertain because of imprecision in both underlying data and modeling assumptions. Therefore major assumptions should be varied and the net present value and other outcomes computed repeatedly to determine how sensitive outcomes are to changes in the assumptions. This so-called *sensitivity analysis* is typically the last step in a CEA. A sensitivity analysis varying the discount rate from 0% up to 7% should always be done (Gold et al. 1996).

As illustrated by Oregon's Medicaid reform efforts in 1990/1991, CEA or other types of economic evaluation cannot be used as sole basis for allocating scarce resources because the question of equity and ethical issues are not addressed by this method. In Oregon, CEA was only 1 of the 13 factors used to prioritize funding of services for the poor (Petitti 1998b).

Since Sir William Petty found out in 1667 that public health expenditures to combat the plague would achieve a benefit-cost ratio of 84 to 1 (Fein 1971), numerous studies of economic evaluation have been carried out, most of them using ratios of cost to effectiveness. The list of interventions that were economically evaluated within the last 10 year spans from influenza vaccination of healthy school-aged children (White et al. 1999) to colonoscopy in screening for colorectal cancer (Sonnenberg and Delco 2002), and preoperative autologous blood donation (Etchason et al. 1995) to reducing the population's intake of salt (Selmer et al. 2000).

24.4.1.2 Weighted Capitation in NHS-Type Health Systems

The central aim of weighted capitation is to distribute a global health budget between geographical areas in accordance with population needs and thus provide equal opportunity of access for equal needs. Currently used formulas of weighted capitation can be described as a modified age standardization of health-care expenditure. The UK Resource Allocation Working Party (RAWP) originally recommended in 1976 that the resources for the hospital and community health services (HCHS) be distributed on the basis of population size, weighted by age and sex, the need for health care, and the costs of providing services (Carr-Hill 1989; Advisory Committee on Resource Allocation (ACRA 1999)). Standardized mortality ratios (SMRs) were used as a proxy measure for relative needs. However, this had been criticized for failing to fully reflect the demand for health-care resources related to chronic disease and deprivation.

In 1995, a new weighted capitation formula for HCHS was introduced. This comprises an age index (based on estimates of national resources spent per capita in eight age groups) and an "additional need" index (additional to that accounted for by demographic variables). The need weighting index takes the form of four indices for acute, psychiatric, non-psychiatric community, and community psychiatric services, which are based on 1991 small-area census socioeconomic variables. It is derived from an empirical model that identified its need indicators as those census-derived health status and socioeconomic variables which, having been adjusted for the independent effects of supply, were most closely correlated with the national average pattern of hospitalization (Carr-Hill et al. 1994).

For all its merits, however, this formula, also called English formula, and the models on which it is empirically based have been criticized. The fundamental criticism relates to the use of utilization-based models to assess need for health care, which implies that historical patterns of service uptake between different care groups (as revealed by utilization) are appropriate (Mays 1995).

Against this background, some scientists pleaded for a radically new approach to health resource allocation, one that distributes NHS resources on the basis of direct measures of morbidity rather than indirect proxies such as health service utilization or deprivation. The Welsh steering group on allocation (Townsend 2001), for example, recommended the use of a morbidity-based budgeting approach. In a study of target allocations for the inpatient treatment of coronary heart disease in a sample of 34 primary care trusts in different areas in England, it was shown that a morbidity-based model would result in a significant shift in hospital resources away from deprived areas, towards areas with older demographic profiles and toward rural areas (Asthana et al. 2004). In the discussion of their findings, the authors concluded by calling for greater clarity between the goals of health-care equity and health equity.

Up from the year 1999, the Advisory Committee on Resource Allocation (ACRA) of the Department of Health took care of the further development of the Weighted Capitation Formula. ACRA picked up the above mentioned critique and incitations and learnt to distinguish between the two objectives "equal access to healthcare" and "reduction of health inequalities." Moreover, an index to estimate unavoidable labor costs, known as the staff Market Forces Factor (MFF), was included in the formula.

The actual formula for 2009–2010 and 2010–2011 allocations is built up by three components: hospital and community health service, prescribing and primary medical services. The corresponding weights are 76%, 12%, and 11%. Each component reflects both the additional needs and the unavoidable costs (the prescribing component does not have an adjustment for unavoidable costs since the prices of drugs do not vary by geographical location.)

The components again are set up by two indices: one (model-based computed) aiming at utilization of services and the other one aiming at health inequalities uses disability-free life expectancy as its measure, combining 2005 life expectancy data with 2001 limiting long-term illness data, and so capturing morbidity as well as mortality (Department of Health 2008).

24.4.1.3 Risk-Adjusted Capitation

When competition is an essential component of a health-care system, it is a widespread belief that capitated payments create incentives to contain costs and to compete on quality. But they also create undesirable incentives for risk selection ("cream skimming"), that is, to attract profitable patients (or enrollees) and to avoid unprofitable ones, and to decrease service intensity.

Risk adjustment is an important tool to reduce cream skimming while encouraging desirable cost and quality competition. This method controls for confounding (comorbidity above all) by calculating the expected health-care costs (or some other measure of an outcome) for members of health plans or insurance companies. This control is realized either by stratification (*cell-based approach*) or by multivariate modeling (*regression approach*). In many developed countries around the world, health-care organizations have established some sort of risk adjustment procedure for resource allocation. Examples exist for the following countries: Austria, Brazil, Canada, Chile, Germany, Hong Kong, Israel, the Netherlands, Spain, Switzerland, Taiwan, and the USA. Most of the risk adjustment procedures are based on a regression model to predict future health expenditure. Models differ with respect to the set of included predictors, the procedure of grouping diagnostic information, and the populations used for calibration.

The exclusive reliance on risk-adjusted capitated payments has been criticized, for example by Newhouse et al. (1997), who pointed out that the common risk adjusters (predictors of cost) are not likely to reduce risk selection problems to negligible levels. This concern was confirmed by a study of Shen and Ellis (2002) who examined the maximum potential profit that plans could hypothetically gain by using their own private information to select low-cost enrollees when payments are made using one of four commonly used risk adjustment models. Their findings – based on simulations using a privately injured sample – suggested that risk selection profits remain substantial (Shen and Ellis 2002).

Against this background, it was recommended to move the financing of health services to partial capitation payments. Partial capitation for an individual enrollee combines capitation methods and some reflection of that person's actual use of services, for example, a fee for service payment. Partial capitation would reduce plans' incentives to select good risks – the intent of risk adjustment – and also reduce the financial incentive to underserve or stint on care (Newhouse et al. 1997).

The General Form of Regression-Based Risk Adjustment Model Frequently used are regression models with untransformed costs as the dependent variable, estimated by ordinary least square (OLS). The standard assumptions of that type of statistical model (namely, a normal distribution, homoscedasticity, and independent observations) are not satisfied sufficiently by utilization data, but for predicting future costs, the model has shown to work about as well as more complex models in real situations (Diehr et al. 1999).

Occasionally a two-part model is applied: One equation predicts the probability that a person has any use, and a second equation predicts (on a log scale) the level of use for users only. In a two-part model, the regression coefficients of the first equation are estimated by logistic regression analysis and those of the second equation by OLS regression. Two-part models tend to meet the assumptions better than one-part models and provide insight into the utilization process, but they are not recommended when the goal is to predict future costs because transformations cause complications in this context (Diehr et al. 1999).

The list of possible predictors of a model for risk-adjusted capitation includes age, sex, and other demographic or socioeconomic variables, as well as binary variables to indicate that a person has been assigned to a diagnosis belonging to a special group from a system of diagnostic groups or has received a drug prescription belonging to a special group from a system of drug categories. To incorporate information on morbidity, some models use hospital diagnoses alone, while others use both inpatient and outpatient diagnoses. It has, however, to be noted that previous utilization is a strong predictor of a future one. This means that the costs in 1 year heavily depend on utilization in the year before for chronically ill patients. Thus, as in any regression analysis, it is important not to control for this variable lying on the causal pathway (Diehr et al. 1999).

The estimated regression coefficients ("regression weights") refer to the so-called calibration population. For diagnosis-based models, generally this is also the population used to establish the diagnostic classification system, the "grouper." Recalibration of a model without a refinement of the grouper therefore may lead to biased estimation. Generally the models are calibrated prospectively (that is, the data of the predictor set refers to the previous year, while the cost data refer to the actual year), but in order to evaluate the predictive power, current calibration (both types of data refer to the same year) has been performed as well.

The standard summary measure of model performance in prediction is R^2, the percentage of the total variance of the dependent variable that is explained by the model. Usually the values of R^2 in prospectively calibrated models do not exceed 20%. Newhouse et al. (1989) used theoretical and empirical arguments to estimate that the maximum possible R^2 in the context of utilization data is about 15% for total expenditure (prospectively modeling).

In addition to the grouper and the regression module, any risk adjustment methodology finally requires a module that links the estimated costs to the payment system or the resource allocation procedure, respectively, that is, a mechanism that controls the way payments or the allocation of resources is based on the predicted health-care expenditure.

Risk Adjustment in the US Setting Up to 1999, Medicare paid the HMOs 95% of the *adjusted average per capita cost (AAPCC)*, an estimate of the expected cost of treating Medicare beneficiaries in the fee-for-service sector in each local area. The AAPCC methodology adjusted for differences between the HMOs enrollees and fee-for-service users with respect to age, sex, welfare status, and whether or not they were in a nursing home (Ellis et al. 1996).

Since its implementation in 1985, the AAPCC had prompted concern about its fairness and accuracy, and it was shown that only about 1% of total variance of the cost of treatment was explained by this concept (Newhouse 1986; Ash et al. 1989). Against this background, the *Health Care Financing Agency (HCFA)* sponsored the development of alternative approaches that include diagnostic information as predictors in the regression-based risk adjustment model, among them the *Diagnostic Cost Groups (DCG)* family and the *Adjusted Clinical Group (ACG)* methodology (Ingber 1998). In the years 2000–2003, AAPCC has been stepwise replaced by the *Principal Inpatient Diagnostic Cost Group* model *(PIP-DCG)* which uses sociodemographic variables and hospital diagnoses to predict next years cost (Pope et al. 2000). In view of the widespread concern about the quality of ambulatory diagnoses, the DCG family was supplemented in 2001 by a model that uses outpatient pharmacy data, grouped into 127 mutually exclusive categories, instead of ambulatory diagnoses (Zhao et al. 2001). From 2004 onward, the CMS/HCC-model,[7] a 100% comprehensive risk adjustment scheme (using full encounter diagnostic data) has been implemented to adjust Medicare capitation payments to private health-care plans for the health expenditure risk of their enrollees (Pope et al. 2004).

Medicaid supported the development of the *Chronic Illness and Disability Payment System (CPDS)* which groups the Medicaid beneficiaries according to a hierarchical diagnostic classification system (Kronick et al. 1996). CPDS, which later on was reconstructed and recalibrated to predict expenditures also for Medicare beneficiaries, has now been established in several US states (Kronick et al. 2002).

Risk Adjustment in a Bismarck-Type European Setting In European countries with a predominating Bismarck-type organization of health services, we find competition among all insurance companies and even among the statutory sickness funds. The main goal of risk adjustment (better: risk equalization) in these settings therefore is to reduce risk selection by the sickness funds and to establish a fair system of income-related contributions. HSR has played a major role in designing and reforming these systems.

Like in the USA, the starting point of risk adjustment in Europe has been set by models based on age, sex, and other sociodemographic variables. The Netherlands, for example, started in 1992 with a prospectively used age- and sex-based model. In 1995, region and disability were included as predictors, and a “high-risk pool” was established in addition. Since 2002, dummy variables were added to the model that indicate prescriptions of drugs falling into 1 out of 13 mutually exclusive categories, the *Pharmacy-based Cost Groups (PCGs)*, each of them closely related to a serious chronic disease (Lamers 1999). From 2004 onward, the Dutch risk-equalization methodology had been further supplemented by an inpatient DCG module that uses hospital diagnoses only.

[7] CMS: Centers for Medicare & Medicaid Services; HCC: Hierarchical Condition Categories

In 1994, Germany introduced a retrospective risk-equalization procedure among statutory sickness funds which was based on the following variables: age, sex, and two dummy variables indicating invalidity or disability pension and the entitlement for sickness allowance. The procedure was also designed to adjust for different incomes because the beneficiaries pay income-related contributions. The largest share of the risk-adjusted financial transfers between sickness funds (up to 60%) results from differences in per capita income of the beneficiaries. From 2002 onward, the German risk-equalization methodology has been extended. First, a retrospective "high-cost pool"[8] was established, and second, a dummy variable was added to the set of risk adjusters indicating that a beneficiary is registered in an accredited disease management program. From 2009 onward, a risk-equalization procedure based on a DCG/HCC module has been established, using inpatient and outpatient diagnoses with respect to 80 (by an expert panel) selected diseases.

24.4.2 Evaluating Effects of Organizational Characteristics and Change

As health services systems in the developed countries tend to go through one reform after another and are more or less continuously exposed to change, evaluation is a permanent task of HSR. But the preconditions do not favor the establishment of scientifically sound designs of research. Experimental designs are extremely rare. The above-cited RAND Health Insurance Study on the effect of cost-sharing measures on utilization is one of the most famous exceptions. In some circumstances, it is even difficult to implement a quasi-experimental design including a control group. Particularly in countries like Germany, where benefits and programs are uniform but the organizational responsibilities are widely scattered over local authorities and institutions, evaluation research is very complex.

Suggested by the structure of available data, perhaps the most frequently used quasi-experimental design for analyzing aggregated annual data in the context of program evaluation is the time series experiment. It can be characterized by a periodic measurement process on some group and the introduction of an experimental change X into this time series of measurements O_i. Adapting a diagram by Campell and Stanley (1966), the time series design can be outlined as follows (whereby the number of observations before or after X, occurring here in year five, may be smaller or larger as in a real problems):

$$O_1, O_2, O_3, O_4, X, O_6, O_7, O_8, O_9$$

The main problem of (internal) validity inherent in a time series design is revealed by seeking likely alternative explanations of the shift in the time series

[8] The high-cost pool consists of insured with high cost in the past year (above a fixed threshold) which are shared by all statutory sickness funds.

other than the effect of X. This problem, of course, could be settled to a great extent by establishing a suitable control group (comparison series) that shares all intervening factors except X with the study group.

A natural approach for analyzing data from a time series design is *segmented* or *piecemeal regression* (e.g., Neter and Wasserman 1974). This method is appropriate when the considered response variable has a linear trend over the range before X (segment one) followed by another linear trend over the range after X (segment two). The year which divides the segments (year five in the above diagram) is known as the join point (or break point). When the hypothetical change of trend line refers only to the slope and not to the intercepts (that means no discontinuity between the both lines), the regression equation for analyzing data from a design as diagrammed above can be specified as follows:

$$E(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_1 x_2,$$

where Y is the response variable, x_1 is the year ($x_1 = 1, 2, 3, 4, 6, 7, 8, 9$) and x_2 is a dummy variable indicating that the year is greater than 5. The parameter β_2 measures the difference in slopes between the lines. If the same trend continues from the first segment to the second segment, then $\beta_2 = 0$. The β_j are estimated, and the hypothesis $\beta_2 = 0$ is tested, using standard procedures in regression. It is easy to expand segmented regression to more than two segments and even to allow for discontinuities between segmented regression lines. Autocorrelated errors or heteroskedasticity can be handled by using standard techniques (e.g., Greene 2003).

A good example for applying this type of analysis to evaluate the impact of a program on the basis of aggregated data is the study of the effect of a regionalized perinatal care program in North Carolina (established in 1965) on perinatal and postneonatal mortality (Gillings et al. 1981). A similar – but due to autocorrelation, more complex – analysis was carried out to evaluate the effects of patient-level payment restrictions for prescription drugs under Medicaid in the years 1981–1983. By this analysis, supplemented by survival analysis to measure the rate of admissions to hospital and nursing homes, it could be shown that the decline in the use of drugs after the cap (a limit of three paid prescriptions per month) had been associated with an increase in rates of admission to nursing homes (Soumerai et al. 1987, 1991).

Regardless of these examples, there is only limited use of OLS regression models for evaluation because of several restrictions. First, costs or the logarithm of costs or other continuously distributed responses are only one type of outcome measure used for evaluation. Counts of specific events, for example, contacts, prescriptions, hospital admissions, etc., and binary response variables like death, accident, or first occurrence of a specific disease are equally important – in some situations, even more important measures. Second, if individual longitudinal data are available, to make full use of the data structure, the model used should be able to handle clustered (correlated) response data, arising from repeated measurements and time-varying covariates. *Generalized linear models* (Nelder and Wedderburn 1972;

McCullagh and Nelder 1983) and the related *generalized estimating equations* (GEEs) (Liang and Zeger 1986; see also chapter ▶Generalized Estimating Equations of this handbook) form the methodological framework of an advanced approach of statistical modeling for evaluation. Consistent parameter estimates in these models are achieved by maximizing likelihood or quasi-likelihood functions using some sort of Gauss-Newton algorithm. Several of the common packages of statistical software, among them SAS, provide corresponding procedures.

The standard model to analyze count data, for example, is the *Poisson regression model*, which is a non-linear regression model that can be formulated as a generalized linear model. Poisson regression is robust insofar as consistent estimation of the regression coefficients does not require that the dependent variable is Poisson distributed. Only a correct specification of the conditional mean is required (Cameron and Trivedi 1998). But Poisson regression is prone to overdispersion. Therefore the condition that the variance equals the mean has to be relaxed by introducing a dispersion parameter that must be estimated as well. Otherwise, testing hypotheses on the regression coefficients could yield misleading rejections of null hypotheses (Cameron and Trivedi 1998).

Poisson regression can also be used to analyze correlated counts from repeated measurements. The within patient correlation is then estimated in the framework of GEEs, whereas the effects of the covariates can be modeled as a generalized linear model. For example, the introduction of reference pricing for angiotensin-converting enzyme (ACE) inhibitors for patients of 65 years of age or older in British Columbia, Canada, in January 1997, was evaluated by using such a type of analysis (Schneeweiss et al. 2002). Several covariates were included in the model, among them age, sex, the adjusted household income, and a chronic disease score computed from prescription medications for every quarter and treated as a time-varying covariate. This ambitious study was based on computerized administrative health databases covering a large proportion of the population, including all types of claims, hospital admissions, admissions for long-term care, diagnoses, and the medications, dose, and dispensed quantity of all prescriptions. Even the deaths within the study cohort were included.

A similar analysis has never been done in Germany, though reference-based prices (RBP) for the beneficiaries of the statutory sickness funds were established in 1992/1993. For reasons of privacy and data protection, cross-institutional linkage of existing scattered administrative databases on drug utilization, ambulatory diagnoses and medical services, and hospital data on an individual level need extensive data protection procedures in Germany. Thus the effects of RBP has to be evaluated on the basis of aggregated data. But any conclusions on the overall economic and public health impact, if obtained solely on the basis of aggregated data, are distorted because of the introduction of fixed drug budgets and the effects of the reunification of Germany (among other confounders) that both took place in the beginning of the 1990s, more or less simultaneously with RBP (Schneeweiss et al. 1998).

Sometimes one has to balance the advantage of using individual longitudinal data – without having a control group – against the advantage of having a control group at the price of rather limited capacities of analysis based on aggregated data. For example, in a study of the effect of premium rebate to reward low utilization of services for beneficiaries of one statutory sickness fund in Germany, the effect on expenditure mainly was analyzed using a long time series of aggregated data together with a control series. In a second step, this analysis was combined with an examination of the effects on non-monetary measures of utilization based on short time series of beneficiary-related data that were primary collected by the sickness fund in order to support administration of premium rebate (Schäfer and Nolde-Gallasch 1999).

24.5 Process of Health Care: Effectiveness, Appropriateness, and Quality

Research on the process of health care considers questions like "Which services are provided in which quantity, by whom, where, and how (Schwartz and Busse 2003)?" The production of health care is a complex result of financing arrangements and of demand- and supply-side factors. The interaction of these different factors is not well understood. An interest in investigating these questions arouse after substantial and unexplained variation in procedures, and hospital admissions were observed between similar hospitals. Some examples for these variations have already been presented in Sect. 24.3.2, for example, the Boston-New Haven Study (Wennberg et al. 1987, 1989). These studies demonstrated the importance of supply-side factors on utilization patterns and frequency, if patient-related factors are controlled for, such as age, sex, case mix, and socioeconomic status. The supply side of a region is primarily described by the density of physicians, hospital beds, and the availability of medical technologies. However, most studies do not analyze the effects of these provider or supply-side characteristics on the health status of the populations concerned (Brook and Lohr 1985). More refined supply-side characteristics determining the use of services comprise provider payment mechanisms, experience and sex of health professionals, organization and equipment of physicians' practices, size and type of hospital, as well as referral patterns between different providers (Schwartz and Busse 2003). "Self-referral" of patients has been identified as an important determinant of small area variation in the use of medical technologies (Childs and Hunter 1972). Self-referral describes the phenomenon of providing expensive medical technology, for example, X-ray examinations, for patients in general practitioners', physicians', or orthopedic surgeons' practices without referring the patient to a radiologist. In comparisons between countries with a comparable standard of health care, the possibility of self-referral for X-ray examinations compared to countries with X-ray examinations exclusively provided by a radiologist increases the overall rate of X-rays by a factor of 4 (Busse 1995). Within a country, differences in examination frequency between doctors with the possibility of self-referral compared to doctors who have to refer patients to a radiologist yield comparable results. In Germany, the rates for X-ray examination for patients with chronic pain were increased by a factor of 2.7, the rates for abdominal ultrasound for patients presenting with gastrointestinal symptoms by a factor of 3.0 in practices with a possibility of self-referral compared to practices who had to refer their patients to other practices (Busse 1995). Of course this observation is linked to the method of physician remuneration. It is a phenomenon which is primarily observed in countries with fee-for-service remuneration such as the United States and Germany. The effects of the structure of financial incentive systems and resulting overutilization on a system level tend to be underestimated. In Germany, fee-for-service remuneration combined with the possibility of self-referral and the widespread practice of non-radiologists to provide X-ray examinations in their practices resulted in 1,655 X-ray examinations being performed per 1,000 inhabitants in 1997 (Deutsche Röntgengesellschaft 2002) – about twice the rate observed in other European countries. It is estimated that unnecessary X-ray examinations during the last decades now cause around 2,000 incident cases of cancer in the country annually (Berrington de Gonzales and Darby 1994).

The extreme variation in health service provision raises the question whether diagnostic and therapeutic procedures are appropriately used in the process of care. To judge whether a procedure is appropriate, knowledge about the effectiveness of the procedure for certain indications or clinical presentations is required. However, this is not the case for the majority of indication-procedure pairs.

24.5.1 Assessing Effectiveness and Appropriateness of Care

In general, the effectiveness of a health-care professional or service is the degree to which the desired outcomes are achieved (Gray 1997). However, the proposition that an intervention is effective implies that there is only one outcome of care and only one objective in the design of that intervention – which is rarely the case (Gray 1997). In addition to a number of beneficial outcomes of care, such as lower mortality and morbidity, the possibility of harmful effects of care has to be considered. Effectiveness research attempts to answer questions, such as "What is the right thing to do?" or "What care confers significant health benefit for a given clinical situation?" (Scott and Campbell 2002).

Another frequently used concept is that of efficacy, which is the impact of an intervention in the best possible circumstances (Gray 1997). These can be achieved in randomized clinical trials (RCTs). However, the reverse conclusion that RCTs always produce efficacy results is not true, as not all RCTs satisfy high quality standards. The distinction between efficacy and effectiveness is important, as the latter represents the impact of an intervention under routine care conditions. The difference between the two concepts in terms of health status outcomes is illustrated in Fig. 24.2 using the example of complications of radical prostatectomy. Data on effectiveness in the example are derived from a meta-analysis of Medicare routine data; efficacy data are taken from a meta-analysis of RCTs.

An important aspect of both efficacy and effectiveness is that they apply to groups of patients. However, the impact of an intervention on the health status of an individual depends to a large extent on individual factors. To answer the

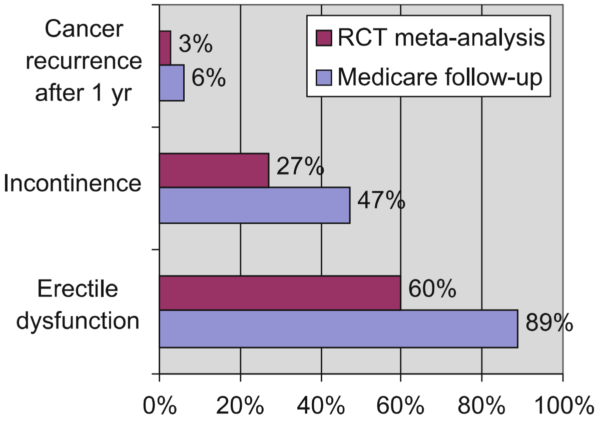

Fig. 24.2 Comparison of effectiveness and efficacy using the example of radical prostatectomy (Adapted from Fowler et al. (1993))

question of whether the most appropriate care was provided given the clinical circumstances is the realm of appropriateness research. An intervention can be considered appropriate, if the expected health benefit exceeds the expected negative consequences by a large enough margin to justify performing the procedure rather than other alternatives (Herrin et al. 1997).

Appropriateness research also addresses the questions of overuse, underuse, or misuse of interventions (Scott and Campbell 2002). We have already discussed the effect of provider remuneration systems and organizational features of a health system on utilization rates. Another major determinant of utilization is clinical judgment. A historical study on clinicians' judgment variation is a study from New York in the 1920s, in which one thousand 11-year-olds had their throats examined (American Child Health Association 1934), cited by Black (1997). In 61% of these children, a tonsillectomy was performed. Of the remaining 39%, the examining doctor thought half would require a tonsillectomy. The half with healthy tonsils were examined by another doctor, who thought that half of them required surgery. The healthy children were again examined by yet another doctor, who declared that half of them required a tonsillectomy, which means that after four examinations only 65 out of 1,000 children would have escaped with their tonsils intact (Black 1997).

During the last 10 years, a number of studies using the RAND/UCLA appropriateness method have been performed. This basically consists in collecting an expert opinion on the appropriateness of an intervention using the Delphi technique. The experts are asked to judge a number of possible indications (that is, case descriptions with clinical information including comorbidity, age, and sex) on whether a specific intervention was appropriate, inappropriate, or even harmful in these cases. In a second step, these judgments are applied to real patient groups in order to determine in how many cases the procedure was appropriate or inappropriate. Most studies using the RAND/UCLA appropriateness method reported appropriate interventions in the range of 50–85% of all interventions performed. Non-US expert groups consistently thought that more procedures were inappropriate compared to US expert groups. This has to be kept in mind when interpreting results from appropriateness studies. An example is a review of the appropriateness of coronary angiography, upper gastrointestinal endoscopy and carotid endarterectomy performed on 4,564 patients in the USA in 1988. The review which was based on a literature review and on an expert panel consensus concluded that, respectively, only 77%, 76%, and 36% of these procedures had been appropriate (Brook et al. 1990). Inappropriate care is more than a nuisance. It can be harmful to health. For example, in a prospective observational study on congestive heart failure admissions, 7% of admissions were found to be the result of improper medical treatment, including fluid overload, procedures, and misuse of drugs. Hospital mortality for this group of patients was 32% compared to 9% in patients without inappropriate treatment (Rich et al. 1996).

24.5.2 Assessing Quality of Care: Clinical Practice Performance

Measures of clinical practice performance continue to be under constant discussion, particularly when they are published routinely, as is the case, for example, for hospitals in the United States and the United Kingdom. There is broad agreement on the dominant paradigm, established by Donabedian (1980), of measuring quality of clinical care in terms of *structure*, *process*, and *outcome*, but each category has advantages and disadvantages which must be assessed in relation to the type and the speciality of the service (e.g., inpatient vs. outpatient care or surgery vs. drug therapy), the condition being treated (e.g., diabetes, hypertension, acute myocardial infarction, or mental disorders), the case mix of the patients, the role of the comparative information, and a variety of other context variables (Shojania et al. 2001).

The type of assessment of clinical practice performance heavily depends on the perspective on quality. Blumenthal (1996) distinguishes four main perspectives on quality: the health-care professional perspective, the perspective of health-care plans and organizations, the purchaser perspective, and the patient perspective. Health-care professionals tend to emphasize technical excellence and the characteristics of interaction between patient and professional (Donabedian 1988). Health-care plans and organizations place greater emphasis on the general health of the enrolled population and on the function of the organization (Leape 1994). Purchasers, of course, additionally incorporate the price and the effectiveness of the delivery of care. Taking into account the preferences and values of patients leads to a definition of quality that emphasizes outcomes such as functional status, morbidity, mortality, or quality of life and encompasses satisfaction with care (Petitti and Amster 1998).

24.5.2.1 Indicators of Structural Quality

Structural measures characterize the resources in the health system. They describe the setting in which care occurs and the capacity of that setting to produce quality (Donabedian 1980; Brook et al. 1996). Quality assurance programs and organizations such as the Joint Commission on the Accreditation of Health

Care Organizations (JCAHO) and the National Committee on Quality Assurance (NCQA) in the USA or the associations of statutory health insurance physicians in Germany rely on structural measures (as listed below) to infer quality and confer accreditation on this basis.

For providers, structural measures include professional characteristics like speciality or board certifications, etc. For hospitals, they include ownership, number of beds, teaching status, licensure status, availability of sophisticated technologies, qualification of personnel, and other organizational factors for inpatient care (e.g., staff-to-patient ratio, closed intensive care units, dedicated stroke units, or the presence of a clinical information system). One frequently used structural measure of quality is patient volume (Shojania et al. 2001). The growing use of this indicator reflects an extensive literature, which documents superior outcome for hospitals and physicians with higher patient volumes for certain indications and procedures (e.g., Luft et al. 1979; Hannan et al. 1989; Phibbs et al. 1996; Thiemann et al. 1999).

When using structural indicators to measure quality of care, the implicit assumption is that structure affects outcome. This is certainly true for the compliance with minimum standards of structure (e.g., rules for hygiene in operating rooms). But on higher levels of structural quality, the link between structure and outcome is less clear (Shojania et al. 2001). For example, specialist care as a quality measure not always results in better outcomes. This is demonstrated by the findings that even cardiologists fail to provide proven therapies to many eligible patients with acute myocardial infarction (Brand et al. 1995). These findings promote the case to measure the processes of health-care delivery directly instead.

24.5.2.2 Indicators of Process Quality

Process indicators permit a glimpse into the inside of the care-delivering units, allowing measurement of the care patients actually receive. They measure the net effect of physicians' clinical decision making. Clinical choices about the use of surgery, medication or diagnostic tests, admission to a hospital, and length of stay account for a large proportion of the costs of services and of outcomes experienced by the patients. Sometimes generic process measures are used (e.g., number of prescriptions, average length of stay, or day case surgery rate). But mostly they are specific to specialities and certain conditions (e.g., antibiotics within 8 h for patients with community-acquired pneumonia, prophylaxis for venous thromboembolism, or beta-blockers for patients with acute myocardial infarction).

Process measures can be reported for individual physicians, groups of practitioners, for hospitals, hospital units, or hospital trusts, or for the entire system of care. They are favored by providers to indicate quality because they are directly related to what providers do. Frequently they are derived from evidence-based clinical guidelines and facilitate individual physician quality improvement. If proven diagnostic and therapeutic strategies are monitored, quality problems can be detected long before demonstrable outcome differences occur (Brook et al. 1996).

Even so there are some arguments against process-based measurement of the quality of care. First, process measures are not necessarily good predictors of outcome, and allocating resources to processes which do not affect outcomes may increase cost without producing any improvement in health (Ellwood 1988). Moreover, collecting process data may be a comparatively elaborate procedure. Finally, it may not be possible to achieve consensus on the recommended process for many clinical problems (Petitti and Amster 1998).

24.5.2.3 Indicators of Outcome Quality and Adjustment for Case Mix

The quality-relevant health outcomes have been described as the "five Ds" – death, disease, disability, discomfort, and dissatisfaction (Elinson 1987), or, more positively turned, when measuring quality of care health outcomes could be summarized as survival, states of physiologic, physical, and emotional health, and patient satisfaction (Lohr et al. 1988). Broader definitions of outcomes include psychosocial functioning, quality of life, resource utilization, and costs of care (Iezzoni 1994).

The use of outcome measures to assess the quality of clinical performance has been criticized for several reasons. First, even for common conditions, it may take years to detect differences in outcomes between groups of patients (Palmer 1997). Moreover, such differences may not be under the control of providers but reflect, among others, patient factors, variations in admission practices, or chance rather than differences in quality of care (Shojania et al. 2001). Many outcomes (e.g., mortality) are rare, and comparisons of quality based on such outcomes often have low statistical power (Brook et al. 1996).

Considerable concern is related to perverse incentives for "upcoding" and "gaming" (McGlynn 1998), whereby gaming means a change of treatment to more expensive forms which are frequently more stressful for the patient and result in a reduced quality of care (e.g., a surgical procedure instead of a drug prescription, an inappropriate hospitalization, or a short hospital admission for a marginal diagnosis).

Incentives for gaming may arise from the criteria used to define target patient populations. For example, restricting inpatient mortality to deaths that literally occur in the hospital allows hospitals to lower their mortality rates simply by discharging patients to die at home or in other institutions (Jencks et al. 1988). Additionally, the incentive for physicians or hospitals to avoid caring for sicker patients remains a substantial concern for outcome-based performance measurement (Hofer et al. 1999). Proliferation of diagnoses related to comorbidity or coding of diagnoses related to severity of illness (upcoding) was observed after the introduction of the prospective payment system for HMO-enrolled beneficiaries of Medicare (Keeler et al. 1990).

The most important concern of research related to outcome-based quality measures focused on the development of case-mix adjustment models for hospital mortality rates. Case-mix adjustment and risk adjustment are based on similar methods, but they use different data sources: Case-mix indices are based on medical records from hospitals or physicians, while risk adjustment is based on administrative data, for example, from health insurances. Models that have originally been designed to predict financial rather than clinical outcomes (see Sect. 24.4.1.3) did not perform sufficiently well in this context because hospital data differ significantly in structure from administrative data. Progress has been made in adopting models to identify the case mix of a group of patients by focusing on specific subgroups of patients instead of overall hospital mortality and using clinical rather than administrative data (Iezzoni 1994).

24.5.3 Examples for Performance Assessment

24.5.3.1 Comparison of HMOs Based on a Performance Indicator System

The federal Centers for Medicare and Medicaid Services (CMS), formerly known as the Health Care Financing Administration (HCA), and the private sector in the USA have supported the development of several performance indicator systems in order to compare the quality of care delivered by HMOs. Perhaps the most popular system, the Health Employer Data and Information Set (HEDIS), was introduced in 1993 and was revised in 1995 and again in 1997. It can be considered as the model for many other performance measurement efforts (Petitti and Amster 1998).

HEDIS was designed by the National Committee for Quality Assurance (NCQA) to evaluate several aspects of health plan performance including clinical quality of care, access to care, satisfaction with care, utilization of services, and the financial performance of the HMO. The clinical quality-of-care indicators included in HEDIS were chosen to address aspects of the care process for which there was strong evidence in the literature to support the relationship between medical care process and desired outcomes (Petitti and Amster 1998). These included indicators for low-birth-weight babies, childhood immunization status, breast cancer screening, eye exams for people with diabetes, and beta-blocker treatment after heart attack.

24.5.3.2 Hospital Ranking

In NHS-type countries, the assessment of the quality of clinical performance focuses on the health of the general population and the function of the health-care system with a special concern on inpatient care. For example, in the United Kingdom, in order to rank hospitals, the publication of clinical indicators in the form of so-called league tables has a long history. As far back as 1983, a set of performance indicators was published covering five areas, one of which was clinical activity. Since then, the set of indicators has been revised several times (British Medical Association 2000). Currently, the published UK league tables are compiled by the Dr Foster organization (separately for England, Wales, Scotland, and North Ireland). They are based on the Department of Health's Hospital Episode Statistics (HES) data and data collected through questionnaires. The indicators fall into five broad categories: standardized mortality rates, waiting times and volumes, staff-to-bed ratios, and – for England only – patient and staff satisfaction and other rating-based scales (clean hospital, good food, etc.). The mortality rates are standardized for age, sex, length of stay, and type of admission (elective or emergency admission). SMRs are calculated for each of 80 ICD9 three-digit primary diagnoses (accounting for 80% of all in-hospital deaths) cited in the final episode of care (Dr Foster 2004a, b). The league tables are criticized for several reasons. The first concern refers to an insufficient control for case mix relating to severity, comorbidity, deprivation, and the availability of places for people to be discharged to nursing homes or hospices. The second refers to the use of HES data, which are based on finished consultant episodes (the NHS's measure of hospital activity), whereas no conversion to hospital spells is provided (HESs are not designed to collect detailed clinical data). Third, the primary diagnosis has been questioned, as diagnostic criteria change. Finally, the focus on inpatient mortality is considered as a shortfall because an increasing proportion of deaths occur outside the hospital (Jacobson et al. 2003). Dr Foster continued to publish the league tables regardless of this critique, and in the Editors' letter of the 2009 report, you can find the following statement: "Over the years, the report has remained a constant as an independent, authoritative guide to hospital care written for the patient, the politician, the civil servant, the manager and the clinician." (Bedford and Kafetz 2009).

In the United States, an annual index of hospital quality ("America's Best Hospitals") is published by *U.S. News & World Report*. This hospital ranking methodology was devised in 1993 by the statistics and methodology department of the National Organization for Research (NORC) at the University of Chicago. The ranking is based on reputation, mortality, and other factors. The reputational scores of a hospital are based on a survey. The index is designed to be used by patients who are looking for the best hospital to treat their health problems. Since 2005, the annual rankings of "America's Best Hospitals" are produced by the Social, Statistical, and Environmental Sciences Division of RTI International (North Carolina).[9] RTI produces hospital rankings with components representing three key aspects of care: structure, process, and outcome. These components are combined to give an overall score for each hospital in twelve medical specialties. For four additional specialties, scores were based on original survey data alone. The mortality score (outcome) is adjusted for case severity. The severity adjustments were derived using the All Patient Refined Diagnosis Related Group (APR-DRG) method designed by 3M Health Information Systems. The APR-DRG adjusts expected deaths for severity of illness by means of principle diagnosis and categories of secondary diagnoses (RTI 2009).

Beginning in 2007, U.S. News & World Report also began publishing separate annual rankings of "America's Best Children's Hospitals." Like Best Hospitals, the Best Children's Hospitals rankings reflect the interrelationship among structure, process, and outcomes. Most structure and outcome data were obtained directly from children's hospitals using the Pediatric Hospital Survey data submission form which is hosted by RTI. In 2010, children's hospitals were evaluated in ten pediatric medical specialties (RTI 2010).

In Germany, there is no published ranking of hospitals except for some studies of limited impact. A methodology of hospital ranking based on routine data of sickness funds and patient questionnaires with respect to total hip replacement was published

[9] This trade name has ist roots in the Research Triangle Institute (RTI), which was established by the universities located in the Triangle's three cities Raleigh, Durham, and Chapel Hill in North Carolina.

(Schäfer et al. 2007; Bitzer et al. 2007) but until now not fully established for public use. Nevertheless, there are some websites which deliver information on quality of hospital performance (structure, process, and outcome). This information is based on data collected by questionnaires from the insured of statutory sickness funds, on data from the quality reports of the hospitals, established by law in 2004, and – for selected diagnoses and procedures (tracer) – on routine inpatient care data of one large statutory sickness fund. For the latter (risk adjusted) approach (cf. Heller and Günster 2008), the hospitals are rated in the following categories: “above average,” “average,” and “below average.”

24.5.3.3 Physician Profiling

The Physician Payment Review Commission of the American Medical Association (AMA) defines physician profiling as “an analytical tool that uses epidemiological methods to compare practice patterns of providers on the dimensions of cost, service use, or quality (process and outcome) of care.” Profiles can be developed for an individual physician, a group of physicians, or physicians within a hospital or managed care plan. They can be broken down by geographical area, speciality, type of practice, or other characteristics. Profiling can focus on many different types of outcome or resource measures. Those resources may be defined globally (e.g., overall charges/costs for the care of a person or group of persons) or they may represent certain subcategories of services (e.g., laboratory, x-ray, physician services, or pharmaceuticals). Profiling is usually applied to compare resources used by cohorts of patients to get a sense of whether their providers do or do not practice efficiently. Even when profiles are not used to modify payment, they may be used to select or reject providers or to determine appropriate patient caseloads for salaried practitioners (Tucker et al. 2002).

The core element of any profiling methodology is risk adjustment by calculating an SMR-like figure, that is, a ratio of observed to expected values of the considered measure. The expected value is adjusted with respect to age, sex of the patients, and to the diagnostic groups that were assigned by the used grouper. Most of the sellers of common models of diagnosis-based risk adjustment (e.g., ACG and DCG) offer the use of their predictive models for profiling.

Profiling may serve as a tool to feed information on care back to the physicians. Also, managed care organizations as a whole have had considerable experience with profiling in order to monitor plan activity. For example, profiling reports, adjusted for case-mix, can be used to distribute bonus or set aside funds that are marked to recognize how well resource management goals are achieved among managed care providers (Tucker et al. 2002). A review of profiling in practice is given by Sutton (2001).

In 1996, the Commonwealth of Massachusetts became one of the first states to implement a comprehensive physician profiling program available to consumers over the Internet. Many other states have adopted similar systems since. In the beginning of the year 2001, physician profiles were available in 30 states, with legislation pending in eight others (Sutton 2001).

In Germany, profiling of physicians has been based on crude measures. Up to now, they have been compared with the average of the regional group of physicians belonging to the same speciality, but a medium-term change to the risk-adjusted profiling system, mandated by law, is scheduled.

24.6 Outcomes of Health Care

24.6.1 Assessing Output and Outcomes of Care

A frequently cited definition of outcomes was given by Donabedian (1985): "Outcomes are those changes, either favorable or adverse, in the actual or potential health status of persons, groups or communities that can be attributed to prior or concurrent care."

The most conventional method of measuring the health status of populations is by means of vital statistics, including statistics of birth and death. Disease-specific incidence rates, cause-specific mortality rates, or other population-based indicators are extensively used to assess the health status of communities, counties, or health systems in general (see Sect. 24.6.3). For example, the Centers for Disease Control (CDC) established a set of 18 population-based health status indicators in 1991 for use at all administrative levels in the United States (Freedman et al. 1991).

Vital statistics may be considered as the key feature of outcome research to study health care and the effect of intervention on a broad range of outcomes, both humanistic and clinical (Petitti 1998a). As population-based measures of health and methods of adjustment are dealt with in chapters ▶Rates, Risks, Measures of Association and Impact and ▶Confounding and Interaction of this handbook and in several sections of this chapter, in the following, we focus on further approaches to measure health status used in outcome research, including patient-based outcomes measurement, adjusted life expectancy, and patient satisfaction. A common feature of most of these outcome measures is that data are collected by questionnaires directly from patients, residents, employees, insured, or HMO-enrolled beneficiaries.

24.6.1.1 Patient-Based Measures of Health Status

Clinicians can make use of a variety of measures which are disease-specific, system- or organ-specific, function-specific (such as instruments that examine sleep or sexual function), or problem-specific (such as back pain) to explore the full range of patients' experience. Disease-specific health status measures have been developed for nearly all chronic conditions, including, for example, asthma, cancer sites, cardiovascular diseases, diabetes, rheumatoid arthritis, prostate disease, epilepsy, hypertension, pneumonia, and migraine (Guyatt et al. 1995). But if there is interest to go beyond the specific illness and to compare the impact of treatments on health-related quality of life (HRQL) across diseases or conditions, one will require a more comprehensive assessment. None of the disease-specific, system- or organ-specific, function-specific, or problem-specific measures are adequate for comparisons across conditions. These comparisons require generic measures designed for administration to people with any underlying health problem (or no problem at all) that cover all relevant areas of HRQL (Guyatt et al. 1995).

Generic health-status questionnaires are usually designed to establish separate scales including physical, mental, and social health, as suggested by the well-known definition of health by the WHO (1947). There are numerous generic health-status measures – for a review and description, see, e.g., Spilker (1995) or McDowell and Newell (1996). Three of these are very popular and have become standard in the health status field: The 36-Item Short Form Questionnaire (SF-36) (Ware and Sherbourne 1992), the Sickness Impact Profile (SIP) (Bergner et al. 1981), and the Quality of Well-Being Scale (QWB) (Kaplan and Anderson 1988). The psychometric properties of these instruments are sufficiently tested, and the reliability is considered high (Petitti 1998a).

In particular, the SF-36 (a shortened version of a battery of 149 health status questions) is one of the most widely accepted, extensively translated, and tested instruments around the world (Tseng et al. 2003). It satisfies rigorous psychometric criteria for validity and internal consistency. Clinical validity was shown by the distinctive profiles generated for each condition, each of which differed from that in the general population in a predictable manner. Furthermore, SF-36 scores were lower in referred patients than in patients not referred and were closely related to general practitioners' perceptions of severity (Garratt et al. 1993).

The SF-36 was designed for use in clinical practice and research, health policy evaluations, and general population surveys. It includes one multi-item scale that assesses eight health concepts: (1) limitations in physical activities because of health problems; (2) limitations in social activities because of physical or emotional problems; (3) limitations in usual role activities because of physical health problems; (4) bodily pain; (5) general mental health (psychological distress and well-being); (6) limitations in usual role activities because of emotional problems; (7) vitality (energy and fatigue); and (8) general health perceptions. See also the measurement concept in Fig. 24.3 and an excerpt of the questionnaire in Fig. 24.4. The survey was constructed for self-administration by persons 14 years of age and older and for administration by a trained interviewer in person or by telephone (Ware and Sherbourne 1992).

In the late 1980s, a European group of researchers started to develop a generic health-status measure – the European Quality of Life Scale (EQ-5D) – simultaneously in several European languages (EuroQol Group 1990; Brooks 1996). The EuroQol Group consisted originally of a network of international multidisciplinary researchers from Europe but nowadays includes members from Canada, Japan, New Zealand, Singapore, South Africa, and the USA. The EQ-5D self-report questionnaire comprises five dimensions of health (mobility, self-care, usual activities, pain/discomfort, anxiety/depression) rated on three levels (no problems, some/moderate problems, extreme problems). A unique EQ-5D health state is defined by combination of these dimensions. EQ-5D is a public domain instrument (http://www.euroqol.org/index.htm).

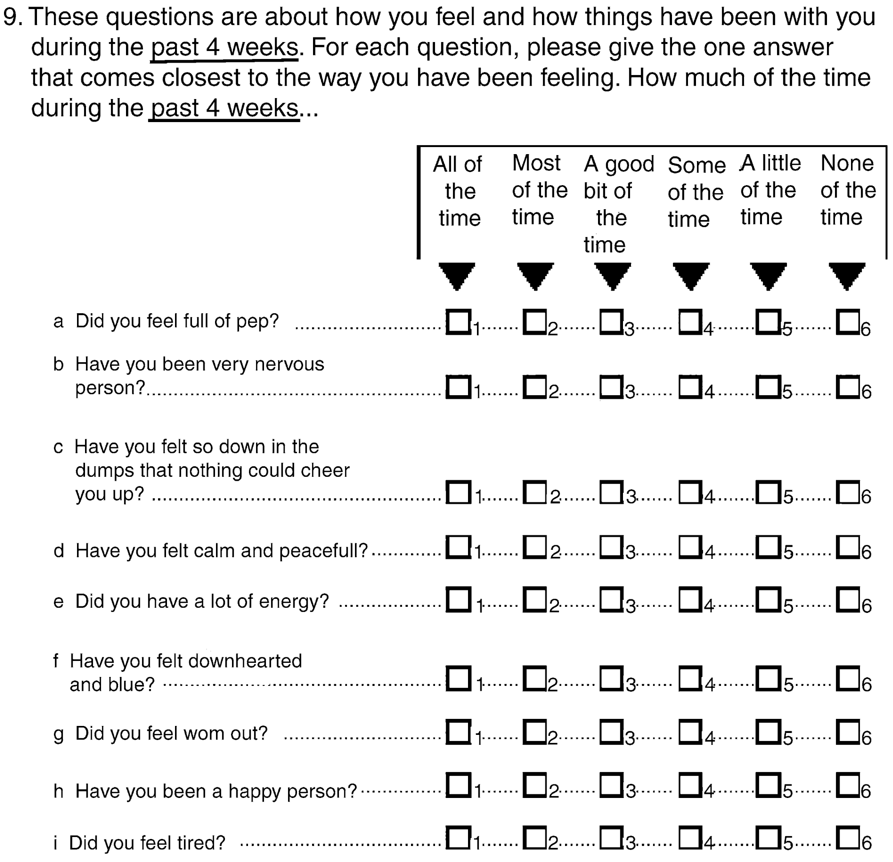
24.6.1.2 Adjusted Life Expectancy

Life expectancy, even without any adjustments, is already a rather complex measure. It is defined as the average future lifetime of a person at birth and is calculated from a current life table (the key tool of actuaries for some 200 years). Consider a large group, or “cohort,” of persons, who were born on the same day. If an actuary could follow the cohort from birth until death, he or she could record the number of individuals alive at each birthday – age x, say – and the number dying during



9. These questions are about how you feel and how things have been with you during the past 4 weeks. For each question, please give the one answer that comes closest to the way you have been feeling. How much of the time during the past 4 weeks...

	All of the time	Most of the time	A good bit of the time	Some of the time	A little of the time	None of the time
	▼	▼	▼	▼	▼	▼
a Did you feel full of pep?	□1	□2	□3	□4	□5	□6
b Have you been very nervous person?	□1	□2	□3	□4	□5	□6
c Have you felt so down in the dumps that nothing could cheer you up?	□1	□2	□3	□4	□5	□6
d Have you felt calm and peacefull?	□1	□2	□3	□4	□5	□6
e Did you have a lot of energy?	□1	□2	□3	□4	□5	□6
f Have you felt downhearted and blue?	□1	□2	□3	□4	□5	□6
g Did you feel wom out?	□1	□2	□3	□4	□5	□6
h Have you been a happy person?	□1	□2	□3	□4	□5	□6
i Did you feel tired?	□1	□2	□3	□4	□5	□6

Fig. 24.4 Excerpt from the SF-36 questionnaire: Item 9 (Source: SF-36 Health Survey Scoring Demonstration (http://www.sf-36.org/demos/SF-36.html))

the following year. The ratio of these is the probability of dying at age x, usually denoted by $q(x)$. It turns out that once the $q(x)$'s are all known, the life table is completely determined. In practice, such "cohort life tables" are rarely used, in part because individuals would have to be followed for up to 100 years, and the resulting life table would reflect historical conditions that may no longer have relevance. Instead, one generally works with a period, or current, life table. This summarizes the mortality experience of persons of all ages in a short period, typically 1 year or 3 years. More precisely, the death probabilities $q(x)$ for every age x are computed for that short period, often using census information gathered at regular intervals (e.g., every 10 years in the US). These $q(x)$'s are then applied to a hypothetical cohort of 100,000 people over their life span to create a current life table (Strauss and Shavelle 2000).

Several approaches have been developed to adjust life expectancy for aspects of health-related quality of life (Drummond et al. 1997). Most often used are the concepts of quality-adjusted life years (QALY) on the one hand and the concept of disability-adjusted life years (DALY) on the other hand (cf. chapter ▶Descriptive Studies of this handbook).

A quality-adjusted life year is a measure that assigns a (utility) value, often called Q, between 0 and 1 to each health state of a year with 0 representing death and 1 representing perfect health. The Q factors are then multiplied with the time spent in the corresponding health states, and these weighted times finally are summed up to achieve the QALY.

Three methods are used alternatively to establish a set of consistent Q values, all derived from consumer choice theory, which describes how consumers decide what to buy on the basis of two fundamental elements: their budget constraints and their preferences. Consumer preferences for different consumables are often represented by the concept of "utility" (Torrance et al. 1972; Torrance 1987; Mankiw 1998). The techniques proposed to measure the utility of specific health states on a linear scale were the Von Neumann-Morgenstern "standard gamble," the "time trade-off" method, and direct scaling techniques (e.g., category rating). These were claimed to produce equivalent and reliable results, but the time trade-off is easier to administer than each of the other two techniques (O'Connor 1993). The results of a simultaneous test of all three methods were that subjects found the time trade-off task the easiest, the standard gamble slightly more difficult (but probably impossible without some props), and the direct scaling task the most difficult. Only the time trade-off task was considered to be capable of being executed without a well-trained interviewer (Torrance 1976; O'Connor 1993). Nevertheless, direct scaling methods are commonly used to derive preferences (Petitti 1998a), probably without observing the necessary methodological diligence.

In a standard gamble, the rater (that is, the person to establish the utilities) must choose between two alternatives. One alternative has a certain outcome (that is, the health state to be rated) and the other involves a gamble with two possible outcomes: the best health state (usually complete health), which is described as occurring with a probability, p, or an alternative state, the worst state (usually death) which is described as occurring with probability 1-p. The probability p is varied until the rater is indifferent to the alternative which is certain and the gamble that may bring the better health state. The time trade-off task also entails a choice between two alternatives, but neither is a gamble. Each is a different health state but for differing periods of time. The rater is asked to value a choice of being in a less desirable health state for a longer time followed by death compared with being in a more desirable state for shorter period of time followed by death. The time in the less desirable health state then is decreased to the point of indifference. In category rating, raters sort the health states into a specified number of categories, and equal changes in preference between adjacent categories are assumed to exist (Petitti 1998a).

QALYs have been widely criticized on ethical, conceptual, operational, and methodological grounds. To begin with the last ones, Prieto and Sacristán (2003) have recently pointed to a considerable problem, which results from the numerical nature of its constituent parts. The appropriateness of the QALY arithmetical operation is compromised by the essence of the utility scale: while life years are expressed in a ratio scale with a true zero, the utility is an interval scale where 0 is an arbitrary value for death. In order to be able to obtain coherent results, both scales would have to be expressed in the same units of measurement. The different nature of these two factors jeopardizes the meaning and interpretation of QALYs. By a simple general linear transformation of the utility scale, the authors demonstrate that the results of the multiplication are not invariant and offer a mathematically solution to these limitations through an alternative calculation of QALYs by means of operations with complex numbers so that the new QALYs have a real part (length of life) and an imaginary part (utility). The revisited formulation of the QALYs provides a less dramatic adjustment of years of life than that implied by the multiplicative model. The maximum penalization represented by living in a suboptimal state of health is capped at 30% of the total time lived in that state, in contrast to the case of the multiplicative model, where the penalization can reach 100% (Prieto and Sacristán 2003).

Ethical concerns arise when QALYs are used in cost-effectiveness or cost-utility analysis for evaluation of alternative health policies, treatment programs, or setting of priorities. A simple ratio cost/QALY is commonly calculated in this type of analysis in order to compare cost-effectiveness of treatments, intervention and programs, etc. But it has been pointed out, among other arguments, that investing in the interventions that have the lowest-cost per QALY ignores the principle of equity (Drummond 1987). In addition, QALYs share a problem of life expectancy as a measure of outcome: they discriminate against the aged and the disabled because these groups of persons have fewer life years to gain from an intervention (Harris 1987).

The main other type of commonly used summary measure which combines information on mortality and morbidity is the disability-adjusted life year. The DALY is the best known example of a “health gap” summary measure, which quantifies the gap between a population’s actual health and a defined goal used to quantify the burden of disease in a country, region, or on the global level (Murray and Lopez 1996). However, DALYs share most of the methodological and ethical difficulties with QALYs, such as utility-weighting and discounting health benefits. The discrimination of elderly people is even more pronounced than with QALYs as an additional age-weighting is performed when constructing DALYs, whereby years lost during the productive phase of life get a higher weight than years lost in childhood or at a more advanced age (Gericke and Busse 2003). Related concepts are disability-free life years (Sullivan 1971) and healthy life expectancy (Robine and Ritchie 1991) which may be based on surveys. DALYs can be calculated exclusively based on life tables from census data and cross-sectional data from official disability statistics (if necessary, on a sample base). The so-called Sullivan method to adjust the conventional life table for disability consists of applying disability rates calculated from cross-sectional data to the person-years of the conventional life table. This calculation results into new estimates of the person-years lived in disability, and the complement of the later, the person-years lived free of disability, the DALYs (Guend et al. 2002).

A related measure is disability-adjusted life expectancy (DALE) used by WHO in a controversial report to display the burden of disease by cause, sex, and mortality stratum in WHO regions (WHO 2000). The disability rates used in the WHO calculations relied on subjective and expert assessment and not on empirical data due to data limitations in many nations.

24.6.1.3 Patient Satisfaction

Interest in measuring satisfaction with health care has grown considerably in recent years around the world, and there is a large and expanding literature in this field. Patient satisfaction and its measurement are undoubtedly important issues for public policy analysts, health-care managers, practitioners, and users. Nevertheless, measurement of satisfaction often lacks a clear definition. In particular, it is not always well understood by the people who measure it that satisfaction is a relative concept which can be measured only against individuals' expectations, needs, or desires (Wüthrich-Schneider 2000; Crow et al. 2002). Despite problems with establishing a tangible definition of "satisfaction" and difficulties with its measurement (among other things those which are predicted by the well-known theory of cognitive dissonance, cf. Festinger 1957), the concept continues to be widely used. However, in many instances, when investigators claim to be measuring satisfaction, more general evaluations of health-care services are being undertaken that tend to result in high levels of satisfaction being recorded (Crow et al. 2002).

Historically patient satisfaction surveys have focused on inpatient health-care services, but in recent years, investigations of patient satisfaction have been carried out in outpatient settings as well. In Germany, for example, a recently developed questionnaire to measure patient satisfaction in generalist and specialist ambulatory medical care comprises 27 single items divided into the four dimensions: "professional competence," "physician-patient interaction," "information," and "organization of the practice." This concept has been tested in a survey of 3,487 patients in 123 physician practices (Gericke et al. 2004). A former international study of patients' priorities with respect to general practice care collected data by postal surveys in UK, Norway, Sweden, Denmark, the Netherlands, Germany, Portugal, and Israel. The study results show that patients in different cultures and health-care systems have many views in common, particularly concerning doctor-patient communication and accessibility of services (Grol et al. 1999).

24.6.2 Assessing Efficiency of Care

In addition to measuring the output of health care in terms of healthy life gained, efficiency is another important dimension in assessing health service output. Unfortunately, the word efficiency is often used inappropriately to describe productivity, that is, relating episodes of care or number of procedures to the inputs or costs (Gray 1997). Efficiency refers to the health system's ability to use whatever resources it has to maximum effect (Le Grand 1998). Efficiency has three levels: technical, productive, and allocative efficiency. Technical efficiency answers the narrow question of whether the same or a better outcome could be obtained by using less of one type of input (Palmer and Torgerson 1999). It is based on effectiveness. Productive or internal efficiency is achieved when the maximum possible improvement in outcome is obtained from a given level of resource inputs or when costs are minimized to obtain a given level of output (Donaldson and Gerard 1993; Palmer and Torgerson 1999). Prerequisite for productive efficiency is technical efficiency.

Allocative or external efficiency refers to the way resources are divided between alternative uses within the health sector (Barr 1998). It implies productive efficiency (Donaldson and Gerard 1993). The theoretical foundation of allocative efficiency rests on the Pareto criterion: a resource allocation is efficient if it is impossible to move to an alternative allocation which would make some people better off and nobody worse off (Begg et al. 1997b). Among other conceptual difficulties, strict adherence to this principle would preclude changes that would make many people much better off at the expense of a few made slightly worse off (Palmer and Torgerson 1999). Therefore, an operational utilitarian decision rule is often used instead: allocative efficiency is achieved when resource allocation maximizes social welfare (Palmer and Torgerson 1999). Cost-effectiveness studies as a tool to put the concept of operational efficiency in health care into practice have already been summarized in Sect. 24.4.1. Cost-benefit studies can address questions of allocative efficiency comparing interventions between different sectors, as output of care is measured in monetary units. As this is politically and ethically difficult to accept for many non-economists, cost-benefit analyses of health interventions are seldom performed.

24.6.3 Assessing the Outcome of Health Systems

In principle, the same methods are used to assess the outcome of health systems which are used to assess the outcome of health services within a country. However, problems with data quality, definitions, and comparability across different cultures make comparisons between different health systems more difficult than health service research limited to a particular country (Schwartz and Busse 2003). As decision makers in countries of all levels of development are faced with common problems as they struggle to make appropriate choices to improve the performance of their health systems, the interest of politicians and scientists in comparative health system research has grown rapidly during the last two decades. A common goal of researchers is to provide policy decision makers and managers with the best available evidence in order to inform policy decision making. In analogy to evidence-based medicine, this movement has been termed evidence-based health policy or evidence-based health care. However, the evidence-base on how to improve the performance of health systems is still weak (Murray and Evans 2003).

24.6.3.1 Cross-Sectional Comparisons

Two methodological approaches are commonly used in comparative health system research: a cross-sectional approach comparing a number of parameters at a particular point in time and a longitudinal approach comparing the development of parameters over a defined time period. To illustrate the advantages and disadvantages of both approaches, we will focus here on two examples. The first is a summary of the approach taken by the World Health Organization (WHO) to assess health system performance on a global scale. In 1998, WHO embarked on a project to assess the health system performance of its member states, culminating in the World Health Report 2000, in which countries' health systems were ranked according to their performance. Health system performance was measured according to the level and distribution of population health, responsiveness, and fairness in financing (World Health Organization 2000; Murray and Evans 2003). Although the provision of comparative data on health system characteristics is recognized as important in improving health-care systems, the report has elicited heavy criticism, summarized by Gravelle et al. (2003). These included the purpose of the exercise (Williams 2001), the definition of some of the performance measures (Braveman et al. 2001), the quality of data (McKee 2001; Williams 2001), and mixed messages (Navarro 2000). Gravelle et al. (2003) furthermore demonstrated that the efficiency rankings and estimates of the magnitude of inefficiency in countries were not robust when compared with other, no less reasonable, methodological choices concerning the econometric methods used. The final rankings for a number of EU countries and ranking results concerning patient satisfaction with health systems are illustrated in Table 24.4 and compared to a number of other parameters which are commonly used to measure the input, process, and outcome of a health system.

It can be noted that parameters differ widely between countries at a similar level of national income and development. Some factors show a close correlation, for example, the health score with patient satisfaction or hospital bed provision with hospital utilization. On the other hand, satisfaction with the health system does not correlate at all with the overall WHO ranking of the health system performance. This results in contradictory results for countries like Denmark and Finland on the one hand, and Spain on the other (Schwartz and Busse 2003). Table 24.4 illustrates some of the issues surrounding the interpretation of cross-sectional data. Different data sources can vary substantially on the same measure. Such discrepancies – if detected at all – demand a thorough investigation of possible causes. A common cause are differences in the numerator, for example, differences between licensed and practicing doctors or beds in acute care hospitals or in all hospitals. Differences in the denominator are also important. For instance, for the measurement of neonatal mortality, it makes a difference whether all births on the territory of a country are counted or all births of nationals of that country (Schwartz and Busse 2003).

The most important difficulty with cross-sectional comparisons of health systems from a policy perspective is probably that health output measured in terms of reduced mortality and health system performance are correlated in a contradictory way. If a country reacts in an appropriate way to high mortality rates and invests in

Table 24.4 Selected input, process, and outcome parameters for some European countries, around 1997. Data from the OECD Health Dataset 2001, the WHO Health for All database 2003, and the World Health Report 2000 (World Health Organization 2000) (Adapted from Schwartz and Busse (2003))

	Financial input: % of GDP (1998)	Structure: Hospital beds/1,000 population (1997)	Structure: Doctors/ 1,000 population (1997)	Process: Hospital cases/100 pop./year (1996)	Process: Hospital days/capita (1996)	Process: Ambulatory doctor-patient contacts/year (1996)	Outcome: Neonatal mortality/ 1,000 (1998)	Outcome: Satisfaction with health system in % [Ranking within EU] (1998)	Outcome: Overall ranking of health system within EU (1999)
Austria	8.0	9.1	2.9	25.1	2.6	6.3	4.9	72.7 [3]	4
Belgium	8.6	7.3	3.7	20.0	2.2	8.0	5.6	62.8 [7]	11
Denmark	8.3	4.6	3.3	19.8	1.4	5.7 (6.6)[a]	4.7	90.6 [1]	15
Finland	6.9	7.9	3.0	26.9	3.2	4.3	4.1	81.3 [2]	14
France	9.4	8.6	3.0	22.5	2.6	6.5	4.6	65.0 [6]	1
Germany	10.3	9.4	3.4	19.7	2.8	6.5	4.7	57.5 [9]	13
Greece	8.4	5.0	4.1	–	1.2	–	5.7 (6.7)[a]	15.5 [15]	6
Ireland	6.8	–	2.1	15.1	1.1	–	6.2	57.9 [8]	10
Italy	8.2	5.8	5.8	18.5	1.7	–	5.3	20.1 [13]	2
Luxembourg	6.0	8.1	3.0 (2.4)[a]	–	2.8	2.9	5.0	66.6 [5]	7
Netherlands	8.7	11.3 (5.3)[a]	–	11.1	3.6	5.4	5.0	69.8 [4]	8
Portugal	7.7	4.1	3.1	11.4	1.1	3.2	5.9	16.4 [14]	5
Spain	7.0	–	2.9	11.4 (10.0)[a]	1.1	–	5.7 (4.9)[a]	43.1 [12]	3
Sweden	7.9	4.0 (5.2)[a]	3.1	18.1	1.3	2.9	3.5	57.5 [9]	12
United Kingdom	6.8	4.4	1.7	15.0 (23.1)[a]	1.3	6.1	5.7	57.0 [11]	9

[a] More than 10% difference between OECD and WHO datasets

health system infrastructure, mortality would fall as a result assuming effectiveness of the measures taken. This longitudinal result cannot be measured in cross-sectional studies. Therefore cross-sectional comparisons cannot indicate whether a high level of inputs in a particular country has obviated even higher mortality rates and we only see average mortality in this country or whether there truly exists an inefficient input-output relation.

24.6.3.2 Longitudinal Comparisons

The other approach consists in comparing the development of input, process, and output parameters in different health systems in a longitudinal perspective. In the 1980s, time series analyses on “avoidable mortality” marked the first attempts at international longitudinal comparisons (Bunker et al. 1994; Charlton and Velez 1986). A common measure for comparing health systems in a longitudinal way is life expectancy. In Fig. 24.5, the development of life expectancy at birth is depicted for a number of selected European countries compared to the EU average for the time period 1970–2000.

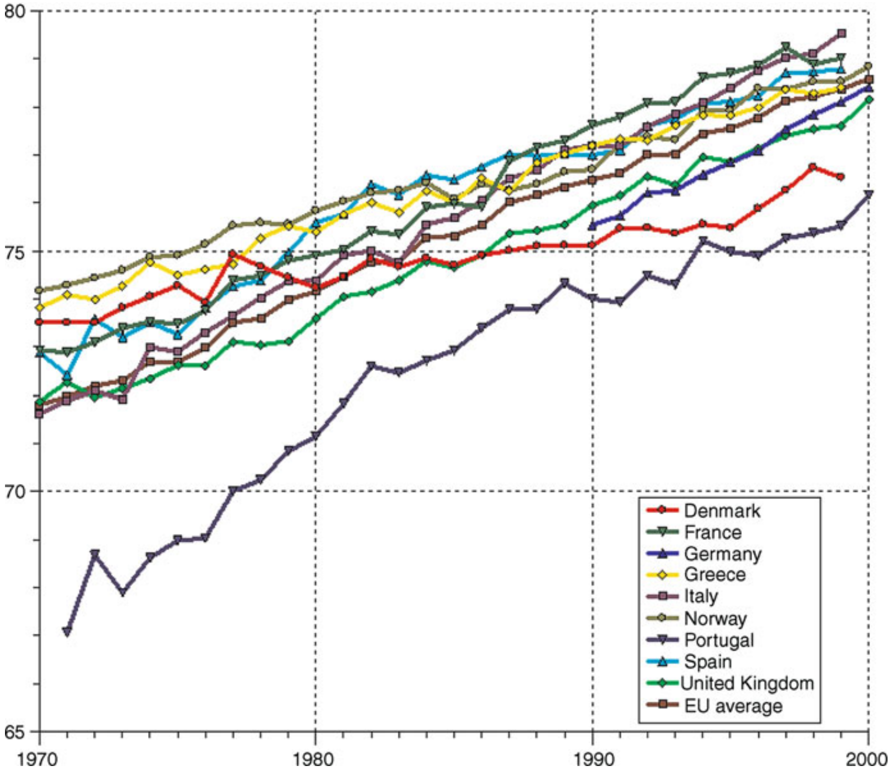


Fig. 24.5 Life expectancy at birth in selected member countries of the European Union 1970–2000. Calculated with data from WHO Health for All database 2003

This is often done although it is well known that life expectancy is influenced by many variables outside the scope of the health system, such as the level of socioeconomic development. However, in general, mortality (on which the calculation of life expectancy is based) is an output measure which is relatively insensitive to common health service endeavours (Schwartz and Busse 2003):

- The overwhelming part of mortality is not amenable to health service activity ("avoidable mortality") but natural mortality.
- In particular for men, a substantial proportion of deaths is due to traffic accidents.
- The commonplace argument that mortality figures do not respond quickly to changes had to be revised after the experience in Russia after the breakdown of the Soviet Union, where life expectancy at birth for males fell by approximately 6 years between 1990 and 1994. Life expectancy in the Eastern part of Germany, however, increased substantially in the 1990s.

Relative changes over time are of particular importance for evaluation and policy decision making. This is illustrated in the development of life expectancy at birth in Denmark and Portugal. Whereas both countries had an average life expectancy at birth of 76 years in the year 2000, Portugal has massively improved on this measure since 1970, up from 67 years. Although life expectancy in Denmark has nominally also increased since 1970, up from 74 years, it has had the smallest relative increase in Western Europe – which is in fact a rather negative development and not an improvement.

24.7 Conclusions

As demonstrated in the examples discussed above, the combination of simple inputs and outputs can be of particular political importance, despite all the methodological difficulties and caveats. The fact that even if life expectancy were a good indicator of health production in the health-care system, the question of why a good result has occurred, that is, examining structure and process, would not have been answered. There is little consensus on how international comparisons of structures and processes should be performed. How inappropriate simplification of health system comparisons can be misleading is demonstrated by the "state versus free market" debate in Germany. Financing of German hospital care on the basis of *per diem* payments has been coined as inefficient, as this payment mechanism creates an incentive for longer hospital stays. Some economists have compared the German system with the US system, where hospital stays are usually shorter, claiming that this was due to payments according to diagnostic-related groups (DRGs). However, they did not consider that at that time, only hospital services for 15% of the population covered under the Medicare scheme were remunerated according to DRGs and that hospital costs per case in the USA were about twice as high as in Germany, "despite" the DRGs. Likewise, the expected rise in ambulatory care costs to compensate for early hospital discharge was not considered (Schwartz and Busse 2003).

International comparisons of health system outcomes along one-dimensional hypotheses have thus to be treated with great caution, in particular, because they are easily misunderstood by policy decision makers (Schwartz and Busse 2003).

25.1 Introduction

> I think you need to give conscious consent to having any data, any personal data used, whether you are identified or not. That's certainly a right. That's your information, it's your medical history. Whether it's identified or not, you should control it.
> Patient 14, in Willison et al. (2003)

> Each public health policy, even a policy of inaction, implies some value or ethical judgment about the good of the individual and the community . . . .
> (Lee 2012)

These two quotes are about values and expectations, about perceived responsibilities, and about community benefits and individual rights in medical care and clinical or epidemiological research and reflect thereby compellingly the tensions, the paradoxes, the different views, and ethical aspects concerning biomedical research (Coughlin 2000). Epidemiology is part of the arena of biomedical research and is particularly focused on determinants of disease occurrences in populations. Ethics is the systematic analysis of values and norms (Weed and Coughlin 1999; Weed and McKeown 2001). Usually ethical reasoning and conduct are not issues that are at the top of an epidemiologist's menu chart (Beauchamp et al. 1991). In previous chapters of this handbook, we have seen that most epidemiological methods are non-interventional, e.g., observational by design, meaning that conventional ethical aspects of experiments with human beings (e.g., protocol review, randomization, placebos, informed consent) are not applicable as such. Many ethical committees have been struggling with the review of protocols of non-interventional studies because of the rationale and design of the study being directed at not influencing the "natural" disease course of patients, but at determining statistical inferences between various exposures (e.g., environment, drug treatment, and medical practice) and effects in the population in a non-experimental fashion. Observational epidemiology possesses the attractiveness, but also the practical paradox, of scientific investigation with a priori objective of not intervening in the normal course of the study object.

There have been several drivers within and outside the field of epidemiology that have changed the picture of ethical aspects significantly over the last decades. First of all, since the mid-1980s, the development and availability of automated record linkage databases, including biobanks, capturing both exposure and outcome data on an individual level, have raised questions about confidentiality of patient's medical records, authorizing access to person-specific information, and misuse of such databases (Knox 1992; Stjernschantz Forsberg et al. 2009). A second driver has been the debate about integrity and conflict of interests related to epidemiological research, in particular in cases of sponsored epidemiological studies and/or when the results of such studies were contradictory and subject of controversy and discourse. Finally, there is a growing interest of epidemiologists in biobanks where massive collections of biological materials and related data (e.g., tissue samples, cytological data, proteomic biomarkers) are assembled for diagnostic or therapeutic purposes and increasingly used for epidemiological research. The booming development of biobanks fuels ethical questions and debate about the design, conduct, informed consent, and competing interests between the individual patient, research objectives, and society as a whole (Stjernschantz Forsberg et al. 2009; Giesbertz et al. 2012).

As a consequence, the last decades have shown that concern about the ethical aspects of their research activities has become engaging epidemiologists as much as others who deal with public health, clinical decision making, and prioritizing and policy making in health care. Ethics guidelines have been prepared and accepted by several epidemiological organizations (Bankowski et al. 1991; IEA International Epidemiological Association 2007) in response to a growing awareness among epidemiologists that ethical conduct is essential to epidemiology. Basic principles of integrity, honesty, truthfulness, fairness and equity, respect for people's autonomy, distributive justice, doing good, and not harming have been made explicit. Essentially, the appreciation of these values has their origins in the follow-up of the Nuremberg trials, the UN Declaration on Human Rights, the Declaration of Helsinki, and many later declarations, guidelines, and codes of conduct. Basically, these declarations and guidelines reflect a major shift in current society from less priority to collective interests and benefits towards the primacy and protection of the individual (World Medical Association 2000; Coughlin 2000).

25.2 Drivers of Awareness of Ethical Aspects in Epidemiology

25.2.1 Surge of Automated Databases

One of the visionary founders of medical registries has been William Farr who understood already in the nineteenth century clearly the importance and potential of keeping person-specific records on diagnoses, medical treatments, environmental factors, and disease course (Farr 1875). Later various approaches of building and linking datasets for evaluating medical treatments and other determinants of health have been developed. In the early 1960s and 1970s, consistent and protocol-based medical record keeping became also recognized as an essential tool for clinical practice, and worldwide famous centers of clinical and epidemiological excellence like the Mayo Clinic or the Oxford Radcliffe Infirmary earned their appreciation mainly because they were champions in collecting and managing clinically relevant person-specific information in an era when paper charts, pencils, and several primitive collecting and retrieving machineries where state-of-the-art technologies (Gostin 1997). The introduction of advanced computer and information technologies changed that picture dramatically in the mid- and late 1980s. Storing, assembling, and linking clinical information became "push button" actions, and fascinating avenues for epidemiological research capturing data of hundreds of thousands, even millions, of individuals became feasible (Quantin et al. 1998). However, the "push button" nature and the big numbers involved of these developments gave rise to various ethical questions, in the beginning still vaguely phrased but later in very pronounced way on the table.

The overwhelmingness of the potentials of new information technologies and the speed of the developments have driven the need for a comprehensive balance sheet of all the social, political, and ethical aspects involved. Moreover, the owners and stakeholders of these automated databases are usually not health-care providers or professionals but third-party payers, e.g., health insurers, health maintenance organizations, or governmental bodies. These organizations have mostly not their origins in the professional and ethical environment of Hippocratic medicine and have invested in these data systems with other purposes (e.g., reimbursement of health-care providers, cost containment, risk management) than supporting medical practice (Gostin 1997).

The surge of automated databases has been stirred by the progress in record linkage techniques. Record linkage is the process by which pairs of correctly matched records of person-specific information are brought together in such a fashion that they may be treated as a single record for one individual (Herings et al. 1992). Record linkage provides a powerful tool in epidemiology in order to stratify exposures according to patient outcomes, e.g., bringing data together on food intake and cancer events, or exposure to sleeping pills and hospitalizations for hip fracture. Record linkage has driven the expansion of automated databases, and from an ethical point of view, there have been at least two major concerns (Herings et al. 1992; Kelman et al. 2002). First of all, the operational process of linkage of individual data from a number of different sources using a unique person-specific ID (identification) requires patient identification. Researchers in epidemiology have developed for that reason probabilistic approaches of record linkage, using sets of in itself not unique identifiers. However, it is believed by some opponents that this approach of record linkage may also violate data confidentiality rules, i.e., each pseudonymized method needs to be validated, and then the use of person-specific data (e.g., name or other ID) is essential (Tondel and Axelson 1999). A second concern related to record linkage has always been the fear that (non-) medical data (e.g., insurance status, lifestyle, sexual behavior, socioeconomic position) are built-in epidemiological data frames enhancing the feasibility of making unintended and/or undesirable statistical inferences that could cause damage or distress to individuals (Kmietowicz 2001). As a consequence, in the advent of a surge in automated databases, many countries both in North America and Europe have taken comprehensive legal action to assure the protection of personal privacy (Vandenbroucke 1992; De Vet et al. 2003).

Today's balance sheet of the role of automated databases in epidemiological research looks very positive. Cancer epidemiology, cardiovascular epidemiology, and pharmacoepidemiology are branches in epidemiology where such databases are key resources. They all have in common complex multivariate and time-dependent exposure-disease occurrences. Confidentiality of person-specific information is one of the most imperative ethical aspects to consider. From that perspective it is impressive to witness how certain countries (e.g., Denmark, Sweden) or environments (e.g., some of the health plans in the USA) have accomplished health-care record systems where unique codes enable to bring person-specific data from different sources together for research in a legally and ethically sound way (Andersson et al. 2011; Bazelier et al. 2012). A key factor for success seems to be active patient, consumer, and citizen engagement in the planning, design, and governance of such systems.

25.2.2 Integrity and Conflict of Interest in Epidemiological Research

In the “ideal” world, basic values of integrity, objectivity, respect, and independence should be key to every field of science. Committed to the discovering of the truth, researchers design, conduct, and report on study results (Levinski 2002). This notion gives the impression of science being a logical and unbiased human activity. Current society has long relied on scientists’ professional commitment to truth and honesty.

However, disclosure of, for instance, a case of fraud by a Dutch neurologist participating in the “European stroke prevention study 2” (ESPS-2), a multicenter stroke study, scandalized both the medical research community and the public (Hoeksema et al. 2003). The neurologist had committed fraud, in the sense that he had used names and fingered data of existing patients without these patients actually being enrolled in the study. The University of Connecticut in the USA announced clear misconduct by a vaccine expert who had falsified preliminary data in two grant applications (Malakoff 2003). The university removed the expert as head of the research center, and a series of lawsuits between the university and the vaccine researchers took place. We notice here two obvious cases of serious misconduct in biomedical science, e.g., doctoring of data. Other examples of questionable and unethical scientific behavior include apparent study sponsor-induced bias, as well known from research sponsored by the tobacco industry into the association between smoking and lung cancer (Barnes and Bero 1998), and at the very end of the spectrum, fraud, and falsification of data. We will come back to industry sponsoring of epidemiological research into drug effects. But there are other more subtle constraints to scientific integrity.

In 2002 Levinski gave a very personal and historical account on how he started as a medical researcher and reflecting visibly on major ethical questions, e.g., the protection and reimbursement of human research subjects, informed consent, disclosure of financial interests, prestige of the academic institution, and personal career building. The account also shows that ethical weighing can vary strongly over time. What we believed as being ethically acceptable in the past might not be today or vice versa:

> In 1963, before the advent of institutional review boards (IRBs), I was a young academic physician studying the regulation of sodium excretion by the kidneys. I paid medical students approximately $50 to serve as subjects for experiments involving only saline infusions and the collection of blood and spontaneously voided urine samples. I do not remember exactly what I told the students about the risks of the experiments but am quite certain that I characterized them as nominal. In one subject, severe phlebitis developed at the site of an intravenous infusion and required extensive therapy. The research project was funded by the National Institutes of Health. I had no possibility of financial gain from it. My primary motive was academic – the desire to advance knowledge about an important physiological mechanism with a bearing on clinical conditions such as edema. A potent secondary motive was to advance my career by publishing the results of the research and maintaining grant support – academic currency that buys prestige and promotion.
> (Levinski 2002)

For epidemiology, conflicts of interest related to research sponsoring are a very contemporary and controversial issue. Thompson has defined conflicts of interests

> as a set of conditions in which professional judgment concerning a primary interest (such as a patient's welfare or the validity of research) tends to be unduly influenced by a secondary interest (such as financial gain).
> (Thompson 1993)

Financial interests related to the tobacco or the pharmaceutical industry have been subject of intense controversy since decades. These industries have been always active in engaging researchers (as well as public media) for promoting messages, sometimes contrary to the available epidemiological evidence on health risks related to smoking or the use of medicines. In the field of epidemiology of drug effects, two archetypal cases have paved the pathway of debate and controversy on the ethics of research sponsoring, conflict of interest, and scientific (mis)conduct:

Cardiovascular Risks of Calcium-Channel Blockers In 1995 Psaty et al. reported in the Journal of the American Medical Association (JAMA) about a population-based case-control study among hypertensive patients in order to assess the association between first myocardial infarction and the use of antihypertensive agents (i.e., beta-blockers, calcium-channel blockers, angiotensin-converting-enzyme inhibitors, diuretics). The main result of the study was that the use of short-acting calcium-channel blockers, especially in high doses, was associated with an increased risk of myocardial infarction (Psaty et al. 1995). An intense controversy on the scientific validity of the study, the consequences for treatment of patients with hypertension, and the financial implications for the companies marketing calcium-channel blockers followed in both the medical literature and the lay press. A surge of commentaries, reviews, and additional papers on the topic emerged in the literature. Stelfox et al. (1998) evaluated the obviously visible signatures of the debate in the medical literature and demonstrated a strong association between authors' opinions about the safety of calcium-channel blockers and their financial relationships with those industries having an apparent interest in the hypertension market. Supportive authors had more financial ties with manufacturers of calcium-channel antagonists, while critical authors were much less likely to be involved in industry sponsoring and other financial connections with manufacturers. Although the paper of Stelfox et al. could be criticized for methodological reasons (lack of adjustment for dynamics of actions-reactions of time in the aftermath of the Psaty et al. paper), the overall message remains valid: there is and has been an association between ties with sponsors, choice of study questions, and, possibly, study results.

Venous Thrombosis Risk of Oral Contraceptives In the same year as the calcium-channel blocker controversy emerged 1995, several case-control studies reported on a twofold increased risk of deep vein thrombosis and pulmonary embolism in females using the so-called third-generation oral contraceptives relative to second-generation oral contraceptives (Skegg 2001). These findings engendered a surge of further (for the most part case-control) studies primarily driven by questions on possible confounding by indication (e.g., health user effect meaning preferential prescribing of third-generation oral contraceptives to females with more

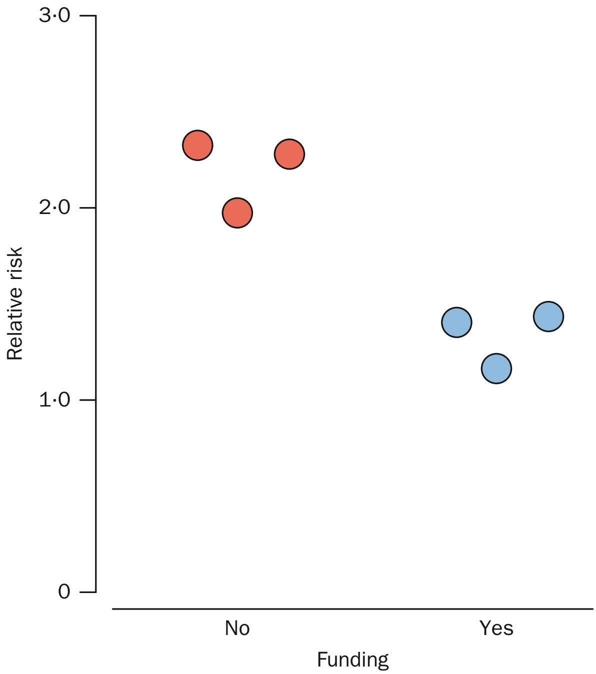

Fig. 25.1 Risk of venous thrombosis with third-generation contraceptives stratified for industry sponsoring (Source: Vandenbroucke 1998)

risk factors of cardiovascular disease) and biases related to the method of exposure ascertainment to oral contraceptives.

Many of these studies were sponsored by the pharmaceutical industry, and Vandenbroucke observed a contrast between the industry-sponsored studies reporting a relative risk of 1.5 or less and the non-funded studies consistently showing an increased risk of about 2.0 (Vandenbroucke 1998) (see also Fig. 25.1).

Answering the question whether this contrast is real, implicating that industry sponsorship is followed by biased research, is much more difficult to answer and is still subject of an ongoing debate. To illustrate the bewildering impression fuelled by the array of conflicting studies captured in Fig. 25.1, Vandenbroucke quotes a pharmacologist involved in early-phase studies for the industry:

> This might very well mean that industry-sponsored studies are the better ones. (Vandenbroucke 1998)

Like in case of the calcium-channel blockers controversy, a surge of commentaries and additional papers on the topic emerged in the literature and the public press. Moreover, as the topic was also subject for several court cases, the legal press covered the issue as well. This controversy has been one of the most striking examples in the last decade of how to find the truth in studying drug exposure-outcome associations, to unravel possible biases and confounding factors, dealing with study sponsor's interests, and at the same time to protect scientific integrity. Researchers are exposed to myriad pressures (e.g., balancing individual and institutional needs, search for professional recognition, and, sometimes, even rivalry). The science arena operates as a function of all the influences and pressures. Most progress to untangle the individual impact of all these factors has been made in demanding at least disclosure of all financial interests of the researcher by virtually all scientific journals and scientific communities (Levinski 2002). Epidemiologists need to continue to improve scientific and ethical conduct, to prevent unwanted conflicts of interest, and to be aware of the great financial interests of the parties involved (Beauchamp et al. 1991; Coughlin 2000). Various avenues to achieve this goal are either proposed or already in place: (1) codes of ethical conduct are adopted by virtually all professional and scientific societies, (2) the same holds for guidelines for disclosure of possible conflict of interests by authors submitting papers to medical-scientific journals, and (3) there is a surge both at the medical and other life science faculties, to include ethics classes in their standard curricula.

Full and transparent disclosure of any potential conflicts of interest affecting an epidemiological study to competent authorities, journal editors, or other regulatory bodies is part of virtually every code of guideline for conducting epidemiological research nowadays (von Elm et al. 2007; European Medicines Agency 2010). Each study should be evaluated in light of any declared conflicts and ensure that adequate means of mitigation are provided. When appropriate, it may also be required that a potentially conflicting interest be part of the information provided to the study subjects of the respondents. If a potentially serious conflict of interest cannot be adequately mitigated, the project should not be approved by the responsible committee.

25.2.3 Molecular Epidemiology and Genetics

Molecular epidemiology is a rapidly emerging field and in chapters ▶Molecular Epidemiology and ▶Statistical Methods in Genetic Epidemiology of this handbook, we have seen up-to-date accounts on scientific achievements and progress. A growing number of population-based molecular epidemiology studies have been set up to explore the roles of molecular factors (e.g., immune response profiling, blood clotting factors, enzymes), genomics (e.g., gene mutations as determinants of disease, gene-environment interactions), and other biomarkers (Maitland-van der Zee et al. 2000; Nuffield Council on Bioethics 2012; Kuehn 2011). Issues about participants' consent, confidentiality of information, and the feedback of findings have been widely addressed. Growing knowledge about molecular pathway-disease associations has led to new opportunities for testing, increasingly important as a guide to prevention, clinical management, and therapy. Tests are likely to vary in their predictive value, analytical and clinical validity, clinical utility, and social implications, e.g., access to and affordability of testing, insurance or employment discrimination, stigmatization, and long-term psychological harms from testing. Molecular epidemiology applying these tests is distinct from most other types of epidemiological research in that such biomarkers or genetic data obtained about an individual also may provide signatures of health about his or her relatives and person-specific future events (Khoury et al. 2011). For example, concerning the latter, the implications of a positive test for the breast cancer genes BRCA1 or BRCA2 mutation differ considerably for a woman who has not yet had children compared with one who has daughters who might be susceptible as well (Burke et al. 1997).

A pivotal and informative case in identifying and understanding the ethical aspects of these developments is the area of pharmacogenetics (Bolt et al. 2002). The increasing knowledge on the genome has resulted on unprecedented advances in understanding why individuals respond differently to drug therapy (Venter et al. 2001; Roses 2000). Pharmacogenetics focuses on the question of the extent to which genetic variants are responsible for inter-individual variability in drug response among recipients of a specific drug therapy. Few drug therapies are effective for everyone. The ultimate goal of pharmacogenetics is to shape therapy with available medicines in an individualized fashion, e.g., “tailor-made pharmacotherapy.” Pharmacogenetics integrates epidemiology, pharmacology, and genetics and is focused on an understanding of the genetic determinants of individual variability in drug therapy (Maitland-van der Zee et al. 2000). This research parallels the surge in discoveries of genes and protein expression patterns affecting the susceptibility to disease. There is ample evidence that certain disease susceptibility genes are also determining drug action and thereby therapy response.

The Nuffield Council on Bioethics (2012) has identified a number of ethical issues specifically raised by pharmacogenetics: (1) consent, privacy, and confidentiality; (2) management of information about response to therapy likelihood; and (3) implications of differentiating individuals into groups based on response to therapy likelihood. The key question in pharmacogenetics is unraveling the genetic traits of efficacy and/or safety of medicines. When that information is available, it can guide prescribers to select specific drugs or dosage schemes. It has been shown that on the one hand, male carriers of the apolipoprotein-E 44 variant are more prone to discontinue therapy with anticholesterol-lowering agents (Maitland-van der Zee et al. 2003). Although the precise mechanism underlying this association is still not known, prescribers, pharmacists, and patients can improve therapy knowing this risk factor of non-persistence by enhancing compliance with the regimen, tailor-made counseling, and the like. On the other hand, we know that apolipoprotein-E is also associated with various cardiovascular and neurological risks (e.g., Alzheimer disease). The level of evidence of the mentioned apolipoprotein-E associations is still subject of ongoing research, and all the three ethical issues mentioned by the Nuffield Council on Bioethics are visibly present in this case. This is particularly true in an area where we do not know today what kind of new genetic traits are discovered tomorrow and what kind of implications that has for already collected biological material (e.g., DNA samples). We see a surge in post hoc genotyping in both clinical and epidemiological research. This is feasible as individual genetics do not change over time, and when biological samples (blood, urine, or buccal cells) are still available, a major ethical question is whether the informed consent (maybe completed decades ago!) still holds for the current new situation. And what about the ethical questions provoked by genotyping cases and controls in, for instance, a case-control study revealing that certain study subjects carry serious susceptibility genes (e.g., BRCA1 or BRCA2 mutations)? Genotyping of the cases may be well covered by informed consent in the protocol, but this may be not valid for the controls sampled from the study base anonymously. And what about the "right not to know" of both the study subjects and their inherited relatives?

The application of genomic information to drug development also fuels ethical questions. Preferential inclusion of tested full responders into clinical trials increases the efficiency of such programs. However, such an approach would hide important information about the actions of the drug in other patients. In case the group of responders would be (too) small to develop the compound to an economically feasible medicine, the industry might decide to discontinue the project. On the one hand, the latter picture has led to the illustrious quote "Will all drugs become orphans?" (Maitland-van der Zee et al. 2000). On the other hand, drug development in many therapeutic areas (e.g., oncology, immune diseases) is increasingly driven by advances in cell biology and insight in molecular pathways of disease, making biomarker-enhanced targeting of drug treatment to the best responders, both in terms of efficacy and safety outcomes, more feasible and the most promising way forwards (Kuehn 2011).

25.3 Ethical Principles: Weighing Ethical "Benefits" and "Costs"

On the background of all the developments addressed so far, ethical principles are highly prevalent but in many cases badly defined, virtually invisible, or denied. Weighing of ethical "benefits" and "costs" is becoming an essential, additional perspective in designing and conducting sound epidemiological research (Nilstun and Westrin 1994). In the late 1980s, the Americans Beauchamp and Childress proposed four ethical principles in order to provide a more or less neutral, analytical framework to help doctors, researchers, and all others who are engaged in medical decision and policy making, when reflecting on moral issues that arise at work: respect for autonomy, beneficence, non-maleficence, and justice (Beauchamp and Childress 1989). Despite rapid and thought-provoking changes in medical technology and the practice of medicine, we believe that these four principles, plus attention to their scope of application, may encompass most of the moral issues that arise in today's health care and public health arena (Gillon 1994, 2003).

25.3.1 Autonomy

Autonomy is a widely discussed principle in bioethics and the word has several meanings. By and large, however, two focuses can be discerned: on the one hand autonomy can be perceived as a right to self-determination and on the other hand as an ideal of deliberated self rule. The first is about sovereignty and the second about authenticity. With respect to research ethics, autonomy is most visible in the practice of informed consent. Autonomy may be infringed if individuals are denied the right to choose whether or not to be enrolled in clinical or epidemiological research. Respecting people's autonomy requires consulting patients or other study subjects and obtaining their agreement before inclusion in a study. Medical confidentiality is an instrument to protect privacy, which in itself is based on the respect for a patient's autonomy.

Privacy refers to freedom of the person to choose for himself or herself the time and circumstances under which and, most importantly, the extent to which, his or her attitudes, beliefs, behavior, and opinions are to be shared with or withheld from others. Confidentiality refers to managing private information; when a subject shares private information with (confides in) an investigator, the investigator is expected to refrain from sharing this information with others without the subject's authorization or some other justification. Without confidentiality patients will be also far less open about all their personal concerns, symptoms, and other pieces of highly private information. Such information is very often critical to assign diagnoses and treatment scenarios to individual patients. This will have implications for clinical practice, but also for research. Study subjects should have more than enough reasons to trust researchers. Respecting autonomy also means not abusing this trust.

25.3.2 Beneficence and Non-Maleficence

The principle of beneficence means that health-care professionals and investigators have a responsibility to do good for those whom they treat. The traditional Hippocratic moral obligation of medicine is to provide net medical benefit to patients with minimal harm. Therefore, beneficence and non-maleficence are viewed as basic components of a balance sheet aiming at producing net benefit over harm. For epidemiology this means that a research project should add to the existing knowledge base on exposure-disease occurrences in order to treat populations of patients effectively and to prevent health hazards or even mortality in the community. In epidemiology the interests, and thereby the benefits, for the individual patient are less obvious, since often no treatment is offered. However, part of the benefit that communities, groups, and individuals may reasonably expect from participating in studies is that they will be told of findings that pertain to their health. Where findings could be applied in public health measures to improve community health, they should be communicated to the health authorities. In informing individuals of the findings and their pertinence to health, their level of literacy and comprehension must be considered. Research protocols should include provision for communicating such information to communities and individuals (Bankowski et al. 1991).

The principle of non-maleficence applied to epidemiology reflects the moral obligation not to do harm to study subjects. In many cases of research, it is still uncertain what the benefits are of a specific intervention (as this is part of the study question). The principle of non-maleficence teaches that at least participating in the study should do no harm and should involve only minimal risks. Likewise, epidemiological investigators studying activities that pose risks to the well-being of subjects are ethically obligated to propose to subjects with whom they interact any feasible steps that can be taken to minimize their exposure to risk. Furthermore, harm may occur, for instance, when scarce health personnel are diverted from their routine duties to serve the needs of a study, or when, unknown to a community, its health-care priorities are changed. It is wrong to regard members of communities as only impersonal material for study, even if they are not harmed. Ethical review must always assess the risk of subjects or groups suffering stigmatization, prejudice, loss of prestige or self-esteem, or economic loss as a result of taking part in a study.

25.3.3 Justice

This principle underpins the moral obligation of a fair distribution of burdens and benefits between people. One way of looking at justice is treating those with equal need equally. Justice can also be described as the requirement to act on the basis of fair settlement between competing claims and demands. Equity is at the heart of justice, and since centuries, people have argued about the morally relevant criteria for regarding and treating people as equals and those for regarding and treating them as unequals. This principle has become prominent in an era of cost-containment and rationing of health-care resources. Allocation of resources may conflict between several common moral concerns (e.g., individual access to and affordability of resources, fair distribution of scarcity, autonomy of professionals to make the best decisions for their patients). All concerns may be morally justified but not all can be fully met simultaneously. Epidemiology is the science of landscaping and explaining differences (in health, socioeconomic status, resources, risk factors) within populations and is thereby a critical "monitor" of (in)equity (Weed and McKeown 2001).

25.3.4 Balancing the Four Principles

Although, all the four principles together are seen as a comprehensive frame for moral reflection in medicine and epidemiology, we can observe a shift in emphasis and a greater prominence of autonomy as the leading manual for ethical conduct. This shift of putting the individual first is welcomed with mixed feelings and has made balancing individual rights with those of the whole society to become a key issue in contemporary Western society:

> Autonomy is, then, de facto given a place of honour because the trust of individualism, whether from the egalitarian left or the market oriented right, is to give people maximum liberty in devising their own lives and values.
> (Callahan 2003)

Table 25.1 Most important possible "benefits" and "costs" when the study is done

	Autonomy	Beneficence/non-maleficence	Justice
Study subjects	Costs	Benefit	Mixed
Physicians	Costs	Benefit	
Industry		Mixed	
Society at large		Benefit	Benefit

Nilstun and Westrin have proposed a model to cross the four ethical principles with the perspectives of each of the parties involved and then to assess and weigh the ethical "benefits" and "costs" for each individual party in the event the study is or is not conducted (Nilstun and Westrin 1994). Earlier in this chapter we have addressed the scientific and political debate about the risk of deep vein thrombosis and pulmonary embolism in females using the so-called third-generation oral contraceptives relative to second-generation agents. In 1999 Herings et al. published a follow-up study on this topic using anonymous exposure data related to females using one of these oral contraceptives and anonymous, but person-specific, outcome data on hospitalizations for either deep vein thrombosis or pulmonary embolism (Herings et al. 1999). The study confirmed the differential risk between the two categories of oral contraceptives and showed that the highest risk was in young females, newly starting with this contraceptive method. We use the study accessible through this chapter to illustrate and flesh out the model of Nilstun and Westrin.

The analysis starts with identifying the relevant parties (females using oral contraceptives, society at large, industry, prescribers). In Table 25.1 possible outcomes of an analysis of the most relevant "benefits" and "costs" are listed concerning the two dimensions of ethical principles and parties involved in the event that the study will be conducted. If the study is done, there are possible "benefits" for society at large, for prescribers, and for (other) women using oral contraceptives. For the industry the conduct of the study results in an ambiguous picture. Manufacturers of the second-generation oral contraceptives considered the study as "good news," for manufacturers of the third generation, the results of the study were less favorable. For industry as a whole, one may argue that every piece of science that contributes to the benefit-risk balance is advantageous, although this is not perceived like this in real life. Although this is reasonably understandable, it marks also the complexity and paradoxal nature of such multi-interest cases. Because the study confirmed earlier findings that most of the risk is concentrated in the very young users, this chapter provided important guidance to decision makers and young females in choosing the most suitable oral contraceptive.

With respect to the potential "costs," respect for autonomy (violating privacy, absence of individual informed consent) of the females and (possibly) the prescribers involved in the study is critical. Data used in the study were anonymous but person-specific, meaning that the investigator could not link the research data to any individual women. The linkage procedure of the Dutch Pharmaco-Morbidity (PHARMO) record linkage database has been internationally acknowledged (PHARMO data have been used in more than 200 studies) and brings community pharmacy and hospital data within established hospital catchments regions, together on the basis of patients' birth date, sex, and general practitioner (GP) code (yielding a sensitivity and specificity of linking person-specific data from two separate databases of over 98% each, which means that 98% are correctly linked) (Herings et al. 1992). In the same fashion, linkage between primary care data, population surveys, laboratory data, cancer, and accident registries has been achieved and applied in numerous epidemiological studies. But also, as previously stated in this chapter, record linkage using unique person-specific codes has shown to be very successful in building datasets for epidemiological studies (Andersson et al. 2011; Bazelier et al. 2012). A critical ethical issue has always been whether and how individual informed consent in such studies could be obtained. For sure, certain autonomy advocates argue that this should be accomplished. However, practical and methodological (those who refuse are mostly most relevant to the research) constraints would make individual informed consent virtually unfeasible. Instead, general informed consent in order to use the data for research purposes is very often obtained at the time a person enters the coverage area of a certain database. Coming back to the OC (oral contraceptives) and VTE (deep vein thrombosis and pulmonary embolism) study and looking at the principle of "beneficence," participating females have contributed (although not in conscious fashion) to the research and have taken their share in the solidarity of bringing together relevant data for solving an important public health problem.

Whatever the outcomes of such an exercise are, they provide a systematic frame for reflection and identification "where things can go wrong." The latter is a pivotal role of ethics in epidemiology (Coughlin 2000). Each preliminary idea of a study protocol should be accompanied with such an "ethical scan" not only for the purpose of moral justification of the research but also for reasons of improving the quality of the research. Experiences in coping with requirements to assure data privacy have been dominated mainly by technical (e.g., probabilistic linking, de-identification, introduction of random error on an individual level, but not on a population level) or procedural (e.g., standard operating procedures, good practice standards, security) dimensions (Roos and Nicol 1999). From a pragmatic view these dimensions may fully satisfy. However, ethical weighing of "benefits" and "costs" also includes critical reflection of the aims, deliverables, and consequences for the stakeholders (e.g., patients, physicians) involved. The latter goes beyond finding "smart tricks" to deal with privacy regulations or clinical trial directives.

As stated before, the ability to link person-specific clinical, exposure, and disease course data is a critical objective of epidemiology. Of all ethical issues and considerations, respecting autonomy by protecting privacy and confidentiality are the most crucial ones. Virtually all current legal systems in the Western world acknowledge the basic right of the patient to be assured that all his/her medical and personal data are confidential. Only in case of few well-defined exceptions, disclosure of person-specific information is allowed, e.g., prevention of serious risk to public health, order by a court of law in a crime case, and, under certain safeguards, scientific research. The tension between assuring personal privacy and access to medical data for epidemiological research has drawn ample attention from various stakeholders (individual patients, the public, politicians, health professionals, and the research community). In Table 25.1 possible violations of personal privacy related to either study subjects or physicians are classified as “costs.”

The scientific community of epidemiologists struggles with these two concepts and tries to convince politicians and policy makers of the importance of collective benefit to society from research with medical data and that we cannot rule out significant adverse effects to public health when epidemiological research has been made virtually impossible. Others take the pragmatic route using methodology that includes contemporary computer and statistical technology in order to build, within the framework of existing privacy legislation, aggregated, de-identified but person-specific, information. Court cases in several parts of Europe have concluded that the use of fully anonymous, de-identified patient data for the purpose of scientific epidemiological or clinical research is permissible under current law. In cases where it is not feasible to use primary data (collected directly from clinical practice for a specific, well-defined, purpose) in an anonymous fashion, informed consent should always be obtained. Epidemiological researchers may rely on access to non-anonymous medical records, but access to patient records for a research purpose requires individual patient informed consent.

The effect on research quality will be determined by the proportion of individuals who refuse consent, or in the case of large automated databases, who are simply not contactable. Researchers, cautioned by privacy advocates, very often overestimate participation proportions in consent procedures. There is growing evidence available that patients are willing to allow personal information to be used for research purposes. Several studies have shown that refusal to comply with consent procedures is most often not higher than in about one out of ten. A study from Canada suggests, however, that study subjects want to be actively consulted before the start of an epidemiological study where personal information is collected, whenever this is practically feasible (Willison et al. 2003). Secondary use of data (use of existing data for purposes other than those for which they were originally obtained) remains controversial as some interpreters of the law feel that secondary data use is prohibited because of the requirement for data to be used only for purposes compatible with those for which they were originally collected. In practice we see that this requirement is solved by obtaining general informed consent, although many researchers have sought exemption from the consent requirements in order to minimize selection bias, logistical obstacles, time consumption, and costs. Record linkage provides a powerful tool for the study of the natural history of diseases, the etiology of rare diseases, or the study of drug-effect associations with a (long) induction period between exposure and outcome (Herings et al. 1992; Sauver et al. 2011). The process of linkage of individual data from a number of sources, such as primary care records, secondary care records, prescribing and mortality data, requires patient identification and in many countries is not permitted because this is believed to breach data protection laws. In order to comply with confidentiality rules, researchers very often rely on medical staff providing them with a list of patients’ names and addresses to be used as a sampling frame. Although no medical details are given, the provision of names and addresses is clearly not anonymous, and this is likely to be in breach of most legal and ethical rules on the issue. Experiences so far in record linkage represent a patchwork of various approaches to link individual sets of drug or other exposure information and clinical data. We see, for instance, in Scandinavia, a surge in record linkage studies based on national unique identifiers (Andersson et al. 2011). In the absence of such linkage codes, researchers have to rely on other approaches for bringing separate datasets together to patient-specific linked records.

25.4 Ethical Issues Specific to Epidemiology

25.4.1 Unethical Quality of Research

This brings us to another ethical angle of epidemiological research, namely poorly conducted research. That kind of research will for sure not benefit patients or society, but may cause harm when it leads to unsubstantiated and wrong decision making in clinical practice or policy making in public health. Taubes (1995) has addressed this issue in his thoughtful paper on the limits of epidemiology where he accused the field for producing repeatedly exposure-outcome associations that do not hold very long because subsequent studies either contradict the findings or are unable to reproduce the main study results. Although scientific controversies are essential to progress and evolution in science, conflicting data and secondary turmoil in epidemiology do most often more harm than good (Vandenbroucke 1998; Skegg 2001). This means that "Good Epidemiology Practices" with the purpose to prevent or adjust a priori poorly designed studies are as important for quality assurance as for ethical reasons (IEA International Epidemiological Association 2007; European Medicines Agency 2010).

25.4.2 Global Bioethics and Inequity

A remaining, but not less important, ethical challenge for future epidemiological research is the gigantic inequity in global health. Large differences in disease burden, variable access to efficacious and safe medical technology, gaps in pharmaceuticals and health services are an enormous concern (World Medical Association 2000). Fighting against inequity in global health as a feature of modern medical and epidemiological ethics goes beyond the application of the Hippocratic oath. It is about prioritizing and about creating affordability and access, and epidemiology is and will be the pivotal science of fuelling policy making and strategic action with quantitative evidence for managing this global problem (Reich 2000; World Health Organization 2003). The triangle global inequity, epidemiology, and ethics contrast extremely with the ethics of individual "autonomy" of, for instance, a patient objecting against participating in a database study in the USA or Europe. So far, ethicists have been struggling with "prioritizing" ethical issues. Questions whether a disease burden of an orphan disease with a prevalence of less than

1:10,000 in the EU is, or should be, as equally important as the burden of a tropical disease affecting millions and millions of people are still difficult to address. There is increasing interest and debate in global bioethics in the context of how different countries deal with solidarity when resources for health care are scarce, when lack of equity means differential allocation of health services or interventions like pandemic influenza vaccination plans. DeBruin et al. (2012) have listed several factors contributing to access barriers including lack of accessible information, distrust of government and public health agencies and programming, lack of insurance and inadequate insurance coverage, poverty, transportation and mobility issues, and distance to care. Epidemiologists are often the providers of data on unequal access and the consequences of these for the individual and the population at large. We will face important challenges for epidemiologists and ethicists involved in these "contrasting" areas. Some criteria, however, have been developed already. Both the Declaration of Helsinki in its fifth amendment (2000) and the CIOMS guidelines for biomedical research (CIOMS 2008) state that research undertaken in populations with limited resources should be responsive to the health needs of the population. Moreover sponsors and investigators must ensure that products or knowledge generated by the research will be made reasonably available for the benefit of the population.

25.4.3 Epidemiological Determinism and Preventive Medicine

In the late 1990s, James Le Fanu, a UK-based general practitioner, wrote a reflecting and alluring book titled the "Rise and Fall of Modern Medicine" (Le Fanu 1999). In his book, the author is very critical about numerous features of contemporary medicine and health care, in particular about the role of epidemiology in medical education, knowledge building, and clinical practice.

Many of his arguments are close to the ethical questions arising from the determinism of epidemiology resulting in stratifying populations in categories of disease susceptibility, consequently leading to screening, "healthy" behavior, and preventive medicine. The promise of genomics and other molecular strategies for improving the practice of medicine must be pursued taking into account the fundamental ethical principles of autonomy, beneficence, non-maleficence, and justice. Because genetics are linked to family ties, the "right of not to know" for instance, goes beyond the individual judgment and decision making of the persons involved in the study themselves.

25.4.4 Precautionary Principle and Scientific Evidence

Closely related to the former issue of epidemiological determinism is the question how strong the evidence of the relationship between a hypothesized cause (i.e., environmental factor, medical intervention, drug treatment) and the effect should be before implementation and public health action is justified (Rogers 2003).

This is at the heart of the science of epidemiology, as we have seen in previous chapters, and there are many cases of “established” exposure-outcome associations which had to be revoked afterwards because new studies and data became available, e.g., reserpine and breast cancer, fenoterol and asthma death, or drinking coffee or tea and pancreas cancer (Fraser 1996; Spitzer et al. 1992; Lee et al. 2007). According to the precautionary principle, a principle widely embraced nowadays by politicians and consumer advocates, particularly in the area of assessing environmental risks, it is uncertainty that justifies and requires proactive measures and regulations and a reversal of the burden of proof. A manufacturer intending the marketing of a new product or a government planning to build a new power plant has the obligation to provide solid evidence on efficacy and safety of the innovation before authorization is granted. The pharmaceutical market knows this system already since the early 1960s, but also other areas of medical technology, food, and environmental exposures anticipate more proactive assessment of the benefits and risks. The application of the precautionary principle is controversial because, according to its opponents, it drives behavior of counterproductive risk-avoidance and defensive strategies in balancing risks and benefits of innovation. Assessment and prediction of health effects of any intervention depend on a synthesis of all available epidemiological and mechanistic evidences to produce a valid estimate of the likely effect. Epidemiology is an important scientific resource to fuel precautionary measures, but also to avoid that decision makers intervene in human behavior without sound evidence. From that perspective the adverse effects of the precautionary principle in terms of, for instance, exclusion of susceptible patients from certain medical technologies because proof of safety is still lacking (e.g., pregnant women, children), or neglecting and discontinuing research and development in specific risky areas, call for ethical reasoning.

25.4.5 Medical Ethics and Epidemiology

Singer and colleagues (2001) have identified a number of important drivers in medical ethics:

- New ethical challenges posed by advances in biotechnology
- Maturation of clinical ethics by strengthening the research base and developing graduate programs and fellowships
- Emphasizing the intersection between clinical ethics and health policy, including a focus on ethics of health-care institutions and health systems
- Increasing public education and involvement
- Developing the conceptual foundations of bioethics
- Changes in the doctor-patient relationship

Epidemiology is very close to clinical medicine, as epidemiologists provide scientific underpinnings of (1) the diagnosis, (2) etiology of the disease, and (3) the prognosis (and determinants of disease) in populations, both healthy and diseased. We anticipate that all major developments in medical genetics will have consequences for epidemiology ethics as well, directly or indirectly. But because epidemiology is frequently directed at the healthy part of the population, meaning those who are not (yet) ill, the field carries specific ethical responsibilities with respect to predictive competences, e.g., identifying risk factors and preventive medicine. Moreover, as stated before, there are not many scenarios in epidemiological research where study subjects individually can benefit directly from the study and/or the research results. Partly this is a consequence of the historical nature of, for instance, retrospective case-control or many cohort studies, the anonymity of the data, and the large numbers involved, making person-specific implementation of the study results to study subjects hardly feasible. These features contrast with clinical research with more options for direct patient benefit. Direct patient benefit (or harm) is also an important driver of the discussion on the ethics of placebo-controlled clinical trials in case there is an efficacious therapy available and not treating might harm the patient for sure, e.g., by severe worsening of the disease or mortality in oncology research, or suicide risk in evaluating antidepressive therapies (Storosum et al. 2001; Michels and Rothman 2003). The general rule is that placebo-controlled trials are only morally acceptable in the absence of proven effective therapy. However, this implies also that in certain areas where large placebo effects are expected, not having access to placebo-controlled data may result in weaker evidence to justify a sound benefit-risk decision.

25.5 Conclusions

Among many other factors, innovation in automated databases and biobanks, the surge in molecular and genetic knowledge, and controversies about scientific integrity, conflict of interest, and global bioethics have increased apprehension of the importance of ethical aspects in epidemiology. In the beginning, concern about loss of privacy has been a key driver of ethical questioning in epidemiology, and various techniques have been developed to cope with the confidentiality issue. The creation of unbiased person-specific histories (including both data on various exposure and outcomes) is a crucial requirement in epidemiology. Ethical weighing of “benefits” and “costs” can play an additional and relevant role as a vehicle for thoughtful reasoning (Beauchamp et al. 1991). Indeed, there have been expressed concerns about the various ways of misusing such data. In particular in the era of genetics and the increased interests of health insurers to reduce their business risks, there is a great need for prudence, protection, and careful weighing (Bolt et al. 2002; Nuffield Council on Bioethics 2012). Discovery of genes determining the response to various exposures including food, environmental factors, and medicines is an emerging area of genomic research as well and will produce new and intriguing ethical questions.

When considering the four ethical principles of beneficence, non-maleficence, autonomy, and justice on a scale of individual versus society as a whole, it is apparent that most of the “benefits” of epidemiological research can be attributed to the collective level (community, society) and that most of the “costs” fall down on the individual level. That makes epidemiology vulnerable for controversies where the individual-collective dimension is sensitive. The two examples of calcium-channel blockers and the users of oral contraceptives exemplified that participating study subjects themselves are virtually not benefiting from the study results. Current or future users of both drug categories however are in a much better position after the research has been done than before.

In this chapter we have used a number of pharmacoepidemiology case examples to illustrate and flesh out main ethical principles and questions relevant for epidemiology. The points addressed however have broader implications also for other fields in epidemiology. Pharmacoepidemiology as a discipline provides a challenging area of angles and perspectives to highlight certain ethical issues. Apart from the science in itself, the field is also heavily aligned with the economic, social, and political dimensions of developing and using medicines in a global scenery.

It is not a rare occurrence that epidemiological researchers perceive ethics as cumbersome, conservative, and antiscientific. Although these feelings may be justifiable in some cases, the ultimate balance sheet of more ethical weighing and reasoning will be positive. Ethical reasoning helps also to be concise in defining the research question, the design, and conduct of the study. Ethics and the linked formal and legal frameworks (e.g., scientific conduct guidelines, privacy protocols, ethical review board) undoubtedly have delivered in terms of quality push, critical reflection, and scientific enlightenment and will continue to do so in the future. The research community, clinical medicine, and patients all are major stakeholders in searching for and achieving mutual benefit from integrating ethics into epidemiological science (Gillon 2003).

26.1 Introduction

This chapter provides an overview of the principal aspects of statistical inference as it is encountered in epidemiology. It makes minimal assumptions about the theoretical background and attempts to provide a simple introduction to both the frequentist and Bayesian approaches. The former still predominates in the applied literature, while theoreticians increasingly argue that it should be replaced by the latter, Bayesian approach. In this chapter, we take the view that these two approaches to inference should not be regarded as antagonistic, but rather as aiming at fundamentally different objectives, which may be regarded respectively as the analysis of data and the weighing of evidence – the latter typically derived from essentially different sources.

In Sect. 26.2, we discuss the essentially inductive nature of statistical inference and the important distinction between statements about the probability of a random event and statements about the uncertainty attaching to essentially unknown quantities such as model parameters and statistical hypotheses. In Sects. 26.3–26.5, we examine the classical modes of statistical inference: point estimation of parameters, hypothesis testing, and the construction of confidence intervals. The importance and role of likelihood is addressed in Sect. 26.6, while Sect. 26.7 gives a brief introduction to Bayesian methods of statistical inference.

26.2 The Nature of Statistical Inference

Statistical inference is the process by means of which we attempt to learn about the nature of random phenomena from observations on the real world. Although the machinery of the subject is mathematical, it is important to understand that the inferential process is inductive and not at all like the deductive processes of mathematics. Induction rather than deduction is essentially the means by which science progresses and by which we learn about the real world. In this sense, statistics is, as an academic discipline, much closer to the sciences than to mathematics.

The inferences of the physical sciences have a degree of logical certainty to them: if an observation is inconsistent with a hypothesis or model of the world, then we can at least deduce with certainty that our model is wrong in some respect, even though we cannot deduce that some other model is certainly correct. In problems requiring a statistical analysis, however, even the negative inference is less certain, since chance plays a role and our statements inevitably involve an element of uncertainty. The mathematically accepted way to quantify the uncertainty attaching to a statement is through the use of probability, conventionally measured on a scale of 0 to 1.

26.2.1 Probability and Uncertainty

In this chapter, we assume that the reader has a basic familiarity with the concepts of probability and probability distributions, which enable us to develop *models* for random phenomena; such models will usually have associated parameters[1] and a primary goal of statistical inference is to make inferences about the values of these parameters. Thus, for example, the proportion of patients in a particular group who are of a specified sex is purely descriptive, but to use this proportion as an estimate of an underlying probability enables us to make inferences about the magnitude of this probability and also to make predictions about future observations. To do this, we consider the observed proportion as a particular realization of a *random variable*, a mathematical entity whose probability distribution describes the behavior of the generality of similar observations.[2] Again, measuring the average blood level of some prognostic indicator in a sample of patients is purely descriptive, but when we use this average to estimate the mean of a probability distribution (which might be assumed to be normal, for example), we are estimating a parameter in a model which will enable us to make inferences about the population of patients as a whole and to make predictions about future observations. We will illustrate the ideas and methods in this chapter by reference to three running examples, which we now introduce.

The Binomial Distribution Our first example is the simplest model of all, that for dichotomous events. The binomial distribution gives us the probabilities of observing a given number x of specific outcomes or attributes (e.g., being male) out of a total of m independent dichotomous trials representing individual outcomes or attributes (e.g., the sex of patients in some group). It is assumed that this probability p is the same for each individual and that the determinations are independent of one another. It is then shown in elementary textbooks on probability theory that the required probability is given by the binomial distribution[3]:

$$\mathrm{P}[X = x] = \binom{m}{x} p^x (1 - p)^{m-x}\ ;\ x = 0, 1, 2, \ldots, m, \tag{26.1}$$

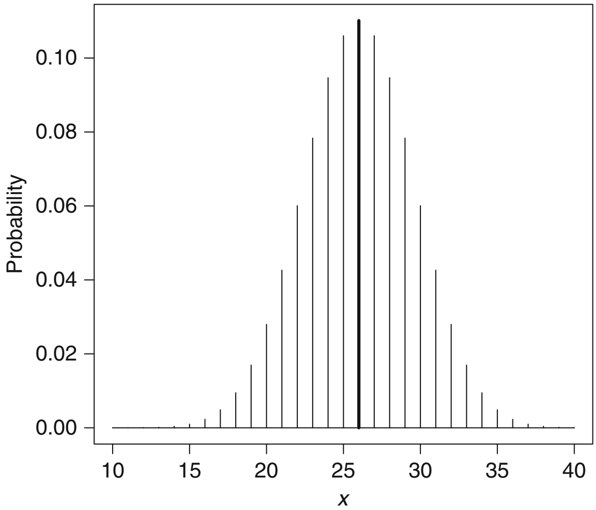
where $0 \le p \le 1$ and $\binom{m}{x} = \dfrac{m!}{x!(m - x)!}$ is the number of ways of choosing x items out of m without regard to order.

[1] This most useful word means a “quantity constant in (the) case considered, but varying in different cases” (Concise Oxford Dictionary). Its use to mean “boundary” (perhaps by confusion with “perimeter”), “limits” or “constraints” is to be deprecated.

[2] Mathematically speaking, a random variable is a function associating each possible outcome of an experiment with a particular numerical value, but at an elementary level, we can take it to be what it sounds like – a quantity that is variable from case to case in a manner that is intrinsically random.

[3] We follow the usual notational convention that a random variable is denoted by an uppercase letter and a specific value by a lowercase letter. P[·] denotes the probability of an event.

Fig. 26.1 Bar diagram showing the probabilities of the binomial distribution with $m = 52$ and $p = 0.5$



Example 26.1. Sex of meningitis patients
Bortolussi et al. (1978) report an investigation of newborn infants (under 31 days old) with meningitis in the Hospital for Sick Children in Toronto. Of the 52 infants they studied, 33 were male. It is reasonable to assume that each case presenting has the same probability p of being male and that the sexes of the children are determined independently, so the conditions for the binomial distribution apply. On the further assumption that boys and girls are equally frequent in the population and equally at risk of being affected by meningitis, we might suppose that $p = \frac{1}{2}$. Applying (26.1) with $m = 52$ and $p = 0.5$ gives the binomial distribution illustrated in Fig. 26.1. In particular, we can calculate that the probability of observing 33 males out of 52 children if $p = \frac{1}{2}$ is 0.017. The fact that this probability seems very small tells us little by itself about the plausibility of our model since it is clear from Fig. 26.1 that there are a lot of contributions to the distribution. On the other hand, it is also clear that this probability is a good deal smaller than the largest contribution, which is $\mathrm{P}[X = 26] = 0.110$.

The Normal Distribution In contrast to Example 26.1, we now consider the most important continuous distribution, conveniently represented by its density function, which may be depicted as a smooth curve with the mathematical formula:

$$f(x; \mu, \sigma^2) = \frac{1}{\sqrt{2\pi}\sigma} \exp(-(x-\mu)^2/2\sigma^2) \,. \qquad (26.2)$$

The parameters μ and σ are the mean and standard deviation (SD) of the distribution, which measure respectively its center and its spread.

Example 26.2. Glycolated haemoglobin levels in a healthy population
Simon et al. (1989) reported a study of glycolated hemoglobin (HbA1c) levels in 3,240 healthy workers at France Telecom. Figure 26.2 illustrates the data as a histogram, together with the best fitting normal distribution, which has $\mu = 5.05$ and $\sigma = 0.54$. Judged visually, the shape of the empirical distribution is reasonably well approximated by the normal

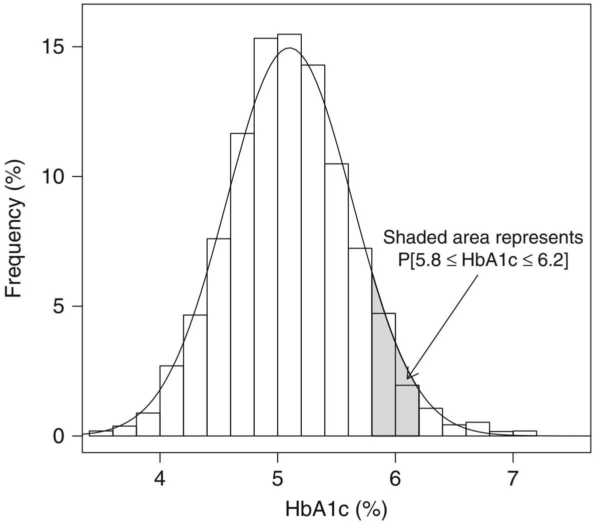


Fig. 26.2 Histogram of HbA1c data with best fitting normal density curve (Figure redrawn for this chapter with kind permission from Springer Science+Business Media from Diabetologia, see Simon et al. (1989), Fig. 1)

distribution. (In fact, a test of the kind introduced in Sect. 26.4.6 reveals a discrepancy resulting from the raised frequency in the right-hand tail, probably due to a small number of workers with poor glucose control.) The numerical value of the density function for a particular value of x is even less informative than in the discrete case and does not itself represent a probability, which necessarily lies between 0 and 1. For example, the most likely value for an observation is evidently at the mean of the distribution and here the density equals 1.37, which clearly could not be a probability. The function has to be interpreted as representing the probability of an observation falling between given values of x determined by the area under the curve between these values (see Fig. 26.2). The calculation of such probabilities is less straightforward than in the discrete case and proceeds by reference to the so-called *standard normal distribution* having $\mu = 0$ and $\sigma = 1$, for which the probabilities can be obtained from published tables or widely available computer programs.

The Poisson Distribution As a third example, we introduce the Poisson distribution, one of the most useful models of epidemiology. It describes the occurrence of events regarded as points in a continuum, for example, accidents regarded as point events in time or geographical space. In epidemiological practice, we do not often observe events this way; however, its use is much more widespread than this rather mathematical description might suggest because of a well-known result in probability theory stating that the Poisson distribution provides a very good approximation to the binomial distribution when the number of events m is large and the probability p of a positive outcome in each of the binomial trials is small. This means that the Poisson distribution provides such an approximation for the occurrences of all but the commonest diseases and for deaths over modest time intervals.

It may be objected that the individuals at risk of death or disease in a large population will generally have very different probabilities of succumbing. However, this is not a problem, since the Poisson distribution has the very important property that the sum of independent counts with different means will also have a Poisson distribution. If we imagine our population of individuals to be stratified, so that the individual probabilities of disease are small but very similar in each stratum, the Poisson distribution will provide an approximation to the number affected in each stratum. If we then sum these numbers, the result just stated ensures that the Poisson distribution will be a good approximation to the distribution of the total number of cases, even though the individual risks may show wide relative differences. Thus, all we need to do is to calculate or estimate the overall mean of the distribution, which is its only parameter. This extraordinary simplicity has far-reaching implications for statistical epidemiology and, indeed, for the whole of statistics.

If we let the mean of the distribution be denoted by λ, the probabilities are given by:

$$\mathrm{P}[X = x] = \mathrm{e}^{-\lambda}\lambda^{x}/x!,\ x = 0, 1, 2, \ldots\ ;\ \lambda > 0. \tag{26.3}$$

All the properties of the distribution are determined by the single parameter λ; in particular, its variance[4] is equal to the mean, λ.

Example 26.3. Emergency admissions to a London hospital
Figure 26.3 shows the distribution of the numbers of female emergency admissions on Saturdays and Sundays at a London teaching hospital in the year ending March 1966 (unpublished report). The mean number of admissions per day was 3.92, and the figure also shows the probabilities in the Poisson distribution with this mean. It will be seen that the agreement appears to be good; we shall examine below (Sect. 26.4.6) methods of assessing how good the fit is. In fact, the mean numbers for other weekdays differ, and we have achieved a good fit here by restricting observations to days with similar admission rates, namely days at the weekend. A more literal model for emergency admissions would consider a large number of individuals at risk of being admitted, though all with widely varying probabilities. But it is highly unlikely that we would have the required information to determine the different probabilities for these individuals and, as discussed above, the situation can be well approximated by the Poisson distribution even when the probabilities vary.

26.2.2 Modes of Inference

Examples 26.1 to 26.3 are typical of the use of probability models to describe data subject to random variation and to make predictions about future observations. All their statements are in the form of a conditional probability such as P[Observation(s) | Model assumptions], where the | indicates the operation of conditioning so that this expression reads “probability of specified observations given that the model assumptions are correct.” Statistical inference, however, requires an inversion of such expressions to read “plausibility of model assumptions given the observations made.”

[4] The variance is the square of the SD and is a measure of spread, or dispersion, that is more convenient than the SD for some purposes.

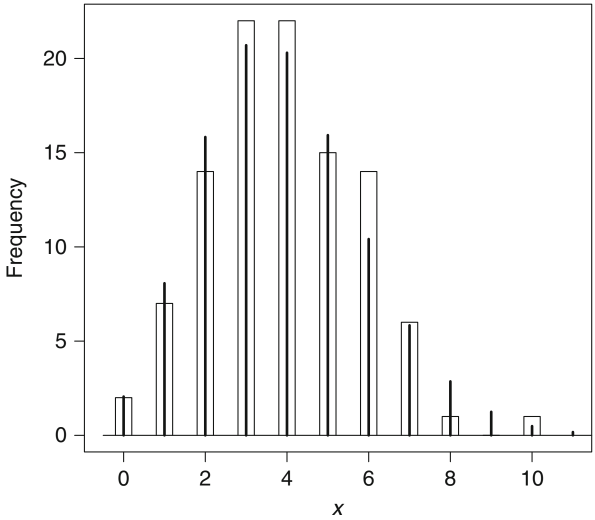

Fig. 26.3 Distribution of the daily numbers of emergency admissions (*unfilled blocks*) and the probabilities for the Poisson distribution with mean 3.92 (*thin black bars*)

The theory of probability is usually developed in the context of random events that are the outcomes of a sequence of experiments which could in principle be repeated indefinitely. Indeed, the easiest approach to probability is the *frequency approach*, which regards it as the limiting proportion of such outcomes in repetitions of a particular kind of experiment.

A moment's reflection, however, will convince us that a scientific statement is not like a random experiment: it is either true or false, and our ignorance of this does not endow it with the properties of a random event. Only by extending the notion of probability to apply to statements that are derived subjectively without reference to a potential frequency verification can we use it to quantify the uncertainty attaching to scientific statements. This is the extension that is espoused by the *Bayesian* school of statistical inference, a school that has gained ground appreciably over the last two decades (cf. chapter ▸Bayesian Methods in Epidemiology of this handbook). The kernel of this idea is Bayes' theorem[5] which provides a method of inverting probabilities by means of the formula:

$$\mathrm{P}[H|D] = \frac{\mathrm{P}[D|H] \times \mathrm{P}[H]}{\mathrm{P}[D]}. \tag{26.4}$$

As long as H and D stand for events in some random experiment, the formula is an uncontroversial consequence of the fundamental laws of probability. The issue becomes more difficult when D denotes some observations on the world, or Data, and H represents some explanatory hypothesis. For then the formula appears to

[5] This key result in statistical inference was first expounded by the Rev. Thomas Bayes (1701–1761), an English Presbyterian minister.

provide a probability for the hypothesis H, which we do not regard as random. It will be seen, however, that the right-hand side involves not only $\mathrm{P}[D|H]$, which is known as the *likelihood* of the data, but also $\mathrm{P}[H]$, that is, the probability of the hypothesis *before* we observe the data, known as the *prior probability* of H. Because it does not involve H, the denominator is of lesser importance, and we can summarize the law in a proportionality form:

$$\text{Posterior probability} \propto \text{Likelihood} \times \text{Prior probability}. \tag{26.5}$$

The more classical approach, often called *frequentist*, still prevails among most medical scientists, however, partly because of the feeling that introducing any subjective element into the argument weakens its scientific value, partly because the analyses are held to be easier to explain, though they are also easier to misinterpret. Because of their ubiquity, this chapter concentrates mostly on the frequentist modes of inference, and we deal in turn with the estimation of parameters, the testing of hypotheses, and the construction of confidence intervals. Each of these modes results in probability statements, but they are all of the form $\mathrm{P}[D|H]$, and their inferential value is correspondingly limited. There is also a tendency for such a statement to be misinterpreted as a statement reflecting $\mathrm{P}[H|D]$, often with very misleading results. The value of the frequentist approach lies in the appeal to the frequency interpretation of probability and its ability to show us the properties of a particular procedure, rather than its ability to assess the plausibility of a particular interpretation.

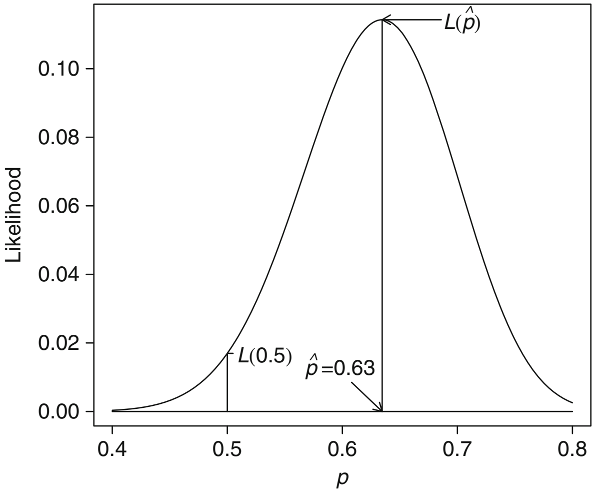
Although the frequentist approach appears to have the advantage of objectivity, it must be remembered that the result of a frequentist analysis expresses information only from the data being analyzed and this may be very modest compared with information we already have from other sources. As scientists, we might be content to weigh the evidence from our data with other evidence purely qualitatively, but this also introduces an element of subjective judgement, just as much as the Bayesian ambition to integrate evidence quantitatively.

Central to both Bayesian and frequentist methods is the concept of likelihood. Some statisticians even base their inferential ideas on it entirely. The concept is so important that we deal with it at the outset, before turning attention to the different modes of inference.

26.2.3 Likelihood and Plausibility

In fact, we have already introduced the likelihood in (26.4), and it will be seen that it appears there in the form of the probability of an observation given some model assumptions. The likelihood is indeed mathematically identical to the probability (mass or density) function, but expressed instead as a function of the unknown parameter with the data fixed, rather than as a function of the observation in a model with a given parameter value.

Fig. 26.4 Likelihood of the observation $x = 33$ from the binomial distribution with $m = 52$ as a function of the parameter p



Binomial Likelihood Thus, in the binomial case (Example 26.1), the likelihood for a given x is

$$L(p; x) = \binom{m}{x} p^x (1-p)^{m-x}\ ;\ 0 \le p \le 1. \tag{26.6}$$

The function is illustrated in Fig. 26.4 for the case $m = 52$, $x = 33$, and this should be compared with Fig. 26.1; it will be seen immediately that, like most likelihoods, it is a smooth function of the parameter of interest – in this case p. Instead of giving us the probabilities of different outcomes, different values now tell us the probabilities of the actual outcome for different values of the parameter. As with the probability function, the absolute magnitude of the likelihood tells us very little. But we have seen that the value of $L(0.5; 33) = 0.017$, which is among the smaller values available, and this suggests that if p really does equal one half, then something unusual has happened. Because unusual things happen rather rarely, it is entirely rational to find a larger value of p to be more plausible. Indeed, the most plausible value of p by this argument is at the maximum of the curve, which is easily seen to be at the value $p = 33/52 = 0.63$, for which $L(0.63; 33) = 0.114$. For obvious reasons, this value of p is termed the maximum likelihood estimate (MLE) of the parameter; it is usually denoted by $\hat{p}$. MLEs generally have good properties and play a major role in statistical inference.

Normal Likelihood Our second example follows the same lines. We first need to appreciate that the probability density of a sample of n independent observations $x_1, x_2, \ldots, x_n$ from the distribution is the product of expressions like that in (26.2); the likelihood is therefore the function of the two parameters μ and σ given by:

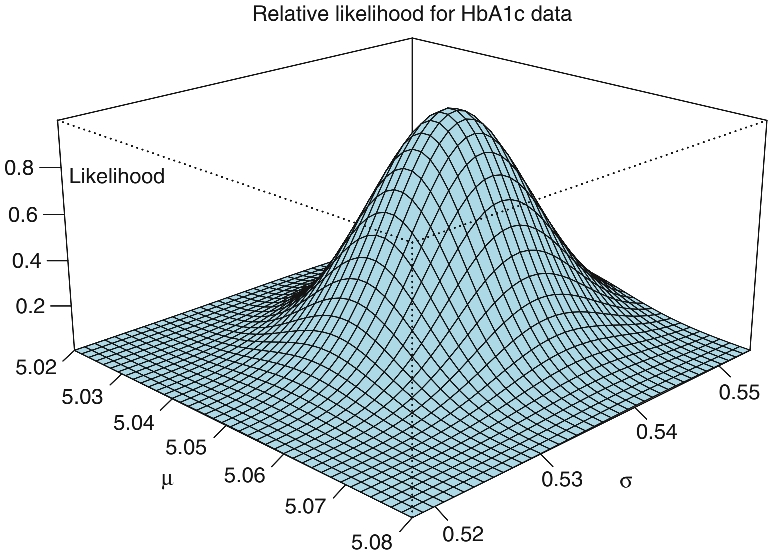


Fig. 26.5 Likelihood surface of μ and σ for HbA1c data having $n = 3,240$, $\bar{x} = 5.05$, and $\hat{\sigma} = 0.54$

$$L(\mu, \sigma; x_1, x_2, \ldots, x_n) = \prod_{i=1}^{n} \frac{1}{\sqrt{2\pi}\sigma} \exp\{-(x_i - \mu)^2/2\sigma^2\} . \tag{26.7}$$

It is more convenient to work with the logarithm of the likelihood, which of course has its maximum for the same parameter values as the likelihood itself. Thus, we write the log-likelihood as

$$\ell(\mu, \sigma) = k - n \log \sigma - \frac{1}{2\sigma^2} \sum_{i=1}^{n} (x_i - \mu)^2 = k - n \log \sigma - \frac{1}{2\sigma^2} \left(Q^2 + n(\bar{x} - \mu)^2\right), \tag{26.8}$$

where $Q^2 = \sum_{i=1}^{n}(x_i - \bar{x})^2$ and k is a constant not depending on the parameters, which is therefore irrelevant for the comparison of different values of ℓ.

This equation tells us important things about the likelihood in this case. In the first place, we need only know the values of $\bar{x}$ and Q^2 in order to compute it for any given parameter values. Hence, these quantities provide summaries of the data containing all the information about the parameters that is available in the likelihood. Such quantities are called *sufficient statistics*. Moreover, it is clear that, regardless of the value of σ, the function is maximized by choosing $\mu = \hat{\mu} = \bar{x}$, the sample mean. It is also quite straightforward to show that ℓ is maximized when $\sigma = \hat{\sigma} = Q/\sqrt{n}$, which is therefore the MLE of the SD of the distribution. Figure 26.5 shows the likelihood surface for the HbA1c data, for which $\hat{\mu} = \bar{x} = 5.05$ and $\hat{\sigma} = 0.54$.

As in the binomial case, relative values of L or different absolute values of ℓ indicate the relative plausibility of different parameter values. For example, with a postulated value of $\mu = 5.039$ (and maintaining the value $\sigma = 0.54$), we have a value of L half as large as the maximum value. Such comparisons give a measure of the plausibility of different parameter values, albeit not on a probability scale.

We can understand why the likelihood is so important if we reflect that it incorporates our understanding of the mechanism by which the data are generated; there is nothing in addition to this specification and the data themselves that gives any insight from our experimental observations. There are two provisos to this. The specification must be complete: sometimes it is hard to be sure which of two models with the same mathematical form for the likelihood actually did generate the data. It must also be correct since otherwise we may be seriously misled. Models are usually only approximately correct at best – for example, real data are never exactly normally distributed. Judgements about the seriousness of such departures from the ideal make up a large part of the business of statisticians and experience is often of more help than mathematical analysis.

26.3 Point Estimation

We have already met the MLE and the idea that the maximum likelihood approach can, in many situations, provide a good method of estimating parameters in a model. But we have not said what we mean by good; nor have we discussed comparisons with other methods. To do this within the frequentist framework, we need to make use of the concepts of an *estimator* and of its *sampling distribution*.

26.3.1 Sampling Distributions

An *estimator* is a function of our observations used for parameter estimation when we regard it as a random variable. This is in distinction to an *estimate*, which is an arithmetical quantity (or an algebraic formula for it) giving its value on the particular occasion we have observed. As a function of random variables, the estimator is also a random variable, and its long-run behavior can in principle be described by the use of probability distributions. Although it is not always easy to distinguish between an estimator and an estimate in a given context, it is nevertheless an important distinction, and it is good practice to observe it by using uppercase letters for the estimator and lowercase ones for the estimate. Thus, we write the estimator $\bar{X} = \sum_1^n X_i/n$ to represent the mean of a sample of observations when we wish to study how the sample mean behaves, but $\bar{x} = \sum_1^n x_i/n$ when we wish to describe how to calculate the sample mean from the observations $x_1, x_2, \ldots, x_n$.

In order to study the properties of an estimator, we must regard it as a random variable with a probability distribution determining the probabilities with which the estimate will have particular values. This probability distribution is known, quite generally, as the *sampling distribution* of the estimator and its properties tell us about the behavior an estimator would have if we could repeat our observations many times. In particular, it would seem desirable that the mean of the sampling distribution, around which successive estimate values would cluster, should be equal to the true parameter value. We say that an estimator with this property is *unbiased*. Unbiasedness sounds like a good property and so indeed it is, other things being equal.

However, we also need to consider the variability of our estimator about the mean of its distribution. One straightforward measure of this is the SD of the sampling distribution, and this is known as the *standard error* – often abbreviated s.e. – of the estimator. The smaller it is, the closer we expect our estimator to be to the unknown parameter – not with certainty on a given occasion, but on average in the rather precise sense of making the average squared error as small as possible. The standard error is an important concept, and estimated standard errors appear beside most published parameter estimates as adjuncts that enable us to judge their likely closeness to the unknown parameter values.

26.3.2 Estimating the Binomial Parameter

In the case of our binomial example, an obvious estimator of p is the sample proportion $\hat{p} = X/m$, and indeed we have already seen that this is the maximum likelihood estimator, for which we also use the abbreviation MLE, the distinction between estimate and estimator usually being clear from the context. Its sampling distribution is easily available since it is just a scaled version of the binomial distribution of X. It is an elementary result of probability theory that the mean of the binomial distribution of X is mp, from which we deduce that the mean of the distribution of $\hat{p}$ is indeed equal to p, that is, $\hat{p}$ is unbiased.

The theory of probability distributions also tells us that the SD of X is $\sqrt{mp(1-p)}$, so the standard error of $\hat{p}$ is the same quantity scaled by $1/m$, that is, $\sqrt{p(1-p)/m}$. We note that this is essentially unknown, since it depends on the parameter we are trying to estimate. Luckily, the function $p(1-p)$ changes rather slowly as p changes, so we may reasonably substitute our estimate into the formula to give the MLE with its s.e. as

$$\hat{p} = x/m \pm \sqrt{x(m-x)/m^3}. \tag{26.9}$$

This estimate of the s.e. will rarely be much in error unless we have small values of x or $m - x$. For the data in Example 26.1, we have $\hat{p} = 0.635 \pm 0.067$.

26.3.3 Estimating the Mean of the Normal Distribution

We have seen in Sect. 26.2.3 that the normal distribution has two parameters, μ and σ, with MLEs $\hat{\mu} = \bar{X}$ and $\hat{\sigma} = Q/\sqrt{n}$. It is mathematically more convenient for estimation purposes to regard the natural second parameter as σ^2, the variance of the distribution. MLEs are "invariant" under increasing transformations,[6] so it easily follows that the MLE of σ^2 is $\hat{\sigma}^2 = Q^2/n$. We will examine the properties of $\hat{\mu}$ and $\hat{\sigma}^2$ in turn.

In the first place, it can be shown that

$$\mathrm{E}[\bar{X}] = \mu \text{ ; and s.e.}[\bar{X}] = \sigma/\sqrt{n}, \tag{26.10}$$

where E[·] is the *expectation*, a term denoting the "mean of the probability distribution of." In fact, this important result applies with (almost) any *parent distribution* – that is, for any distribution from which the sample is drawn. From it, we can see that the inaccuracy in the estimate resulting from randomness decreases in proportion to $1/\sqrt{n}$. Thus, we need 100 times as many observations to improve our estimate by a factor of 10, a fact of life that is rather discouraging.

Another fact of life immediately clear from (26.10) is that the standard error of $\bar{X}$ depends on σ, which we will not usually know other than from the data and which therefore has to be estimated too. This is analogous to the situation with the standard error of $\hat{p}$, which requires a value of p. It is reasonable to use the MLE of σ for this purpose. The actual distribution of $\bar{X}$ is known in the case of a normal parent – it is in fact normal with the mean and SD given in (26.10).[7] Figure 26.6 shows the sampling distributions of $\bar{X}$ (a) for our actual data and (b) for a hypothetical sample of size 100; the first gives an idea of the precision[8] of our estimate obtained from the real data. The curves may also be compared with that for the parent (or population distribution) with $\sigma = 0.54$ (Fig. 26.2); this helps to emphasize the importance of the distinction between the SD of the parent and the standard error of the mean. To avoid confusion, it would be better when reporting the results of surveys to use the symbol ± to denote the s.e. rather than the SD, but the reader is warned that this convention is not always observed in the medical literature and there is a consequential risk of confusion.

[6] An increasing transformation of x returns a value $f(x)$ with the property that $f(x_2) > f(x_1)$ whenever $x_2 > x_1$.

[7] In other cases, it may be difficult or impossible to determine exactly, but the important Central Limit Theorem ensures that it will be very nearly normal in most circumstances.

[8] Technically, the precision is the reciprocal of the square of the s.e., that is, of the variance of the sampling distribution.

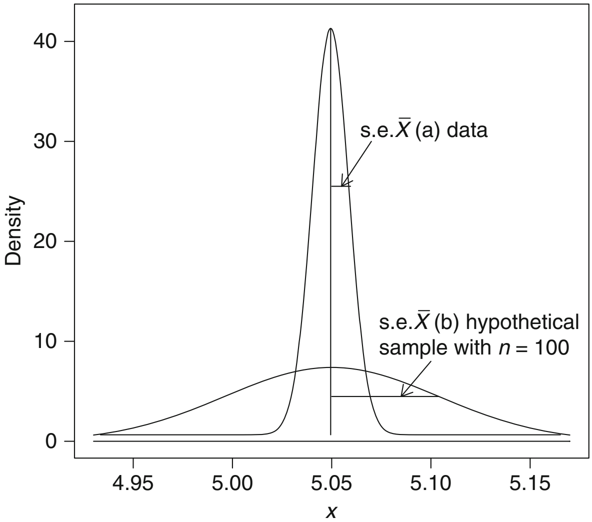

Fig. 26.6 Sampling distribution of $\bar{X}$ for samples of different sizes (**a**) for actual HBA1c data; (**b**) for a hypothetical sample of size 100

26.3.4 Estimating the Variance of the Normal Distribution

The same fundamental issues apply to the properties of $\hat{\sigma}$, but – as noted above – the theory works out better if we consider the properties of the variance estimator $\hat{\sigma}^2 = Q^2/n$. Elementary probability theory tells us that

$$\mathrm{E}[Q^2] = (n-1)\sigma^2, \tag{26.11}$$

so we can see that the MLE of σ^2 is biased, the unbiased estimator being $Q^2/(n-1) = S^2$, say. Unless n is small, the difference will not be important, but it is more usual to use the unbiased estimator than the MLE; we confine our attention to the properties of this estimator from here onwards.[9]

As with $\bar{X}$, the distribution of S^2 may be very hard to determine in general, though for a normal parent it has a distribution known as the chi-squared with $n-1$ degrees of freedom (d.f.).[10] For a general distribution, the standard error of S^2 is more difficult to determine than that of $\bar{X}$ since it depends on further properties of the parent distribution, but it is known for a normal parent and is given by s.e. $[S^2] = \sigma^2 \times \sqrt{2/(n-1)}$. We rarely make use of this, however, since the distribution of S^2 is skew – making its s.e. less informative – and in any case estimation of the variance of a sample is of secondary importance compared with estimating its mean.

[9] Interestingly, because the unbiased estimator has slightly greater variability, neither this nor the MLE has the smallest mean squared error – the estimator with this property is $Q^2/(n+1)$.

[10] The chi-squared distribution with k d.f., denoted by χ^2_k, may be defined as the distribution of the sum of squares of k independent variates having the standard normal distribution.

26.3.5 Estimating the Mean of the Poisson Distribution

The log-likelihood for a sample of n observations $x_1, x_2, \ldots, x_n$ from the Poisson distribution is given, from (26.3), by:

$$\ell(\lambda; x_1, x_2, \ldots, x_n) = k - n\lambda + \log \lambda \times \sum_{i=1}^{n} x_i, \quad \lambda > 0, \tag{26.12}$$

where, as before, k is a constant not dependent on the parameter. From this, we easily find that the MLE of λ is $\hat{\lambda} = \bar{X}$, the sample mean, and it can also be seen that this a sufficient statistic. The standard error of $\hat{\lambda}$ is $\sqrt{\lambda/n}$, and this is best estimated by $\sqrt{\hat{\lambda}/n}$, not by reference to the sample variance s^2. We can see too that the total count over the whole sample, that is, $T = \sum X_i$, is a sufficient statistic, and we know that it also has a Poisson distribution, with mean $n\lambda$. It follows that we could just as well estimate λ using the total count, the individual observations providing no further information as long as they really do have a Poisson distribution.

26.4 Hypothesis Testing

We turn now to a second major mode of frequentist inference, namely the testing of hypotheses. Typically, this is concerned with the testing of specific values of some parameters in a model like those of our first three examples. Very often, the values of these parameters are indicative of the data *not* establishing anything unusual, such as a hypothesis that there is no difference between two populations or that some parameter value has the value predicted by a simple model. For this reason the hypothesis tested is known as a *null hypothesis* and is universally referred to as H_0. A result leading to the rejection of H_0 is said to be *statistically significant* and the process of determining the test outcome is sometimes referred to as *significance testing*.

Some null hypotheses are so far reduced to fundamentals that they avoid specifying a parametric model at all. An example of this is the hypothesis that cases of a particular disease are no nearer to one another in space and time than would be expected by chance and it is possible to test this hypothesis by a procedure that makes no assumptions about the actual spatio-temporal distribution of the population at risk (cf. chapter ▶Geographical Epidemiology of this handbook). It is generally agreed that such tests are inherently less informative than tests in parametric models, but it can easily be realized that specifying a parametric model for the clustering of disease cases is very far from easy; such *non-parametric tests* are consequently attractive and very popular.

The actual procedure for testing a hypothesis appears in two related forms, which we deal with in turn.

26.4.1 The Formal Approach

The first approach follows that of Neyman and Pearson (1933), whose work in the second quarter of the twentieth century put the theory of testing on a firm foundation for the first time. Following the frequentist line of thought, they considered the repetition of a given testing procedure and defined the probabilities of making two kinds of error, the (type I) error of rejecting H_0 when it is true and the (type II) error of failing to reject H_0 when it is false. The probabilities of these two errors are usually denoted by α and β, and it is clear that if we choose a test procedure to reduce one of these probabilities, we will almost certainly increase the other so that there is a trade-off between the two types of error. To some extent, the choice of a test procedure then depends on the relative importance the experimenter attaches to each. We note, however, that the calculation of β is often far from straightforward since it requires the specification of an *alternative hypothesis* – usually denoted by H_1 – and it is generally unclear what this should be. We return to this point below.

This rather formal approach then proceeds along the following (rather simplified) lines:

1. A *simple* hypothesis H_0 is specified – that is, one that completely determines the distribution of the observed data, including the values of any parameters;
2. The set of all possible outcomes for the experiment (the so-called *sample space*) is identified and a *critical* (or *rejection*) *region* $\mathcal{R}$ is defined such that:
    a. The probability of the experimental outcome falling in $\mathcal{R}$ when H_0 is true equals a preassigned probability α, typically chosen to be 5%.
    b. Such an event casts doubt on H_0 in some scientifically significant way.
3. We reject H_0 if and only if this outcome is actually observed.

If we adhere to this procedure – which we assume to be specified in advance of observing the data – then we can be sure that, in the long run, we will make the type I error of wrongly rejecting H_0 on $100\alpha\%$ of occasions on which H_0 is true. It cannot be emphasized too strongly that this says nothing about how probable it is that we are wrong on a particular given occasion: all we can conclude from a rejection of H_0 is that something has happened that would be unusual if H_0 were true. The specification of $\mathcal{R}$ as a region suggests an almost unlimited number of different possibilities, but it frequently turns out that $\mathcal{R}$ can be defined in terms of a range of values for one particular statistic, such as a sample mean or a proportion.

26.4.2 Testing the Mean of a Normal Distribution

We have already studied the sampling distribution of the mean of a random sample from a normal distribution. Suppose we have such a sample and we wish to test the null hypothesis that the population from which the sample was drawn has a specified mean, μ_0, say. For simplicity, we will assume that the SD of the population

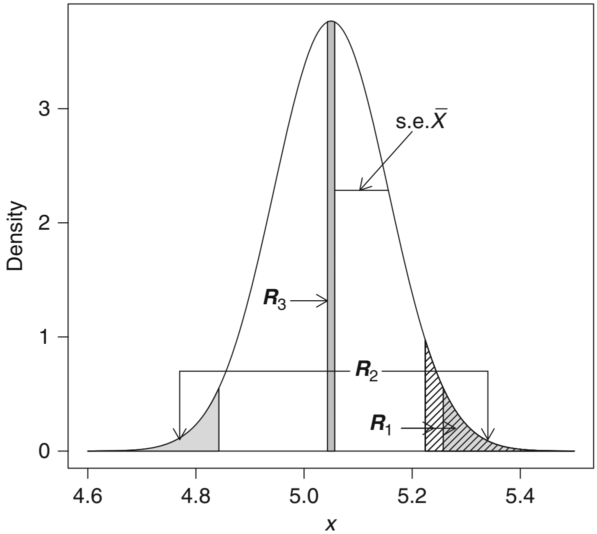

Fig. 26.7 Three different critical regions for a test of $H_0 : \mu = 5.05$ based on the HbA1c data (see text); the one-sided region (R_1) is *hatched*; the two-sided (R_2) and central (R_3) regions are *shaded*

distribution is known or specified and equal to σ_0, say. We know that the MLE of μ is $\bar{X}$, and we have also seen that it is sufficient, so it is a reasonable choice of test statistic, that is, we will use values of $\bar{x}$ to define a suitable critical region $\mathcal{R}$. Our critical region is then defined as a region on the $\bar{x}$ axis such that the probability that $\bar{X}$ falls in $\mathcal{R}$ is equal to our chosen α, which we will take to be 5%.

This does not in itself determine the region we should use; for example, Fig. 26.7 shows three critical regions of the right size, that is, three regions each having the property that the area under the normal density curve for $\bar{X}$ is $\alpha = 0.05$. There is no obvious choice for an alternative value of μ in this case, so we consider a *composite* alternative, that is, one that permits more than one possible value of μ. In particular, we might specify merely that $H_1 : \mu > \mu_0$. In this case, it would be sensible to choose the critical region $\mathcal{R}_1$ for $\bar{X}$ in the right-hand tail of the distribution under H_0, as shown hatched in Fig. 26.7. It is easily determined from tables of the normal distribution that, for $\alpha = 0.05$, the critical value of $\bar{x}$ is $\bar{x}_0 = \mu + 1.645\sigma_0/\sqrt{n}$; this region is termed one-sided.

However, we recall that this choice of test must be determined *before* we see the data, and it could have been the case that the mean for our patients would be *less* than μ_0. If we choose a one-sided test, such as that determined by $\mathcal{R}_1$, we must of course accept H_0 however small $\bar{x}$ may be. Such a result might be completely unexpected in the light of what we know about diabetes and blood glucose, for example, but it could nevertheless be very important to report it. Because nobody would expect an experimenter to ignore something important that was entirely unexpected, one would be right to be sceptical about the use of a one-sided test, and it is recommended practice in such situations always to use a test capable of detecting a deviation on either side of the null value.

Such a *two-sided* test is provided by the region $\mathcal{R}_2$, which has two parts (shown shaded). It is obvious that we now have to share the probability α between the two tails and – provided we keep α the same – this necessarily pushes the critical value(s) further out into the tails, thus reducing the chance that a positive deviation will fall in the critical region. The critical value of $\bar{x}$ is now 1.96 standard errors of $\bar{X}$ away from the mean.

The reader may wonder about the region $\mathcal{R}_3$ shown in Fig. 26.7. Such a region – although having the correct value of α – would be very unusual: clearly it will not detect values of μ very different from the hypothetical value. Indeed, it will reject H_0 if the sample mean is *too close* to μ_0; such a test might be appropriate if we suspected that the data were "too good to be true" in some sense; more usefully it could be an indicator of something wrong with the calculations in the test procedure, though it is unlikely that this alternative hypothesis would have been postulated a priori.

Example 26.4. Comparing HbA1c data with a standard
Czerniawska et al. (2008) studied the levels of HbA1c in 77 patients diagnosed as suffering from obstructive sleep apnea (OSA) and 22 controls. We will examine just the 26 OSA patients who were classified as not obese. To determine whether these patients have a "normal level" of glycolated hemoglobin, it might be thought reasonable to test the hypothesis that the patients have a distribution like that reported in Example 26.2, that is, a normal distribution with mean $\mu = 5.05$ and SD $\sigma = 0.54$. For this sample of 26 patients, a 5% two-sided test would have critical values of $\bar{x}$ satisfying $|\bar{x} - \mu_0| > 1.96\,\sigma_0/\sqrt{n}$, that is, outside the interval (4.84, 5.26). The non-obese OSA patients actually had a mean HbA1c of 5.4, which is therefore clearly in the critical region; we say that the OSA patients have a mean HbA1c significantly larger than the France Telecom population.

Testing the Difference of Two Means The same distribution theory leads to a test of the hypothesis that two samples come from normal distributions with the same mean, albeit that they may have different variances. It is an important property of the normal distribution that the sum or difference of two independent normal variates is also normally distributed, with mean and variance equal to the two respective sums. It follows that, if $n_1, n_2, \bar{x}_1, \bar{x}_2, s_1, s_2$ are the sizes, means, and standard deviations of samples from two normal distributions, then the statistic

$$z = \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{s_1^2/n_1 + s_2^2/n_2}} \tag{26.13}$$

has approximately a standard normal distribution, that is, with mean zero and variance one.

Example 26.5. Child IQ and maternal depression
Table 26.1 summarizes two samples of data on children's IQs according to whether their mothers had suffered from postnatal depression; the data were from Dr. Channi Kumar of the Institute of Psychiatry in London and are reported in full in Everitt (1994).

Table 26.1 Summary of IQs of children of depressed and non-depressed mothers

	No. of cases	Mean	SD	s.e.
Depressed	15	101.1	27.0	6.97
Not depressed	79	112.8	14.3	1.61

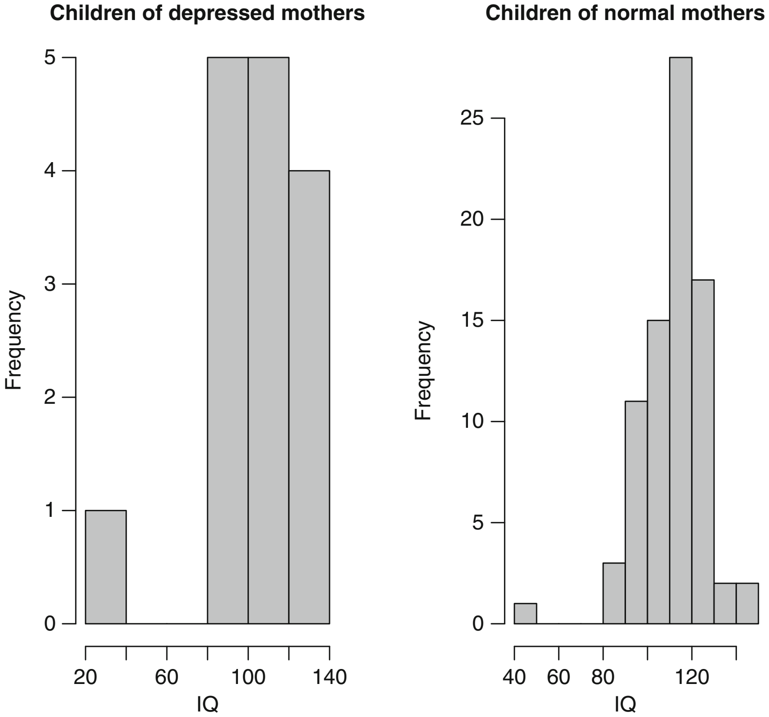

Fig. 26.8 Distributions of child's IQ in samples of depressed (*left*) and non-depressed (*right*) mothers

Applying (26.13) to these data gives $z = -1.64$, for the difference between the IQs of the children in the depressed and not depressed groups. We would not reject H_0 in a two-sided test, even when $\alpha = 0.10$. The distributions of the data are shown in Fig. 26.8, and we note that, although the samples are quite small, there is at least an appearance of non-normality in the data. We will consider alternative methods of analysis in Sects. 26.4.7 and 26.4.8, Examples 26.10 and 26.11.

26.4.3 The Power of a Test

The formal approach outlined above (Sect. 26.4.1) does not require us to specify the distribution of the observations when H_0 is not true. It is important to realize that whether we should really believe H_0 should depend on whether there are other hypotheses to be considered that are reasonably plausible in the light of the data. It may be, for example, that a small p-value can be matched by a comparably small value under a very plausible alternative "null" hypothesis, in which case it would seem more reasonable to ascribe the results to chance, at least in part. A non-significant result, on the other hand, might be due to a high value of β.

Calculating β in advance of an experiment is generally held to be an important part of the planning stage, and this is usually done in terms of the *power* of the test, defined as $1 - \beta$. A study with a low power is quite reasonably less likely to attract funding. Our problem is that, in most situations, we can only make an intelligent guess at an alternative hypothesis; the resulting power calculation will be hypothetical. Nevertheless, it is a useful discipline to make this calculation – perhaps for a range of different alternative hypotheses.

It is tempting to calculate the power after a study, using the parameter estimates as suitable values for the alternative hypothesis. This so-called "observed power" is sometimes used to assess the weight of the evidence for the null hypothesis, using the argument that a non-significant result might be due to low power, thus making it more likely that H_0 is true. This can be a very misleading argument and lead to what Hoenig and Heisey (2001) call the "power approach paradox." Imagine two experimental outcomes giving non-significant p-values, with $p_1 < p_2$. Because observed power is inversely related to the p-value, p_1 is indicative of higher "observed power"; this means that the p_1 experiment should have had a better chance of rejecting H_0 and the fact that it did not makes it more likely that H_0 is true, which contradicts the usual argument that a smaller p-value is associated with stronger evidence *against* H_0. In this rather unsettling example of flawed statistical reasoning, the essential error is the familiar confusion of the assessment of the probability characteristics of the testing procedure with the weighing of evidence from a particular analysis, though this manifestation of the confusion is heavily disguised and not generally recognized. The relative plausibility of different hypotheses is better quantified using the ideas discussed in Sect. 26.2.3 and again in Sects. 26.6 and 26.7.

In our description of the testing process, we appear to have conjured up a procedure largely on intuitive grounds. There is, however, an important result in mathematical statistics (the Neyman-Pearson lemma) which provides – at least in simple situations – a method of identifying the best $\mathcal{R}$ in the important sense of minimizing β for a fixed α. In particular, our choice of $\bar{X}$ and the critical region $\mathcal{R}_1$ is guaranteed to provide the most powerful test of H_0 against any one-sided alternative of the form $\mu = \mu_1 > \mu_0$. The situation is more complicated for other testing situations, but the lemma is nevertheless important, not least because it demonstrates the central role played by the likelihood in constructing a best test. In the normal case, the power for a given μ_1 is easily calculated; Fig. 26.9 illustrates how this can be done by considering the distribution of $\bar{X}$ under H_1 for a particular alternative value of μ_1. Thus, for example, we have a 65.6% chance of detecting an actual mean HbA1c of 5.3 in a two-sided test with $\alpha = 0.05$. If we repeat the calculation for many different values of μ_1, we generate the *power functions* shown in Fig. 26.10 for the one-sided and two-sided tests.

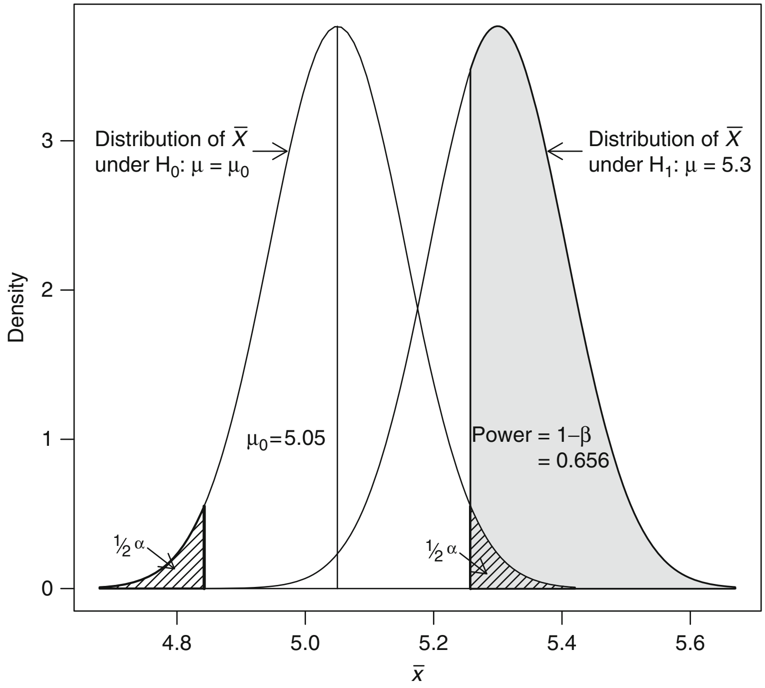

Fig. 26.9 Power of the two-sided 5% test of $H_0 : \mu = 5.05$ against $H_1 : \mu_1 = 5.3$ (HbA1c data)

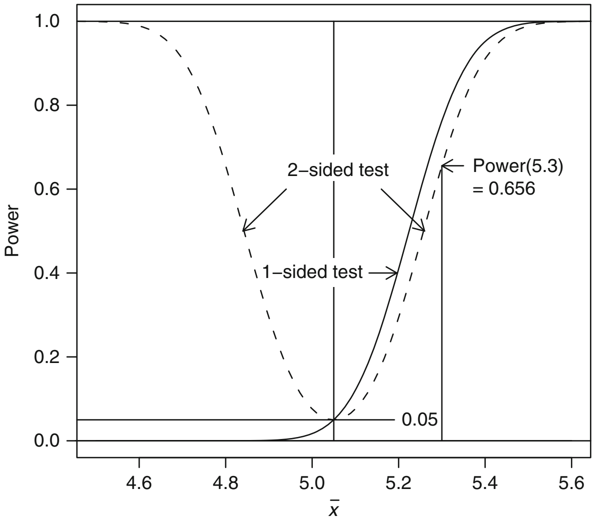

Fig. 26.10 Power functions for the one- and two-sided tests of the HbA1c data: test of H$_0$: μ = 5.05. The latter is indicated by the *broken line*

The normal model is extremely useful and is easily adapted to testing parameters in a wide variety of other models, using the fact that many parameter estimates are approximately normally distributed with standard errors that can be estimated reasonably well.

26.4.4 The p-Value Approach

One of the objections often raised against the formal Neyman-Pearson approach to testing hypotheses is that it is too "hard and fast." When we reject a null hypothesis, we are not establishing a logical statement since our conclusions inevitably involve uncertainty. It seems ridiculous to come to radically different conclusions according to whether our value of a sample mean is 1.95 or 1.97 standard errors bigger than μ_0. Arguably, we need a quantitative measure of the plausibility of H_0. Such a measure often advocated is known as the p-value. This is defined in the normal case as $\mathrm{P}[\bar{X} \geq \bar{x}_{\text{obs}}|H_0]$, that is, the probability that – if H_0 is true – we would observe a value of $\bar{X}$ at least as different from μ_0 as $\bar{x}_{\text{obs}}$, the value we actually did observe. In our Example 26.4, we have $\mathrm{P}[\bar{X} \geq 5.4] = 0.000475$; a two-sided test therefore has a p-value of 0.00095, and we immediately conclude from the fact that this is less than 5% that we would reject H_0 at the level $\alpha = 0.05$. We have the further information that we would have rejected H_0 even if we had specified a much smaller value of α, say 0.1%.

26.4.5 Discrete Distributions

When we have a discrete distribution for our test statistic, it will generally be impossible to find a critical region $\mathcal{R}$ with a probability α exactly equal to some prespecified value. In this situation, it becomes convenient to use the p-value approach since we can still calculate the probability in the tail of the distribution. The resulting p-value tells us whether our statistic would be in a critical region of a given size if it were possible to construct one. We illustrate these ideas by continuing our binomial Example 26.1.

Example 26.6. Testing the probability in the meningitis data
An obvious null hypothesis for the meningitis data is $H_0 : p = 0.5$, that is, the assumption that males and females are equally likely, which we made in Example 26.1. It is a familiar result that the binomial distribution is well approximated by the normal distribution with the same mean and variance. We can use this to obtain a good approximation to the p-value by treating the sample proportion X/m as a normal variate with $\mu = p = 0.5$, $\sigma = \sqrt{\frac{1}{2} \times \frac{1}{2} \times \frac{1}{m}} = 0.0693$. Hence, the probability of observing a value of $\hat{p} = X/m$ greater than or equal to the observed $33/52 = 0.635$ is approximately the same as the probability that a standard normal variate (i.e., one with zero mean and SD $= 1$) is greater than or equal to $(0.635 - 0.5)/0.0693 = 1.94$. The probability of this can be determined from tables to be 0.026. This should be doubled to give a two-sided test since we have no a

priori reason to suppose that males are more frequent in this context. We are thus led to the conclusion that we should not reject H_0 at the 5% level and we can quote a p-value of $P = 0.052$.

Alternatively, we can carry out an *exact test* by simply calculating $\mathrm{P}[X \geq 33|p = 0.5] = 0.0352$, giving a two-sided p-value of 7%. This exemplifies the fact that the normal approximation underestimates the exact p-value quite seriously for moderately small values of m, p, or $1 - p$. In fairness, the approximation would be considerably improved if we applied a *continuity correction*, which consists in reducing the absolute difference $|0.635 - 0.5|$ by $1/2m$; applying this adjustment gives a one-sided p-value of 0.0357, in good agreement with the exact calculation. The adjustment tends to overcorrect (and is therefore conservative) when m is small or p is near zero or one, but the relative error is substantially smaller than for the uncorrected approximation.

The Poisson Distribution Testing a simple null hypothesis specifying that one or more observations come from a Poisson distribution with a prescribed mean proceeds in a similar manner to the equivalent problem for the binomial distribution. Use of a normal approximation needs care when the information is limited. As a rule of thumb, the expected total of the observations should equal at least 100 to obtain reasonable accuracy in the tails; otherwise it is safer to conduct an "exact" test, summing the probabilities in the tails; see Armitage et al. (2002, Sect. 3.8) for comparisons between the exact and approximating values.

Although full information on a sample of n values $x_1, x_2, \ldots, x_n$ gives no more information about λ than the total $\sum x_i$, it does provide the possibility of checking the Poisson assumption by comparing the sample mean $\bar{x}$ and variance s^2. The ratio of these two statistics should be about one, and we can test it by forming $D = (n-1)s^2/\bar{x} = \sum(x_i - \bar{x})^2/\bar{x}$; this has an approximately chi-squared distribution with $n - 1$ degrees of freedom (d.f.) under the null hypothesis that the observations come from a Poisson distribution. We can use this to check our judgment that the emergency admissions data in Example 26.3, Fig. 26.3, are distributed in accordance with a Poisson distribution.

Example 26.7. Dispersion test for emergency admissions data

The sample of daily emergency admissions in Example 26.3 has mean 3.92 and variance 3.39. The "dispersion test" statistic described above is therefore $103 \times 3.39/3.92 = 89.1$. We can test it by reference to the chi-squared distribution with 103 d.f., which has an upper 5% tail point of 127.7, so that the mean and variance are not significantly different, testing at the 5% level. We justify using a one-sided test on the grounds that there is no plausible reason why the variance should be less than the mean. A variance greater than the mean, however, is very common, and it is indicative of the different observations having expectations that vary for one reason or another. In our case, for example, there could have been a seasonal effect leading to an inflation of the variance. Such data are termed *overdispersed* and the phenomenon is sometimes called *extra-Poisson variation*. It is not, however, necessary to abandon the Poisson distribution itself as an underlying mechanism; it will occur wherever occurrences of the phenomenon being counted are truly independent of each other. Infections or genetic diseases are likely to violate the independence requirement, but other diseases generally do not.

26.4.6 Goodness-of-Fit Tests

The dispersion test described above is an example of a goodness-of-fit test; such tests are important because can they provide a check on the assumptions of our model. There are many such tests and we illustrate here the elementary chi-squared test, attributed to Karl Pearson,[11] which is used for comparing a set of frequencies with expectations computed under a suitable model.

We suppose that we have a collection of k counts $f_1, f_2, \ldots, f_k$, as for example in a histogram. We compute a matching set of expectations $e_1, e_2, \ldots, e_k$ under assumptions about the origin of the frequencies that we wish to test. It will often be helpful to arrange the frequencies in the form of a table like Table 26.2; in more complicated situations, the same basic test can be applied to multi-dimensional tables. The statistic is calculated as

$$X_\nu^2 = \sum_{i=1}^{k} (f_i - e_i)^2 / e_i, \tag{26.14}$$

which has approximately a chi-squared distribution with ν d.f., where $\nu = k - c$ and c is the number of constraints between the frequencies and their expectations. There will usually be at least one such constraint since we will calculate the $\{e_i\}$ to ensure that $\sum e_i = \sum f_i$. Further constraints will arise in various ways, for example, from the estimation of parameters of a distribution determining the $\{e_i\}$. For the chi-squared approximation to work well, we should ensure that the expectations are not too small and this can be achieved by judicious grouping; a lower limit of 5 is generally regarded as being quite safe.

Example 26.8. Goodness of fit of emergency admissions data
Table 26.2 shows the frequencies displayed in Fig. 26.3 for Example 26.3, together with expectations calculated by multiplying the probabilities of the Poisson distribution by the total number of observations, 104. The tail of the original distribution was truncated as shown, and for testing purposes, the first two cells were also grouped in order to ensure that there are no expectations much smaller than five. The resulting Pearson's chi-squared statistic is 3.53, and this has $8 - 2 = 6$ d.f. since we have estimated the mean of the data. Since $P = 0.74$, this clearly confirms the impression that the fit of the data to the Poisson distribution is very good. Neither this test nor the dispersion test (Example 26.7)

Table 26.2 Daily female admissions to a London teaching hospital on Saturdays and Sundays and the frequencies expected in a Poisson distribution with the same mean

No. of admissions:	0	1	2	3	4	5	6	7	8+
Observed	2	7	14	22	22	15	14	6	2

[11] Karl Pearson (1857–1936) effectively founded the discipline of scientific statistics at University College, London, in the first quarter of the twentieth century; his son E.S. Pearson was the first Professor of Statistics in the same college.

rejects the hypothesis that the data come from a Poisson distribution. We should note that they are sensitive to different kinds of departure – individual frequencies that are too high or too low and overall spread, respectively. Thus, although the dispersion test will not be powerful for detecting aberrant frequencies, Pearson's chi-squared test (26.14) will be less good at detecting outlying individual values, which will typically have to be grouped in a neighboring cell.

The same method can be used to test for the goodness of fit to the other distributions we have introduced, remembering that for the normal distribution, for example, we need to deduct a further degree of freedom to allow for the estimation of the variance. The asymptotic chi-squared distribution of X_ν^2 results from approximation theory related to the Central Limit Theorem. An alternative approach also commonly encountered is based on asymptotic likelihood theory and involves a "deviance statistic" of the general form:

$$D = 2\sum_i [f_i \log(f_i/e_i) - (f_i - e_i)], \qquad (26.15)$$

reflecting individual contributions to the log-likelihood. This statistic also has an approximate chi-squared distribution when the expectations are not too small; the number of d.f. is the same as for X_ν^2. With moderately large amounts of information, it will give very similar results to Pearson's chi-squared. For Example 26.8, the value is 1.95, for which $P = 0.92$; in larger datasets, the two statistics will be closer for theoretical reasons. The deviance is frequently encountered for testing agreement in more complicated models, such as logistic and Poisson regressions (cf. chapter ▶Geographical Epidemiology of this handbook).

Example 26.9. Dispersion of traffic accident data
As a further example, we consider the annual numbers of road accidents in the UK town of Bolton, Lancashire, in the 10 years 1999–2008, posted on the Greater Manchester Transportation Unit website (http://www.gmtu.gov.uk/). The counts are shown in Table 26.3; there are too few to perform a goodness-of-fit test to the shape of each distribution. The dispersion test for the distribution of the 98 fatal accidents gives $X_9^2 = 12.4$ ($P = 0.19$), with 9 d.f., and this test is equivalent to the Pearson's chi-squared test (26.14) of the hypothesis that all the expectations e_i are equal to $98/10 = 9.8$. Substituting into the deviance statistic (Eq. 26.15) instead, we obtain $D = 12.9$, a value close to the dispersion statistic. It also has a chi-squared distribution with 9 d.f. Neither result is significant, but if we apply the same tests to the non-fatal serious accidents, we find a significant departure from the null hypothesis, with $X_9^2 = 17.81$, $D = 17.70$, $P = 0.037$, 0.039, respectively. This is not really surprising since traffic volumes and conditions will have changed quite a lot over 10 years, inducing different expectations for the different years. The fact that fatal accident rates appear not to depart from the null hypothesis is almost certainly due to the

Table 26.3 Annual numbers of road accidents in Bolton, Lancashire, by severity

Year	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008
Slight	1,124	1,234	1,149	1,023	1,017	942	947	857	797	698
Serious	102	96	84	77	98	83	107	77	74	69
Fatal	4	15	11	10	7	14	7	14	7	9

smaller numbers. This is borne out by the dispersion statistic for the more numerous slight accident data, $X_9^2 = 253$, which is so extreme that it is not worth calculating the p-value.

26.4.7 Non-Parametric Tests

In Sect. 26.4.2 (Example 26.5), we tested the difference between two means using the fact that sample means are at least approximately normally distributed. This methodology assumes that we can ignore sampling variations in the estimation of the variances, which will be less true for small samples. The well-known t-distribution known as Student's t-distribution (see Sect. 26.5.1) provides methods allowing for this problem, but their reliability and effectiveness depend on the normality assumption. In small samples and with very non-normal parent distributions, these methods may give misleading p-values, and we seek different methods not dependent on assumptions about the form of the parent distribution. Tests of this kind are termed *non-parametric* tests.

Centrally important in such methods are those based on ranks. For the comparison of two independent samples, for example, the rank sum test ranks *all* the observations (in order of increasing magnitude) and then determines the sum W of the ranks in the smaller sample: a sum that is smaller than might be expected by chance is clearly indicative of a distribution located below that of the larger sample. Tables are available to determine the significance of W for given sample sizes, the null hypothesis being that the two samples come from the same parent distribution, which is the only assumption made. This test is usually known as the Mann-Whitney U-test, though it is also attributed to Wilcoxon (1945); variant tests based on ranks are available for the case of related samples (of paired observations) and for more complicated situations.

Example 26.10. Rank sum test of IQ depression data
Applying the method described above to the IQ depression data from Example 26.5 requires an adjustment for breaking the ties. The resulting sum of the ranks in the smaller sample is $W = 408.5$, giving $P = 0.058$ in a two-sided test, smaller than the p-value of 0.11 for the normal-based test in Example 26.5. One might have expected to find a smaller p-value in the procedure based on the normal distribution since it makes stronger distributional assumptions. In this example, however, the reliability and the power of the normal-theory procedure are impaired by the inflation of the variance estimate caused by the outliers – that is, the unusually small IQs – in both samples.

26.4.8 Monte Carlo Tests

The rank sum test is one of a class of tests known as *permutation tests*. The null hypothesis merely specifies that any of the values actually observed is equally likely to have come from either sample, subject only to the requirement that n_1 of the combined sample of $n_1 + n_2$ must come from the first sample. We can imagine writing the values on individual cards, shuffling the pack and selecting n_1 from the resulting pack to constitute an imitation first sample, the remaining ones constituting the second sample, of course. If we repeated this procedure a large number, say N, of times, we could compute a sequence of values $W_1, W_2, W_3, \ldots, W_N$, and this would provide an estimate of the true null distribution of W, which we could then use to check the calculated p-value for our observed statistic W_{obs}, say. Specifically, the proportion of the simulated Ws that are greater than or equal to (or less than or equal to) W_{obs} provides an unbiased estimate of the true p-value of the null distribution in a one-sided test of the right (or left)-hand tail of the distribution.

In fact, this check is unnecessary for the rank sum test since it is possible to calculate the null distribution of W for any given n_1, n_2. This is because the value of W depends only on the ranks, not the values of the actual observations. The idea does, however, suggest a very wide-ranging method for estimating the p-value for any test of a simple null hypothesis. We could, for example, test the difference between two independent samples using a suitable function of the actual observations, such as the z-statistic (Eq. 26.13) we have already used in Example 26.5; the permutation test allows us to estimate the p-value without having to specify any model for the parent distribution. Clearly, the precision of the estimate of the true p-value depends on N, and its s.e. is easily estimated using the binomial distribution. Tests of this kind are known as Monte Carlo tests.

Example 26.11. Monte Carlo test of IQ depression data
In an application of the Monte Carlo method to the IQ depression data (Example 26.5), 10,000 datasets were constructed by sampling from the 94 IQs observed in the two samples and selecting 15 IQs at random (and without replacement) for the depressed sample. Applying (26.13) to each dataset in turn yielded a set of z scores with mean -0.15 and variance 1.11, both substantially different from the expected theoretical values of 0 and 1. Of the simulated values, 322 were greater than or equal to the observed value $z_{\text{obs}} = 1.64$ so that a two-sided p-value is estimated to be 0.064. We might have expected the actual z-value to have the smaller p-value, but the latter is inflated by the large variances induced by the outlying observations. In any case, comparing individual p-values for different tests is not a good guide to the respective powers of the tests.

A variant of this procedure – also known as a Monte Carlo test – provides an exact test with a specified type I error (Marriott 1979). More generally, the term "Monte Carlo" includes a wide range of methods for statistical inference of considerable importance in modern statistics. None of them, however, is as simple and effective as the procedure described above for testing a simple null hypothesis.

26.5 Confidence Intervals

We saw in Sect. 26.3 that the sampling distribution of an estimator provides a way of quantifying how close an estimate is likely to be to the *estimand* or parameter it estimates. We now describe how to make this more precise by constructing *confidence limits* and *confidence intervals*.

26.5.1 Confidence Limits for the Normal Mean

Since we know that the mean of a sample from a normal distribution is itself normally distributed with mean μ and SD equal to $\sigma/\sqrt{n}$ (see Sect. 26.3.3), we can write, for example,

$$0.025 = \mathrm{P}[\bar{X} > \mu + 1.96\sigma/\sqrt{n}] = \mathrm{P}[\mu < \mu_L] \text{ where } \mu_L = \bar{X} - 1.96\sigma/\sqrt{n}. \tag{26.16}$$

The quantity μ_L so defined is known as a *lower 97.5% confidence limit* for μ and has the interpretation that if we calculate it from a large number of independent samples in the same manner, then it will be less than μ on 97.5% of occasions.

In the same way, we can calculate an upper limit, namely $\mu_U = \bar{X} + 1.96\sigma/\sqrt{n}$. Then we have $\mathrm{P}[\mu > \mu_U] = \mathrm{P}[\mu < \mu_L] = 0.025$, and so these two limits define a 95% *confidence interval*:

$$\mathrm{P}[\mu_L < \mu < \mu_U] = 0.95, \tag{26.17}$$

and the probability on the right-hand side of this equation is known as the *confidence coefficient* of the interval. This equation needs to be interpreted with care. At first sight, it looks like a prediction interval for a random variable called μ, giving the probability that μ lies between two fixed limits. But in the frequency approach to inference, this is quite wrong. We must interpret it instead as a probability statement about a random interval, giving the probability that it contains the unknown parameter μ. We must envisage hypothetical repetitions of the experiment in which some intervals do, and some do not, contain the unknown μ, as illustrated in Fig. 26.11. The confidence interval calculated on a given occasion tells us nothing else about the probability that this particular interval contains μ.

Example 26.12. Confidence limits for the HbA1c data
The non-obese OSA patients had a mean HbA1c of 5.4 and SD of 0.8 so, using the expressions above, it is straightforward to calculate a 95% confidence interval for the mean HbA1c in the non-obese OSA patients as $5.4 \pm 1.96 \times 0.8/\sqrt{26} = (5.09, 5.71)$. Note that we have used the SD for the sample because we are no longer making the assumption that the sample was drawn from the standard population of Telecom subjects.

Because the sample is quite small and we have used an estimate of the underlying SD, which is itself subject to error, we can improve our calculation. It can be shown that, for a sample of size n from the normal distribution with parameters μ and σ, the statistic $T = \sqrt{n}(\bar{X} - \mu)/s$ has the distribution known as the Student's t-distribution[12] with $n - 1$ degrees of freedom (d.f.) – a parameter reflecting the number of observations contributing to the estimate of the variance – *regardless of the value of* σ. This remarkable result can be used to refine many of the procedures involving small samples from the normal distribution. It is one of the few really

[12] Student was the pen name of W.S. Gosset (1876–1937), who worked for Guinness, by whom he was not permitted to publish the results of his work.

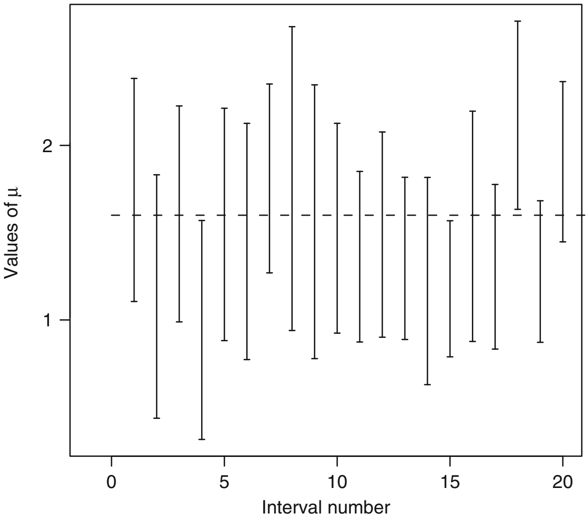

Fig. 26.11 Hypothetical repeated calculations of a 95% confidence interval for μ, which is shown by the *dotted line* since its precise position is unknown. Intervals 4, 15, and 18 just fail to include the true μ, compared with one interval expected

elegant and exact results in statistics and is unique to the normal parent distribution. As might be expected, the t-distribution looks quite like the normal distribution if n is not too small and indeed it gets closer as the sample size increases. For $n = 26$, the 97.5% upper limit of the appropriate t-distribution (i.e., with 25 d.f.) is 2.06, around 5% larger than 1.96. A recalculation of the confidence interval in Example 26.12 therefore gives $5.4 \pm 2.06 \times 0.8/\sqrt{26} = (5.08, 5.72)$, which is also about 5% longer than the approximate interval based on the normal distribution. We note that this interval does not include the reference (Telecom) value of 5.05, and it is quite easy to see from the arithmetic that this means that we would have rejected the null hypothesis $H_0 : \mu = 5.05,\ \sigma = 0.8$ in a two-sided t-test at the 5% level.

26.5.2 Confidence Intervals and Hypothesis Tests

This observation – that we would reject a null hypothesis concerning a parameter that does not fall in the confidence interval – is perfectly general, and it affords a powerful approach to the construction of confidence intervals. We have the following principle:

> ***Equivalence Principle:*** *Given a test of a simple null hypothesis $H_0 : \mu = \mu_0$, with type I error α, the set of all values of μ_0 that would not be rejected by this test defines a $1-\alpha$ confidence interval for μ.*

Clearly, if we construct a $1 - \alpha$ confidence interval in this manner from a particular test statistic and the value μ_0 is not included in this interval, then the test will reject $H_0 : \mu = \mu_0$ at level α. We assume that the resulting set of parameters forms a single interval; otherwise we can use the word "region." This word also covers the case where we have more than one parameter and the resulting region is in two or more dimensions. It is frequently much easier to carry out a test of a simple parametric hypothesis than to calculate the corresponding confidence interval or region; in this case, the limits of such an interval can often be conveniently calculated by considering a number of hypothesis tests. An example follows in the following subsection.

26.5.3 Confidence Limits for Binomial Data

As with hypothesis testing, discrete data pose a problem. We consider, for example, a confidence interval for the parameter p of the binomial distribution. As with the hypothesis testing situation, we could use a normal approximation to the distribution of X with a SD of $\sqrt{mp(1-p)}$. But to substitute $\hat{p}$ for p is unsatisfactory for constructing a confidence interval since we cannot assume a single value for p – it is after all our object to estimate this unknown parameter. However, if we can find values (p_L, p_U) of p such that

$$\frac{x - mp_L - \frac{1}{2}}{\sqrt{mp_L(1-p_L)}} = 1.96 \text{ and } \frac{x - mp_U + \frac{1}{2}}{\sqrt{mp_U(1-p_U)}} = -1.96, \qquad (26.18)$$

then these values of p will be 95% confidence limits for p to a good approximation provided mp and $m(1-p)$ are not too small – say, at least 10. As before, the $\frac{1}{2}$s are a continuity correction that can substantially improve the approximation.

For smaller values of mp and $m(1-p)$, however, we should like to find a method analogous to the exact test described in Sect. 26.4.5. Now we must find the critical values of p that just make the observation x significant in the left- or right-hand tails, that is, we seek solutions p_L, p_U to the equations:

$$\sum_{j=0}^{x} \binom{m}{j} p_U^j (1-p_U)^{m-j} = \sum_{j=x}^{m} \binom{m}{j} p_L^j (1-p_L)^{m-j} = \alpha/2. \qquad (26.19)$$

Evaluating the terms in these sums for a given p and solution by trial and error is feasible, though not very elegant. In fact, an analytical solution exists that enables the answer to be evaluated using available computer routines or statistical tables; the reader is referred for a simple account to Armitage et al. (2002, Sect. 4.6). This so-called "exact" method is not quite as perfect as it sounds since it is actually conservative: the *coverage probability* or probability that the interval really does cover the true value of the parameter is guaranteed to be at least $1-\alpha$ but may in fact be appreciably higher.

Example 26.13. Confidence interval for probabilities in the meningitis data
If we apply the normal approximation (26.18) to the proportion discussed in Example 26.1, Sect. 26.2.1, we find a 95% confidence interval of (0.489,0.760). Multiplying the interval by $m = 52$ gives (25.4,39.5) for the mean of the binomial distribution, which is therefore almost certainly greater than 10; this suggests that the normal approximation should be

satisfactory. The conservative “exact” method, for comparison, gives (0.490,0.763), which is in good agreement. The fact that the interval just includes 0.5 accords with the finding that we cannot quite reject H_0.

Neither interval is truly exact, of course. The actual coverage error depends on the true value of p, and numerical calculations for different values of p lead to the conclusion that the errors in both intervals can be considerable and vary rapidly with changing values of p. Much recent work has been concerned with identifying the best method to use in given circumstances. For example, in a recent review, Agresti and Gottard (2007) recommend a method based on the “mid-P,” a modification to the exact test in which only half the probability of the observed x is included in the tail probability.

Example 26.14. Survival probability in meningitis data
A more challenging example is provided by data on the survival of the children with meningitis. Those with platelet counts below 10^{11} per liter have a markedly poorer survival, only 4 of the 21 in this category surviving the disease. Applying the normal approximation to this gives a 95% confidence interval for p of (0.063,0.426); 21 times the lower limit is only 1.32, which indicates that the normal approximation is unlikely to be good in this case. Application of the exact conservative method yields (0.054,0.419), and this method should probably be regarded as preferable in this case.

26.5.4 Confidence Limits for Poisson-Distributed Data

As with the binomial distribution, use of the normal distribution with the estimated standard error of the mean λ can be unsatisfactory for the construction of confidence intervals since this estimate is itself subject to significant sampling error; in any case, the true value that would be relevant is the value near the upper or lower limit we are trying to construct. It is not recommended that this approach should be used for the Poisson distribution unless the mean of the data exceeds 100 (see Armitage et al. 2002, Sect. 26.5.2). However, we can use the method analogous to (26.18), which gives us the following quadratic equations for the 95% limits, (λ_L, λ_U), based on a single observation x:

$$\frac{x - \lambda_L - \frac{1}{2}}{\sqrt{\lambda_L}} = 1.96 \text{ and } \frac{x - \lambda_U + \frac{1}{2}}{\sqrt{\lambda_U}} = -1.96. \qquad (26.20)$$

The exact method also proceeds along the same lines as in the binomial case (26.19), but using the probabilities for the Poisson distribution; this is to be preferred for inference from small observations, although, as with the binomial, it can be very conservative. Further details of this method are given by Armitage et al. (2002), Sect. 26.5.2.

Example 26.15. Daily rate of emergency admissions
We apply the different methods to the emergency admissions data from Example 26.3, remembering that for our purposes the data are equivalent to a single observation equal to the total number of admissions, 408. To obtain an interval for the mean number of admissions per day, we merely divide by 104, the number of observations. Because the

total is quite large, we would expect the methods to give very similar results, and this is indeed the case: (26.20) is perhaps the method of choice here and gives a 95% confidence interval of (3.56,4.33) for the daily mean. The rather cruder interval $\hat{\lambda} \pm 1.96\sqrt{(}\hat{\lambda})$ gives (3.54,4.30), while the exact method, choosing the values of λ to give tail probabilities of 2.5% (or referring to Eq. 5.6 in Armitage et al. (2002)), gives (3.55,4.32).

26.5.5 Perspective on Confidence Intervals

As mentioned above, we can construct confidence regions in multiparameter situations, to give, for example, an elliptical region for a pair of parameters. As might be expected, the methodology is distinctly more difficult, since we are no longer able to invert a simple inequality as we did in Eq. 26.16; only in a few cases is there any analytical theory available to help us, and we often have to resort to serious amounts of computational trial and error. An even more challenging problem arises in multiparameter situations when we try to construct an interval for a single parameter. Difficulties arise because parameters are generally interrelated – we should avoid speaking of their independence in a frequentist context since this is a property of random variables, and their probability distributions. But more frequently than not, parameter estimates are themselves dependent variables and this means that information on one parameter conveys information (albeit fairly indirectly) on other parameters. It is therefore not generally permissible merely to substitute estimates of the uninteresting, so-called *nuisance* parameters and construct an interval using methods that assume we know the other parameters. It is true that this is what we have already done in this chapter when we used a large-sample estimate for σ in a normally distributed sample, for example – but there are special considerations that apply to the normal distribution. We should be aware that this does increase the uncertainty in our inferential process somewhat and avoid doing it when the sample sizes are small. Fortunately, there are approximate methods available for this problem through the use of the likelihood (Sect. 26.6).

It is generally agreed that constructing a confidence interval or region is more valuable and informative than the execution of a single significance test, not least because, as the equivalence principle discussed above shows, every confidence interval incorporates many hypothesis tests of interest, whereas a single hypothesis test does not permit construction of an interval. However, the same principle makes it clear that the difference is not of a fundamental kind. The confidence interval still describes long-run properties of a procedure using probabilities on the experimental scale, *not* on the scale of plausibility of our model. It may even be that, as with the p-value, the apparent quantification of uncertainty can give an impression that is more misleading than a formal significance test. Assessing the likeliness of a parameter value still requires a similar inferential inversion: we could, for example, conclude that it is unlikely that μ lies outside the calculated limits only because, if it does, something relatively unlikely has occurred and we know this does not happen very often. It is very important to keep this limitation in mind in all forms of frequentist inference.

26.6 Likelihood-Based Inference

We return now to the use of the likelihood, which – as we have already seen – provides a good general method for constructing point estimates. We have also intimated that the further a parameter value is from the MLE, the less plausible it is as a contending value, and we can quantify this statement by measuring plausibility in terms of the ratios of the likelihood L. Thus, we can construct a *likelihood interval* for a parameter μ containing all the values of μ for which $L(\mu) > \rho L(\hat{\mu})$, where ρ is a fraction such as 0.25, which we may call a *plausibility fraction*. We would then declare that values within the interval are at least a quarter as likely as the most likely estimate, where "likely" refers to plausibility in terms of the probability of the observed results for given values of μ. The value of ρ remains arbitrary, and it is not obvious that there is anything "universal" about our chosen value – that is, that it would make as much sense in one statistical context as another.

There is, however, a close connection with the frequentist concept of a confidence interval. The Neyman-Pearson lemma referred to in Sect. 26.4.3 determines a best test criterion in terms of the ratio of the likelihoods under two hypotheses, and consideration of the equivalence principle suggests that – as well as being a good way of establishing a test statistic and critical region for formal testing purposes – the ratio also provides a sensible way of establishing a confidence interval. Thus, we are led once more to the choice of an interval based on values of the likelihood, but now we will hope to choose the critical ratio ρ in such a way that it corresponds to a known confidence coefficient. We try this out for the normal mean, continuing Example 26.2.

26.6.1 Likelihood Interval for the Normal Mean

Working with the log of the likelihood and remembering that we are assuming σ to be known, we easily find from (26.8) that

$$\Lambda = \log(L(\hat{\mu})/L(\mu)) = \ell(\hat{\mu}) - \ell(\mu) = n(\bar{x}-\mu)^2/2\sigma^2 \tag{26.21}$$

since $\hat{\mu} = \bar{x}$. Hence, a region given by $L(\hat{\mu})/L(\mu) < 1/\rho$ is equivalent to one determined by

$$n(\bar{x}-\mu)^2/\sigma^2 < -2\log(\rho), \text{ or equivalently } \bar{x} - z_{\alpha/2}\,\sigma/\sqrt{n} < \mu < \bar{x} + z_{\alpha/2}\,\sigma/\sqrt{n}, \tag{26.22}$$

where $z_{\alpha/2}$ is the $1-\alpha/2$ percentile of the standard normal distribution for some probability α. Thus, the likelihood interval is equivalent to the interval we have already constructed in Eq. 26.17. Moreover, we can now relate the confidence coefficient $1-\alpha$ to the plausibility fraction ρ through the equations

$$\rho = \exp(-\tfrac{1}{2}z_{\alpha/2}^2) = 0.147 \text{ in the case } \alpha = 0.05. \tag{26.23}$$

Thus, a 95% confidence interval corresponds to the values of μ which are at least $\rho = 14.7\%$ as likely as the MLE. Our original proposal of $\rho = 0.25$ corresponds to a confidence coefficient of $1 - \alpha = 0.904$, just over 90%.

26.6.2 Likelihood-Ratio Tests

The same ideas apply of course to hypothesis testing – as we would expect in view of the equivalence principle (Sect. 26.5.2). If we can find the distribution of the likelihood ratio or its logarithm under a given H_0, then it will, in many circumstances, provide a good test. This will apply even when the ratio cannot be expressed in terms of a simple statistic and when H_0 specifies several parameters. Very often the distribution theory will not permit us to compute the distribution of the likelihood ratio exactly, but there is a very useful approximation theorem available.

Suppose that we have a simple null hypothesis $H_0 : \theta = \theta_0$, where θ is a parameter that may have several – say k – elements. Then, under fairly general conditions, and for reasonably large samples, the quantity $\Lambda = 2 \log \left(L(\hat{\theta})/L(\theta_0) \right) = 2(\ell(\hat{\theta}) - \ell(\theta_0))$ has a distribution that is approximately the chi-squared distribution with k degrees of freedom almost regardless of the true underlying distribution of the data. The approximation improves as the sample size increases, and it becomes useful for samples of moderate size in many situations. Moreover, the same result holds when H_0 is a composite hypothesis, requiring the estimation of $p < k$ parameters, in which case Λ has an approximately chi-squared distribution with p d.f. provided $L(\theta_0)$ is taken to be the maximum value of L consistent with H_0. This is one of a number of "asymptotic" results of considerable importance in statistics.

L-R Test for Difference of Two Proportions From (26.6), we find that the log-likelihood for binomial data is given by

$$\ell(p, m; x) = C + x \log(p) + (m - x) \log(1 - p), \tag{26.24}$$

where C is a constant which will cancel when we form the log-likelihood ratio. The log-likelihood for the two binomial samples is simply $\ell(p_1, m_1; x_1) + \ell(p_2, m_2; x_2)$, and the maximum value of this is obtained by substituting $\hat{p}_i = x_i/m_i$ for $i = 1, 2$. Under $H_0 : p_1 = p_2$, however, both ps are estimated by the same parameter, and it can be seen that this must be $\hat{p} = (x_1 + x_2)/(m_1 + m_2)$. Substituting these values into the expression for the binomial log-likelihood (26.24) gives the statistic Λ:

$$\Lambda = 2(\ell(\hat{p}_1, m_1; x_1) + \ell(\hat{p}_2, m_2; x_2) - \ell(\hat{p}, m_1 + m_2; x_1 + x_2)), \tag{26.25}$$

which has a χ^2_1-distribution.

Example 26.16. Comparison of survival rates in children with meningitis
Bortolussi et al. (1978) also record the survival of the children with meningitis according to their birthweight: of 26 children who were underweight (<2,500 g) at birth, 17 died, compared with 8 out of 26 with normal weights. Substituting these figures into Eq. 26.25 gives $\Lambda = 6.37$, which is significant at the 5% level ($P = 0.0116$).

26.6.3 Likelihood-Based Regions

The same theoretical result, in conjunction with the equivalence principle, provides a general method for constructing an approximate interval when there is no exact distribution theory, and also for confidence regions when there are two or more parameters. For example, Fig. 26.12 shows an approximate likelihood-based confidence region for the parameters (μ, σ) in the HbA1c data formed by the intersection of the log-likelihood surface and the plane $\ell(\mu, \sigma) = \ell(\hat{\mu}, \hat{\sigma}) - 3.00$, the constant 3.00 being half the 95% percentile of the chi-squared distribution with 2 d.f., that is, $\mathrm{P}[\chi^2_2 > 5.99] = 0.95$.

26.6.4 The Likelihood Approach

We have been at pains to emphasize that the probabilities derived in the frequentist inferential framework represent the long-run performance of statistical procedures, not the uncertainty in individual cases. Although this long-run performance is an invaluable guide to the choice of procedure, it leaves many statisticians unhappy and keen to find an alternative way to quantify the individual uncertainties. The support for different values of a parameter offered by the likelihood is undoubtedly

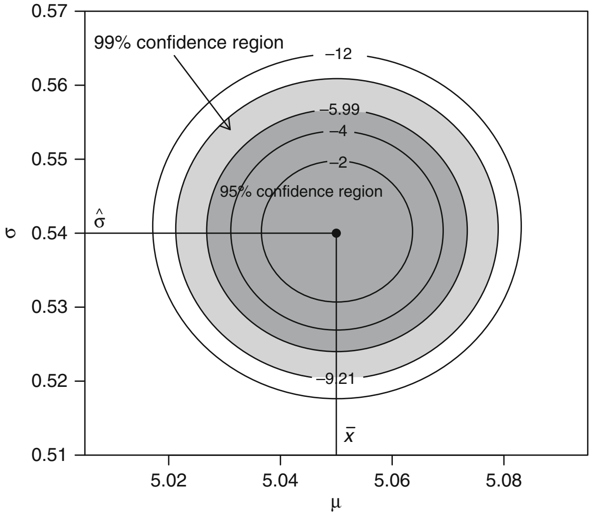

Fig. 26.12 Contours of the log-likelihood showing 95% and 99% confidence regions for μ and σ from the HbA1c data ($n = 3,240$; $\bar{x} = 5.05$; $\hat{\sigma} = 0.54$)

meaningful, and some authors[13] speak of the "supported range" for a parameter, meaning the range of values at least ρ times as likely as the maximum. We are now in a position to answer the question posed at the beginning of this section – namely whether the value of ρ we use would have the same significance in different situations. In terms of the coverage probability, the answer would seem to be "yes," but only provided we have the same number of parameters in the different situations. For example, a supported range with $\rho = 0.147$ corresponding to 95% coverage with one parameter should be compared with a *supported region* with $\rho = 0.05$ when there are two parameters, as in Fig. 26.12. In words, this means that a two-dimensional 95% confidence region corresponds approximately to those parameter values for which the likelihood is at least 5% of the maximum value.[14]

26.7 The Bayesian Approach

We saw in Sect. 26.2.2 that Bayes' theorem can be used to derive a probability for the truth of some statement about our model, for example, that a parameter lies in a given interval. We also saw that the posterior probabilities yielded by a Bayesian analysis depend on the prior probabilities that represent our scientific preconceptions.

We illustrate the ideas by revisiting our former examples, starting with the binomial distribution. We first introduce a notation to help to distinguish the different distributions involved. When necessary, we will continue to use forms of the symbol f to denote densities of observations, as in (26.2), for example. Because parameters commonly encountered are real numbers as opposed to integers, we also need to describe their probability distributions by means of density functions; to avoid confusion, we will use the symbol g instead of f for the densities of the parameters. We will distinguish between the prior and posterior densities for a parameter θ by using the symbols $g_0(\theta)$ and $g_1(\theta)$, respectively. The relationship between these follows from Bayes' theorem in the general form:

$$g_1(\theta|x) \propto L(\theta; x) \times g_0(\theta), \qquad (26.26)$$

that is, the posterior density (of the parameter) is proportional to the likelihood times the prior density. It will be seen that the likelihood is the factor that introduces the information in the data to modify our perception of where θ is likely to lie. It is generally not necessary to specify the proportionality factor since this can

[13] In an epidemiological context, see, for example, the book by Clayton and Hills (1993).

[14] It is an interesting mathematical property of the χ^2_2-distribution that this value of ρ is exact, and indeed, the plausibility fraction for a two-dimensional $1-\alpha$ confidence region is α for *any* α, at least to the extent that 2Λ is approximately distributed as χ^2_2.

be obtained by requiring that the posterior density integrates to one (i.e., has area underneath it equal to one).

26.7.1 Bayesian Estimation of the Binomial Parameter

Suppose we have observed x positive responses out of m trials in a binomial experiment and that we wish to estimate the probability p of a positive response. Applying (26.26) to the parameter p, we have

$$g_1(p;x) \propto L(p;x) \times g_0(p), \tag{26.27}$$

where $L(p;x)$ is the binomial likelihood, as defined in Eq. 26.6, and $g_0(p)$ is the supposed density of the parameter p prior to the observation of any data.

A major issue is the question of how to choose the prior density given that, by its very nature, it will usually be subjective. We will need a family of prior densities defined on the interval [0, 1], and this is provided by the so-called beta distribution family, with density:

$$g_0(p;a,b) = p^{a-1}(1-p)^{b-1}/\mathrm{B}(a,b)\ ,\ 0 \le p \le 1,\ a,b > 0, \tag{26.28}$$

where a and b are parameters taking any real values greater than zero. (We need not be concerned with the proportionality factor $\mathrm{B}(a,b)$, which involves factorial-like quantities depending only on a and b.) The mean and variance of this distribution are $a/(a+b+1)$ and $ab/(a+b)^2(a+b+1)$, while its *mode* (or the value of p with the largest density) is at $(a-1)/(a+b-2)$, provided $a,b > 1$. Figure 26.13 shows different members of the family as a and b vary. If, for example, we thought in advance of the observation that the most plausible value for p was 0.25, we could ensure that the distribution has this value for the mode by choosing $b = 3a - 2$. If we then choose $a = 2$, $b = 4$ we will have a SD of $\sigma = 0.178$. The spread of this distribution represents our view of how close the true value is likely to be to its center; if we were more confident that 0.25 was the most likely value for p, we might choose $a = 6$, $b = 16$, giving $\sigma = 0.093$, about half the previous value. If we really had no idea of an appropriate value before seeing the data, we could opt for the *rectangular distribution*, which has constant density and assigns to all intervals of a given length the same prior probability of containing p. Such a choice gives what is known as an *uninformative prior*, for obvious reasons.

Any (positive) values of a and b can be substituted into (26.28), giving for the posterior density

$$g_1(p) = p^{a+x-1}(1-p)^{b+m-x-1}/\mathrm{B}(a+x, b+m-x), \tag{26.29}$$

which is another beta distribution but with revised parameters. Comparison with Eq. 26.28 enables us to see that the posterior mean and mode are given by

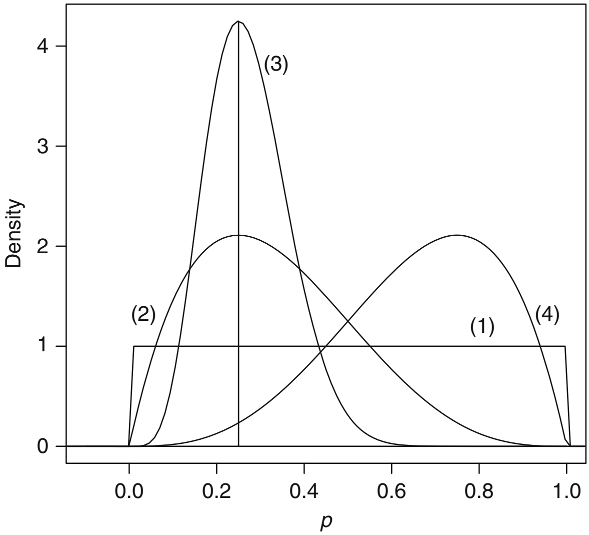

Fig. 26.13 Density of the beta distribution for various values of (a, b): (1) (1,1) – rectangular distribution; (2) (2,4) – see text; (3) (6,16) – same mode; (4) (4,2) – note the symmetry of distributions (2) and (4)

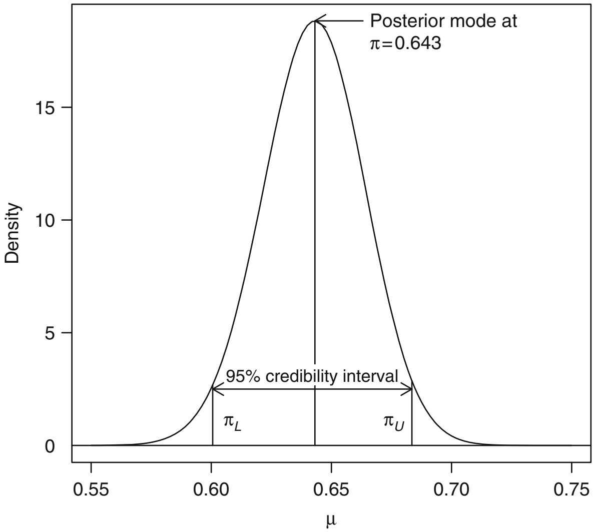
$$\text{mean: } (a+x)/(a+b+m+1) \text{ and mode: } (a+x-1)/(a+b+m-2), \text{ respectively.} \quad (26.30)$$

With binomial data, the prior and posterior densities have the same form only for the beta family of densities; a prior family with this attractive feature is called a *conjugate prior*. It is clear that the posterior distribution has the form obtained by increasing a and b by x and $m - x$, respectively. This suggests that the information in a beta prior distribution with parameters a and b can be compared with that in a binomial experiment in which a successes are observed in $a + b$ trials. Hence, if, prior to our study, we only have information from a previous study with this outcome, we might think it rational to choose our prior with these parameters. Furthermore, we may, even in the absence of such information, represent our beliefs in terms equivalent to hypothetical observed data: thus, we may represent our belief about a binomial probability by imagining an experiment in which we have observed a positive outcomes in $a+b$ trials. This *information equivalence* is a helpful way of thinking about the synthesis of prior and current information and is made possible by the use of the conjugate prior.

Example 26.17. Bayesian estimation of the sex ratio in the meningitis data
Continuing Example 26.13, we need to fix a prior distribution for p, the probability of a child being male. In fact, it is now well known that male children are far more susceptible to infections than females, though the reasons for this is are undoubtedly complicated and still rather obscure. A decade before Bortolussi et al.'s (1978) study (which was not primarily concerned with the sex ratio), Washburn et al. (1965) had reported a very large search of the literature on the sex ratio, covering many common infections. For meningitis in newborn infants (i.e., under 1 month old), the search revealed 296 males out of 460 children with meningitis (64.3%). The information equivalence concept suggests that we might reasonably choose a prior distribution for p having $a = 296$, $b = 460 - 296 = 164$ to represent the previously available information. We could then combine this with the

Fig. 26.14 Posterior density of μ for meningitis data, showing the symmetric 95% credibility interval



Bortolussi data of 33 males out of 52 children to give a posterior distribution with mean $(33 + 296)/(52 + 460 + 1) = 0.641$ and SD 0.021, though this would only make sense if we believed that the experimental contexts were very similar. It will be seen that this distribution is heavily dominated by the large amount of prior information in the Washburn study; it is shown in Fig. 26.14, with a 95% *credibility interval*, that is, an interval encompassing 95% of the posterior probability. The latter is sometimes called a *Bayesian confidence interval*, but the former term is perhaps to be preferred, in order to avoid conceptual confusion. There are of course many ways in which the interval could be chosen: one might, for example, wish to ensure that the probability of passing either limit is the same, say $\alpha/2 = 2.5\%$; alternatively, we might want the shortest possible interval, which is achieved by taking the *highest posterior density (HPD) interval*, containing just those points p whose density is above an appropriate value. Figure 26.14 shows the first of these methods, which is significantly easier to compute and returns a credibility interval of (0.601,0.684). In this case, the 95% HPD limits are the same to three significant figures, though the two-tail probabilities are respectively 2.4% and 2.6%, that is, it makes little difference which method we choose when the distribution is reasonably symmetric. The most “likely value” of p is at the posterior mode, which is 0.643, only slightly larger than the posterior mean; the choice between mean and mode to summarize the data depends on how we wish to interpret the results. We observe that the interval is very considerably shorter than the confidence interval of (0.489,0.760) given in Example 26.13. This is clearly due to the extra information imported from the earlier study.

26.7.2 Bayesian Estimation of the Normal Mean

For the normal distribution, we will for convenience consider a single observation x, though this will not, of course, preclude us from taking x to be a more complicated statistic, such as a sample mean. We continue to focus on inference for the mean, making the assumption that we know the variance σ_x^2 of x well enough to be able to consider it known; this will be reasonable for inference on μ from moderately large samples. From the structure of the likelihood (26.7) – that is, from the quadratic term in the exponent – we can see that the conjugate prior is itself normal, so we suppose that μ is normally distributed with, say, mean τ_0 and variance κ_0^2. The resulting probability densities are easily manipulated to give the posterior density as another normal distribution, its mean and variance being respectively:

$$\tau_1 = \frac{x/\sigma_x^2 + \tau_0/\kappa_0^2}{1/\sigma_x^2 + 1/\kappa_0^2}\,; \qquad \kappa_1^2 = \frac{\sigma_x^2 \times \kappa_0^2}{\sigma_x^2 + \kappa_0^2} = \left(\frac{1}{\sigma_x^2} + \frac{1}{\kappa_0^2}\right)^{-1}. \tag{26.31}$$

It will be seen that the posterior mean is a weighted average of the observed value x and the prior mean τ_0 using the reciprocals of the variances as weights. This is very reasonable since the information we have from each of the two sources is well described by the inverse of the variance. A similar view of information as the reciprocal of variance enables us to see that the information in the posterior distribution $(1/\kappa_1^2)$ is the sum of that in the prior distribution and that from the observation.

As with the binomial distribution, we could consider the parameters of the prior distribution as representing prior information equivalent to a previous experiment, in which we have an observation from a normal distribution with parameters τ_0, κ_0, remembering that our single observation may well be the mean of a sample with standard error κ_0. The formulae in (26.31) then merely represent a pooling of the information in the two samples. However, using a large previous experiment to provide prior information is likely to give it overwhelming weight, and this only makes sense if we believe that the population in that experiment has the same mean as the one we are trying to estimate from our present data, though, in this case, we would hardly need the present data to provide new information. In practice, it is most unlikely that a population studied previously is completely relevant to our present context, and so we must then consider the question of how different the respective populations might be, a question which of course has nothing to do with the precision implied by the small sampling error in a big experiment.

Example 26.18. Bayesian estimation of the mean HbA1c for OSA data
Choosing the prior distribution in this example is distinctly challenging. If we use the Telecom study and invoke the principle of information equivalence discussed above, we obtain a prior distribution with mean and SD given by:

$$\tau_1 = \frac{5.4 \times 26/0.8^2 + 5.05 \times 3,240/0.54^2}{26/0.8^2 + 3,240/0.54^2} = 5.051\,;$$

$$\kappa_1 = \left(\frac{26}{0.8^2} + \frac{3,240}{0.54^2}\right)^{-\frac{1}{2}} = 0.0095. \tag{26.32}$$

The posterior distribution is heavily influenced by the Telecom data, which we have implicitly assumed to reflect a population with the same mean HbA1c as in the OSA study. In the light of the very highly significant difference between the two means, we know this

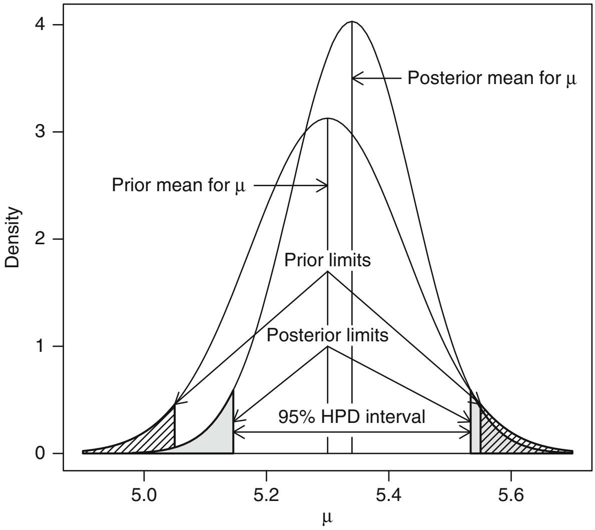


Fig. 26.15 Prior and posterior densities for the HbA1c – OSA data chosen by the method of prior limits, showing the resulting 95% credibility interval

is almost certainly quite wrong. For one thing, it is known that HbA1c depends on such factors as age and sex and we should ideally take account of this information. Moreover, the Telecom study is a sample of workers who will almost certainly be younger and healthier than the patients in the OSA sample. A scientist familiar with the nature of the pathologies involved would anticipate a connection of OSA with high HbA1c levels since both are associated with overweight, though with no other information to go on it would be difficult to know the extent of the difference. This illustrates one of the difficulties of a simple Bayesian analysis: the process requires us to choose the prior distribution in advance of seeing the current data, yet the latter may tell us that the assumptions on which the choice of prior is based are quite mistaken. We will suppose, for the sake of our example, that a more reasonable prior distribution is chosen, with mean $\tau = 5.30$ and SD $\kappa = 0.125$. We will discuss below (Sect. 26.7.4) how this might have been arrived at. The resulting posterior distribution now has mean 5.34 and SD 0.098 and is illustrated in Fig. 26.15. It gives a 95% HPD credibility interval (which is also of course symmetric) of (5.15,5.53).

26.7.3 Choosing the Prior

The problem of prior choice is central to a Bayesian analysis. Some workers are quite happy to use an uninformative prior, but there are serious difficulties with this. For one thing, in most cases (including the normal), the range over which a parameter must be specified is infinite, and it is not possible to specify a constant density over such a range that is *proper*, that is, that integrates to one. This turns out not to matter too much: it merely means that the density of the parameter, being constant, does not appear on the right-hand side of equations like (26.27) and this does not prevent us from finding the proportionality constant that delivers a proper posterior density. In this case, the density is just a scaled version of the likelihood so that the HPD credibility interval is then just a likelihood interval; indeed, in the case of the normal distribution with known σ^2, it is also equivalent to the frequentist confidence interval, reflecting the fact that no prior information has been provided.

A more serious difficulty is that uninformative priors are not invariant under changes of scale of the parameter. Suppose, for example, that we wanted to specify that the density of the logit[15] of a probability parameter p was constant, we would require a density that is quite different from the rectangular density we obtain by putting $a = b = 1$ in Eq. 26.28; needless to say, it would lead to different results. The implication is that there is no such thing as a truly uninformative prior distribution: by choosing a constant density function, we are implicitly choosing a scale on which we believe the density is constant, and this conveys information in itself.

In any case, it is usually quite unreasonable to claim that all values of a parameter are equally likely. Nobody could believe that a diastolic blood pressure, for example, is as likely to lie between 1,000 and 1,001 mm Hg as between 90 and 91 mm, since it is certain that a patient could not survive such a high blood pressure. Dependence on uninformative priors is forcefully attacked on these grounds by Greenland (2006) in an important paper advocating Bayesian methods. His solution is to use what we might call *prior limits*.[16]

26.7.4 Prior Limits

Given that some of the most useful outcomes of a Bayesian analysis will be statements like $\mathrm{P}[\mu > \mu_U] = 0.025$, we observe first that the general statement of Bayes' theorem, Eq. 26.4, permits us to consider such statements about our model and so in principle to derive the posterior version of this probability from the prior version. Unfortunately, we cannot do this without specifying the whole prior distribution and integrating over it in a calculation that will not generally be straightforward.

However, once we have specified a prior distribution family with, say, k parameters, we can in principle determine those parameter values by specifying k limits like that for μ specified above. We can achieve this, for example, using an upper and a lower limit with either a beta or a normal prior. It has to be admitted that only in the case of the normal distribution is the determination of the corresponding parameters really straightforward: the beta prior, for example, requires us to be able to manipulate the quantiles of the beta distribution, which

[15] logit(p) is defined as $\log(p/(1-p))$.

[16] In spite of the usefulness of this approach, this expression does not appear regularly in the literature as yet.

may put off those without a facility for mathematics and access to a good computing system.[17] Part of Greenland's argument, however, is that – just as in the frequentist approach – Bayesian analyses can be carried out using normal approximations, and the comparative simplicity of the calculation for the normal distribution makes this an attractive general method: he exemplified it with an example for the log of the odds ratio based on its asymptotic normal distribution.

For the normal distribution, we could, for example, choose upper and lower prior limits μ_{0U}, μ_{0L} such that we believe that

$$\mathrm{P}[\mu > \mu_{0U}] = \mathrm{P}[\mu < \mu_{0L}] = 0.025. \tag{26.33}$$

We can then find the mean and variance of the prior distribution from the equations

$$\tau_0 = \frac{1}{2}(\mu_{0U} + \mu_{0L})\ ; \quad \kappa_0 = \frac{\mu_{0U} - \mu_{0L}}{2 \times 1.96} \sim \frac{1}{4}(\mu_{0U} - \mu_{0L}). \tag{26.34}$$

Hence, we have easy formulae for determining the parameters τ_0, κ_0 of the prior distribution from two limits, which we still need to specify, of course. In many ways, however, choosing such limits is a more natural subjective exercise than choosing the mean and standard deviation of the prior density. We can invoke the language of betting to answer questions such as "What are the odds that the mean of the blood pressure lies above μ_{0U}?"; we emphasize that these odds refer to our probabilistic beliefs about where the true population mean lies, not to where we might expect the mean of a sample to lie. The answers to any two such questions determine our prior normal distribution; if we can invert the question to arrive at odds of 39:1, we can use the simple formulae of (26.34).

Example 26.19. Prior limits for HbA1c data
Continuing Example 26.18, we might suppose that an investigator is aware of the Telecom study, but also of the fact that OSA patients are likely to have raised HbA1c levels – he may, for example, have seen a number of cases where the level was higher than 6.0. He will also be aware that HbA1c assay standards have changed since the Telecom study was carried out and more typical values for HbA1c in the adult population have $\mu = 5.25, \sigma = 0.70$ (see, e.g., Myint et al. 2007). He will perhaps regard the Telecom study as representing a floor below which it is highly unlikely that his patients will record values; he might therefore choose the Telecom mean of 5.05 as his 2.5% lower limit. He might think that the few cases he has seen are high partly by chance and choose 5.55 as his 2.5% upper limit (always remembering that this is a limit for how high the mean probably is, not the percentile of the population). In this case, his (normal) prior distribution will have a mean of $\tau = 5.30$ and a standard deviation of $\kappa = 0.125$ (using the approximating denominator of 4 in (26.34)). Substituting into (26.31) and remembering that the quantity x stands for the sample mean $\bar{x}$ with estimated variance s^2/n, we obtain the limits illustrated in Fig. 26.15.

[17] It is relatively easy to write a function performing these calculations in R, for example.

26.7.5 Bayesian Hypothesis Testing

Hypothesis testing is a less common component of Bayesian analyses, which typically tend to place the emphasis on the estimation of parameters. This is partly because such analyses are invariably formulated in terms of parametric models, for which hypotheses can be represented as statements about the values of the parameters. The probability that a particular hypothesis is true can thus be derived from the (prior or posterior) distribution of the parameter. For example, the probability that a certain composite one-parameter hypothesis is true can be represented as the probability that the parameter takes particular values.

For simple hypotheses, however, a typical conjugate prior density for a parameter will assign the probability zero to a specific parametric hypothesis such as $p = 0.5$. This is a warning that it is rarely reasonable to regard a simple hypothesis as *exactly* true: for example, the probability of a male child will in practice deviate from 0.5 for many biological reasons. When we test such a hypothesis in the frequentist manner, we are effectively asking not whether a null hypothesis is really true, so much as whether the extent of our evidence is sufficient to detect that it is not. For such situations, a Bayesian analyst would be more likely to test a composite hypothesis like $H_0 : p \leq 0.5$ in order to detect an excess of male children. For a discussion of this approach and a comparison with the issues arising in frequentist hypothesis testing, see Armitage et al. (2002).

There are situations, however, where there is a real interest in the probability that a simple hypothesis $H_0 : \theta = \theta_0$ is exactly true, and in this case we must resort to a prior distribution which assigns positive probability at least to the point θ_0. The simplest situation is to test H_0 against a simple alternative $H_1 : \theta = \theta_1$, for which we need a discrete two-point distribution on the parameter values $\{\theta_0, \theta_1\}$. The probability that H_0 is true is then self-evidently $\mathrm{P}[\theta = \theta_0]$. Because the marginal distribution of the data cancels out from the two denominators involved, Bayes' theorem tells us that the posterior probabilities of H_0, H_1 have a ratio given by:

$$\frac{\mathrm{P}[H_0|x]}{\mathrm{P}[H_1|x]} = \frac{\mathrm{P}[H_0]}{\mathrm{P}[H_1]} \times \frac{L(\theta_0; x)}{L(\theta_1; x)} = \frac{\mathrm{P}[H_0]}{\mathrm{P}[H_1]} \times R(\theta_0, \theta_1; x), \text{ say.} \tag{26.35}$$

Each of the ratios of probabilities gives us the odds in favor of H_0 and (26.35) shows that the effect of observing the data x is to multiply the prior odds in favor of H_0 by the likelihood ratio $R(\theta_0, \theta_1; x)$, which is also known as the *Bayes factor* in this context.

This can be a useful way of weighing evidence presented in terms of a hypothesis test but appears at first sight to apply only to a single simple alternative H_1. However, the same result holds for *any* alternative value θ_1 of θ so that we can calculate the posterior odds as a function of the prior odds and θ_1. For each θ_1, we have $\mathrm{P}[H_1] = 1 - \mathrm{P}[H_0]$ and hence

$$\mathrm{P}[H_0|x] = \frac{\mathrm{P}[H_0] \times R(\theta_0, \theta_1; x)}{1 + \mathrm{P}[H_0] \times (R(\theta_0, \theta_1; x) - 1)}. \tag{26.36}$$

Example 26.20. Probability of raised risk near a nuclear installation
There is much concern about the possibility that there is an excess risk of leukemia in young people near nuclear installations in the UK and elsewhere. The issue was first raised as a result of a television program in 1983 concerning cancer in the village of Seascale in Cumbria, near the Sellafield nuclear plant. Numerous investigations have taken place since, for example, a study by Draper et al. (1993), which reported five cases of leukemia and non-Hodgkin lymphoma under the age of 25 in Seascale during the years 1963–1983. Using national cancer rates, the expected number of cases was calculated to be $\lambda_0 = 0.493$, so it would be reasonable to use the Poisson distribution to test $H_0 : \lambda = \lambda_0$ against an alternative $H_1 : \lambda = \lambda_1 = \mathrm{RR}\times\, \lambda_0$, where RR is the "relative risk" or ratio of the risk in Seascale to the national average. This gives a one-sided p-value of 0.000161, which should be regarded as highly significant and leading to rejection of H_0, though we should remember that this is an observation selected from a large number of possible combinations of time, place, and diagnosis. In any case, we reemphasize that the p-value does not tell us the probability that H_0 is true; this intrinsically Bayesian question can be arrived at via (26.36) as follows. From (26.3), we know that the ratio of the likelihoods under H_0 and H_1 is given by

$$R(\lambda_0, \lambda_1; x) = \exp((\mathrm{RR} - 1)\lambda_0) \times \mathrm{RR}^{-x}. \tag{26.37}$$

Substituting this into (26.36) allows us to calculate $\mathrm{P}[H_0|x]$ as a function of RR and $\mathrm{P}[H_0]$, and contours of this function are depicted in Fig. 26.16. Suppose, for example, that we wish to test H_0 against the hypothesis that the true relative risk is $\mathrm{RR} = 2$. In the absence of a belief in one hypothesis rather than the other, we might take $\mathrm{P}[H_0] = 0.5$. From the contour plot – or directly from (26.36) – we obtain a posterior probability of $P[H_0|x = 5] = 0.049$. The observed count of $x = 5$ is of course substantially greater than λ_0 and the posterior probability of H_0 is reduced accordingly.

26.7.6 Other Bayesian Methods

The Bayesian paradigm has proved very fruitful, and there are numerous variations and extensions of the themes we have illustrated in this section. We can only introduce here a few possibilities that the epidemiologist is likely to meet.

There are circumstances in which frequency data are available that provide information on prior distributions. An important medical example arises in the area of diagnosis, where H denotes the hypothesis that a patient has a particular disease and D represents diagnostic information; prior probabilities can then be objectively estimated from disease frequencies in the population. This approach is known by the term *Empirical Bayes* (EB). The argument can be given a frequency interpretation, and for this reason, some authors regard EB methods as not really Bayesian at all, restricting the scope of the latter to problems where priors are inherently subjective. A classical example of an epidemiological EB analysis is described in chapter ▸Geographical Epidemiology of this handbook.

Hierarchical modeling is also a feature of Bayesian analyses. Instead of choosing the parameters of the prior distribution subjectively, they are themselves given suitable prior distributions: the parameters of the latter are known as *hyperparameters*. The issues that arise in the first place are transferred to the second level of prior distribution; in principle, the process can be extended, but it is not clear that this is a useful operation. As we have argued above, there is no such thing as an

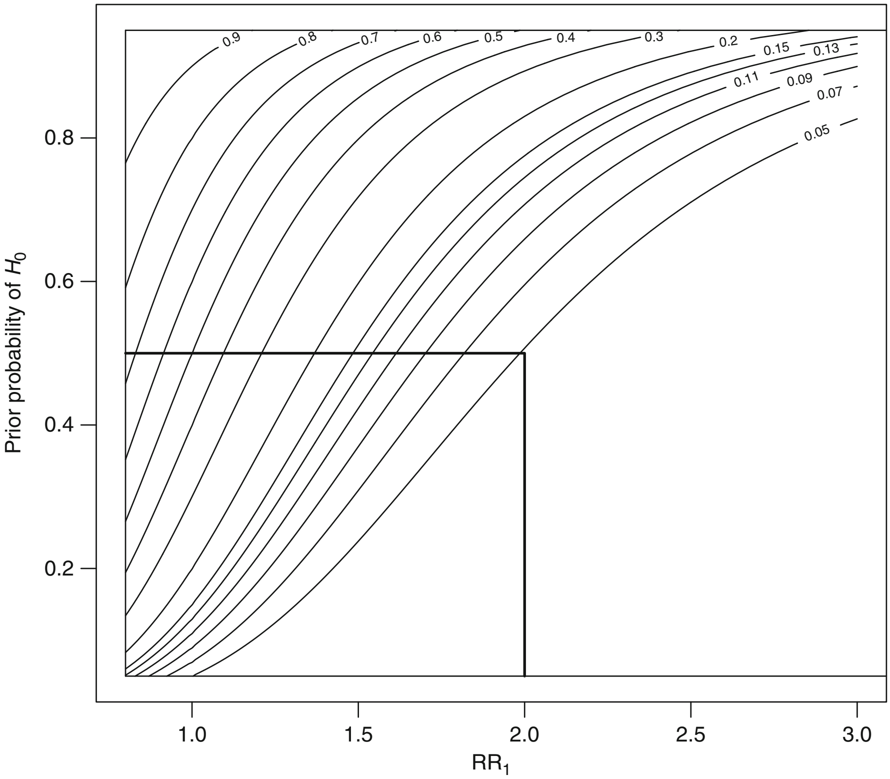

Fig. 26.16 Contours for the posterior probability of $H_0 : \lambda = 0.493$ in the Seascale data, given as a function of RR_1, the alternative value of the relative risk, and the prior probability of H_0

information-free assumption about prior distributions, and the information that is indirectly conveyed by complex Bayesian assumptions is not generally easy to assess: it is certainly not safe to assume that it can be ignored.

Highly complex models of this kind clearly pose computational challenges, and the Bayesian analyst frequently has recourse to simulation or "Monte Carlo" methods. In particular, a class of methods known as Markov chain Monte Carlo is available for estimating posterior distributions using sophisticated ideas that are beyond the scope of this chapter. The interested reader will find a comprehensive introduction in Gamerman and Lopes (2006). The methods have become very popular because of their apparent ability to model problems of arbitrary complexity and to incorporate any unknown quantities, such as hyperparameters and missing data. There is a computing system known as BUGS (Bayesian inference Using Gibbs Sampling) available on the website of the MRC Biostatistics Unit at Cambridge on http://www.mrc-bsu.cam.ac.uk/bugs/, which implements these models in a way that removes the need for any theoretical knowledge or understanding. The reader is warned, however, that this very accessibility represents a real danger for the unsophisticated user, as does the difficulty of interpreting the results.

The Bayesian paradigm is undoubtedly useful, however, for the insight it gives into the nature of statistical analysis and for enabling us to understand such problems as *model uncertainty* – that is, the extent to which we are injecting extra information into our data analysis by selecting a particular model – and the effect of making different model choices.

26.8 Further Reading

Throughout this chapter, there have been numerous references to the book by Armitage et al. (2002), which provides a wide-ranging but non-mathematical introduction to statistical methods, and also to the underlying probability theory and the general concepts of statistical inference. Many of the ideas apply across the field of medical science, of course, and the chapter on epidemiology in Armitage et al. (2002) employs a much wider definition of the subject than we have taken for this chapter. A more mathematically ambitious but clear account of statistical inference is given in Rice (2007), though there is less emphasis on methods than in Armitage et al. (2002). Clayton and Hills (1993) give an account of models in epidemiology from a likelihood standpoint. Armitage et al. (2002) have two useful chapters addressing Bayesian ideas, while Lee (2004) presents the theory at a mathematically reasonably level. At a substantially more advanced level, Cox (2006) discusses more difficult problems in the theory of statistical inference in a book that integrates classical and Bayesian ideas.

26.9 Conclusions

We have identified three different though connected approaches to statistical inference: the frequentist approach provides test procedures and estimates of parameters, but the calculation of probabilities is restricted to the description of the long-run performance of the procedures used; the likelihood approach allows a meaningful measure of how likely parameter values may be in terms of what we have called a plausibility fraction; only the Bayesian approach is capable of relating this quantity to probability statements about hypotheses or parameters.

On the face of it, the first and third of these at least are attempting fundamentally different epistemological operations. Frequentist methods may be regarded as strictly *analytical*: the estimation of parameters in a model for the data is merely a mathematical codification of the relationships that we think exist between variables in our data, while the construction of confidence intervals and the execution of significance tests are merely methodologies for assessing the role of chance in this process. Bayesian methods, on the other hand, are essentially *synthetic*: they are integrating the evidence from the data with our knowledge of the underlying scientific theory. Both operations are sensible parts of the process of scientific inference and it is arguably a mistake to put them into any kind of antagonism or competition. Doing so invites the very confusion of ideas that bedevils statistical inference: the frequentist who believes that her data represent a universal truth about her field of science is as much in error as the Bayesian who believes he is achieving a true analysis, with all the overtones of precision and objectivity that the word implies.

In one sense, the Bayesian is a statistician who believes that the integration of evidence of essentially different kinds can usefully be quantified: the extent to which this is really true will surely depend on the context. The use of subjective probability, for example, through the nomination of prior limits or odds, is dependent on an essentially frequentist view of probability. It is an interesting conjecture as to whether a "naive" mind, with no experience of any kind of repetition of experience, could usefully attach any meaning to a subjective probability merely as a result of an understanding of the axioms of probability. This difficulty parallels that of assigning any particular significance to a given plausibility or likelihood ratio in the absence of any way of relating them to a frequency theory.

That is not to say that the Bayesian approach is of no value but rather to say that it is not the fundamental solution to the problem of scientific inference that it is often held to be. This author's own view is that its value lies more in the enlightenment we gain from the Bayesian paradigm than from its use in data analysis. No doubt, opinions will continue to differ on this question, but it is to be hoped that the antagonism of the ideas to one another will become less pronounced since it is so often counterproductive.

27.1 Introduction

Data in epidemiological studies are obtained from several sources such as questionnaires, medical records, medical devices, or laboratory tests. Data management includes the transfer of such data into a (central) database as well as all subsequent processing activities and quality control. This chapter describes the most essential steps related to the collection, entry, storage, transport, cleaning, maintenance, and statistical processing of epidemiological data, which embrace all steps from raw data to the final dataset for statistical analysis.

The main objective of an effective data management is the accurate conversion of study subjects' information into an error-free database, which is easy to handle for all subsequent analyses. Such a database builds the foundation for all statistical analyses and the conclusions drawn from the study. It is quite evident that such inferences are just as good as the quality of data. Data of poor quality, containing a great amount of random noise, decrease the power of a study and can cause type II errors (Whitney et al. 1998).

Several papers describe quality assurance and quality control procedures of clinical trials with focus on the necessity of study protocols and training of study personnel (Gassman et al. 1995; Prud'homme et al. 1989), but there is less literature in the context of epidemiological studies, where most of the corresponding data are based on the collection of personal information from individuals. Such data may be obtained via questionnaires, physical examinations, clinical laboratories (biological/genetic markers), or readouts of (medical) measurement devices. Furthermore, routine data that are mainly collected for administrative purposes are an issue of growing interest in epidemiology. Typical sources are vital and medical records, that is, disease registries, vital statistics, notification systems (especially for infectious diseases), clinical records (e.g., hospital discharge diagnoses), and health insurance claims data. Also aggregate level data may be used like census data or Bureau of Labor Statistics (BLS) data as well as information provided by geographic information systems (GIS).

Although it is desirable to avoid any errors, they occur even with careful data collection and entry. Therefore, given the huge amount of work, money, and time usually involved in the collection of data for epidemiological studies, it is crucial to avoid additional errors during the transfer of data from paper-based forms or measurement devices to digital data. Even if many data errors will be detected by chance at different stages of data management and analysis (other than data cleaning), it is more efficient to screen systematically for errors before the statistical analysis is carried out (Van den Broeck et al. 2005).

A wide range of software products is available for data entry. Most software packages support the user during the process of data entry. For numerical variables, the data entry can be restricted to plausible ranges only and for alphanumerical variables to valid codes. It is also possible to force data entry for compulsory fields. Regardless of any procedure to assure data quality during entry, corresponding errors can be minimized by entering data twice by different persons and by subsequent comparison of both entries. Discordant values are then cross-checked against the original document, and the valid value is kept in the corrected dataset.

However, even with the most careful verification of data entry, it is necessary to perform additional checks before beginning data analysis. Plausibility checks can be run automatically and comprise queries regarding the plausible range as well as cross-checks of variable values. Finally, sometimes "…a data review meeting before database lock, which involves all parties, to discuss the data and remaining implausibilities (with the consequence of a possible exclusion of data) is also recommended" (Theobald et al. 2009). By all means, all plausibility checks are to be determined before any analysis of data starts.

This chapter is organized in four main sections, based on our experience in data management and on several publications in which many of the concerns in this field have been described in detail. We introduce the issue on how to set up a data management infrastructure to handle data from diverse sources. The second section addresses the entry, storage, and transfer of data, followed by a section focusing on the main steps of data cleaning, that is, to detect, correct, or discard invalid values and records from a database. The last section deals with key concerns on how to prepare the final analysis dataset containing all variables, original, and derived, on which all calculations are performed.

27.2 Setting Up the Data Management Infrastructure

Epidemiological studies vary considerably with respect to use of data sources, recruitment of participants, and study purpose. Data may be collected directly from study subjects or may be retrieved from secondary data such as administrative databases, clinical records, or registries. Such a collection of data as well as the data management procedures should be planned carefully and timely to avoid waste of time and invalid data. Retroactive correction of mistakes requires additional time and manpower and is often impossible. The complete set of software tools and devices should be well tested, and their handling should be trained. All procedures have to be laid down, for example, as standard operation procedures. Sufficient time and resources to plan and set up all data management procedures should be allocated from the very beginning of a study.

This section describes the necessary infrastructure and data management procedures to handle data from such diverse sources.

27.2.1 Requirements, Tools, and Set-Up

Data sources and used methods of data collection or retrieval have to be defined before planning the data management (see chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook). Procedures differ depending on the source of the data, the data collection procedures, and the measurement devices used. The choice of tools and software may be influenced by the skills, knowledge, and experience of the staff.

27.2.1.1 Source of Data

Secondary Data When data are extracted from an existing database, data management is comparatively simple. The structure of the data is predefined; they are grouped in tables, the relations between these tables are defined and the types of the variables (e.g., numeric or character) are given. Problems can arise if the data have to be transferred to a different database system. Pitfalls might be the different representation of variables in different systems (e.g., length of an integer value) or the coding of missing values.

If the study data arise from different sources with differing data structures or if the given structure cannot be used, the data management is more demanding. In this case, data have to be selected, linked, transformed, and integrated into one uniform structure. In order to combine two datasets, key variables are required to merge corresponding data records. For example, usually it is not feasible to merge records from a cancer registry and a clinical dataset only by the name of a patient. Since different patients may have the same name, further information is required (e.g., date of birth) in both datasets to generate a unique identifier to merge corresponding records accurately. If a unique identifier is not available, it will be complicated, if not impossible, to combine the data.

Another challenge in combining existing datasets is the use of differing classifications for coding. For example, diseases are usually classified according to the International Classification of Diseases (ICD; World Health Organization 2009). However, the ICD revision used for coding may differ between data sources, for example, ICD Version 9 or 10. Another simple example is the use of different codes for the same variable values (e.g., male/female coded as 0/1, 1/2, or m/f). Such differences have to be identified, and the coding has to be harmonized.

Primary Data If data are newly collected by interviews or measurements, the data management requirements have to be formulated while planning and designing the study. Selection and configuration of instruments and measurement devices should be done bearing the final data integration in mind. A unique identifier (see Sect. 27.2.3.2) on all forms, questionnaires, and measurement outputs allows to merge all records of a given study participant. Coding of character variables should be done according to predefined classifications. It is advisable that all requirements are known and that the used software tools, coding systems, and structure of the resulting database are defined before the data collection starts. A change in a questionnaire after commencement of data collection usually leads to immense difficulties in the data management.

27.2.1.2 Methods for Data Collection

A wide variety of techniques for data collection is in use: paper questionnaires or touchscreens for self-completion or for use by an interviewer in face-to-face interviews, computer-assisted telephone (CATI), or computer-assisted personal (CAPI) interviews, and web-based solutions where the study participant enters the data directly in a web-form hosted on the server in the study center. All of them have strengths and limitations. The choice depends on the requirements of the study, the technical equipment, the budget, the skills of the personal, and the characteristics of study participants. For example, it will be a challenge to motivate elderly persons to enter data in a web-form. However, entering data directly into a central database eliminates problems from merging and updating isolated databases. The final choice of methods and procedures should therefore be discussed in the study team, where the person responsible for data management can contribute possible solutions and ensures consideration of IT aspects.

27.2.1.3 Measurement Devices

When using measurement devices like sphygmomanometers, accelerometers, or ergometers, additional data management issues have to be considered. For example, the possibilities of downloading and processing of the collected data must be verified. Will it be possible to process the data with standard programs, or is there a need for specialized software? In any case, the configuration of the devices must be checked and tested. In most cases, the interval of measuring must be defined, or the collection of additional parameters must be switched on or off. It is absolutely necessary to define a standard configuration and a robust procedure to ensure an identical set-up if several devices are used and to enable a rapid replacement of lost or broken devices.

27.2.1.4 Software Tools to Support Fieldwork and Data Management

When collecting data in a large epidemiological study, specific IT tools can help to recruit study participants, to clean the data, or to manage biological material.

Tools to Manage the Recruitment of the Study Participants Surveys are an integral part of most epidemiological studies. The overall quality of the study does not only depend on the appropriateness of the study design and the validity of the measurements, it also depends on the fieldwork. Usually the complex fieldwork procedures are not well documented. Information about the recruitment of potential study participants, their tracking, and the characteristics of non-responders are extremely important to assess potential selection bias and to judge the generalizability of the study results (Morton et al. 2006; Olson et al. 2002; Tooth et al. 2005; Vrijheid et al. 2009). Besides the response proportion there are many other aspects of the fieldwork that should be documented to allow assessment of the study quality (Hartge 2006). Mode, date, time, and outcome of each contact with potential study participants must be documented to monitor adherence to defined contact procedures and to analyze reasons for non-response. A field management tool will reduce the required resources for management and documentation drastically. One approach is to set up a small database with the contact details of all potential study participants to control contact mailings and reminders. Appointments for interview and examination could be documented in a separate system, for example, in a timetable. A more sophisticated approach uses a specialized system integrating all required functions like MODYS – a modular control and documentation system for

recruitment of study participants in epidemiological studies (Reineke et al. 2014). MODYS was designed to standardize and record all participant contacts during the recruitment phase of a study. It provides functions to store the contact data for each potential study participant, to generate mailings and reminders for individuals or groups, to manage appointments (e.g., for interviews and examinations), and to document each contact with date, time, involved persons (staff member, participant, see Fig. 27.1), and outcome. MODYS can be configured according to the specific contact procedures in a study. The course of the recruitment is arranged in the system in a tree-like structure reflecting the stage of recruitment for each potential study participant. After all activities foreseen for a given stage are completed (e.g., a letter was printed and the corresponding documentation was generated), the potential participant enters the next stage in the tree. The system thus forces that the recruitment follow a predefined process in a controlled way and ensures proper documentation of each step. Thus, MODYS allows to monitor the survey progress and to optimize the workflow.

Tools for Data Cleaning Data cleaning is particularly demanding, especially in multicenter studies. To find implausible or wrong values, queries have to be generated by standardized plausibility checks of raw data, and resulting corrections must be carried out and documented. Typically, lists of queries will be generated in the data coordinating center (DCC), sent to the study centers, and processed, and the results will be sent back to the DCC. Development of a correction database including all queries and questionable values can facilitate the necessary procedures. In each study center, all corrections have to be entered in this database. Finally the corrected data will be transferred to the DCC where they are easily integrated in the central database. Documentation of all changes is included in the correction database. Section 27.4 gives an overview of procedures for checking and cleaning of data.

Tools to Manage Biological Material Collection, processing, shipment, storage, maintenance, and supply of biological material should be documented for each single sample. Biobanks are used to manage collections of biological materials such as blood, urine, and cell cultures and to record storage locations throughout the workflow including volume tracking. Procedures and conditions (e.g., dates of freezing and thawing, storage temperatures) should be controlled and recorded throughout the storage period to safeguard storage conditions and to allow evaluation of negative effects of unforeseen deviations from standard operating procedures.

A broad range of systems is available from small spreadsheet-based solutions up to databases to store information about thousands of biosamples with an integrated retrieval function and a web-based user front end. For each single sample, a tool to manage biological material should provide information about:

- Storage location (tube, container, freezer, room, building…)
- Type and volume
- Date and time of freezing/collection
- Freezing temperature and all deviations
- Date and time of sample shipments
- Date and time of thawing

27.2.2 Data Protection

Working with personal information given by study participants is a privilege that must be respected. Over and above legal requirements, epidemiologists should seek to minimize (or better exclude) the risk of disclosure of personal information through appropriate technical solutions and procedures.

Procedures and techniques to ensure the confidentiality of the study data depend on the type of the study, source of data, and local laws and specific regulations applying to these data. Although always the same general principles of data protection have to be considered, a universal data protection procedure, suitable for any kind of study, does not exist. Each study needs its own adaptation. Some general rules and guidelines have been worked out for the IEA-Guidelines for Good Epidemiological Practice (IEA International Epidemiological Association 2007).

Central principles are described in the International Ethical Guidelines for Epidemiological Studies (CIOMS 2008).

27.2.2.1 Personal Identifiers

Personal identifiers such as names, addresses, phone numbers, social security numbers, or email addresses must be detached from other data of a given study subject as soon as possible after data collection. If their storage is necessary, for example, for follow-up, personal identifiers have to be kept separately from study data under lock and key. Data containing personal identifiers may only be used if it is absolutely necessary where access to these data requires special authorization of personnel that is legally committed to observe all confidentiality rules. In general, such data are needed during the data collection, for example, to contact study participants as part of the data cleaning process or in longitudinal studies to follow-up individuals. Separation of study data and personal identifiers needs to be reflected in the organizational structure, where only field staff may have access to identifiers while scientists are allowed to access pseudonomized study data only. A pseudonym, that is, a study-specific identification number, is used to allow linkage of epidemiological study data and personal identifiers (see Fig. 27.2). Sometimes it can be necessary to use several different pseudonyms for one and the same person. If, for example, DNA is collected, it is now common practice to provide these data with another pseudonym than the study data. This is done to prevent misuse of DNA or re-identification of study subjects by their genetic profile (see Sect. 27.2.3.4).

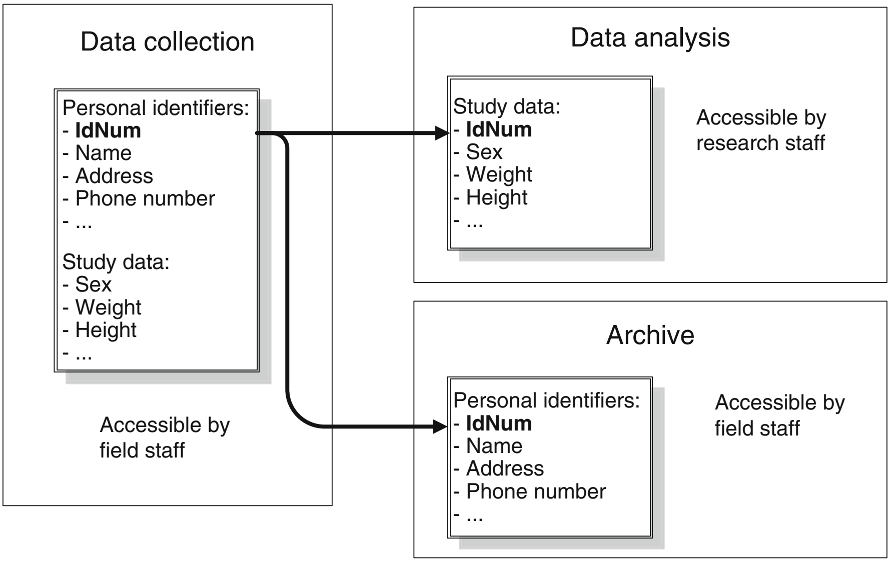

Fig. 27.2 Scheme illustrating of the separation of personal identifiers and study data

27.2.2.2 Data Protection on Mobile Devices

Data containing personal identifiers should not be stored on computers outside the study center (e.g., a laptop used at home). In case the data have to be used (or collected) by mobile storage media or if data have to be transferred, extra safeguarding procedures are necessary. Confidential data should never be sent in any electronic form (by mail or as CD) unless they are encrypted. Additional procedures include shipment by personal courier or by special delivery mail. If personal data have to be used on laptops in the field, they have to be protected on the hard disk. Several software products and, recently, more hardware-based solutions are available to encrypt data on a hard disk automatically. External hard disks with an integrated encryption are inexpensive and can thus be used in each study. If such a disk gets lost, the data will be secure: without a password or key, the data on the disk cannot be read. Another possibility is to use encrypted partitions on a laptop. User-friendly products like BitLocker (integrated in Microsoft Windows) or TrueCrypt (2012) are widely used.

27.2.2.3 Authorization of Data Access

Access to the study data and especially to the personal identifiers has to be restricted to authorized staff members. Different access rights should be granted depending on the role of each person in the project (e.g., researcher, interviewer, data manager; cf. Fig. 27.2). Access rights have to be withdrawn if a staff member leaves the study team.

Today, every computer system provides mechanisms based on user accounts and corresponding access rights to restrict the access to files or directories. Different access rights have to be granted to each user. An individual user account is more useful than an account for a group of users. In contrast to that, the access rights for each user depend on the duties and tasks, that is, the individual role of the user. For example, since interviewers need other access rights than statisticians, two roles, one for interviewers (*R_Interv*) and one for statisticians (*R_Stat*), can be defined. User accounts of statisticians will then receive the role *R_Stat* and user accounts of interviewers the role *R_Interv*. Access can then be withdrawn by deletion of the link between a user account and the role instead of deleting several access rights.

The need for confidentiality and data protection does not end with the completion of a study because data must be kept under lock and key for several years beyond the study period to allow verification of published results. Backup copies (see Sect. 27.3.3) must be subject to the same degree of data protection.

27.2.3 Set-Up and Implementation

The set-up and implementation of the data management routines could start if all general definitions have been made and all requirements are known. The choice of procedures and tools may depend on the size and complexity of the study.

27.2.3.1 Creating a Database

Collected data are usually entered and stored in a tabular format, apart from special forms, for example, data stored in images. In the case of a questionnaire, each respondent is represented by a row in the table, a so-called record. Each record contains a series of variables, one for each item in the questionnaire. Separate tables are used to store data derived from different sources.

The methods and functionalities to store and manage diverse tables depend on the software. The decision for a software product depends on the complexity of the study and the instruments used for data collection. In a small study it is sufficient to store data in a spreadsheet-like flat file. In a large study, a database management system (DBMS) which integrates several tables may be more efficient, although its set-up requires more resources.

Management of a small amount of data in a flat file where each variable defines a column is easy. The name of the variables can be entered in the first row of the table followed by the data of the participants in subsequent rows (see Fig. 27.3). Since the allowed length of variable names is limited, they are usually abbreviated. Full names and further specifications like variable format and length have to be specified in a data dictionary (see Sect. 27.2.3.5).

27.2.3.2 Complex Data Model

If the data model becomes more complex, however, it will be difficult to store the complete data of an individual participant in a single row. If, for example, a complete job history is recorded, it is bad practice to reserve as many columns (variables) in a spreadsheet as there are needed to record the maximum number of job periods reported in a given study. For each job period, several variables have to be recorded like job title, start and end date, branch of industry etc.; hence, a huge number of columns have to be foreseen to record such phase-related information. Not least it is difficult to estimate the maximal number of columns needed. If too few columns are foreseen in the database, it would have to be changed while the study is ongoing. If too many columns are reserved, most of them will remain empty.

Allowing a separate record for each job period is more flexible. This can be achieved by the use of a second spreadsheet with a link variable, for example, the identification number, to the first one, where the first one entails basic characteristics of the study subject like age and sex, while the second one stores each job period in

a separate row. Each study participant can get as many rows as needed to record all his/her job periods (see Fig. 27.4).

27.2.3.3 Appropriate Software

The selection of the appropriate software to conduct a study depends on the amount, type, and form of data to be collected. If data from hundreds or more persons have to be collected or if complex relationships between variables have to be mapped, a database management system is required. If the structure of data is less complex, a more simple and easy to use system should be chosen. However, the selection should not only depend on the technical possibilities and requirements. The expertise of the staff is also an important criterion. Even if a system is semi-optimal, it can be a good choice if it is well known by the staff.

Database Management Systems In the context of DBMS, the connections between spreadsheets as shown in Fig. 27.4 are called relations. A DBMS is able to connect records between tables by a link variable, for example, the ID (identification number) of the participant, and provides functions to store and retrieve the data. A DBMS thus avoids redundancies, reduces the possibility of errors, and eases data management procedures. Several DBMS products are available, starting with systems like Microsoft ACCESS®, which are easy to use but limited in their ability to manage big amounts of data. More specialized systems are ORACLE®, Microsoft SQL-Server®, IBMsDB2®, or MySQL®, designed to manage big and complex databases.

Other than flat file solutions, most DBMS can be used by several persons simultaneously, that is, different data entry clerks could enter data at the same time. This can accelerate data entry, while all plausibility checks are done against the complete database. If, instead, data were entered in parallel into independent copies of the database, some checks would not work. For example, the check whether a given questionnaire has already been entered could only be done separately for each single copy. Then, inadvertently, a single questionnaire might be entered twice resulting in a duplicate in the final dataset. In general a DBMS stores all data in one big file on the hard disk. Within the DBMS the data are organized in separate tables (spreadsheet = table). Other systems use several files to store the data (spreadsheet = file).[1]

Statistical Systems To enter, store, and manage the data directly in the system used for analysis is another widely used solution. Systems like SAS®, SPSS®, STATA®, or R® provide the capability to enter and manage the study data. The data can be analyzed directly without any transformation, but none of these statistical packages provide as many functionalities for data management as a DBMS.

Systems Used in Epidemiological Studies Some specialized systems combine several functions needed to conduct an epidemiological study. Such systems provide, for example, a database engine to store the data, a form generator to build data entry forms, and a component to analyze the data. One of those systems is Epi Info™ developed by the CDC Centers for Disease Control and Prevention (2011). Epi Info™ is a public domain software package designed to provide a base framework for conducting an epidemiological study. Some other systems with differing functionalities can be found in the internet, for example, EpiData (EpiData Association 2010), or OpenEpi (Dean et al. 2011). Depending on the requirements of the planned study, these systems are certainly candidates to consider.

27.2.3.4 Configuration

The number of tables required to store and manage the data and their relations has to be defined. Each item of a questionnaire has to be assigned to a variable. The number of variables and their types (e.g., numeric or text) directly depend on the questionnaire, but the method to store it in the computer and the conventions to name them are predefined by the data management system. For example, the possibilities to name a variable can be limited in length or by the disposable characters.

Unique Identifiers Unique identifiers (UIDs or IDs) are used to identify participants, to link separate records and biological samples of the same participant, and, more technically, to define the relations between tables in the database. In Fig. 27.4,

[1] The definition is simplified. From the perspective of a database administrator, for example, an ORACLE database consists of several files, and it is also possible to store more than one spreadsheet in one R file.

for example, the variable *ID* defines which rows in the table *jobs* are connected to which row in the table *participants*.

Sometimes one ID number can be used for all purposes: to link all datasets, all biological samples, and all questionnaires of an individual. In other cases, different identifiers are preferable. It is, for example, good practice to enforce data protection by using different IDs for participant data and their biological material. For example, DNA is often considered to be particularly vulnerable to misuse. Assignment of different pseudonyms for reported data and DNA samples provides an additional barrier against re-identification of study subjects by unauthorized persons.

The construction of IDs depends on the intended purpose of the study and the legal requirements that have to be observed. Natural identifiers like the name of the participant or the social security number should not to be used as an ID. As discussed in Sect. 27.2.2.1, all personal identifiers have to be separated from the other study data. Therefore, the ID that is used in the study dataset should be a pseudonym (see Sect. 27.2.2.1) to hinder direct identification of study subjects. An ID should include all information necessary but as few information as possible. A simple method to generate such an ID is to number participants consecutively as they are entered into the database. The link between the participant name and number can be stored under lock and key in a translation list or file. Without such a list, the link of a record in the database to the corresponding participant is impossible. To avoid an association between the ID and the time when the participant was recruited, a random number is useful. Such a simple ID consisting of a five-digit random number may look like the following:

ID:	1	4	5	4	6
	random number				

More sophisticated approaches incorporate additional information in the ID, like the number of a study center in a multicenter study, the number of examinations in longitudinal studies, or a characteristic of the participant (male/female, age group, company number, etc.).

To avoid errors while entering the ID into the database, a checksum should be used. In this case, the last digit of the ID is a checksum calculated out of all other digits according to a predefined algorithm (e.g., Gumm 1986). A more complex ID containing a study center number, a five-digit random number, and a checksum may look like the following:

ID:	1	2	1	4	5	4	6	8
	center		random number					checksum

In study center 12, the participant 14546 was recruited. Out of 1214546, a checksum of 8 was generated. This method to create an ID is used in the German

National Cohort Study (Wichmann et al. 2012). In general it is advisable to avoid leading zeros (e.g., in this case a study center 09). If the ID is stored as numeric variable a leading zero will be truncated.

The inclusion of characteristics of the participant into the ID should be decided with care. If, for example, the number of a company is included and the participant changes his/her employer, this part of the ID is no longer valid. To change the ID in an ongoing study is complicated and error prone. Also it is not advisable to include information that is related to exposure or outcome, like the case-control status of the participant, since this could unblind study staff and thus hinder blind assignment of codes to study subjects. An incorrect ID on a questionnaire or a sample tube causes an incorrect (or missing) link to the participant. Using a barcode scanner to read IDs automatically will reduce typing errors.

Naming Variables Each variable name identifies a unique variable in the database. Each name should

- Recollect the meaning and/or position of the question or data item in the original document.
- Be consistent and short (shorter names are easier to use, some software programs only allow eight characters, and variable names will usually be displayed in graphs).
- Use lower-case letters to prevent errors if case-sensitive software is used (e.g., UNIX systems vs. MS Windows).
- Avoid special (national) characters like a German ä or a French è.
- Not contain spaces or punctuation marks.

Variable Types Common types of variables are alphanumeric (char, varchar, text, string, etc.), numeric (byte, integer, long integer), logical, and date. The format of a variable defines the possible number of characters or digits and how it is presented by the system. A date variable is stored in the computer as an integer number (e.g., days since December 30th, 1899 + seconds since midnight) and could be presented as 10.01.2011 or as January 10th 2011 or 10 Jan 2011. Text variables may contain letters or other special characters.

A string variable of length three contains up to three characters. A numeric variable of type byte contains numbers between 0 and 254. For each variable, valid values can be defined to allow for plausibility checks which can be programmed with the data entry forms to integrate related checks. Often it is advisable to use numeric variables or to convert non-numeric information to numeric variables because they are generally more comfortable during data analysis. But sometimes data handling is easier if a variable is coded as a string variable even though it only consists of numbers (e.g., zip codes with leading zeros).

It may be suitable to use more than one variable for one data item. For example, the name of a participant is commonly defined as two variables, one for the surname and one for the family name, even if only a single text field is provided. Separation of a calendar date into three separate (numeric) variables allows entering of incomplete information. For example, if a participant only recalls the year and the month of starting a job period, the exact day may be omitted.

Table 27.1 Examples of codes for missing values

Code	Type of missing	Description
−6	Not applicable	Question not applicable for the respondent; e.g. number of deliveries of a male respondent
−7	Refused to answer	Respondent refused to answer that question
−8	Don’t know	Respondent does not know the answer
−9	Missing	Left empty although question is applicable

Coding of Variables An important issue, following the data collection, is the coding of variables, that is, the translation of questionnaire information into numerical values, representing the answers to the questions. Nominal variables allow for only qualitative classification; that means it is not possible to quantify or even rank the categories. A typical example is a question concerning the marital status. A possibility of coding would be married = 1, living in a marital-type relationship = 2, single = 3, divorced/separated = 4, and widowed = 5, ideally supplemented by special codes for missing values (see Table 27.1). The attribute ordinal refers to nominal variables with a natural order (e.g., school grades, income levels). In surveys, ordinal variables are often used to measure the respondents’ attitudes or opinions by asking the extent to which they agree or disagree to a series of statements (Likert scale 1932). A typical Likert scale would be “strongly agree (1),” “agree (2),” “not sure/undecided (3),” “disagree (4),” and “strongly disagree (5).”

Special codes are needed to document and classify non-responses, which may occur for several reasons. Knowledge on these reasons is helpful for in-depth analyses of non-response. It is therefore a good idea to distinguish between causes like “refused to answer,” “don’t know,” or “not applicable” and to assign numbers to these categories which should be outside the range of codes for valid answers (see Table 27.1).

Analysis of answers to open-ended questions is generally less straightforward since responses given as free text are not directly accessible to data analysis. In the phase of programming, it is not feasible to assign a code to all possible answers. Open-ended questions therefore need to be coded after data collection with the help of available classification systems, for example, the International Standard Classification of Occupations (ISCO) to code job titles (International Labour Office 1968), the International Standard Industrial Classification (ISIC) of All Economic Activities (United Nations Publications 1971) to the branch of industry, or, for the coding of diseases, the International Classification of Diseases (World Health Organization 2009). However, sometimes open-ended questions require the development of a separate code frame in order to assign codes to the returned plain text answers.

27.2.3.5 Data Dictionary/Codebook

All variable definitions should be documented in a list called codebook or data dictionary (see Table 27.2). The data dictionary is the blueprint to set up the database and the key document for the data management that will be used throughout the whole study (van Es 1996) for defining the data collection forms, the data entry screens, the study database, and the analysis datasets. It is one of the main sources provided to the data users to understand the meaning of the collected data. An excerpt from a data dictionary is given in Table 27.2 where the column

- *Q-No.* indicates the number of the question in the questionnaire.
- *Name of variable* shows the name of the variable in the database and should be retained throughout all steps of data analysis.
- *Description of variable* includes a short description of the variable.
- *Type and format* describes the type and the length of data (numeric, character).
- *Value list/definition* describes the valid values of the variable (range, missing codes, etc.) or refers to a more complex definition in the appendix of the data dictionary.
- *Plausibility checks* describe, possible plausibility checks to be considered during programming; complex checks are defined in the appendix of the data dictionary or in a separate document.
- *Data source* contains the name of the table in the database or the name of the file (see Sect. 27.2.3.3) where the variable is stored in.

The codebook describes both collected and derived variables. Collected variables represent original questionnaire items like weight, height, or job titles, whereas derived variables are calculated from one or more of these collected variables, for example, the body mass index (BMI) which is calculated as the ratio of body weight (in kg) over square of height (in meters), or the derived variable *list_A_dur* which is the duration (years) of employment in occupations and industries known to be associated with lung cancer, the so-called *list A* (Ahrens and Merletti 1998). The codebook connects both types of variables with their names, types, formats, and further information. The data dictionary should at least include the unique name, the type, and all permissible values of a given variable.

27.2.3.6 Creating Forms for Data Entry

Well-designed entry forms are a prerequisite for reliable data entry. Special data entry forms have several advantages over the direct entry into an unformatted table of a database. A clear and neatly arranged design of the data entry screen, a defined order of entry boxes, and hot key short cuts can reduce the error rate and accelerate data entry. A data entry form can resemble the layout of the original paper form or questionnaire. This supports the data entry operator to not accidentally skip entries as he/she is guided intuitively through the form field by field. The implementation of automatic skip patterns ensures that the cursor automatically moves to the next input field when the maximum number of characters was entered in the current input field. Skip-and-fill rules make sure that fields are filled automatically as a function of previous responses or that fields are skipped if they are not applicable. For example,

Table 27.2 Example of a data dictionary (the variables id_name and id_sname are stored in an extra table and should be kept separately from study data under lock and key)

Q-No.	Name of variable	Description of variable	Type and format	Value list/ definition	Plausibility checks (description or reference)	Data source (name of table/file)
1.	*idnum*	Participant ID in the study	Number 8.0 digits	[a]	Checksum	ident_tab main_tab
1.1	*id_name*	Participant name	String 30 char			ident_tab
1.2	*id_sname*	Participant surname	String 30 char			ident_tab
. . . ..						
4.1	*height*	Participant height (centimeter)	Number 3.0 digits	Missing = −9	Range: 130–215 or −9	main_tab
4.2	*weight*	Participant weight (kilogram)	Number 3.0 digits	Missing = −9	Range: 40–150 or −9	main_tab
4.3	*dat_d*	Participant day of birth	Number 2.0 digits	Missing = −9	Range: 1–31 or −9	main_tab
4.3	*dat_m*	Participant month of birth	Number 2.0 digits	Missing = −9	Range: 1–12 or −9	main_tab
4.3	*dat_y*	Participant year of birth	Number 4.0 digits	Missing = −9	Range: >1912 or −9	main_tab
4.4	*sex*	Participant sex	Number 1.0 digit	Male = 1 Female = 2 Missing = −9	Range: 1, 2, or −9	main_tab

(*continued*)

Table 27.2 (Continued)

Q-No.	Name of variable	Description of variable	Type and format	Value list/ definition	Plausibility checks (description or reference)	Data source (name of table/file)
4.5	*n_child*	Number of deliveries	Number 2.0 digits	Missing = −9	Range: 0–20 or −9 (valid only for females >14 years)	main_tab
. . . ..						
4.7	*edu_lev*	Educational level	Number 1.0 digit	Elem. school = 1 Mid. school = 2 High school = 3 Other school = 4 not applicable = −6 Refused = −7 don't know = −8 Missing = −9		main_tab
4.7	*edu_lev_t*	Other educational level	String 30 char			main_tab
4.1–4.2	*bmi*	Body mass index (kilogram per square meter)	Number 2.1 digits	Derived variable[a]	See appendix	main_tab
5.1–5.2	*smoke_dur*	Duration of smoking (years)	Number 2.0 digits	Derived variable[a]	See appendix	main_tab
6.4–6.2	*list_A_dur*	Duration in industries/occupations known to be associated with lung cancer	Number 2.0 digits	Derived variable[a]	0–60 or −9	jobs_tab

[a] The definition of these variables can be seen in the appendix of this data dictionary

if *Question 1* asks whether a study participant ever smoked cigarettes and *Question 2* asks for the average number of smoked cigarettes per day, then a response of "Never" to *Question 1* could automatically imply a code for "not applicable" into *Question 2* and a skip of the cursor to *Question 3*. If possible, the plausibility checks defined in the data dictionary should already be active during the data entry process. While developing forms for data entry, the following aspects should be considered:

- Instant plausibility checks during entry should be an integral component, but too many restrictions could lead to a higher error rate or impede data entry. Each invalid value will interrupt the process. Some flexibility to enter "invalid" values is therefore necessary. Any system should therefore foresee the option to check back the original data source and to revisit data entry at the same point later on.
- Key variables like IDs must be treated with maximum care. Double entry or use of barcodes may reduce errors.
- Wherever applicable, a list of valid values of a variable should be provided.
- ID of data entry clerk and date of entry should be recorded.
- Fields not used should be disabled or completely hidden to prevent erroneous entries. If, for example, the question for smoking is negated, a subsequent field to enter the number of smoked cigarettes should be disabled.
- Disabled fields should be distinguished from fields erroneously skipped by the data entry operator; they should be filled with a default value for "not applicable" (see Table 27.1).
- The data entry system should track version numbers of questionnaires or data forms (in case that instruments are updated during the study).

Data entry is a critical process. It introduces several sources of errors and should be standardized and conducted with a high degree of reliability; see chapter ▶Quality Control and Good Epidemiological Practice of this handbook.

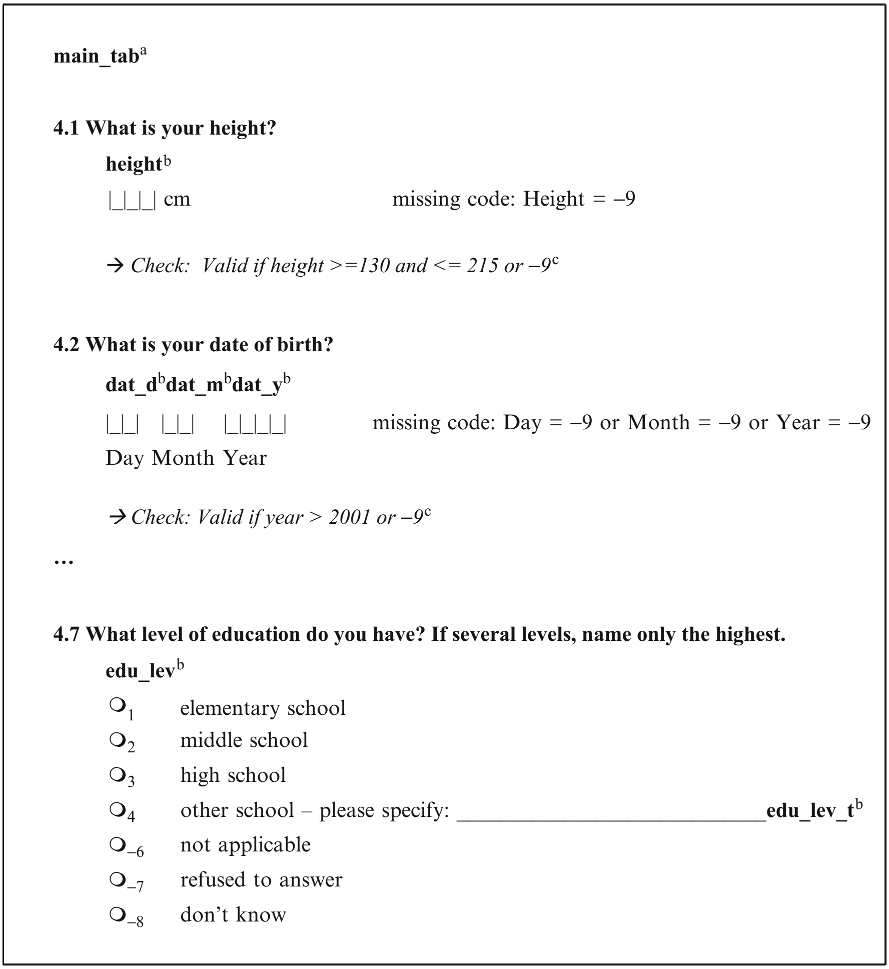
27.2.3.7 The Annotated Questionnaire

The annotated questionnaire is a paper or electronic version of the questionnaire enriched by the names of variables (used for storing the data) of questions, measurements, and other collected data items. Further annotations may relate to skip patterns, ranges of valid questionnaire responses, or interviewer instructions. It is advisable to use an electronic version of the questionnaire, for example, a file out of the word processing system or a PDF file, for annotation (see Fig. 27.5).

27.3 Entry, Storage, and Transfer of Data

27.3.1 Data Entry and Visual Editing

As described in detail in Sect. 27.2.1.2, a wide variety of techniques for data collection is in use. The entry of the data into an electronic database is the final step of data collection. Data entry depends on several preconditions and should be performed



main_tab[a]

4.1 What is your height?

height[b]

|_|_|_| cm missing code: Height = –9

→ *Check: Valid if height >=130 and <= 215 or –9*[c]

4.2 What is your date of birth?

dat_d[b]**dat_m**[b]**dat_y**[b]

|_|_| |_|_| |_|_|_|_| missing code: Day = –9 or Month = –9 or Year = –9

Day Month Year

→ *Check: Valid if year > 2001 or –9*[c]

…

4.7 What level of education do you have? If several levels, name only the highest.

edu_lev[b]

○$_{1}$ elementary school

○$_{2}$ middle school

○$_{3}$ high school

○$_{4}$ other school – please specify: ____________________________**edu_lev_t**[b]

○$_{-6}$ not applicable

○$_{-7}$ refused to answer

○$_{-8}$ don't know

[a]Name of the table or file where the data are stored

[b]Name of the variable in the table

[c]Plausibility check

Fig. 27.5 Excerpt of an annotated questionnaire

with the same care and attention as other procedures in the study. It should start as soon as possible after commencement of data collection. If data entry only starts after completion of the fieldwork, feedback of problems encountered during entry to the field team is useless, and adjustment of field procedures or amendment of instructions for the editing team (cf. visual editing) is no longer possible.

Data entry systems provide suitable data entry forms, control the workflow, provide lists of possible values for each item, and check the entered values for validity. Despite this technical support, the organizational procedures around data entry have to be standardized.

27.3.1.1 Visual Editing

Since unreadable or inconsistent values impede data entry, questionnaires should be checked and edited beforehand in a step called visual editing. In case of personal interviews, the interviewer should check the data for consistency while the study participant is still present. Discrepancies, missing values, errors, or out-of-range values could be clarified on the spot. If questionnaires are collected by mail, a member of the field staff should check each questionnaire immediately after receipt. If possible, discrepancies should be clarified promptly by phone. Visual editing addresses the following aspects:

- Are entries complete and readable?
- Were more than one response option chosen although only one was allowed?
- Have skip patterns been observed correctly?

Each correction has to be documented in the questionnaire including a notice on who has done it, why, and when.

27.3.1.2 Data Entry

Guidelines describing all procedures and specifications should be laid down in a manual before data entry starts. The manual has to be handed out to the data entry staff together with hard copies of blank questionnaires and data forms. The guidelines include specifications of how to handle unreadable items and invalid values or how to use the computer system. The data entry clerk has to know whether he/she is allowed to correct the value in the questionnaire/data form or whether he/she has to enter all values just as they are written. As a true value may well fall outside predefined ranges that are based on assumptions regarding valid value ranges, the entry of implausible values should be possible. However, the entry of an implausible value should trigger an acoustic or visual warning signal.

An easy to comprehend and clearly structured manual is a prerequisite to standardize procedures between different staff members involved in data entry. Based on the guidelines, the data entry staff has to be trained on how to enter the data efficiently and accurately into the system, how to navigate through the entry system, and what should be entered (e.g., interviewer notes, comments added by the person who has done the visual editing). As part of the guideline, data entry clerks should be instructed to note his/her names (or initials) and the date of data entry on each paper questionnaire as the counterpart to the corresponding note in the database.

To motivate the data entry staff and to let them strive for maximum accuracy, they should be provided with sufficient background information about the data entry system, all screens, and the questionnaires/data forms to be entered. Additional information about the study, its goals, and context will improve the motivation, too.

The data entry system and all related procedures should be tested, including the coding and checking procedures. Such a test can best be done based on a sample of real questionnaires.

Data entry is a monotonous business carried out by a human. A data entry system can support the process, but it cannot prevent all possible errors. Errors will occur.

Table 27.3 Error proportions of data entry (first vs. second entry) for numerical variables by study center in the IDEFICS study (Taken from Ahrens et al. 2011)

	Recording sheet				
Study center	Physical examination (fasting) (%)	Physical examination (non-fasting) (%)	Parental core questionnaire (%)	Parental CEHQ[a] (%)	Physical fitness (%)
A	0.29	0.21	0.34	0.05	0.21
T	0.97	4.15	0.21	0.18	0.87
S	2.22	7.26	6.88	3.88	1.84
V	5.37	4.01	4.42	2.19	5.05
G	3.70	3.27	2.05	0.84	3.57
D	0.80	0.68	0.85	0.40	1.13
P	1.10	0.78	2.76	1.59	0.18
Z	9.42	4.36	2.58	2.96	4.85

[a] *CEHQ* Childrens's Eating Habit Questionnaire

A common approach to improve accuracy is to enter the data twice, where the second entry is preferably done by another person in a separate database. The need of (at least partial) double entry depends on reasons like the complexity of the questionnaires, the doubts concerning the correctness of data, or the required reliability and precision of data. Results from the European IDEFICS study provide a good example for the magnitude of errors occurring during data entry (Table 27.3).

Table 27.3 summarizes the comparison of first and second data entry for all numerical variables of the main questionnaires and recording sheets of the IDEFICS study. The percentage values reflect the proportion of values that differed between first and second entry averaged over all variables of the respective questionnaire/recording sheet. Further details may be found in Ahrens et al. (2011).

When the second entry is finished, the two databases can be compared, and discrepancies can be corrected. Another method is to correct the discrepancies during the second entry, where a signal indicates discrepancies. The data entry operator then instantly chooses the correct value. Reentry of only a random sample of the data may be an alternative if time and resources are limited. A tolerance limit of error frequencies should be defined prior to the comparison of both entries. If the proportion of mismatches between the first and the second entry is below the tolerance limit, a complete second entry may be considered as not necessary.

27.3.2 Data Processing

Entered data have to pass several checks and compilation procedures until they can be considered as cleaned and ready for statistical analysis (see Fig. 27.6).

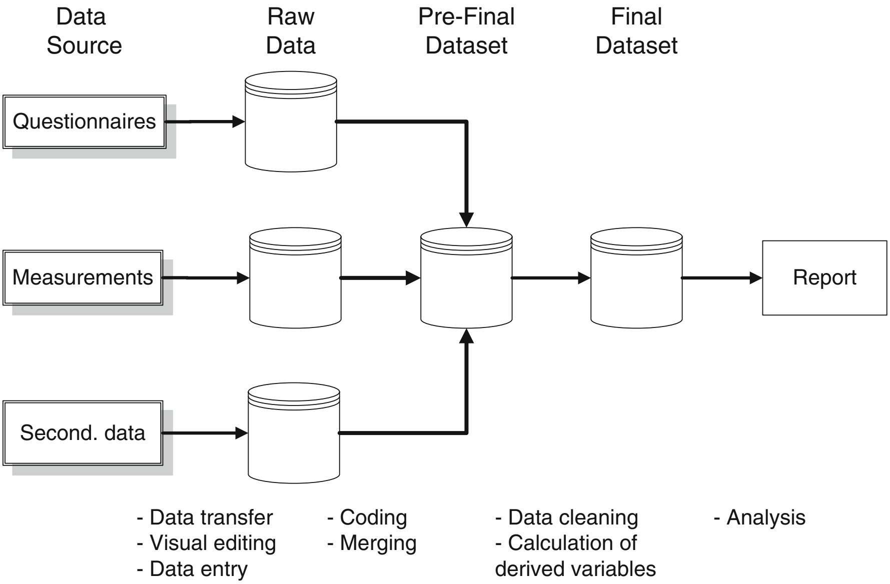


Fig. 27.6 Stages of data processing

27.3.2.1 Raw Data

The data entered from the questionnaires or collected by a measurement device are usually referred to as raw data. They reside in several data files with unequal file formats. Before the process of merging, adding, and cleaning starts, a backup copy of the raw data has to be saved. This copy is the fall-back option to restart the process in case of an error in later steps. It also serves as reference to trace back all subsequent corrections and changes.

27.3.2.2 Pre-Final Dataset

The raw data have to be linked, transformed, merged, and integrated into a uniform data structure (pre-final dataset) with uniform file formats (possibly divided into more than one data file). Codings will be harmonized and additional codes added, for example, to distinguish different sources of data.

27.3.2.3 Final Dataset

The correction of errors and inconsistencies and the exclusion of irrelevant information are part of the data-cleaning process (see Sect. 27.4), which may require continuous updates that result in a clean database for the final analyses. The enrichment of this clean database with derived variables of central importance yields the final dataset on which all statistical analyses are based. This ensures that different users work with identical data. To ease the analysis, labels and descriptions should be assigned to each variable including codes for missing values.

27.3.2.4 Processing

The necessary tasks to clean the data involve manual (by editing the data) and programmed correction routines. In contrast to manual editing, programmed routines offer the possibility to redo all changes, since these changes are documented in the program code. To give an example: In a study, social position is assigned to each participant based on an index that is composed of several variables (e.g., education, vocational training, income). In a later stage of data processing, plausibility checks show that the composed index is inaccurate. In this case the index can be recalculated with the corrected routine for all study subjects at once.

However, to benefit from programmed correction routines, each of them has to be documented, and all corrections have to be recorded in the dataset, even if an error is detected only late during data analysis. Otherwise, a correction that is only made in a specific analysis program cannot be considered in other programs. A proper documentation of correction routines and incorporation of corrections in the data ensure that all researchers always work with the latest cleaned version of the dataset.

Documentation of manual corrections should include a detailed description of which value was changed, why it was changed, and who made the change. Some database systems provide a mechanism called audit trail. If activated, all changes in the data are recorded automatically in the database. This may serve as one element to document changes made during data cleaning. A copy of the data (snapshot) should be saved after each processing step. In case of an error, the last snapshot can be used to restart the process.

If newly derived variables are generated from original variables, the original values of all source variables must be saved in addition to the new ones. Otherwise, it is impossible to recalculate the derived variables, for example, if the algorithm for their generation has to be corrected. This is particularly important if derived variables are based on outputs of measurement devices or special software products. If raw values are available, they should always be stored in addition to the resulting scores or statistics. Sometimes the manufacturer changes the algorithm of calculation in a new version of the device or software. The recalculation of the old results will be impossible without the raw data.

Generating a cleaned dataset out of the raw data is a time-consuming process, often requiring reiteration of process steps. Errors found during the data analysis can require a reimport of raw data and the repetition of various steps of the above-described process.

27.3.3 Backup and Archiving

One of the most underestimated tasks while planning and conducting a study is the development of a backup and archiving strategy for the collected data, programs, and results. Lots of efforts were undertaken to collect the data, to clean them, and to analyze them. However, everything can be lost in a few milliseconds by a hardware failure or a mistake of the user. Therefore, well-planned and carefully conducted backups are necessary. In order to set up a backup strategy, the following points have to be considered:

- Which data have to be backed up?
- Which data have to be archived?
- When should a backup be performed?

27.3.3.1 Backup of Data

It is common practice to routinely dump all files from all servers to a tape every night and keep them preserved for a certain time window. This safeguards ongoing work against hardware failures and inconsiderate maloperation. Such backup routines should be run automatically, for example, as a regular dump of all electronic data to a tape, hard disk, or DVD. Most PCs come with backup software that can also be downloaded from the internet. Such software facilitates automatic and regular backups allowing both full backups or only incremental ones without user interaction. Larger environments require a backup strategy with different levels. The choice of techniques, devices, and media (CDs, DVDs, tape archives, or hard disks) used for the backup depends on the amount of data and the requirements. In order to minimize the backup and restore time in the first level, hard disks may be used to store the backup. In the second level, the files from these disks can be written on tapes. A detailed description of possible backup scenarios can be found in De Guise (2008), Little and Chapa (2003), Nelson (2011), and Preston (2007).

Any backup mechanism has to be tested. Such a test must include a restore of some (or all) data and a check against the original data. The functionality of the backup and the restore mechanism should be tested regularly. If the data have to be restored in case of crashes, accidental deletions, or even inconsiderate disk formatting and the restore procedure does not work properly, all work is lost. The tapes or DVDs used have to be labeled with meaningful names and stored in a secure place. Old equipment and tapes should be replaced before they lose their function. It is bad practice to keep the backup on a tape or DVD drive in the computer or in the same computer rack. If the computer is destroyed, for example, by a fire, the backup will be destroyed as well. Backups must be stored in another location than the original data, preferably in a different building. Depending on the value of the data, the size of the study, and the expense needed to restore the data, additional backups may be kept in a protected place.

27.3.3.2 Archiving Data

Data have to be archived for longer time periods at the end of a project or as a snapshot of the data at the time of an interim analysis. Regular backups will be overwritten after a period of time. To archive data, another hard disk, tape, or DVD has to be used.

If the archived data have to be restored after some years, the IT environment may have changed. It cannot be excluded that archived data may not be accessible without an appropriate documentation and the programs used to store them in the first place. It is therefore good practice to archive a dataset together with its documentation (data dictionary, etc.) and any necessary files for reading and interpreting the data. If special programs (e.g., for a measurement device) use their own file formats, it must be guaranteed that these files can still be read after several years. The original program should be kept, or even better the data should be exported into a common file format (e.g., comma-separated values (csv-) file) before archiving. For example, if tables were saved as Microsoft Excel files, these files can be used for the next couple of years, also with newer versions of the program. Nevertheless, if the data were generated by a special measurement device, manufactured by a small company, the company and the device might no longer exist some years later.

The media used for archiving may be prone to ageing. Tapes, for example, could still be readable after a couple of years. DVDs should be usable too, but nobody knows exactly for how long. All the data have to be restored after a couple of years and copied to new media. Another aspect is technical innovation. Currently different types of tape drives are available, but constantly new types replace the older models. If a device is replaced by a new one, the new one must be able to read tapes used by the former one or all data have to be restored and copied to the newer models.

Many data have become inaccessible because of lost or unusable tapes or because of the unavailability of the necessary technical equipment to restore old tapes. For example, the whereabouts of data tapes of the Apollo 11 moon landing and the possibility for restoring them were unknown for a long time.[2]

27.4 Data Cleaning

The Dictionary of Epidemiology (Portas 2008) defines data cleaning "…as the process of excluding the information in incomplete, inconsistent records or irrelevant information collected in a survey or other form of epidemiological study before analysis begins. This may mean excluding information that would distort the results but it can also introduce biases. The fact that this step has been taken should be reported, along with the results of the study of analyzed data." Errors arise for a number of reasons like questionnaire faults, errors made by the interviewer, respondent misunderstanding, and (un-)intentional misreporting (response errors), laboratory and device errors, or processing errors during collection and handling of data.

Table 27.4 gives an overview of sources of erroneous (questionnaire) data in epidemiological studies. Of course, such errors should be avoided by means of well-designed, piloted questionnaires and forms, a properly designed data entry system, and well-trained and motivated staff. Anyway, errors occur in spite of such error-prevention strategies, and the process of data cleaning targets to detect, correct, or remove invalid values and records from a database. Nevertheless, data cleaning has

[2] http://en.wikipedia.org/wiki/Apollo_11_missing_tapes, last access: July 19, 2012

Table 27.4 Basic types of errors (Adapted from Van den Broeck et al. (2005))

	Type of error	
Data step	Lack or excess of data	Outliers and inconsistencies
Raw data	• Form missing/lost • Form filled in twice • Answering box left blank • Multiple answers to single choice questions	• Answer misplaced in wrong field • Illegible • Writing/typing error • Reported value outside expected range
Pre-final dataset	• Lack or excess of data carried over from questionnaire • Form or field not entered • Data erroneously entered twice • Value entered in wrong field • Inadvertent deletion or duplication of records during database handling	• Outliers and inconsistencies carried over from questionnaire • Value incorrectly entered • Data entered in wrong column of data table • Value incorrectly changed during data cleaning • Transformation (programming) error
Final dataset	• Lack or excess of data carried over from database • Data extraction or transfer error • Deletions or duplications by analyst	• Errors, outliers, or inconsistencies carried over from database • Data extraction or transfer error • Sorting errors (spreadsheets) • Data-cleaning errors

a somewhat dim existence in the context of reporting and presenting results from epidemiological studies – perhaps because it may erroneously be associated to the term data manipulation in its worst sense.

27.4.1 Steps of Data Cleaning

Usually, several people are involved in the data-cleaning process. In studies with face-to-face interviews, this process starts with the interviewers. It has early been recognized (Williams 1942) that interviewers have to follow standardized instructions exactly when using the questionnaire. They have to be neutral and to stick to the wording of questions as laid down in the questionnaire. Moreover, they should not change the order of questions in the questionnaire and always give the respondents sufficient time to make up their mind before answering. The interviewer must transfer the answers in the corresponding fields of the questionnaire with maximum care. For further details of conducting an interview, see chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook. After completion of an interview, the interviewer has to cooperate with the team that is responsible for the visual inspection of questionnaires regarding missing or inconsistent information.

After questionnaires have been checked and edited, they are ready to be entered into the computer. Entry of data from written or printed documents is a potential source of errors in databases. Entering the correct value in the wrong field, transposition errors (entering a "57" instead of a "75"), and typing errors (entering a "3" instead of a "9") are the most common types of error. Fortunately, these can be detected by double data entry.

Finally, also the user of data has his/her place in the data-cleaning process by giving feedback to the data center when implausible values become apparent during data analysis. However, some basic strategies should be implemented to identify errors in a standardized way already before the analysis dataset is released.

In epidemiological studies, there is a great need of appropriate tools to clean data because manual data cleaning is laborious, time-consuming, and error prone. Therefore, it should only be applied when automatic control is impossible (e.g., correcting typos in plain texts) or uneconomical (e.g., small databases).

According to Van den Broeck et al. (2005), data cleaning can be considered as a multistage process, passing through the stages screening, diagnosing/validation, and correction, in order to identify distinctive values and to verify whether they are correct or not. One of the major problems in this process is the fact that it is not always clear whether a value is incorrect or not. Therefore, standardized algorithms on how to deal with suspect values should be developed. At this point it should be stressed that, depending on the questionnaire or the measuring instrument, there will always be some degree of deviation between measured and real values. For example, the accuracy of skinfold measurement is sensitive to the type of caliper used and also to the individual's body fat distribution. In the following we are not considering such kinds of unavoidable measurement error but only those errors that exceed small technical variations.

The following three sections highlight the three basic steps of data cleaning: data screening, diagnosing/validation, and correction of errors.

27.4.2 Data Screening

The screening of data comprises the following checks:

1. Duplicates and non-existent IDs
2. Missing or invalid values and values outside plausible value ranges
3. Inconsistencies between variables

It is advisable to proceed in this order since several inconsistencies may not occur when out-of-range checks have been made in the first place. However, detailed knowledge of the collected data and the requirements of the final analysis are needed to identify and correct wrong or inconsistent data values.

27.4.2.1 Duplicates and Non-Existent IDs

A first step in data cleaning should be to investigate whether observations occur more than once in a database. In the simplest case, a record with identical variable values occurs twice (or more). In such a case, all redundant observations have to be deleted. The situation is more complicated if a record occurs more than once and values vary between records, for example, if different data values for the same person have been entered with the correct ID several times or if the same ID has been allocated to different people. As mentioned earlier, the majority of problems with incorrect IDs, of course, may be avoided by double entry of such key variables or by use of barcodes. Anyway, for a downstream check, for example, SAS/STAT® software offers procedures like PROC SQL to search for duplicate sets of values from a predefined set of variables across two or more rows of a dataset. Cody (2008) describes such and additional very helpful procedures (PROC FREQ, PROC SORT), options (NODUPKEY, NODUPRECS), and tricks based on SAS software which automatically identify and eliminate multiple observations. These procedures are also very helpful to verify that there is a minimum number of observations per ID in a database or to check whether all IDs have exactly the same number of observations, for example, in the case of repeated measurements.

Any database should be checked for completeness, that is, whether all questionnaires and measurements from all study participants have been entered. In the ideal case, fieldwork documentation can help to check whether all paper forms, questionnaires, and electronic records of a study subject have found their way into the final analysis dataset.

27.4.2.2 Missing Values

Missing values may occur for various reasons. For example, some study participants may refuse to answer questions felt as being offensive (e.g., questions concerning income, sexual practices), or they may skip answers simply because they do not understand the question. Other respondents (or interviewers) perhaps only forget to address a question. In other situations, measurements cannot be performed for medical or ethical reasons (e.g., X-rays in pregnant women). All these situations may result in item non-response.

Missing values may also occur because a question does not apply. The answer “No” to the question “Did you ever smoke cigarettes?” should always result in a missing value or better a corresponding code for the subsequent question that is legitimately skipped (see below): “How many cigarettes did you smoke per day?” Conversely, if the number of cigarettes smoked per day has been reported but the answer to the previous question whether the respondent ever smoked cigarettes is missing, then the answer can be imputed as “Yes” ex post during data cleaning.

Different codes should be used to distinguish between item non-response and missing values for other reasons to allow quality checks of their respective frequency. As mentioned above, it is recommended to use values that are out of range of the valid values of a given variable to represent different types of missing values (see Table 27.1). Nevertheless, whenever possible, missing information may be replaced by valid values from available sources. For example, a missing value for the variables sex or date of birth in a longitudinal study may be substituted by the corresponding information obtained during follow-up.

If there is no relationship between item non-response and the values of other variables, these missing values are called missing completely at random (MCAR). If the probability of missing data depends on other observed variables, this is a systematic error. However, when the missing values are at random after controlling for these other observed variables, that is, when they are conditionally random, such missing values are called missing at random (MAR). Finally, if the missing values are not completely random and may not be completely explained by other variables in the dataset, then such missings are considered as not missing at random (NMAR), which means that the probability that values are missing depends on other variables of interest or on the variable itself (e.g., the probability that self-reported survey data on weight is missing is higher for overweight participants of a study). Whenever it is likely that data are not missing at random, it is important "to carefully assess the sensitivity of results to a variety of plausible assumptions concerning the missingness process" (Fitzmaurice 2008). Many different methods have been proposed to handle missing data during statistical analysis. A comprehensive overview may be found in Sterne et al. (2009) and in chapter ▸Missing Data of this handbook.

27.4.2.3 Implausible Values

The search for incorrect or implausible data values starts with a univariate, descriptive analysis of single variables. For identifying data errors, one examines the distribution of a variable, possibly using a graphical approach, but in any case calculating measures of location (quartiles, mean, median, minimum, and maximum) and variation (standard deviation or variance). In this context, descriptive statistics are useful tools for explorative data analysis and especially for the detection of suspected values.

Often it is difficult to identify implausible values only by means of univariate methods, that is, without considering a broader context. Some data values may not catch one's eye before they are combined with other variables, that is, certain values only fall outside an expected range when considered in combination with another variable. Such a bivariate inspection of data may also be considered as a consistency check (see below). Let us assume that a child's true body weight of 18 kg was erroneously entered as 10 kg. Data cleaning should find ways to identify such errors. In this example, a useful plausibility check would combine the variable body weight with height, for example, by means of a scatterplot as a simple tool for spotting outliers. In a scatterplot, each subject is presented as a point on the x- and y-axis. Most subjects will fall within the cloud of points, while outliers tend to be located outside the cloud. Figure 27.7 shows such a plot of height and weight of 2- to 9-year-old children. The weight value of a child in the above example becomes suspect with the unusual combination of 10 kg and a height of 118 cm.

Nevertheless, it can be easily conceived that such an approach is not always successful. If, in the above-mentioned example, the body weight has been erroneously entered as 28 kg, the mistake remains undetected.

Boxplots are another approach to detect and visualize implausible data values (Tukey 1977). For a continuous variable a boxplot summarizes several statistical measures like mean, median, upper and lower quartiles, as well as minimum and maximum data values in a graph which displays a variable's location, spread, and

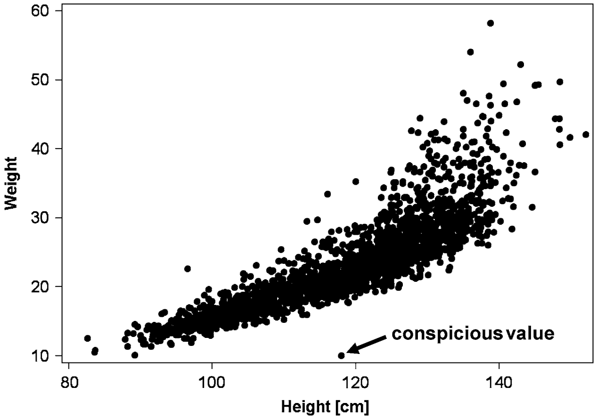

Fig. 27.7 Scatterplot of height and weight of 2- to 9-year-old children

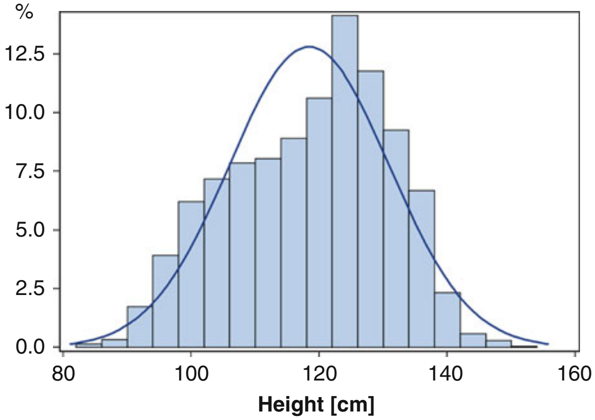

Fig. 27.8 Histogram and density (height)

outliers at a glance. Boxplots may be stratified by a second correlated categorical variable to detect outliers. The univariate distribution of the variable "height" of 2- to 9-year-old children is shown in Fig. 27.8. This graphical presentation shows no abnormalities in terms of implausible values. Only when stratified by age the side-by-side boxplots reveal several values of body height as suspect (Fig. 27.9).

Table 27.5 gives an overview for the variable height regarding the most important measures of location and dispersion as well as reasonable age-specific ranges. From this table it may be seen that the observed range for 2- to 3-year-old children is completely covered by the corresponding expected ranges, which contrasts to the observed range in the group of 5- to 6-year-old children.

27.4.2.4 Consistency Checks

Data combinations that are logically impossible may occur when data have been entered correctly but when the interviewer or the study participant made a mistake when filling in the questionnaire. Such errors can be identified by finding impossible

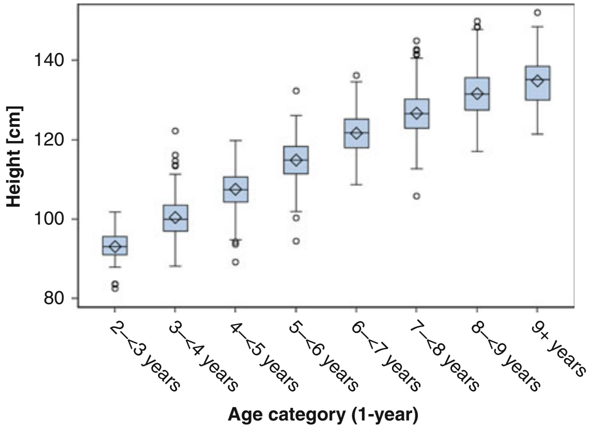

Fig. 27.9 Age-specific boxplots for height

Table 27.5 Descriptive statistics of height by age of children (Hebestreit and Ahrens 2012)

Summary descriptive table	Expected (“reasonable”) values of height[a]	Number of children	Height (cm)						
			Mean	SD	Min	Q1	Median	Q3	Max
Age group									
2–<3 years	79–103 cm	46	93.2	4.2	82.6	91.1	93.2	95.6	101.8
3–<4 years	87–111 cm	255	100.5	4.9	88.2	97.0	100.0	103.5	122.3
4–<5 years	93–118 cm	337	107.5	4.9	89.2	104.3	107.4	110.7	119.8
5–<6 years	99–125 cm	238	114.9	5.2	94.5	111.5	115.0	118.4	132.4
6–<7 years	106–133 cm	333	121.7	5.2	108.7	118.0	121.8	125.2	136.2
7–<8 years	112–140 cm	476	126.7	5.8	105.9	123.0	126.6	130.3	145.0
8–<9 years	117–146 cm	334	131.7	5.8	117.1	127.5	131.5	135.7	149.9
9–<10 years	121–152 cm	46	134.9	6.4	121.5	130.1	135.3	138.6	152.1
All		2,065	118.4	12.5	82.6	108.5	120.0	128.0	152.1

[a] Expected values of height are based on the 3th and 97th percentile published by Kuczmarski et al. (2000)

or extremely unusual combinations of variable values such as male patients who reported a Caesarean section, female patients with prostate cancer, or if the date of admission to a hospital precedes the subject’s date of birth. Unfortunately, it is nearly impossible to create consistency checks for all conceivable combinations of variable values in a dataset. Many inconsistencies are only revealed during data analysis. In any case, it has to be documented how observed inconsistencies are treated.

If several questionnaires are used within a study or variables are recorded repeatedly (e.g., in follow-ups), one should check whether specific characteristics such as date of birth and sex are consistent. Inconsistencies between such repeatedly collected variables might suggest that the forms belong to different respondents.

27.4.3 Data Validation and Correction of Errors

Data validation and correction of errors means the process of checking information in the database for consistency and plausibility in order to identify errors and correct them. At this point we are not referring to the validation and correction of first and second data entry or first and second codings (e.g., for job tasks, branches of industries, or diseases) – such discrepancies should be corrected considering the original questionnaire data or discussed and solved by the coding experts at regular team meetings through consensus. Here we are thinking of reviewing the data against established criteria in order to accept or reject suspect values. One opportunity for validation is the revision or confirmation of data values using external sources, when, for example, researchers review medical records to confirm the occurrence of events reported by patients.

Checks of value ranges serve to identify outliers, that is, values of a variable that fall outside the range of reasonable values for that variable. For example, a percentage measurement must be in the range of 0 and 100, or the height of an adult person must be in the range of 50–250 cm. Therefore, if you detect values above 250 cm, it is obvious that an error was made, either by filling the questionnaire or during the data entry process. Of course, range checks should be first of all part of data entry to allow immediate cross-checks with the data source (cf. Sect. 27.3.1) or to accept only responses within a specified range. In the absence of reference data or obvious normal ranges, it becomes difficult to define the upper and lower limits of observed values. In these cases, objective and systematic rules for the detection of outliers, that is, observations that deviate "too much" from other observations, are needed. As a simple rule of thumb, (Osborne 2010) suggested to consider observations that deviate by more than three standard deviations (SDs) from the mean of a normally distributed variable as "not generated by the population of interest" (Osborne 2010). In any case, one should be very cautious before correcting or removing an outlier. The deletion of an outlier leads to a smaller "new" standard deviation. As a consequence now, other previously unsuspected values may appear as outliers. Figure 27.10 shows the distribution of data and possible cut-offs to distinguish between questionable and impossible values. However, in the case of non-normal distributions, data have to be normalized by appropriate transformations before looking for outliers.

According to Van den Broeck et al. (2005), there are three options to treat a suspect value: correcting, deleting, or leaving unchanged. Close attention should be paid to the question at which stage of data processing one carries out these changes. In general, the raw dataset should never be changed, perhaps with one exception: a mismatch between the information on the questionnaire and the corresponding value in the data file; such discrepancies should be corrected immediately in the raw dataset. All other types of errors and inconsistencies should be identified and removed during the data-cleaning process. Impossible values should be set to missing or changed to a value (e.g., −9) that indicates that the original value is incorrect. Unchanged suspect values may be flagged. Flagged suspect values can be easily excluded from subsequent sensitivity analyses. If the reason for a false

value can be traced back, it may be justified to use other variables to reconstruct the correct value and to replace the suspect value by a plausible value (cf. Sect. 27.4.3). However, often information is insufficient to clarify suspect values. Then removal of the questionable values may be the only choice.

In general, automatic corrections should only be made in unambiguous situations (see the example in Table 27.6 where the respondents mixed up the week of delivery with the weeks before the calculated delivery date). Suspect values that cannot be corrected by a standardized routine should be clarified case by case by experienced researcher staff that is able to define hard cut-offs or to decide whether an extreme value is still (biologically) possible. Hard cut-offs should always be set in a conservative way in order to minimize the chance that a suspect value is deleted although it is true.

By means of simple analysis procedures in statistical software packages, it is possible to produce the so-called exception reports, sorted by ID number. An exception report is a listing of suspect values that have become conspicuous in the course of data screening. Since such values in general fall outside a predefined range, a listing of additional information may be helpful for assessing the implausibility (triangulation). For example, if the weight of a child seems unusually high, it may be helpful to list further additional information such as height, waist circumference, or skinfold thickness. Different approaches for creating such lists by means of the SAS program package can be found in Cody (2008).

Table 27.6 shows an excerpt from such an exception report. As a first check of suspect values, data entry errors should be ruled out by comparison with the original data source. If a suspect value roots in the original documents or the original data files, it may be useful to clear it with the staff involved in data collection or data entry. In general, such mutual consultations between interviewers, study nurses, data typists, physicians, statisticians, and epidemiologists involved in the study may help to decide difficult cases and to settle decision rules. All principal decisions regarding

Table 27.6 Example for an exception report taken from the IDEFICS study (Ahrens et al. 2011)

ID	Question: variable	Description	Value	Confirm or correct
1122	Q1: Child's date of birth	Out of range (01.01.1999; 31.12.2005)	25.04.2007	25.04.2000
3243	Q3: Weeks before calculated date (weeks)	Weeks before calculated date >> upper limit (6 weeks)	34	6
5243	Q4: Birth – child's weight (g)	Child's birth weight << lower limit (1,400 g)	1,380	✓
1467	Q5: Birth – child's height (cm)	Child's birth height << lower limit (45 cm)	44	✓
1499	Q2: What sex is the child?	Different information from T0 and T1	Male	Male ✓

the data-cleaning process should be agreed with the staff that is responsible for data management. Corrections should be made on the listing first (last column of Table 27.6) and in the data file subsequently.

In this example, the child's date of birth for ID 1122 was mistyped, and the correct date as given in the questionnaire was entered manually in the last column of the list. The birth weight of ID 5243 as well as the birth height of ID 1467 was confirmed by inspection of the original questionnaire. Often it is useful to complete such a list with additional information that helps to verify questionable values. For instance, it can be useful to list the complete questionnaire information on preterm delivery, birth weight, and height simultaneously to facilitate the validation of suspect values at a glance. The value of 34 weeks for preterm birth of ID 3243 was correctly transferred from the questionnaire. Obviously parents completing the questionnaire misunderstood the question in this case and reported the week of delivery instead of the weeks before the calculated date of delivery. In such obvious situations it may be justified to recalculate the value in question. Here, the difference between the full term and the reported week of delivery has to be calculated as $40 - 34 = 6$ weeks before calculated date. This example shows that it may be justified to perform corrections automatically. Here the following correction algorithm was implemented: if reported value $x > 30$, then calculate the corrected value as $x' = 40 - x$. For ID 1499, contradicting information was noted for sex of the child reported at baseline (T0) and at follow-up (T1). Depending on the study protocol, such disagreements may be set to missing or corrected (in case there is an additional trustworthy data source), or the original respondent may be contacted for verification.

It is advisable to carry out the whole process of data cleaning within a command file. This ensures a complete documentation of changes made to a dataset (see Table 27.7).

Table 27.7 Example for an SAS-based command file for the correction of errors

```
Data libname.final_data;
    set libname.pre_final_data;
              ...
                If id_no=1122 then year_of_birth=2000;
                If id_no=1499 then sex_child=1;
                If weeks_before>30 then weeks_before=40-weeks_before;
            ...
            ...
```

Again, it is strongly recommended to never change the raw data and to store all programs that have been used at different time points to create the final dataset. This ensures that also intermediate versions of the database can be reconstructed. After the correction of errors, the above-described methods of data screening should be repeated to make sure that data that are out of range of reasonable limits have been corrected.

27.5 Preparing the Final Dataset

A study protocol of an epidemiological study describes the hypotheses and the means by which these are investigated and tested. On an operational level, precise definitions of the study variables and a description of the planned statistical analyses are necessary. This may include a description of the statistical models to be used, a list of variables to be included in the models, the specification of a variable selection procedure, and the planned subgroup and sensitivity analyses. In preparing these proceedings, one can learn from the conduct of clinical trials, where the consent of regulatory authorities is obtained on the basis of definitions and operational procedures laid down in a so-called Statistical Analysis Plan (SAP). An outline of such plan is given in Box 27.1.

To allow for new questions and hypotheses that emerge in course of a study, an SAP may be updated where revisions are numbered and each version is documented.

27.5.1 Final Dataset

Statistical analyses should be performed on a prepared analysis dataset (Chang and Wong 2005), which we call the final dataset. It contains all variables, original and derived, on which the planned final calculations are performed. In this way, the final dataset serves as a repository of all variables on which the final statistical outputs are based. Separating the final dataset from data management processes like merging, cleaning, or creating derived variables has several advantages: (i) reproducibility – all steps leading from raw data to statistical outputs can easily be reproduced;

Box 27.1. Outline of a Statistical Analysis Plan (SAP)

Suggested outline of an SAP:

(i) *Introduction*: background and aim(s) of the study

(ii) *Data management*: methods for the collection and use of data
   (a) Data flow
   (b) Analysis datasets
      – Inclusion/exclusion criteria for participants
      – Variables (original and derived) to be included for the analyses
      – Definition of derived variables (see below)
      – Handling of missing values and outliers
      – Matching strategies (if applicable)

(iii) *Statistical analyses*: planned statistical evaluations
   (a) Descriptive analyses
   (b) Primary analyses, with full model specification (covariates, reference categories, etc.)
   (c) Statistical methods, if these are not standard
   (d) Subgroup and sensitivity analyses and power calculations

(iv) Measures to assure quality
   (a) Program documentation and validation

(ii) comprehensibility – distinct steps of data processing are clearly separated; and (iii) simplicity – the analysis programs become more simple. For studies incorporating a wide variety of potential risk factors, the final dataset may be structured according to different areas, for example, demography, lifestyle, and occupational exposure.

27.5.2 Quantification of Exposure

Operationalizing "exposure," be it chemical agents in a working environment or personal habits like physical exercise or smoking, is almost always a substantive task requiring interdisciplinary collaboration, as it is extensively documented in this handbook. This task requires considerably more person-time than the final statistical analysis. The process of transforming raw data, comprising the information collected for each participant, into numerical variables that can be used in statistical procedures is called quantification.

Definitions and computational details for derived variables should be laid down in the SAP or/and a similar document (data dictionary, see Table 27.2 for present and later reference). When quantifying the exposure, the first step is to choose an appropriate metric; often, more than one metric will be derived (see chapter ►Exposure Assessment of this handbook). In Table 27.8 four examples are given, starting with quantifying demographic variables.

Table 27.8 Example of a calculation table describing study variables of an analysis dataset

Variable name	Description	Details
	Physical activity	
PHYS_ACTIV	Hours of physical activity per week	*PHYS_ACTIV = 5*(PLWEEKD_H + PLWEEKD _M/60) + 2*(PLWEEKEN_H + PLWEEKEN_M/60) + (CLUB_H + CLUB_M/60)*
	Demographic variables	
YEAR	Year of interview	e.g., 2009
AGE	Age at cohort entry in years calculated by "entry year – birth year"	Positive integer, e.g., 56
AGE_CAT	Categorization of *AGE*	1: $AGE \leq 40$ 2: $40 < AGE \leq 50$ 3: . . . . .
AGE_C	*AGE* centered at 55 years	*AGE_C = AGE – 55*
	Smoking	
PACKY	Pack-years (sum over smoking periods (in years) times number of smoked packages per day)	Data from smoking biography, assuming *J* smoking periods, each starting with *YBEG*, ending with *YEND*, with *PACK* (per day) $PACKY = \sum_j (YEND_j - YBEG_j + 1)*PACK_j$
PACK_CAT	Categorization of *PACKY*	0: Never smoked cigarettes $1: 0 < PACKY \leq 10$ $2: 10 < PACKY \leq 20$ $3: 20 < PACKY \leq 40$ $4: PACKY > 40$
LOG_PY	Log(pack-years + 1)	*LOG_PY*=log(*PACKY*+*1*)
SMOKE_DUR	Duration of smoking	$\sum_j (YEND_j - YBEG_j + 1)$
SMOKER	Person has smoked cigarettes, cigars, or pipes	=1, if (*PACKY*>½ or person has smoked cigar or pipe for more than 1 year) =0 otherwise
	Occupation	
ASBESTOS	Self-reported occupational asbestos exposure	0: No 1: Yes
List_A_Dur	Duration in industries/occupations known to be associated with lung cancer (for the list of corresponding codes, see Ahrens and Merletti 1998)	Data from job periods, assuming *J* periods of occupations that belong to List A, each starting with JOB_*BEG*, ending with JOB_*END* $List\_A\_Dur = \sum_j (JOB\_END_j - JOB\_BEG_j + 1)$

The second example comes from an ongoing cohort study (Ahrens et al. 2011) and describes measurement of a child's weekly physical activity. Total "hours of physical activity per week" may be expressed as the total time per week performing physical activity including outdoor activities and the time spent in a sports club.

The derived variable for this summary measure, *PHYS_ACTIV*, is calculated from the (questionnaire) variables *PLWEEKD_H* and *PLWEEKD_M* (hours and minutes the child was playing outdoors on weekdays), the variables *PLWEEKEN_H* and *PLWEEKEN_M* (hours and minutes the child was playing outdoors on weekend days), and the variables *CLUB_H* and *CLUB_M* (hours and minutes a child spent in a sports club per week). Single missing values are set to zero. The exact quantification of this variable can be seen in Table 27.8.

The third example describes quantification of smoking data from a case-control study where participants reported a detailed smoking history. The interview assessed changes of smoking behavior over time and recorded type and amount smoked for each period over which smoking behavior was stable. The following variables are available for each smoking period: *YBEG* (first year of smoking period), *YEND* (last year of smoking period), and *PACK* (packages (20 cigarettes) per day). Cigarette smoking is often quantified in terms of a cumulative measure called pack-years (see chapter ▸Environmental Epidemiology of this handbook). This metric combines duration and intensity of cigarette smoking by multiplying the number of smoked packages per day with duration in years. Further variables like smoking categories or a log-transformed variable log(pack-years + 1) can be derived from this metric. Other frequently used exposure variables are ever/never exposed (*SMOKER*) and duration of exposure in years (*SMOKE_DUR*).

Also based on the data from a case-control study, the fourth example describes the quantification of occupational hazards. To evaluate the total impact of occupational exposure on lung cancer, Pohlabeln et al. (2000) used the work of Ahrens and Merletti (1998) which translated occupations and industries that are known (List A) or suspected (List B) to be associated with lung cancer into the corresponding ISCO (International Labour Office 1968) and/or ISIC codes (United Nations Publications 1971). Based on these codes it was possible to calculate, for example, the duration of employment in List A occupations.

Sometimes a transformation of variable values (e.g., logarithm, square root) is necessary to accommodate the assumptions underlying a statistical model (e.g., normality, constant variance) or the assumed biological dose-effect relationship. The three main reasons for transforming data are (i) to change their distributional form (usually to make it closer to a normal distribution), (ii) to stabilize variance, and (iii) to linearize relationships (Armitage et al. 2002). For some well-investigated factors like smoking, certain transformations of the corresponding metric were shown to be useful. For example, the previously mentioned log-transformed variable log(pack-years + 1) often produces a better fit in regression models compared to the untransformed variable (Breslow and Day 1980). For further methods of fitting continuous variables for statistical modeling, for instance, building polynomial expressions, see chapter ▸Analysis of Continuous Covariates and Dose-Effect Analysis of this handbook).

Three aspects should be considered when variables are transformed or otherwise fitted for statistical modeling: (i) quality assurance, that is, documentation and validation (e.g., in the form of program code review or even by double programming) of the program code, is of utmost importance; (ii) transparency and clarity have to be enhanced by labeling of variables and by using formats for categorical variables; and (iii) full precision of the recorded data (no "rounding" of intermediate results) has to be used for calculations.

Quantification may also involve the application of complex statistical concepts and procedures like, for instance, a principal component analysis to condense the number of variables of a food frequency questionnaire or propensity score methodology in a pharmacoepidemiological study. For example, in an investigation on adverse events related to the use of a drug, a propensity score adjusted analysis is foreseen. Calculating the propensity score itself relies on prior quantification of co-medication and comorbidities thought to be related to drug prescription. Prior quantification is also necessary for simpler measures like the Charlson comorbidity score (Sax and Charlson 1987) that is also employed in the field of pharmacoepidemiology.

A different type of quantification concerns the integration of extraneous information to enhance exposure assessment, as, for example, with job exposure matrices (JEMs) in occupational epidemiology (see chapter ▸Occupational Epidemiology of this handbook). Here the coded occupations experienced during a subject's job history are linked to a JEM to infer agent exposures which are inferred from job titles. An even more thorough (and more expensive) assessment would make the complete working biography accessible to industrial hygienists to perform an individual exposure rating (Pohlabeln et al. 2002, see also chapter ▸Exposure Assessment of this handbook).

Finally, two major considerations should be kept in mind when deriving study variables:

(i) Time-related exposure variables have to be truncated prior to disease onset of cases and a corresponding point in time of referents to avoid misinterpretation (e.g., reverse causation). In chronic disease epidemiology the time of disease onset usually is unknown as is the induction period of an exposure to a suspected agent, that is, the time between exposure and its effect in form of clinical disease manifestation. It is therefore prudent to restrict exposure duration to a period that ends a considerable time prior to interview or diagnosis. The approach may be formalized by computing time-weighted cumulative exposure measures (see chapter ▸Environmental Epidemiology of this handbook or Breslow and Day (1987)). As an example of what might go wrong, consider a case-control study on risk factors of leukemia. Diagnostic X-rays are discussed as a potential risk factor of leukemia and lymphoma (Boice Jr. et al. 1991). If – in a case-control study – assessment of X-ray exposure would include the time period of disease manifestation, the history of cases would include all the diagnostic X-ray exposures caused by diagnostics to localize the disease. As non-diseased persons (controls) would usually not experience this exposure, reverse causation might occur, that is, X-ray exposures are the result of the diagnosis (not the other way round).

(ii) With secondary data, often outcome variables have to be constructed. In epidemiological field studies, disease status is usually observed directly, and great scrutiny is exercised in ascertaining the case status of a patient. For example, in studies of lung cancer, a diagnosis has to be histologically confirmed by tissue material obtained via bronchoscopy or surgery. When working with secondary data like claims data of statutory health insurances, outcome variables like disease status are not observed directly. Therefore, proxy indicators of the disease status of a subject have to be derived out of several choices. Here, high specificity deserves priority; otherwise, the case series would include a large number of false positives, leading to biased relative risk estimates. The following may serve as an example: Based on claims data, an investigator wants to assess the impact of certain medical risk factors on the onset of gastrointestinal bleeding (GIB). The diagnosis of a GIB event may be recorded, both, in ambulatory or hospital data. In this case it is recommended to use hospital records only, specifically the discharge diagnosis, being the most reliable one.

27.6 Conclusions

Data management in epidemiological studies includes the collection, entry, and quality control of data as well as the preparation of a cleaned database. One of the basic prerequisites for the provision of a high-quality database is, of course, that it has to be ensured that field staff adheres to standardized instructions in using questionnaires and measurement devices. Any automatical transfer of data from the devices to the database should ensure that the actually measured values are transferred. Dealing with missing values, the criteria for the definition of implausible values and the reasons which lead to the exclusion of entire records, as well as the quantification and operationalization of derived variables, must be described comprehensibly in the study manual.

According to Chin and Lee (2008), an error detection arsenal consists of five major tools: visual inspection, data entry programs, descriptive statistics, graphing, and logical checks. Data collected by questionnaires should always be visually inspected and entered twice (double data entry). In addition, data entry should be technically restricted to plausible ranges and valid codes (for alphanumerical variables). Immediately after entering the first few records, one should start the process of checking the incoming data for completeness, plausibility, and consistency. This can be done by simple descriptive statistics (minimum, maximum, frequency of missing values), possibly supplemented by graphical methods (e.g., boxplots). Stratification by selected variables (e.g., age or country) as well as multidimensional graphical methods (e.g., scatterplots) may help to identify implausible combinations of values. Conspicuous values then should be identified by a program and printed out as lists (exception report) which may be supplemented by further variables that can be helpful in assessing the plausibility (triangulation).

Corrections in the original questionnaire and the raw dataset should be avoided, perhaps with one exception: If it can be proved beyond doubt that the collected information is really incorrect, then the error should be corrected in the original questionnaire as well as in the raw dataset – accompanied, of course, by a corresponding documentation in the questionnaire. All other corrections should be implemented by a computer program which leaves the raw data files unchanged but generates a so-called pre-final dataset. This pre-final dataset should ideally only comprise variables with plausible and valid values, whereas, of course, conspicuous values that were validated and found to be correct (e.g., if a child indeed weighs 120 kg) remain unchanged.

Data entry and verification of the data should be done as soon as possible to identify and resolve any emerging systematic errors, caused, for example, by faulty devices. Based on the verified and corrected pre-final dataset, the final dataset (analysis dataset) will be generated by means of a well-documented computer program. This database contains all variables, original and derived, on which the final calculations are performed. In this way, the final dataset serves as a repository of all variables on which the final statistical outputs are based.

Chin and Lee (2008) made a nice comparison between the process of data management and cooking: "Before cooking, a good chef checks the quality of the ingredients (e.g., how fresh are the vegetables and fish, what is the grade of the meat) and then carefully converts the ingredients into usable forms (e.g., removes the bones from the fish, dices the vegetables, and tenderizes the meat). Without good quality ingredients, no chef [. . .] can prepare good quality dishes. Without properly preparing the ingredients, the dishes also will suffer." Comparable to that, ". . . poor quality data can only yield poor quality results that can only generate very limited conclusions."

28.1 Introduction

When planning a research project, an epidemiologist must consider how many subjects should be studied. While factors such as available budget certainly present constraints on the maximum number of subjects that might actually be included in a study, statistical considerations are extremely important. To address the statistical questions about appropriate sample size, the researcher must first specify the study design, the nature of the outcome variable, the aims of the study, the planned analysis method, and the expected results of the study. Is the goal of the study to distinguish between hypotheses about the value of a parameter or function of parameters, or is the goal to provide a confidence interval estimate of a parameter such as the odds ratio or relative risk?

This chapter is organized as follows. We introduce the issue of how to choose sample size for estimation of a parameter or for a hypothesis test regarding a parameter in the context of one-sample studies in which it is desired to estimate or test a population proportion. We continue on to two-sample studies involving comparisons between two proportions and one- and two-sample studies involving estimation or testing of population means. We conclude with a section on sample size for logistic regression.

In this chapter, we will provide a brief introduction to power and sample size computation and only address sample size issues for a few of the procedures that are most commonly used in epidemiological research. However, we do hope that the reader will gain a sense for what one can accomplish by planning a study with appropriate attention to sample size considerations.

A focus on sample size considerations when the study is first being planned is critical for the ultimate likelihood that a study proposal is accepted for funding and that the final manuscript will be accepted for publication. To ignore the issue of sample size would greatly increase the likelihood of embarking on a costly and time-consuming epidemiological study with little likelihood of finding any definitive results.

28.2 One-Group Designs, Inferences About Proportions

The simplest study design is one in which interest focuses on results for a single group. One is often interested in making inferences about the value of a population proportion. In this section, we will illustrate how to choose sample size for the following examples:

Example 28.1.
A district medical officer seeks to estimate the proportion of children in the district receiving appropriate childhood vaccinations. Assuming a simple random sample is to be selected from a community, how many children must be studied if the resulting estimate is to fall within 10 percentage points of the true proportion with 95% confidence?

Example 28.2.
Consider the information given in Example 28.1, only this time we will determine the sample size necessary to estimate the proportion vaccinated in the population to within 10% (not 10 percentage points) of the true value.

Example 28.3.
During a virulent outbreak of neonatal tetanus, health workers wish to determine whether the rate is decreasing after a period during which it had risen to a level of 150 cases per 1,000 live births. What sample size is necessary to test the null hypothesis that the population proportion is 0.15 at the 0.05 level if it is desired to have a 90% probability of detecting a decrease to a rate of 100 per 1,000 if that were the true proportion?

The first two examples involve estimation and confidence intervals, while the third involves a statistical hypothesis test.

The usual model underlying testing or estimation of a population proportion assumes that the design involves a simple independent random sample from a population in which the probability of a "success" is constant. The distribution of the number of successes in a sample of size n with a true underlying proportion of successes denoted by π is given by the binomial distribution. However, formulas are simplified when power and sample size determinations are made on the basis of using the normal approximation to the binomial.

The sampling distribution of the sample proportion "p" is approximately normal with mean of π (the expected value of p, $E\,(p) = \pi$) and variance of p, $\mathrm{Var}\,(p) = \pi\,(1-\pi)/n$; the standard deviation is $\sqrt{\pi\,(1-\pi)/n}$.

We begin by discussing sample size determination for estimation (the confidence interval approach) and then turn to sample size determination for hypothesis testing problems.

28.2.1 Confidence Intervals for a Single Population Proportion

Two-sided $100\,(1-\alpha)\,\%$ confidence intervals for a parameter, θ, based on using the normal approximation can be stated in general as

$$\hat{\theta} \pm z_{1-\alpha/2}\widehat{\mathrm{SE}}\left(\hat{\theta}\right), \tag{28.1}$$

where $z_{1-\alpha/2}$ is the $100(1-\alpha/2)$th percentile of the normal (or Gaussian) distribution. For the commonly used two-sided 95% confidence interval, $z_{1-\alpha/2} = 1.96$. The $100\,(1-\alpha)\,\%$ confidence interval for π based on the estimated proportion, p, is given by

$$p \pm z_{1-\alpha/2}\sqrt{\frac{p(1-p)}{n}}. \tag{28.2}$$

Letting ω be the half-width of the confidence interval for the expected true value π, we have

$$\omega = z_{1-\alpha/2}\sqrt{\frac{\pi(1-\pi)}{n}}. \tag{28.3}$$

Table 28.1 Sample size for 95% two-sided confidence interval for a proportion (using the normal approximation) to have expected width, ω

	ω	
π	±0.05	±0.10
0.50	385	97
0.25	289	73
0.10	139	35

The sample size necessary to achieve a confidence interval of width ω is given by

$$n = \left(\frac{z_{1-\alpha/2}}{\omega}\right)^2 [\pi(1-\pi)]\,. \tag{28.4}$$

Returning to Example 28.1, we begin by assuming that the rate of vaccinated children is expected to be about 75%. We would then set $\pi = 0.75$, $\omega = 0.10$, and $z_{1-\alpha/2} = 1.96$. From Eq. 28.4, we find that $n = 72.03$. Note that for sample size calculations, we round up. We conclude that to estimate the expected population proportion to within ±0.10, a sample of 73 children would be required.

If we do not really know what rate to expect, we can make use of the fact that n will be largest for $\pi = 0.50$ and use this value to solve for n. For Example 28.1, we require a sample size of 97 to be sure that the confidence interval width will be no wider than plus or minus 10 percentage points no matter what the observed proportion is.

Table 28.1 presents the required sample sizes for selected values of π and ω.

Proceeding to Example 28.2, we consider the information given in Example 28.1, only this time we will determine the sample size necessary to estimate the proportion vaccinated in the population to within 10% (not 10 percentage points) of the true value.

Let θ be the unknown population parameter as before and let $\hat{\theta}$ be the estimate of θ. Let ε, the desired precision, be defined as

$$\varepsilon = \frac{\left|\hat{\theta} - \theta\right|}{\theta}.$$

In the present example, based on the confidence limits using the normal approximation to the distribution of p, it follows that

$$|p - \pi| = z_{1-\alpha/2}\frac{\sqrt{\pi\,(1-\pi)}}{\sqrt{n}}$$

and, dividing both sides by π, an expression similar to the one presented above for ε is obtained. That is,

$$\varepsilon = \frac{|p-\pi|}{\pi} = z_{1-\alpha/2}\frac{\sqrt{1-\pi}}{\sqrt{n\pi}},$$

and squaring both sides and solving for n gives

$$n = z_{1-\alpha/2}^{2} \frac{1-\pi}{\varepsilon^{2}\pi}. \tag{28.5}$$

Assuming $\pi = 0.75$, we would find that a sample size of 129 would be required to assure that the 95% confidence interval would be within 10% of the true value.

28.2.2 Hypothesis Testing for a Single Population Proportion

Suppose we would like to test a null hypothesis about the value of the population proportion

$$H_0 : \pi = \pi_0$$

versus the one-sided alternative hypothesis

$$H_a : \pi > \pi_0.$$

Statistical hypothesis testing involves balancing the two types of errors that can be made. Type I error is defined as the error of rejecting the null hypothesis when it is in fact true. We denote the probability of making a type I error as "α"; a commonly used choice for α is 0.05. The critical value of the test statistic is then chosen so that the probability of rejecting the null hypothesis when it is true will be α.

To choose the necessary sample size, we need to address type II error as well. A type II error is the error of failing to reject the null hypothesis when it is in fact false. To determine the probability of a type II error (denoted by "β"), we must specify a particular value of interest for the alternative hypothesis, say, π_a. The probability of rejecting the null hypothesis when it is false is defined as the *power* of the test, $1-\beta$. Typically, we require the power at the alternative of interest to be 80% or 90%.

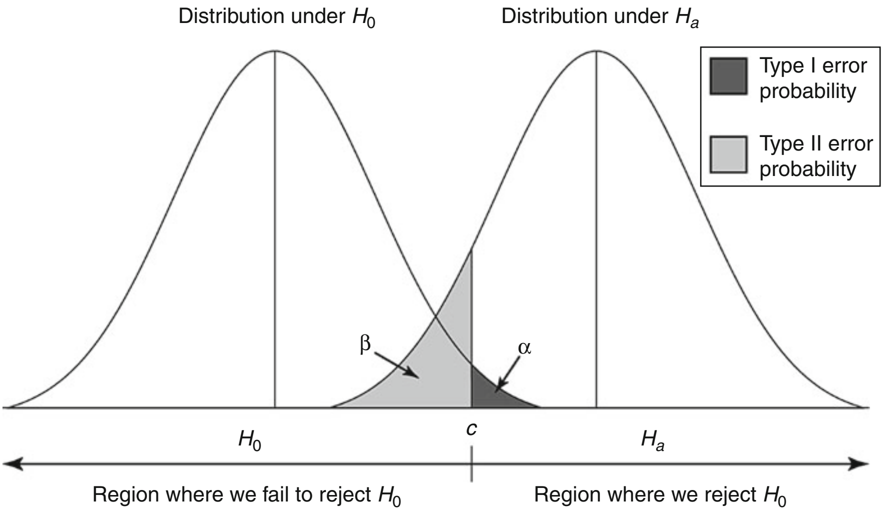
Based on the normal approximation to the binomial, the test statistic for a test of the null hypothesis is given by

$$z = \frac{p-\pi_0}{\sqrt{\frac{\pi_0(1-\pi_0)}{n}}}.$$

To set the probability of a type I error equal to α, we plan to reject the null hypothesis if $z > z_{1-\alpha}$. To choose n, we fix the probability that $z > z_{1-\alpha}$ if the population proportion equals π_a to be $1-\beta$. This may be represented graphically as shown in Fig. 28.1.

In this figure, the point "**c**" represents the upper 100αth percent point of the distribution of p for the sampling distribution centered at π_0 (i.e., the distribution which would result if the null hypothesis were true):

$$c = \pi_0 + z_{1-\alpha}\sqrt{\pi_0\,(1-\pi_0)/n}.$$



Distribution under H_0
Distribution under H_a
Type I error probability
Type II error probability
β
α
H_0
c
H_a
Region where we fail to reject H_0
Region where we reject H_0

Fig. 28.1 Sampling distributions for one-sample hypothesis test

For the sampling distribution centered at π_a (i.e., the distribution which would result if the alternate hypothesis were true), "**c**" represents the lower 100βth percent point of the distribution of p:

$$c = \pi_a + z_\beta \sqrt{\pi_a (1 - \pi_a)/n}.$$

In order to find n, we set the two expressions equal to each other. From this, it follows that

$$\pi_0 + z_{1-\alpha} \sqrt{\pi_0 (1 - \pi_0)/n} = \pi_a + z_\beta \sqrt{\pi_a (1 - \pi_a)/n}.$$

Noting that $z_{1-\beta} = -z_\beta$, we find

$$\pi_a - \pi_0 = \left\{ z_{1-\alpha} \sqrt{\pi_0 (1 - \pi_0)} + z_{1-\beta} \sqrt{\pi_a (1 - \pi_a)} \right\} \Big/ \sqrt{n},$$

and, solving for n, we find that the necessary sample size, for this single sample hypothesis testing situation, is given by the formula

$$n = \frac{\left\{ z_{1-\alpha} \sqrt{\pi_0 (1 - \pi_0)} + z_{1-\beta} \sqrt{\pi_a (1 - \pi_a)} \right\}^2}{(\pi_a - \pi_0)^2}. \tag{28.6}$$

Notice that as π_a gets further and further away from π_0, the necessary sample size decreases.

Table 28.2 Sample size for 0.05-level, two-sided test that the proportion equals π_0 versus the alternative π_a for specified levels of power (based on normal approximation)

		Power	
π_0	π_a	80%	90%
0.50	0.40	194	259
0.50	0.30	47	62
0.20	0.10	108	137
0.15	0.10	363	471
0.10	0.05	239	301

To illustrate, we return to Example 28.3 in which we wish to test the null hypothesis that $\pi = 0.15$ at the one-sided 5% level and have 90% power to detect a decrease to a rate of 0.10. Using Eq. 28.6, it follows that

$$n = \frac{\left\{ 1.645\sqrt{0.15\,(0.85)} + 1.282\sqrt{0.10\,(0.90)} \right\}^2}{(0.05)^2} = 377.90.$$

Hence, we see that a total sample size of 378 live births would be necessary.

To plan sample size for a two-sided test, we need only substitute $z_{1-\alpha/2}$ for $z_{1-\alpha}$ in Eq. 28.6 to obtain

$$n = \frac{\left\{ z_{1-\alpha/2}\sqrt{\pi_0\,(1-\pi_0)} + z_{1-\beta}\sqrt{\pi_a\,(1-\pi_a)} \right\}^2}{(\pi_a - \pi_0)^2}. \tag{28.7}$$

To have 90% power for a two-sided 5% level test for Example 28.3 would require a total of 471 subjects to detect the difference between the null hypothesis proportion, π_0, of 0.15 and the alternative proportion, π_a, of 0.10. Note that the sample size required to achieve 90% power for the specified alternative is larger when a two-sided 5% level test is planned than when a one-sided 5% level test is planned, so that the investigator needs to be clear as to whether the planned test is to be one-sided or two-sided when making sample size computations.

Table 28.2 presents the required sample sizes for selected values of π_0, π_a, and power. For a two-sided test, unless the null hypothesis proportion equals 0.5, computed sample sizes for alternative proportions given by $\pi_{aL} = \pi_0 - \delta$ and $\pi_{aU} = \pi_0 + \delta$ will differ; the larger estimate of sample size will be obtained for the alternative proportion closer to 0.5.

28.2.3 Additional Considerations and References

Good introductions to sample size computations for tests and confidence intervals for a single proportion can be found in Dixon and Massey (1983), Lemeshow et al. (1990), Fleiss (1981), and Lachin (1981). Books containing sample size tables are available (e.g., Machin and Campbell 1987; Machin et al. 1997; Lemeshow et al. 1990). Commercially available sample size software such as nQuery Advisor

Release 5 (Elashoff 2002) can be used to compute sample size for confidence intervals or hypothesis tests (based on either the normal approximation or an exact binomial test) for a single proportion as well as for a wide variety of other sample size problems.

For values of π near 0 or 1 (or for small sample sizes), sample size methods involving a continuity correction (Fleiss et al. 1980), methods designed for rare events (e.g., Korn 1986; Louis 1981), or methods based on exact tests (Chernick and Liu 2002) may be preferable.

Note that an actual field survey is unlikely to be based on a simple random sample. As a result, the required sample size would go up by the amount of the "design effect" which is determined by the details of the actual sampling plan. The "design effect" is the ratio of the standard error of the estimated parameter under the study design to the standard error of the estimate under simple random sampling; a text on sample surveys should be consulted for details (see Levy and Lemeshow 1999). For example, if a cluster sampling plan with a design effect of 2 were to be employed, the sample size computed using the above formulas would need to be doubled.

28.3 Comparison of Two Independent Proportions

28.3.1 Study Designs, Parameters, and Analysis Methods

More sample size literature exists for the problem of comparing two independent proportions than for any other sample size problem. This has come about because there are several basic sampling schemes leading to problems of this type. There are different parameterizations of interest and a variety of test and estimation procedures that have been developed. Sample size formulations depend on the parameter of interest for testing or estimation as well as the specifics of the test or estimation procedure.

The basic study designs relevant to epidemiological studies are experimental trials, cohort studies, and case-control studies. We describe each study type briefly and give an example. The examples will be addressed in more detail in subsequent sections.

Experimental Trial $2n$ subjects are recruited for a study; n are randomly assigned to group 1 and n to group 2. The intervention is applied according to the design. Subjects are followed for a fixed time and success-failure status is recorded. Experimental trials are usually randomized, often double blind, and always prospective. For example, patients with intestinal parasites are randomly assigned to receive either the standard drug or a new drug and followed to determine whether they respond favorably. The observed proportion responding favorably in group i is denoted by p_i and the true population proportion in group i by π_i.

Experimental trials are typically analyzed in terms of the difference in proportions, or the risk difference:

$$\text{Population risk difference} = \pi_1 - \pi_2. \tag{28.8}$$

$$\text{Estimated risk difference} = p_1 - p_2. \tag{28.9}$$

Cohort Study *n* subjects are recruited from group 1 and *n* from group 2; subjects are followed for a fixed time and success-failure status is recorded. Cohort studies are typically prospective studies. For example, workers with asbestos exposure and workers in the same industry without asbestos exposure are followed for the development of lung disease.

Cohort studies may be analyzed in terms of the risk difference or in terms of the relative risk:

$$\text{Population relative risk} = RR = \pi_2/\pi_1 \tag{28.10}$$

$$\text{Estimated relative risk} = rr = p_2/p_1. \tag{28.11}$$

Referring to the example, π_1 denotes the true proportion of diseased workers in the unexposed group, while π_2 denotes the true proportion of diseased workers in the exposed group, and p_1 and p_2 are the corresponding observed proportions.

Case-Control Studies *n* subjects (cases) are recruited from among those who have developed a disease, and *n* subjects (controls) are recruited from a similar group without the disease. Subjects from both groups are studied for the presence of a relevant exposure in their background. For example, tuberculosis (TB) cases and controls are assessed for whether they had been vaccinated with BCG (Bacillus Calmette-Guérin vaccine). Case-control studies are inherently retrospective studies, and interest is focused on the odds ratio:

$$\text{Population odds ratio} = OR = \pi_2\,(1 - \pi_1)/(1 - \pi_2)\pi_1. \tag{28.12}$$

$$\text{Estimated odds ratio} = or = p_2\,(1 - p_1)/(1 - p_2)p_1. \tag{28.13}$$

Referring to the example, π_1 denotes the true proportion of vaccinated subjects among the controls, while π_2 denotes the true proportion of vaccinated subjects among the TB cases, and p_1 and p_2 are the corresponding observed proportions.

We begin by discussing sample size determination for estimation (the confidence interval approach) and then turn to sample size determination for hypothesis testing problems.

28.3.2 Confidence Intervals for the Risk Difference

Example 28.4.

A pilot study with 20 subjects randomized to receive the standard drug to control intestinal parasites and 20 to receive a new drug found that 13 subjects (65%) receiving the standard drug responded favorably, while 17 (85%) of the subjects receiving the new drug responded favorably.

Question 4a: Do these data establish that the new drug is better (lower limit of confidence interval is greater than zero) and, if not, might it still be enough better to warrant a larger clinical trial? We address this question with a confidence interval below.

Question 4b: What sample size would be required for the larger clinical trial? We address this question in the context of a confidence interval later in this section and in the context of a hypothesis test in the following section.

The estimated value of the risk difference, $\pi_1 - \pi_2$, is given by $p_1 - p_2$, the observed difference in proportions. The variance of $p_1 - p_2$ for independent proportions when the sample sizes, n, in each group are equal is

$$\mathrm{Var}(p_1 - p_2) = \frac{\pi_1(1-\pi_1) + \pi_2(1-\pi_2)}{n}. \tag{28.14}$$

This formula is based on the assumption that the data come from independent random samples from the populations of interest. In population i, the probability of a success is a constant, π_i, and therefore the number of successes observed for each group has a binomial distribution with parameters n and π_i.

The standard error of this estimate, $p_1 - p_2$, is estimated by substituting the observed proportions for the true proportions and is given by

$$\mathrm{SE}(p_1 - p_2) = \frac{\sqrt{p_1(1-p_1) + p_2(1-p_2)}}{\sqrt{n}}. \tag{28.15}$$

Referring to the basic formula for a confidence interval based on the normal approximation given in Eq. 28.1, a two-sided 95% confidence interval for the difference in the proportions responding favorably to the new drug in comparison to the old drug is given by

$$0.85 - 0.65 \pm 1.96 \frac{\sqrt{0.85(1-0.85) + 0.65(1-0.65)}}{\sqrt{20}}.$$

The limits are 0.20 ± 0.209 or –0.009 to 0.409, suggesting that although we cannot rule out a difference of zero, the data indicate that the new drug might work markedly better than the standard.

The investigator wants to plan a definitive study to assess how much the success rates really do differ. What sample size would be necessary to obtain a confidence interval whose width is less than or equal to ±0.05?

We require that the confidence interval for $\pi_1 - \pi_2$, be $p_1 - p_2 \pm \omega$, where for Example 28.4, $\omega \le 0.05$. To obtain a confidence interval width satisfying these conditions, we must have

$$z_{1-\alpha/2} \frac{\sqrt{\pi_1(1-\pi_1) + \pi_2(1-\pi_2)}}{\sqrt{n}} \le \omega.$$

Table 28.3 Sample size per group for 95% two-sided confidence interval (using normal approximation) for risk difference to have expected width, ω

		ω	
π_1	π_2	± 0.05	± 0.10
0.50	0.50	769	193
0.50	0.25	673	169
0.50	0.10	523	131
0.25	0.25	577	145
0.25	0.10	427	107
0.10	0.10	277	70

Solving this equation for n, the sample size in each group, we obtain Eq. 28.16:

$$n = \frac{z_{1-\alpha/2}^2\left[\pi_1(1-\pi_1)+\pi_2(1-\pi_2)\right]}{\omega^2}. \tag{28.16}$$

For Example 28.4, an n per group of 546 would be required to obtain an expected 95% two-sided confidence interval width of approximately ±0.05 if we expect to see about the same proportions as we did in the pilot study.

Table 28.3 presents the sample size in each group necessary to obtain specified confidence interval widths for a few selected examples. This table should provide investigators with a quick idea of the order of magnitude of required sample sizes. Note that since the confidence interval width depends on the postulated proportions only through the terms $\pi_i\ (1-\pi_i)$, this table can also be used for proportions greater than 0.5.

If an investigator is a bit uncertain about what proportions to expect and wants to ensure that the confidence interval width is less than some specified amount $\pm\omega$ no matter what proportions are observed, we can use the fact that the confidence interval is widest when $\pi_1 = \pi_2 = 0.5$. In this case, the sample size required for each group is

$$n \le \frac{z_{1-\alpha/2}^2}{2\,\omega^2}. \tag{28.17}$$

For a two-sided 95% confidence interval, this becomes approximately $2/\omega^2$. For Example 28.4, the maximum sample size per group required for a confidence interval width of no more than ±0.05 is 769.

28.3.3 Confidence Interval for Relative Risk (Ratio)

Example 28.5.
Workers with asbestos exposure and workers in the same industry without asbestos exposure are followed for the development of lung disease. Suppose that disease occurs in 20% of the unexposed group, how large a sample would be needed in each of the exposed and unexposed study groups to estimate the relative risk to within 10% of the true value with 95% confidence assuming that the relative risk is approximately 1.75?

Forthis purpose, we define group 1 as the unexposed group and group 2 as the exposed group. The estimate of the relative risk (cf. chapter ▶Rates, Risks, Measures of Association and Impact of this handbook) is

$$\widehat{RR} = rr = p_2/p_1.$$

Since we are dealing with a ratio, which can be expected to have a skewed distribution with a lognormal shape, we need to take logs to normalize the distribution so that the normal approximation can be used to construct the confidence interval.

We obtain the standard deviation for the estimate for the case where the sample sizes in the two groups are equal by using the approximation

$$\mathrm{Var}(\ln(rr)) \quad \approx \quad \frac{1-\pi_1}{n\pi_1} + \frac{1-\pi_2}{n\pi_2}. \tag{28.18}$$

The estimated standard deviation is obtained by substituting the estimated proportions for the population proportions and taking the square root.

The 100 $(1-\alpha)$ % confidence limits for ln (RR) are given by ln $(rr) \pm \omega$ where

$$\omega = z_{1-\alpha/2}\widehat{SE}\left(\ln(rr)\right) \quad = \quad z_{1-\alpha/2}\sqrt{\frac{1-\pi_1}{n\pi_1} + \frac{1-\pi_2}{n\pi_2}}.$$

Then the confidence limits for RR are given by exp $(\ln(rr_L))$ and exp $(\ln(rr_U))$, where ln (rr_L) and ln (rr_U) are the lower and upper confidence limits for ln (RR).

To choose the sample size necessary to obtain a confidence interval of a desired width for ln (RR), we could simply specify ω and solve for n:

$$n = \frac{z^2{}_{1-\alpha/2}\left[\frac{1-\pi_1}{\pi_1} + \frac{1-\pi_2}{\pi_2}\right]}{\omega^2}. \tag{28.19}$$

Alternatively, an investigator may wish to specify the width in terms of how close the limits are to RR. For example, suppose that we are thinking in terms of values of $RR > 1$ and that we want the difference between RR and RR_L to be no greater than εRR; that is, we set $RR - RR_L = \varepsilon RR$ which we rearrange to get $RR\,(1-\varepsilon) = RR_L$. Then, taking logs, we have $\ln(RR) + \ln(1-\varepsilon) = \ln(RR_L)$ and $\ln(RR) - \ln(RR_L) = -\ln(1-\varepsilon) = \omega$, so

$$\omega = z_{1-\alpha/2}\sqrt{\frac{1-\pi_1}{n\,\pi_1} + \frac{1-\pi_2}{n\,\pi_2}} = -\ln(1-\varepsilon)\,.$$

Then to find the necessary sample size for each group, we solve for n to obtain

$$n = \frac{z^2{}_{1-\alpha/2}\left[\frac{1-\pi_1}{\pi_1} + \frac{1-\pi_2}{\pi_2}\right]}{[\ln(1-\varepsilon)\,]^2}. \tag{28.20}$$

Table 28.4 Sample size per group for 95% two-sided confidence interval for the relative risk to have lower limit $(1-\varepsilon)RR$

		ε	
RR	π_1	0.10	0.20
1.25	0.20	2,423	540
1.50	0.20	2,192	489
1.75	0.20	2,027	452
2.00	0.20	1,904	424
1.25	0.40	866	193

A version of this, which substitutes the expected RR for π_2, is

$$n = \frac{z^2{}_{1-\alpha/2}\left[\frac{1+RR}{RR\pi_1} - 2\right]}{[\ln(1-\varepsilon)]^2}. \tag{28.21}$$

Returning to Example 28.5, the expected $RR = 1.75$, and $\pi_1 = 0.20$, and we have requested that the lower limit of the confidence interval for RR be within 10% of the true value of RR. Therefore, $\varepsilon = 0.1$, and $1-\varepsilon = 0.9$, and the required sample size would be 2,027 per group or 4,054 total.

Table 28.4 presents the sample size in each group necessary to obtain specified confidence interval widths for a few selected examples.

28.3.4 Confidence Intervals for the Odds Ratio

Example 28.6.
The efficacy of BCG vaccine in preventing childhood tuberculosis is in doubt, and a study is designed to compare the immunization coverage rates in a group of tuberculosis cases compared to a group of controls. Available information indicated that roughly 30% of controls are not vaccinated, and we wish to estimate the odds ratio to within 20% of the true value. It is believed that the odds ratio is likely to be about 2.0.

For problems involving estimation of the odds ratio (cf. chapter ▶Rates, Risks, Measures of Association and Impact of this handbook), we let group 1 denote the controls and group 2 denote the cases. Our estimate of the odds ratio is

$$or = \frac{p_2(1-p_1)}{(1-p_2)\,p_1}.$$

Since we are dealing with a ratio, we need to take logs so that the normal approximation can be used to construct the confidence interval.

We obtain the standard deviation for the estimate for the case where the sample sizes in the two groups are equal, by using the approximation

$$\mathrm{Var}(\ln(or)) \approx \frac{1}{n\pi_1(1-\pi_1)} + \frac{1}{n\pi_2(1-\pi_2)}. \tag{28.22}$$

Table 28.5 Sample size per group for 95% two-sided confidence interval for *OR* to have lower limit $(1-\varepsilon)\,OR$

		ε	
OR	π_1	0.10	0.20
1.25	0.30	3,171	708
1.50	0.30	3,101	692
1.75	0.30	3,061	683
2.00	0.30	3,040	678
1.25	0.50	2,786	621

The estimated standard deviation is obtained by substituting the estimated proportions for the population proportions and taking the square root.

To obtain a $100\,(1-\alpha)\,\%$ confidence interval for $\ln(OR)$ of width ω where $\omega = z_{1-\alpha/2}\mathrm{SE}\,(\ln(or))$ when the sample sizes in the two groups are equal, we require a sample size per group of

$$n = \frac{z^2_{1-\alpha/2}\left[\frac{1}{\pi_2(1-\pi_2)} + \frac{1}{\pi_1(1-\pi_1)}\right]}{\omega^2}. \tag{28.23}$$

In situations where we assume that the odds ratio is greater than 1.0, to specify that the lower limit of the confidence interval be no less than $(1-\varepsilon)\,OR$, we would set $\omega = -\ln(1-\varepsilon)$ as we did in the previous section for the relative risk. We then obtain

$$n = \frac{z^2_{1-\alpha/2}\left[\frac{1}{\pi_2(1-\pi_2)} + \frac{1}{\pi_1(1-\pi_1)}\right]}{[\ln(1-\varepsilon)]^2}. \tag{28.24}$$

Solving for π_2 using Eq. 28.12, we have

$$\pi_2 = \frac{OR\,\pi_1}{OR\,\pi_1 + (1-\pi_1)}$$

and we can obtain sample size expressed in terms of π_1 and OR:

$$n = z^2_{1-\alpha/2}\left[\frac{OR + (1-\pi_1+OR\pi_1)^2}{\pi_1(1-\pi_1)OR[\ln(1-\varepsilon)]^2}\right]. \tag{28.25}$$

For Example 28.6, we have $OR = 2$, $\pi_1 = 0.30$, $(\pi_2 = 0.462)$, and $(1-\varepsilon) = 0.8$, so we need 678 subjects per group.

Table 28.5 presents the sample size in each group necessary to obtain specified confidence interval widths for *OR* for a few selected examples.

28.3.5 Testing the Difference Between Two Proportions

The goal is to test

$H_0 : \pi_1 = \pi_2$ versus $H_1 : \pi_1 \neq \pi_2$.

If it can be assumed that the samples of size n from both groups arise from independent binomial distributions, the test for H_0 can be performed using the normal approximation to the binomial.

The test statistic is

$$z = \frac{\sqrt{n}\,(p_1 - p_2)}{\sqrt{2\bar{p}\,(1-\bar{p})}}, \tag{28.26}$$

where $z \sim N\,(0, 1)$, i.e., z is normally distributed with mean 0 and variance 1, and where, in the general case with unequal sample sizes in the two groups,

$$\bar{p} \;=\; \frac{n_1 p_1 \;+\; n_2 p_2}{n_1 \;+ n_2},$$

whereas for equal sample sizes,

$$\bar{p} \;=\; \frac{p_1 \;+\; p_2}{2}.$$

(Note that the two-sided z test given by Eq. 28.26 is algebraically equivalent to the standard χ^2 test.)

The sample size in each group required for a two-sided $100\,(1-\alpha)\,\%$ test to have power $1-\beta$ is

$$n = \frac{\left[z_{1-\alpha/2}\,\sqrt{2\overline{\pi}(1-\overline{\pi})} + z_{1-\beta}\,\sqrt{\pi_1\,(1-\pi_1) + \pi_2\,(1-\pi_2)}\right]^2}{(\pi_1 - \pi_2\,)^2}. \tag{28.27}$$

and $\overline{\pi}$ is defined by analogy with $\overline{p}$.

Example 28.7.
Typically, the outcome measure for placebo controlled double-blind trials for acute duodenal ulcer healing is the proportion of patients whose ulcer has healed by 4 weeks as ascertained by endoscopy. The healing rate for the placebo group is typically about 40%. H_2-blocking active drugs usually result in 70% healed. The investigator wishes to evaluate a new drug with the expectation of seeking FDA (US Food and Drug Administration) approval; the results will be assessed by comparing observed proportions healed using the χ^2 test at the two-sided 5% significance level. Such trials are expensive to mount so that if the new drug is as effective as those currently approved, the investigator wants a 90% chance that the trial will yield a significant result.

Using Eq. 28.27 for a two-sided 5% test, a sample size of 56 patients per group or a total sample size of 112 patients would be required to achieve 90% power.

Table 28.6 presents the sample size in each group necessary for a 5% two-sided χ^2 test comparing two independent proportions to have specified power for a few selected examples.

Table 28.6 Sample size per group for 5% two-sided χ^2 test for the difference between two independent proportions to have specified power

		Power	
π_1	π_2	80%	90%
0.10	0.05	435	582
0.25	0.10	100	133
0.50	0.25	58	77
0.50	0.10	20	26

Table 28.7 Sample size per group for 5% two-sided test that the relative risk equals 1 to have specified power

		Power	
RR	π_1	80%	90%
1.25	0.20	1,094	1,464
1.50	0.20	294	392
1.75	0.20	138	185
2.00	0.20	82	109
1.25	0.40	388	519

28.3.6 Testing the Relative Risk

In a cohort study, where we want to focus attention on a test of the relative risk

$$H_0 : RR = \frac{\pi_2}{\pi_1} = 1,$$

the large sample test for this null hypothesis is the same as for the null hypothesis that the difference in proportions is zero and therefore the sample size formulas are the same. If we substitute *RR* into Eq. 28.27, we obtain

$$n = \frac{\left[z_{1-\alpha/2}\sqrt{(1+RR)[1-\pi_1(1+RR)/2]} + z_{1-\beta}\sqrt{[1+RR-\pi_1(1+RR^2)]}\right]^2}{\pi_1(1-RR)^2}. \tag{28.28}$$

Example 28.8.
Two competing therapies for a particular cancer are to be evaluated by the cohort study strategy in a multicenter clinical trial. Patients are randomized to either treatment A or B and are followed for recurrence of disease for 5 years following treatment. How many patients should be studied in each of the two arms of the trial in order to have 90% power to reject $H_0 : RR = 1$ in favor of the alternative $RR = 0.5$, if the test is to be performed at the two-sided $\alpha = 0.05$ level and it is assumed that $\pi_1 = 0.35$?

For Example 28.8, we substitute $\pi_1 = 0.35$ and $RR = 0.5$ into Eq. 28.28 and find that the required sample size per group would be 131 or 262 total. Or we could have noted that $\pi_2 = 0.175$ and used Eq. 28.27.

Table 28.7 presents the sample size in each group necessary for a 5% two-sided normal approximation test of the null hypothesis that the relative risk is 1.0 to have specified power for a few selected examples.

28.3.7 Testing the Odds Ratio

The null hypothesis that the odds ratio equals 1.0 can be tested using Eq. 28.26 as for the test of difference in proportions. Sample size formulas can be modified to be based on π_2 and OR by algebraic substitution in Eq. 28.27 if desired; however, formulas are simpler if we use Eq. 28.12 to solve for the other proportion and use Eq. 28.27 directly.

Example 28.9.
The efficacy of BCG vaccine in preventing childhood tuberculosis is in doubt, and a study is designed to compare the immunization coverage rates in a group of tuberculosis cases compared to a group of controls. Available information indicates that roughly 30% of the controls are not vaccinated, and we wish to have an 80% chance of detecting whether the odds ratio is significantly different from 1 at the 5% level. If an odds ratio of 2 would be considered an important difference between the two groups, how large a sample should be included in each study group?

For Example 28.9, $\pi_1 = 0.3$ and $OR = 2$ and thus $\pi_2 = 0.462$, so using Eq. 28.27, we find that to obtain 80% power for a two-sided 5% level test would require 141 subjects per group or 282 total.

Table 28.8 presents the sample size in each group necessary to obtain specified power for tests of $OR = 1$ for a few selected examples.

28.3.8 Additional Considerations and References

Good introductions to sample size computations for tests and confidence intervals for comparing two independent proportions can be found in Dixon and Massey (1983), Lemeshow et al. (1990), Fleiss (1981), and Lachin (1981). Books containing sample size tables are available (e.g., Machin and Campbell 1987; Machin et al. 1997; Lemeshow et al. 1990). Commercially available sample size software such as nQuery Advisor Release 5 (Elashoff 2002) can be used to compute sample size (or width) for confidence intervals and sample size (or power) for hypothesis tests for the two proportion case (based on either the normal approximation, continuity corrected normal approximation, or Fisher's exact test) as well as for a wide variety of other sample size problems.

For values of π near 0 or 1 (or for small sample sizes), sample size methods involving a continuity correction (Fleiss et al. 1980), or methods based on exact tests (Chernick and Liu 2002) may be preferable.

Table 28.8 Sample size per group for 5% two-sided test of $OR = 1$ to have specified power

		Power	
OR	π_1	80%	90%
1.25	0.30	1,442	1,930
1.50	0.30	425	569
1.75	0.30	219	293
2.00	0.30	141	188
1.25	0.50	1,267	1,695

When plans call for the sample sizes in the two groups to be unequal, the formulas for sample size and power must incorporate the expected ratio of the sample sizes, see references above. Generally, for the same total sample size, power will tend to be higher and confidence interval widths narrower when sample sizes are equal; for comparisons of proportions, total sample size will depend on whether the proportion closer to 0.5 has the larger or the smaller sample size.

Note that the sample size methods discussed above do not apply to correlation/agreement/repeated measures (or pair-matched case-control) studies in which N subjects are recruited and each subject is measured by two different raters, or is studied under two different treatments in a crossover design. These designs cannot be analyzed using the methods described for independent proportions; for example, sample size computations for the difference between two correlated proportions are based on the McNemar test (Lachin 1992).

28.4 One-Group Designs, Inferences About a Single Mean

We turn to consideration of continuous outcomes and to inferences about the population mean. We denote the true but unknown mean in the population by μ and assume that the standard deviation for the population is given by σ. For a random sample of size n from a population with a normal (Gaussian) distribution, the distribution of the observed sample mean, $\bar{x}$, will also be normal with mean μ and standard deviation (also referred to as the standard error) given by $\mathrm{SE}(\bar{x}) = \sigma \big/ \sqrt{n}$. By the central limit theorem, the sampling distribution of the sample mean can usually be expected to be approximately normal for sample sizes of 30 or above even when the underlying population distribution is not normal.

28.4.1 Confidence Intervals for a Single Mean

Example 28.10.
Suppose an estimate is desired of the average retail price of 20 tablets of a commonly used tranquilizer. A random sample of retail pharmacies is to be selected. The estimate is required to be within 10 cents of the true average price with 95% confidence. Based on a small pilot study, the standard deviation in price, σ, can be estimated as 85 cents. How many pharmacies should be randomly selected?

Using the normal approximation, the two-sided $100\,(1-\alpha)\,\%$ confidence interval for the true mean, μ, for the case where the standard deviation is known, is given by

$$\bar{x} \;\pm\; z_{1-\alpha/2}\,\sigma \,/\sqrt{n}. \tag{28.29}$$

So the sample size required to obtain a confidence interval of width ω is

$$n \;=\; \frac{z^2_{1-\alpha/2}\,\sigma^2}{\omega^2}. \tag{28.30}$$

For Example 28.10, expressing costs in dollars,

$$n = \frac{(1.96)^2\,(0.85)^2}{(0.10)^2} = 277.6.$$

Therefore, a sample size of 278 pharmacies should be selected.

We should note however that usually the standard deviation must be estimated from the sample. Then the actual confidence interval for a sample mean would be given by

$$\bar{x} \pm t_{n-1,\,1-\alpha/2}\, s\,/\sqrt{n}, \tag{28.31}$$

where s is the observed standard deviation and $t_{n-1,1-\alpha/2}$ denotes the $100\,(1-\alpha/2)$th percentile of the t distribution with $n-1$ degrees of freedom. The value of $t_{n-1,1-\alpha/2}$ is always greater than $z_{1-\alpha/2}$; the values are close for large n, but t may be considerably larger than z for very small samples.

The required sample size would need to be larger than given by Eq. 28.30 simply to reflect the fact that $t_{n-1,1-\alpha/2} > z_{1-\alpha/2}$. In addition, the value of the standard deviation estimated from the sample will differ from the true standard deviation. The observed value of s may be either smaller or larger than the true value of the standard deviation, σ, and it can be expected to be larger than σ in about half of samples. So, even for large n, the observed confidence interval width will be greater than the specified ω in about half of planned studies.

To ensure that the observed confidence width will be shorter than ω more than half the time, we must take the distribution of s into account in the sample size computations. To solve for the required sample size for a confidence interval whose width has a specified probability, $1-\gamma$, of being narrower than ω requires the use of sample size software since an iterative solution based on the F and χ^2 distributions must be used (Kupper and Hafner 1989).

Returning to Example 28.10, specifying, for example, in nQuery Advisor, that the observed confidence interval width needs to be shorter than 0.1 with a probability of 50% ($1-\gamma = 0.5$) yields a required sample size of 280, only slightly larger than that given by Eq. 28.30. However, to increase the likelihood that the observed confidence interval width will be shorter than ω from 50% to 90% would require an increase in sample size from 280 to 309 (see Table 28.9).

Table 28.10 shows the required sample sizes for two-sided 95% confidence intervals to have specified widths (expressed in terms of ω/σ).

Table 28.9 Confidence interval for mean based on t (with coverage probability)

	1	2
Confidence level, $1-\alpha$	0.950	0.950
1- or 2-sided interval?	2	2
Coverage probability, $1-\gamma$	0.500	0.900
Standard deviation, σ	0.850	0.850
Distance from mean to limit, ω	0.100	0.100
N	280	309

Table 28.10 Sample size for 95% two-sided confidence interval for a single mean to have width less than or equal to ω with probability

	$100\,(1-\gamma)$	
ω/σ	50%	90%
0.05	1,539	1,609
0.10	386	421
0.20	98	116
0.30	45	56
0.50	18	24

Note that nQuery Advisor has been used to compute the sample sizes displayed in all the rest of the tables in this chapter.

28.4.2 Hypothesis Testing for a Single Population Mean

Suppose we would like to test the hypothesis

$$H_0 : \mu = \mu_0$$

versus the alternative hypothesis

$$H_a : \mu > \mu_0$$

and we would like to fix the level of the type I error to equal α and the type II error to equal β. That is, we want the power of the test to equal $1 - \beta$. We denote the actual value of the population mean under the alternative hypothesis as μ_a. Following the same development as for hypothesis testing about the population proportion (with the additional assumption that the variance of $\bar{x}$ is equal to σ^2/n under both H_0 and H_a), the necessary sample size for this hypothesis testing situation is given by

$$n = \frac{\sigma^2 \left[z_{1-\alpha} + z_{1-\beta}\right]^2}{\left[\mu_0 - \mu_a\right]^2}. \tag{28.32}$$

Alternatively, defining the effect size as

$$\delta = \frac{\mu_0 - \mu_a}{\sigma}, \tag{28.33}$$

we have

$$n = \frac{\left[z_{1-\alpha} + z_{1-\beta}\right]^2}{\delta^2}. \tag{28.34}$$

Example 28.11.
Pre- and poststudies with placebo in a variety of studies indicated that the standard deviation of blood pressure change was about 6 mmHg and that the mean reduction in the placebo group was typically close to 5 mmHg. To make a preliminary estimate of the value of a new intervention designed to lower blood pressure, it was planned to enroll subjects and

test the null hypothesis that mean reduction was 5 mmHg. The new intervention would be of interest if the mean reduction was 10 or greater. How large a sample would be necessary to test, at the 5% level of significance with a power of 90%, whether the average blood pressure reduction is 5 mmHg versus the alternative that the reduction is 10 mmHg when it is assumed that the standard deviation is 6 mmHg?

Using Eq. 28.32, we have

$$n = \frac{6^2\,(1.645 + 1.282)^2}{(10 - 5)^2} = 12.33.$$

Therefore, a sample of 13 patients with high blood pressure would be required.

A similar approach is followed when the alternative is two-sided. That is, when we wish to test

$$H_0 : \mu = \mu_0$$

versus

$$H_a : \mu \neq \mu_0.$$

In this situation, the null hypothesis is rejected if $\bar{x}$ is too large or too small. We assign area $\alpha/2$ to each tail of the sampling distribution under H_0. The only adjustment to Eq. 28.32 is that $z_{1-\alpha/2}$ is used in place of $z_{1-\alpha}$ resulting in

$$n = \frac{\sigma^2 \left[z_{1-\alpha/2} + z_{1-\beta}\right]^2}{\left[\mu_0 - \mu_a\right]^2}. \tag{28.35}$$

Returning to Example 28.11, a two-sided test could be used to test the hypothesis that the average reduction in blood pressure is 5 mmHg versus the alternative that the average reduction in blood pressure has increased and that a reduction of 10 mmHg would be considered important. Using Eq. 28.35 with $z_{1-\alpha/2} = 1.960$, $z_{1-\beta} = 1.282$, and $\sigma = 6$,

$$n = \frac{6^2\,(1.960 + 1.282)^2}{(10 - 5)^2} = 15.1.$$

Thus, 16 patients would be required for the sample if the alternative were two-sided.

Since usually the true standard deviation is unknown, a more accurate solution for the necessary sample size would require use of sample size software (computations are based on the central and non-central t distributions). Unlike the situation for confidence intervals, the normal approximation formula works well for computing sample size for a test; its accuracy can be improved by adding the correction factor

$$\frac{z^2_{1-\alpha/2}}{2} \tag{28.36}$$

before rounding up. For Example 28.11, this would lead to a sample size estimate of 18 (which agrees with the result given by nQuery Advisor).

Table 28.11 Sample size for two-sided 5% level *t* test to detect effect size $\delta = \mu_1 - \mu_2/\sigma$

δ	80% Power	90% Power
0.2	199	265
0.4	52	68
0.6	24	32
0.8	15	19
1.0	10	13
1.2	8	10

Table 28.11 presents the sample sizes necessary for 80% or 90% power for two-sided 5% level tests for specified effect sizes, δ.

28.5 Comparison of Two Independent Means

28.5.1 Confidence Intervals for the Difference Between Two Means

The difference between two population means is represented by a new parameter, $\mu_1 - \mu_2$. An estimate of this parameter is given by the difference in the sample means, $\bar{x}_1 - \bar{x}_2$. The mean of the sampling distribution of $\bar{x}_1 - \bar{x}_2$ is

$$E\left(\bar{x}_1 - \bar{x}_2\right) = \mu_1 - \mu_2,$$

and the variance of this distribution when the two samples are independent is

$$\mathrm{Var}\left(\bar{x}_1 - \bar{x}_2\right) = \mathrm{Var}\left(\bar{x}_1\right) + \mathrm{Var}\left(\bar{x}_2\right) = \frac{\sigma_1^2}{n_1} + \frac{\sigma_2^2}{n_2},$$

where n_1 and n_2 are the sample sizes in the two groups.

In order for the distribution of the difference in sample means, $\bar{x}_1 - \bar{x}_2$, to have a *t* distribution, we must assume that $\sigma_1^2 = \sigma_2^2 = \sigma^2$. When the variances are equal and both sample sizes are equal to n, the formula for the variance of the difference can be simplified to

$$\mathrm{Var}\left(\bar{x}_1 - \bar{x}_2\right) = \frac{2\sigma^2}{n}.$$

The value σ^2 is an unknown population parameter, which can be estimated from sample data by pooling the individual sample variances, s_1^2 and s_2^2, to form the **pooled variance**, s_p^2, where, in the general case,

$$s_p^2 = \frac{(n_1 - 1)\, s_1^2 + (n_2 - 1)\, s_2^2}{(n_1 - 1) + (n_2 - 1)}.$$

Example 28.12.
Nutritionists wish to estimate the difference in caloric intake at lunch between children in a school offering a hot school lunch program and children in a school that does not. From

other nutrition studies, they estimate that the standard deviation in caloric intake among elementary school children is 75 calories and they wish to make their estimate to within 20 calories of the true difference with 95% confidence.

Using the normal approximation, the two-sided $100\,(1-\alpha/2)\,\%$ confidence interval for the true mean, $\mu_1 - \mu_2$, is given by

$$\bar{x}_1 \; - \; \bar{x}_2 \pm \; z_{1-\alpha/2}\, 2\sigma \,/\sqrt{n}. \tag{28.37}$$

So the sample size in each group required to obtain a confidence interval of width ω is

$$n \;=\; \frac{z^2_{1-\alpha/2}\, 2\sigma^2}{\omega^2}. \tag{28.38}$$

For Example 28.12,

$$n \;=\; \frac{(1.96)^2\,(2)(75)^2}{(20)^2} \;=\; 108.05.$$

Thus, a sample size of 109 children from each school should be selected.

We note, however, that the actual confidence interval for the difference in sample means would be given by

$$\bar{x}_1 \; - \; \bar{x}_2 \pm \; t_{2n-2,\,1-\alpha/2}\, s_p \sqrt{2}\,/\sqrt{n}, \tag{28.39}$$

where s_p is the observed pooled standard deviation and $t_{2n-2,1-\alpha/2}$ denotes the $100\,(1-\alpha/2)$ percentile of the t distribution with 2(n-1) degrees of freedom. So, as explained in the section on confidence intervals for a single mean, to solve for the required sample size for a confidence interval whose width has a specified probability, $1-\gamma$, of being narrower than ω requires the use of sample size software.

For Example 28.12, we show in Table 28.12 (pasted from nQuery Advisor) that a sample of 109 per group provides a 50% probability that the observed 95% confidence interval will have half-width less than 20, while to have a 90% probability that the confidence interval half-width will be less than 20 would require a sample of 123 children per school.

Table 28.12 Confidence interval for difference of two means (coverage probability) (equal n's)

	1	2
Confidence level, $1-\alpha$	0.950	0.950
1- or 2-sided interval?	2	2
Coverage probability, $1-\gamma$	0.500	0.900
Common standard deviation, σ	75.000	75.000
Distance from difference to limit, ω	20.000	20.000
n per group	109	123

Table 28.13 Sample size per group for 95% two-sided confidence interval for the difference in means to have width less than or equal to $\pm\omega$ with probability $(1-\gamma)$

	$100\,(1-\gamma)$	
ω/σ	50%	90%
0.05	3,075	3,145
0.10	770	805
0.20	193	211
0.30	87	98
0.50	36	39

Table 28.13 presents the sample sizes in each group required so that the two-sided 95% confidence interval for the difference in two independent means will be no wider than $\pm\omega$ with probability $(1-\gamma)$.

28.5.2 Testing the Difference Between Two Means (Two-Sample *t* Test)

The two-sample t test is used to test hypotheses about the population means in two independent groups of subjects. It is based on the assumptions that the underlying population distributions have equal standard deviations and that the population distributions are Gaussian (normal) in shape or that the sample sizes in each group are large. (In most cases, the distribution of the sample mean will be approximately Gaussian for sample sizes greater than 30.)

We consider tests of the null hypothesis:

$$H_0 : \mu_1 = \mu_2 \text{ or}$$

$$H_0 : \mu_1 - \mu_2 = 0$$

versus either

$$H_a : \mu_1 \neq \mu_2 \text{ for a two-sided test or}$$

$$H_a' : \mu_1 > \mu_2 \text{ or } H_a'' : \mu_1 < \mu_2 \text{ for one-sided tests.}$$

To avoid repetitions of formulas with minor changes, we write formulas only in terms of a two-sided test.

The sample size required in each group, to achieve a power of $1-\beta$, is

$$n = \frac{2\sigma^2(z_{1-\alpha/2} + z_{1-\beta})^2}{(\mu_1 - \mu_2)^2}. \tag{28.40}$$

Setting

$$\delta = \frac{\mu_1 - \mu_2}{\sigma}, \tag{28.41}$$

where δ is the effect size, we have a simpler version

$$n = \frac{2(z_{1-\alpha/2} + z_{1-\beta})^2}{\delta^2}. \tag{28.42}$$

Table 28.14 Sample size in each group for two-sided 5% level t test to have specified power

δ	80% Power	90% Power
0.2	394	527
0.4	100	133
0.6	45	60
0.8	26	34
1.0	17	23
1.2	12	16

To improve the approximation, the correction factor in Eq. 28.43 may be added to Eq. 28.42 before rounding up:

$$\frac{z^2_{1-\alpha/2}}{4}. \tag{28.43}$$

Example 28.13.
A two-group, randomized, parallel, double-blind study is planned in elderly females after hip fracture. Patients will be studied for 2 weeks; each patient will be randomly assigned to receive either new drug or placebo three times per week. The sample sizes in the two groups will be equal. Plans call for a 5% level two-sided t test. The outcome variable will be change in hematocrit level during the study. Prior pilot data from several studies suggest that the standard deviation for change will be about 2.0% and it would be of interest to detect a difference of 2.2% in the changes observed in placebo and treated groups. What sample size in each group would be required to achieve a power of 90%?

For Example 28.13, the effect size is $2.2/2 = 1.1$. Using Eq. 28.42, we find

$$n = \frac{2(1.96 + 1.28)^2}{(1.1)^2} = 17.4.$$

Adding the correction factor of 0.96 and rounding up, we have a required sample size of 19 per group, which is the solution given using nQuery Advisor (computations are based on iterative methods and the central and non-central t, see Dixon and Massey 1983 or O'Brien and Muller 1983).

Table 28.14 shows the sample size needed in each group for a two-sided 5% level t test to achieve 80% or 90% power for the specified alternative, δ.

28.5.3 Additional Considerations and References

Good introductions to sample size computations for tests and confidence intervals for a single mean or for comparing two independent means can be found in Dixon and Massey (1983), O'Brien and Muller (1983), Lemeshow et al. (1990), Lachin (1981), and Rosner (2000). Books containing sample size tables are available (e.g., Machin and Campbell 1987; Machin et al. 1997). Commercially available sample size software such as nQuery Advisor Release 5 (Elashoff 2002) can be used to compute sample size (or width) for confidence intervals and sample size or power for hypothesis tests for means for either the single-group or two-group designs, as well as for a wide variety of other sample size problems.

When plans call for the sample sizes in the two groups to be unequal, the formulas for sample size and power must incorporate the expected ratio of the sample sizes, see references above. For the two-sample t test, for any given total sample size, N, power will be highest when both groups have the same sample size. For this reason, we generally prefer to plan equal sample sizes for a two-group study. However, sometimes investigators wish to plan a study with unequal n's; perhaps one type of subject is easier to accrue, or perhaps the investigator wants to maximize the number of subjects receiving the presumably superior treatment, or to accumulate extra safety information for the new treatment.

When the standard deviations in the two groups are markedly unequal, the usual t test with pooled variances is no longer the appropriate test. In many situations, the standard deviations show a patterned lack of homogeneity in which groups with higher means have higher standard deviations. In such cases, it is frequently advisable that sample size predictions (and later analysis) should be done on a transformed version of the variable. If the relationship between variance and mean is linear, this suggests using the square root of the variable. Such a transformation is likely to be desirable if the data represent counts or areas (note that the variable cannot be less than zero). If the relationship between standard deviation and mean is linear, this suggests using the log of the variable. This transformation is likely to be desirable for biological measures like viral load, triglyceride level, or variables ranging over several orders of magnitude (note that the variable cannot be negative or zero). If transformation does not seem to provide a solution to the problem of inequality of variances, it is possible that comparison of means is no longer the most appropriate method of analysis to address the question of interest. Assuming that transformation is not useful and comparison of means using a two-sample t test is still deemed appropriate, a modification of the t test may be planned; see, for example, Moser et al. (1989) and sample size tables for the Satterthwaite t in nQuery Advisor.

If non-normality is an issue, planning a large study or considering transformations as above may be helpful; another possibility is to plan to use a non-parametric procedure instead, such as the two-sample Mann-Whitney/Wilcoxon rank test. For a description of this test, see Rosner (2000), and for methods to determine sample size and power, see Hettmansperger (1984) and Noether (1987), or sample size tables in nQuery Advisor.

Note that the sample size methods for comparisons of two independent means discussed above do not apply to correlation/agreement/repeated measures (or pair-matched case-control) studies in which N subjects are recruited and each subject is measured by two different raters, or is studied under two different treatments in a crossover design. These designs cannot be analyzed using the methods described for independent means but must be analyzed using the paired t test or a repeated measures analysis of variance; see Rosner (2000) for information on the paired t test and Muller and Barton (1989) or sample size tables in nQuery Advisor for information about sample size and power for repeated measures tests.

28.6 Logistic Regression Models

In prior sections of this chapter, we discussed sample size problems for estimation or testing of a proportion in one or two groups. In this section, we consider study designs in which it is planned to evaluate several predictor variables for a binary outcome variable. Specifically, we consider studies in which we plan to fit a logistic regression model which is one of the most common tools in epidemiology. Readers needing an introduction to the logistic regression model and test procedures should consult Hosmer and Lemeshow (2000) (see also chapter ▸Regression Methods for Epidemiological Analysis of this handbook).

In our experience, there are two sample size questions, prospective and retrospective. The prospective question is: How many subjects do I need to observe to test the significance of a specific predictor variable or set of variables? The retrospective question is: Do I have enough data to fit this model? In this section, we consider methods for choosing a sample size first and then discuss the importance of having an adequate number of events per covariate.

With respect to planning sample size for logistic regression, we distinguish two situations: (1) only a single covariate is of interest, and (2) the addition of one covariate to a model already containing k covariates is of interest. In addition, we must distinguish whether the covariate of interest is dichotomous or continuous.

The basic sample size question is as follows: What sample size does one need to test the null hypothesis that a particular slope coefficient, say for covariate 1, is equal to zero versus the alternative that it is equal to some specified value?

28.6.1 Single Dichotomous Covariate

If the logistic regression model is to contain a single dichotomous covariate, then one may use conventional sample size formulas based on testing for the equality of two proportions. Hsieh et al. (1998) recommend using the following method to obtain sample sizes for logistic regression with a dichotomous covariate. (Although Whitemore (1981) provides a sample size formula for a logistic regression model containing a single dichotomous covariate, this formula, based on the sampling distribution of the log of the odds ratio, was derived under the assumption that the logistic probabilities are small and may be less accurate than the method we outline.)

Let the covariate X define two groups: group 1 contains those subjects for which $x = 0$ and the probability that the outcome of interest $y = 1$ for the subjects in this group is π_1, while group 2 contains those subjects for which $x = 1$ and the probability that $y = 1$ for these subjects is π_2.

Example 28.14.
Suppose that about 1% of the population is expected to have a particular adverse reaction to a certain drug used to treat a severe illness. It is thought that those with a specific preexisting condition (expected to be about 20% of the population) will be much more likely to have such a reaction; it will be important to detect an odds ratio of 2 for the likelihood of a reaction in this group using a 5% two-sided likelihood ratio test.

Table 28.15 Two-group χ^2 test of equal proportions (odds ratio = 1) (unequal n's)

Test significance level, α	0.050	0.050	0.050
1- or 2-sided test?	2	2	2
No condition proportion, π_1	0.010	0.010	0.010
Preexisting proportion, π_2	0.020	0.029	0.039
Odds ratio, $\psi = \pi_2(1 - \pi_1) / [\pi_1(1 - \pi_2)]$	2.000	3.000	4.000
Power (%)	90	90	90
n_1	7,620	2,468	1,345
n_2	1,905	617	337
Ratio n_2/n_1	0.250	0.250	0.250
$N = n_1 + n_2$	9,525	3,085	1,681

To compute the required sample size for Example 28.14 by hand would require using a modification of Eq. 28.27 for comparison of two proportions with unequal sample sizes, see references given in that section. Table 28.15 shows the table of results pasted from nQuery Advisor. (In this table, the symbol ψ is used to denote the odds ratio.) Defining group 1 as those without the preexisting condition and group 2 as those with, the ratio of the sample size in group 2 to the sample size in group 1 will be $20/80 = 0.25$. Using $\pi_1 = 0.01$ for group 1 (no preexisting condition), and $OR = 2$, we find $\pi_2 = 2\,(0.01)/(2\,(0.01) + 0.99) = 0.02$. Table 28.15 shows that to detect an odds ratio of 2 with 90% power for this example would require a sample size of 9,525. Consequently, the investigator may be interested in looking at the sample sizes required to detect odds ratios of 3 or 4 (3,085 and 1,681, respectively).

28.6.2 Single Continuous Covariate

If the single covariate we plan to include in the model is continuous, approximate formulas for this setting have been derived by Hsieh (1989) and implemented in sample size software packages such as nQuery Advisor. However, Hsieh et al. (1998) demonstrate that this approximate formula gives larger than required sample sizes and recommend using the following method to obtain sample sizes for logistic regression with a continuous covariate.

Let the response Y define two groups: group 1 contains cases in which $Y = 1$ with $N\pi_1$ cases expected, while group 2 contains cases in which $Y = 0$ with $N(1 - \pi_1)$ cases expected. The ratio of the expected sample size in group 2 to the expected sample size in group 1, r, is $(1 - \pi_1)/\pi_1$. The natural log of the odds ratio, the coefficient β of the covariate, x, is equal to the difference between the mean of the covariate in group 1 and the mean of the covariate in group 2 divided by the within-group standard deviation of x (denote this by δ). Therefore, a sample size formula or table for the two-group t test with unequal n's can be used to estimate sample size for logistic regression with one continuous covariate.

Example 28.15.
Patients with blocked or narrowed coronary arteries may undergo interventions designed to increase blood flow. Typically, about 30% of patients followed for a year will have renewed

blockage, called "restenosis," of the artery. A study is to be planned to use logistic regression to assess factors related to the likelihood of restenosis. One such factor is serum cholesterol level. Based on the results of a large screening trial, mean serum cholesterol in middle-aged males is about 210 mg/dL; one standard deviation above the mean (which corresponds to about the 85th percentile) is approximately 250 mg/dL. In the screening study, the odds ratio for the 6-year death rate for these two cholesterol levels was about 1.5. The study should be large enough to detect an effect of serum cholesterol on arterial restenosis of a size similar to that seen for death rate. We plan to conduct the test of the predictive effect of cholesterol level on the probability of restenosis using a 5% two-sided test and want to have 90% power to detect an odds ratio of 1.5 for values of cholesterol of 250 mg/dL versus 210 mg/dL. We set the effect size, $\delta = (\mu_1 - \mu_2)/\sigma = 0.405$, which is the value of the natural log of the odds ratio, 1.5. The ratio of sample sizes expected to be in the no-restenosis versus the restenosis groups, r, equals 0.7/0.3 = 2.333.

The required sample size could be computed using a version of Eq. 28.42 modified for unequal sample sizes, see references in the preceding section. In Table 28.16, we show the table of results pasted from the software nQuery Advisor.

To obtain a power of 90% to detect an odds ratio of 1.5 using the covariate cholesterol to predict restenosis at 1 year, we find that a total sample size of 310 is required.

28.6.3 Adjusting Sample Size for Inclusion of *k* Prior Covariates (Variance Inflation Factor)

It is rare in practice to have final inferences based on a univariate logistic regression model. However, the only sample size results currently available for the multivariable situation are based on very specific assumptions about the distributions of the covariates. We can, however, use a "variance inflation factor" to adjust the sample size results obtained for a single covariate for the situation in which k covariates have already been added to the model before the new covariate is considered.

The sample size, N_k required to test for the significance of a covariate after inclusion of k prior covariates in the model, is given by

$$N_k = N\left(\frac{1}{1-\rho^2}\right), \tag{28.44}$$

Table 28.16 Two-group t test of equal means (unequal n's)

Test significance level, α	0.050
1- or 2-sided test?	2
Effect size, $\delta = \lvert\mu_1 - \mu_2\rvert/\sigma$	0.405
Power (%)	90
n_1	93
n_2	217
Ratio n_2/n_1	2.333
$N = n_1 + n_2$	310

where the factor $1/\left(1-\rho^2\right)$ is called the "variance inflation factor"

$$VIF = \left(\frac{1}{1-\rho^2}\right) \tag{28.45}$$

and ρ^2 is the squared multiple correlation of the covariate of interest with the covariates already included in the model. This can be estimated using any multiple regression software.

For Example 28.14, the total sample size was computed as $N = 1{,}681$ for testing the significance of one dichotomous covariate. Now, assume that four patient demographic variables will be entered into the logistic regression model prior to testing the covariate indicating presence or absence of the preexisting condition (x_1 say) and that these demographic variables have a squared multiple correlation with x_1 of 0.2. Then a total sample size of at least 2,100 patients would be required:

$$N_4 = 1{,}681\left(\frac{1}{1-0.2}\right) = 2{,}101.$$

In Example 28.15, if two other covariates with a squared multiple correlation with cholesterol of 0.15 are to be entered into the logistic regression first, multiply the sample size obtained for a single covariate by the variance inflation factor, Eq. 28.44, $1/\left(1-\rho^2\right) = 1.18$, to increase the required sample size to 365.

28.6.4 Assessing the Adequacy of Data Already Collected

So far, we have discussed planning what sample size should be obtained to fit specific logistic regression models. A second consideration, and one relevant to any model being fit, is the issue of what is the maximum number of covariates it is reasonable to enter into the model and still obtain reliable estimates of the regression coefficients and avoid excessive shrinkage when the model is assessed for new cases. An ad hoc rule of thumb is to require that there be 10 "events" per variable included in the model. Here, the "event" of relevance is the least frequent of the outcomes. For example, suppose the study discussed in Example 28.15 was planned with 365 cases. Further, suppose that complete 1-year follow-up was only obtained for 351 cases of which 81 had restenosis at 1 year. There are 81 cases with restenosis and 270 without, so the least frequent "event" is restenosis. Based on these 81 cases, only 8 variables should be fit; this means that no more than 8 covariates (or covariates plus covariate interaction terms) should be entered into the model.

This rule of thumb was evaluated and found to be reasonable by Peduzzi et al. (1996) using only discrete covariates. However, as is the case with any overly simple solution to a complex problem, the rule of 10 should only be used as a guideline and a final determination must consider the context of the total problem. This includes the actual number of events, the total sample size, and most importantly, the mix of discrete, continuous interaction terms in the model. The "ten events per parameter" rule may work well for continuous covariates and discrete covariates with a balanced distribution. However, its applicability is less clear in settings where the distributions of discrete covariates are weighted heavily to one value.

28.7 Practical Issues in Sample Size Choice

In earlier sections, we outlined formulas for sample size computation for estimation and testing in simple designs for proportions and for means. We have shown only formulas to compute sample size from specifications of confidence interval width or desired power, but it is also possible to compute the confidence interval width or power which would be obtainable with a specified sample size. Sample size methods exist for many more complex designs and for other parameters. Software such as nQuery Advisor (Elashoff 2002) can be helpful.

For complex study designs or complex statistical methods, however, there may be no easily applied formulas or available software solutions. In such cases, sample size choices may be based on simplifications of the design or statistical methods (as we illustrated in the section on logistic regression), or in some cases a simulation study may be warranted.

For studies involving complex survey designs, sample size computations might be based on one of several approaches: (1) regarding the cluster itself as the study "subject" and using intraclass correlation values to estimate the appropriate variance to use in making computations, (2) multiplying sample sizes for a simpler design by a computed "design effect" (2 may be a sensible ad hoc choice), or (3) using simulation methods.

Although study sample sizes are usually chosen to assure desired precision or power for the primary outcome variable, investigators may also need to investigate whether that sample size choice will be adequate for evaluations of secondary outcomes, or for analyses of predefined subsets.

Sample size values obtained from formulas or software will generally need to be inflated to allow for expected dropout or loss to follow-up of study subjects or other sources of missing data (cf. chapter ▸Missing Data of this handbook). It is important to remember, however, that subjects who drop out may not be similar to those remaining in the study. This consideration may affect the parameter values which should be used for sample size computations, and even analyses using missing data techniques may not remove biases due to dropout.

Anotherissue of great concern to epidemiologists is that exposure or response may be misclassified (cf. chapter ▸Misclassification of this handbook). Such misclassification might have a dramatic impact on the actual power of a planned study unless sample sizes are computed based on modeling the expected type and extent of misclassification using simulation methods.

For brevity, our examples used only one set of parameter values to compute required sample sizes. In practice, investigators need to keep in mind that the estimated parameter values used in computations are only estimates and perhaps not very accurate ones. It is a good idea to compute necessary sample size for several different sets of parameter choices to evaluate sample size sensitivity to varying realistic possibilities for the true parameter values. Tables and plots can be helpful in these evaluations.

Finally, sample size justification statements in protocols, grant proposals, and manuscripts need to be complete. Details of the outcome variable, the study design, the planned analysis method, confidence level or power, one- or two-sided, and all the relevant distributional parameters (proportions, means, standard deviations) need to be included in the statement. For Example 28.13, a minimal sample size justification might read as follows: *A sample size of 19 in each group will have 90% power to detect a difference in means of 2.2 (the difference between an active drug mean change in hematocrit of 2.2% and a placebo mean change of 0.0) assuming that the common standard deviation is 2.0 and using a two-group t* test *with a 0.05 two-sided significance level. The planned enrollment will be 25 subjects per group (50 total) to allow for 20% dropout.* It is also desirable to provide information about sample size for other parameter choices and details about how these parameter values were selected, including references to previous studies which were consulted in selecting the values.

28.8 Conclusions

An important part of planning any research study is to assess what sample size is needed to assure that meaningful conclusions can be drawn about the primary outcome. To do this, the investigator must detail the study design, define the primary outcome variable, choose an analysis method, and specify desired or expected results of the study. Then formulas, tables, and sample size software of the sort outlined in this chapter can assist with computations. The most essential part of the process, though, is to make a thorough investigation of other information and research results concerning the outcome variable to support reasonable specification of hypothesized values for use in making computations. Beginning investigators often protest: “But this study has never been done before; how do I know what the results will be?” In most cases, however, much information about rates, means, and standard deviations can be gleaned from other contexts and used to infer what kinds of outcomes would be important to detect or likely to occur. Sample size computations are not just a pro forma requirement from funding agencies but provide the basis for deciding whether a planned study is likely to be worth the expense.

29.1 Introduction

When analyzing data from an epidemiological study, some features are rather specific for a particular study design. Those are dealt with among others in chapters ▶Descriptive Studies, ▶Cohort Studies, to ▶Modern Epidemiological Study Designs and ▶Survival Analysis of the handbook. Other features are generally relevant; see chapters ▶Rates, Risks, Measures of Association and Impact and ▶Confounding and Interaction. This chapter focusses on the analysis of continuous covariates where it will be discussed how such variables can be modeled to capture their potential association with an outcome of interest and to best describe the shape of such an association. We present classical methods based on categorization and subsequent contingency table analysis. The major part of the chapter, however, deals with the analysis of continuous covariates using regression models commonly used in epidemiology (see also chapter ▶Regression Methods for Epidemiological Analysis of this handbook). Each of the proposed techniques to model continuous covariates is illustrated by a real data example taken from a case-control study on laryngeal cancer and smoking as well as alcohol consumption that has been conducted in Germany during the 1990s. The chapter ends with practical recommendations and conclusions.

When planning the data analysis, we may distinguish between the following:

- Descriptive analysis
- Analytical statistical modeling

where the descriptive part may precede the analytical part. A thorough and careful descriptive analysis of the data can save enormous time. This involves univariate analysis of all variables of interest by graphical or other methods as described in textbooks on descriptive statistics (e.g., Bernstein and Bernstein 1998).

In practice, the analysis step is often started before the descriptive analysis has been completed. This is sometimes driven by impatient clinicians who would like to know immediately whether "the result is significant," that is, directly after data collection is finished and before plausibility checks of the data have been performed (see chapter ▶Data Management in Epidemiology of this handbook). However, the first p-value generated in the analysis step is rarely found in the publication. Instead, some peculiarities in the data are found such that one has to go back to the descriptive analysis. Then, we have an iterative process which should be made explicit. If used in an exploratory approach, an iterative process could provide a deeper insight and lead to general conclusions that may have not been envisioned at the outset.

In this chapter, we give an overview of methods to analyze continuous covariates in epidemiological studies. For a long time, it has been common to categorize them into $K \geq 2$ groups and to estimate appropriate parameters (e.g., odds ratio or relative risk) that describe the effect for a certain level of the variable relative to an arbitrarily defined baseline level or to perform tests for trend based on this categorization. This procedure was exclusively used in the past because classical methods to analyze epidemiological data, for example, the Mantel-Haenszel estimator, are mostly based on some form of contingency table analysis that requires a categorization of continuous variables. In the last decades, they have largely been replaced by regression models that allow, but do not require, a categorization. With increasing availability of powerful computers and standard software, these methods have become most common.

We will describe and compare different methods for the analysis of continuous covariates in classical epidemiological studies (such as case-control or cohort studies) and for the analysis of morbidity and mortality data. The aim is either (i) to analyze the relation between the outcome variable Y and the continuous covariate X or (ii) to appropriately adjust for X if one wishes to analyze the relation between Y and Z, where Z is another covariate which may be confounded by X (see also chapters ▸Basic Concepts and ▸Confounding and Interaction of this handbook). For (i), this is commonly done in epidemiology by estimating a relative risk or odds ratio function $\mathrm{R}(\cdot)$, where $(\cdot)$ denotes dependence on an arbitrary argument. For (ii), one has additionally the possibility to condition on X.

We will also consider the common situation that a proportion of individuals have exposure zero, and among those exposed, we have a continuous distribution of X. This is called a semicontinuous variable (Olsen and Schafer 2001), a spike at zero, (Robertson et al. 1994; Schisterman et al. 2006), mass at zero, or clump of zeros. Typical examples are occupational exposures, for example, asbestos exposure, or alcohol and tobacco consumption where a proportion of individuals may be completely unexposed, and the exposure of those who had been exposed follows a continuous (positive) distribution.

29.2 Classical Methods of Analyzing Continuous Covariates Based on Contingency Tables

Before the theory of generalized linear models was developed, contingency table analysis was the common tool in our field. The famous paper by Mantel and Haenszel (1959) is still well known, mainly because the ideas developed therein facilitated the path to modern techniques. In this section, we will therefore outline odds ratio estimation, tests for trend, and simple confounder adjustment approaches based on these classical methods. Although less often used today, these methods are still helpful for a general understanding of epidemiological data analysis. It should be emphasized, however, that the methods presented here have been augmented by modern regression methods which are now to be preferred.

29.2.1 General Aspects

We assume that a continuous covariate X has been collected and that Y is a binary variable that denotes the disease or the event of interest. The classical methods first require a categorization of X which can formally be described by the function

$$f(x) = \sum_k x_k I_{x \in I_k}(x),$$

where I is the indicator function being 1 if x belongs to I_k, which are disjunct exposure categories with $k = 1, \ldots, K$ covering the whole set of possible values of X, and 0 otherwise. The indicator functions are then multiplied with values x_k where a common method is to choose $x_k = k$, such that the kth largest group is assigned the value k, but it is also possible to assign x_k the mean exposure level in category k.

The practical questions are:

(i) How to choose the number of categories K
(ii) How to choose the intervals I_k

For neither question exists a unique or optimal answer. Since categorization is an important method also in regression modeling as described later, the final result obtained from the same dataset will most likely differ, if two statisticians use different categories when analyzing the same dataset.

Some general rules may help as a guideline for building categories:

- Choose the limits and the number of categories such that a comparison with earlier studies is possible.
- If a natural baseline exists (e.g., “0” for non-exposed) and a low exposure is a priori regarded as relevant (e.g., smoking), choose the natural baseline (in the example: the non-smokers) as a separate category.
- K should not be larger than 10, but for small datasets, fewer categories are to be preferred. Three to six categories are most often used in practice.
- Choose the limits and number of categories a priori, that is, do not base this choice on risk estimates derived from the same data.

A categorization by quartiles or quintiles of the distribution of the variable is often done. This is statistically correct, but then comparison with other studies is somewhat hampered since the limits follow the exact observed distribution of the covariate. It is perhaps better to report “Individuals whose diastolic blood pressure is above 90 mm Hg have a risk of … to get disease D” than to say “Individuals in the upper quartile of the diastolic blood pressure have a risk of … to get disease D.” Again referral to previous studies may help to derive meaningful cut-offs rather than quantile values.

29.2.2 Odds Ratio Estimation

Assume now a categorization has been performed yielding a 2xK table as displayed in Table 29.1. Crude odds ratio estimation for a given exposure level k is done by

$$\widehat{OR}_k = \frac{a_k c_1}{c_k a_1}, k = 2, \ldots, K,$$

Table 29.1 A 2xK table with, for example, the first exposure level chosen as reference category

		Cases	Controls	Total
Exposure level	x_1	a_1	c_1	m_1
	x_2	a_2	c_2	m_2
	…	…	…	…
	x_K	a_K	c_K	m_K
Total		n_1	n_0	N

Table 29.2 Alcohol consumption in males; laryngeal cancer case-control study; Germany

		Cases		Controls			
		a_k	(%)	c_k	(%)	$\widehat{OR}$	95% CI
Alcohol intake	<= 25	57	24.2	303	43.2	1.0	
(g ethanol/day)	25− <=50	51	21.6	169	24.1	1.60	(1.05–2.45)
	50− <=75	39	16.5	113	16.1	1.83	(1.16–2.91)
	75+	89	37.7	117	16.7	4.04	(2.72–6.00)
Total		236	100.0	702	100.0		

and asymptotic 95% confidence intervals are given as

$$\left(\exp(\ln(\widehat{OR}_k) - 1.96\sqrt{\hat{\text{var}}(\widehat{OR}_k)}), \quad \exp(\ln(\widehat{OR}_k) + 1.96\sqrt{\hat{\text{var}}(\widehat{OR}_k)})\right)$$

with

$$\hat{\text{var}}(\ln(\widehat{OR}_k)) = \frac{1}{a_k} + \frac{1}{c_1} + \frac{1}{a_1} + \frac{1}{c_k}.$$

(see Example 29.1). The odds ratios can be displayed graphically such that the exposure level within each group is plotted on the x-axis, and the odds ratio on the y-axis. This is a useful first presentation of the results.

Example 29.1.
As an example, we consider data from a laryngeal cancer case-control study where the variable X, daily alcohol consumption, is categorized into four group as depicted in Table 29.2.
In this study, average alcohol intake 10 years before interview was assessed by asking for the frequency and amount of the consumption of different types of alcoholic beverages (beer, wine, liqueur, spirits). Average alcohol content of these beverages was then used to calculate the daily ethanol intake. The second last column gives the unadjusted (i.e., not adjusted for confounders, such as smoking) odds ratio in comparison with the baseline category (see chapter ►Rates, Risks, Measures of Association and Impact of this handbook for an introduction of the Mantel-Haenszel estimate of the adjusted odds ratio), and the corresponding 95% confidence intervals as obtained from the equations above are added in the last column. We observe an increasing odds ratio with increasing dose.

The classical methods to analyze continuous covariates based on contingency tables have become less and less common in the recent literature. This is because:

(i) A categorization necessarily results in a loss of information.
(ii) The classical analysis is embedded in regression models as a special case.
(iii) The possibility to adjust for multiple confounders is limited.
(iv) There are only limited options for a dose-response analysis.

29.2.3 Test for Trend

Instead of presenting an effect measure for separate categories, one is often interested in the general question whether the effect increases (or decreases) with increasing dose. Very often, the presentation of the results goes with the presentation of a “test for trend.” Although this is sometimes more specifically referred to as “test for linear trend,” this is not sufficient, since there is no unique “test for (linear) trend,” and it often remains unclear what the authors of a paper actually have done. Moreover, such a statistical test may yield a significant result indicating a trend even if the single risk estimates are only increased in the lower dose range but approach baseline risk at higher doses (Maclure and Greenland 1992). Also, if there is a non-monotonic relation between exposure and disease, does this mean that there is no trend?

Based on Table 29.1, two common tests for trend can be derived: The first test to be introduced here is the Mantel-Haenszel χ^2-test for linear trend which is based on the following test statistics:

$$\chi^2 = \frac{N^2(N-1)\left[\sum_{k=1}^{K} x_k(a_k - e_k)\right]^2}{n_1 n_0\left[N\sum_{k=1}^{K} x_k^2 m_k - \left(\sum_{k=1}^{K} x_k m_k\right)^2\right]},$$

where $e_k = \mathrm{E}(a_k) = \frac{m_k n_1}{N}$ is the expected number of cases in category k.

Under the null hypothesis of no trend, this test statistic has an asymptotic χ^2-distribution with 1 degree of freedom (d.f.). As typical for χ^2-test statistics, it compares the observed number in each category with the one expected under the null hypothesis where the x_k serve as weights. To achieve an asymptotic χ^2-distribution, the resulting squared sum of weighted differences in the nominator has to be appropriately standardized by accounting for the weighted sample sizes for each exposure level $x_k m_k$, the numbers of cases n_1 and controls n_0, as well as the total number of subjects N.

The second test to be mentioned here is the Cochran-Armitage test for trend which is based on the test statistic,

$$T = \frac{\left[\sum_{k=1}^{K} x_k(a_k n_0 - c_k n_1)\right]}{\sqrt{\frac{n_0 n_1}{N}\left[\sum_{k=1}^{K} x_k^2 m_k(N - m_k) - 2\sum_{i=1}^{K-1}\sum_{j=i+1}^{K} x_i x_j m_i m_j\right]}},$$

that is asymptotically standard normally distributed under the null hypothesis.

In practice, the weights x_k are often chosen as k. This is appropriate when the differences of the mean levels between two adjacent categories are similar, which is, for instance, fulfilled if the categories are equidistant. If this is not the case, the result of a trend test can highly differ whether x_k (e.g., defined as the midpoint of the exposure category) or simply k is used in the formula above. For the last, open-ended category, there is no unique best solution to assign a weight x_k. Given that the rank k is not used as weight, the best solution would be to investigate the distribution of the variable and to use as x_k the expected value given the observations are larger than the lower limit of this category. Since this may be difficult, a quick and pragmatic solution is to take the lower limit of this category multiplied by 1.5. If few observations are in this category, the value used for x_k is not crucial. In any case, however, an exact description of the method used is important (see Example 29.2).

Example 29.2.
We consider the data from the case-control study on laryngeal cancer as presented in Table 29.2. For the Mantel-Haenszel χ^2-test, we have $\chi^2 = 48.51$, and for the Cochran-Armitage test, we get $T = 6.97$ with $x_k = k$ which are both highly significant ($p < 0.001$). Thus, our observation of an increasing odds ratio with increasing dose is supported by both statistical tests.

The underlying principle is identical for contingency table analysis and for regression models, but for the latter, there exists a larger variety of methods to perform a trend test (Agresti 2002).

29.2.4 Concluding Remarks on Classical Methods

In summary, methods for analyzing contingency tables, which have mainly been developed before 1980, have served as analytical techniques for analyzing epidemiological studies for a long time. For a more detailed treatment of such methods, we refer to classical textbooks like Breslow and Day (1980). It has become apparent, however, that these methods have their limits, as best seen in the analysis of continuous covariates. The major drawbacks are:

- The need to categorize continuous covariates, leading to a loss of information
- Limited possibilities to derive a dose-response curve
- Limited ability for confounder adjustment

In addition, the interpretation of the results may vary with the choice of the cut-points of the categories.

Nevertheless, these methods have one general advantage which should not be underestimated: they are simple, and some can easily be calculated with a small pocket calculator. As a first step, following a descriptive analysis of the data, they are still useful although these results will rarely find their way into high ranking journals today.

In the following, the most relevant regression models in epidemiological research are briefly summarized (see also chapter ▶Regression Methods for Epidemiological Analysis of this handbook) before several methods to analyze continuous covariates are presented.

29.3 Regression Models and Risk Functions

It has already been mentioned several times that regression modeling is the method of choice for the analysis of epidemiological data. The advantages of these are particularly apparent when continuous covariates have to be analyzed since they allow the analysis of the data without categorization. In this section, we introduce relevant regression models and a notation which is useful for the subsequent presentation of the methods to analyze continuous covariates.

Let Y be the outcome variable, and let X and Z be two covariates (X continuous, Z unspecified). In this chapter, we consider (a) the logistic regression model, where the outcome variable Y is dichotomous, $Y = 1$ (diseased), $Y = 0$ (not diseased); (b) the Poisson regression model, where $\mu = D/PY$ is the outcome variable with D the observed number of events, for example, deaths, and PY (person-years) the observation time for all individuals; and (c) the Cox regression model, where $\lambda(t)$ is the hazard function and one observes the individual survival time t and a censoring indicator (for a general discussion of regression models, see chapter ▶Regression Methods for Epidemiological Analysis of this handbook; for models of the latter type, we also refer to chapter ▶Survival Analysis). Although Cox regression is conceptually different from linear, logistic, or Poisson regression, the handling of continuous covariates follows the same principles. Therefore, these regression models are considered jointly here.

The commonly used (log-linear) form of the logistic, Poisson, or Cox model reads as follows for the logistic regression model:

$$P(Y = 1|x, z) = \frac{\exp(\beta_0 + \beta_1 x + \beta_2 z)}{1 + \exp(\beta_0 + \beta_1 x + \beta_2 z)}$$

the Poisson regression model:

$$\mu = \exp\left(\beta_0 + \beta_1 x + \beta_2 z\right),$$

and for the proportional hazards (Cox) regression model:

$$\lambda(t) = \lambda_0(t)\exp(\beta_1 x + \beta_2 z),$$

where β_1 and β_2 are the regression coefficients for X and Z, respectively, and β_0 is an intercept parameter. This standard form is not very flexible since a specific functional relation between the covariates and the outcome is fixed (see Sect. 29.4 for details). A more general form of these models allows transformations of X and Z with functions f and g, and the exponential function exp is replaced by R. The general form then becomes for the logistic regression model:

$$P(Y=1|x,z) = \frac{\exp(\beta_0)R_X(f(x),\beta_1)R_Z(g(z),\beta_2)}{1+\exp(\beta_0)R_X(f(x),\beta_1)R_Z(g(z),\beta_2)},$$

Poisson regression model:

$$\mu = \exp(\beta_0)R_X(f(x),\beta_1)R_Z(g(z),\beta_2),$$

and for the Cox regression model:

$$\lambda(t) = \lambda_0(t)R_X(f(x),\beta_1)R_Z(g(z),\beta_2),$$

where R_X and R_Z are risk functions.

For illustration, let us consider the logistic model first. In the classical form as given above, a dose-effect function for the variable X, given as $OR(X = x$ vs. $X = x_0)$, is given by

$$OR(X = x \text{ vs. } X = x_0) = \frac{P(Y=1|x,z)P(Y=0|x_0,z)}{P(Y=1|x_0,z)P(Y=0|x,z)} = \exp(\beta(x-x_0)),$$

thus automatically yielding a specific (exponential) form of the dose-effect curve. This is not sufficient for most analyses, and the more general form is given as

$$OR(X = x \text{ vs. } X = x_0) = \frac{P(Y=1|x,z)P(Y=0|x_0,z)}{P(Y=1|x_0,z)P(Y=0|x,z)} = R(\beta(f(x)-f(x_0))).$$

In the history of the development, different choices for R have been considered first (see Sect. 29.4.4). Transformations of the covariate X before entering it in the regression model have also been common for quite a while, but only after the development of fractional polynomials this has been investigated in a more systematic way (Royston and Altman 1994; Royston and Sauerbrei 2008; see section “Fractional Polynomials” in Sect. 29.4.3). The correct functional form of the relative risk function is commonly unknown, and unless biological knowledge can be added to support a specific shape, one has to base the decision on statistical grounds. For assessing the dose-effect curve associated with X, different approaches are used in the literature which are dealt with in the next section.

It is possible in some cases to analytically derive the appropriate model if the distribution of the covariates is known. If, for instance, X is normally distributed in cases and controls with equal variance and (possibly) different mean, then the classical form $R(\cdot) = \exp(\cdot)$ and $f = \mathrm{id}$ (where id denotes identity, i.e., $f(x) = x$) is the correct one. In practice, however, it is more complex and it is necessary to find a statistical procedure for building the model and for discriminating between models (Becher 1993; Becher et al. 2012).

It is noteworthy at this point that $R(\cdot) = \exp(\cdot)$ describes the odds ratio (or relative risk or rate ratio) for the value of $X = x$ relative to a reference level $X = x_0$. For example, if X denotes the number of cigarettes smoked, then $R(10)$ describes the odds ratio for smoking 10 cigarettes compared to smoking zero, but likewise, the odds ratio for smoking 20 cigarettes compared to 10. This is the reason why the odds ratio function often does not fit to the estimates obtained by categorization of X where the odds ratio for each exposure category is estimated in comparison to the same baseline category, a fact that is nicely described in Breslow and Day (1980, pp. 220f). They estimated the risk for esophageal cancer for different amounts of tobacco consumption. Compared to the baseline (non-smoker), even moderate smokers have a considerable risk (odds ratio about 4.3). The increase in risk with increasing dose, defined as four different amounts of tobacco consumption, is clearly not log-linear (see Fig. 6.4 in Breslow and Day (1980), p. 221). When estimating the risk with the classical logistic model, the odds ratio function is, however, forced to be log-linear with $\log(OR(X = x \text{ vs. } X = x_0)) = \beta(x - x_0)$ which does not fit the data well.

The risk function R may be embedded in the Poisson regression in a similar way as in logistic regression. However, there is one principal difference when applying this regression model. Here, a rate is modeled which results from the observed number of events in a category divided by the corresponding observed person-time (see chapter ▶Cohort Studies of this handbook). Therefore, a categorization of a continuous covariate is necessary for the allocation of person-time (see Breslow and Day 1987, pp. 85–86). For example, if the effect of average daily alcohol consumption X (in g ethanol per day) on a particular disease is analyzed from a cohort study with Poisson regression, then X has to be categorized first, for example, in categories 0, >0–10, >10–20, >20–40, >40–80, and 80+ g/day. Then, the observed number of cases and corresponding person-years are calculated for each exposure category, and finally the Poisson regression can be performed using one of the methods as described later. The dose-effect analysis is then based on an average exposure level within an exposure category for which the mean of all individuals falling into the respective category can be used.

29.4 Methods to Analyze Continuous Covariates in Regression Models

In this section, several approaches will be described to include continuous covariates in regression models where we will first briefly state the underlying principle of the respective approach before this will be further acknowledged and illustrated by applying it to the case-control study on laryngeal cancer.

29.4.1 Categorization of the Covariate into K Categories

Underlying principle: A continuous variable X is transformed into K binary variables. In the regression model, $K-1$ regression coefficients are estimated.

Here we use

$$R(\cdot) = \exp(\cdot);\ f(x) = (I_{x \in I_1}(x), \ldots, I_{x \in I_K}(x)),$$

where I is the indicator function and I_K are the exposure categories $1, \ldots, K$, as defined in Sect. 29.2.1.

This method is still commonly used in epidemiology. It corresponds to classical methods for the analysis of grouped data. In contrast to categorization of the continuous covariate and building contingency tables as described in Sect. 29.2, the covariate is split into K binary variables which then enter the regression model. These are also called "dummy variables." The category that defines the baseline, usually the non-exposed or the low exposed, is left out of the model. The criteria for choosing the number of categories and their limits are the same as for the classical methods described in Sect. 29.2.

This approach has the advantage that it leads to results that can be easily interpreted. It is therefore popular among non-statisticians, and it is "model-free" in the sense that it does not assume a specific shape of the dose-effect relationship. It is a useful step within the overall analysis procedure; however, it also has some serious drawbacks. Among these are an arbitrary choice of the baseline category, cut-points, and number of categories. The full information from the data is not used and the risk function is by definition a step function:

$$\mathrm{R}(x) = \exp\left(\sum_{k=1}^{K} \beta_{1k} I_{x \in I_k}(x)\right).$$

If X is a confounder for Z and if K is small (e.g., $K = 2$), a high degree of residual confounding is likely to occur. If K is large, residual confounding is less likely, but then a high number of parameters has to be estimated which may not be feasible if the sample size is small. Often, a categorization (dichotomization) of X is made such that the p-value is minimal. This procedure, though often found in literature, yields false results if this p-value is used without adjustment. Uncritical use of the minimal p-value approach would result in a marked increase in the false-positive error rate, and many factors that have no risk potential would be labeled erroneously as risk factors, increasing the existing problems in epidemiological research of simultaneous assessment of associations between many potential risk factors and disease outcome (Altman et al. 1994; Schulgen et al. 1994).

A "test for linear trend" which parallels the classical test introduced in Sect. 29.2.3 is given by assigning the values $1, 2, 3, \ldots, K$ to the K categories of X and entering X with these values into the regression model. The advantage

Table 29.3 Alcohol consumption in males; laryngeal cancer case-control study; Germany. Analysis with logistic regression, Method of Sect. 29.4.1

Parameter	Estimate	Standard error	Wald χ^2	p-value	$\widehat{OR} = \exp(\hat{\beta}_i)$	95% CI
α	-1.69	0.15	134.73	<0.0001		
β_2	0.47	0.22	4.70	0.0301	1.60	(1.046 − 2.449)
β_3	0.67	0.23	8.37	0.0038	1.96	(1.234 − 3.101)
β_4	1.41	0.20	48.89	<0.0001	4.12	(2.768 − 6.119)

over the methods described in Sect. 29.2.3 is the possibility to simultaneously adjust for other covariates which is only possible to a limited degree using the classical methods. The disadvantage, namely, the restriction to a specific functional form of the dose-response function, however, is the same as before, and therefore it is not recommended for general use.

This approach also works for variables with a spike at zero. In this case, the baseline category is typically given by the non-exposed ($X = 0$). Problems may arise if this category is sparse. In that case, as in the example below, a category "no or low exposure" may be more appropriate because otherwise the standard errors of regression coefficients become large.

In the following, we will illustrate the above approach by using the data from the case-control study presented in Table 29.2 where alcohol consumption is now coded as a dummy variable and modeled as potential risk factor for laryngeal cancer using a logistic model (see Example 29.3).

Example 29.3.
Using the data from Table 29.2, we can fit a logistic model with alcohol consumption coded as dummy variable with the lowest category $i = 1$ (<=25 g/day) as the baseline category. The model then reads as logit$(P(Y = 1|\text{alcohol level } i) = \alpha + \beta_i$, $i = 2, 3, 4$, and the odds ratio estimates OR(alcohol level i vs. alcohol level 1) are obtained by $\exp(\hat{\beta}_i)$. Using the above model with the SAS-statement

```
Proc logistic descending; model y = x₂ x₃ x₄;
```

where X_2, X_3, X_4 are binary variables which take the value 1 if the observation falls in the i-th category and 0 otherwise, we get the results given in Table 29.3 (adapted from the SAS output).

The result corresponds to the result from the classical method as given in Table 29.2.

29.4.2 Leaving the Covariate Untransformed

Underlying principle: Values of X are included into the regression model as recorded. One regression coefficient is estimated.

Thus, we get

$$f(x) = x; R(\cdot) = \exp(\cdot), \text{yielding } R = \exp(\beta x).$$

This is the standard approach which uses the full information of the measured variable. It can be applied also for variables with a spike at zero. However, it has the serious drawback that it assumes the exponential function as the dose-effect curve. This method is valid only in special situations, for example, if X has a normal distribution in cases and controls with equal variance. In many papers, one finds statements like "odds ratio estimates are adjusted for age" which often simply means that this method has been employed to adjust for X (age). The method can easily yield false results. In Example 29.8, we present data from a case-control study in which this method is not appropriate. The Method described in this section has a strong underlying model assumption, namely, that the risk function is log-linear. If this assumption is violated and the method is nevertheless applied, it has the following consequences: (i) the resulting dose-response curve does not represent the true relationship between the factor and the outcome and (ii) the regression estimates of other variables in the model are not appropriately adjusted for the effect of X.

Testing the null hypothesis of no effect of the exposure, that is, H_0: $\beta = 0$, the corresponding p-value for $\hat{\beta}$ as obtained from the model fit may be regarded as the result of a "test for linear trend." In that context, "linear" means that the log odds ratio increases linearly with dose. (see Example 29.4).

Example 29.4.
We illustrate Method 4.2 with the individual data on alcohol consumption, X, from the case-control study on laryngeal cancer. The model logit $P(Y = 1|x) = \beta_0 + \beta_1 x$ with the SAS-statement

```
Proc logistic descending; model y=x;
```

yields the results given in Table 29.4 (adapted from the SAS output).
Under the model assumption that the log odds ratio linearly depend on the alcohol dose, we get the dose-effect curve $OR(X = x* \text{ vs. } X = x_0) = \exp(0.00878(x * -x_0))$. A further evaluation whether this assumption is justified is not performed.

Table 29.4 Alcohol consumption in males; laryngeal cancer case-control study; Germany. Analysis with logistic regression, Method of Sect. 29.4.2

Parameter	Estimate	Standard error	Wald χ^2	p-value
α	−1.59	0.1073	220.93	<0.0001
β	0.0088	0.00125	49.22	<0.0001

29.4.3 Monotonic Transformations of the Covariate and Fractional Polynomials

Underlying principle: X is transformed before entering the regression model. Monotonic and non-monotonic dose-effect functions can be obtained.

Here, X undergoes a monotonic transformation with common functions, such as the logarithm or square root before it enters the regression model. This has been a common "ad hoc" method. Such monotonic transformations can be easily realized within the various software routines for calculating regression models.

Figure 29.1 shows the shape of the dose-effect curve for three common transformations

$$f_1(x) = \sqrt{x}, \quad f_2(x) = x^2, \quad f_3(x) = \log(x+1),$$

for which the regression coefficient is chosen such that $R(1) = \exp(1)$. It is seen that f_1 generates an almost linear dose-effect relationship within the given dose range, f_2 generates a strictly increasing (quadratic) curve, and f_3 a concave dose-effect curve (see also Sect. 29.4.4 for comparison).

For f_3, a specific feature must be noted: if the covariate X can be zero or negative, then the simple log transformation is not possible, and instead of $\log(x)$, $\log(x+k)$ has to be used (see also Sect. 29.4.5 below).

Different approaches have been proposed to discriminate between models as in Fig. 29.1 which are called "non-nested models" (e.g., Royston and Thompson 1995; Mizon and Richard 1986). These approaches are beyond the scope of this chapter. It is also possible to use a higher-dimensional transformation, for example, $f(x) = (x, x^2)$. Then, not only X is included into the model but also X^2. A formal test on whether the second component significantly improves the goodness of fit is readily available as the difference of deviances which is asymptotically

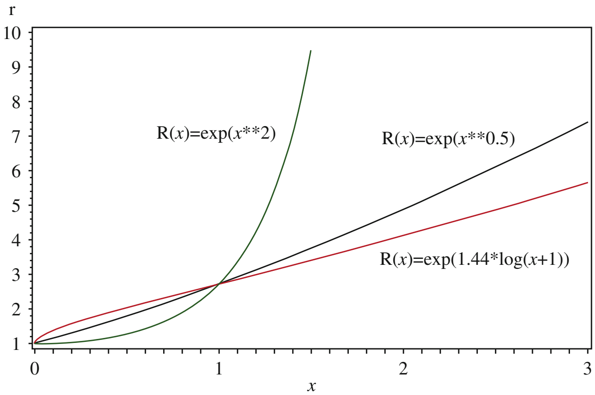

Fig. 29.1 Possible shapes of dose-effect curves as obtained from the transformations $f_1(x) = \sqrt{x}$, $f_2(x) = x$, $f_3(x) = \log(x+1)$

χ^2-distributed. A non-monotonic dose-effect function may result from this approach, if, for example, the regression coefficients have different signs.

An open problem so far is how the covariate should be transformed to achieve the best monotonic or non-monotonic dose-effect function in the sense of an optimal model fit. Royston and Altman (1994) have developed a stringent procedure which they called "fractional polynomials." A monograph by Royston and Sauerbrei (2008) gives a full account of the method which is further outlined below.

Fractional Polynomials The idea of fractional polynomials (FP) is to allow the variable to enter the model after it has been transformed where the transformation used is selected from a predefined set of eight different functions. This set is defined as $H_1(x) = x^p$ with $p \in \{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}$ with x^0 being defined as $\log(x)$. In an FP of degree 1, the variable is entered successively using these eight transformations. In an FP of degree 2, the variable enters the model a second time with $H_2(x) = x^q$ with $q \in \{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}$ and with $H_2(x) = x^p \log(x)$ in case that $q = p$. Royston and Altman (1994) showed that the fractional polynomials of degree 2 cover a very rich family of dose-effect relationships. Thus, a huge variety of dose-effect relationships can be fitted where often different FPs yield very similar fits with very similar dose-effect relationships (Royston and Altman 1994).

Embedding FPs in the above framework, we have $R(\cdot) = \exp(\cdot)$, and we use as linear predictor

$$\beta_0 + \sum_{j=1}^{J} \beta_j H_j(x) \quad ,$$

where, for example, for a first-order FP, J is equal to 1 and $H_1(x) = x^p$ as defined above. For a second-order FP (FP2), we have $J = 2$, and the models are of the form $\beta_0 + \beta_1 x^p + \beta_2 x^q$. FPs of higher order rarely occur in practice. In practice, $J = 2$ is most often used. If it can be assumed on biological grounds that the relation with the disease is monotonic, the FP method can be restricted to FPs of degree 1 ($J = 1$).

As already mentioned above, FPs were developed to provide a procedure to systematically search for the optimal transformation of the covariate. For this purpose, a closed test procedure, called FSP (function selection procedure), has been suggested which is described in detail in Royston and Sauerbrei (2008). This procedure consists of three steps which are described in the following:

Step 1: Test the best FP2 model for the covariate X at a significance level α against the null model (without the covariate X) using 4 d.f. If the test is not significant, the procedure has to be stopped concluding that the effect of X is "not significant" at level α. Otherwise, continue with Step 2.

Step 2: Test the best FP2 for X against a straight line (i.e., X remains untransformed) at significance level α using 3 d.f. If the test is not significant, the procedure has to be stopped concluding that the final model is a straight line. Otherwise, continue with Step 3.

Step 3: Test the best FP2 for X against the best FP1 at significance level α using 2 d.f. If the test is not significant, it can be concluded that the final model is FP1; otherwise, the final model is FP2 and the procedure ends.

The test used in Step 1 checks for an overall association of the outcome with the covariate X. The test at Step 2 examines the evidence for non-linearity in X. The test at Step 3 is used to select between a simpler or more complex model. All tests are based on the difference of deviances using the asymptotic χ^2-distribution.

In many practical situations (excluding the common spike at zero situation which is considered separately), the continuous exposure variable X is positive (e.g., blood pressure, vitamin A intake, body mass index). If X is an exposure variable which can take values smaller or equal zero (e.g., weight gain from age 20 to 40), they recommend to add a constant c to X in order to make all transformations possible. As an example for this case, consider as X the change in body mass index from age 20 to 30. This variable has a continuous distribution, and the observation range covers positive and negative values. In order to allow application of the FP procedure, a transformation $X \to X + c$ is required, where c has to be chosen being larger than the smallest observation of X, that is, $c > x_{\text{min}}$.

In general, please note that an FP of degree 1 yields monotonic dose-effect functions, whereas an FP of degree 2 allows for non-monotonic dose-response functions (see Example 29.5).

Example 29.5.

We illustrate the FP procedure with data of the case-control study on laryngeal cancer. We are interested in the effect of smoking dose among the smokers where the covariate smoking is considered as cumulative dose in pack-years. A SAS macro is available for this analysis. The analysis with a second degree FP gives the results shown in Table 29.5.

The best FP2 (where X is transformed to the power of 0.5 and 1) is compared with the null model at level $\alpha = 0.01$ using 4 d.f. The model identified at that stage is therefore logit $P(Y = 1|X = x) = \beta_0 + \beta_1\sqrt{x} + \beta_2 x$. We observe a difference of deviances of 257.46 which is highly significant. In the next step, we compare the best FP2 with the linear model at $\alpha = 0.01$ with 3 d.f. We get 35.69, which is also highly significant. Finally,

Table 29.5 Laryngeal cancer case-control study. Application of the standard FSP procedure to smoking dose (among smokers), $N = 766$

	Deviance	Deviance difference	d.f.	p-value	Power(s)
FP2	800.77		1	1.00	(0.5, 1)
Null		257.46	4	<0.001	–
Linear		35.69	3	<0.001	(1,–)
FP1		2.21	2	0.33	(0,–)

we compare the best FP2 with the best FP1 at $\alpha = 0.01$ using 2 d.f. The best FP1 is a polynomial of degree 0 which thus has the form logit $P(Y = 1|X = x) = \beta_0 + \beta_1 \log(x)$ (log transformation of the covariate). The result is 2.21 and non-significant. Therefore, the final result is an FP1 with the power 0. This is, in the notation of the FPs, the transformation $\log(\cdot)$. The estimated regression coefficient has the value 1.09, and the estimated dose-effect curve follows:

$$OR(X = x^* \text{vs. } X = x_0) = \exp(1.09 \times (\log(x^*) - \log(x_0))).$$

29.4.4 Additive (Linear) Risk Functions

Underlying principle: It is assumed that the risk function increases linearly with dose (as opposed to Sect. 29.4.2, where a log-linear risk function is assumed). One parameter is estimated.

In this case, we thus assume that

$$f(x) = x, R(x) = 1 + \beta x.$$

This risk function, though often described in the literature and also available in some software packages, is not very often used in practice. The method dates back to Breslow and Storer (1985). To get some guidance on which risk function should be used in a given situation, a goodness-of-fit statistic to compare the linear and exponential relative risk function, that is

$$R_1(x) = \exp(\beta x) \text{ vs. } R_2(x) = 1 + \beta x,$$

would be desirable. However, a simple test for the hypothesis, H_0: "Both models fit the data equally well" vs. H_1: "One model fits the data better than the other" is not available because the models are not nested and the difference of the deviances has an unknown distribution under the null hypothesis. The restriction $f(x) = x$ can easily be relaxed, that is, by a transformation of X with a function as given in Sect. 29.4.3, but this has also rarely been done in practice.

In this model, the risk when comparing two covariate values x_1 and x_2, $0 \leq x_1 < x_2$, does not only depend on $x_2 - x_1$ as it is the case for the log-linear risk function (see Sect. 29.4.2) since it holds

$$R(X = x_2 \text{ vs. } X = x_1) = \frac{1 + x_2\beta}{1 + x_1\beta} < 1 + (x_2 - x_1)\beta.$$

For example, let us assume $\beta = 1$. Then,

$$R(X = 1 \text{ vs. } X = 0) = \frac{1 + 1}{1 + 0} = 2,$$

whereas

$$R(X = 2 \text{ vs. } X = 1) = \frac{1+2}{1+1} = 1.5,$$

although the difference of the arguments is the same in both cases.

Note 1 A linear dose-effect curve is also obtained under $R(\cdot) = \exp(\cdot)$ by using $f(x) = \log(\beta x + 1)$ and choosing β such that $\gamma = 1$. It follows that $R(x) = \exp(\log(\beta x + 1)) = (1 + \beta x)$. This algebraic equivalence is used in the Example 29.6 below to fit an additive (linear) risk function with standard software, which usually has $R(\cdot) = \exp(\cdot)$ as default.

Example 29.6.
In this example, we illustrate the fit of an additive (linear) risk function of the form $R(x) = 1 + \beta x$. In order to use standard software, such as PROC LOGISTIC in SAS, the property shown in the note above is taken advantage of. We consider again the case-control study on laryngeal cancer and alcohol consumption as risk factor. We use the model $\text{logit}(X = x|Y = 1) = \alpha + \gamma \log(\beta x + 1)$ with $\beta = 0.02975$. We get a difference of deviances of 54.24 ($p < 0.001$) with 1 d.f. and a parameter estimate $\hat{\gamma} = 1$. Note again that β was chosen such that the regression parameter estimate $\hat{\gamma}$ becomes 1. As a linear risk function, we then get

$$OR(X = x^* \text{ vs. } X = x_0) = \exp(1 \times \log(0.02975x + 1)) = 1 + 0.02975x.$$

The inference for β is done by comparing the deviances of the models with and without the transformed variable X. The difference of deviances is asymptotically χ^2-distributed with 1 d.f. under the null hypothesis $\beta = 0$.

29.4.5 Spike at Zero

Underlying principle: X has a spike at zero which requires special consideration. X is transformed before it is entered the regression model according to a specified procedure. For this procedure a binary exposure indicator (exposed/nonexposed) is introduced. Monotonic and non-monotonic dose-effect functions can be obtained.

This method was motivated by the fact that there are covariates whose distribution has a discrete and a continuous component. The most prominent example is smoking where a certain proportion of the population are non-smokers referred to as $X = 0$, that is, $P(X = 0) > 0$. Among smokers, the distribution of smoking dose is continuous. In this situation, there are both statistical problems and difficulties to interpret the results. From the statistical point of view, the presence of zero exposure precludes some of the transformation, such as log or the inverse function. A suggested ad hoc procedure is to add a small constant to each observation, but this lacks theoretical justification. With regard to interpretation, the relative risk for smoking k cigarettes daily compared to 0 may not be the same as smoking $2k$ cigarettes compared to k.

Jedrychowski et al. (1992) took account of this problem by entering a binary variable smoker/non-smoker into the model in addition to the (transformed) dose variable (see examples). However, this was an ad hoc approach without giving a formal rationale for the procedure. The method was more formally described in Robertson et al. (1994). The first parameter then represents the effect of exposure, and the second parameter represents the effect of the categories of exposure among those who are exposed. But note that Robertson did not suggest a formal model selection procedure.

Recently, the spike at zero situation has been considered using an extended FP approach (Royston et al. 2010; Becher et al. 2012). The second paper by Becher et al. (2012) modifies the method by Royston et al. (2010) which leads to slightly better properties of this method. We therefore will only describe the modified version from Becher et al. (2012).

The function selection procedure (FSP) has four steps, which are given below:

1. Generate a binary indicator Z indicating whether the exposure X is present or not.
2. Fit the most complex model (binary indicator Z + 2nd degree FP) and compare the deviance of this model with the deviance of the null model using the χ^2-distribution with five degrees of freedom. If the corresponding test is not significant, stop the procedure concluding that the effect of the exposure is "not significant" at level α. The transformations are applied to the positive values of X only.
3. If significant, follow the same FP function selection procedure *with* Z included (first stage) as in the simple case without a spike.
4. Test both Z and the remaining FP (respective the linear component) for removal.

A more detailed description of the method is given in the following. The FSP-spike procedure for selecting a model has two stages. In the first stage (Steps 2 and 3), the most complex model comprising Z and $\text{FP2}+(X;p,q)$ is compared with the null model on 5 d.f. (4 d.f. from the FP2 model plus 1 d.f. from the binary Z term). If the test is significant, the steps of the FSP for selecting an FP function are followed, but with Z always included in the model. The result after this stage is either that an effect of the exposure cannot be shown (null hypothesis not rejected) or a model with a binary indicator plus an FP of degree 1 or 2.

In the second stage (Step 4), Z and the remaining FP or linear component are each tested for removal from the model. If both parts are significant, the final model includes both; if one or both parts are non-significant, the one with the smaller deviance difference is removed. In the latter case, the final model comprises either the binary dummy variable or the selected FP function. If only an FP function is selected, the spike at zero plays no further role and is removed.

Since the selection of an FP function may be affected by the presence of the binary dummy variable, the resulting model may differ from that of a standard FP analysis. An example for the approach is given in Example 29.7; further examples are given in Becher et al. (2012).

Example 29.7.
In this example, we illustrate the FSP-spike procedure with the extended FP approach. We are interested in the general effect of amount of smoking in comparison to non-smokers

Table 29.6 Laryngeal cancer case-control study. Application of the FP-spike procedure to smoking dose (smokers and non-smokers included), $N = 938$

	Deviance	Deviance difference	d.f.	p-value	Power(s)
First stage					
FP2 + spike	846.09		1	1.00	(0.5, 1)
Null		212.13	5	<0.001	–
Linear + spike		35.60	3	<0.001	(1,–)
FP1 + spike		4.95	2	0.08	(0,–)
Second stage					
FP1 + spike	851.04		3		
FP1 (dropping spike)		0.62	1	0.43	
Spike (dropping linear)		132.06	4	<0.001	

in the case-control study on laryngeal cancer with the exposure variable cumulative dose in pack-years. The general model has the form logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_2 x^p + \beta_3 x^q$, where $z = I_{[X=0]}(x)$ represents the binary indicator, p and q represent the powers in the FP model, and β_1 is the coefficient for the binary indicator variable. The analysis with a second-degree FP-spike gives the results shown in Table 29.6.

In the first stage, we identify the best FP2-spike model among all FPs. This model has powers 0.5 and 1 and includes the spike. The model identified at that stage is therefore logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_2 \sqrt{x} + \beta_3 x$. It has a deviance of 846.09. We compare this model with the null model at the level $\alpha = 0.01$ using 5 d.f. We observe a difference of deviances of 212.13 which is highly significant ($p < 0.001$) and conclude that the exposure has a significant effect on the outcome variable.

In the next step we compare the best FP2-spike with the linear model with spike at $\alpha = 0.01$ with 3 d.f. We get a difference of deviances between the best model and the linear model of 35.60 which is also highly significant. We conclude that the model logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_3 x$ is not sufficient to describe the data. Finally, we compare the best FP2-spike with the best FP1-spike at $\alpha = 0.01$ using 2 d.f. The best FP1-spike is a polynomial of degree 0 (log transformation) and has the form logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_2 \log(x)$. The difference of deviances between this model and the above best FP2-model is 4.95. This difference is not significant ($p = 0.08$), and we select the model logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_2 \log(x)$ in the first stage. This model has a deviance of 851.04.

In the second stage, we check whether either the spike or the selected FP1 can be omitted. Removal of the spike yields a slightly worse fit with a difference of deviances of 0.62. The spike variable is not significant ($p = 0.43$). The selected FP1, however, is highly significant with a difference of deviances of 132.06. This results from comparison of the model logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_2 \log(x)$ with the model logit $P(Y = 1|X = x) = \beta_0 + \beta_1 z$. Therefore, the final result is a FP1 of the form logit $P(Y = 1|X = x) = \beta_0 + \beta_2 \log(x)$. The resulting regression coefficient taken from this model is $\hat{\beta}_2 = 0.926$ and yields the estimated dose-effect curve:

$$OR(X = x^* \text{vs. } X = x_0 | x_0 > 0) = \exp(0.926 \times (\log(x^*) - \log(x_0)))$$

and

$$OR(X = x^* \text{vs. } X = 0) = \exp(0.926 \times \log(x^*)) = (x^*)^{0.926}.$$

We can conclude that the estimated odds ratio increases almost linearly with dose.

29.4.6 Conditioning on a Confounder

Underlying principle: X is a continuous confounder. The aim is to adjust for the confounding effect of X, but not to estimate its effect on the outcome variable.

There is no primary interest in assessing the relation between X and Y if X is a confounder of the variable Z where Z is the variable of primary interest. Here, the main focus lies on the correct and complete adjustment of the effect of Z for X. All previous methods may be applied; however, all these methods cannot exclude residual confounding. We therefore suggest to eliminate the effect of the confounder X by conditioning on X using fine strata. This method can readily be applied to case-control studies. It means that the regression coefficients of the logistic model are estimated by maximizing the conditional likelihood, where it is conditioned on the observations in the matched sets which are formed post hoc with fine strata according to X. Details may be found in Neuhäuser and Becher (1997). This method performs rather well in simulation studies with respect to bias and precision of the estimates in comparison to traditional methods to adjust for confounding by inclusion in the model as a covariate.

To further illustrate this idea, let us assume a case-control study with n_0 controls and n_1 cases. The logistic model with covariates X and Z reads as follows:

$$\text{logit } P(Y = 1|X = x) = \beta_0 + \beta_1 z + \beta_2 f(x).$$

The unconditional likelihood function of this logistic model is then given as

$$L_{\text{uncond}} = \prod_{i=1}^{n_0} \frac{1}{1 + \exp(\beta_0 + \beta' f(x) + \gamma z)} \prod_{i=n_0+1}^{n_0+n_1} \frac{\exp(\beta_0 + \beta' f(x) + \gamma z)}{1 + \exp(\beta_0 + \beta' f(x) + \gamma z)}.$$

To adjust for the confounding effect of X, it is common practice to include X into the model either untransformed (see Sect. 29.4.2), as a categorical variable (see Sect. 29.4.1), or using another transformations according to the methods described in Sect. 29.4.3. Instead, it is proposed to adjust for X via the conditional likelihood as

$$L_{cond} = \prod_{h=1}^{H} \frac{\prod_{j=1}^{n_{1h}} \exp(\gamma z_{hj})}{\sum_{l_j} \prod_{j=1}^{n_{1h}} \exp(\gamma z_{hl_j})}.$$

Here, we have defined H strata according to an appropriate categorization of X. Each stratum consists of n_{1h} cases and n_{0h} controls. The sum in the denominator ranges over the $l_j = \binom{n_{1h} + n_{0h}}{n_{1h}}$ choices to select n_{1h} observations out of the total number of observations in stratum h. It is possible to extend the method to more than one covariate, for example, sex and age. In that case, all individuals with the same sex and the same age group build one stratum. Since the likelihood is conditioned on the observations of the confounder X, this variable cancels out from the likelihood (Breslow and Day 1980).

This post hoc stratification method has a practical limitation. On the one hand, one aims at defining fine strata to avoid residual confounding. On the other hand, if these strata are too fine, several of these may contain no cases or no controls. For example, if strata are defined through "year and month of birth," then in a medium-sized study many will be uninformative since either cases or controls are missing. In that case, they do not contribute to the estimation since they cancel out from the likelihood function above. This, in turn, results in a loss of power. See Example 29.8 for a practical application of the method.

For an individually matched case-control study, this method can only be used to control for another confounder if the original matching is broken and new strata are formed according to the primary matching factors and the confounder in addition. Properties of this procedure have not yet been investigated.

Example 29.8.
We consider an unmatched case-control study on laryngeal cancer risk factors (Zatonski et al. 1991). Here, age is the continuous covariate X, and Z, smoking, is the variable of main interest. We are interested in an optimal adjustment for the confounding effect of X, not in a dose-effect analysis. Since the age distribution differs between cases and controls (see Table 29.7), adjustment for age is necessary.
Coding age as a dummy variable as described in Sect. 29.4.1 was used in the original paper with six age categories in an unconditional logistic regression model. However, this method may not be fully satisfactory as some residual confounding may still remain. Here, the proposed approach to condition on the confounder may be advisable. As alternative approach fractional polynomials could be used. Table 29.8 shows the estimated regression coefficients for cigarette consumption, given as log (no. of cigarettes smoked +1), and standard errors for different adjustment methods. Due to the confounding of the association of laryngeal cancer and smoking by age, the regression coefficients for smoking become smaller, the better the adjustment for age is. Considering age as dummy variable in the model (see Sect. 29.4.1) with six age categories reduces the estimate for smoking from

Table 29.7 Age distribution in cases and controls, Polish laryngeal cancer case-control study (Zatonski et al. 1991)

	Controls		Cases	
Age group (years)	N	%	N	%
25–34	275	28.5	7	2.8
35–39	163	16.9	7	2.8
40–44	96	10.0	19	7.6
45–49	90	9.3	27	10.9
50–54	110	11.4	71	28.5
55–59	123	12.7	62	24.9
60–65	108	11.2	56	22.5
Total	965	100.0	249	100.0

Table 29.8 Selected regression coefficients for smoking by adjustment method, Polish laryngeal cancer case-control study (Zatonski et al. 1991)

Method of adjustment for age	Deviance	$\hat{\beta}_{\text{smoking}}$	Standard error (s.e.)
No adjustment	960.4	1.732	0.153
Categorical (2 age groups)	946.0	1.440	0.162
Categorical (6 age groups)	919.7	1.236	0.163
Fractional polynomial degree 1 (age^{-2})	931.6	1.193	0.160
Fractional polynomial degree 2 (age^3, log(age)×age^3)	918.7	1.185	0.159
41 age strata (1-year interval)	–	1.161	0.159

1.732 to 1.236. The best fractional polynomials of degrees 1 and 2 yield an estimate of 1.193 and 1.185, respectively. Conditioning on age using 1-year intervals further reduces the estimate to 1.161. The differences between these latter estimates do not have practical relevance; however, they confirm the simulations by Neuhäuser and Becher (1997) showing that conditioning is an appropriate method to control for the confounding effect of X since (i) the confounding effect of age appears to be adjusted best and (ii) the standard error of the estimate is virtually identical to that of the other models.

29.4.7 Generalized Additive Models (GAM's)

Underlying principle: The effect of X on the outcome variable is estimated by an unspecified function.

The class of generalized additive models (GAM's) proposed by Hastie and Tibshirani (1986, 1990) is a method to model an unspecified relation between a set of k covariates $X_1, \ldots, X_k$ and a response variable Y.

In the framework of the logistic regression model and for the simplest case with one covariate X, the common logistic model logit $P(Y = 1|x) = \beta_0 + \beta_1 x$ is replaced by logit $P(Y = 1|x) = \beta_0 + f(x)$ or logit $P(Y = 1|x) = \beta_0 + \beta_1 x + f(x)$ where $f(x)$ is a unspecified ("non-parametric") function. This function is estimated in a flexible manner using a scatterplot smoother. The estimated function $\hat{f}(x)$ can reveal possible non-linearities in the effect of X. Such unspecified smooth functions are estimated by local scoring algorithms further described in Hastie and Tibshirani (1986, 1990). This method has been used in several epidemiological studies on air pollution and health effects (e.g., Stieb et al. 2000; Rossi et al. 1999). The method is intuitively appealing since it provides a flexible method for identifying non-linear covariate effects. However, this approach is more data driven than the previous techniques described in this chapter, and it is not possible to take biological knowledge of the shape of the dose-effect curve into account. In some software packages, for example, in SAS, a procedure is available (PROC GAM) to fit a generalized additive model. It has the disadvantage, however, that it is not possible to plot the dose-effect curve (see Example 29.9).

Example 29.9.
In this example, we illustrate the application of the GAM and compare it with the standard logistic regression approach. We use the dataset from the laryngeal cancer study and estimate the risk associated with smoking among smokers (non-smokers are excluded from the analysis). We first fit the common logistic model logit $P(Y = 1|x) = \beta_0 + \beta_1 x$ with X being the cumulative amount of smoking (in pack-years/10). Using the procedure LOGISTIC in SAS using the statement

```
Proc logistic descending; model y=x;
```

the logistic model can be estimated, and we get a highly significant estimate for the effect of smoking on laryngeal cancer ($\hat{\beta}_1 = 0.36, \text{s.e.}(\hat{\beta}_1) = 0.037, p < 0.0001$). To check whether the log odds ratio increases linearly with dose, we fit a GAM using the statement

```
Proc gam plots=components(clm commonaxes);model y
(event='1') = spline(x,df=3)/dist=binomial;
```

Using this specification, the procedure estimates a linear component β_1 and a smoothing function $f(x)$ to describe the deviation from linearity over the observation range. Here, we get a highly significant linear component ($\hat{\beta}_1 = 0.33, \text{s.e.}(\hat{\beta}_1) = 0.037, p < 0.0001$) and also a highly significant smoothing component ($\chi^2 = 24.4, p < 0.0001$). The plot of the smoothing component (Fig. 29.2) suggests that the risk increase is strongest in the range of two to six and lower otherwise.
When including $\log(x)$ in the model instead of x, we get a highly significant linear component ($\hat{\beta}_1 = 1.03, \text{s.e.}(\hat{\beta}_1) = 0.11, p < 0.0001$), whereas the smoothing component ($\chi^2 = 2.65, p = 0.27$) is no longer significant. The corresponding plot of the smoothing component (Fig. 29.3) shows that the smoothing component does indeed differ only slightly from zero.

29.4.8 Spline Regression

Underlying principle: Spline regression is a smoothly joined piecewise regression. It is a non-parametric regression technique and can be seen as an extension of linear models that automatically models non-linearities and interactions between variables with a large flexibility:

$$f(x) \text{ polynomial (see below); } R(\cdot) = \exp(\cdot).$$

Greenland (1995) has proposed spline regression within the logistic model (see also chapter ▶Regression Methods for Epidemiological Analysis of this handbook) as a valuable method when important non-linearities are anticipated and software for more general non-parametric regression approaches is not available. Desquilbet and Mariotti (2010) described restricted cubic splines for dose-response analyses and present a SAS macro for analysis. Boucher et al. (1998) used this method for analyzing a case-control study on colon cancer and described several advantages of the method in comparison to the categorical analysis based on dummy variables (see Sect. 29.4.1). While using dummies, the risk is assumed to be constant within a

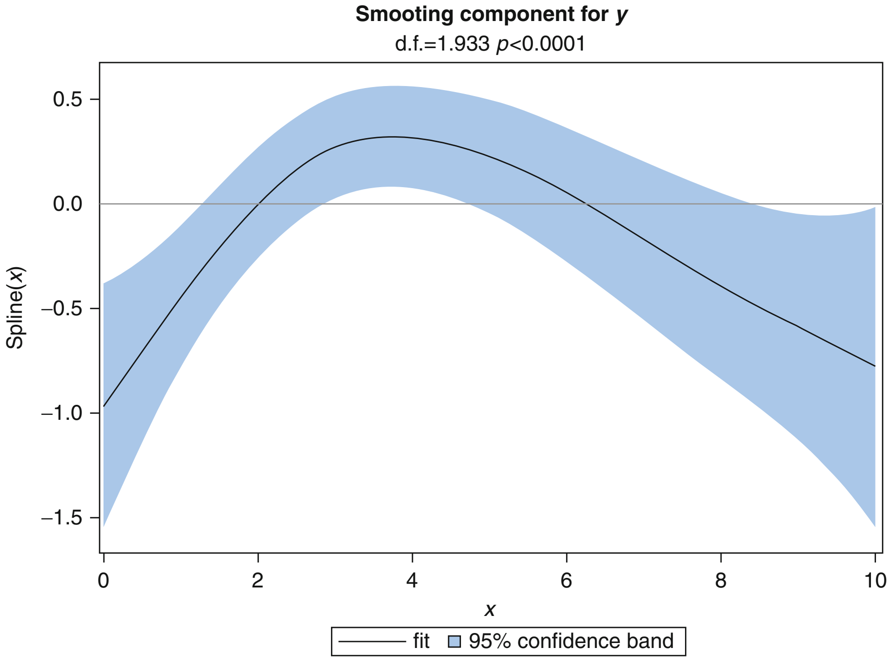

Fig. 29.2 Plot of the smoothing component

category and increases stepwise from category to category; with spline regression, the fitted risk changes continuously within and across categories. The method can also be applied to the other regression models considered in this chapter. Spline regression is formally described as follows: Let X be divided into K categories indexed by $k = 1, \ldots, K$ with $K - 1$ internal cut-points $c_1, \ldots, c_{K-1}$. For the so-called linear spline regression, we have $f(x) = \alpha + \beta_1 x + \beta_2 s_2 + \ldots + \beta_K s_K$, where $s_k = 0$ if $x \leq c_k$ and $s_k = x - c_k$ if $x > c_k$ and $R(\cdot) = \exp(\cdot)$. Using this model, one gets a continuous dose-effect function with slopes changing at each cut-point.

A more general spline regression avoids the biologically implausible fact that the first derivative of the dose-effect function is not continuous. Here, a quadratic term for X is added, and squared values of s_k are entered into the model such that

$$f(x) = \alpha + \beta_1 x + \gamma_1 x^2 + \beta_2 s_2^2 + \ldots + \beta_K s_K^2.$$

More details can be found in Greenland (1995) and Desquilbet and Mariotti (2010).

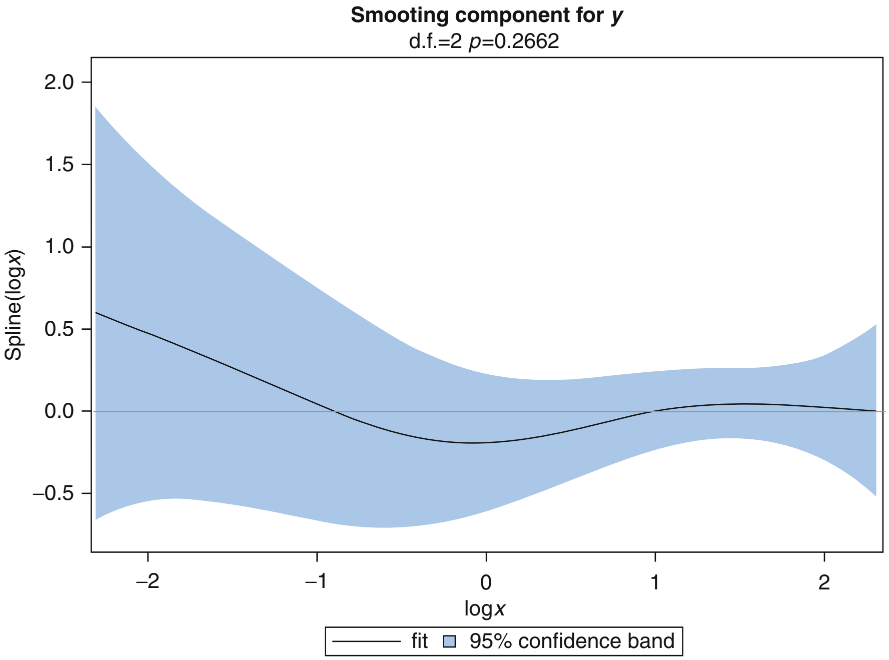

Fig. 29.3 Plot of the smoothing component

29.5 Conclusions

After a descriptive analysis, which may include some of the methods described in Sect. 29.2 – some of these are automatically carried out by some software packages when contingency tables are generated – more elaborate methods come into play. But there is no fixed analysis strategy such that each possible situation is treated appropriately. However, some general recommendations may help to develop an appropriate strategy in a given situation.

Figure 29.4 provides a possible decision tree which is further described below.

If X is not the variable of primary interest, conditioning is the recommended method in case-control studies to control for the confounding effect of X on the covariate of interest to minimize residual confounding. Some care must be taken to define the strata appropriately. For example, if an adjustment for age is done by defining strata as "year of birth," this will result in large strata for the most frequent age groups and small strata for the extreme ages. In Neuhäuser and Becher (1997), an adaptive method which depends on the study size and distribution of X is further discussed in the framework of the logistic regression. For other regression models, this method for control of confounding has not yet been investigated.

b) Dose-effect analysis, e.g. FP-spike (Sect. 29.4.5)

Fig. 29.4 Suggested decision tree for including continuous covariates

If there are several confounders simultaneously for which the risk estimate is not of interest, the method can in principle be used by forming strata according to the cross-classification of all these variables. If, however, the number of strata becomes large in comparison to the number of observations, the method has reached its limit.

If X is the variable of primary interest, the situation is more complex. If possible, biological knowledge should be taken into account when choosing the regression model. If the risk function is assumed to be non-monotonic, fractional polynomials are a good choice. Another option would be GAM's or spline regressions; however, as Royston et al. (2000) pointed out, the latter may exhibit artifacts which can make their interpretation difficult. But if the risk function is monotonic, FPs can be used for modeling the relationship between the continuous covariate X and the outcome by simply restricting to FPs of degree 1.

For the less frequent case that not the dose-effect curve itself is of interest but simply the hypothesis that there is a relation between the variable X and the response, the recommended procedure is as follows: Perform the analysis for X as for estimating the dose-effect curve and use the corresponding p-value.

Many of the methods presented above for assessing the dose-effect curve can yield very similar results although they may look very different at first sight. The models are often very closely related, and obviously the power to detect model misspecification is very small. While a categorization into two categories (high/low exposure) is generally not recommended, a categorization into four or more categories is, although not the optimal method, a useful first step in course of the analysis because it gives a first impression on the effect of the variable for different dose levels. This is especially true if a natural baseline level exists as for smoking where this is the case for non-smokers. For nutritional variables like "fat consumption," it is more difficult to define an appropriate baseline. Among the common methods are the construction of tertiles, quartiles, etc., or to use the same cut-points as in previous studies in order to allow a comparison of the results.

The availability of appropriate software is an important practical aspect since typically it is not possible to develop new software tools or even new statistical methods when data are routinely analyzed within the framework of an epidemiological study.

Both GAM's and spline regression have drawbacks; however, user-friendly software is available, and as an exploratory tool, these may be useful. As Royston et al. (2000) pointed out, "there are artefacts in the curve shapes, and possible overinterpretation of the data that may accompany them." Royston et al. (1999) stated, "we do not think that [GAM's and spline regression] are suitable as definitive models in epidemiology for the following reasons. The mathematical expressions for the curves are often very complex, so reporting of results must be by graphs or by extensive tabulation. The situation is unsatisfactory when similar studies are to be compared, and impossible if meta-analysis is intended. Data dependence of the final model is more marked than for parametric models and the curves may be more difficult to interpret." We also think that the suggested parametric models such as the fractional polynomial method with or without spike, depending on the situation, provide sufficient flexibility on the one hand and allow inclusion of a priori assumptions on the shape of the dose-response curve (monotonous, U-shaped) on the other hand.

If a complex epidemiological study is analyzed independently by different statisticians, the results will typically not be identical. This is particularly true when continuous covariates are among the variables to be considered (not to mention other issues that make the analysis of epidemiological studies non-standard, such as the treatment of missing values, variable selection procedures, model building, and others). Readers can be reassured, however, that if an analysis is performed with sufficient care, the results and their interpretation will not differ very much.

30.1 Introduction

Basic tabular and graphical methods are an essential component of epidemiological analysis and are often sufficient, especially when one need consider only a few variables at a time. They are, however, limited in the number of variables that they can examine simultaneously and in detail they can consider continuous variables. Even sparse-strata methods (such as Mantel-Haenszel) require that some strata have two or more subjects; yet, as more and more variables or categories are added to a stratification, the number of subjects in each stratum may eventually drop to 0 or 1.

Regression analysis encompasses a vast array of techniques designed to overcome the numerical limitations of simpler methods. This advantage is purchased at a cost of stronger assumptions, which are compactly represented by a *regression model.* Such models (and hence the assumptions they represent) have the advantage of being explicit; a disadvantage is that the models may not be well understood by the intended audience or even the user. Regression models can and should be tailored by the analyst to suit the topic at hand; the latter process is sometimes called *model specification.* This process is part of the broader task of *regression modeling*.

To ensure that the assumptions underlying the regression analysis are reasonable approximations, it is essential that the modeling process be actively guided by the scientists involved in the research, rather than be left solely to mechanical algorithms. Such active guidance requires familiarity with the variety and interpretation of models. Hence, this chapter will focus primarily on forms of models and their interpretation, rather than on the more technical issues of model fitting and testing. Because this chapter provides only outlines of key topics, it should be supplemented by readings in more detailed treatments of regression analysis, as can be found in texts such as McCullagh and Nelder (1989), Hosmer and Lemeshow (2000), and Jewell (2004). For a classic in-depth treatment of the difficulties and limitations of regression analysis in non-experimental studies, see Leamer (1978) or Berk (2004).

Achieving competence in regression analysis requires comfort with basic geometry and algebra. While the ensuing discussion attempts to be self-contained, readers who feel lacking or weak in mathematical skills would do well to review a textbook in high school mathematics or college algebra (focusing especially on functions, graphs, and natural logarithms) before studying regression methods.

30.2 Regression Functions

There are two primary interpretations of regression, frequentist and Bayesian, which correspond to two different interpretations of probability (see Greenland 2006 for a basic comparison of interpretations). This chapter uses the frequentist interpretation, but briefly discusses the Bayesian interpretation at the end of this section. In both interpretations, the term *regression* is often used as a shorthand for *regression function*.

30.2.1 Frequentist Regression

In the frequentist view, the *regression* of a variable Y on another variable X is the function that describes how the average (mean) value of Y changes across population subgroups defined by levels of X (sometimes the median or some other quantile is used in place of the mean). This function is distinct from a *model* for that function. A regression *model* is another, simpler function used to approximate or estimate the true regression function. This distinction is often obscured and even unrecognized in elementary treatments of regression, which in turn has generated much misunderstanding of regression modeling. Therefore, this chapter will begin by focusing on regression functions and then will turn to regression models.

The regression function is often written as $E(Y|X = x)$, which should be read as "the average of Y when the variable X takes on the specific value x." The "E" part of the notation stands for "expectation," which here is just another word for "population mean." As an example, suppose Y stands for "height" to the nearest centimeter at some time t, X stands for "weight" to the nearest kilogram at time t, and the population of interest is that of Denmark at time t. If we subclassify the Danish population at t into categories of weight X, compute the average height in each category and tabulate or graph these average heights against the weight categories, the result displays the regression, $E(Y|X = x)$, of height Y on weight X in Denmark at time t. Several important points should be emphasized:

1. The *concept* of regression involves no modeling. Some would describe this fact by saying that the concept of regression is essentially "non-parametric." The regression of Y on X is just a graphical property of the physical world, like the orbital path of the earth around the sun.
2. There is nothing mathematically sophisticated about the regression function. Each point on a regression curve could be computed by taking the average of Y within a subpopulation defined as having a particular value of X. In the example, the value of the regression function at $X = 50$ kg, $E(Y|X = 50)$, is just average height at time t among Danes who weigh 50 kg at time t.
3. A regression function cannot be unambiguously computed until we carefully define X, Y, *and* the population over which the averages are to be taken. We will call the latter population the *target population* of the regression. This population is all too often left out of regression definitions, often resulting in confusion.

   Some ambiguity is unavoidable in practice. In our example, is time t measured to the nearest year, day, minute, or millisecond? Is the Danish population all citizens, all residents, or all persons present in Denmark at t? We may decide that leaving these questions unanswered is tolerable because varying the definitions over a modest range would not change the result to an important extent. But if we left time completely out of the definition, the regression would become hopelessly ambiguous, for now we would not have a good idea of who to include or exclude from our average: Should we include people living in Denmark in prehistoric times or in the time of King Canute (a 1,000 years ago) or in the distant future (a 1,000 years from now)? The choice could have a strong effect on our answer because of the large changes in height-to-weight relations that have occurred over time.

When considering a regression function $E(Y|X = x)$, the variable Y is termed the dependent variable, outcome variable, or *regressand,* and the variable X is termed the independent variable, predictor, covariate, or *regressor.* The "dependent/independent" terminology is common but also problematic because it invites confusion of distinct probabilistic and causal concepts of dependence and independence. For example, if Y is age and X is blood pressure, $E(Y|X = x)$ represents the average age of persons given blood pressure, X. But it is blood pressure X that causally depends on age Y, not the other way around. This brings us to another important point.

4. For any pair of variables X and Y, we can consider either the regression of Y on X, $E(Y|X = x)$, or the regression of X on Y, $E(X|Y = y)$. Thus, the concept of regression does not necessarily imply any causal or even temporal relation between the regressor and the regressand.

For example, Y could be blood pressure at the start of follow-up of a cohort, and X could be blood pressure after 1 year of follow-up; then $E(Y|X = x)$ would represent the average *initial* blood pressure among cohort members whose blood pressure after 1 year of follow-up is x. This is an example of a non-causal regression. Causal regression will be discussed below.

30.2.2 Other Concepts of Population

It is important to distinguish between a "target population" and a "source population." The target population of regression is defined without regard to our observations; for example, the regression of diastolic blood pressure on cigarette usage in China is defined whether or not we conduct a study in China (the target for this regression). A source population is a source of subjects for a particular study and is defined by the selection methods of the study; for example, a random-sample survey of all residents of Beijing would have Beijing as its source population. The concepts of target and source populations connect only insofar as inferences about a regression function drawn from a study are most easily justified when the source population of the study is identical to the target population of the regression. Otherwise, issues of generalization from the source to the target have to be addressed (see Rothman et al. 2008, Chap. 9).

In some literature, regression functions (and many other concepts) are defined in terms of averages within a "superpopulation" or "hypothetical universe." A superpopulation is an abstraction of a target population, sometimes said to represent the distribution (with respect to all variables of interest) of all possible persons that ever were or ever could be targets of inference for the analysis at hand. Because the superpopulation approach focuses on purely hypothetical distributions, it has encouraged substitution of mathematical theory for the more prosaic task of connecting study results to populations of immediate public-health concern. Thus, this chapter defines regression functions in terms of averages within real (target) populations.

30.2.3 Binary Regression

The concept of regression applies to variables measured on any scale: The regressand and the regressor may be continuous or discrete or even binary. For example, Y could be an indicator of diabetes ($Y = 1$ for present, $Y = 0$ for absent), and X could be an indicator for sex ($X = 1$ for female, $X = 0$ for male). Then $E(Y|X = 1)$ would represent the average of the diabetes indicator Y among females, and $E(Y|X = 0)$ would represent the average of Y among males.

When the regressand Y is a binary indicator (0, 1) variable, $E(Y|X = x)$ is called a *binary regression,* and this regression simplifies in a very useful manner. Specifically, when Y can be only 0 or 1, the average $E(Y|X = x)$ equals the proportion of population members who have $Y = 1$ among those who have $X = x$. For example, if Y is the diabetes indicator, $E(Y|X = x)$ is the proportion with diabetes (i.e., with $Y = 1$) among those with $X = x$. To see this, let N_{yx} denote the number of population members who have $Y = y$ and $X = x$. Then the number of population members with $X = x$ is $N_{1\mathrm{x}} + N_{0\mathrm{x}} = N_{+\mathrm{x}}$, and the average of Y among these members, $E(Y|X = x)$, is

$$\frac{N_{1x} \cdot 1 + N_{0x} \cdot 0}{N_{1x} + N_{0x}} = \frac{N_{1x}}{N_{+x}},$$

which is just the proportion with $Y = 1$ among those with $X = x$.

The epidemiological ramifications of the preceding relation are important. Let $\Pr(Y = y|X = x)$ stand for "the proportion (of population members) with $Y = y$ among those with $X = x$" (which is often interpreted as the probability of $Y = y$ in the subpopulation with $X = x$). If Y is a binary indicator, we have just seen that

$$E(Y|X = x) = \Pr(Y = l|X = x),$$

that is, the average of Y when $X = x$ equals the proportion with $Y = 1$ when $X = x$. Thus, if Y is an indicator of *disease presence* at a given time, the regression of Y on X, $E(Y|X = x)$, provides the proportion *with* the disease at that time, or prevalence proportion, given $X = x$. For example, if $Y = 1$ indicates diabetes presence on January 1, 2010, and X is weight on that day, $E(Y|X = x)$ provides diabetes prevalence as a function of weight on that day. If Y is instead an indicator of *disease incidence* over a time interval (cf. Rothman et al. 2008, Chap. 3, and chapter ►Rates, Risks, Measures of Association and Impact of this handbook), the regression of Y on X provides the proportion getting disease over that interval, or incidence proportion, given $X = x$. For example, if $Y = 1$ indicates stroke occurrence in 2010 and X is weight at the start of the year, $E(Y|X = x)$ provides the stroke incidence (proportion) in 2010 as a function of initial weight.

30.2.4 Multiple Regression

The concept of multiple regression is a simple extension of the ideas discussed above to situations in which there are multiple (two or more) regressors. To illustrate, suppose Y is a diabetes indicator, X_1 stands for "sex" (coded 1 for females, 0 for males), and X_2 stands for "weight" (in kilograms). Then the regression of Y on X_1 and X_2, written $E(Y|X_1 = x_1, X_2 = x_2)$, provides the average of Y among population members of a given sex X_1 and weight X_2. For example, $E(Y|X_1 = 1, X_2 = 70)$ is the average diabetes indicator (and, hence, the diabetes prevalence) among women who weigh 70 kg.

We can use as many regressors as we want. For example, we could include age (in years) in the last regression. Let X_3 stand for "age." Then $E(Y|X_1 = x_1, X_2 = x_2, X_3 = x_3)$ would provide the diabetes prevalence among population members of a given sex, weight, and age. Continuing to include regressors produces a very clumsy notation, however, and so we adopt a simple convention: We will let $\boldsymbol{X}$ represent the ordered list of all the regressors we want to consider. Thus, in our diabetes example, $\boldsymbol{X}$ will stand for the horizontal list (X_1, X_2, X_3) of "sex," "weight," and "age." Similarly, we will let $\boldsymbol{x}$ stand for the horizontal ordered list of values (x_1, x_2, x_3) for $\boldsymbol{X} = (X_1, X_2, X_3)$. Thus, if we write $E(Y|\boldsymbol{X} = \boldsymbol{x})$, it is merely a shorthand for

$$E(Y|X_1 = x_1, X_2 = x_2, X_3 = x_3)$$

when there are three regressors under consideration.

More generally, if there are n regressors $X_1, \ldots, X_n$, we will write $\boldsymbol{X}$ for the ordered list $(X_1, \ldots, X_n)$ and $\boldsymbol{x}$ for the ordered list of values $(x_1, \ldots, x_n)$. The horizontal ordered list of variables X is called a *row vector* of regressors, and the horizontal ordered list of values $\boldsymbol{x}$ is called a *row vector* of values. Above, the vector $\boldsymbol{X}$ is composed of the $n = 3$ items "sex," "weight," and "age," and the list $\boldsymbol{x}$ is composed of specific values for sex (0 or 1), weight (kilograms), and age (years). The number of items n in $\boldsymbol{X}$ is called the length or dimension of $\boldsymbol{X}$.

The term *multivariate* (or multiresponse) *regression* is usually reserved for regressions in which there are multiple *regressands* (Izenman 2008). To illustrate, suppose Y_1 is an indicator of diabetes presence, Y_2 is diastolic blood pressure, and $\boldsymbol{Y}$ is the list (Y_1, Y_2) composed of these two variables. Also, let $\boldsymbol{X}$ be the list (X_1, X_2, X_3) composed of the sex indicator, weight, and age, as before. The multivariate regression of diabetes and blood pressure on sex, weight, and age provides the average diabetes indicator *and* average blood pressure for each combination of sex, weight, and age:

$$E(Y_1, Y_2|X_1 = x_1, X_2 = x_2, X_3 = x_3) = E(\boldsymbol{Y}|\boldsymbol{X} = \boldsymbol{x}).$$

In general, there may be any number of regressands in the list $\boldsymbol{Y}$ and regressors in the list $\boldsymbol{X}$ of a multivariate regression. Multivariate regression notation allows one to express the separate regressions for each regressand in one equation.

30.2.5 Regression and Causation

Because regression functions do not involve any assumptions of time order or causal relations, regression coefficients and quantities derived from them represent measures of association, not measures of effect. To interpret the coefficients as measures of causal effects, it is important that the regression function being modeled provides a representation of the effects of interest that is approximately unconfounded (for a general discussion of the concept of confounding, see Rothman et al. 2008, Chap. 4 and chapter ▶Confounding and Interaction of this handbook).

To make this no-confounding assumption more precise, suppose $\boldsymbol{X}$ contains the exposures of interest and $\boldsymbol{Z}$ contains the other regressors. Suppose we write "Set($\boldsymbol{X}=\boldsymbol{x}$)" for the act of setting (forcing) the value of $\boldsymbol{X}$ to $\boldsymbol{x}$, assuming that can be done; another notation for the same concept is "Do($\boldsymbol{X}=\boldsymbol{x}$)" (Pearl 2009). We may then write

$$E[Y|\text{Set}(\boldsymbol{X}=\boldsymbol{x}),\ \boldsymbol{Z}=z]$$

for the average value Y would have *if* everyone in the target population with $\boldsymbol{Z}=z$ had their $\boldsymbol{X}$ value set to $\boldsymbol{x}$. In other words, it is what the mean of Y would have been among those with $\boldsymbol{Z}=z$ if everyone in the population had received $\boldsymbol{X}=\boldsymbol{x}$ (which is what "Set" means).

There are many variables (such as sex and age) for which the use of "Set" will make little sense or be too vague to be useful (Greenland 2005a; Hernán 2005); such variables should thus appear only in the stratification variables ($\boldsymbol{Z}$ in the above expression). But even for potential intervention variables for which "Set" can makes sense (such as smoking behavior or air-pollutant levels), an average like $E[Y|\text{Set}(\boldsymbol{X}=\boldsymbol{x}),\ \boldsymbol{Z}=z]$ cannot be estimated from observational data without making strong assumptions because it may represent a *counterfactual* state, that is, a condition that did not in fact occur. In particular, it can be very different from the observable average $E(Y|\boldsymbol{X}=\boldsymbol{x},\ \boldsymbol{Z}=z)$. The latter refers only to those population members with $\boldsymbol{X}=\boldsymbol{x}$ and $\boldsymbol{Z}=z$, whereas $E[Y|\text{Set}(\boldsymbol{X}=\boldsymbol{x}),\ \boldsymbol{Z}=z]$ refers to *all* population members with $\boldsymbol{Z}=z$, including those who actually had $\boldsymbol{X}$ equal to values other than $\boldsymbol{x}$.

As an example, suppose the target population is all persons born during 1901–1950 surviving to age 50, Y is an indicator of death by age 80, $\boldsymbol{X}$ contains only $X_1=$pack-years of cigarettes smoked by age 50, and $\boldsymbol{Z}=(Z_1,\ Z_0)$ where $Z_1=1$ if female, 0 if male and $Z_2=$year of birth. Then

$$E[Y|X_1=20,\ \boldsymbol{Z}=(1,1940)]$$

would be the average risk of dying by age 80 (mortality proportion) among women born in 1940 and surviving to age 50 who smoked 20 pack-years by age 50. In contrast,

$$E[Y|\text{Set}(X_1=20),\ \boldsymbol{Z}=(1,1940)]$$

would be the average risk of dying by age 80 among all women born in 1940 and surviving to age 50 *if* all such women had smoked 20 pack-years by age 50. If some women in this cohort smoked 10 pack-years or 30 pack-years or none by age 50, the latter average would be counterfactual and hence could be estimated only by making special assumptions that we now explore.

In regression analysis, we may define effect measures as contrasts of average outcomes (such as incidence) in the same population under different conditions. Consider the ratio effect measure contrasting the average of Y in the subpopulation with $\boldsymbol{Z} = \boldsymbol{z}$ when $\boldsymbol{X}$ is set to $\boldsymbol{x}^*$ versus that average when $\boldsymbol{X}$ is set to $\boldsymbol{x}$:

$$\frac{E[Y|\text{Set}(\boldsymbol{X} = \boldsymbol{x}^*), \boldsymbol{Z} = \boldsymbol{z}]}{E[Y|\text{Set}(\boldsymbol{X} = \boldsymbol{x}), \boldsymbol{Z} = \boldsymbol{z}]}.$$

In the example,

$$\frac{E[Y|\text{Set}(X_1 = 20),\ \boldsymbol{Z} = (1, 1940)]}{E[Y|\text{Set}(X_1 = 0),\ \boldsymbol{Z} = (1, 1940)]}$$

represents the *effect* of smoking 20 pack-years by age 50 versus no smoking on the risk of dying by age 80 among women born in 1940. On the other hand, the ratio measure

$$\frac{E[Y|X_1 = 20,\ \boldsymbol{Z} = (1, 1940)]}{E[Y|X_1 = 0,\ \boldsymbol{Z} = (1, 1940)]}$$

represents only the *association* of smoking 20 pack-years by age 50 versus no smoking with the risk among women born in 1940 because it contrasts two different subpopulations (one with $X_1 = 20$, the other with $X_1 = 0$).

To infer that all associational measures estimated from our analysis equal their corresponding effect measures, we would have to make the following assumption of no confounding given $\boldsymbol{Z}$ (which is sometimes expressed by stating that there is no residual confounding):

$$E(Y|\boldsymbol{X} = \boldsymbol{x}, \boldsymbol{Z} = \boldsymbol{z}) = E[Y|\text{Set}(\boldsymbol{X} = \boldsymbol{x}),\ \boldsymbol{Z} = \boldsymbol{z}].$$

This assumption states that the average we observe or estimate in the subpopulation with both $\boldsymbol{X} = \boldsymbol{x}$ and $\boldsymbol{Z} = \boldsymbol{z}$ is equal to what the average in the larger subpopulation with $\boldsymbol{Z} = \boldsymbol{z}$ would have been if everyone had $\boldsymbol{X}$ set to $\boldsymbol{x}$. It is important to appreciate the strength of the assumption. In the above example, the no-confounding assumption would entail

$$E[Y|X_1 = 20,\ \boldsymbol{Z} = (1, 1940)] = E[Y|\text{Set}(X_1 = 20),\ \boldsymbol{Z} = (1, 1940)].$$

This equation states that, in the cohort of women born in 1940 and surviving to age 50, the risk we observe among those who smoked 20 pack-years by age 50 equals the risk we would have observed if *all* women in the cohort had smoked 20 pack-years by age 50. The social variables associated with both smoking and death should lead us to doubt that the two quantities are even approximately equal.

If only a single summary measure of effect is desired, the covariate-specific no-confounding assumption can be replaced by a less restrictive assumption tailored to that measure. To illustrate, suppose in the above example, we are only interested in what the effect of smoking 20 versus 0 pack-years would be on *everyone* in the target, regardless of sex or birth year, as measured by the causal risk ratio

$$E[Y|\text{Set}(X_1 = 20)]/E[Y|\text{Set}(X_1 = 0)].$$

The corresponding measure of association is the risk ratio for 20 versus 0 pack-years, standardized to the total population:

$$\frac{\sum_z E(Y|X_1 = 20,\ \mathbf{Z} = z)\,\Pr(\mathbf{Z} = z)}{\sum_z E(Y|X_1 = 0,\ \mathbf{Z} = z)\,\Pr(\mathbf{Z} = z)},$$

where $\Pr(\mathbf{Z} = z)$ is the proportion with $\mathbf{Z} = z$ in the target. The no-confounding assumption we need here is that the standardized ratio equals the causal ratio. This summary assumption could hold even if there was confounding within levels of sex and birth year (although it would still be implausible in this example).

The dubiousness of no-confounding assumptions is often the chief limitation in using epidemiological data for causal inference. This limitation applies to both tabular and regression methods. Randomization of persons to levels of $\mathbf{X}$ can largely overcome this limitation because it ensures that effect estimates follow a quantifiable probability distribution centered around the true effect. Randomization is not an option in most settings, however.

The default strategy is to ensure there are enough well-measured confounders in $\mathbf{Z}$ so that the no-confounding assumption is at least plausible. This strategy often leads to few subjects at each level $\mathbf{x}$ of $\mathbf{X}$ and $\mathbf{z}$ of $\mathbf{Z}$, which in turn lead to the sparse-data problems that regression modeling attempts to address (Robins and Greenland 1986; Greenland 2000a, b; Greenland et al. 2000). A major limitation of this strategy is that, often, key confounders are poorly measured or unmeasured and so cannot be used in ordinary modeling; prior distributions for the missing confounders must be used instead (Greenland 2003, 2005b, 2009b; Greenland and Lash 2008; see also the chapter on Sensitivity Analysis and Bias Analysis in this handbook).

30.2.6 Frequentist Versus Bayesian Regression

In frequentist theory, an expectation is interpreted as an average in a specific subgroup of a specific population. The regression $E(Y|\mathbf{X} = \mathbf{x})$ thus represents an objective functional relation among theoretically measurable variables (the average of Y as a function of the variables listed in $\mathbf{X}$). It may be that this relation has not been observed, perhaps because it exists but we are unable to measure it or because it does not yet exist. Examples of the former and latter are the regressions of blood pressure on weight in Spain 10 years ago and 10 years from now. In either situation, the regression is an external relation that one tries to estimate, perhaps by projecting (extrapolating) from current knowledge about presumably similar relations. For example, one might use whatever survey data one can find on blood pressure and weight to estimate what the regression of blood pressure on weight would look like in Spain 10 years ago or 10 years from now. In this approach, one tries to produce an *estimate* $\hat{E}(Y|\boldsymbol{X} = \boldsymbol{x})$ of the true regression $E(Y|\boldsymbol{X} = \boldsymbol{x})$.

In subjective Bayesian theory (cf. Greenland 2006 and chapter ▶Bayesian Methods in Epidemiology of this handbook), an expectation is what we would or should expect to see in a given target population. This notion of expectation corresponds roughly to a prediction of what we would see if we could observe the target in question. The regression $E(Y|\boldsymbol{X}=\boldsymbol{x})$ does not represent an objective relation to be estimated but instead represents a subjective (personal) expectation about how the average of Y varies across levels of $\boldsymbol{X}$ in the target population. Like the frequentist regression estimate, however, it is something one constructs from whatever data one may find that seems informative about this variation.

When analogous models and fitting criteria are adopted in both approaches, frequentist and Bayesian methods typically yield similar interval estimates. Divergences are usually due to differences in underlying models and differences in criteria for a “good” estimate; for example, frequentists traditionally prefer unbiasedness (having an average error of zero), whereas Bayesians more often prefer closeness (e.g., having the smallest average squared error possible).

Nonetheless, even when their numeric results are the same, Bayesians and frequentists interpret these results differently. The Bayesian presents a prediction, denoted by $E(Y|\boldsymbol{X}=\boldsymbol{x})$, which he or she interprets as his or her “best bet” about the average of Y when $\boldsymbol{X}=\boldsymbol{x}$, according to some criteria for “best bet.” The frequentist presents a prediction, denoted by $\hat{E}(Y|\boldsymbol{X}=\boldsymbol{x})$ (or, more commonly, $\hat{Y}_{X=x}$), which he or she interprets as “the” best estimate of the average of Y when $\boldsymbol{X}=\boldsymbol{x}$, according to some criteria for “best estimate” (such as minimum variance among statistically unbiased estimators). Too often, the latter criteria are presumed to be universally shared, but are not really shared or even properly understood by epidemiologists; one could and would reach different conclusions using other defensible criteria (such as minimum mean squared error). For these reasons, when conducting regression analyses, it can be valuable to consider both frequentist and Bayesian interpretations of methods and results.

30.3 Basic Regression Models

In any given instance, the true regression of Y on $\boldsymbol{X}$, $E(Y|\boldsymbol{X}=\boldsymbol{x})$, is an extremely complicated function of the regressors $\boldsymbol{X}$. Thus, even if we observe this function without error, we may wish to formulate simplified pictures of reality that yield *models* for this regression. These models, while inevitably incorrect, can be very useful. A classic example is the representation of the distance from the earth to the sun, Y, as a function of day of the year T. To the nearest kilometer, this distance is a complex function of T because of the gravitational effects of the moon and of the other planets in the solar system. If we represent the orbit of the earth around the sun as a circle with the sun at the center, our regression model will predict the distance $E(Y\,|\,T=t)$ by a single number (about 150 million kilometers) that does not change with t. This model is adequate if we need only predict the distances to 2% accuracy. If we represent the orbit of the earth as an ellipse, our regression model will predict the earth-sun distance as smoothly and cyclically varying over the course of a year (within a range of about 147–153 million kilometers). Although it is not perfectly accurate, this model is adequate if we need to predict the distances to within 0.2% accuracy.

30.3.1 Model Specification and Model Fitting

Our description of the above models must be refined by distinguishing between the *form* of a model and a *fitted* model. "Circle" and "ellipse" refer to forms, that is, general classes of shapes. The circular model form corresponds to assuming a constant earth-sun distance over time; the elliptical model form allows this distance to vary over a temporal cycle. The process of deciding between these two forms is a simple example of *model specification.*

If we decide to use the circular form, we must also select a value for the radius (which is the earth-sun distance in the model). This radius specifies which circle (out of the many possible circles) to use as a representation of the earth's orbit and is an example of a model *parameter.* The process of selecting the "best" radius is an example of *model fitting,* and the circle that results is sometimes called the *fitted model* (although the latter term is sometimes used to refer to the model form instead). There are two important relations between a set of data and a model fit to those data. First, there is "distance" from the fitted model to the data; second, there is "resistance" or "stability" of the fitted model, which is the degree to which the parameter estimates change when the data themselves are changed.

Depending on our accuracy requirements, we may have on hand several simplified pictures of reality and hence several candidate models. At best, our choice might require a trade-off between simplicity and accuracy, as in the preceding example. There is an old dictum (often referred to as "Occam's razor") that one should not introduce needless complexity. According to this dictum, if we need only 2% accuracy in predicting the earth's distance from the sun, then we should not bother with the ellipse model and instead use the constant distance derived from the circle model.

There is a more subtle benefit from this advice than avoiding needless mental exertion. Suppose we are given two models, one (the more complex) containing the other (the more simple) as a special case, and some data with which to fit the two models. Then the more complex model will be able to fit the available data more closely than the simpler model, in the sense that the predictions from the more complex model will (on average) be closer to what was seen in the data than will the predictions from the simpler model. This is so in the above example because the ellipse contains the circle as a special case. Nonetheless, there is a penalty for this closeness to the data: The predictions obtained from the more complex model tend to be less stable than those obtained from the simpler model.

Consider now the use of the two different model forms to predict events outside of the data set to which the models were fit. An example would be forecasting the earth's distance from the sun; another would be predicting the incidence of AIDS 5 years in the future. Intuitively, we might expect that if one model is both closer to the data and more stable than the other, that model will give more accurate predictions. The problem is that the choice among models is rarely so clear-cut: Usually, one model will be closer to the data, while the other will be more stable, and it will be difficult to tell which will be more accurate. This is one dilemma we often face in a choice between a more complex and simpler model.

To summarize, model specification is the process of selecting a model form, while model fitting is the process of using data to estimate the parameters in a model form. There are many methods of model fitting, and the topic is so vast and technical that we will only superficially outline a few key elements. Nearly all commercial computer programs are based on one of just a few fitting methods so that nearly all users (statisticians as well as epidemiologists) are forced to base their analyses on the assumptions of these methods. We will briefly discuss specification and fitting methods below.

30.3.2 Background Example

The following epidemiological example will be used at various points to illustrate specific models. There has been controversy over whether women with no history of breast cancer but thought to be of high risk (due to family history and perhaps other factors) should be given the drug tamoxifen as a prophylactic regimen. At one point, it was suggested that tamoxifen might prevent breast cancer but also increase risk of certain other cancers.

One measure of the net impact of tamoxifen prophylaxis up to a given age is the change in risk of death by that age. Suppose the regressand Y is an indicator of death by age 70 ($Y = 1$ for dead, 0 for alive). The regressors $\boldsymbol{X}$ include:

$$\begin{aligned}
X_1 &= \text{years of tamoxifen therapy,}\\
X_2 &= \text{age (in years) at start of tamoxifen therapy,}\\
X_3 &= \text{age at menarche,}\\
X_4 &= \text{age at menopause,}\\
X_5 &= \text{parity.}
\end{aligned}$$

The target population is American women born during 1945–1950 who survive to age 50 and do not use tamoxifen before that age. If tamoxifen is not taken during follow-up, we set age at tamoxifen start (X_2) to 70 because women who start at 70 or later and women who never take tamoxifen have the same exposure history during the age interval under study.

In this example, the regression $E(Y|\boldsymbol{X}=\boldsymbol{x})$ is just the average risk, or incidence proportion, of death by age 70 among women in the target population who have $\boldsymbol{X}=\boldsymbol{x}$. Therefore, we will write $R(x)$ as a shorthand for $E(Y|\boldsymbol{X}=\boldsymbol{x})$. We will also write R for the crude (overall) average risk $E(Y)$, $R(x_1)$ for the average risk $E(Y|X_1=x_1)$ in the subpopulation defined by having $X_1=x_1$ (without regard to the other variables), and so on.

30.3.3 Vacuous Models

A model so general that implies nothing at all, but simply reexpresses the overall average risk R in a different notation, is

$$E(Y) = R = \alpha,\ 0 < \alpha < 1. \tag{30.1}$$

(This model does exclude $R=0$ or 1, but it allows R to be arbitrarily close to 0 or 1, so this exclusion is of no practical consequence.) There is only one regression parameter (or coefficient) α in this model, and it corresponds to the average risk in the target population. A model such as model 1 that has no implication (i.e., that imposes no restriction or constraint) is said to be *vacuous.*

Two models are said to be equivalent if they have identical implications for the regression. A model equivalent to model 1 is

$$E(Y) = R = \exp(\alpha),\ \alpha < 0. \tag{30.2}$$

This model has no implication. In this model, α is the natural logarithm of the overall average risk:

$$\alpha = \ln(R).$$

Another model equivalent to models 1 and 2 is

$$E(Y) = R = \text{expit}(\alpha), \tag{30.3}$$

where expit(α) is the *logistic* transform of α, defined as

$$\text{expit}(\alpha) = \frac{\exp(\alpha)}{1 + \exp(\alpha)}.$$

Again, model 3 has no implication. Now, however, the parameter α in model 3 is the logit (log odds) of the overall average risk:

$$\alpha = \ln\left(\frac{R}{1-R}\right) = \text{logit}(R).$$

For an introduction to risk measures in general see Rothman et al. (2008), Chap. 3 and chapter ►Rates, Risks, Measures of Association and Impact of this handbook.

30.3.4 Constant Models

In comparing the complexity and implications of two models A and B, we say that model A is more general, more flexible, or more complex than model B or that A contains B, if all the implications of model A are also implications of model B, but not vice versa (i.e., if B imposes some restrictions beyond those imposed by A). Other ways of stating this relation are that B is simpler, stronger, or stricter than A, B is contained or nested within A, or B is a special case of A. The following model is superficially similar to model 1, but is in fact much more strict:

$$E(Y|X_1 = x_1) = R(x_1) = \alpha \tag{30.4}$$

for all x_1. This model implies that the average risks of the subpopulations defined by years of tamoxifen use are identical. The parameter α represents the common value of these risks. This model is called a *constant* regression because it allows no variation in average risks across levels of the regressor. To see that it is a special case of model 1, note that $E(Y)$, the overall average, is just an average of all the X_1-specific averages $E(Y|X_1 = x_1)$. Hence, if all the X_1-specific averages equal α, as in model 4, then the overall average must equal α as well, as in model 1.

The following two models are equivalent to model 4:

$$R(x_1) = \exp(\alpha), \tag{30.5}$$

which can be rewritten

$$\ln[R(x_1)] = \alpha,$$

and

$$R(x_1) = \text{expit}(\alpha) = e^{\alpha}/(l + e^{\alpha}), \tag{30.6}$$

which can be rewritten

$$\text{logit}[R(x_1)] = \alpha.$$

In model 5, α is the common value of the log risks $\ln[R(x_1)]$, while in model 6, α is the common value of the logits, $\text{logit}[R(x_1)]$. Each of the equivalent models (models 4–6) is a special case of the more general models (models 1–3).

A constant regression is of course implausible in most situations. For example, age is related to most health outcomes. In the above example, we should expect the average death risk to vary across the subgroups defined by age at start (X_2). There is an infinitude of ways to model these variations. The problem of selecting a useful model from among the many choices is discussed below. For now, we only describe some of the more common choices, focusing on models for average risks (incidence proportions), incidence odds, and person-time incidence rates. The models for risks and odds can also be used to model prevalence proportions and prevalence odds.

30.3.5 Linear Risk Models

Consider the model

$$R(x_1) = \alpha + \beta_1 x_1. \tag{30.7}$$

This model allows the average risk to vary across subpopulations with different values for X_1, but only in a linear fashion. The model implies that subtracting the average risk in the subpopulation with $X_1 = x_1$ from that in the subpopulation with $X_1 = x_1 + 1$ will always yield β_1, *regardless* of what x_1 is. Under model 7,

$$R(x_1 + 1) = \alpha + \beta_1(x_1 + 1),$$

and

$$R(x_1) = \alpha + \beta_1 x_1,$$

so

$$R(x_1 + 1) - R(x_1) = \beta_1.$$

Thus, in our example, β_1 represents the difference in risk between the subpopulation defined by having $X_1 = x_1 + 1$ and that defined by having $X_1 = x_1$. The model implies that this difference does not depend on the reference level x_1 for X_1, used for the comparison.

Model 7 is an example of a *linear* risk model. It is a special case of model 1; it also contains model 4 as a special case (model 4 is the special case of model 7 in which $\beta_1 = 0$, and so average risks do not vary across levels of X_1). Linear risk models (such as model 7) are easy to understand, but have a severe technical problem that makes them difficult to fit in practice: There are combinations of α and $\beta_1$that would produce impossible values (less than 0 or greater than 1) for one or more of the risks $R(x_1)$. Several models partially or wholly address this problem by transforming the linear term $\alpha + \beta_1 x_1$ before equating it to the risk. We will study two of these models below.

30.3.6 Recentering

Under model 7,

$$R(0) = \alpha + \beta \cdot 0 = \alpha,$$

so α represents the average risk for the subpopulation with $X_1 = 0$. In the present example, 0 is a possible value for X_1 (tamoxifen), and so this interpretation of α presents no problem. Suppose, however, we modeled X_3 (age at menarche) instead of X_1:

$$R(x_3) = \alpha + \beta_3 x_3.$$

Because age at menarche cannot equal zero, α would have no meaningful interpretation in this model. In order to avoid such interpretational problems, it is a useful practice to recenter a variable for which zero is impossible (such as X_3) by subtracting some frequently observed value from it before putting it in the model. For example, age 13 is a frequently observed value for age at menarche. We can redefine X_3 to be "age at menarche minus 13 years." With this redefinition, $R(x_3) = \alpha + \beta_3 x_3$ refers to a different model, one in which $R(0) = \alpha$ represents the average risk for women who were age 13 at menarche. We will later see that such recentering is advisable when using any model and is especially important when product terms ("interactions") are used in a model.

30.3.7 Rescaling

A simple way of describing β_1 in model 7 is that it is the difference in risk per unit increase in X_1. Often the units used to measure X_1 are small relative to exposure increases of substantive interest. Suppose, for example, that X_1 was diastolic blood pressure (DBP) measured in mm Hg; β_1 would then be the risk difference per millimeter increase in DBP. A 1 mm Hg increase would, however, be of no clinical interest; instead, we would want to consider increases of at least 5 and possibly 10 or 20 mm Hg. Under model 7, the difference in risk per 10 mm Hg increase would be $10\beta_1$. If we wanted to have β_1 represent the difference in risk per 10 mm Hg, we need only redefine X_1 as DBP divided by 10; X_1 would then be DBP in cm Hg.

Division of a variable by a constant, as just described, is sometimes called *rescaling* of the variable. Such rescaling is advisable whenever it changes the measurement unit to a more meaningful value. Unfortunately, rescaling is often done in a way that makes the measurement unit *less* meaningful, by dividing the variable by its sample standard deviation (SD). The sample SD is an irregular unit unique to the study data and depends heavily on how subjects were selected into the analysis. For example, the SD of DBP might be 12.7 mm Hg in one study and 15.3 mm Hg in another study. Suppose each study divided DBP by its SD entering it in model 7. In the first study, β_1 would refer to the change in risk per 12.7 mm Hg increase in DBP, whereas in the second study, β_1 would refer to the change in risk per 15.3 mm Hg. The rescaling would thus have rendered the coefficients interpretable only in peculiar and different units so that they could not be compared directly to one another or to coefficients from other studies.

We will later see that rescaling is even more important when product terms are used in a model. We thus recommend that rescaling be done using simple and easily interpreted constants for the divisions. Methods that involve division by sample SDs (such as transformations of variables to Z-scores), however, should be avoided, whether comparing the same variables across different populations or comparing different variables in the same population (Greenland et al. 1986, 1991). In the latter case, use of quantiles (e.g., comparing risks at 90th and 10th percentiles) may be more defensible, as long as the actual values of the variable at those quantiles are given to allow comparison to other studies of the same variable.

30.3.8 Exponential Risk Models

Consider the following model:

$$R(x_1) = \exp(\alpha + \beta_1 x_1). \tag{30.8}$$

Since the exponential function (exp) is always positive, model 8 will produce positive $R(x_1)$ for any combination of α and β_1. Model 8 is sometimes called an *exponential* risk model. It is a special case of the vacuous model 2; it also contains the constant model 5 as the special case in which $\beta_1 = 0$.

To understand the implications of the exponential risk model, we can recast it in an equivalent form by taking the natural logarithm of both sides:

$$\ln[R(x_1)] = \ln[\exp(\alpha + \beta_1 x_1)] = \alpha + \beta_1 x_1. \tag{30.9}$$

Model 9 is often called a *log-linear* risk model. The exponential/log-linear model allows risk to vary across subpopulations defined by X_1, but only in an exponential fashion. To interpret the coefficients, we may compare the log risks under model 9 for the two subpopulations defined by $X_1 = x_1 + 1$ and $X_1 = x_1$:

$$\ln[R(x_1 + 1)] = \alpha + \beta_1(x_1 + 1)$$

and

$$\ln[R(x_1)] = \alpha + \beta_1 x_1,$$

so

$$\ln[R(x_1 + 1)] - \ln[R(x_1)] = \ln[R(x_1 + 1)/R(x_1)] = \beta_1.$$

Thus, under models 8 and 9, β_1 represents the log risk ratio comparing the subpopulation defined by having $X_1 = x_1 + 1$ and that defined by $X_1 = x_1$, regardless of the chosen reference level x_1. Also, ln $[R(0)] = \alpha + \beta \cdot 0 = \alpha$ if $X_1 = 0$; thus, α represents the log risk for the subpopulation with $X_1 = 0$ (and so is meaningful only if X_1 can be zero).

We can derive another (equivalent) interpretation of the parameters in the exponential risk model by noting that

$$R(x_1 + 1) = \exp[\alpha + \beta_1(x_1 + 1)]$$

and

$$R(x_1) = \exp(\alpha + \beta_1 x_1),$$

so

$$\begin{aligned} R(x_1+1)/R(x_1) &= \exp[\alpha+\beta_1(x_1+1)-(\alpha+\beta_1 x_1)] \\ &= \exp(\beta_1). \end{aligned}$$

Thus, under models 8 and 9, β_1 represents the *ratio* of risks between the subpopulations defined by $X_1 = x_1 + 1$ and $X_1 = x_1$, and this ratio does not depend on the reference level x_1 (because x_1 does not appear in the final expression for the risk ratio). Also, $R(0) = \exp(\alpha + \beta \cdot 0) = e^{\alpha}$, so e^{α} represents the average risk for the subpopulation with $X_1 = 0$.

As with linear risk models, exponential risk models have the technical problem that some combinations of α and β_1 will yield risk values greater than 1, which are impossible. This will not be a practical concern, however, if all the fitted risks and their confidence limits fall well below 1.

30.3.9 Logistic Models

Neither linear nor exponential risk models can be used to analyze case-control data if no external information is available to allow estimation of risks in the source population, whereas the following model can be used without such information:

$$\begin{aligned} R(x_1) &= \operatorname{expit}(\alpha+\beta_1 x_1) \\ &= \frac{\exp(\alpha+\beta_1 x_1)}{1+\exp(\alpha+\beta_1 x_1)}. \end{aligned} \tag{30.10}$$

This model is called a *logistic* risk model, after the logistic function (expit) in the core of its definition. Because the range of the logistic function is between 0 and 1, the model will only produce risks between 0 and 1, regardless of the values for α, β_1, and x_1. The logistic model is perhaps the most commonly used model in epidemiology, so we examine it in some detail. Model 10 is a special case of model 3, but unlike model 3, it is not vacuous because it constrains the X_1-specific risks to follow a particular (logistic) pattern. The constant model 6 is the special case of the logistic model in which $\beta_1 = 0$.

To understand the implications of the logistic model, it is helpful to recast it as a model for the odds. First, note that, under the logistic model (30.10),

$$\begin{aligned} 1-R(x_1) &= 1-\frac{\exp(\alpha+\beta_1 x_1)}{1+\exp(\alpha+\beta_1 x_1)} \\ &= \frac{1}{1+\exp(\alpha+\beta_1 x_1)}. \end{aligned}$$

Since $R(x_1)/[1-R(x_1)]$ is the odds, we divide each side of Eq. 30.10 by the last term and find that, under the logistic model, the odds of disease $O(x_1)$ when $X_1 = x_1$ is

$$O(x_1) = \frac{R(x_1)}{1 - R(x_1)} = \frac{\frac{\exp(\alpha + \beta_1 x_1)}{1 + \exp(\alpha + \beta_1 x_1)}}{\frac{1}{1 + \exp(\alpha + \beta_1 x_1)}}$$
$$= \exp(\alpha + \beta_1 x_1). \tag{30.11}$$

This equation shows that the logistic risk model is equivalent to an exponential *odds* model.

Taking logarithms of both sides of Eq. 30.11, we see that the logistic model is also equivalent to the log-linear odds model

$$\ln[O(x_1)] = \alpha + \beta_1 x_1. \tag{30.12}$$

Recall that the logit of risk is defined as the log odds:

$$\text{logit}[R(x_1)] = \ln[R(x_1)/(1 - R(x_1))] = \ln[O(x_1)].$$

Hence, from Eq. 30.12, the logistic model can be rewritten in one more equivalent form,

$$\text{logit}[R(x_1)] = \alpha + \beta_1 x_1. \tag{30.13}$$

This equivalent of the logistic model is often called the logit-linear risk model or *logit model.*

As a general caution regarding terms, note that "log-linear model" can refer to any of several different models, depending on the context: In addition to the log-linear risk model (30.9) and the log-linear *odds* model (30.12) given above, there are also log-linear *rate* models and log-linear *incidence-time* models, which will be described below.

We can derive two equivalent interpretations of the logistic model parameters. First,

$$\ln[O(x_1 + 1)] = \alpha + \beta(x_1 + 1),$$
$$\ln[O(x_1)] = \alpha + \beta_1 x_1,$$

so

$$\ln[O(x_1 + 1)] - \ln[O(x_1)] = \ln[O(x_1 + l)/O(x_1)] = \beta_1.$$

Thus, under the logistic model (30.10), β_1 represents the log odds ratio comparing the subpopulations with $X_1 = x_1 + 1$ and $X_1 = x_1$. Also, $\ln[O(0)] = \alpha + \beta_1 \cdot 0 = \alpha$; thus, α is the log odds (logit) for the subpopulation with $X_1 = 0$ (and so is meaningful only if X_1 can be zero). Equivalently, we have

$$O(x_1 + l)/O(x_1) = \exp(\beta_1),$$

and

$$O(0) = \exp(\alpha)$$

so that $\exp(\beta_1)$ is the odds ratio comparing the subpopulations with $X_1 = x_1 + 1$ and $X_1 = x_1$, and $\exp(\alpha)$ is the odds for the subpopulation with $X_1 = 0$.

Logistic models may be applied to case-control studies by reinterpreting the odds $O(x)$ as the case-control ratio in the study (Breslow and Day 1980, Chap. 6; Jewell 2004, Sect. 13.3; Greenland 2008a). For an introduction to case-control studies see Rothman et al. (2008), Chap. 8 and chapter ▸Case-Control Studies of this handbook.

30.3.10 Stratified Models and Conditional Logistic Regression

It is often the case that one wishes to use a model which is "stratified" in the sense that the intercept is allowed to vary over a series of strata. As an example, suppose we had defined 8 strata indexed by $k = 1, 2, \ldots, 8$ that represented various combinations of age and sex. A *stratified* logistic model for the dependence of risk on X_1 would then be

$$R_k(x_1) = \operatorname{expit}(\alpha_k + \beta_1 x_1).$$

Note how this differs from Eq. 30.10: Risk may now depend on the stratum k as well as on the level of X_1.

Stratified models are most commonly applied when the data have been collected with matching on the stratification variables so that each stratum k represents a particular matched set. In these applications, there may be many matched sets and thus too many intercepts to estimate using ordinary estimation techniques. A common solution is to fit a stratified logistic model using a special technique, *conditional logistic regression*, which does not estimate the intercepts but instead estimates only the regressor coefficients (β_1 above). See McCullagh and Nelder (1989), Hosmer and Lemeshow (2000), or Harrell (2001) for further details.

30.3.11 Graphical Comparison of Different Models

Suppose a particular cohort has a 1-year risk of a cardiovascular event that is 0.02 at age 50 rising to 0.32 at age 80, an absolute risk increase of 0.30, a ratio risk increase of 0.32/0.02 = 16-fold, and a ratio odds increase of $(0.32/0.68)/(0.02/0.98) = 23.06$. The average annual absolute risk increase is 0.30/30 = 0.01, but the way this increase is distributed over ages could be quite different under different models.

If the risk increase is linear in age and x is age, the linear model for the risk from age 51 to 80 would be $R(x) = \alpha_1 + \beta_1(x - 50)$. Solving $R(50) = 0.02$ and $R(80) = 0.32$, we get $\alpha_1 = 0.02$ and $\beta_1 = 0.30/30$ year $= 0.01$/year, a constant absolute increase in risk of 0.01 for each of age.

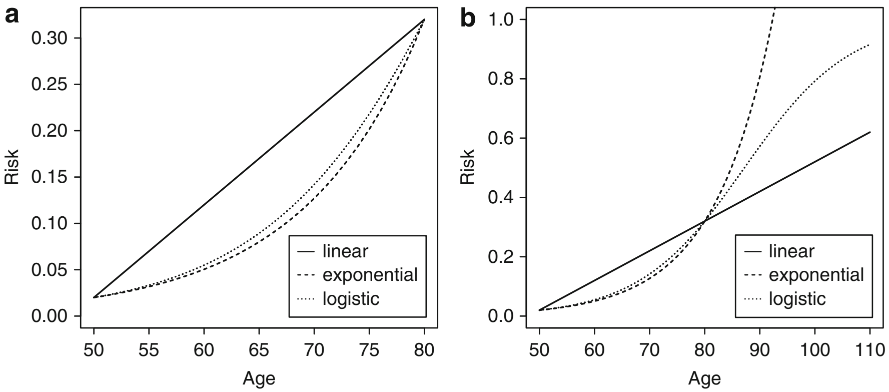

Fig. 30.1 (**a**) Risks from linear, exponential, and logistic model from age 50 to age 80 with a 1-year risk of 0.02 at age 50 and 0.32 at age 80; (**b**) risks from linear, exponential, and logistic model extrapolated to age 110 with a 1-year risk of 0.02 at age 50 and 0.32 at age 80

Now suppose the increase is exponential rather than linear. The log-linear form of the exponential model would be $\ln[R(x)] = \alpha_1 + \beta_1(x - 50)$. Solving $R(50) = 0.02$ and $R(80) = 0.32$, we now get $\alpha_1 = \ln(0.02) = -3.912$ and $\beta_1 = \ln(16)/30$ year $= 0.09242$/year, corresponding to a constant proportionate risk increase of $e^{0.09242} = 1.097$ or about 9.7% for each year of age. This corresponds to an absolute risk increase of only about 0.002 going from age 50 to 51, but of about 0.03 (15 times more) going from age 79 to 80.

Finally, suppose the increase is logistic. The logit version of the logistic model would be $\text{logit}[R(x)] = \alpha_1 + \beta_1(x - 50)$. Solving $R(50) = 0.02$ and $R(80) = 0.32$, we now get $\alpha_1 = \text{logit}(0.02) = -3.892$ and $\beta_1 = \ln(23.06)/30$ year $= 0.1046$/year, corresponding to a constant proportionate *odds* increase of $e^{0.1046} = 1.11$ or about 11% for each year of age. This corresponds to an absolute *risk* increase of only about 0.002 going from age 50 to 51, but of about 0.022 (11 times more) going from age 79 to 80.

Figure 30.1a gives plots of the risks from the above three models from age 50 to 80. The linear model produces a straight line, whereas the exponential model produces an exponential curve; these shapes will always hold when x is not transformed. The logistic curve is between the two, but is much closer in shape to the exponential for risks below 0.25, and almost the same as the exponential for risks below 10%. As shown in Fig. 30.1b, the logistic curve gradually straightens out and is close to linear for risks between 30% and 60%; above that point it begins to level off, becoming nearly flat (horizontal) as it approaches 1. In contrast, the linear and exponential curves will eventually continue on above 1 and so produce impossible values for risks (which is a problem if the actual risks could get large). For negative β_1, the curves would instead go downward from left to right.

30.3.12 Other Risk and Odds Models

In addition to those given above, several other risk models are occasionally mentioned but rarely used in epidemiology. The linear odds model is obtained by replacing the average risk by the odds in the linear risk model:

$$O(x_1) = \alpha + \beta_1 x_1. \tag{30.14}$$

Here, β_1 is the *odds* difference between subpopulations with $X_1 = x_1 + 1$ and $X_1 = x_1$, and α is the odds for the subpopulation with $X_1 = 0$. Like risk, the odds cannot be negative; unfortunately, some combinations of α and β_1 in model 14 will produce negative odds. As a result, this model (like the linear risk model) is difficult to fit and gives unsatisfactory results in many settings.

Another model replaces the logistic transform (expit) in the logistic model (30.10) by the inverse of the standard normal distribution, which also has a range between 0 and 1. The resulting model, called a*probit* model, has seen much use in bioassay. Its absence from epidemiological use may stem from the fact that (unlike the logistic) its parameters have no simple epidemiological interpretation, and the model appears to have no general advantage over the logistic in epidemiological applications.

Finally, several attempts have been made to use models that are mixtures of different basic models, especially for multiple regressions (discussed below). These mixtures have various drawbacks, including difficulties in fitting the models and interpreting the parameters (Moolgavkar and Venzon 1987). We thus do not discuss them here.

30.3.13 Rate Models

Instead of modeling average risks, we could model person-time incidence rates. If we let Y denote the *rate* observed in a study subpopulation (so that Y is the observed number of cases per unit of observed person-time), the regression $E(Y|\boldsymbol{X}=\boldsymbol{x})$ represents the average number of cases per unit of person-time in the target subpopulation defined by $\boldsymbol{X}=\boldsymbol{x}$. We will denote this expected rate or "average rate" by $I(\boldsymbol{x})$.

Most rate models are analogues of risk and odds models. For example, the model

$$I(x_1) = E(Y|X_1 = x_1) = \alpha + \beta_1 x_1 \tag{30.15}$$

is a linear *rate* model, analogous to (but different from) the linear risk and odds models (30.7 and 30.14). This rate model implies that the difference in average rates between subpopulations with $X_1 = x_1 + 1$ and $X_1 = x_1$ is β_1, regardless of x_1. Also, α is the average rate for the subpopulation with $X_1 = 0$. This model can be problematic because some combinations of α and β_1 in model 15 would produce negative rate values, which are impossible.

To prevent the latter problem, most rate modeling begins with an exponential *rate* model such as

$$I(x_1) = \exp(\alpha + \beta_1 x_1). \tag{30.16}$$

Because the exponential (exp) can never be negative, this model will not produce negative rates, regardless of α, β_1, or x_1. The model is equivalent to the log-linear *rate* model

$$\ln[I(x_1)] = \alpha + \beta_1 x_1. \tag{30.17}$$

The parameter β_1 in models 16 and 17 is the log of the rate ratio comparing the subpopulation with $X_1 = x_1 + 1$ to the subpopulation with $X_1 = x_1$, regardless of x_1; hence, $\exp(\beta_1)$ is the corresponding rate ratio $I(x_1 + 1)/I(x_1)$. Also, α is the log of the rate for the subpopulation with $X_1 = 0$; hence, $\exp(\alpha)$ is the average rate $I(0)$ when $X_1 = 0$. The exponential rate model (model 16) is analogous to, but different from, the exponential risk model (30.8) and the exponential odds model (30.11).

30.3.14 Incidence-Time Models and Hazard Models

We can also model the average time to occurrence of an event, starting from some designated zero time such as birth (in which case "time" is age), start of treatment, or some calendar date. These are called incidence-time, waiting-time, failure-time, or survival-time models (see chapter ►Survival Analysis of this handbook). Let T stand for time of the event measured from zero. One approach to incidence-time regression is to use a linear model for log incidence-time, such as

$$E[\ln(T)|X_1 = x_1] = \alpha - \beta_1 x_1. \tag{30.18}$$

Because T is always positive, $\ln(T)$ is always defined. In this model, α is the average log incidence-time in the subpopulation with $X_1 = 0$, and β_1 is the difference in average log incidence-times when comparing the subpopulation with $X_1 = x_1 + 1$ to the subpopulation with $X_1 = x_1$ (regardless of the value x_1). Model 18 is an *accelerated-life model* (Cox and Oakes 1984).

Note that the sign of β_1 in the model is reversed from its sign in earlier models. This reversal is done so that, if the outcome event at T is undesirable, then as in earlier models positive values of β_1 will correspond to harmful effects from increasing X_1, and negative values will correspond to beneficial effects. For example, under the model, if T is death time and β_1 is positive, an increase in X_1 will be associated with earlier death. Because this sign reversal is not always done, one should check what convention is followed by software used to fit model 18.

A model similar, but not identical, to model 18 is the log-linear model for expected incidence-time:

$$\ln[E(T|X_1 = x_1)] = \alpha - \beta_1 x_1. \tag{30.19}$$

Model 19 differs from model 18 because the log of an average is greater than the average of the logs (unless T does not vary). Model 19 can be rewritten

$$\begin{aligned} E(T|X_1 = x_1) &= \exp(\alpha - \beta_1 x_1) = \exp(-\beta_1 x_1)e^{\alpha} \\ &= \exp(-\beta_1 x_1)T_0, \end{aligned}$$

where $T_0 = E(T|X_1 = 0) = e^{\alpha}$. Under model 19, e^{α} is the average incidence-time in the subpopulation with $X_1 = 0$, and $e^{-\beta_1}$ is the ratio of average incidence-times in the subpopulation with $X_1 = x_1 + 1$ and the subpopulation with $X_1 = x_1$. As with model 18, the sign of β_1 is negative so that positive values of β_1 will correspond to harmful effects.

More common approaches to modeling incidence-times impose a model for the risk of the event up to each point in time or for the rate of the event at each point in time. The most famous such model is the *Cox model,* also known as the *proportional hazards model.* We can give an approximate description of this model as follows: Suppose we specify a time span Δt that is small enough so that the risk of having the event in any interval t to $t + \Delta t$ among those who survive to t without the event is very small. In its usual (exponential) form, the Cox model assumes that the rates in any such short interval will follow an exponential model like Eq. 30.16, with α, but not β_1, allowed to vary with time t.

If we write $I(t; x_1)$ for the average rate in the interval t to $t + \Delta t$ among persons who survive to t and have $X_1 = x_1$, the Cox model implies that

$$I(t; x_1) \approx \exp(\alpha_t + \beta_1 x_1). \tag{30.20}$$

Under the model, the approximation ($\approx$) improves as Δt gets smaller. Note that the intercept α_t may vary with time, but in this simple Cox model, the X_1-coefficient β_1 is assumed to remain constant. This means that, at any time t, the rate ratio comparing subpopulations with $X_1 = x_1 + 1$ and $X_1 = x_1$ will be

$$I(t; x_1 + 1)/I(t; x_1) \approx \exp[\alpha_t + \beta_1(x_1 + l)]/\exp(\alpha_t + \beta_1 x_1) = \exp(\beta_1)$$

so that β_1 is the log of the rate ratio per unit of X_1, regardless of either the reference level x_1 *or* the time t at which it is computed.

Under the Cox model (30.20), the rate at time t for the subpopulation with $X_1 = 0$ is given by $I(t; 0) = \exp(\alpha_t)$. If we denote this "baseline" rate by $\lambda_0(t)$ instead of $\exp(\alpha_t)$, we have

$$I(t; x_1) \approx \exp(\alpha_t + \beta_1 x_1) = \exp(\alpha_t + \beta_1 x_1) = \lambda_0(t)\exp(\beta_1 x_1) = \exp(\beta_1 x_1)\lambda_0(t).$$

The last expression is the standard form of the model given in most textbooks. The term "Cox model" has become fairly standard, although a special case of the model was proposed by Sheehe (1962) some 10 years before Cox (1972).

The approximate form of the Cox model (30.20) may be seen as an extension of the exponential rate model (30.16) in which the rates may vary over time. Other rate models (such as 30.15) may be used instead for the dependence of the rate on the regressor. Regardless of the particular rate model used for this dependence, the statistical theory behind the model assumes that, at each time t, the rate $I(t; x_1)$ approaches a limit $\lambda(t; x_1)$ as Δt goes to zero. This limit is usually called the *hazard* or *intensity* of the outcome at time t. A Cox model is then defined as a model in which this hazard factorizes into a term showing its dependence on the regressors and a term showing its direct dependence on time. With exponential dependence on the regressors, this factorization becomes

$$\lambda(t; x_1) = \exp(\beta_1 x_1)\lambda_0(t).$$

In epidemiological studies, these hazards are purely theoretical quantities; thus, it is important to understand the approximate forms of the model given above and what those forms imply about observable rates.

The Cox model may be extended to allow regressors to vary over time. Suppose we write $X_1(t)$ as an abbreviation for "the exposure as of time t" and $x_1(t)$ for the actual numerical value of $X_1(t)$ at time t. Then the exponential form of the *Cox model with time-dependent covariates* implies that the incidence rate at time t in the subpopulation that has exposure level $x_1(t)$ at time t is

$$I[t; x_1(t)] \approx \exp[\beta_1 x_1(t)]\lambda_0(t). \tag{30.21}$$

This model may be the most widely used model for time-dependent exposures. Usually, a time-dependent exposure $X_1(t)$ is not defined as the actual amount at time t but instead is some cumulative and lagged index of exposure up to t. For example, if time is measured in months and exposure is cumulative tamoxifen lagged 3 months, $X_1(t)$ would mean "cumulative amount of tamoxifen taken up to month $t - 3$" and $x_1(t)$ would be a value for this variable.

Serious biases can arise in use of Cox models to estimate causal effects of time-dependent exposures when time-dependent confounders are also present (Robins and Greenland 1994). Similar problems arise from the use of standard correlated-outcome ("GEE"; see chapter ▶Generalized Estimating Equations of this handbook) models for longitudinal data analysis (Robins et al. 1999). These problems can be addressed using a special class of accelerated-life models known as *structural failure-time models* (Robins et al. 1992; Robins and Greenland 1994) or by using *marginal structural models* (Robins et al. 2000). For brief descriptions of these models and their relations to conventional models, see Diggle et al. (2002) or Greenland (2008a).

30.3.15 Trend Models: Exposure Transforms

Consider again the linear risk model (30.7). If this model were correct, a plot of average risk across the subpopulations defined by X_1 (i.e., a plot of risk against X_1) would yield a line. Ordinarily, however, there is no compelling reason to think the model is correct, and we might wish to entertain other possible models for the pattern of risk traced out as exposure increases, which may involve changes in direction. We will call this pattern the *trend* in risk (in contrast to the use of "trend" to mean the general or average direction of changes in risk).

We can generate an unlimited variety of such models by *transforming* exposure, that is, by replacing X_1 in the model by some function of X_1. To illustrate, we could replace years exposed in model 7 by its logarithm, to get

$$R(x_1) = \alpha + \beta_1 \ln(x_1). \tag{30.22}$$

This is still called a linear risk model, because a plot of average risk against the new regressor $\ln(X_1)$ would yield a line. But it is a very different model from model 7 because if model 22 were correct, a plot of average risk against years exposed (X_1) would yield a *logarithmic curve* rather than a line. Such a curve starts off very steep for $X_1 < 1$, but levels off rapidly beyond $X_1 > 1$.

One technical problem can arise in using the logarithmic transform: It is not defined if X_1 is negative or zero. If the original exposure measurement can be negative or zero, it is common practice to add a number c to X_1 that is big enough to insure $X_1 + c$ is always positive. The resulting model is

$$R(x_1) = \alpha + \beta_1 1\mathrm{n}(x_1 + c). \tag{30.23}$$

The shape of the curve represented by this model (and hence results derived using the model) can be very sensitive to the value chosen for c, especially when the values of X_1 may be less than 1. Frequently, c is set equal to 1, although there is usually no compelling reason for this choice.

Among other possibilities for exposure transforms are simple power curves of the form

$$R(x_1) = \alpha + \beta_1 x_1^p, \tag{30.24}$$

where p is some number (typically 1/2 or 2) chosen in advance according to some desired property. For example, with X_1 as years exposed, use of $p = 1/2$ yields the *square-root* model

$$R(x_1) = \alpha + \beta_1 x_1^{1/2},$$

which produces a trend curve that levels off as X_1 increases above zero. In contrast, use of $p = 2$ yields the simple *quadratic* model

$$R(x_1) = \alpha + \beta_1 x_1^2,$$

which produces a trend that rises more and more steeply as X_1 increases above zero. One technical problem can arise when using the power model (30.24): It is not defined if p is fractional and X_1 can be negative. To get around this limitation, we may add some number c to X_1 that is big enough to insure $X_1 + c$ is never negative and then use $(X_1 + c)^p$ in the model; again, however, the result may be sensitive to choice of c.

The trend implications of linear and exponential models are vastly different, and hence the implications of exposure transforms are also different. Consider again the exponential risk model (30.8). If this model were correct, a plot of average risk against X_1 would yield an exponential curve, rather than a line. If β_1 is positive, this curve starts out slowly but rises more and more rapidly as X_1 increases; it eventually rises more rapidly than does any power curve (Eq. 30.24). Such rapid increase is often implausible, and we might wish to use a slower-rising curve to model risk.

One means of moderating the trend implied by an exponential model is to replace x_1 by a fixed power x_1^p with $0 < p < 1$, for example,

$$R(x_1) = \exp(\alpha + \beta_1 x_1^{1/2}).$$

Another approach is to take the logarithm of exposure. This transform produces a new model:

$$\begin{aligned} R(x_1) &= \exp[\alpha + \beta_1 1\mathrm{n}(x_1)] \\ &= \exp(\alpha)\exp[\beta_1 \ln(x_1)] \\ &= e^{\alpha}\exp[1\mathrm{n}(x_1)]^{\beta_1} = e^{\alpha} x_1^{\beta_1}. \end{aligned} \tag{30.25}$$

A graph of risk against exposure under this model produces a power curve, but now (unlike model 24), the power is the unspecified (unknown) coefficient β_1 instead of a prespecified value p, and the multiplier of the exposure power is e^{α} (which must be positive) instead of β_1. Model 25 might thus appear more appropriate than model 24 when we want the power of X_1 to appear as an unknown coefficient β_1 in the model, rather than as a prespecified value p. As earlier, however, X_1 must always be positive in order to use model 25; otherwise, one must add a constant c to it such that $X_1 + c$ is always positive. When β_1 is negative in model 25, risk declines more and more gradually across increasingly exposed subpopulations. For example, if $\beta_1 = -1$, then under Eq. 30.25 $R(x_1) = e^{\alpha}\ x_1^{-l} = e^{\alpha}/x_1$, which would imply risk declines 50% (from e^{α}/l to $e^{\alpha}/2$) when going from $X_1 = 1$ to $X_1 = 2$, but declines less than 10% (from $e^{\alpha}/10$ to $e^{\alpha}/11$) when going from $X_1 = 10$ to $X_1 = 11$.

The exposure transforms and implications just discussed carry over to the analogous models for odds and rates. For example, we can modify the logistic model (which is an exponential odds model) by substituting the odds $O(x_1)$ for the risk $R(x_1)$ in models 22–25. Similarly, we can modify the rate models by substituting the rate $I(x_1)$ for $R(x_1)$. Each model will have implications for the odds or rates analogous to those described above for the risk; because the risks, odds, and rates are functions of one another (see Rothman et al. 2008, Chap. 3), each model will have implications for other measures as well.

Any trend in the odds will appear more gradual when transformed into a risk trend. To see this, note that

$$R(x_1) = O(x_1)/[1 + O(x_1)] < O(x_1),$$

and hence,

$$O(x_1)/R(x_1) = 1 + O(x_1).$$

This ratio of odds to risk grows as the odds (and the risks) get larger. Thus, the logistic risk model, which is an exponential odds model, implies a less than exponential trend in the risk. Conversely, any trend in the risks will appear steeper when transformed into an odds trend. Thus, the exponential risk model implies a greater than exponential trend in the odds, although when risks are uniformly low (under 10% for all possible X_1 values), the risks and odds will be close and so there will be little difference between the shape of the curves produced by analogous risk and odds models.

The relation of risk and odds trends to rate trends is more complex in general, but in typical applications follows the simple rule that rate trends tend to fall between the less steep risk and more steep odds trends. For example, an exponential rate model typically implies a less than exponential risk trend but more than exponential odds trend. To see why these relations can be reasonable to expect, recall that, if incidence is measured over a span of time Δt in a closed cohort, then $R(x_1) < I(x_1)\Delta t < O(x_1)$. When the risks are uniformly low, we obtain

$R(x_1) \approx I(x_1)\Delta t \approx O(x_1)$, and so there will be little difference in the curves produced by analogous risk, rate, and odds models.

30.3.16 Interpreting Models After Transformation

One drawback of models with transformed regressors is that the interpretation of the coefficients depends on the transformation. As an example, consider the model 25, which has $\ln(x_1)$ in place of x_1. Under this model, the risk ratio for a one-unit increase in X_1 is

$$\begin{aligned} R(x_1 + 1)/R(x_1) &= e^{\alpha}(x_1 + 1)^{\beta_1}/\mathrm{e}^{\alpha}x_1^{\beta_1} \\ &= [(x_1 + 1)/x_1]^{\beta_1}, \end{aligned}$$

which will depend on the value x_1 used as the reference level: If β_1 equals 1 and x_1 is 1, the risk ratio is 2, but if β_1 equals 1 and x_1 is 2, the ratio is 1.5. Here, β_1 is the power to which x_1 is raised and so determines the shape of the trend. The interpretation of the intercept α is also altered by the transformation. Under model

25, $R(1) = e^{\alpha} 1^{\beta_1} = e^{\alpha}$; thus, α is the log risk when $X_1 = 1$, rather than when $X_1 = 0$, and so is meaningful only if 1 is a possible value for X_1.

As a contrast, consider again the model $R(x_1) = \exp(\alpha + \beta_1 x_1^{1/2})$. Use of $x_1^{1/2}$ rather than x_1 moderates the rapid increase in the slope of the exponential dose-response curve but also leads to difficulties in coefficient interpretation. Under the model, the risk ratio for a one-unit increase in X_1 is

$$\exp[\alpha + \beta_1(x_1 + 1)^{1/2}]/\exp(\alpha + \beta_1 x_1^{1/2}) = \exp\{\beta_1[(x_1 + 1)^{1/2} - x_1^{1/2}]\}.$$

Here, β_1 is the log risk ratio per unit increase in the *square root* of X_1, which is rather obscure in meaning. Interpretation may better proceed by considering the shape of the curve implied by the model, for example, by plotting $\exp(\alpha + \beta_1 x_1^{1/2})$ against possible values of X_1 for several values of β_1. (The intercept α is less important in this model because it only determines the vertical scale of the curve, rather than its shape.) Such plotting is often needed to understand and compare different transforms.

30.4 Multiple-Regression Models

Suppose now we wish to model the full multiple regression $E(Y|X = x)$. Each of the previous models for the single-regression $E(Y|X_1 = x_1)$ can be extended to handle this more general situation by using the following device: In any model for the single regression, replace $\beta_1 x_1$by

$$\beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_n x_n. \tag{30.26}$$

To illustrate the idea, suppose we wish to model average risk of death by age 70 across female subpopulations defined by

$$\begin{aligned} X_1 &= \text{years of tamoxifen therapy,} \\ X_2 &= \text{age at start of tamoxifen use,} \\ X_3 &= \text{age at menarche.} \end{aligned}$$

with $\boldsymbol{X} = (X_1, X_2, X_3)$. Then the multiple linear risk model for $R(\boldsymbol{x})$ is

$$R(\boldsymbol{x}) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3,$$

while the multiple-logistic risk model is

$$R(\boldsymbol{x}) = \text{expit}(\alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3).$$

If instead we wished to model the death rate, we could use the multiple linear rate model

$$I(\boldsymbol{x}) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3$$

or a multiple exponential rate model

$$I(\boldsymbol{x}) = \exp(\alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3).$$

Because formula 26 can be clumsy to write out when there are three or more regressors ($n \geq 3$), several shorthand notations are in use. Let us write $\boldsymbol{\beta}$ for the vertical list (column vector) of coefficients $\beta_1, \ldots, \beta_n$. Recall that x stands for the horizontal list (row vector) of values $x_1, \ldots, x_n$. We will let $\boldsymbol{x\beta}$ stand for $\beta_1 x_1 + \ldots + \beta_n x_n$. We can then represent the multiple linear risk model by

$$R(\boldsymbol{x}) = \alpha + \boldsymbol{x\beta} = \alpha + \beta_1 x_1 + \ldots + \beta_n x_n, \tag{30.27}$$

the multiple-logistic model by

$$R(\boldsymbol{x}) = \text{expit}(\alpha + \boldsymbol{x\beta}), \tag{30.28}$$

the multiple exponential rate model by

$$I(\boldsymbol{x}) = \exp(\alpha + \boldsymbol{x\beta}), \tag{30.29}$$

and so on for all the models discussed earlier.

30.4.1 Relations Among Multiple-Regression Models

The multiple-regression models 27–29 are not more general than the single-regression models given earlier, nor do they contain those models as special cases. This is because they refer to entirely different subclassifications of the target population: The single-regression models refer to variations in averages across subpopulations defined by levels of just one variable; in contrast, the multiple-regression models refer to variations across the much finer subdivisions defined by the levels of several variables. For example, it is possible for $R(x_1)$ to follow the single-logistic model (30.10) without $R(\boldsymbol{x})$ following the multiple-logistic model (30.28); conversely, it is possible for $R(\boldsymbol{x})$ to follow the multiple-logistic model without $R(x_1)$ following the single-logistic model.

The preceding point is often overlooked because the single-regression models are often confused with multiple-regression models in which all regressor coefficients but one are zero. The difference is, however, analogous to the differences discussed earlier between the vacuous models 1–3 (which are so general as to imply nothing) and the constant regression models 4–6 (which are so restrictive as to be unbelievable in typical situations). To see this, consider the multiple-logistic model

$$R(\boldsymbol{x}) = \text{expit}(\alpha + \beta_1 x_1). \tag{30.30}$$

The right side of this equation is the same as in the single-logistic model (30.10), but the left side is crucially different: It is the multiple-risk regression $R(\boldsymbol{x})$, instead of the single-regression $R(x_1)$. Unlike model 10, model 30 *is* a special case of the multiple-logistic model (30.28), the one in which $\beta_2 = \beta_3 = \ldots = \beta_n = 0$. Unlike model 10, model 30 asserts that risk *does not vary* across subpopulations defined by $X_1, X_2, \ldots, X_n$ *except* to the extent that X_1 varies. This is far more strict than model 28, which allows risk to vary with $X_2, \ldots, X_n$ as well as X_1 (albeit only in a logistic fashion). It is also far more strict than model 10, which says absolutely nothing about whether or how risk varies across subpopulations defined by $X_2, \ldots, X_n$ within specific levels of X_1.

More generally, we must be careful to distinguish between models that refer to different multiple-regression functions. For example, compare the two exponential rate models:

$$I(x_1, x_2) = \exp(\alpha + \beta_1 x_1 + \beta_2 x_2), \tag{30.31}$$

and

$$I(x_1, x_2, x_3) = \exp(\alpha + \beta_1 x_1 + \beta_2 x_2). \tag{30.32}$$

These are different models. The first is a model for the regression of rates on X_1 and X_2 only, while the second is a model for the regression of rates on X_1, X_2, and X_3. The first model in no way refers to X_3, while the second asserts that rates do not vary across levels of X_3 if one looks within levels of X_1 and X_2. Model 32 is the special case of

$$I(x_1, x_2, x_3) = \exp(\alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3)$$

(the case in which $\beta_3 = 0$), while model 31 is not, and this special case implies model 31.

Many textbooks and software manuals fail to distinguish between models such as models 31 and 32, and instead focus only on the appearance of the right-hand side of the models. Most software fits the model that ignores other covariates (Eq. 30.31 in the above example) rather than the more restrictive model (30.32) when requested to fit a model with only X_1 and X_2 as regressors. Note that if the less restrictive model is inadequate, then the more restrictive model must also be inadequate.

Unfortunately, the converse is not true: If the less restrictive model appears adequate, it does *not* follow that the more restrictive model is also adequate. For example, it is possible for the model form $\exp(\alpha + \beta_1 x_1 + \beta_2 x_2)$ to describe adequately the double regression $I(x_1, x_2)$ (which means it describes adequately rate variation across X_1 and X_2 when X_3 is ignored) and yet at the same time describe poorly the triple regression $I(x_1, x_2, x_3)$ (which means that it describes inadequately rate variation across X_1, X_2, and X_3). That is, a model may describe poorly the rate variation across X_1, X_2, and X_3 even if it describes adequately the rate variation across X_1 and X_2 when X_3 is ignored. The decision as to whether the model is acceptable should depend on whether rate variation across X_3 is relevant to the analysis objectives. For example, if the objective is to estimate the effect of changes in X_1 on the death rate, and X_2 and X_3 are both potential confounders (as in the tamoxifen example), we would want the model to describe adequately rate variation across all three variables. But if X_3 is instead affected by the study exposure X_1 (as when X_1 is past estrogen exposure and X_3 is an indicator of current uterine bleeding), we would ordinarily not want to include X_3 in the regression model (because we would not want to adjust our exposure effect estimate for X_3).

30.4.2 Product Terms (Statistical Interactions)

Each model form described above has differing implications for measures of association derived from the models. Consider again the linear risk model with three regressors X_1, X_2, and X_3 and let x_1* and x_1 be any two values for X_1. Under the model, the risks at $X_1 = x_1$* and $X_1 = x_1$ and their difference *RD* when $X_2 = x_2$ and $X_3 = x_3$ are

$$\begin{aligned}
&R(x_1{}^*, x_2, x_3) = \alpha + \beta_1 x_1{}^* + \beta_2 x_2 + \beta_3 x_3,\\
&R(x_1, x_2, x_3) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3,\\
&RD = \beta_1(x_1{}^* - x_1).
\end{aligned}$$

Thus, the model implies that the risk difference between two subpopulations with the same X_2 and X_3 levels depends only on the difference in their X_1 levels. In other words, the model implies that the risk differences for X_1 within levels of X_2 and X_3 will not vary across levels of X_2 and X_3. Such an implication may be unacceptable, in which case we can either modify the linear model or switch to another model. A simple way to modify a model is to add *product terms.* For example, suppose we want to allow the risk differences for X_1 to vary across levels of X_2. We then may add the product of X_1 and X_2 to the model as a fourth variable. The risks and their differences will then be

$$\begin{aligned}
R(x_1{}^*, x_2, x_3) &= \alpha + \beta_1 x_1{}^* + \beta_2 x_2 + \beta_3 x_3 + \gamma_{12} x_1 {*} x_2,\\
R(x_1, x_2, x_3) &= \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \gamma_{12} x_1 x_2,
\end{aligned} \tag{30.33}$$

$$RD = \beta_1(x_1{}^* - x_1) + \gamma_{12}(x_1{}^* - x_1)x_2 = (\beta_1 + \gamma_{12} x_2)(x_1{}^* - x_1). \tag{30.34}$$

Under model 33, the risk difference for $X_1 = x_1$* versus $X_1 = x_1$ is given by formula 34, which depends on X_2.

A model (e.g., 30.33) that allows variation of the risk difference for X_1 across levels of X_2 will also allow variation in the risk difference for X_2 across levels of X_1. As an example, let x_2* and x_2 be any two possible values for X_2. Under model 33, the risks at $X_2 = x_2$* and $X_2 = x_2$ and their difference *RD* when $X_1 = x_1$, $X_3 = x_3$ are

$$\begin{aligned}
&R(x_1, {x_2}^*, x_3) = \alpha + \beta_1 x_1 + \beta_2 {x_2}^* + \beta_3 x_3 + \gamma_{12} x_1 {x_2}^*,\\
&R(x_1,\ x_2,\ x_3) = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \gamma_{12} x_1 x_2,\\
&RD = \beta_2({x_2}^* - x_2) + \gamma_{12} x_1 ({x_2}^* - x_2) = (\beta_2 + \gamma_{12} x_1)({x_2}^* - x_2).
\end{aligned} \tag{30.35}$$

Thus, under the model, the risk difference for $X_2 = x_2*$ versus $X_2 = x_2$ is given by formula 35, which depends on X_1. Formulas 34 and 35 illustrate how product terms modify a model in a symmetric way. The term $\gamma_{12} x_1 x_2$ allows the risk differences for X_1 to vary with X_2 and the risk differences for X_2 to vary with X_1.

A model without product terms is sometimes called a "main-effects only" model and can be viewed as the special case of a model with product terms in which all the product coefficients γ_{ij} are set to zero; it thus represents a very restrictive model. If we have three regressors in a model, we have three unique two-way regressor products ($x_1 x_2$, $x_1 x_3$, $x_2 x_3$) that we can put in the model as well. More generally, with n regressors, there are $\binom{n}{2}$ pairs and hence $\binom{n}{2}$ two-way products we can use. It is also possible to add triple products (e.g., $x_1 x_2 x_3$) or even more complex combinations to the model, but such additions are rare in practice. Notable exceptions are indices such as the body mass index (BMI) kg/m^2; however, in these situations, analysts usually neglect to examine components of the index in the model, which can introduce bias (Michels et al. 1998).

Consider next an exponential risk model with the above three variables. Under this model, the risks at $X_1 = x_1*$ and $X_1 = x_1$ and their ratio RR when $X_2 = x_2$, $X_3 = x_3$ are

$$\begin{aligned}
R({x_1}^*, x_2, x_3) &= \exp(\alpha + \beta_1 {x_1}^* + \beta_2 x_2 + \beta_3 x_3),\\
R(x_1, x_2, x_3) &= \exp(\alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3),\\
RR &= \exp[\beta_1({x_1}^* - x_1)].
\end{aligned} \tag{30.36}$$

Thus, the model implies that the risk ratio comparing two subpopulations with the same X_2 and X_3 levels depends only on the difference in their X_1 levels. In other words, the model implies that the risk ratios for X_1 will be constant across levels of X_2 and X_3. If this implication is unacceptable, product terms can be inserted, as with the linear model. These terms allow the risk ratios to vary in a limited fashion across levels of other variables.

The preceding discussion of product terms can be applied to linear and exponential models in which the odds or rate replaces the risk. For example, without product terms, the logistic model implies that the odds ratios for each regressor are constant across levels of the other regressors (because the logistic model is an exponential odds model); we can add product terms to allow the odds ratios to vary. Likewise, without product terms, the exponential rate model implies that the rate ratios for each regressor are constant across levels of the other regressors; we can add product terms to allow the rate ratios to vary.

Although product terms can greatly increase the flexibility of a model, the type of variation allowed by-product terms can be very limited. For example, model 33 implies that raising X_2 by one unit (i.e., comparing subpopulations that have $X_2 = x_2 + 1$ instead of $X_2 = x_2$) will yield a risk difference for X_1 of

$$[\beta_1 + \gamma_{12}(x_2 + 1)](x_1{}^* - x_1) = (\beta_1 + \gamma_{12}x_2)(x_1{}^* - x_1) + \gamma_{12}(x_1{}^* - x_1).$$

In other words, the model implies that shifting our comparison to subpopulations that are one unit higher in X_2 will change the risk difference for X_1 in a linear fashion, by an amount γ_{12} $(x_1{}^* - x_1)$, regardless of the reference values x_1, x_2, x_3 of X_1, X_2, X_3.

30.4.3 Trends and Product Terms

Each of the above models forces or assumes a particular shape for the graph obtained when average outcome (regression) is plotted against the regressors. Consider again the tamoxifen example. Suppose we wished to plot how the risk varies across subpopulations with different number of years exposed but with the same age at start of exposure and the same age at menarche. Under the linear risk model, this would involve plotting the average risk

$$R(x_1, x_2, x_3) = \alpha + \beta x_1 + \beta_2 x_2 + \beta_3 x_3$$

against X_1, while keeping X_2 and X_3 fixed at some values x_2 and x_3. In doing so, we would obtain a line with an intercept equal to $\alpha + \beta_2 x_2 + \beta_3 x_3$ and a slope equal to β_1. Whenever we changed X_2 and X_3 and replotted $R(x)$ against X_1, the intercept would change (unless $\beta_2 = \beta_3 = 0$), but the slope would remain β_1. Because lines with the same slope are parallel, we can say that the linear risk model given above implies *parallel linear* trends in risk with increasing tamoxifen (X_1) as one moves across subpopulations of different starting age (X_2) and menarche age (X_3). This means that each change in X_2 and X_3 adds some constant (possibly negative) amount to the X_1 curve. For this reason, the linear risk model is sometimes called an *additive* risk model.

If we next plotted risks against X_2, we would get analogous results: The linear risk model given above implies parallel linear relations between average risk and X_2 as one moves across levels of X_1 and X_3. Likewise, the model implies parallel linear relations between average risk and X_3 across levels of X_1 and X_2. Thus, the linear model implies additive (parallel) relations among all the variables.

If we are unsatisfied with the linearity assumption but we wish to retain the additivity (parallel-trend) assumption, we could transform the regressors. If we are unsatisfied with the parallel-trend assumption, we can allow the trends to vary across levels of other regressors by adding product terms to the model. For example, adding the product of X_1 and X_2 to the model yields model 33, which can be rewritten

$$R(x_1, x_2, x_3) = \alpha + (\beta_1 + \gamma_{12}x_2)x_1 + \beta_2 x_2 + \beta_3 x_3.$$

From this reformulation, we see that the slope for the line obtained by plotting average risk against X_1 while keeping X_2, X_3 fixed at x_2, x_3 would be $\beta_1 + \gamma_{12}x_2$. Thus, the slope of the trend in risk across X_1 would vary across levels of X_2 (if $\gamma_{12} \neq 0$), and so the trend lines for X_1 would not be parallel. We also see that γ_{12} is the difference in the X_1-trend slopes between subpopulations with the same X_3-value but one unit apart in their X_2-value.

An entirely different approach to producing non-parallel trends begins with an exponential model. For example, under the exponential risk model (30.36), a plot of average risk against X_1 while keeping X_2 and X_3 fixed at x_2 and x_3 would produce an *exponential* curve, rather than a line. This exponential curve would have intercept $\exp(\alpha + \beta_2 x_2 + \beta_3 x_3)$. If, however, we changed the value of X_2 or X_3 and replotted risk against X_1, we would *not* obtain a parallel risk curve. Instead, the new curve would be *proportional* to the old: A change in X_2 or X_3 *multiplies* the entire X_1 curve by some amount. For this reason, the exponential model is sometimes called a *multiplicative risk* model. If we were unsatisfied with this proportionality-of-trends assumption, we could insert product terms into the model, which would allow for certain types of non-proportional trends. Proportional trends in risk appear parallel when plotted on a logarithmic vertical scale; when product terms with non-zero coefficients are present, logarithmic trends appear non-parallel.

Analogous comments and definitions apply if we substitute odds or rates for risks in the above arguments. For example, consider the multiple-logistic model in the exponential odds form:

$$O(\boldsymbol{x}) = \exp(\alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3).$$

A plot of the disease odds $O(\boldsymbol{x})$ against X_1 while keeping X_2 and X_3 fixed would produce an exponential curve; a plot of the log odds (logit) against X_1 while keeping X_2 and X_3 fixed would produce a line. If we changed the value of X_2 or X_3 and replotted the odds against X_1, we would obtain a new curve proportional to the old; that is, the new odds curve would equal the old multiplied by some constant amount. Thus, the logistic model is sometimes called a multiplicative-odds model. For analogous reasons, the exponential rate model is sometimes called a multiplicative-rate model. In both these models, inserting product terms into the model allows certain types of departures from proportional trends.

30.4.4 Interpreting Product-Term Models

Several important cautions should be highlighted when attempting to build models with product terms and interpret coefficients in models with product terms. First, the so-called “main-effect” coefficient β_j will be meaningless when considered alone if its regressor X_j appears in a product with another variable X_k that cannot be zero.

In the tamoxifen example, X_1 is years of exposure, which can be zero, while X_3 is age at menarche (in years), which is always above zero. Consider the model

$$\begin{aligned} R(x_1, x_2, x_3) &= \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \gamma_{13} x_1 x_3 \\ &= \alpha + \beta_1 x_1 + \beta_2 x_2 + (\beta_3 + \gamma_{13} x_1) x_3 \qquad (30.37) \\ &= \alpha + (\beta_1 + \gamma_{13} x_3) x_1 + \beta_2 x_2 + \beta_3 x_3. \end{aligned}$$

Under this model, $\beta_1 + \gamma_{13} x_3$ is the slope for the trend in risks across X_1 given $X_2 = x_2$ and $X_3 = x_3$. Thus, if X_3 was 0, this slope would be $\beta_1 + \gamma_{13} \cdot 0 = \beta_1$, and so β_1 could be interpreted as the slope for X_1 in subpopulations of a given X_2 and with $X_3 = 0$. But X_3 is age at menarche and so cannot be zero; thus, β_1 has no simple epidemiological interpretation. In contrast, because X_1 is years exposed and so can be zero, β_3 does have a simple interpretation: Under model 37, $\beta_3 + \gamma_{13} x_1$ is the slope for X_3 given $X_1 = x_1$; hence, $\beta_3 + \gamma_{13} \cdot 0 = \beta_3$ is the slope for X_3 in subpopulations with no tamoxifen exposure ($X_1 = 0$).

As mentioned earlier, if a regressor X_j cannot be zero, one can insure a simple interpretation of the intercept α by recentering the regressor, that is, by subtracting a reference value from the regressor before entering it in the model. Such recentering also helps provide a simple interpretation for the coefficients of variables that appear with X_j in product terms. In the example, we could recenter by redefining X_3 to be age at menarche -13 years. With this change, β_1 in model 37 would now be the slope for X_1 (years of tamoxifen) in subpopulations of a given X_2 (age at start of tamoxifen) in which this new X_3 was 0 (i.e., in which the age at menarche was 13).

Rescaling can also be important for interpretation of product-term coefficients. As an example, suppose X_1 is serum cholesterol in mg/dl and X_2 is diastolic blood pressure (DBP) in mm Hg and that the product of X_1 and X_2 is entered into the model without rescaling, say as $\gamma_{12} x_1 x_2$ in an exponential rate model. Then γ_{12} would represent the difference in the log of the rate ratio for a 1 mg/dl increase in cholesterol when comparing subpopulations 1 mm Hg apart in DBP. Even if this term was important, it would appear very small in magnitude because of the small units used to measure cholesterol and DBP. To avoid such deceptive appearances, we could rescale X_1 and X_2 so that their units now represented important increases in cholesterol and DBP. For example, we could redefine X_1 as cholesterol divided by 20 and X_2 as DBP divided by 10. With this rescaling, γ_{12} would represent the difference in the log of the rate ratio for a 20 mg/dl increase in cholesterol when comparing subpopulations 10 mm Hg apart in DBP.

Another caution is that, in most situations, a product term in a model should be accompanied by terms for all variables and products contained within that product. For example, if one enters $\gamma_{12} x_1 x_2$ in a model, $\beta_1 x_1$ and $\beta_2 x_2$ should also be included in that model, and if one enters $\delta_{123} x_1 x_2 x_3$ in a model, all of $\beta_1 x_1, \beta_2 x_2, \beta_3 x_3, \gamma_{12} x_1 x_2, \gamma_{13} x_1 x_3$, and $\gamma_{23} x_2 x_3$ should be included in that model. This rule, sometimes called the "hierarchy principle" (Bishop et al. 1975), is useful in avoiding models with bizarre implications. As an example, suppose X_1 is serum-lead concentration and X_2 is age minus 50 years. If $\gamma_{12} > 0$, the 1-year mortality-risk model

$$R(x_1, x_2) = \exp(\alpha + \beta_2 x_2 + \gamma_{12} x_1 x_2)$$

implies that serum-lead is positively related to risk among persons above age 50 ($X_2 > 0$), is unrelated to risk among persons of age 50 ($X_2 = 0$), and is negatively related to risk among persons below age 50 ($X_2 < 0$); if $\gamma_{12} < 0$, it implies a negative relation over 50 and a positive relation below 50. Rarely (if ever) would we have grounds for assuming such unusual relations hold. To prevent use of absurd models, many regression programs automatically enter all terms contained within a product when the user instructs the program to enter the product into the model.

Models violating the hierarchy principle often arise when one variable is not defined for all subjects or when a variable is included that is a composite of other variables (e.g., body mass index). As an example of the former, suppose in a study of breast cancer in women that X_1 is age at first birth (AFB) and X_2 is parity. Because X_1 is undefined for nulliparous women ($X_2 = 0$), one sometimes sees the breast-cancer rate modeled by a function in which age at first birth appears only in a product term with parity, such as $\exp(\alpha + \beta_2 x_2 + \gamma_1 x_1 x_2)$. The rationale for this model is that the rate will remain defined even when age at first birth (X_1) is undefined because $x_1 x_2$ will be zero when parity (X_2) is zero.

One can sometimes avoid violating the hierarchy principle if there is a reasonable way to extend variable definitions to all subjects. Thus, in the tamoxifen example, age at start of tamoxifen was extended to the untreated by setting it to age 70 (end of follow-up) for those subjects and for those subjects who started at age 70 or later. The rationale for this extension is that, within the age interval under study, untreated subjects and subjects starting tamoxifen at age 70 or later would have identical exposures.

Our final caution is that product terms are commonly labeled "interaction terms" or "statistical interactions." We avoid these labels because they may inappropriately suggest the presence of biological (mechanical) interactions between the variables in a product term. In practice, regression models are applied in many situations in which there is no effect of the regressors on the regressand (outcome). Even in causal analyses, the connections between product terms and biological interactions can be very indirect and can depend on many biological assumptions; see Rothman et al. (2008), Chap. 5 and chapter ▸Confounding and Interaction of this handbook.

30.4.5 Categorical Regressors

Consider a regressor whose possible values are discrete and few and perhaps purely nominal (i.e., with no natural ordering or quantitative meaning). An example is marital status (never married, currently married, formerly married). Such regressors may be entered into a multiple-regression model using *category indicator variables.* To use this approach, we first choose one level of the regressor as the *reference level,* against which we want to compare risks or rates. For each of the remaining levels (the *index* levels), we create a binary variable that indicates whether a person is at that level (1 if at the level, 0 if not). We then enter these indicators into the regression model.

The entire set of indicators is called the *coding* of the original regressor. To code marital status, we could take "currently married" as the reference level and define

$$\begin{aligned}X_1 &= 1 \text{ if formerly married, 0 if currently or never married,}\\ X_2 &= 1 \text{ if never married, 0 if ever married (i.e., currently or formerly married).}\end{aligned}$$

There are $2 \cdot 2 = 4$ possible numerical combinations of values for X_1 and X_2, but only three of them are logically possible. The impossible combination is $X_1 = 1$ (formerly married) and $X_2 = 1$ (never married). Note, however, that we need two indicators to distinguish the three levels of marital status because one indicator can only distinguish two levels.

In general, we need $J - 1$ indicators to code a variable with J levels. Although these indicators will have 2^{J-1} possible numerical combinations, only J of these combinations will be logically possible. For example, we will need four indicators to code a variable with five levels. These indicators will have $2^4 = 16$ numerical combinations, but only five of the 16 combinations will be logically possible.

Interpretation of the indicator coefficients depends on the model form and the chosen coding. For example, in the logistic model

$$R(x_1, x_2) = \text{expit}(\alpha + \beta_1 x_1 + \beta_2 x_2), \tag{30.38}$$

$\exp(\beta_2)$ is the odds ratio comparing $X_2 = 1$ persons (never married) to $X_2 = 0$ persons (ever married) within levels of X_1. Because one cannot have $X_2 = 1$ (never married) and $X_1 = 1$ (formerly married), the only level of X_1 within which we can compare $X_2 = 1$ to $X_2 = 0$ is the zero level (never or currently married). Thus, $\exp(\beta_2)$ is the odds ratio comparing never married ($X_2 = 1$) to currently married ($X_2 = 0$) people among those never or currently married ($X_1 = 0$). In a similar fashion, $\exp(\beta_1)$ compares those formerly married to those currently married among those ever married.

In general, the type of indicator coding described above, called *disjoint category coding,* results in coefficients that compare each index category to the reference category. With this coding, for a given person, no more than one indicator in the set can equal 1; all the indicators are zero for persons in the reference category. Another kind of coding is *nested indicator coding.* In this coding, levels of the regressor are grouped, and then codes are created to facilitate comparisons both within and across groups. For example, suppose we wish to compare those not currently married (never or formerly married) to those currently married and also compare those never married to those formerly married. We can then use the indicators

$$\begin{aligned} Z_1 &= 1 \text{ if never or formerly married (i.e., not currently married),} \\ &\quad\ 0 \text{ otherwise (currently married),} \\ Z_2 &= 1 \text{ if never married, 0 if ever married.} \end{aligned}$$

Z_2 is the same as the X_2 used above, but Z_1 is different from X_1. The combination $Z_1 = 0$ (currently married), $Z_2 = 1$ (never married) is impossible; $Z_1 = Z_2 = 1$ for people who never married. In the logistic model

$$R(z_1, z_2) = \text{expit}(\alpha + \beta_1 z_1 + \beta_2 z_2), \tag{30.39}$$

$\exp(\beta_2)$ is now the odds ratio comparing those never married ($Z_2 = 1$) to those ever married ($Z_2 = 0$) within levels of Z_1. Note that the only level of Z_1 in which this comparison can be made is $Z_1 = 1$ (never or formerly married). Similarly, $\exp(\beta_1)$ is now the odds ratio comparing those formerly married ($Z_1 = 1$) among those never married ($Z_2 = 0$).

There can be quite a large number of options for coding category indicators. The choice among these options may be dictated by which comparisons are of most interest. As long as each level of the regressor can be uniquely represented by the indicator coding, the choice of coding will not alter the assumptions represented by the model. There is, however, one technical point to consider in choosing codes. The precision of the estimated coefficient for an indicator will directly depend on the numbers of subjects at each indicator level. For example, suppose in the data there were 1,000 currently married subjects, 200 formerly married subjects, and only 10 never married subjects. Then any indicator that had "never married" as one of its levels (0 or 1) would have a much less precise coefficient estimate than other indicators. If "never married" were chosen as the reference level for a disjoint coding scheme, all the indicators would have that level as its zero level, and so all would have very imprecise coefficient estimates. To maximize precision, many analysts prefer to use disjoint coding in which the largest category (currently married in the above example) is taken as the reference level.

In choosing a coding scheme, one need not let precision concerns dominate if they get in the way of interesting comparisons. Coding schemes that distinguish among the same categories produce equivalent models. Therefore, one may fit a model repeatedly using different but equivalent coding schemes in order to easily examine all comparisons of interest. For example, one could fit model 38 to compare those never or formerly married with those currently married, then fit model 39 to compare the never with formerly married.

Although indicator coding is essential for purely nominal regressors, it can also be used to study quantitative regressors as well, especially when one expects qualitative differences between persons at different levels. Consider number of marriages as a regressor. We might suspect that people of a given age who have had one marriage tend to be qualitatively distinct from people of the same age who have had no marriage or two marriages and that people who have had several marriages are even more distinctive. We thus might want to code number of marriages in a manner that allowed qualitative distinctions among its levels. If "one marriage" was the most common level, we might take it as the reference level and use

$$X_1 = 1 \text{ if never married, 0 otherwise,}$$

$$X_2 = 1 \text{ if two marriages, 0 otherwise,}$$

$$X_3 = 1 \text{ if three or more marriages, 0 otherwise.}$$

We use one variable to represent "three or more" because there might be too few subjects with three or more marriages to produce acceptably precise coefficients for a finer division of levels. The coding just given would provide comparisons of those never married, twice married, and more-than-twice married to those once married. Other codings could be used to make other comparisons.

30.5 Trend Models with Multiple Parameters

Multiple-regression models can be extended to produce much more flexible trend models than those provided by simple transformations. The latter restrict trends to follow basic shapes, such as quadratic or logarithmic curves. The use of multiple terms for each exposure and confounder allows more detailed assessment of trends and more complete control of confounding than possible with simple transformations.

30.5.1 Categorical Trends

One way to extend trend models is to categorize the regressor and then use a category-indicator coding such as discussed above. The resulting analysis may then parallel the categorical (tabular) trend methods. To the extent allowed by the data numbers and background information, the categories should represent scientifically meaningful constructs within which risk is not expected to change dramatically. Purely mathematical categorization methods such as percentiles (quantiles) can do very poorly compared to meaningful categories. Most importantly, the choices of categories should *not* be dictated by the results produced; for example, manipulation of category boundaries to maximize the effect estimate will produce an estimate biased away from the null, while manipulation of boundaries to minimize a p-value will produce a downwardly biased p-value. Similarly, manipulation to minimize the estimate or maximize the p-value will produce a null-biased estimate or an upwardly biased p-value.

There are two common types of category codes used in trend models. *Disjoint coding* produces estimates that compare each index category (level) to the reference level. Consider coding weekly servings of fruits and vegetables with

$$X_1 = 1 \text{ for } < 15, 0 \text{ otherwise}$$
$$X_2 = 1 \text{ for } 36 - 42, 0 \text{ otherwise}$$
$$X_3 = 1 \text{ for } > 42, 0 \text{ otherwise.}$$

In the rate model

$$\ln[I(x_1, x_2, x_3)] = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3, \tag{30.40}$$

$\exp(\beta_1)$ is the rate ratio comparing the "<15" category with the "15–35" category (which is the referent), and so on, while $\exp(\alpha)$ is the rate in the "15–35" category (the category for which all the X_j are zero). When Eq. 30.40 is fit, we can plot the fitted rates on a graph as a step function. This plot provides a crude impression of the trends across (but not within) categories.

Confounders may be added to the model in order to control confounding, and these too may be coded using multiple indicators or any of the methods described below. We may plot the model-adjusted trends by fixing each confounder at a reference level and allowing the exposure level to vary.

Incremental coding (nested coding) can be useful when one wishes to compare each category against its immediate predecessor (Maclure and Greenland 1992). For "number of servings per week," we could use

$$Z_1 = 1 \text{ for } >14, 0 \text{ otherwise,}$$
$$Z_2 = 1 \text{ for } >35, 0 \text{ otherwise,}$$
$$Z_3 = 1 \text{ for } >42, 0 \text{ otherwise.}$$

Note that if $Z_2 = 1$, then $Z_1 = 1$, and if $Z_3 = 1$, then $Z_1 = Z_2 = 1$. In the model

$$\ln[I(z_1, z_2, z_3)] = \alpha + \beta_1 z_1 + \beta_2 z_2 + \beta_3 z_3, \tag{30.41}$$

$\exp(\beta_1)$ is the rate ratio comparing the 15–35 category ($Z_1 = 1$ and $Z_2 = Z_3 = 0$) to the <15 category ($Z_1 = Z_2 = Z_3 = 0$). Similarly, $\exp(\beta_2)$ is the rate ratio comparing the 36–42 category ($Z_1 = Z_2 = 1$ and $Z_3 = 0$) to the 15–35 category ($Z_1 = 1$ and $Z_2 = Z_3 = 0$). Finally, $\exp(\beta_3)$ compares the >42 category ($Z_1 = Z_2 = Z_3 = 1$) to the 36–42 category ($Z_1 = Z_2 = 1$ and $Z_3 = 0$). Thus, $\exp(\beta_1)$, $\exp(\beta_2)$, and $\exp(\beta_3)$ are the incremental rate ratios across adjacent categories. Again, we may add confounders to the model and plot adjusted trends.

Another form of coding for trend analysis is called *floating absolute risk*, which avoids distortion of uncertainty assessments of trends by eliminating the need for a potentially arbitrary reference category (Easton et al. 1991; Greenland et al. 1999). In the above example, this coding would be achieved by eliminating the intercept term α from the model replacing it with an indicator $X_{1.5}$ for the (former) reference category of 15–35 servings,

$$X_{1.5} = 1 \text{ if 15–35 servings, 0 otherwise,}$$

and then using the disjoint-coding indicators for the remaining categories. The resulting model is

$$\ln[I(x_1, x_{1.5}, x_2, x_3)] = \beta_1 x_1 + \beta_{1.5} x_{1.5} + \beta_2 x_2 + \beta_3 x_3.$$

With this coding, coefficient antilogs such as $\exp(\beta_1)$ no longer represent rate ratios, but instead represent rates (if the data represent a full cohort) or expected case-control ratios (if the data represent a case-control study). The advantage is that plots of the estimated antilogs against the category scores, along with their confidence limits, will provide a more balanced picture of statistical uncertainty about the trend.

30.5.2 Regression with Category Scores

A common practice in epidemiology is to divide each covariate into categories, assign a score to each category, and enter scores into the model instead of the original variable values. Ordinal scores or codes (e.g., 1, 2, 3, 4, 5 for a series of five categories) should be avoided, as they can yield quantitatively meaningless dose-response curves and harm the power and precision of the results (Lagakos 1988; Greenland 1995b, c). Category midpoints can be much less distortive but are not defined for open-ended categories; category means or medians can be even less distortive and are defined for open-ended categories.

Unfortunately, if there are important non-linear effects within categories, no simple scoring method will yield an undistorted dose-response curve, nor will it achieve the power and precision obtainable by entering the uncategorized covariates into the model (Greenland 1995b, c). We thus recommend that when possible, categories be kept narrow and that scores be derived from category means or medians, rather than from midpoints or (worse) ordinal scores. We further recommend that one examine models with uncategorized covariates whenever effects are clearly present.

30.5.3 Power Models

Another approach to trend analysis and confounder control is to use multiple power terms for each regressor. The resulting model is usually called a *polynomial model* or *power model* (Ruppert et al. 2003). Such an approach does not require categorization but does require care in selection of terms. Traditionally, the powers used are positive integers (e.g., x_1, x_1^2, x_1^3), but fractional powers may also be used (Royston and Sauerbrei 2008). As an illustration, suppose X_1 represents the actual number of servings per week (instead of an indicator). We could model trends across this regressor by using X_1 in the model along with the following powers of X_1:

$$X_2 = X_1^{1/2} = \text{square root of } \mathrm{X}_1,$$
$$X_3 = X_1^2 \quad = \text{square of } \mathrm{X}_1.$$

The multiple-regression model

$$\ln[I(x_1, x_2, x_3)] = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3$$

is now just another way of writing the power model

$$\ln[I(x_1)] = \alpha + \beta_1 x_1 + \beta_2 x_1^{1/2} + \beta_3 x_1^2. \tag{30.42}$$

We can plot fitted rates from this model using very fine spacings to produce a *smooth curve* as an estimate of rate trends across X_1. As always, we may also include confounders in the model and plot model-adjusted trends.

Power models have several advantages over categorical models. Most importantly, they make use of information about differences within categories, which is ignored by categorical models and categorical analyses (Greenland 1995a, b, c). Thus, they can provide a more complete picture of trends across exposure and more thorough control of confounders. They also provide a more smooth picture of trends. One disadvantage of power models is a potentially greater sensitivity of estimates to *outliers,* that is, persons with unusual values or unusual *combinations* of values for the regressors. As discussed below, this problem can be partially addressed by performing delta-beta analysis and by switching to other model forms such as splines.

30.5.4 Regression Splines

Often it is possible to combine the advantages of categorical and power models through the use of *spline models.* Such models can be defined in a number of equivalent ways, and we present only the simplest. In all approaches, one first categorizes the regressor, as in categorical analysis (although fewer, broader categories may be sufficient in a spline model). The boundaries between these categories are called the *knots* or *join points* of the spline. Next, one chooses the *power* (or order) of the spline, according to the flexibility one desires within the categories (higher powers allow more flexibility).

Use of category indicators corresponds to a zero-power spline, in which the trend is flat within categories but may jump suddenly at the knots; thus, category-indicator models are just special and unrealistic types of spline models. In a first-power or *linear* spline, the trend is modeled by a series of connected line segments. The trend within each category corresponds to a line segment; the slope of the trend may change only at the knots, and no sudden jump in risk (discontinuity in trend) can occur.

To illustrate how a linear spline may be represented, let X_1 again be "number of servings per week" but now define

$$X_2 = X_1 - 14 \text{ if } \mathrm{X}_1 > 14, 0 \text{ otherwise}$$
$$X_3 = X_1 - 35 \text{ if } \mathrm{X}_1 > 35, 0 \text{ otherwise}$$

Then the log-linear rate model

$$\ln[I(x_1, x_2, x_3)] = \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 \tag{30.43}$$

will produce a log-rate trend that is a series of three line segments that are connected at the knots (category boundaries) of 14 and 35. To see this, note that when X_1 is less than 14, X_2 and X_3 are zero, so the model simplifies to a line with slope β_1:

$$\ln[I(x_1, x_2, x_3)] = \alpha + \beta_1 x_1$$

in this range. When X_1 is greater than 14 but less than 35, the model simplifies to a line with slope $\beta_1 + \beta_2$:

$$\begin{aligned}\ln[I(x_1, x_2, x_3)] &= \alpha + \beta_1 x_1 + \beta_2 x_2\\ &= \alpha + \beta_1 x_1 + \beta_2(x_1 - 14)\\ &= \alpha - 14\beta_2 + (\beta_1 + \beta_2)x_1.\end{aligned}$$

Finally, when X_1 is greater than 35, the model becomes a line with slope $\beta_1 + \beta_2 + \beta_3$:

$$\begin{aligned}\ln[I(x_1, x_2, x_3)] &= \alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3\\ &= \alpha + \beta_1 x_1 + \beta_2(x_1 - 14) + \beta_3(x_1 - 35)\\ &= \alpha - 14\beta_2 - 35\beta_3 + (\beta_1 + \beta_2 + \beta_3)x_1.\end{aligned}$$

Thus, β_1 is the slope of the spline in the first category, β_2 is the change in slope in going from the first to second category, and β_3 is the change in slope in going from the second to third category.

The trend produced by a linear spline is generally more realistic than a categorical trend, but can suddenly change its slope at the knots. To smooth out such sudden changes, we may increase the order of the spline. Increasing the power to 2 produces a second-power or *quadratic* spline, which comprises a series of parabolic curve segments smoothly joined together at the knots. To illustrate how such a trend may be represented, let X_1, X_2, and X_3 be as just defined. Then the model

$$\ln[I(x_1, x_2, x_3)] = \alpha + \beta_1 x_1 + \gamma_1 x_1^2 + \gamma_2 x_2^2 + \gamma_3 x_3^2 \tag{30.44}$$

will produce a log-rate trend that is a series of three parabolic segments smoothly connected at the knots of 14 and 35. The coefficient γ_1 corresponds to the curvature of the trend in the first category, while γ_2 and γ_3 correspond to the changes in curvature when going from the first to second and second to third category. A still smoother curve could be fit by using a third-power or *cubic* spline, but for epidemiological purposes the quadratic spline is often smooth and flexible enough.

Although for simplicity it was not done in the above examples, as mentioned earlier, it is best to recenter quantitative variables before model fitting. For splines, this will require recentering the knots as well. Thus, suppose we begin analysis by subtracting 20 from number of servings X_1. The knots to create X_2 and X_3 from this recentered X_1 (which is number of servings −20) must then also be recentered to become $14 - 20 = -6$ and $35 - 20 = 15$. With this recentering $X_1 = X_2 = X_3 = 0$, and so the intercept α will be the log-rate at 20 servings.

One disadvantage of quadratic and cubic splines is that the curves in the end categories (tails) may become very unstable, especially if the category is open-ended. This instability may be reduced by *restricting* one or both of the end categories to be a line segment rather than a curve. To restrict the lower category to be linear in a quadratic spline, we need only drop the *first* quadratic term $\gamma_1 x_1^2$ from the model; to restrict the upper category, we must subtract the *last* quadratic term from all the quadratic terms and drop the last term out of the model. To illustrate an upper category restriction, suppose we wish to restrict the above quadratic spline model for log-rates (Eq. 30.44) so that it is linear in the upper category only. Define

$$\begin{aligned} Z_1 &= X_1 = \text{number of servings per week}, \\ Z_2 &= X_1^2 - X_3^2, \\ Z_3 &= X_2^2 - X_3^2. \end{aligned}$$

Then the model

$$\ln[I(z_1, z_2, z_3)] = \alpha + \beta_1 z_l + \beta_2 z_2 + \beta_3 z_3 \tag{30.45}$$

will produce a log-rate trend that comprises smoothly connected parabolic segments in the first two categories ("<14" and "15–35"), and a line segment in the last category (">35") that is smoothly connected to the parabolic segment in the second category. (If we also wanted to force the log-rate curve in the first category to follow a line, we would drop Z_2 from the model.)

To plot or tabulate a spline curve from a given spline model, we select a set of X_1 values spaced across the range of interest, compute the set of spline terms for each X_1 value, combine these terms with the coefficients in the model to get the model-predicted outcomes, and plot these predictions. To illustrate, suppose X_1 is servings per week and we wish to plot model 45 with $\alpha = -6.00$, $\beta_1 = -0.010$, $\beta_2 = -0.001$, and $\beta_3 = 0.001$ over the range 0–50 servings per week in 5-serving increments. We then compute Z_1, Z_2, Z_3 at $0, 5, 10, \ldots, 50$ servings per week and compute the predicted rate

$$\exp(-6.00 - 0.010z_1 - 0.001z_2 + 0.001z_3)$$

at each set of Z_1, Z_2, Z_3 values and plot these predictions against the corresponding X_1 values 0, 5, 10, ..., 50. For example, at $X_1 = 40$, we get $Z_1 = 40$, $Z_2 = 40^2$–$(40–35)^2 = 1575$, and $Z_3 = (40–14)^2$–$(40–35)^2 = 651$ for a predicted rate of

$$\exp[-6.00 - 0.010(40) - 0.001(1575) + 0.001(651)] = 2/1000 \text{ year.}$$

As with other trend models, we may obtain model-adjusted trends by adding confounder terms to our spline models. The confounder terms may be splines or any other form we prefer; spline plotting will be simplified, however, if the confounders are centered before they are entered into the analysis, for then the above plotting method may be used without modification.

For discussion of splines and their extensions and relations to more general regression techniques, see, for example, Hastie et al. (2009), Harrell (2001), or Ruppert et al. (2003).

30.5.5 Exclusion of Individuals from Trend Fitting

In many settings, there may be concern that individuals at a particular exposure level are qualitatively different from other individuals with respect to unmeasured or poorly measure risk factors. If such differences exist, inclusion of these individuals in the analysis will distort a fitted trend curve away from the true causal dose-response form. For example, in studies of alcohol and health outcomes, there may be concern that non-drinkers of alcohol include many individuals who do not drink due to poor health, thus creating elevated risk among non-drinkers and the confounded appearance of a protective effect of alcohol.

A simple way to address such concerns is to exclude such individuals from trend estimation. This exclusion will however reduce the number of individuals available for measured-confounder control (note that the effects of measured confounders need not be estimated in an unbiased fashion in order to control confounding; they may reflect unmeasured confounder effects as well). An alternative is to then include the individuals along with an indicator variable that separates them from the trend curve. In the alcohol example, this would involve adding an indicator for "non-drinker" to the model. The resulting fitted trend for alcohol would exclude non-drinkers, but the latter would still contribute to estimating, for example, age and sex effects. For further discussion of this strategy, see Greenland and Poole (1995).

30.5.6 Models for Trend Variation

We may allow trends to vary across regressor levels by entering products among regressor terms. For example, suppose X_1, X_2, X_3 are power terms for fruit and vegetable intake, while W_1, W_2, W_3, and W_4 are spline terms for age. To allow the fruit-vegetable trend in log-rates to vary with age, we could enter into the model all $3 \cdot 4 = 12$ products of the X_j and W_k, along with the X_j and W_k. If in addition there was an indicator $Z_1 = 1$ for female, 0 for males, the resulting model would be

$$\begin{aligned}
&\ln[R(x_1, x_2, x_3, w_1, w_2, w_3, w_4, z_1)]\\
&=\alpha + \beta_1 x_1 + \beta_2 x_2 + \beta_3 x_3 + \beta_4 w_1 + \beta_5 w_2 + \beta_6 w_3 + \beta_7 w_4 + \beta_8 z_1\\
&\quad + \gamma_{11} x_1 w_1 + \gamma_{12} x_1 w_2 + \ldots + \gamma_{33} x_3 w_3 + \gamma_{34} x_3 w_4.
\end{aligned}$$

The same model form may be used if X_1, X_2, and X_3 and W_1, W_2, W_3, and W_4 represent category indicators or other terms for fruit-vegetable intake and age.

Models with products among multiple trend terms can be difficult to fit and may yield quite unstable results unless large numbers of cases are observed. Given enough data, however, such models can provide more realistic pictures of dose-response relations than can simpler models. Results from such models may be easily interpreted by plotting or tabulating the fitted trends for the key exposures of interest at various levels of the “modifying” regressors. In the above example, this process would involve plotting the model-fitted rates against fruit and vegetable intake for each of several ages (e.g., for ages evenly spaced within the range of case ages).

30.6 Extensions of Logistic Models

Outcomes that are polytomous or continuous are often analyzed by reducing them to just two categories and applying a logistic model. For example, CD4 counts might be reduced to the dichotomy $\leq$200, $>$200; cancer outcomes might be reduced to cancer and no cancer. Alternatively, multiple categories may be created with one designated as a referent and the other categories compared one at a time to the referent using separate logistic models for each comparison. While not necessarily invalid, these approaches disregard the information contained in differences within categories, in differences between non-reference categories, and in ordering among the categories. As a result, models specifically designed for polytomous or continuous outcomes can yield more precision and power than simple dichotomous-outcome analyses.

This section briefly describes several extensions of the multiple-logistic model (30.28) to polytomous and ordinal outcomes. Analogous extensions of other models are possible.

30.6.1 Polytomous Logistic Models

Suppose an outcome variable Y has $I+1$ mutually exclusive outcome categories or levels $y_0, \ldots, y_I$, where category y_0 is considered the reference category. For example, in a case-control study of relations of exposures to types of cancer, Y is a disease outcome variable, with $y_0 =$ all control as the reference category, and I other categories $y_1, \ldots, y_I$, which correspond to the cancer outcomes (leukemia, lymphoma, lung cancer, etc.). Let $R_i(\boldsymbol{x})$ denote the average risk of falling in outcome category $Y_i (i = 1, \ldots, I)$ given that the regressors $\boldsymbol{X}$ equal $\boldsymbol{x}$; that is, let

$$R_i(\boldsymbol{x}) = \Pr(Y = y_i | \boldsymbol{X} = \boldsymbol{x}).$$

The *polytomous logistic model* for this risk is then

$$R_i(\boldsymbol{x}) = \frac{\exp(\alpha_i + x\beta_i)}{1 + \sum\limits_{j=1}^{I} \exp(\alpha_j + x\beta_j)}. \tag{30.46}$$

This is a model for the risk of falling in cancer category y_i. When Y has only two levels, I equals 1, and so formula 46 simplifies to the binary multiple-logistic model (30.28).

Model 46 represents I separate logistic risk equations, one for each non-reference outcome level $y_1, \ldots, y_I$. Each equation has its own intercept α_i and vector of coefficients $\boldsymbol{\beta}_i = (\beta_{i1}, \ldots, \beta_{in})$ so that there is a distinct coefficient β_{ik} corresponding to every combination of a regressor X_k and non-reference outcome level $y_i (i = 1, \ldots, I)$. Thus, with n regressors in $\boldsymbol{X}$, the polytomous logistic model involves I intercepts and $I \cdot n$ regressor coefficients. For example, with seven non-reference outcome levels and three regressors, the model would involve seven intercepts and $7 \cdot 3 = 21$ regressor coefficients, for a total of 28 model parameters.

The polytomous logistic model can be written more simply as a model for the odds. To see this, note that the risk of falling in the reference category must equal one minus the sum of the risks of falling in the non-reference categories:

$$\begin{aligned} R_0(\boldsymbol{x}) &= \Pr(Y = y_0 | \boldsymbol{X} = \boldsymbol{x}) \\ &= 1 - \sum_{i=1}^{I} \exp(\alpha_i + \boldsymbol{x\beta}_i) / [1 + \sum_{j=1}^{I} \exp(\alpha_j + \boldsymbol{x\beta}_j)] \\ &= 1/[1 + \sum_{j=1}^{I} \exp(\alpha_j + \boldsymbol{x\beta}_j)]. \end{aligned} \tag{30.47}$$

Dividing Eq. 30.47 into Eq. 30.46, we get a model for $O_i(\boldsymbol{x}) = R_i(\boldsymbol{x})/R_0(\boldsymbol{x})$ = the odds of falling in outcome category y_i versus category y_0:

$$\begin{aligned} O_i(\boldsymbol{x}) &= \frac{\exp(\alpha_i + \boldsymbol{x\beta}_i)/[1 + \sum_j \exp(\alpha_j + \boldsymbol{x\beta}_j)]}{1/[1 + \sum_j \exp(\alpha_j + \boldsymbol{x\beta}_j)} \\ &= \exp(\alpha_i + \boldsymbol{x\beta}_i). \end{aligned} \tag{30.48}$$

This form of the model shows that the polytomous model is equivalent to assuming I binary logistic models comparing each of the I non-reference categories to the reference category y_0 (see Eq. 30.11). The advantage of combining the models into one formula comes in the fitting stage: Fitting Eq. 30.46 produces more precise estimates than fitting I equations separately.

Equation 30.48 also provides a familiar interpretation for the coefficients. Suppose $\boldsymbol{x}_1$ and $\boldsymbol{x}_0$ are two different vectors of values for the regressors $\boldsymbol{X}$. Then the ratio of the odds of falling in category y_i versus y_0 when $\boldsymbol{X} = \boldsymbol{x}_1$ and $\boldsymbol{X} = \boldsymbol{x}_0$ is

$$\frac{O_i(\boldsymbol{x}_1)}{O_i(\boldsymbol{x}_0)} = \frac{\exp(\alpha_i + \boldsymbol{x}_1\boldsymbol{\beta}_i)}{\exp(\alpha_i + \boldsymbol{x}_0\boldsymbol{\beta}_i)} = \exp[(\boldsymbol{x}_1 - \boldsymbol{x}_0)\boldsymbol{\beta}_i].$$

From this equation, we see that the antilog $\exp(\beta_{ik})$ of a coefficient β_{ik} corresponds to the proportionate change in the odds of outcome i when the regressor X_k increases by one unit.

The polytomous logistic model is most useful when the levels of Y have no meaningful order, as with the cancer types. For further reading about the model, see McCullagh and Nelder (1989) and Hosmer and Lemeshow (2000).

30.6.2 Ordinal Logistic Models

Suppose that the levels $y_0, \ldots, y_I$ of Y follow a natural order. Order arises, for example, when Y is a clinical scale, such as y_0 = normal, y_1 = dysplasia, y_2 = neoplasia, rather than just a cancer indicator; Y is a count, such as number of malformations found in an individual; or the Y levels represent categories of a physical quantity, such as CD4 count (e.g., >500, 200–500, <200). There are at least four different ways to extend the logistic model to such outcomes.

Recall that the logistic model is equivalent to an exponential odds model. The first extension uses an exponential model to represent the odds of falling in outcome category y_i versus falling in category y_{i-1} (the next lowest category):

$$\frac{R_i(\boldsymbol{x})}{R_{i-1}(\boldsymbol{x})} = \frac{\Pr(Y = y_i|\boldsymbol{X} = \boldsymbol{x})}{\Pr(Y = y_{i-1}|\boldsymbol{X} = \boldsymbol{x})} = \exp({\alpha_i}^* + \boldsymbol{x\beta}^*) \tag{30.49}$$

for $i = 1, \ldots, I$. This may be called the *adjacent-category logistic model,* because taking logarithms of both sides yields the equivalent *adjacent-category logit* model

(Agresti 2002). It is a special case of the polytomous logistic model: From Eq. 30.48, the polytomous logistic model implies that

$$\frac{R_i(x)}{R_{i-1}(x)} = \frac{R_i(x)/R_0(x)}{R_{i-1}(x)/R_0(x)} = \frac{\exp(\alpha_i + \boldsymbol{x\beta}_i)}{\exp(\alpha_{i-1} + \boldsymbol{x\beta}_{i-1})}$$
$$= \exp[(\alpha_i - \alpha_{i-1}) + \boldsymbol{x}(\boldsymbol{\beta}_i - \boldsymbol{\beta}_{i-1})].$$

The adjacent-category logistic model sets $\alpha_i{}^* = \alpha_i – \alpha_{i-1}$ and forces the I coefficient differences $\boldsymbol{\beta}_i – \boldsymbol{\beta}_{i-1} (i = 1,\ldots, I)$ to equal a common value $\boldsymbol{\beta}^*$. If there is a natural distance d_i between adjacent outcome categories y_i and y_{i-1} (such as the difference between the category means), the model can be modified to use these distances as follows:

$$R_i(\boldsymbol{x})/R_{i-1}(\boldsymbol{x}) = \exp(\alpha_i{}^* + \boldsymbol{x\beta}^* d_i) \tag{30.50}$$

for $i = 1, \ldots, I$. This model allows the coefficient differences $\boldsymbol{\beta}_i – \boldsymbol{\beta}_{i-1}$ to vary with the distances d_i between categories.

The second extension uses an exponential model to represent the odds of falling *above category* y_i versus*falling in or below* category y_i:

$$\frac{\Pr(Y > y_i|\boldsymbol{X} = \boldsymbol{x})}{\Pr(Y \le y_i|\boldsymbol{X} = \boldsymbol{x})} = \exp(\alpha_i{}^* + \boldsymbol{x\beta}^*), \tag{30.51}$$

where $i = 0, \ldots, I$. This is called the *cumulative-odds* or *proportional-odds* model. It can be derived by assuming that Y was obtained by categorizing a special type of continuous variable.

The third extension uses an exponential model to represent the odds of falling *above outcome* category y_i versus *in* category y_i:

$$\frac{\Pr(Y > y_i|\boldsymbol{X} = \boldsymbol{x})}{\Pr(Y = y_i|\boldsymbol{X} = \boldsymbol{x})} = \exp(\alpha_i^* + \boldsymbol{x\beta}^*), \tag{30.52}$$

where $i = 0, \ldots, I$. This is called the *continuation-ratio model.* When Y represents the time of disease incidence, Eq. 30.52 is the discrete-time analogue of the Cox model (30.20) but with coefficient signs reversed.

The fourth extension uses an exponential model to represent the odds of falling *in* category y_i versus falling *below* y_i:

$$\frac{\Pr(Y = y_i|\boldsymbol{X} = \boldsymbol{x})}{\Pr(Y < y_i|\boldsymbol{X} = \boldsymbol{x})} = \exp(\alpha_i^* + \boldsymbol{x\beta}^*), \tag{30.53}$$

where $i = 1, \ldots, I$. This model may be called the *reverse continuation-ratio model.* It can be derived by reversing the order of the Y levels in model (30.52), but in any given application, it is not equivalent to model (30.52) (Greenland 1994).

How does one choose from the variety of ordinal models? Certain guidelines may be of use, although none is compelling. First, the adjacent-category and cumulative-odds models are *reversible* in that only the signs of the coefficients change if the order of the Y levels is reversed. In contrast, the two continuation-ratio models are not reversible. This observation suggests that the continuation-ratio models may be more appropriate for modeling irreversible disease stages (e.g., osteoarthritic severity), whereas the adjacent-category and cumulative-odds models may be more appropriate for potentially reversible outcomes (e.g., blood pressure, cell counts) (Greenland 1994). Second, because the coefficients of adjacent-category models contrast pairs of categories, the model appears best suited for discrete outcomes with few levels (e.g., cell types along a normal-dysplastic-neoplastic scale). Third, because the cumulative-odds model can be derived from categorizing certain special types of continuous outcomes, it is often considered most appropriate when the outcome under study is derived by categorizing a single underlying continuum (e.g., blood pressure) (McCullagh and Nelder 1989). For a more detailed comparative discussion of ordinal logistic models and guidelines for their use, see Greenland (1994) and Ananth and Kleinbaum (1997).

All the above ordinal models simplify to the ordinary logistic model when there are only two outcome categories ($I = 2$). One advantage of the continuation-ratio models over their competitors is of special importance: Estimation of the coefficients $\boldsymbol{\beta}*$ in those models can be carried out if the levels of Y are numerous and sparse; Y may even be continuous. Thus, one can apply the continuation-ratio models without any categorization of Y. This advantage can be important because results from all the above models (including the cumulative-odds model) may be affected by the choice of the Y categories (Greenland 1994; Strömberg 1996). The only caution is that conditional (as opposed to unconditional) maximum likelihood must be used to fit the continuation-ratio model if the observed outcomes are sparsely scattered across the levels of Y (as would be inevitable if Y were continuous). See Greenland (1994) for further details and Cole and Ananth (2001) for further extensions of the model.

30.7 Generalized Linear Models

Consider again the general form of the exponential risk and rate models, $R(\boldsymbol{x}) = \exp(\alpha + \boldsymbol{x}\boldsymbol{\beta})$ and $I(\boldsymbol{x}) = \exp(\alpha + \boldsymbol{x}\boldsymbol{\beta})$ and the logistic risk model $R(\boldsymbol{x}) = \text{expit}$ $(\alpha + \boldsymbol{x}\boldsymbol{\beta})$. There is no reason why we cannot replace the "exp" in the exponential models or the "expit" in the logistic model by some other reasonable function. In fact, each of these models is of the general form

$$E(Y|\boldsymbol{x}) = f(\alpha + \mathbf{x}\boldsymbol{\beta}), \tag{30.54}$$

where f is some function that is smooth and strictly increasing (i.e., as $\alpha + \boldsymbol{x}\boldsymbol{\beta}$ gets larger, $f(\alpha + \boldsymbol{x}\boldsymbol{\beta})$ gets larger, but never jumps or bends suddenly).

For any such function f, there is always an inverse function g that "undoes" f, in the sense that $g[f(u)] = u$ whenever $f(u)$ is defined. Hence, a general form equivalent to Eq. 30.54 is

$$g[E(Y|\boldsymbol{x})] = \alpha + \boldsymbol{x\beta}. \tag{30.55}$$

A model of the form Eq. 30.55 is called a *generalized linear model.* The function g is called the *link function* for the model; thus, the link function is ln for the log-linear model and logit for the logit-linear model. The term $\alpha + \boldsymbol{x\beta}$ in it is called the *linear predictor* for the model and is often abbreviated η (Greek letter eta); that is, $\eta = \alpha + \boldsymbol{x\beta}$ by definition.

Subject to some technicalities concerning how to define the expected values, all the models we have discussed can be viewed as generalized linear models or transforms of them. Ordinary linear models (such as the linear risk model) are the simplest examples, in which *f* and *g* are both the identity function $f(u) = g(u) = u$, so that

$$E(Y|x) = \alpha + \boldsymbol{x\beta}.$$

The inverse of the exponential function exp is the natural-log function ln(u). Hence, the generalized linear forms of the exponential risk and rate models are the log-linear risk and rate models

$$\ln[R(\boldsymbol{x})] = \alpha + \boldsymbol{x\beta} \quad \text{and} \quad \ln[I(\boldsymbol{x})] = \alpha + \boldsymbol{x\beta};$$

that is, the exponential risk and rate models correspond to a natural-log link function because ln[exp(u)] = u. Similarly, the inverse of expit, the logistic function, is the logit function logit (u). Hence, the generalized linear form of the logistic risk model is the logit-linear risk model

$$\text{logit}[R(\boldsymbol{x})] = \alpha + \boldsymbol{x\beta};$$

that is, the logistic model corresponds to the logit link function because logit[expit(u)] = u.

The choices for f and g are virtually unlimited. In epidemiology, however, only the logit link $g(u) = \text{logit}(u)$ is in common use for risks, and only the log link $g(u) = \ln(u)$ is in common use for rates. In practice, these link functions are almost always the default and are sometimes the only options in commercial software for risk and rate modeling. Some packages, however, allow easy selection of linear risk, rate, and odds models, which use the identity link. Some software (e.g., GLIM) allows the user to define their own link function.

The choice of link function can have a profound impact on the shape of the trend or dose-response surface allowed by the model, especially if exposure is represented by only one or two terms. For example, if exposure is represented by a single term $\beta_1 x_1$ in a risk model, use of the identity link results in a linear risk model and a linear trend for risk, use of the log link results in an exponential (log-linear) risk model and an exponential trend for risk, and use of a logit link results in a logistic model and an exponential trend for the odds. Generalized linear models encompass a broader range than the linear, log-linear, and logistic forms, however. One example is the complementary log-log risk model,

$$R(x) = 1 - \exp[-\exp(\alpha + \boldsymbol{x\beta})],$$

which translates to the generalized linear form

$$\ln[-\ln(l - R(\boldsymbol{x}))] = \alpha + \boldsymbol{x\beta}.$$

This model corresponds to the link function ln[−ln(l−u)] and arises naturally in certain biology experiments. For further reading on this and other generalized linear models, see McCullagh and Nelder (1989).

30.8 Model Searching

How do we find a model or set of models acceptable for our purposes? There are far too many model forms to allow us to examine most or even much of the total realm of possibilities. There are several systematic, mechanical, and traditional algorithms for finding models (such as stepwise and best-subset regression) that lack logical or statistical justification and that perform poorly in theoretical, simulation, and case studies; see Sclove et al. (1972), Bancroft and Han (1977), Draper et al. (1979), Freedman (1983), Flack and Chang (1987), Freedman et al. (1988), Hurvich and Tsai (1990), Faraway (1992), Weiss (1995), Greenland (1993, 2000a, 2001), Harrell (2001), Viallefont et al. (2001), and Steyerberg (2009, Chap. 11).

One serious problem is that the p-values and standard errors obtained when variables are selected using significance-testing criteria (such as "F-to-enter" and "F-to-remove") will be downwardly biased, usually to a large degree. In particular, standard errors obtained from the selected model underestimate the standard deviations of the point estimates obtained by applying the algorithms across different random samples. As a result, the algorithms will tend to yield p-values that are too small and confidence intervals that are too narrow (and hence fail to cover the true coefficient values with the stated frequency). Unfortunately, significance-testing criteria are the basis for most variable-selection procedures in standard packaged software.

Other criteria for selecting variables, such as "change-in-point-estimate" criteria, do not necessarily perform better than significance testing (Maldonado and Greenland 1993a). Viable alternatives to significance testing in model selection have emerged only gradually with recent advances in computing and with deeper insights into the problem of model selection. We first outline the traditional approaches after reinforcing one of the most essential and neglected starting points for good modeling: laying out existing information in a manner that can help the search avoid models in conflict with established facts. A powerful alternative to model selection is provided by hierarchical regression, also known as multilevel, mixed-model, penalized, ridge, shrinkage, or random-coefficient regression (Greenland 2000a, b; Harrell 2001; Ruppert et al. 2003).

30.8.1 Role of Prior Information

The dependence of regression results on the chosen model can be either an advantage or a drawback. The advantage comes from the fact that use of a model structure capable of reasonably approximating reality can elevate the accuracy of the estimates over those from the corresponding tabular analysis. The drawback comes from the fact that use of a model incapable of even approximating reality can decrease estimation accuracy below that of tabular analysis.

This duality underscores the desirability of using flexible (and possibly complex) models. One should take care to avoid models that are entirely unsupported by background knowledge. For example, in a cohort study of lung cancer, it is reasonable to restrict rates to increase with age because there is enormous background literature documenting that this trend is found in all human populations. In contrast, one would want to avoid restricting cardiovascular disease (CVD) rates to strictly increase with alcohol consumption because there are considerable data to suggest the alcohol-CVD relation is not strictly increasing (Maclure 1993).

Prior knowledge about most epidemiological relations is usually too limited to provide much guidance in model selection. A natural response might be to use models as flexible as possible (a flexible model can reproduce a wide variety of curves and surfaces). Unfortunately, flexible models have limitations. The more flexible the model, the larger the sample needed for the usual estimation methods (such as maximum likelihood) to provide approximately unbiased coefficient estimates. Also, after a certain point, increasing flexibility may increase variability of estimates so much that the accuracy of the estimates is decreased relative to estimates from simpler models, despite the greater faithfulness of the flexible model to reality. As a result, it is usual practice to employ models that are severely restrictive in arbitrary ways, such as models without product terms or models that set "non-significant" coefficients to zero (Robins and Greenland 1986). Hierarchical methods can help alleviate some of these problems by allowing one to fit larger models than one can with ordinary methods (Greenland 2000b, 2008a, b).

Fortunately, estimates obtained from the most common epidemiological regression models, exponential (log-linear) and logistic models, retain some interpretability even when the underlying (true) regression function is not particularly close to those forms (Maldonado and Greenland 1993b; Greenland and Maldonado 1994). For example, under reasonably common conditions, rate-ratio or risk-ratio estimates obtained from those models can be interpreted as approximate estimates of standardized rate or risk ratios, using the total source population as the standard (Greenland and Maldonado 1994). To ensure such interpretations are reasonable, the model used should at least be able to replicate qualitative features of the underlying regression function. For example, if the underlying regression may have a reversal in the slope of the exposure-response curve, we should want to use a model capable of exhibiting such reversal (even if it cannot replicate the exact shape of the true curve).

A major problem for epidemiology is that key variables may be unmeasured or poorly measured. No conventional method can account for these problems. Unmeasured variables may be modeled using prior information on their relation to measured variables, but the results will be entirely dependent on that information (Leamer 1978; Greenland 2003, 2005b, 2009a, b; Gustafson 2005). Occasionally, measurement-error information may be in the form of data that can be used in correction techniques (Gustafson 2003; Carroll et al. 2006; Greenland and Lash 2008; cf. chapter ▸Measurement Error of this handbook); otherwise, sensitivity analyses or special modeling methods will be needed (Greenland and Lash 2008; Greenland 2005b, 2009a, b; Lash et al. 2009; cf. chapter ▸Sensitivity Analysis and Bias Analysis of this handbook).

30.8.2 Selection Strategies

Even with ample prior information, there will always be an overwhelming number of model choices, and so model search strategies will be needed. Many strategies have been proposed, although none has been fully justified.

Some strategies begin by specifying a minimal model form that is among the most simple credible forms. Here "credible" means "compatible with available information." Thus, we start with a model of minimal computational or conceptual complexity that does not conflict with background information. There may be many such models; in order to help insure that our analysis is credible to the intended audience, however, the starting model form should be one that most researchers would view as a reasonable possibility.

To specify a simple yet credible model form, one needs some knowledge of the background scientific literature on the relations under study. This knowledge would include information about relations of potential confounders to the study exposures and study diseases as well as relations of study exposures to the study diseases. Thus, specification of a simple yet credible model can demand much more initial effort than is routinely used in model specification.

Once we have specified our minimal starting model, we can add complexities or terms that seem necessary in light of the data. Common criteria for adding terms are discussed below in Sect. 30.10.3 "Tests of Fit." Such a search process is sometimes called an *expanding* search (Leamer 1978). Its chief drawback is that often there are too many possible expansions to consider within a reasonable length of time. If, however, one neglects to consider any possible expansion, one risks missing an important shortcoming of the initial model. For example, if our minimal model involves only single "first-order" terms ("main effects") for 12 variables, we would have $\binom{12}{2}=66$ possible two-way products among these variables to consider, as well as 12 quadratic terms, for a total of 78 possible expansions with just one second-order term. An analyst may not have the time, patience, or resources to examine all the possibilities in detail; this predicament usually leads to use of automatic significance-testing procedures to select additional terms, which (as referenced above) can lead to distorted statistics.

Some strategies begin by specifying an initial model form that is flexible enough to approximate any credible model form. A flexible starting point can be less demanding than a simple one in terms of need for background information.

For example, rather than concern ourselves with what the literature suggests about the shape of a dose-response curve, we can employ a starting model form that can approximate a wide range of curves. Similarly, rather than concern ourselves with what the literature suggests about joint effects, we can employ a form that can approximate a wide range of joint effects. We can then search for a simpler but adequate model by removing from the flexible model any complexities that appear unnecessary in light of the data. Such a search process, based on simplifying a complex model, is sometimes called a *contracting* or simplifying search (Leamer 1978). The same criteria for adding terms can instead be used for deleting terms; again, see Sect. 30.10.3 "Tests of Fit."

The chief drawback of a purely contracting search is that a sufficiently flexible prior model may be too complex to fit to the available data. This is because more complex models generally involve more parameters; with more parameters in a model, more data are needed to produce trustworthy point and interval estimates. Standard model-fitting methods may yield biased estimates or may completely fail to yield any estimates (e.g., not converge) if the fitted model is too complex. For example, if our flexible model for 12 variables contains all first- and second-order terms, there will be 12 first-order plus 12 quadratic plus 66 product terms, for a total of 90 coefficients. Fitting this model may be well beyond what our data or computing resources can support.

Because of potential fitting problems, contracting searches begin with something much less than a fully flexible model. Some begin with a model as flexible as can be fit or maximal model. As with minimal models, maximal models are not unique. In order to produce a model that can be fit, one may have to limit flexibility of dose-response, flexibility of joint effects, or both. It is also possible to start a model search anywhere in between the extremes of minimal and maximal models and proceed by expanding as seems necessary and contracting as seems reasonable based on the data (although again, resource limitations usually lead to mechanical use of significance tests for this process). Unsurprisingly, such *stepwise* searches share some advantages and disadvantages with purely expanding and purely contracting searches. Like other searches, care should be taken to insure that the starting and ending points do not conflict with prior information.

The results obtained from a model search can be very sensitive to the choice of starting model. One can check for this problem by conducting several searches, starting at different models. However, there are always too many possible starting models to check them all. Thus, if one has many variables (and hence many possible models) to consider, model search strategies will always risk producing a misleading model form. A traditional but potentially cumbersome way to address this problem is to present results from a number of different models, which leads into issues of how to select which models to present.

Modern methods to address this problem and other modeling issues can be found in the literature on statistical learning, for example, under topics such as cross-validation, model averaging, semi-parametric and non-parametric regression, smoothing, bootstrapping, algorithmic modeling, and boosting (Harrell 2001; Breiman 2001; Ruppert et al. 2003; Hastie et al. 2009). There is also a large Bayesian literature on the topic (e.g., Brown et al. 2002). Some of these methods reduce the selection problem by merging models or their results, for example, by averaging over competing models (Draper 1995; Raftery 1995; Carlin and Louis 2000; Viallefont et al. 2001; Hastie et al. 2009), by embedding the models in a hierarchical model that contains them all as special cases (Greenland 1999), or by using inferential methods that account for the selection process (Ye 1998; Harrell 2001; Ruppert et al. 2003; Efron 2004; Shen et al. 2004; Hastie et al. 2009).

30.9 Model Fitting

30.9.1 Residual Distributions

Different fitting methods can lead to different estimates; thus, in presenting results, one should specify the method used to derive the estimates. The vast majority of programs for risk and rate modeling use *maximum-likelihood* (ML) estimation, which is based on very specific assumptions about how the observed values of Y tend to distribute (vary) when the vector of regressors $\boldsymbol{X}$ is fixed at a given value $\boldsymbol{x}$. This distribution is called the error distribution or *residual distribution* of Y.

If Y is the person-time rate observed at a given level $\boldsymbol{x}$ of $\boldsymbol{X}$, and T is the corresponding observed person-time, it is conventionally assumed that the number of cases observed, $A = YT$, would tend to vary according to a Poisson distribution if the person-time were fixed at its observed value. Hence, conventional ML regression analysis of person-time rates is usually called *Poisson regression.* If, on the other hand, Y is the proportion of cases observed at a given level $\boldsymbol{x}$ of $\boldsymbol{X}$ out of a person-count total N, it is conventionally assumed that the number of cases observed, $A = YN$, would tend to vary according to a *binomial distribution* if the number of persons (person count) N was fixed at its observed value. Hence, conventional ML regression analysis of prevalence or incidence proportions (average risks) is sometimes called *binomial regression.* Note that if $N = 1$, the proportion diseased Y can be only 0 or 1; in this situation, $A = YN$ can be only 0 or 1 and is said to have a Bernoulli distribution (which is just a binomial distribution with $N = 1$). The binomial distribution can be deduced from the homogeneity and independence assumptions. Its use is inadvisable if there are important violations of either assumption, for example, if the disease is contagious over the study period.

If Y is the number of exposed cases in a 2 × 2 table, the conventionally assumed distribution for Y is the *hypergeometric;* ML fitting in this situation is usually referred to as *conditional maximum likelihood* (CML). CML fitting is the method used for conditional logistic regression; it is closely related to partial-likelihood methods, which are used for fitting Cox models in survival analysis.

Basics of maximum likelihood in epidemiology can be found in Breslow and Day (1980, 1987), Hosmer and Lemeshow (2000), Jewell (2004), and Greenland and Rothman (2008). More advanced treatments of maximum likelihood and its extensions to partial, conditional, penalized, and other types of likelihood can be found in many books, including McCullagh and Nelder (1989), Harrell (2001), and Ruppert et al. (2003).

30.9.2 Overdispersion

What if the residual distribution of the observed Y does *not* follow the conventionally assumed residual distribution? Under a broad range of conditions, it can be shown that the resulting ML fitted values (ML estimates) will remain approximately unbiased if no other source of bias is present (White 1994). Nonetheless, the standard errors obtained from the program will be biased. In particular, if the actual variance of Y given $X = x$ (the *residual variance)* is larger than that implied by the conventional distribution, Y is said to suffer from *overdispersion* or *extravariation,* and the standard errors and p-values obtained from an ordinary maximum-likelihood regression program will be too small.

In Poisson regression, overdispersion is sometimes called "extra-Poisson variation"; in binomial regression, overdispersion is sometimes called "extrabinomial variation." Typically, such overdispersion arises when there is dependence among the recorded outcomes, as when the outcome Y is the number infected in a group, or Y is the number of times a person gets a disease. As an example, suppose Y is the number of eyes affected by glaucoma in an individual. In a natural population, $Y = 0$ for most people and $Y = 2$ for most of the remainder, with $Y = 1$ very infrequently. In other words, the Y values would be largely limited to the extremes of 0 and 2. In contrast, a binomially distributed variable with the same possible values (0, 1, or 2) and the same mean as Y would have a higher probability of 1 than 2 and hence a smaller variance than Y.

Various approaches have been developed to cope with potential overdispersion, most of which are based on modeling the residual distribution. One approach is to use maximum likelihood, but with a residual distribution that allows a broader range of variation for Y, such as the negative binomial in place of the Poisson or the beta-binomial in place of the binomial (McCullagh and Nelder 1989). Such approaches have been implemented in some software. Another, simpler approach is to model only the residual variance of Y, rather than completely specify the residual distribution, as in quasilikelihood or pseudolikelihood estimation (McCullagh and Nelder 1989; Ruppert et al. 2003). An even simpler approach uses robust ("sandwich") variance estimation (Harrell 2001; Ruppert et al. 2003), as is the norm in generalized estimating equation (GEE) methods (Diggle et al. 2002).

30.9.3 Sample-Size Considerations

One drawback of all the above fitting methods is that they depend on "large-sample" (asymptotic) approximations, which usually require that the number of parameters in the model is much less than the number of cases observed; a minimum of 10:1 for the case/parameter ratio is a common empirical criterion (e.g., Pike et al. 1980; Peduzzi et al. 1996), although in some examples, even that appears insufficient (Greenland et al. 2000). When the sample size is insufficient, highly distorted estimates may result.

Methods that do not use large-sample approximations (exact methods) can be used to fit certain models. These methods require the same strong distributional assumptions as maximum-likelihood methods. An example is exact logistic regression (Hirji 2006). Unfortunately, exact fitting methods for incidence and prevalence models have both computational and theoretical demands that have limited their use to only a narrow range of models. Also, they do not address all the problems arising from coefficient instability in small samples, such as failure to constrain the size of estimated relative risks (Greenland et al. 2000; Greenland 2006). Alternative approaches are available that meet these objections while providing approximately valid small-sample results. These alternatives include penalized likelihood estimation and related "shrinkage" methods of Stein estimation, random-coefficient regression, ridge regression, and Bayesian regression (Efron and Morris 1975; Copas 1983; Titterington 1985; Le Cessie and van Houwelingen 1992; Carlin and Louis 2000; Greenland 2000b, 2001, 2007; Harrell 2001; Ruppert et al. 2003).

30.9.4 Data Grouping and Count Data

The usual input to regression programs is in the form of an observed numerator of case counts and a corresponding denominator of counts or person-time, one pair for each observed value $\boldsymbol{x}$ of the vector of regressors $\boldsymbol{X}$. It is commonly thought that rate models such as Eq. 30.17 require the regressors to be grouped into categories. This is not so: Most rate-regression programs can make use of ungrouped regressor data, in which an individual record contains an indicator of whether the individual got disease, which serves as the case count (1 if the individual got disease, 0 if not) and also contains the person-time at risk observed for the person. The only issue is then whether there are sufficient data overall to allow the fitting methods to work properly (Greenland et al. 2000). Conversely, suppose that each component of $\boldsymbol{X}$ is a categorical (discrete) variable, such as marital status, parity, sex, and age category. The multiway contingency table formed by cross-classifying all subjects on each $\boldsymbol{X}$ component then has a cell for each value $\boldsymbol{x}$ of $\boldsymbol{X}$. Such tables are often analyzed using a log-linear model for the number of observations (subject count) A_x expected in cell $\boldsymbol{x}$ of the table, $\ln(A_x) = \alpha + \boldsymbol{x\beta}$. Although software for log-linear count modeling is available in some packages, count data can be easily analyzed using any program for Poisson (rate) regression, by entering A_x as the rate numerator at regressor value $\boldsymbol{x}$, and giving each count a person-time denominator of 1. This approach eliminates the need for special software and provides greater modeling flexibility than is available in many tabular-analysis packages.

30.10 Model Checking

It is important to check a fitted model against the data. The extent of these checks may depend on what purpose we wish the model to serve. At one extreme, we may only wish the fitted model to provide approximately valid *summary* estimates or trends for a few key relationships. For example, we might wish only to estimate the average increment in risk produced by a unit increase in exposure. At the other extreme, we may want the model to provide approximately valid *regressor-specific* predictions of outcomes, such as exposure-specific risks by age, sex, and ethnicity. The latter goal is more demanding and requires more detailed scrutiny of results, sometimes on a subject-by-subject basis.

Model diagnostics can detect discrepancies between data and a model only within the range of the data and then only where there are enough observations to provide adequate diagnostic power. For example, there is much controversy concerning the health effects of low-dose radiation exposure (exposures that are only modestly in excess of natural background levels). This controversy arises because the natural incidence of key outcomes (such as leukemia) is low, and few cases have been observed in low-dose cohorts. As a result, several proposed dose-response models "fit the data adequately" in the low-dose region in that each model passes the standard battery of diagnostic checks. Nonetheless, the health effects predicted by these models conflict to an important extent.

More generally, one should bear in mind that a good-fitting model is not the same as a correct model. In particular, a model may appear correct in the central range of the data, but produce grossly misleading predictions for combinations of covariate values that are poorly represented or absent in the data.

30.10.1 Tabular Checks

Both tabular methods (such as Mantel and Haenszel 1959) and regression methods produce estimates by merging assumptions about population structure (such as that of a common odds ratio or of an explicit regression model) with observed data. When an estimate is derived using a regression model, especially one with many regressors, it may become difficult to judge how much the estimate reflects the data and how much it reflects the model.

To investigate the source of results, we recommend one compare model-based results to the corresponding tabular (categorical-analysis) results. As an illustration, suppose we wish to check a logistic model in which X_1 is the exposure under study, and four other regressors X_2, X_3, X_4, X_5 appear in the model, with X_1, X_2, X_3 continuous, X_4, X_5 binary, and products among X_1, X_2, and X_4 in the model. Any regressor in a model must appear in the corresponding tabular analysis. Because X_2 and X_4 appear in products with X_1 and the model is logistic, they should be treated as modifiers of the X_1 odds ratio in the corresponding tabular analysis. X_3 and

X_5 do not appear in products with X_1 and so should be treated as pure confounders (adjustment variables) in the corresponding tabular analysis. Because X_1, X_2, X_3 are continuous in the model, they must have at least three levels in the tabular analysis so that the results can at least crudely reflect trends seen with the model. If all three of these regressors were categorized into four levels, the resulting table of disease (two levels) by all regressors would have $2 \times 4^3 \times 2^2 = 512$ cells and perhaps many zero cells.

From this table, we would attempt to compute 3 (for exposure strata 1,2,3, versus 0) adjusted odds ratios (e.g., Mantel-Haenszel) for each of the $4 \times 2 = 8$ combinations of X_2 and X_4, adjusting all $3 \times 8 = 24$ odds ratios for the $4 \times 2 = 8$ pure-confounder levels. Some of these 24 adjusted odds ratios might be infinite or undefined due to small numbers, which would indicate that the corresponding regression estimates are largely model projections. Similarly, the tabular estimates might not exhibit a pattern seen in the regression estimates, which would suggest that the pattern was induced by the regression model rather than the data. For example, the regression estimates might exhibit a monotone trend with increasing exposure even if the tabular estimates did not. Interpretation of such a conflict would depend on the context: If we were certain that dose-response was monotone (e.g., smoking and esophageal cancer), the monotonicity of the regression estimates would favor their use over the tabular results; in contrast, doubts about monotonicity (e.g., as with alcohol and coronary heart disease) would lead us to use the tabular results or search for a model that did not impose monotonicity.

30.10.2 Tests of Regression and R^2

Most programs supply a "test of regression" or "test of model," which is a test of the hypothesis that all the regression coefficients (except the intercept α) are zero. For instance, in the exponential rate model

$$I(\boldsymbol{x}) = \exp(\alpha + \boldsymbol{x}\boldsymbol{\beta}),$$

the "test of regression" provides a p-value for the null hypothesis that all the components of $\boldsymbol{\beta}$ are zero, that is, that $\beta_1 = \ldots = \beta_n = 0$. Similarly, the "test of R^2" provided by linear regression programs is just a test that all the regressor coefficients are zero. A small p-value from these tests suggests that the variation in outcomes observed across regressor values appears improbably large under the hypothesis that the regressors are unrelated to the outcome. Such a result suggests that at least one of the regressors is related to the outcome. It does *not,* however, imply that the model fits well or is adequate in any way.

To understand the latter point, suppose that $\boldsymbol{X}$ comprises the single indicator $X_1 = 1$ for smokers, 0 for non-smokers, and the outcome Y is average year risk of lung cancer. In most any study of reasonable size and validity, "the test of regression" (which here is just a test of $\beta_1 = 0$) would yield a small p-value. Nonetheless, the model would be inadequate to describe variation in risk because

Table 30.1 Hypothetical cohort data illustrating inappropriateness of R^2 for binary outcomes (see text)

	$X = 1$	$X = 0$
$Y = 1$	1,900	100
Total	100,000	100,000

Risk ratio = 19, $R^2 = 0.008$

it neglects amount smoked, age at start, and sex. More generally, a small p-value from the test of regression only tells us that at least one of the regressors in the model should be included in some form or another; it does not tell us which regressor or what form to use, nor does it tell us anything about what was left out of the model. Conversely, a large p-value from the "test of regression" does not imply that all the regressors in the model are unimportant or that the model fits well. It is always possible that transformations of those regressors would result in a small p-value, or that their importance cannot be discerned given the random error in the data.

A closely related mistake is interpreting the squared multiple-correlation coefficient R^2 for a regression as a goodness-of-fit measure. R^2 only indicates the proportion of Y variance that is attributable to variation in the fitted mean of Y. While $R^2 = 1$ (the largest possible value) does correspond to a perfect fit, R^2 can also be close to zero under a correct model if the residual variance of Y (i.e., the variance of Y around the true regression curve) is always close to the total variance of Y.

The preceding limitations of R^2 apply in general. Correlational measures such as R^2 can become patently absurd measures of fit or association when the regressors and regressand are discrete or bounded (Rosenthal and Rubin 1979; Greenland et al. 1986; Cox and Wermuth 1992; Greenland 1996). As an example, consider Table 30.1 showing a large association of a factor with a rare disease. The logistic model $R(x) = \text{expit}(\alpha + \beta x)$ fits these data perfectly because it uses two parameters to describe only two proportions. Furthermore, $X = 1$ is associated with a 19-fold increase in risk. Yet the correlation coefficient for X and Y (derived using standard formulas) is only 0.09, and the R^2 for the regression is only 0.008.

Correlation coefficients and R^2 can give even more distorted impressions when multiple regressors are present (Greenland et al. 1986, 1991). For this reason, we strongly recommend against their use as measures of association or effect when modeling incidence or prevalence.

30.10.3 Tests of Fit

Tests of model fit check for non-random incompatibilities between the fitted regression model and the data. To do so, however, these tests must assume that the fitting method used was appropriate; in particular, test validity may be sensitive to assumptions about the residual distribution that were used in fitting. Conversely, it is possible to test assumptions about the residual distribution, but these tests usually have little power to detect violations unless a parametric regression model is assumed. Thus, useful model tests cannot be performed without making some assumptions.

Many tests of regression models are *relative* in that they test the fit of an index model by assuming the validity of a more elaborate *reference* model that contains it. A test that assumes a relatively simple reference model (i.e., one that has only a few more coefficients than the index model) will tend to have better power than a test that assumes a more complex reference model, although it will be valid only under narrower conditions.

When models are fit by maximum likelihood (ML), a standard method for testing the fit of a simpler model against a more complex model is the *deviance test,* also known as the likelihood-ratio test. Suppose that X_1 represents cumulative dose of an exposure and that the index model we wish to test is

$$R(x_1) = \text{expit}(\alpha + \beta_1 x_1)$$

a simple linear-logistic model. When we fit this model, an ML program should supply either a "residual deviance statistic" $D(\tilde{\alpha}, \tilde{\beta}_1)$ or a "model log-likelihood" $L(\tilde{\alpha}, \tilde{\beta}_1)$, where $\tilde{\alpha}, \tilde{\beta}_1$ are the ML estimates for this simple model. Suppose we wish to test the fit of the index model taking as the reference the fractional-polynomial logistic model

$$R(x_1) = expit(\alpha + \beta_1 x_1 + \beta_2 x_1^{1/2} + \beta_3 x_1^2).$$

We then fit this model and get either the residual deviance $D(\hat{\alpha}, \hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3)$ or the log-likelihood $L(\hat{\alpha}, \hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3)$ for the model, where $\hat{\alpha}, \hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3$ are the ML estimates for this power model. The deviance statistic for testing the linear-logistic model against the power-logistic model (i.e., for testing $\beta_2 = \beta_3 = 0$) is then

$$\Delta D(\beta_2, \beta_3) = D(\tilde{\alpha}, \tilde{\beta}_1) - D(\hat{\alpha}, \hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3).$$

This statistic is related to the model log-likelihoods by the equation

$$\Delta D(\beta_2, \beta_3) = -2[L(\tilde{\alpha}, \tilde{\beta}_1) - L(\hat{\alpha}, \hat{\beta}_1, \hat{\beta}_2, \hat{\beta}_3)]$$

(McCullagh and Nelder 1989). If the linear-logistic model is correct (so that $\beta_2 = \beta_3 = 0$) and the sample is large enough, this statistic has an approximate χ^2 distribution with 2 degrees of freedom, which is the difference in the number of parameters in the two models.

A small p-value from this statistic suggests that the linear-logistic model is inadequate or fits poorly; in some way, either or both the terms $\beta_2 x_1^{1/2}$ and $\beta_3 x_1^2$ capture deviations of the true regression from the linear-logistic model. A large p-value does *not,* however, imply that the linear-logistic model is adequate or fits well; it means only that no need for the terms $\beta_2 x_1^{1/2}$ and $\beta_3 x_1^2$ was detected by the test. In particular, a large p-value from this test leaves open the possibility that $\beta_2 x_1^{1/2}$ and $\beta_3 x_1^2$ are important for describing the true regression function, but the test failed to detect this condition; it also leaves open the possibility that some other terms not present in the reference model may be important in the same sense. These unexamined terms may involve X_1 or other regressors.

Now consider a more general description. Suppose that we wish to test an index model against a reference model in which it is nested (contained) and that this reference model contains p more unknown parameters (coefficients) than the index model. We fit both models and obtain either residual deviances of D_i and D_r for the index and reference models or log-likelihoods L_i and L_r. If the sample is large enough and the index model is correct, the deviance statistic

$$\Delta D = D_i - D_r = -2(L_i - L_r) \tag{30.56}$$

will have an approximate χ^2 distribution with p degrees of freedom. Again, a small p-value suggests that the index model does not fit well, but a large p-value does *not* mean the index model fits well, except in the very narrow sense that the test did not detect a need for the extra terms in the reference model.

Whatever the size of the deviance p-value, its validity depends on three assumptions (in addition to absence of the usual biases). First, it assumes that ML fitting of the models is appropriate; in particular, there must be enough subjects to justify use of ML to fit the reference model, and the assumed residual distribution must be correct. Second, it assumes that the reference regression model is approximately correct. Third, it assumes that the index model being tested is nested within the reference model. The third is the only assumption that is easy to check: In the previous example, we can see that the linear-logistic model is just the special case of the power-logistic model in which $\beta_2 = \beta_3 = 0$. In contrast, if we used the linear-logistic model as the index model (as above) but used the power-linear model

$$R(x_1) = \alpha + \beta_1 x_1 + \beta_2 x_1^{1/2} + \beta_3 x_1^2$$

as the reference model, the resulting deviance difference would be meaningless because the latter model does *not* contain the linear-logistic model as a special case.

Comparison of non-nested models is a more difficult task unless the compared models have the same number of parameters. Criteria that have been commonly suggested for comparison purposes include the *Akaike information criterion* (AIC), often defined as the model deviance plus $2p$, where p is the number of model parameters; the Schwarz information criterion or *Bayesian information criterion* (BIC), often defined as the model deviance plus $p \cdot \ln(N)$, where N is the number of observations; criteria based on *cross-validation*; and criteria based on *Bayes factors*. Larger values of these criteria suggest poorer out-of-sample predictive performance of the model. The definitions of AIC and BIC vary considerably across textbooks; fortunately, the differences do not affect the ranking of models by each criterion. For details on these criteria, see Harrell (2001), Ruppert et al. (2003), or Hastie et al. (2009).

30.10.4 Global Tests of Fit

One special type of deviance test of fit can be performed when Y is a proportion or rate. Suppose that, for every distinct regressor level $\boldsymbol{x}$, at least four cases would be expected if the index model were correct; also, if Y is a proportion, suppose at least four non-cases would be expected if the index model were correct. (This criterion, while somewhat arbitrary, originated because it ensures that the chance of a cell count being zero is less than 2% if the cell variation is Poisson and the index model is correct.) We can then test our index model against the *saturated* regression model

$$E(Y|\boldsymbol{X} = \boldsymbol{x}) = \alpha_x,$$

where α_x is a distinct parameter for every distinct observed level $\boldsymbol{x}$ of $\boldsymbol{X}$; that is, α_x may represent a different number for every level of $\boldsymbol{X}$ and may vary in any fashion as $\boldsymbol{X}$ varies. This model is so general that it contains all other regression models as special cases.

The degrees of freedom for the test of the index model against the saturated model is the number of distinct $\boldsymbol{X}$-levels (which is the number of parameters in the saturated model) minus the number of parameters in the index model and is often called the *residual degrees of freedom* for the model. This *residual* deviance test is sometimes called a "global test of fit" because it has some power to detect any systematic incompatibility between the index model and the data. Another well-known global test of fit is the *Pearson* χ^2 *test,* which has the same degrees of freedom and sample-size requirements as the saturated-model deviance test.

Suppose we observe K distinct regressor values and we list them in some order, $x_1, \ldots, x_K$. The statistic used for the Pearson test has the form of a residual sum of squares:

$$RSS_{Pearson} = \sum\nolimits_k (Y_k - \hat{Y}_k)^2/\hat{V}_k = \sum\nolimits_k [(Y_k - \hat{Y}_k)/\hat{S}_k]^2,$$

where the sum is over all observed values $1, \ldots, K$, Y_k is the rate or risk observed at level $\boldsymbol{x}_k$, $\hat{Y}_k$ is the rate or risk predicted (fitted) at x_k by the model, $\hat{V}_k$ is the estimated variance of $\hat{Y}_k$ when $\boldsymbol{X} = \boldsymbol{x}_k$, and $\hat{S}_k = \hat{V}_k^{1/2}$ is the estimated standard deviation of Y_k under the model. In Poisson regression, $\hat{Y}_k = \exp(\hat{\alpha} + \boldsymbol{x}_k\hat{\boldsymbol{\beta}})$ and $\hat{V}_k = \hat{Y}_k/T_k$, where T_k is the person-time observed at x_k; in binomial regression, $\hat{Y}_k = \text{expit}(\hat{\alpha} + \boldsymbol{x}_k\hat{\boldsymbol{\beta}})$ and $\hat{V}_k = \hat{Y}_k(1 - \hat{Y}_k)/N_k$, where N_k is the number of persons observed at $\boldsymbol{x}_k$. The quantity $(Y_k - \hat{Y}_k)/\hat{S}_k$ is sometimes called the *standardized residual* at level $\boldsymbol{x}_k$; it is the distance between Y_k and $\hat{Y}_k$ expressed in units of the estimated standard deviation of Y_k under the model.

Other global tests have been proposed that have fewer degrees of freedom and less restrictive sample-size requirements than the deviance and Pearson tests (Hosmer and Lemeshow 2000). A major drawback of all global tests of fit, however, is their low power to detect model problems (Hosmer et al. 1997). If any of the tests yields a low p-value, we can be confident the tested (index) model fails to fit in some fashion and thus may need modification or replacement, depending on the nature of the failure (albeit the tests provide no clue as to how to proceed).

On the one hand, if the only purpose of the model is to estimate and compare average risks over broad subgroups, as in model-based standardization (Greenland 2004, 2008a), only very large or qualitative discrepancies may be of concern. On the other hand, if prediction of individual outcomes is the goal, as in clinical applications (Steyerberg 2009), a high p-value from all global tests does not mean the model is satisfactory. In fact, the tests are unlikely to detect any but very large conflicts between the fitted model and the data. Therefore, global tests should be regarded as crude preliminary screening tests only to allow quick rejection of grossly unsatisfactory models.

The deviance and Pearson statistics are sometimes used directly as measures of distance between the data and the model. Such use is most easily seen for the Pearson statistic. The second form of the Pearson statistic shows that it is the sum of squared standardized residuals; in other words, it is a sum of squared distances between data values and model-fitted values of Y. The deviance and Pearson global test statistics can also be transformed into measures of prediction error under the model (McCullagh and Nelder 1989; Hosmer and Lemeshow 2000).

30.10.5 Model Diagnostics

Suppose now we have found a model that has passed preliminary checks such as tests for additional terms and global tests of fit. Before adopting this model as a source of estimates, it is wise to further check the model against the basic data and assess the trustworthiness of any model-based inferences we wish to draw. Such activity is subsumed under the topic of *model diagnostics* and its subsidiary topics of residual analysis, influence analysis, and model sensitivity analysis. These topics are vast, and we can only mention a few approaches here. In particular, we neglect the classical topic of residual analysis, largely because its proper usage involves a number of technical complexities when dealing with the censored data and non-linear models predominant in epidemiology. Detailed treatments of diagnostics for such models can be found in Hosmer and Lemeshow (2000), Harrell (2001), and Ruppert et al. (2003).

30.10.6 Delta-Beta Analysis

One important and simple diagnostic tool available in some packaged software is *delta-beta* ($\Delta\beta$) *analysis.* For a data set with N subjects total, estimated model coefficients (or approximations to them) are recomputed N times over, each time deleting exactly one of the subjects from the model fitting. Alternatively, for individually matched data comprising N matched sets, the delta-beta analysis may be done deleting one set at a time. In either approach, the output is N different sets of coefficients estimates: These sets are then examined to see if anyone subject or matched set influences the resulting estimates to an unusual extent.

To illustrate, suppose our objective is to estimate the rate ratio per unit increase in an exposure X_1, to be measured by $\exp(\hat{\beta}_1)$, where $\hat{\beta}_1$ is the estimated exposure coefficient in an exponential rate model. For each subject, the entire model (confounders included) is re-fit without that subject. Let $\hat{\beta}_{1(-i)}$ be the estimate of $\hat{\beta}_1$ obtained when subject i is excluded from the data. The difference $\hat{\beta}_{1(-i)} - \hat{\beta}_1 \equiv \Delta\hat{\beta}_{1(-i)}$ is called the *delta-beta* for β_1 for subject i. The influence of subject i on the results can be assessed in several ways. One way is to examine the impact on the rate-ratio estimate. The proportionate change in the estimate from dropping subject i is

$$\exp(\hat{\beta}_{1(-i)}) / \exp(\hat{\beta}_1) = \exp(\hat{\beta}_{1(-i)} - \hat{\beta}1) = \exp(\Delta\hat{\beta}_{1(-i)}),$$

for which a value of 1.30 indicates dropping subject i increases the estimate by 30%, and a value of 0.90 indicates dropping subject i decreases the estimate by 10%. One can also assess the impact of dropping the subject on confidence limits, p-values, or any other quantity of interest.

Some packages compute "standardized" delta-betas, $\Delta\hat{\beta}_{1(-i)}/\hat{s}_1$ where $\hat{s}_1$ is the estimated standard deviation for $\hat{\beta}_1$. By analogy with Z-statistics, any standardized delta-beta below -1.96 or above 1.96 is sometimes interpreted as being unusual. This interpretation can be misleading, however, because the standard deviation used in the denominator is not that of the delta-beta. A standardized delta-beta is only a measure of the influence of an observation expressed in units of standard error.

It is possible that one or a few subjects or matched sets are so influential that deleting them alters the conclusions of the study, even when N is in the hundreds (Pregibon 1981). In such situations, comparison of the records of those subjects to others may reveal unusual combinations of regressor values among those subjects. Such unusual combinations may arise from previously undetected data errors and should at least lead to enhanced caution in interpretation. For instance, it may be only mildly unusual to see a woman who reports having had a child at age 45 or a woman who reports natural menopause at age 45. The combination in one subject, however, may arouse suspicion of a data error in one or both regressors, a suspicion worth the labor of further data scrutiny if that woman or her matched set disproportionately influences the results.

Delta-beta analysis must be replaced by a more complex analysis if the exposure of interest appears in multiple model terms, such as indicator terms, power terms, product terms, or spline terms. In that situation, one must focus on changes in estimates of specific effects or summaries, for example, changes in estimated risk ratios.

30.10.7 Model Sensitivity Analysis

A valuable diagnostic procedure, which is often a by-product of the model-selection approaches described earlier, is model sensitivity analysis (Draper 1995;

Saltelli et al. 2000). Given the variety of models available for fitting, it is inevitable that quite a few can be found that fit reasonably well by all standard tests and diagnostics. Model sensitivity analysis seeks to identify a spectrum of such acceptable models and asks whether various estimates and tests are sensitive to the choice of model used for inference. On the one hand, those results that are consistent (stable) across acceptable model-based and stratified analyses can be presented using any one of the analyses. On the other hand, results that vary across analyses need to be reported with much more uncertainty than is indicated by their (unstable) confidence intervals; in particular, one should report the fact that the estimates were unstable.

The credibility, value, and results of a sensitivity analysis are themselves sensitive to the spectrum of models investigated for acceptability. Most such analyses cover limited territory, in part because most software has a restricted range of model forms that can be examined easily. Typically, only exponential-Poisson and Cox models for rates and binomial-logistic models for risks are available, although some packages supply linear rate and linear odds models. The similar restrictions imposed by these models result in severe limitations on the range of analysis. Nonetheless, within these limits, there are vast possibilities for the terms representing the effects of exposures, confounders, and modifiers.

30.11 Conclusions

The topic of regression modeling is vast and even an extended chapter such as the present one can provide only brief overviews of its key concepts and tools. This present chapter has focused on concepts and model interpretation rather than model fitting and computational methods in the hopes of providing a foundation for proper use of those methods. For more detailed coverage of concepts and methods in the general regression context, see the cited textbooks, in particular Berk (2004) and Harrell (2001).

31.1 Introduction

This chapter gives a self-contained introduction to the Bayesian approach to statistical inference. Standard epidemiological problems such as diagnostic tests, the analysis of prevalence, case-control, and cohort data will serve as examples. More advanced topics, such as empirical Bayes methods and Markov chain Monte Carlo techniques, are also covered.

The Bayesian approach is easy to understand, if the reader is able to follow the actual calculations. Only some basic knowledge of the rules of probability and calculus is needed. A reader, willing to dive into these fairly simple technicalities, will be able to fully appreciate the beauty and simplicity of the Bayesian approach. An appendix summarizes the required technical background.

Modern Bayesian statistics is often performed using so-called Monte Carlo methods based on random numbers simulated on a computer. Many quantities of interest can be computed very easily using Monte Carlo. From time to time, I will show very short programming code in `R` to illustrate the simplicity of Monte Carlo methods. Understanding of the code is, however, not necessary for an understanding of this chapter.

To understand Bayesian methods, in particular Bayes' theorem, the most important concept is that of a *conditional probability*. In Sect. 31.2, we will illustrate the notion of conditional probabilities and Bayesian updating in the context of diagnostic testing. Further details on conditional probabilities are listed in Appendix A. The Bayesian approach to parameter estimation is discussed in Sect. 31.3. Appendix B summarizes important properties of the distributions used in this section and their implementation in `R`. After a brief introduction to Bayesian prediction, Sect. 31.4 discusses techniques for prior criticism and Bayesian model selection. Empirical Bayes methods and Markov chain Monte Carlo techniques are described in Sect. 31.5. We close with some discussion in Sect. 31.6.

31.2 Conditional Probabilities and Diagnostic Testing

The use of Bayes' theorem is routine in the context of diagnostic testing.

Example 31.1. Diagnostic testing
Suppose a simple diagnostic test for a specific disease, which produces either a positive or a negative test result, is known to have 90% sensitivity. This means that the probability of a positive test result, if the person being tested has the disease, is 90%. This is a *conditional* probability since we know that the person has the disease and we write $\Pr(T+ \mid D+) = 0.9$, the probability (Pr) of a positive test result $(T+)$ *given* disease $(D+)$ is 0.9. Now, assume that the test also has 90% specificity and write $D-$ if the person being tested is free of the disease. Similarly, let $T-$ denote a negative test result. A 90% specificity simply means that $\Pr(T- \mid D-) = 0.9$.

Conditional probabilities behave just like ordinary probabilities if we always condition on the same event, for example, on $D+$, say. In particular, they must be numbers between 0 and 1 and $\Pr(T- \mid D+)$ must be equal to $1 - \Pr(T+ \mid D+)$, that is, the conditional probability of a negative test result is 1 minus the conditional probability of a positive test result, if both probabilities are conditional on $D+$. The same of course holds if we condition on $D-$ rather than on $D+$.

However, the real power of conditional probabilities emerges if we condition on different events and relate conditional to ordinary (unconditional) probabilities. The most important formula to do this is *Bayes' theorem* (see Appendix A for a derivation). In the diagnostic testing context, we can use Bayes' theorem to compute the conditional probability of disease given a positive test result:

$$\Pr(D+ \mid T+) = \frac{\Pr(T+ \mid D+)\Pr(D+)}{\Pr(T+)}. \tag{31.1}$$

The prevalence $\Pr(D+)$ is an example of an ordinary (unconditional) probability.

The denominator $\Pr(T+)$ in (31.1), the (unconditional) probability of a positive test result, is unknown, but we know from above that $\Pr(D+ \mid T+)$ and

$$\Pr(D- \mid T+) = \frac{\Pr(T+ \mid D-)\Pr(D-)}{\Pr(T+)} \tag{31.2}$$

must add to unity, from which we can easily deduce that

$$\Pr(T+) = \Pr(T+ \mid D+)\Pr(D+) + \Pr(T+ \mid D-)\Pr(D-). \tag{31.3}$$

This equation is sometimes called the *law of total probability*. Thus, we can calculate $\Pr(T+)$ if we know the sensitivity $\Pr(T+ \mid D+)$, the prevalence $\Pr(D+)$, and $\Pr(T+ \mid D-)$, which is 1 minus the specificity $\Pr(T- \mid D-)$.

Equation 31.1 exemplifies the process of *Bayesian updating*: We update the prior risk $\Pr(D+)$ in the light of a positive test result $T+$ to obtain the posterior risk $\Pr(D+ \mid T+)$, the conditional probability of disease given a positive test result, also known as the *positive predictive value*.

Example 31.1. (Continued)
In the following we assume that the prevalence $\Pr(D+) = 1\%$ for the disease considered above. Then

$$\Pr(T+) = 0.9 \cdot 0.01 + 0.1 \cdot 0.99 = 0.108$$

and hence

$$\Pr(D+ \mid T+) = \frac{0.9 \cdot 0.01}{0.108} \approx 0.083,$$

i.e. the disease risk increases from 1% to 8.3% after a positive test result. It is up to the reader to write down the corresponding formula to (31.1) to compute the *negative predictive value* $\Pr(D- \mid T-)$, which turns out to be approximately 0.999. Thus, the disease risk decreases from 1% to $\Pr(D+ \mid T-)=1 - \Pr(D- \mid T-) = 100\% - 99.9\% = 0.1\%$ if the test was negative. The disease risk changes in the expected direction depending on the test result.

Equation 31.1, with the denominator $\Pr(T+)$ replaced by (31.3), is often referred to as Bayes' theorem in probability textbooks. However, the resulting formula is somewhat complex and not particularly intuitive. A simpler version of

Bayes' theorem can be obtained if we switch from probabilities to *odds*. In general, whenever we take a probability, and divide it by 1 minus that probability, the resulting ratio is referred to as the corresponding odds. Of course, every probability refers to a particular event happening and 1 minus that probability is the probability that the event is *not* happening. Odds are hence nothing more than a ratio of two probabilities: the probability of an event happening divided by the probability that the event is not happening. For example, a probability of 10% corresponds to odds of 1/9, often described as 1 to 9. Conversely, 3 to 1 odds, say, correspond to a probability of $3/4 = 0.75$.[1]

We can now derive a simple version of Bayes' theorem in terms of odds, if we divide (31.1)–(31.2):

$$\frac{\Pr(D+ \mid T+)}{\Pr(D- \mid T+)} = \frac{\Pr(T+ \mid D+)}{\Pr(T+ \mid D-)} \times \frac{\Pr(D+)}{\Pr(D-)}. \tag{31.4}$$

We will refer to this equation as Bayes' theorem in *odds form*. Here $\Pr(D+)/\Pr(D-)$ are the *prior odds*, $\Pr(D+ \mid T+)/\Pr(D- \mid T+)$ are the *posterior odds* and $\Pr(T+ \mid D+)/\Pr(T+ \mid D-)$ is the so-called *likelihood ratio* for a positive test result, which we can easily identify as the sensitivity divided by 1 minus the specificity. Bayesian updating is thus just one simple mathematical operation: Multiply the prior odds with the likelihood ratio to obtain the posterior odds.

Example 31.1. (Continued)
The prior odds are 1/99 and the likelihood ratio (for a positive test result) is $0.9/0.1 = 9$. The posterior odds are therefore $9 \cdot 1/99 = 1/11 \approx 9.1\%$. So the prior odds of 1 to 99 change to posterior odds of 1 to 11 in the light of a positive test result. If the test result was negative, then the prior odds need to be multiplied with the likelihood ratio for a negative test result, which is $\Pr(T- \mid D+)/\Pr(T- \mid D-) = 0.1/0.9 = 1/9$. (Note that the likelihood ratio for a negative test result is 1 minus the sensitivity divided by the specificity.) This leads to posterior odds of $1/9 \cdot 1/99 = 1/891$. We leave it up to the reader to check that these posterior odds correspond to the positive and the negative predictive value, respectively, calculated earlier. Figure 31.1 illustrates Bayesian learning using odds in this example.

We now discuss an important formal aspect. Formula (31.1) is specified for a positive test result $T+$ and a diseased person $D+$ but is equally valid if we replace a positive test result $T+$ by a negative one, that is, $T-$, or $D+$ by $D-$, or both. In fact, we have already replaced $D+$ by $D-$ to write down (31.2).

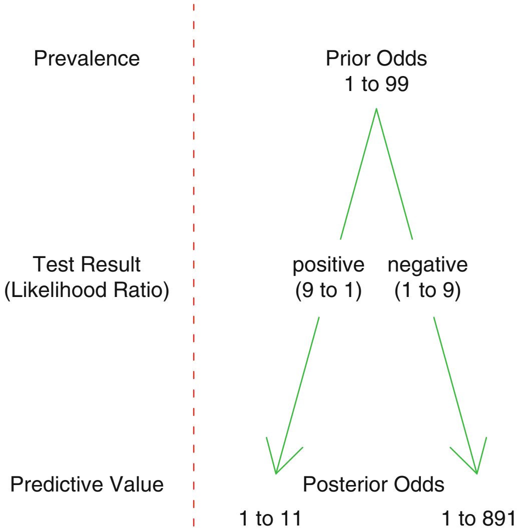
A more general description of Bayes' theorem is given by

$$\mathrm{p}(D = d \mid T = t) = \frac{\mathrm{p}(T = t \mid D = d) \times \mathrm{p}(D = d)}{\mathrm{p}(T = t)}, \tag{31.5}$$

where D and T are binary *random variables* which take the values d and t, respectively. In the diagnostic setting outlined above, d and t can be either "+"

[1] Odds $\omega = \pi/(1 - \pi)$ can be back-transformed to probabilities π using $\pi = \omega/(1 + \omega)$.

Fig. 31.1 Schematic representation of Bayesian learning in a diagnostic test example



or "–". Note that we have switched notation from Pr(.) to p(.) to emphasize that (31.5) relates to general *probability functions* of the random variables D and T, and not only to probabilities of the events $D+$ and $T+$, say.

An even more compact version of (31.5) is

$$\mathrm{p}(d \mid t) = \frac{\mathrm{p}(t \mid d) \times \mathrm{p}(d)}{\mathrm{p}(t)}. \tag{31.6}$$

Note that this equation also holds if the random variables D or T can take more than two possible values. The formula is also correct if it involves continuous random variables, in which case $\mathrm{p}(\cdot)$ denotes a density function.[2]

In reality, information on prevalence is typically estimated from a prevalence study while sensitivity and specificity are derived from a diagnostic study. However, the uncertainty associated with these estimates has been ignored in the above calculations. In the following, we will describe the Bayesian approach to quantify the uncertainty associated with these estimates. This can subsequently be used to assess the uncertainty of the positive and negative predictive values.

31.3 Bayesian Parameter Estimation

Conceptually, the Bayesian approach to parameter estimation treats all unknown quantities as random variables with appropriate prior distributions. Some knowledge of important elementary probability distributions is therefore required. Appendix B summarizes properties of the distributions used in this chapter.

[2] Probability statements for continuous random variables X can be obtained through integration of the density function, for example, $\Pr(a \leq X \leq b) = \int_a^b \mathrm{p}(x)dx$.

A *prior distribution* $\mathrm{p}(\theta)$ represents our knowledge about an unknown parameter θ, which we would like to update in the light of observed data x, whose probability of occurrence depends on θ. For example, x might be the results from an epidemiological study. The conditional probability function $\mathrm{p}(x \mid \theta)$ of x given θ is called the *likelihood function*. Combined with the prior distribution $\mathrm{p}(\theta)$, we can calculate the *posterior distribution* $\mathrm{p}(\theta \mid x)$ using Bayes' theorem:

$$\mathrm{p}(\theta \mid x) = \frac{\mathrm{p}(x \mid \theta) \times \mathrm{p}(\theta)}{\mathrm{p}(x)}. \tag{31.7}$$

This formula is of course just Eq. 31.6 with d replaced by θ and t replaced by x.

Note that the denominator $\mathrm{p}(x)$ does not depend on θ, its particular value is therefore not of primary interest. To compute the posterior distribution $\mathrm{p}(\theta \mid x)$ (up to a multiplicative constant), a simplified version of Bayes' theorem

$$\mathrm{p}(\theta \mid x) \propto \mathrm{p}(x \mid \theta) \times \mathrm{p}(\theta)$$

is sufficient.[3] In words, this formula says that the posterior distribution is proportional to the product of the likelihood function $\mathrm{p}(x \mid \theta)$ and the prior distribution $\mathrm{p}(\theta)$. Note that $\mathrm{p}(x \mid \theta)$, originally the probability or density function of the data x given the (unknown) parameter θ, is used as a function of θ for fixed x. It is convenient to write $\mathrm{L}_x(\theta)$ for $\mathrm{p}(x \mid \theta)$ to emphasize this fact:

$$\mathrm{p}(\theta \mid x) \propto \mathrm{L}_x(\theta) \times \mathrm{p}(\theta). \tag{31.8}$$

Note also that we need to know $\mathrm{L}_x(\theta)$ and $\mathrm{p}(\theta)$ only "up to scale," that is, we can ignore any multiplicative factors which do not depend on θ. This will often make the computations simpler.

A likelihood approach to statistical inference, see, for example, Pawitan (2001), uses only the likelihood $\mathrm{L}_x(\theta)$ and calculates the *Maximum Likelihood estimate* (MLE) $\hat{\theta}_{ML}$ defined as that particular value of θ which maximizes $\mathrm{L}_x(\theta)$. The likelihood function can also be used to compute frequentist *confidence intervals* based on the likelihood ratio test statistic. Alternatively, a Wald confidence interval can be calculated based on the *standard error* $\mathrm{se}(\hat{\theta}_{ML})$ of $\hat{\theta}_{ML}$, an estimate of the standard deviation of the MLE in (fictive) repeated experiments under identical conditions. The standard error can be calculated based on the curvature of the logarithm of the likelihood function (the so-called *log likelihood*) at the MLE.

In contrast, Bayes' theorem formalizes the fundamental principle of Bayesian inference in that the prior assumptions $\mathrm{p}(\theta)$ about θ are updated using the likelihood $\mathrm{p}(x \mid \theta)$ to obtain the posterior distribution $\mathrm{p}(\theta \mid x)$. The posterior distribution provides all information about the quantity of interest, but usually, we want to summarize it using point and interval estimates. The *posterior mean*, the mean of the posterior distribution, is the most commonly used point estimate, alternatively the

[3] The mathematical symbol $\propto$ stands for "is proportional to."

posterior median and the *posterior mode* may also be used. For interval estimation, any interval $[\theta_l, \theta_u]$ with $\Pr(\theta_l \leq \theta \leq \theta_u \,|\, x) = 1 - \alpha$ serves as a $(1 - \alpha) \cdot 100\%$ *credible interval*. A common choice is $\alpha = 5\%$, in which case we obtain 95% credible intervals. Often, *equi-tailed* credible intervals are used, where the same amount $(\alpha/2)$ of probability mass is cut-off from the left and right tail of the posterior distribution, that is,

$$\Pr(\theta < \theta_l \,|\, x) = \Pr(\theta > \theta_u \,|\, x) = \alpha/2.$$

So-called *highest posterior density* (HPD) intervals are also commonplace. They have the defining feature that the posterior density at any value of θ inside the credible interval must be larger than anywhere outside the credible interval. It can be shown that HPD credible intervals have the smallest width among all $(1-\alpha)$ credible intervals. If the posterior distribution is symmetric, for example, normal, then posterior mean, mode, and median coincide and HPD credible intervals are also equi-tailed. For non-symmetric posterior distributions, these quantities typically differ.

31.3.1 Choice of Prior Distribution

Compared with a classical approach to inference, the prior distribution has to be chosen appropriately, which often causes concerns to practitioners. In particular, a Bayesian analysis is often feared to introduce more unrealistic assumptions than a standard frequentist analysis. However, this is viewed as a misconception by many authors who consider the possibility to specify a prior distribution as something useful (Spiegelhalter et al. 2004; Greenland 2006, 2007).

The prior distribution should reflect the knowledge about the parameter of interest (e.g., a relative risk parameter in an epidemiological study). Ideally, this prior distribution should be elicited from experts (Spiegelhalter et al. 2004; O'Hagan et al. 2006). In the absence of expert opinions, simple *informative* prior distributions (e.g., that the relative risk parameter is with prior probability 95% between 0.5 and 2) may still be a reasonable choice. A sensitivity analysis with different prior distributions will help to examine how the conclusions depend on the choice of prior.

However, there have been various attempts to specify non-informative or reference priors to lessen the influence of the prior distribution. Reference priors used in such an "objective Bayes" approach typically correspond to rather unrealistic prior beliefs. However, "non-informative" priors provide a reference posterior where the impact of the prior distribution on the posterior distribution is minimized. Quite interestingly, such reference analyses may have equally good or even better frequentist properties than truly frequentist procedures (Bayarri and Berger 2004).

The most commonly used reference prior is *Jeffreys' prior*, named after the British physicist Harold Jeffreys (1891–1989). He proposed a general device to derive a non-informative prior distribution for a given likelihood function. It is interesting that the resulting non-informative reference prior is not necessarily a uniform prior. In many cases it is *improper*, that is, it does not sum or integrate to unity. For example, if the parameter θ can be any non-negative integer (without an upper limit) and we assume the same prior probability for each possible value of θ, then, this constitutes an improper prior distribution. In contrast, a *proper* prior will be a proper distribution in the mathematical sense. A proper prior can be easily achieved in this example by fixing an upper limit, that is, setting the prior probability of all values above that upper limit to zero. Operationally, improper priors are not a problem for parameter estimation, but they do cause problems in model selection, as we will see in Sect. 31.4. We will see some examples of Jeffreys' prior in the following.

31.3.2 Bayesian Analysis of Prevalence Data

The prevalence π is defined as the proportion of people in a population that has a specific disease. A simple prevalence study selects a random sample of n individuals from that population and counts the number x of diseased individuals. If the number of people in the population is large, then a binomial model $X \mid \pi \sim Bin(n, \pi)$[4] is appropriate to describe the statistical variability occurring in such a study design, see Appendix B for properties of the binomial distribution. Note that the MLE of π is $\hat{\pi}_{ML} = x/n$.

It is commonplace to select a beta distribution as prior distribution for π, because the beta distribution can only take values within the unit interval, that is, within the range of possible values of π. So assume that $\pi \sim Be(\alpha, \beta)$ a priori with $\alpha, \beta > 0$. Properties of the beta distribution are listed in Appendix B. Multiplying the binomial likelihood

$$\mathrm{L}_x(\pi) \propto \pi^x (1-\pi)^{n-x}$$

with the beta prior density

$$\mathrm{p}(\pi) \propto \pi^{\alpha-1}(1-\pi)^{\beta-1},$$

one easily obtains the posterior density

$$\begin{aligned}\mathrm{p}(\pi \mid x) &\propto \mathrm{L}_x(\pi) \times \mathrm{p}(\pi)\\ &\propto \pi^{\alpha+x-1}(1-\pi)^{\beta+n-x-1},\end{aligned}$$

compare Eq. 31.8. This can easily be identified as yet another beta distribution with parameters $\alpha + x$ and $\beta + n - x$:

$$\pi \mid x \sim Be(\alpha + x, \beta + n - x). \tag{31.9}$$

[4] The mathematical symbol $\sim$ stands for "is distributed as."

Compared with the prior distribution $\pi \sim Be(\alpha, \beta)$, the number of successes x is added to the first parameter while the number of failures $n - x$ is added to the second parameter. Note that the beta distribution is called *conjugate* to the binomial likelihood since the posterior is also beta distributed. Both prior and posterior density function are displayed in Fig. 31.2 for a simple example.

It is convenient to think of the $Be(\alpha, \beta)$ prior distribution as that which would have arisen had we started with an improper $Be(0, 0)$ prior and then observed α successes in $\alpha + \beta$ trials. Thus, $n_0 = \alpha + \beta$ can be viewed as a *prior sample size* and $\alpha/(\alpha + \beta)$ is the *prior mean*. This interpretation of the prior parameters is useful in order to intuitively assess the weight attached to the prior distribution, as we will see soon. It also stresses an important feature of Bayesian inference, the consistent processing of sequentially arising data. Indeed, suppose new independent data x_2 from the same $Bin(n, \pi)$ distribution arrives, then the posterior distribution following the original observation (with x now renamed to x_1) becomes the prior for the next observation x_2:

$$\mathrm{p}(\pi \mid x_1, x_2) \propto \mathrm{p}(x_2 \mid \pi) \times \mathrm{p}(\pi \mid x_1).$$

Here, we have been able to replace $\mathrm{p}(x_2 \mid \pi, x_1)$ by $\mathrm{p}(x_2 \mid \pi)$ due to the conditional independence of x_1 and x_2, given π. Now, $\mathrm{p}(\pi \mid x_1)$ is of course proportional to $\mathrm{p}(x_1 \mid \pi) \times \mathrm{p}(\pi)$, so an alternative formula is

$$\begin{aligned} \mathrm{p}(\pi \mid x_1, x_2) &\propto \mathrm{p}(x_2 \mid \pi) \times \mathrm{p}(x_1 \mid \pi) \times \mathrm{p}(\pi) \\ &= \mathrm{p}(x_1, x_2 \mid \pi) \times \mathrm{p}(\pi). \end{aligned}$$

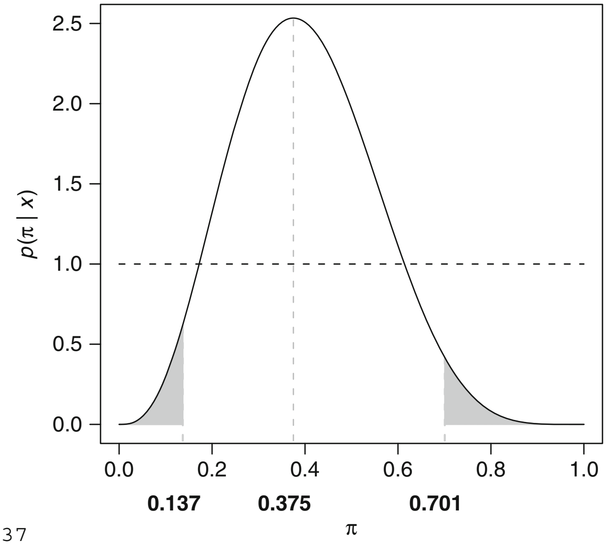


Fig. 31.2 A $Be(4, 6)$ posterior density $\mathrm{p}(\pi \mid x)$ (*solid line*) obtained from combining a $Be(1, 1)$ prior density (*dashed line*) with an observation $x = 3$ in a binomial experiment with $n = 8$ trials. The posterior mean is 0.4 and the posterior mode is 0.375. The equi-tailed 95% credible interval with limits $\theta_l = 0.137$ and $\theta_u = 0.701$ is also shown. The limits are calculated using the `R` function qbeta, that is, `qbeta(0.025,4,6) = 0.137`

In other words, $p(\pi \mid x_1, x_2)$ is the same whether or not the data are processed sequentially. Cornfield (1966, 1976) discusses this issue extensively in the context of clinical trials, see also Spiegelhalter et al. (2004, Sect. 4.3.2). Viewed from that perspective, every prior distribution is a posterior distribution based on the information available prior to the processing of the current data, and it makes sense to speak of a prior sample size. Bayesian inference is therefore sometimes described as Bayesian *learning*, which emphasizes the sequential nature inherent in the approach.

We now return to the posterior distribution in the binomial experiment. There are particularly simple explicit formulae for the mean and mode of a $Be(\alpha, \beta)$-distribution, see Appendix B for details. For example, the mean is simply $\alpha/(\alpha + \beta)$. Therefore, the posterior mean of $\pi \mid x \sim Be(\alpha + x, \beta + n - x)$ is

$$\frac{\alpha + x}{\alpha + \beta + n}.$$

Rewriting this as

$$\frac{\alpha + x}{\alpha + \beta + n} = \frac{\alpha + \beta}{\alpha + \beta + n} \cdot \frac{\alpha}{\alpha + \beta} + \frac{n}{\alpha + \beta + n} \cdot \frac{x}{n}$$

shows that the posterior mean is a weighted average of the prior mean $\alpha/(\alpha + \beta)$ and the MLE $\bar{x} = x/n$ with weights proportional to the prior sample size $n_0 = \alpha + \beta$ and the data sample size n, respectively. This further supports the interpretation of n_0 as a prior sample size. The *relative prior sample size* $n_0/(n_0+n)$ quantifies the weight of the prior mean in the posterior mean. Note that the relative prior sample size decreases with increasing data sample size n.

The case $\alpha = \beta = 1$ is of particular interest, as it corresponds to a uniform prior distribution on the interval $(0, 1)$, a natural "non-informative" choice. The prior sample size n_0 is now 2, one success and one failure. This is in fact exactly the prior used by Thomas Bayes (1702–1761) in his famous essay (Bayes 1763). The posterior mean is now $(x + 1)/(n + 2)$ and the posterior mode equals the MLE $\bar{x}$.

Incidentally, we note that Jeffreys' reference prior is not the uniform prior for π, but a beta distribution with both parameters α and β equal to 1/2, that is, $p(\pi) \propto \pi^{-0.5}(1 - \pi)^{-0.5}$ (compare Appendix B). This prior is proper and favors extreme values of π, that is, those which are close to either zero or one. From the above, we observe that Jeffreys' prior sample size n_0 is 1, half a success and half a failure.

Example 31.1. (Continued)
We now revisit the diagnostic test example discussed in Sect. 31.2 under the more realistic scenario that the disease prevalence $\pi = \Pr(D+)$ is not known, but only estimated from a prevalence study. For example, suppose there was $x = 1$ diseased individual in a random sample of size $n = 100$. Using a uniform $Be(1, 1)$ prior, the posterior distribution of π is Be(2,100), with posterior mean $1/51$ and posterior mode $1/100$.

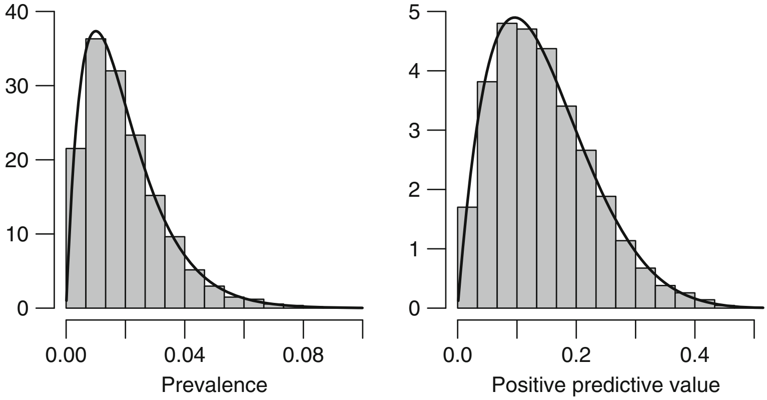

Fig. 31.3 *Left*: Posterior distribution of the prevalence. *Right*: Posterior distribution of the positive predictive value. Shown are histograms based on samples from these distributions. The *solid bold line* is the exact posterior density

It is tempting to replace the fixed prevalence $\Pr(D+) = 1/100$ in (31.1) with this $Be(2, 100)$ distribution to acknowledge the uncertainty involved in the prevalence estimation. The positive predictive value then follows a particular distribution, which can be computed analytically. However, it is much simpler to generate a random sample from the distribution of the positive predictive value using samples from the posterior distribution of π (Mossman and Berger 2001; Bayarri and Berger 2004). The following R-code illustrates this. Histograms of $n = 10{,}000$ samples from the prevalence and the associated positive predictive value are shown in Fig. 31.3.

```
> nsamples = 10000
> prev = rbeta(nsamples, 2, 100)
> sens = 0.9
> spec = 0.9
> ppv = sens * prev/(sens * prev + (1 - spec) * (1 - prev))
```

It is interesting that there is quite large uncertainty about the positive predictive value with 95% equi-tailed credible interval [0.02,0.34], which can be calculated from the corresponding quantiles of the sample. The 95% HPD credible interval is [0.009,0.31], so shifted to the left and slightly narrower, as expected. Note that the posterior mean is 0.145 (14.5%) and the posterior mode is 0.096 (9.6%). Both are larger than the positive predictive value 8.3% obtained for a fixed prevalence $\Pr(D+) = 0.01$ (see Sect. 31.2).

Mossman and Berger (2001) have considered a more general scenario where the characteristics of the diagnostic test are also not known exactly but based on estimates from a diagnostic study. Then, sensitivity `sens` and specificity `spec` in the above R-code needs to be replaced by corresponding samples from suitable beta (posterior) distributions, and the positive predictive value will have even more variation.

31.3.3 Bayesian Analysis of Incidence Rate Data

Incidence rate data typically consist of the number of cases x observed over the total person-time e. Alternatively, e may represent the expected number of cases under a specific assumption. A common approach, see, for example, Rothman (2002), is to assume that $X \sim Po(e\lambda)$, that is, the number of cases X is Poisson distributed with mean $e\lambda$ where e is a known constant and $\lambda > 0$ is an unknown parameter. If e is person-time, then λ represents the unknown incidence rate and if e is the number of expected cases, then λ is the unknown *rate ratio*, also called the *relative risk*.

It is commonplace to select a gamma distribution $Ga(\alpha, \beta)$ as prior distribution for λ, because it is conjugate to the Poisson likelihood, see Appendix B for details on the gamma distribution. The likelihood function of a Poisson observation with mean $e\lambda$ is

$$\mathrm{L}_x(\lambda) \propto \lambda^x \exp(-e\lambda).$$

It is easy to show that the MLE of λ is $\hat{\lambda}_{ML} = x/e$. Combining $\mathrm{L}_x(\lambda)$ with the density

$$\mathrm{p}(\lambda) \propto \lambda^{\alpha-1} \exp(-\beta\lambda)$$

of the gamma $Ga(\alpha, \beta)$ prior distribution, one obtains the posterior distribution of λ:

$$\begin{aligned}\mathrm{p}(\lambda \,|\, x) &\propto \mathrm{L}_x(\lambda) \times \mathrm{p}(\lambda) \\ &\propto \lambda^{\alpha+x-1} \exp(-(\beta + e)\lambda).\end{aligned}$$

This can be identified as another gamma distribution with parameters $\alpha + x$ and $\beta + e$:

$$\lambda \,|\, x \sim Ga(\alpha + x, \beta + e). \tag{31.10}$$

Compared with the prior distribution $Ga(\alpha, \beta)$, the number of observed counts x are added to the first parameter and the number of expected counts e are added to the second parameter.

The mean of a $Ga(\alpha, \beta)$ distribution is α/β, so the posterior mean is

$$\frac{\alpha + x}{\beta + e} = \frac{\beta}{\beta + e} \cdot \frac{\alpha}{\beta} + \frac{e}{\beta + e} \cdot \frac{x}{e}.$$

This equation illustrates that the posterior mean can be written as a weighted average of the prior mean α/β and the Maximum Likelihood estimate x/e with weights proportional to β and e, respectively. Hence, for Poisson data, there is a similar decomposition of the posterior mean as in the binomial case, see Sect. 31.3.2. Note that now β can be interpreted as prior sample size n_0 while e represents the data sample size.

Example 31.2. Breast cancer after fluroscopic examinations of the chest
For illustration, consider an example taken from Boice and Monson (1977), see also Greenland and Rothman (2008). A total of $x = 41$ breast cancer cases have been reported in a cohort of women treated for tuberculosis with x-ray fluoroscopy. Only $e = 23.3$ cases

were expected based on age-specific rates among women in Connecticut. We are interested in the posterior distribution of the rate ratio λ.

As prior distribution for the rate ratio λ, we may assume a gamma distribution with $\alpha = \beta$, and hence a prior mean of 1.0, that is, a prior expectation of a breast cancer rate after exposure to x-ray fluoroscopy equal to the overall rate in Connecticut. With a specific choice of α, we specify a range of plausible values around 1.0 which we consider believable a priori. For example, for $\alpha{=}\beta{=}8.78$, we believe that λ is in the range $[0.5, 2]$ with approximately 95% probability. Using this prior and Eq. 31.10, we obtain the posterior distribution $\lambda \mid x \sim Ga(8.78{+}41, 8.78{+}23.3) = Ga(49.78, 32.08)$. Note that the relative prior sample size is $8.78/32.08 \approx 27\%$, so the selected prior does have some weight in the posterior distribution.

The posterior mean of the relative risk λ is $49.78/32.08 = 1.55$. The equi-tailed 95% posterior credible interval for λ is $[1.15, 2.01]$. Thus, there is some evidence of an excess of breast cancers among x-rayed women relative to the reference group, but with quite large uncertainty about the actual size of the effect.

The above prior may be criticized for placing too much prior weight on relative risk values below unity with $\Pr(\lambda < 1) = 0.54$ and $\Pr(\lambda < 0.5) = 0.04$, but only $\Pr(\lambda > 2) = 0.01$. As a possible remedy, one may still pick a gamma prior with probability mass of 95% in the interval $[0.5, 2]$; however, one might want achieve symmetry by choosing a gamma prior which fulfills $\Pr(\lambda < 0.5) = \Pr(\lambda > 2) = 0.025$. This leads to the prior parameters $\alpha = 8.50$ and $\beta = 7.50$ and the posterior distribution $\lambda \mid x \sim Ga(49.50, 30.80)$. The posterior mean of the relative risk λ is now 1.61. The equi-tailed 95% posterior credible interval for λ is $[1.19, 2.08]$. The new prior gives very similar results compared to the original one.

Jeffreys' prior for the Poisson likelihood is a gamma distribution with parameters $\alpha = 1/2$ and $\beta = 0$. Since $\beta = 0$, it is an improper distribution but the associated posterior will be proper as long as $e > 0$. In the above example, the posterior mean 1.78 under Jeffreys' prior is larger as well as the limits of the 95% credible interval, which are 1.28 and 2.36.

31.3.4 Bayesian Analysis of Case-Control Data

We now turn to the Bayesian analysis of counts in a 2×2 table, with particular focus on the analysis of case-control studies with dichotomous exposure. Let E denote exposure and D disease, so let $\pi_1 = \Pr(E{+} \mid D{+})$ denote the probability that a case was exposed and $\pi_0 = \Pr(E{+} \mid D{-})$ the corresponding probability for a control. Assuming independent cases and controls and suitable (independent) priors for π_1 and π_0, we can easily derive the corresponding posterior distributions of π_1 and π_0, which are still independent. We may now proceed to infer the posterior distribution of the *odds ratio* $[\pi_1/(1 - \pi_1)]/[\pi_0(1 - \pi_0)]$. Conceptually, this is a simple mathematical problem; however, analytical calculation of the posterior density can be quite tedious (Nurminen and Mutanen 1987), so we use a simple Monte Carlo approach instead. The method gives independent samples from the posterior distribution of the odds ratio, as illustrated in the following example.

Example 31.3. Childhood leukemia and residential magnetic fields
Consider case-control data from Savitz et al. (1988), as reported in Greenland (2008), investigating a possible association between residential magnetic fields and childhood leukemia. For simplicity, the exposure variable was dichotomized based on a threshold of 3 milligauss (mG) exposure. The data are shown in Table 31.1. The entries of the 2×2 table are denoted by x_1 and y_1 for the exposed and unexposed cases, respectively, and x_0 and y_0

Table 31.1 Case-control data on residential magnetic field exposure and childhood leukemia

		Exposure	
		Exposed	Unexposed
Disease status	Cases	$x_1 = 3$	$y_1 = 5$
	Controls	$x_0 = 33$	$y_0 = 193$

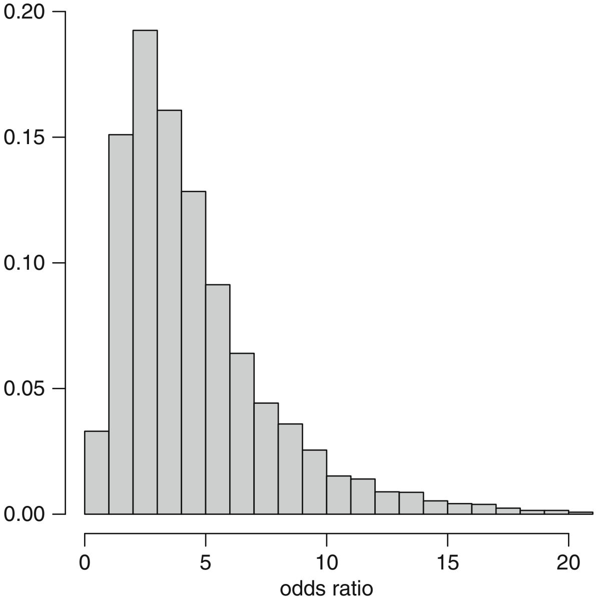

Fig. 31.4 A histogram based on 10,000 samples from the posterior odds ratio

for the corresponding controls. For simplicity, we continue to use the generic symbol x to denote all the available data for both cases and controls.

We assume independent uniform prior distributions for π_1 and π_0. It then follows that π_1 and π_0 are also a posteriori independent: $\pi_1 \,|\, x \sim Be(x_1 + 1 = 4, y_1 + 1 = 6)$ and $\pi_0 \,|\, x \sim Be(x_0 + 1 = 34, y_0 + 1 = 194)$, compare Sect. 31.3.2. In fact, Fig. 31.2 has shown the posterior of π_1. The following R-code illustrates a Monte Carlo approach to generate random samples from the posterior distribution of the odds ratio.

```
> nsamples = 10000
> pi1 = rbeta(nsamples, 4, 6)
> pi0 = rbeta(nsamples, 34, 194)
> or = (pi1/(1 - pi1))/(pi0/(1 - pi0))
```

Figure 31.4 gives a histogram of the posterior samples from the odds ratio `or`. The resulting posterior mean of the odds ratio is 4.7 with equi-tailed 95% credible interval [0.9,14.3]. Thus, there is large uncertainty about the odds ratio with values around unity not completely unrealistic.

The odds ratio $[\pi_1/(1-\pi_1)]/[\pi_0/(1-\pi_0)]$ is the odds $\pi_1/(1-\pi_1)$ to be exposed for a case divided by the odds $\pi_0/(1-\pi_0)$ to be exposed for a control, the so-called *exposure odds ratio*. Of more practical interest is the *disease odds ratio*, that is, the odds to be a case if exposed divided by the odds to be a case if not exposed. As Jerome Cornfield (1912–1979) has shown (Cornfield 1951) through yet another application of Bayes' theorem, the exposure odds ratio is in fact equal to the disease odds ratio. Cornfield's proof is quite simple: Bayes theorem (31.4) in odds form gives

$$\frac{\Pr(D+\,|\,E+)}{\Pr(D-\,|\,E+)} = \frac{\Pr(E+\,|\,D+)}{\Pr(E+\,|\,D-)} \times \frac{\Pr(D+)}{\Pr(D-)}.$$

and likewise

$$\frac{\Pr(D+\,|\,E-)}{\Pr(D-\,|\,E-)} = \frac{\Pr(E-\,|\,D+)}{\Pr(E-\,|\,D-)} \times \frac{\Pr(D+)}{\Pr(D-)}.$$

Dividing the first through the second equation gives after some rearrangement

$$\frac{\Pr(D+\,|\,E+)/\Pr(D-\,|\,E+)}{\Pr(D+\,|\,E-)/\Pr(D-\,|\,E-)} = \frac{\Pr(E+\,|\,D+)/\Pr(E-\,|\,D+)}{\Pr(E+\,|\,D-)/\Pr(E-\,|\,D-)}.$$

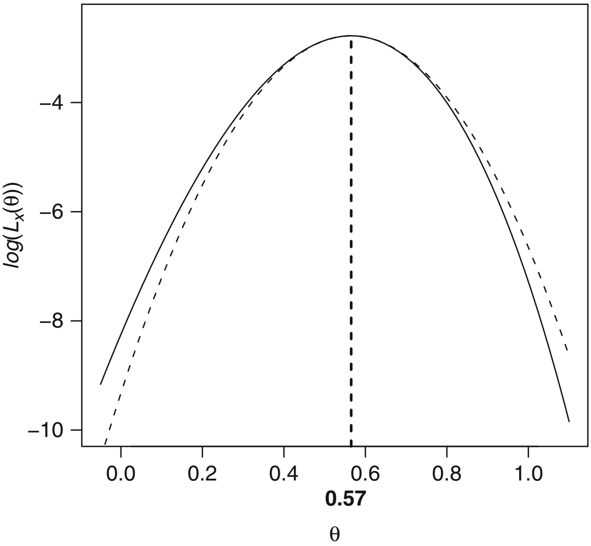
The left side of this equation is the disease odds ratio and the right side is the exposure odds ratio. For more details on statistical issues of the case-control study, see, for example, Breslow (1996) or chapter ▸Case-Control Studies of this handbook.

31.3.5 Approximate Bayesian Analysis

The shapes of many log likelihood functions $\log \mathrm{L}_x(\theta)$ are approximately quadratic, see, for example, Clayton and Hills (1993, Chap. 9). The log likelihood function of the normal distribution is exactly quadratic, and this fact can be used to apply techniques based on the normal distribution for approximate Bayesian inference (Greenland 2008). Methods based on approximate likelihoods are particularly important because the quadratic approximation becomes closer to the true likelihood as the sample size increases. Figure 31.5 illustrates this for the log likelihood of a Poisson observation $x = 41$ with mean $e \cdot \lambda$ where $e = 23.3$ (Example 31.2). Note that the log likelihood is shown not with respect to λ, but in terms of the log relative risk $\theta = \log(\lambda)$. The normal approximation is typically better if the parameter of interest is unrestricted, so it is better to approximate the log relative risk rather than the relative risk, which can take only positive values.

It is often appropriate to approximate a likelihood function of an unknown parameter θ by viewing the MLE as the actually observed (normal) data x. The associated standard error serves as (known) standard deviation $\sigma = \mathrm{se}(\hat{\theta}_{ML})$ of that normal distribution: $\hat{\theta}_{ML} \sim N(\theta, \sigma^2)$. The original likelihood function is hence replaced with its quadratic approximation, a likelihood function of one single normal observation x (the MLE) with known variance σ^2 (the squared standard

Fig. 31.5 Log likelihood function $\log \mathrm{L}_x(\theta)$ of a Poisson observation $x = 41$ with mean $e \cdot \exp(\theta) = 23.3 \cdot \exp(\theta)$ (*solid line*). Also shown is the MLE $\hat{\theta}_{ML} = 0.57$ and the quadratic approximation to the log likelihood (*dashed line*)



error). The unknown parameter θ is the mean of that normal distribution. Such an approach makes approximate Bayesian inference particularly simple, as we will see in the following.

So let X denote a sample from a normal $N(\theta, \sigma^2)$ distribution with mean θ and known variance σ^2. The corresponding likelihood function is

$$\mathrm{L}_x(\theta) \propto \exp\left\{-\frac{(x-\theta)^2}{2\sigma^2}\right\}.$$

Combined with a normal prior distribution for the unknown mean $\theta \sim N(\nu, \tau^2)$ with mean ν and variance τ^2, that is,

$$\mathrm{p}(\theta) \propto \exp\left\{-\frac{(\theta-\nu)^2}{2\tau^2}\right\}.$$

the posterior distribution is given by

$$\begin{aligned}\mathrm{p}(\theta \mid x) &\propto \mathrm{L}_x(\theta) \times \mathrm{p}(\theta)\\ &\propto \exp\left\{-\frac{1}{2}\left(\frac{(x-\theta)^2}{\sigma^2} + \frac{(\theta-\nu)^2}{\tau^2}\right)\right\}.\end{aligned}$$

It can be shown that this is the density function of yet another normal distribution with variance $\tilde{\tau}^2 = 1/(1/\sigma^2 + 1/\tau^2)$ and mean $\tilde{\nu} = \tilde{\tau}^2(x/\sigma^2 + \nu/\tau^2)$:

$$\theta \mid x \sim N(\tilde{\nu}, \tilde{\tau}^2). \tag{31.11}$$

Table 31.2 A comparison of posterior characteristics for various prior distributions in the breast cancer study. Shown is the posterior mean $\hat{\lambda}$, the limits λ_l and λ_u of the equi-tailed 95% credible interval, and the tail probability $\Pr(\lambda < 1|x)$

Prior distribution	$\hat{\lambda}$	λ_l	λ_u	$\Pr(\lambda < 1\|x)$
$Ga(8.78, 8.78)$	1.55	1.15	2.01	0.00226
$Ga(8.5, 7.5)$	1.61	1.19	2.08	0.00116
$Ga(0.5, 0.0)$ (Jeffreys' prior)	1.78	1.28	2.36	0.00042
$LN(0, 0.125)$ (approximate)	1.62	1.21	2.12	0.00047
$LN(0, 0.125)$ (exact)	1.60	1.17	2.10	0.00170
$LN(0, \infty)$ (approximate)	1.78	1.30	2.39	0.00015

As for binomial samples, the posterior mean is a weighted mean of the prior mean ν and the data x with weights proportional to $1/\tau^2$ and $1/\sigma^2$, respectively. The relative prior sample size is thus $\tilde{\tau}^2/\tau^2$.

Example 31.2. (Continued)

It is well-known that the MLE $\hat{\theta}_{ML} = \log(x/e)$ of the log relative risk $\theta = \log(\lambda)$ is approximately normally distributed with mean equal to the true log relative risk θ and standard error $\sigma = 1/\sqrt{x}$ (Clayton and Hills 1993, Chap. 9). Using the data on breast cancer incidence after fluroscopic examinations of the chest from Sect. 31.3.3 where $x = 41$ and $e = 23.3$, the MLE of θ is hence 0.57 with standard error 0.16.

The MLE $\hat{\theta}_{ML}$ serves now as a summary of the information in the data to update our prior beliefs about θ. As prior distribution for θ, we select a mean-zero normal distribution such that the relative risk $\lambda = \exp(\theta)$ is between 0.5 and 2 with 95% probability. The corresponding normal distribution has variance $\tau^2 = (\log(2)/1.96)^2 \approx 1/8$. Note that a normal distribution for the log relative risk corresponds to a so-called *log-normal distribution* for the relative risk, where explicit formulae for the mean and mode are available (see Appendix B).

Using Eq. 31.11, the posterior variance is $\tilde{\tau}^2 = 1/(x+8) \approx 0.02$ and the posterior mean is $\tilde{\nu} = \tilde{\tau}^2(\hat{\theta}_{ML}/\sigma^2) = 0.47$. This corresponds to a posterior mean of $\exp(\tilde{\nu} + \tau^2/2) = 1.62$ for the relative risk λ (see the formula for the mean of a log-normal distribution in Appendix B). The associated 95% equi-tailed credible interval for the relative risk is $[1.21, 2.12]$. Note that the relative prior sample size is $\tilde{\tau}^2/\tau^2 \approx 0.16$, that is, 16%.

If we combine the exact Poisson likelihood with a normal prior for the log relative risk parameter θ, then the posterior distribution is no longer analytically tractable. However, posterior characteristics can be computed using numerical techniques. One obtains the posterior mean 1.60 and the 95% credible interval [1.17,2.10] for λ. These results are very similar to those based on the approximate analysis.

If we let the prior variance τ^2 of a normal prior $N(0, \tau^2)$ for the log relative risk parameter θ go to infinity, we obtain a "locally uniform" or flat prior, $p(\theta) \propto 1$, which is sometimes described as "non-informative." In this case, the posterior Eq. 31.11 simplifies to

$$\theta \mid x \sim N(x, \sigma^2). \tag{31.12}$$

Therefore, the point estimate of θ is simply the MLE $\hat{\theta}_{ML}$, and the limits of the equi-tailed 95% credible interval are numerically identical to the limits of the standard 95% Wald confidence interval:

$$\hat{\theta}_{ML} \pm 1.96 \cdot \sigma.$$

Results based on this approximate analysis with a flat prior for the log relative risk parameter θ are similar to the ones based on the reference prior for the Poisson mean λ, see Table 31.2. A standard frequentist analysis can thus be regarded as a Bayesian analysis using a reference prior. This connection between frequentist and Bayesian parameter estimates can be established in many other situations, at least approximately. However, viewed from a Bayesian perspective, the frequentist approach uses a rather unrealistic prior which gives large weight to unrealistically extreme values of relative risk.

31.3.6 Bayesian Tail Probabilities

In classical hypothesis testing, a commonly encountered procedure is the so-called *one-sided hypothesis test* (see, e.g., Cox (2005)) where the evidence against a null hypothesis $H_0 : \theta \leq \theta_0$ is quantified using a p-value:

$$p\text{-value } = \Pr(T(X) \geq T(x) \,|\, \theta = \theta_0),$$

here $T(X)$ is a suitable summary of the data X, for example, the mean. The p-value obtained from such a one-sided hypothesis test has sometimes a Bayesian interpretation as the posterior probability of H_0:

$$\Pr(H_0 \,|\, x) = \Pr(\theta < \theta_0 \,|\, x).$$

For illustration, consider a simple scenario with $n = 1$ observation $T(X) = X$ from a normal distribution with unknown mean θ and known variance σ^2. Under the assumption of a reference prior $\mathrm{p}(\theta) \propto 1$, the posterior distribution is $\theta \,|\, x \sim N(x, \sigma^2)$, see (31.12). Therefore,

$$\Pr(H_0 \,|\, x) = \Pr(\theta < \theta_0 \,|\, x) = \Phi((\theta_0 - x)/\sigma),$$

where Φ denotes the cumulative distribution function of the standard normal distribution. On the other hand, the p-value against H_0 is

$$p\text{-value } = \Pr(X \geq x \,|\, \theta = \theta_0) = 1 - \Phi((x - \theta_0)/\sigma) = \Phi((\theta_0 - x)/\sigma),$$

so is numerically equal to the posterior probability $\Pr(H_0 \,|\, x)$.

Of course, posterior probabilities can be calculated also for other prior distributions, in which case the analogy between posterior probabilities and p-values will usually be lost.

Example 31.2. (Continued)
Table 31.2 lists the posterior probability $\Pr(\lambda < 1 \,|\, x)$ for different prior assumptions on the relative risk parameter λ. It can be seen that there is some variation of these tail probabilities depending on the prior distribution and on the usage of an exact or an approximate approach, respectively. The frequentist p-value based on the Poisson distribution is $\Pr(X \geq 41 \,|\, \lambda = 1, e = 23.3) = 0.00057$, so within the range of the reported tail probabilities.

Note that the posterior probability $\Pr(\lambda < 1 \,|\, x) = 0.00047$ using the approximate approach is somewhat different from the corresponding one calculated with the exact likelihood, which is 0.00170. The reason for this discrepancy is the approximation of the Poisson log likelihood through a quadratic function, which corresponds to the approximate normal distribution of the log relative risk. Figure 31.5 shows that the quadratic approximation is good around the MLE, but not so good for small values of θ, with larger values of the log likelihood than its quadratic approximation. This explains the difference between the approximate and the exact results.

In the following, we show that the relationship between p-values and posterior tail probability may also hold (approximately) in quite unexpected circumstances. However, it is important to emphasize that the apparent analogy between p-values and posterior tail probabilities holds only in special cases and does not extend to the commonly used *two-sided* hypothesis test $H_0 : \theta = \theta_0$ versus $H_1 : \theta \neq \theta_0$, as we will see later.

31.3.6.1 A Tail Probability for Case-Control Data

In 1877, the medical doctor Carl von Liebermeister (1833–1901) proposed a Bayesian approach for the analysis of counts in a 2 × 2 table (Liebermeister 1877). Carl von Liebermeister was at that time professor in the Medical Faculty at the University of Tübingen in southern Germany. A Bayesian approach was selected by Liebermeister, as it was the inferential method of its time, following the tradition of Thomas Bayes and Pierre-Simon Laplace.

In the following, we will adopt the notation from Sect. 31.3.4 on the Bayesian analysis of case-control data, with π_1 and π_0 denoting the probability that a case and a control was exposed, respectively. Liebermeister had the ingenious idea to consider the posterior probability

$$\Pr(\pi_1 \leq \pi_0 \,|\, x) \tag{31.13}$$

in order to assess if there is evidence for a "significant" difference between cases and controls with respect to the underlying exposure risk. Liebermeister selected independent uniform priors for the unknown probabilities π_1 and π_0, directly following the approach by Thomas Bayes. Note that in modern epidemiological terminology, Eq. 31.13 is the posterior probability that the *relative risk* π_1/π_0 is smaller or equal to one. Furthermore, this probability is identical to the posterior probability that the odds ratio $\pi_1(1-\pi_0)/(\pi_0(1-\pi_1))$ is smaller or equal to one, because $\pi_1/\pi_0 \leq 1$ if and only if $\pi_1(1-\pi_0)/(\pi_0(1-\pi_1)) \leq 1$. Analytical computation of Eq. 31.13 is far from trivial, as reviewed in Seneta (1994). Quite interestingly, it turns out that Eq. 31.13 is the p-value of Fisher's one-sided exact test when testing the null hypothesis $\pi_1 \leq \pi_0$ against the one-sided alternative $\pi_1 > \pi_0$, if the diagonal entries x_1 and y_0 of the 2 × 2 table (here we adapt the notation from Table 31.1) are both increased by one count. Note that addition of 1 on the diagonal increases the empirical odds ratio and hence decreases the p-value of the above test.

The close connection to Fisher's test, which was developed more than 50 years later (Fisher 1934), has led Seneta (1994) to call the Liebermeister approach a "Bayesian test procedure." Seneta and Phipps (2001) studied frequentist properties of Eq. 31.13, viewed as a classical p-value. They showed that it has better average frequentist properties than the p-value obtained from Fisher's original test.

Altham (1969) has derived formulae for Eq. 31.13 in the more general setting of two independent beta distributions for π_0 and π_1 with arbitrary parameters. Nurminen and Mutanen (1987) have further generalized these results and have provided formulae for the whole posterior distribution of the risk difference, the risk ratio and the odds ratio. An interesting review of the Bayesian analysis of the 2 × 2 table can be found in Howard (1998). Note that all these authors have apparently been unaware of the original work by Liebermeister.

An alternative approximate approach for Bayesian inference in the 2 × 2 table, sometimes called *semi-Bayes*, has also been suggested. The basic idea is to re-parameterize the model in terms of a parameter of interest (e.g., the log odds ratio) and a so-called nuisance parameter (e.g., the log odds in the control group). A posterior distribution is then derived for the parameter of interest, assuming a suitable prior distribution. It is well known that the likelihood function for the log odds ratio ψ is approximately normal with mean $\log(x_1 \cdot y_0)/(x_0 \cdot y_1)$ and variance $(1/x_1 + 1/y_1 + 1/x_0 + 1/y_0)$, see Clayton and Hills (1993, Chap. 17). Adopting a flat (improper) prior for ψ, the posterior distribution is therefore also approximately normal with that mean and variance, which allows for the computation of (approximate) Bayesian p-values based on the normal distribution function. Proper normal priors can be easily incorporated in this approach using the techniques described in Sect. 31.3.5.

Example 31.3. (Continued)
Consider again the case-control example described in Sect. 31.3.4. The p-value from Fisher's one-sided test is 0.108, whereas Liebermeister's probability Eq. 31.13, calculated as the p-value of Fisher's test applied to Table 31.1 with diagonal entries increased to 4 and 194, respectively, is 0.036. Using the approximate approach with a flat improper reference prior for ψ, the posterior probability that the log odds ratio is equal to or smaller than zero (and hence the odds ratio is equal to or smaller than one) turns out to be 0.048, so quite similar. Greenland (2008) suggests an informative mean-zero normal prior distribution for ψ with variance 1/2. This distribution implies that the prior probability for an odds ratio between 1/4 and 4 is (approximately) 95%. Then, the posterior probability that the odds ratio is equal to or smaller than one is 0.127, so larger than before.

31.4 Prior Criticism and Model Choice

Various statistical researchers have emphasized the importance of modeling and reporting uncertainty in terms of *observables*, as opposed to inference about (unobservable) parameters. However, the latter, more traditional approach to inference can be seen as a limiting form of *predictive* inference about observables (Bernardo and Smith 1994). Parametric inference can therefore be seen as an intermediate structural step in the predictive process.

A predictive model for observables, for example, future outcomes of a clinical trial, can be constructed easily within the Bayesian framework. As we will see in this section, the prior predictive distribution plays also a key role in prior criticism and Bayesian model choice.

31.4.1 Bayesian Prediction

Suppose we want to predict future data x^{new}, say, which is assumed to arise from the same likelihood function as the original data x. Bayesian prediction is based on the simple identity

$$\mathrm{p}(x^{\text{new}} \mid x) = \int \mathrm{p}(x^{\text{new}} \mid \theta) \times \mathrm{p}(\theta \mid x)\, d\theta, \tag{31.14}$$

so the *predictive distribution* of x^{new} given x is the integral of the likelihood function of x^{new} times the posterior distribution $\mathrm{p}(\theta \mid x)$ with respect to θ.

For example, consider the binomial model with unknown success probability π as described in detail in Sect. 31.3.2. Suppose we want to predict a future observation $X^{\text{new}} \sim Bin(1, \pi)$. It is easy to show that $X^{\text{new}} \mid x$ has a Bernoulli distribution with success probability equal to the mean of $\pi \mid x$.

The predictive distribution (31.14) is sometimes called *posterior predictive distribution* since it is conditional on the observed data x. In contrast, the *prior predictive distribution*

$$\mathrm{p}(x) = \int \mathrm{p}(x \mid \theta) \times \mathrm{p}(\theta)\, d\theta \tag{31.15}$$

is derived from the likelihood and the prior distribution alone. The prior predictive distribution plays a key role in Bayesian model criticism and model selection, as we will see in the following section.

Note that calculation of the prior predictive distribution requires that $\mathrm{p}(\theta)$ is proper; otherwise, $\mathrm{p}(x)$ would be undefined. Note also that $\mathrm{p}(x)$ is the denominator in Bayes' theorem (31.7). Therefore,

$$\mathrm{p}(x) = \frac{\mathrm{p}(x \mid \theta) \times \mathrm{p}(\theta)}{\mathrm{p}(\theta \mid x)}, \tag{31.16}$$

which holds for any value of θ. This formula is very useful if both prior and posterior are available in closed form, in which case the integration in definition (31.15) can be avoided. However, it is necessary to include all normalizing constants in $\mathrm{p}(x \mid \theta)$, $\mathrm{p}(\theta)$, and $\mathrm{p}(\theta \mid x)$, which makes the calculations slightly more tedious.

31.4.2 Prior Criticism

Box (1980) has suggested an approach to compare priors with subsequent data. The method is based on a p-value obtained from the prior predictive distribution and the actually observed datum. Small p-values indicate a *prior-data conflict*, that is, incompatibility of prior assumptions and the actual observations.

Box's p-value is defined as the probability of obtaining a result with prior predictive ordinate $\mathrm{p}(X)$ equal to or lower than at the actual observation x:

$$\Pr(\mathrm{p}(X) \leq \mathrm{p}(x)).$$

If both data and prior are normal, $X \mid \theta \sim N(\theta, \sigma^2)$ and $\theta \sim N(\nu, \tau^2)$, then the prior predictive distribution is $X \sim N(\nu, \sigma^2 + \tau^2)$. It can be shown that Box's p-value is then the upper tail probability of a chi-squared distribution with 1 degree of freedom (a more common name for a $Ga(1/2, 1/2)$ distribution) evaluated at

$$v^2 = \frac{(x-\nu)^2}{\sigma^2 + \tau^2}.$$

Example 31.3. (Continued)
Let us revisit the case-control study from Sect. 31.3.4. The MLE of θ is $x = \log(3 \cdot 193/(5 \cdot 33)) \approx 1.255$ with standard error $\sigma = \mathrm{se}(\hat{\theta}_{ML}) = \sqrt{1/3 + 1/193 + 1/5 + 1/33} = 0.754$. Greenland's prior mean for the log odds ratio θ was $\nu = 0$ and the prior variance was $\tau^2 = 0.5$. We, hence, obtain

$$v^2 = \frac{1.255^2}{0.754^2 + 0.5} = 1.47$$

with an associated p-value of `1 - pgamma(1.47, 1/2, 1/2)`=0.22. Thus, by this check, the prior and the actually observed data appear to be fairly compatible, because Box's p-value is not remarkably small.

31.4.3 Bayesian Model Selection

Suppose we entertain two competing Bayesian models M_0 and M_1 and we are interested to know which one describes the data x better. Bayesian model choice is based on a variant of Eq. 31.4. Suppose we denote by $\Pr(M_0)$ and $\Pr(M_1)$ the prior probabilities of model M_0 and M_1, respectively, with $\Pr(M_0) + \Pr(M_1) = 1$. Then, the following fundamental equality holds:

$$\frac{\Pr(M_0 \mid x)}{\Pr(M_1 \mid x)} = \frac{\mathrm{p}(x \mid M_0)}{\mathrm{p}(x \mid M_1)} \times \frac{\Pr(M_0)}{\Pr(M_1)}. \tag{31.17}$$

Here, $\Pr(M_0)/\Pr(M_1)$ are the *prior odds*, $\Pr(M_0 \mid x)/\Pr(M_1 \mid x)$ are the *posterior odds*, and $\mathrm{p}(x \mid M_0)/\mathrm{p}(x \mid M_1)$ is the so-called *Bayes factor*, the ratio of the prior predictive distributions of the two models, both evaluated at the observed data x. The Bayes factor, which can be larger or smaller than one, summarizes the evidence of the data for the two models. If the Bayes factor is larger than one, then there is evidence for model M_0; otherwise, there is evidence for model M_1. Note that the Bayesian approach to model selection treats the two models M_0 and M_1 in a symmetric fashion, whereas classical hypothesis tests can only reject, but never accept the simpler model.

The term $\mathrm{p}(x \mid M)$ is also known as the *marginal likelihood*, to contrast it with the ordinary (conditional) likelihood $\mathrm{p}(x \mid \theta, M)$. The marginal likelihood can be calculated based on the prior predictive distribution (31.15).

Example 31.3. (Continued)
We revisit the approximate Bayesian analysis for case-control data and compare model M_0 with a fixed odds ratio of one with model M_1, where we use as before a $N(0, 0.5)$ prior for the log odds ratio ψ. This model comparison is the Bayesian version of the classical

two-sided hypothesis test for the null hypothesis that the odds ratio equals one. As before, we adopt an approximate Bayesian analysis assuming that the observed log odds ratio $\hat{\psi} = 1.26$ is normally distributed with known variance 0.57. The (marginal) likelihood in model M_0 is thus simply the density of a normal distribution with mean zero and variance 0.57, evaluated at $\hat{\psi} = 1.26$. This turns out to be 0.13. The prior predictive distribution in model M_1 is also normal with mean zero, but with variance $0.5 + 0.57 = 1.07$, so the marginal likelihood in model M_1 is 0.18. The Bayes factor of model M_0 relative to model M_1 is therefore $0.13/0.18 = 0.72$. Assuming 1 to 1 prior odds, the posterior odds for M_0 versus M_1 are therefore 0.72, and the corresponding posterior probability of model M_0 has decreased from 0.5 to $0.72/(1 + 0.72) = 0.42$ using the formula in Footnote 1 on page 1164.

It is somewhat surprising that the posterior probability has barely changed, despite a fairly small p-value obtained from Fisher's two-sided test ($p = 0.11$). The corresponding Wald test gives a similar result ($p = 0.096$). This illustrates that the correspondence between Bayesian model selection and p-values is typically lost for the standard two-sided hypothesis test (Berger and Sellke 1987). In particular, p-values cannot be interpreted as posterior probabilities of the null hypothesis.

In the following, we will study the two-sided hypothesis test $M_0 : \theta = 0$ versus $M_1 : \theta \neq 0$ in more detail, assuming that the MLE $\hat{\theta}_{ML}$ is normal distributed with unknown mean θ and known variance σ^2, equal to the squared standard error of $\hat{\theta}_{ML}$. This scenario reflects, at least approximately, many of the statistical procedures found in epidemiological journals.

We now have the possibility to calculate a *minimum Bayes factor* (MBF) (Edwards et al. 1963; Goodman 1999a,b), a lower bound on the evidence against the null hypothesis. The idea is to consider a whole family of prior distributions and to derive a lower bound for the Bayes factor in that family, the minimum Bayes factor. The approach can be taken to the limit by considering all possible prior distributions, in which case the minimum Bayes factor is a universal bound on the evidence of the data against the null hypothesis. Interestingly, the prior distribution $\mathrm{p}(\theta)$ in model M_1 with smallest Bayes factor is concentrated at the MLE $\hat{\theta}_{ML}$, that is, assumes $\theta = \hat{\theta}_{ML}$ a priori. If a z-value $z = \hat{\theta}_{ML}/\mathrm{se}(\hat{\theta}_{ML})$ has been calculated for this two-sided test, then the following formula can be used to calculate this universal minimum Bayes factor (Goodman 1999b):

$$\mathrm{MBF} = \exp\left(-\frac{z^2}{2}\right).$$

For example, if $z = 1.96$, where the two-sided p-value is 0.05, then $\mathrm{MBF} = \exp(-1.96^2/2) \approx 0.15$. If we assume 1 to 1 prior odds, then a universal lower bound on the posterior probability of the null hypothesis M_0 is therefore $0.15/(1+0.15) = 0.13$.

However, the above approach has been criticized since a prior distribution concentrated at the MLE is completely unrealistic since we do not know the MLE a priori. In addition, since the alternative hypothesis has all its prior density on one side of the null hypothesis, it is perhaps more appropriate to compare the outcome of this procedure with the outcome of a one-sided rather than a two-sided test, in which case MBF ≈ 0.26, so considerably larger.

Minimum Bayes factors can also be derived in more realistic scenarios. A particularly simple approach (Sellke et al. 2001) leads to the formula

$$\mathrm{MBF} = c \cdot p \log(p),$$

where $c = -\exp(1) \approx -2.72$ and p denotes the p-value from the two-sided hypothesis test (assumed to be smaller than $\exp(-1) \approx 0.37$). For example, for $p = 0.05$, we obtain MBF ≈ 0.41.

Example 31.3. (Continued)
In the case-control example, $z = 1.255/0.754 \approx 1.66$, and we obtain the minimum Bayes factor of $\exp(-1.66^2/2) \approx 0.25$, that is, 1 to 4, and a lower bound of 0.2 on the corresponding posterior probability of model M_0 (assuming 1 to 1 prior odds). Thus, it is impossible that the posterior probability of the null hypothesis is smaller than 0.2 if our prior probability was 0.5.

Of course, from the above, z-value a p-value can be easily calculated, which turns out to be $p = 0.096$. Using this p-value, the more realistic Sellke et al. (2001) approach gives a minimum Bayes factor of 0.61, which corresponds to a lower bound of 0.38 on the corresponding posterior probability. We conclude that for two-sided hypothesis tests, the evidence against the null hypothesis is by far not as strong as the p-value seems to suggest. This general finding is discussed extensively in the literature (Edwards et al. 1963; Berger and Sellke 1987; Goodman 1999a,b; Sellke et al. 2001; Goodman 2005).

31.5 Further Topics

We now discuss more advanced techniques of Bayesian inference: empirical Bayes approaches and Markov chain Monte Carlo methods.

31.5.1 Empirical Bayes Approaches

Empirical Bayes methods are a combination of the Bayesian approach with likelihood techniques. The general idea is to estimate parameters of the prior distribution $\mathrm{p}(\theta)$ from multiple experiments, rather than fixing them based on prior knowledge. Strictly speaking, this is not a fully Bayesian approach, but it can be shown that empirical Bayes estimates have attractive theoretical properties. Empirical Bayes techniques are often used in various applications. For a general discussion, see also Davison (2003, Sect. 11.5). Here, we sketch the idea in an epidemiological context discussing shrinkage estimates of age-standardized relative risks for use in disease mapping.

Suppose that for each region $i = 1, \ldots, n$ the observed number of cases x_i of a particular disease are available as well as the expected number e_i under the assumption of a constant disease risk. We now present a commonly used empirical Bayes procedure which is due to Clayton and Kaldor (1987).

Assume that $x_1, \ldots, x_n$ are independent realizations from $Po(e_i \lambda_i)$ distributions with known expected counts $e_i > 0$ and unknown region-specific parameters λ_i. A suitable prior for the λ_i's is a gamma distribution, $\lambda_i \sim Ga(\alpha, \beta)$, due to the conjugacy of the gamma distribution to the Poisson likelihood. The posterior of λ_i turns out to be

$$\lambda_i \mid x_i \sim Ga(\alpha + x_i, \beta + e_i) \tag{31.18}$$

with posterior mean $(\alpha + x_i)/(\beta + e_i)$, compare Sect. 31.3.3. If α and β are fixed in advance, the posterior of λ_i does not depend on the data x_j and e_j from the other regions $j \neq i$.

Empirical Bayes estimates of λ_i are based on (31.18), but the parameters α and β of the prior distribution are not fixed in advance but estimated based on all available data. This is done by maximizing the implied prior predictive distribution or marginal likelihood, which depends only on α and β. One obtains MLEs $\hat{\alpha}_{ML}$ and $\hat{\beta}_{ML}$ of α and β, which are plugged into Formula (31.18). The resulting posterior mean estimates

$$\frac{\hat{\alpha}_{ML} + x_i}{\hat{\beta}_{ML} + e_i} \tag{31.19}$$

are called *empirical Bayes estimates* of λ_i. They will always lie between the MLEs x_i/e_i and the estimated mean $\hat{\alpha}_{ML}/\hat{\beta}_{ML}$ of the gamma prior; thus, the MLEs are shrunk toward the common value $\hat{\alpha}_{ML}/\hat{\beta}_{ML}$. This phenomenon is called *shrinkage*.

Example 31.4. Lip cancer in Scotland
Consider data on the incidence of lip cancer in $n = 56$ regions of Scotland, as reported in Clayton and Kaldor (1987). Here we obtain $\hat{\alpha}_{ML} = 1.88$ and $\hat{\beta}_{ML} = 1.32$. Figure 31.6 displays the empirical Bayes estimates and the corresponding 95% equi-tailed credible intervals, ordered with respect to the MLEs. Figure 31.6 shows clearly that the MLEs x_i/e_i are shrunk to the prior mean, that is, the empirical Bayes estimates lie between these two extremes. A map of Scotland with the empirical Bayes estimates is shown in Fig. 31.7.

31.5.2 Markov Chain Monte Carlo

Application of ordinary Monte Carlo methods is difficult if the unknown parameter is of high dimension. However, *Markov chain Monte Carlo* (MCMC) methods will then be a useful alternative. The idea is to simulate a *Markov chain* $\theta^{(1)}, \ldots, \theta^{(m)}, \ldots$ in a specific way such that it converges to the posterior distribution $\mathrm{p}(\theta \mid x)$. After convergence, one obtains random samples from the target distribution, which can be used to estimate posterior characteristics as in ordinary Monte Carlo approaches. To ensure that the samples are taken from the target distribution, in practice, the first iterations, the so-called *burn-in*, are typically ignored. However, note that these samples will be dependent, an inherent feature of Markov chains.

The theory of MCMC is beyond the scope of this chapter, but we will illustrate the procedure in the context of disease mapping as discussed in Sect. 31.5.1. We

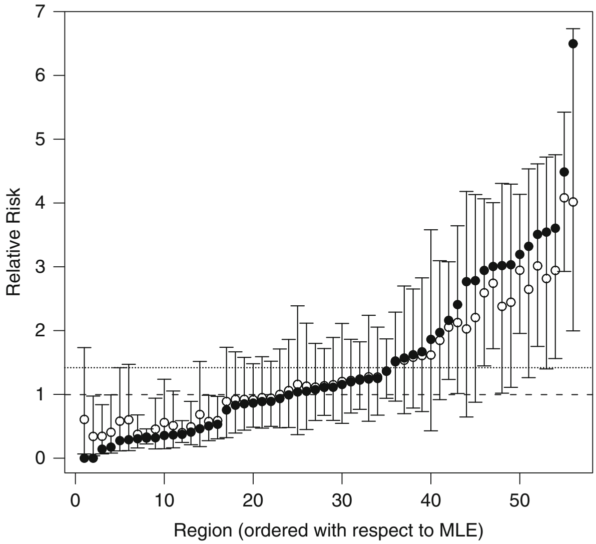


Fig. 31.6 Ninety-five percent equi-tailed credible intervals for Scottish lip cancer incidence rates λ_i $(i = 1, \ldots, 56)$, calculated with an empirical Bayes approach. The *dotted line* marks the MLE $\hat{\alpha}_{ML}/\hat{\beta}_{ML} = 1.42$ of the prior mean. *Open circles* denote the posterior mean estimates of λ_i. The regions are ordered with respect to their MLEs x_i/e_i, shown as *filled circles*

now specify a prior on the log relative risks $\theta_i = \log(\lambda_i)$ which takes into account spatial structure and thus allows for spatial dependence (Besag et al. 1991). More specifically, we use a *Gaussian Markov random field* (GMRF), most easily specified through the conditional distribution of θ_i given $\theta_{j \neq i}$, that is, the log relative risks in all other regions $j \neq i$. A common choice is to assume that

$$\theta_i \mid \theta_{j \neq i}, \tau^2 \sim N\left(\bar{\theta}_i, \frac{\tau^2}{n_i}\right), \tag{31.20}$$

here $\bar{\theta}_i = n_i^{-1} \sum_{j \sim i} \theta_j$ denotes the mean of the n_i spatially neighboring regions of region i and τ^2 is an unknown variance parameter. Some decision has to be made to connect the two islands shown in Fig. 31.7 to the rest of Scotland. Here, we assume that they are both adjacent to the nearest mainland region.

To simulate from the posterior distribution a specific MCMC approach, the *Gibbs sampler*, iteratively updates the unknown parameters $\theta_1, \ldots, \theta_n, \tau^2$. We omit details here but refer the interested reader to the relevant literature, for example, Rue and Held (2005).

Example 31.4. (Continued)
We now revisit the lip cancer incidence data in the $n = 56$ geographical regions of Scotland, allowing for spatial dependence between the relative risk parameters as described above. The following results are based on a Markov chain of length 100,000 where the first 10,000 samples were disregarded as burn-in. Figure 31.8 displays the corresponding posterior mean relative risks. Compared with the empirical Bayes estimates shown in Fig. 31.7, obtained from a model without spatial dependence, a spatially smoother picture can be observed.

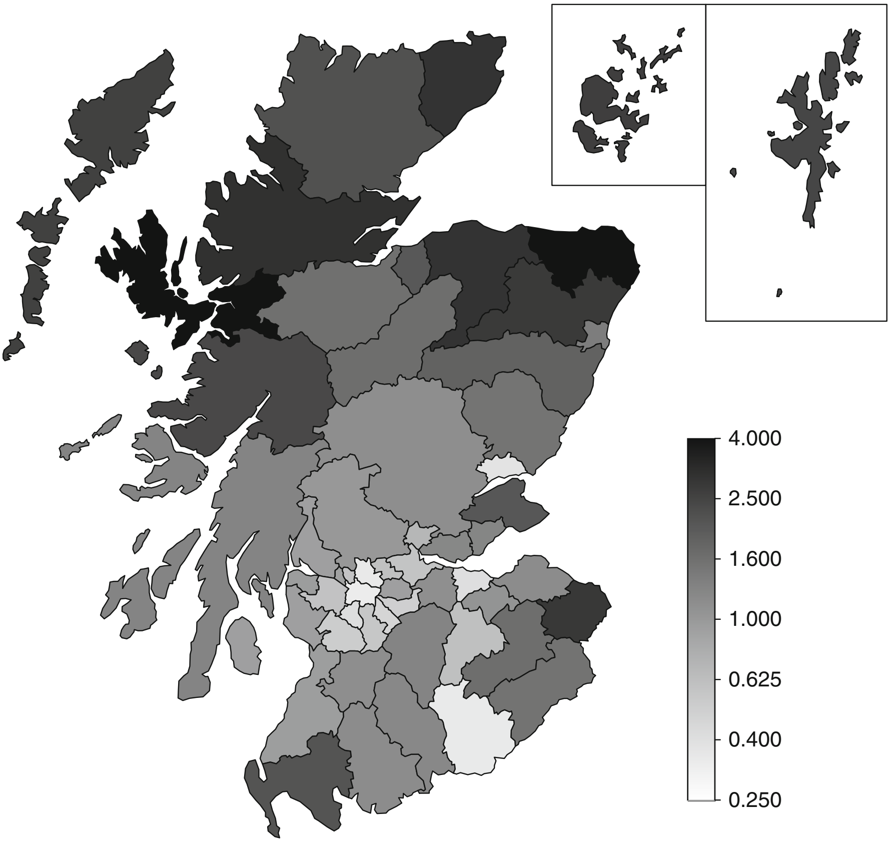

Fig. 31.7 Geographical distribution of the empirical Bayes estimates of the relative risk of lip cancer in Scotland

31.6 Conclusions

The Bayesian approach to statistical inference offers a coherent framework, in which both parameter estimation and model selection can be addressed. The key ingredient is the prior distribution, which reflects our knowledge about parameters or models before we integrate new data in our analysis. Bayesian statistics produces statements about the uncertainty of unknown quantities conditional on known data. This natural approach is in sharp contrast to frequentist procedures, which produce probability statements about hypothetical repetitions conditional on the unknown parameter and model.

The key to Bayesian statistics is the representation of prior beliefs through appropriate probability distributions. The key technique to update these prior beliefs in the light of new data is Bayes' theorem. Bayesian inference thus provides a

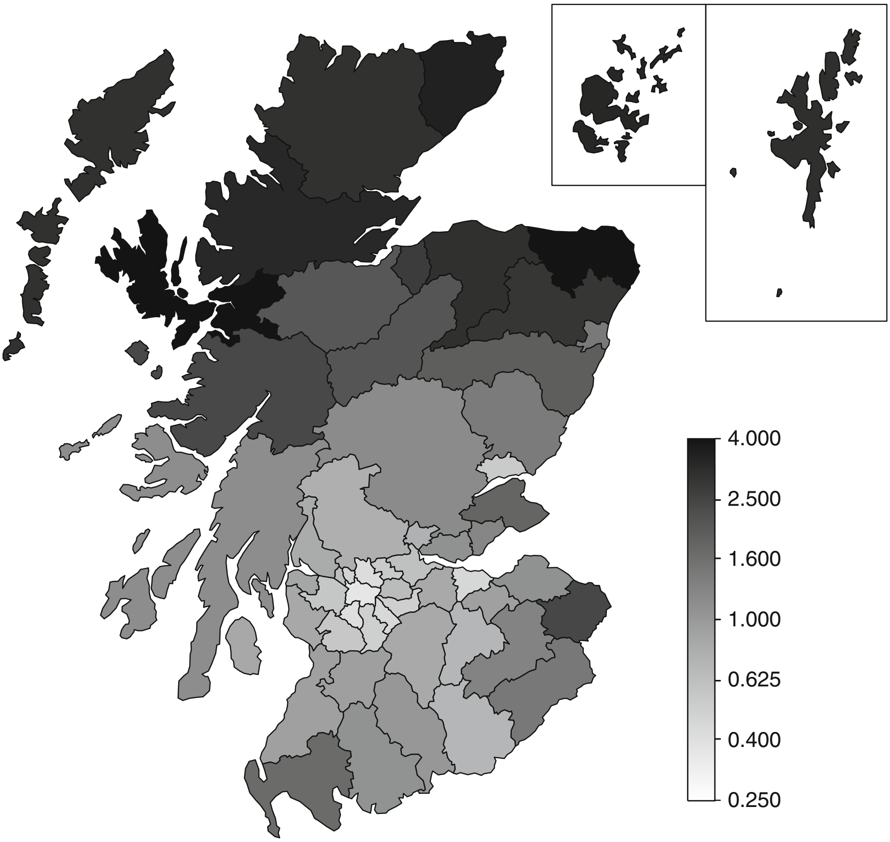

Fig. 31.8 Geographical distribution of the posterior mean relative risk estimates of lip cancer in Scotland, obtained through a GMRF approach

coherent way to update our knowledge in the light of new data. In the absence of conjugacy, the computation of the posterior distribution may require certain advanced numerical techniques such as Markov chain Monte Carlo.

I think it is important to emphasize relationships and differences between the frequentist and the Bayesian approach in order to appreciate what each of the different inference schools has to offer. A frequentist approach to parameter estimation based on the likelihood function alone can be regarded as a limited Bayesian form of inference in the absence of any prior knowledge. Such an approach typically leads to numerically similar results of both point and interval estimates. However, the possibility to specify a prior distribution is increasingly considered as something useful, avoiding implicit unrealistic assumptions of a frequentist analysis. Empirical Bayes approaches, which estimate a prior distribution from multiple experiments, are a compromise between the frequentist and Bayesian approach.

However, the frequentist and the Bayesian approach can lead to very different answers when it comes to hypothesis testing. A striking example is the two-sided hypothesis test, where the evidence against the null hypothesis, quantified by the Bayes factor, is by far not as strong as the p-value might suggest.

Appendix A. Rules of Probability

In this appendix, we summarize basic rules from probability theory. We also give a summary of important probability distributions.

A.1. Probabilities and Conditional Probabilities

Any experiment involving randomness can be modeled with probabilities. Probabilities are assigned to events such as "It will be raining tomorrow" or "I will suffer a heart attack in the next year." The *certain event* has probability one while the *impossible event* has probability zero. From a Bayesian perspective, probabilities are subjective in the sense that they quantify personal uncertainty that the event considered actually happens. Subjective probabilities can be elicited with a simple bet. If the actual realization of the event considered gives a return of 100 US dollar, say, and somebody is willing to bet up to but not more than p US dollars on that event happening, then his personal probability for the event is $p/100$.

Any event A has a disjoint, *complementary event* A^c such that $\Pr(A)+\Pr(A^c) = 1$. For example, if A is the event that "It will be raining tomorrow" then A^c is the event that "It will be not raining tomorrow." More generally, a series of events $A_1, A_2, \ldots, A_n$ is called a *partition* if the events are pairwise disjoint and if $\Pr(A_1) + \ldots + \Pr(A_n) = 1$.

Conditional probabilities $\Pr(A \mid B)$ are calculated to update the probability $\Pr(A)$ of a particular event under the additional information that a second event B has occurred. They can be calculated via

$$\Pr(A \mid B) = \frac{\Pr(A, B)}{\Pr(B)}, \tag{A.1}$$

where $\Pr(A, B)$ is the probability that both A and B occur. Rearranging this equation gives $\Pr(A, B) = \Pr(A \mid B) \Pr(B)$, but $\Pr(A, B) = \Pr(B \mid A) \Pr(A)$ must obviously also hold. Equating and rearranging these two formulas gives Bayes' theorem:

$$\Pr(A \mid B) = \frac{\Pr(B \mid A) \Pr(A)}{\Pr(B)}. \tag{A.2}$$

Conditional probabilities behave like ordinary probabilities if the conditional event is fixed, so $\Pr(A \mid B) + \Pr(A^c \mid B) = 1$. It then follows that

$$\Pr(B) = \Pr(B \mid A)\Pr(A) + \Pr(B \mid A^c)\Pr(A^c), \tag{A.3}$$

and more generally,

$$\begin{aligned}\Pr(B) = \Pr(B \mid A_1)\Pr(A_1) + \Pr(B \mid A_2)\Pr(A_2) + \ldots \\ \ldots + \Pr(B \mid A_n)\Pr(A_n)\end{aligned} \tag{A.4}$$

if $A_1, A_2, \ldots, A_n$ is a partition. This is called the *law of total probability*. Equation (A.3) and (A.4) may be useful to calculate the denominator in Eq. (A.2).

A.2. Probability Functions

We now switch notation and replace Pr with p and events A and B with possible realizations x and y of *random variables* X and Y to indicate that the rules described in Appendix A.1 hold for any event considered. The formulas also hold if continuous random variables are considered, in which case $\mathrm{p}(\cdot)$ is a *density function*. For example, Eq. (A.1) now reads

$$\mathrm{p}(x \mid y) = \frac{\mathrm{p}(x, y)}{\mathrm{p}(y)} \tag{A.5}$$

while Bayes' theorem (A.2) translates to

$$\mathrm{p}(x \mid y) = \frac{\mathrm{p}(y \mid x)\,\mathrm{p}(x)}{\mathrm{p}(y)}. \tag{A.6}$$

Similarly, the law of total probability (A.4) now reads

$$\mathrm{p}(y) = \int \mathrm{p}(y \mid x)\,\mathrm{p}(x) dx, \tag{A.7}$$

where the integral $\int dx$ with respect to x is to be understood as a sum over x if $\mathrm{p}(x)$ is the probability function of a discrete random variable X. Combining equations (A.5) and (A.7) shows that the variable x has to be integrated out of the joint density $\mathrm{p}(x, y)$ to obtain the marginal density $\mathrm{p}(y)$ of Y:

$$\mathrm{p}(y) = \int \mathrm{p}(x, y)\, dx. \tag{A.8}$$

Appendix B. Important Probability Distributions

The following table gives some elementary facts about the probability distributions used in this chapter. A random variable is denoted by X, and its probability or density function is denoted by $\mathrm{p}(x)$. For each distribution, the mean $\mathrm{E}(X)$, variance $\mathrm{var}(X)$, and mode $\mathrm{mod}(X)$ is listed, if appropriate.

In the first row, we list the name of the distribution, an abbreviation, and the core of the corresponding `R`-function (*e.g.* `_norm`). Depending on the first letter, represented by the placeholder "`_`," these functions can be conveniently used as follows:

`r` stands for *r*andom and generates independent random numbers from that distribution. For example, `rnorm(n, mean = 0, sd = 1)` generates n random numbers from the standard normal distribution.

`d` stands for *d*ensity and returns the probability and density function, respectively. For example, `dnorm(x)` gives the density of the standard normal distribution.

`p` stands for *p*robability and gives the so-called *distribution function* of X. For example, if X is standard normal, then `pnorm(0)` returns 0.5 while `pnorm(1.96)` is 0.975.

`q` stands for *q*uantile and gives the *quantile function*. For example, `qnorm(0.975)` is $1.959964 \approx 1.96$.

The first argument `arg` depends on the particular function used. It is either the number n of random variables generated, a value x in the domain of the random variable, or a probability p with $0 < p < 1$.

Binomial: $Bin(n, \pi)$	`_binom(arg, size =` n`, prob =` π`)`
$0 < \pi < 1, n \in \{1, \dots, n\}$	$x \in \{0, \dots, n\}$
$\mathrm{p}(x) = \binom{n}{x}\pi^x(1-\pi)^{n-x}$	$\mathrm{L}_x(\pi) \propto \pi^x(1-\pi)^{n-x}$
$\mathrm{E}(X) = n\pi$	$\mathrm{var}(X) = n\pi(1-\pi)$
If $n = 1$ one obtains the *Bernoulli distribution*.	

Poisson: $Po(\lambda)$	`_pois(arg, lambda =` λ`)`
$\lambda > 0$	$x \in \{0, 1, \dots\}$
$\mathrm{p}(x) = \frac{\lambda^x}{x!}\exp(-\lambda)$	$\mathrm{L}_x(\lambda) \propto \lambda^x \exp(-\lambda)$
$\mathrm{E}(X) = \lambda$	$\mathrm{var}(X) = \lambda$

Beta: $Be(\alpha, \beta)$	`_beta(arg, shape1 =` α`, shape2 =` β`)`
$\alpha, \beta > 0$	$0 < x < 1$
$\mathrm{p}(x) = \mathrm{const} \cdot x^{\alpha-1}(1-x)^{\beta-1}$	
$\mathrm{E}(X) = \frac{\alpha}{\alpha+\beta}$	$\mathrm{mod}(X) = \frac{\alpha-1}{\alpha+\beta-2}$ if $\alpha, \beta > 1$
For $\alpha = \beta = 1$ one obtains the uniform distribution on the interval (0, 1).	

Gamma: $Ga(\alpha, \beta)$	`_gamma(arg, shape =` α`, rate =` β`)`
$\alpha, \beta > 0$	$x > 0$
$\mathrm{p}(x) = \mathrm{const} \cdot x^{\alpha-1}\exp(-\beta x)$	
$\mathrm{E}(X) = \alpha/\beta$	$\mathrm{mod}(X) = (\alpha-1)/\beta$ if $\alpha > 1$

Normal: $N(\theta, \sigma^2)$	$\_\texttt{norm}(\texttt{arg}, \texttt{mu} = \theta, \texttt{sd} = \sigma)$
$\sigma^2 > 0$	
$\mathrm{p}(x) = \text{const} \cdot \frac{1}{\sigma} \exp\left(-\frac{1}{2}\frac{(x-\theta)^2}{\sigma^2}\right)$	$\mathrm{L}_x(\theta) \propto \exp\left(-\frac{1}{2}\frac{(x-\theta)^2}{\sigma^2}\right)$
$E(X) = \theta$	$\mathrm{var}(X) = \sigma^2$
$N(0,1)$ is called standard normal distribution.	

Log–normal: $LN(\theta, \sigma^2)$	$\_\texttt{lnorm}(\texttt{arg}, \texttt{meanlog} = \theta, \texttt{sdlog} = \sigma)$
$\sigma^2 > 0$	$x > 0$
$E(X) = \exp(\theta + \sigma^2/2)$	$\mathrm{mod}(X) = \exp(\theta - \sigma^2)$
$\mathrm{var}(X) = (\exp(\sigma^2) - 1) \cdot E(X)^2$	
If X is normal, i.e. $X \sim N(\theta, \sigma^2)$, then $\exp(X) \sim LN(\theta, \sigma^2)$.

32.1 Introduction

The term survival analysis originally referred to statistical study of the time to death of a group of individuals. From a mathematical perspective, it is irrelevant whether one is studying time until death or time to any other event, and so the term has come to be applied to methods for analyzing "time-to-event data." Although often not explicitly stated, we are always interested in the time between two events. For instance, one might be studying the age of death (the time from birth until death), survival of cancer patients (the time from diagnosis until death), or the incubation time of a virus (time from infection until the development of symptomatic disease). Survival analysis is more complicated than the analysis of other measurements because one often has only partial information regarding the survival time for some individuals. The most common form of partial information arises when a study is stopped before all participants have died. At that point, we might know that Mrs Patel survived for at least 3.7 years, but not know whether she will die a week later or 25 years later. The observation on Mrs Patel is said to be (right) censored at 3.7 years.

The goal of a survival analysis might be to describe the survival distribution for a group of individuals. One might wish to present the median age at onset of a particular disease and add that 90% of cases occur before a certain age. More often, epidemiologists are interested in factors that influence survival. In such instances, the aim of survival analysis is to estimate the effect of the factors on survival times.

Occasionally, survival times may vary little between individuals: the vast majority of humans is born at the end of 36 to 42 weeks of gestation. More frequently, survival times can vary hugely: the duration of a detectable viral infection could be anything from a few days to many years. In such circumstances, it is convenient to describe the rate at which the event (clearance of the virus) occurs. Using rates is particularly appealing when the event will never be observed in the majority of individuals being studied. It makes sense to talk about the average rate of breast cancer in a population even though the majority of the population will never get breast cancer. Studying disease rates and the factors that influence them is indeed central to much of epidemiology.

In this chapter, we consider three major objectives of survival analysis:

- The description of the survival experience of a group of individuals
- Comparison of the survival between two or more groups
- Regression analysis of variables that influence survival

We describe analyses appropriate for the most common study designs in epidemiology and briefly discuss methods that can be used in more complicated settings. The chapter is intended to give the reader a broad overview of the main techniques in survival analysis and to provide examples of the sorts of epidemiological problems that are amenable to survival analysis. There are now a number of texts on survival analysis written for a non-mathematical audience. Most are written either from the perspective of clinical trials or engineering. The book by Marubini and Valsecchi (1995) is written for a clinical audience and provides detailed worked examples. The book by Breslow and Day (1987) is written specifically for cancer epidemiologists but focuses on design and analysis of cohort studies rather than specifically on survival analysis. More recent books on survival analysis written primarily for medical statisticians are Hosmer and Lemeshow (1999) and Therneau and Grambsch (2000). The book by Selvin (2008) is specifically written for epidemiologists.

32.2 Data

The data from epidemiological survival analysis studies might be categorized into two types. The first are large data sets that can be analyzed at an aggregate level, even if the data are available at an individual level. Analyses of these data sets, perhaps obtained from a cancer registry, often focus on changes in rates of disease over time. The second sort of data are from smaller studies, and the analysis is carried out using individual-level data. Information about the characteristics of each person (e.g., his/her sex and blood pressure) is recorded with his/her survival data. Such data are commonly found in cohort studies. To provide a taste of the wide variety of survival data sets from epidemiological studies, we next present some examples. Their analysis will be described later on.

Example 32.1. Rates of cervical cancer
Data from different countries' cancer registries were extracted for the years 1982–1989 by Sasieni and Adams (1999). The aim was to compare the rate at which women in each country developed cervical cancer.

Example 32.2. Skin cancer in organ transplant recipients
Organ transplant recipients have an increased risk of skin cancer post-operation. Harwood et al. (2013) considered 931 patients in the UK who were transplanted with a kidney and were followed for more than 6 months. They analyzed the time to first and subsequent skin cancers by relating them to risk factors, in order to inform possible surveillance strategies.

Example 32.3. Cervical cancer in England and Wales since 1950
Cervical cancer mortality rates changed considerably during the second half of the twentieth century. It is well known that the rates vary with age, being essentially 0 until the age of 20 and then increasing slowly at first and rapidly in the 30s before reaching a plateau at about age 55. One explanation for the changing rates of cervical cancer over time is the cohort effect, whereby women's exposure to the human papilloma virus (HPV) during their teens and 20s largely determines their risk of cervical cancer throughout the rest of their lives. Thus, cervical cancer rates may be seen to vary as a function of the year of birth. Additionally changes in calendar time may affect the mortality rate from cervical cancer regardless of a woman's underlying risk of the disease. For example, improvements in treatment might reduce the mortality from cervical cancer at all ages. Sasieni and Adams (2000) used data from England and Wales to investigate age, birth cohort, and the secular trends that may be attributed to screening.

Example 32.4. Breast cancer screening
Lawrence et al. (2009) examined all breast cancers notified to the UK West Midlands Cancer Intelligence Unit and diagnosed in women aged between 50 and 74, from 1988 to 2004. The 26,766 cases were made up of 10,100 who were detected at screening and 15,862 with symptomatic diagnosis, of whom 6,009 women were diagnosed between screens (interval cancers) and 9,853 who had not attended screening. The endpoint used was death from breast cancer. The aim of the analysis was to compare the survival of screen-detected and symptomatic cases.

Example 32.5. Cohort of individuals exposed to medicinal arsenic
A cohort of 478 patients treated with Fowler's solution (potassium arsenite) between 1945 and 1965 were followed until the end of 1990 during which period 188 patients died (Cuzick et al. 1992). The endpoint of interest was death from cancer. Completeness of follow-up was achieved through flagging determined from the death certificates.

Example 32.6. Blood transfusions and AIDS
De Gruttola and Lagakos (1989) studied two groups of hemophiliacs who received blood transfusions after 1978 and before blood was screened for HIV infection. One group of 105 patients had a light treatment and received less of the blood factor; there were 157 who were heavily treated. The aim of the analysis was to compare the two groups' times of infection and symptoms.

Example 32.7. Assessment of survival following liver transplantation
Keiding et al. (1990) compared the survival experience of the first 38 primary biliary cirrhosis patients treated in the Nordic countries with liver transplantation with the directly standardized survival of 82 patients receiving transplants in England.

Example 32.8. Bone marrow transplant in childhood leukemia
Galimberti et al. (2002) considered the disease-free survival of 30 children with acute lymphoblastic leukemia (ALL) who were treated with allogenic bone marrow transplants while in first remission.

Example 32.9. Skin cancer
Leung and Elashoff (1996) considered data on $1,548$ patients with melanoma. The patients were followed periodically to detect changes in disease stage. The authors were primarily interested in the time from metastasis to death, but they also wanted to investigate whether this was dependent on the time from stage II disease to metastasis.

Example 32.10. Testing a treatment for primary biliary cirrhosis
Christensen et al. (1985) followed up 216 patients with primary biliary cirrhosis in a clinical trial, who were randomized to either azathioprine or a placebo. Twenty-five explanatory variables on the patient were also recorded. The primary endpoint of interest was death. Recruitment was over 6 years and follow-up a further 6 years. One hundred of the 216 patients died.

Example 32.11. Infant mortality
Moger and Aalen (2005) had survival data on $48,357$ infants from $24,077$ multiple births (e.g., twins, triplets) in Norway between 1967 to 2002 and examined all infants who survived the first week of life. There were 443 deaths, including 23 sibships with two deaths and one sibship with three deaths. The authors aimed to estimate the survival taking into account that the data might not be independent due to common genetic and environmental factors that affect siblings.

32.3 Concepts

This section covers some concepts that are helpful to analyze data such as described above, where the outcome measurement is the time to an event.

32.3.1 Walking Backwards into the Future

A key feature, perhaps the key feature of survival analysis, is that it relates to events that occur in time. In Western cultures, we tend to think in terms of looking forward into the future or backwards into the past. When thinking about survival analysis, it is useful to have the opposite picture. Imagine that you are walking backwards into the future so that the past is in front of you. You can look down to see things in the present and up to view things in the distant past. In order to look into the future, you would need to turn your head around, which is, alas, impossible. Rather the future is revealed as you walk backwards into it. Such a metaphor is important when deciding start and endpoints, which is considered further in Sect. 32.4.2.

32.3.2 Fundamental Quantities

In her first year, a gyneco-oncologist treated eight women with newly diagnosed cervical cancer. One died within 6 months, two more died over the next 3 years, and one died from a stroke 4 years later. Six years after she started, four of the patients were still alive. How should one summarize the survival times of the eight patients? Even with 800 patients and 20 years of follow-up, the problem is not trivial and there is no optimal solution, but some common quantities that help are presented next. Although some of this material may seem to be rather abstract and of little direct relevance to epidemiologists, it is necessary to have a rudimentary understanding of the different concepts in order to be able to critically assess studies analyzed using survival methods.

The random variable of interest in survival analysis is the time from an initiating event to a terminal event. There are several equivalent ways to describe the distribution of this random variable. Outside of survival analysis, one might define the distribution through its density or distribution function or choose to describe only certain features such as the mean and variance. With time-to-event data, it is more usual to define the distribution in terms of either the *survival function* $S(t)$ or the *hazard* or event-rate function $\lambda(t)$, where t is a chosen time after the initiating event. If time is discrete, so that for instance the event can only occur at $t = 1, 2, 3, \ldots$, then the hazard is the probability of an event at t, given survival to t. Most of this chapter is concerned with continuous time, where the survival is a real number greater than zero. For this setup, the hazard function is defined by considering the rate of an event in a short period of time after t (the probability of an event in a short period of time after t given survival to t divided by the length of the period), as the short period gets progressively smaller. In summary, if T is used to denote the continuous random survival time, then:

The Survival Function $S(t)$ is the probability that an event did not occur before t, that is, the event time T is greater or equal to t, and

The Hazard Function $\lambda(t)$ is the instantaneous rate of an event occurring at t, given that it has not yet happened by t.

For example, if interest is in time from contracting a disease to death, then given the time t since diagnosis, the survival function provides the probability of survival to date; the hazard function gives the rate of death at the current time t, given the individual is still alive. For this reason, the hazard function is sometimes called the force of mortality. In symbols

$$S(t) = \Pr(T \geq t) \quad \text{and} \quad \lambda(t) = \lim_{\Delta \to 0} \Pr(T < t + \Delta | T \geq t)/\Delta.$$

Thus, $\lambda(t)\Delta$ is the approximate probability of the event between t and $t + \Delta$; equivalently $1-\lambda(t)\Delta$ is the approximate probability of no event. One can therefore see a relationship between the hazard and survivor functions: $S(t) \approx S(t-\Delta)\{1-\lambda(t)\Delta\}$. That is, the survival function at t is approximately the survival function at t minus a small time Δ, multiplied by the approximate probability of no event in the short period.

Another fundamental quantity used in survival analysis is the cumulative hazard function $\Lambda(t)$, defined as the area under the $\lambda(t)$ curve, or integral of $\lambda(t)$, between 0 and t. By definition, it is also related to $\lambda(t)$ over a small time period Δ through $\lambda(t)\Delta \approx \Lambda(t+\Delta) - \Lambda(t)$. We can therefore rewrite the relationship between the hazard and survivor function as $S(t) \approx S(t-\Delta)[1-\{\Lambda(t+\Delta)-\Lambda(t)\}]$. Extending the argument using a series of short time intervals Δ between $0 = s_0 < s_1 < \ldots < s_n = t$, the survival function at t is given by

$$S(t) \approx \prod_{i=1}^{n} [1 - \{\Lambda(s_i) - \Lambda(s_{i-1})\}] \, .$$

This is useful for Kaplan–Meier estimation later on in Sect. 32.5.2 and is also one way that leads to a compact relationship between the hazard and survivor functions where

$$S(t) = \exp\{-\Lambda(t)\}.$$

32.3.3 Censoring

One of the advantages of working in terms of the hazard function is that it can easily be estimated even in the presence of *right-censored* data (provided the censoring is independent of the event of interest). Right-censoring is the term used to describe the situation in which some individuals are known to have survived for a particular length of time, but it is unknown when beyond that time they died (or will die). Formally, we can consider a death time and a censoring time for each individual. We observe only the smaller of the two times and the knowledge of which came first. In order to be able to interpret analyses of censored data, one usually needs to assume that the censoring time imparts no information regarding the timing of the event of interest other than the fact that the event of interest had not happened by the censoring time. Censoring individuals because they become too ill to attend follow-up clinic, for instance, would create problems because censored individuals will probably have greater mortality in the short-term than uncensored individuals.

An extreme example of censoring is given by the study of disease incidence from a disease registry. The annual hazard or incidence rate is estimated by the number of events during the year divided by the number of individuals (half way through the year) at risk of getting the disease. Ideally, the incidence rate should be calculated for a cohort identified at the beginning of the year, but this is rarely done by population registries. By using the number at risk, one is able to deal not only with individuals who die without getting the disease but also those healthy individuals who immigrate into the area covered by the disease registry. The immigrants are subject to delayed entry or *left-truncation*: we do not know about disease in immigrants before they arrive. Analysis is undertaken assuming that had they got the disease before immigrating they would never have been recorded in the registry.

32.3.4 Competing Risks

The last concept introduced is competing risks or event causes. In previous sections, we have assumed that there is only a single, possibly censored, event of interest. A common approach taken in survival analysis is to treat all censored times in the same way. In practice, there may be many different causes of censoring. These can lead to unrealistic independent censoring assumptions, and the competing risks might need to be considered explicitly in order to draw meaningful conclusions about the event of interest.

For example, when looking at cause-specific mortality, one needs to think carefully about the interaction between different causes of death. The interaction may be structural as in the case when one considers the effect of coding rules on the mortality rates from pneumonia (immediate cause) and cancer (underlying cause) or on cancer of the "uterus site not otherwise specified" and cancer of the "cervix uterus." In these examples, an increase in one may be linked to a decrease in the other. In other examples, certain causes of death will be related due to a common underlying risk factor. Smokers are at substantially increased risk of lung cancer, cardiovascular disease, and respiratory disease. Similarly, obesity can lead to death from a variety of causes. Despite these examples, many researchers treat different causes of death as if they are independent; they concentrate on a particular cause of death and treat all other deaths as independent censoring events. Such an approach is particularly tempting when one is interested in an event other than death: in estimating the age at natural menopause, one would probably treat death as an independent source of censoring. In general, however, the assumption of independence may not hold, and it is meaningless to ask what would happen in the absence of all other causes of death. The key is to concentrate on observable quantities and not to make unsubstantiated guesses at what might happen in the absence of a particular cause. Competing risk is discussed further in Sect. 32.8.2.

A popular approach in epidemiology to side-stepping a full-blown competing risks model is to consider the excess hazard or the relative survival function. Given a standard hazard λ_0 from a reference population, the excess hazard λ_e is the difference between the observed hazard λ and the standard hazard: $\lambda_e = \lambda - \lambda_0$. The relative survival function S_r that follows is $S_r = S/S_0$, where S_0 is the survival function from the reference population. It is useful to contrast the relative survival for patients with a particular type of cancer to the cause-specific survival. If the cause of death is well determined, one might expect the two quantities to be similar. The cause-specific survival (i.e., the survival treating death from other causes as independent censoring) might be bigger than the relative survival if patients who die *with* cancer are incorrectly recorded as having died *from* cancer. Differences will also exist if the population is heterogeneous and those who get (and survive) cancer are not representative of the whole population. For instance, breast cancer patients (particularly those that survive) tend to be of higher social class and therefore have lower rates of mortality from other causes; by contrast, lung cancer patients tend to be smokers and have higher rates of mortality from other causes. Methods for relative survival are considered further in Sect. 32.6.5.

Example 32.12. Mortality from other causes in cancer patients
Sasieni et al. (2002) considered the probability of not dying prematurely as a measure of the proportion cured of a particular cancer. They compared (1) the probability of not dying from the excess hazard before dying from background mortality, (2) the probability of not dying from the cause-specific hazard before dying from background mortality, and (3) the probability of not dying from the excess mortality of other causes before dying from background mortality. For breast cancer, these three probabilities (given as percentages) were 67%, 76%, and 98%, respectively. Thus women with breast cancer are more likely to die of something other than breast cancer than are women without breast cancer, but the excess mortality due to other causes is small. By contrast, the three percentages for women with lung cancer were 11%, 16%, and 60%. So, $100 - 16 = 84\%$ of women with lung cancer die of it, and $100 - 60 = 40\%$ of those who don't still die prematurely.

32.4 Study Design

In this section, we consider some important ingredients for planning or critically assessing a study. The data from pooled, cohort, and period approaches are described, followed by the importance of choosing appropriate start and endpoints and the baseline group to make comparisons. The section ends with a brief overview of some designs covered elsewhere in this handbook that might be useful for survival analysis studies.

32.4.1 Survival Experience

Suppose that the aim of a study is to examine survival over a 20-year period. Then, three fundamental approaches to gathering data for survival analysis are:

1. *Pooled*. Use all patients diagnosed over a 20-year period.
2. *Cohort*. Use a cohort of patients, and follow them up for 20 years.
3. *Period*. Use patients who died in a particular (recent) period and who were diagnosed up to 20 years previously.

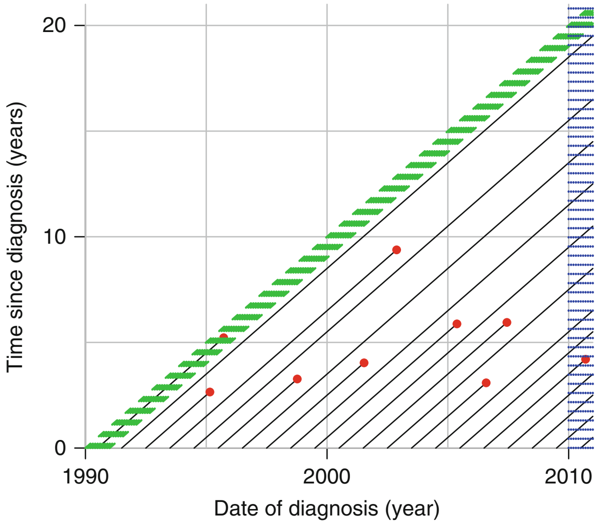

Fig. 32.1 A Lexis diagram to demonstrate some features of epidemiological survival data sets. On the x-axis is the calendar time that an individual had his/her initiating event. The y-axis shows his/her survival time: a line grows at a 45° angle until the terminating event shown by a *dot*. To explore survival, one might (i) pool all events, (ii) follow a cohort, or (iii) use the deaths from a recent period. To demonstrate, the first examines all the individual *lines* plotted, the second follows people from 1990 to 2010 (the *diagonal dashed bar*), and the third examines all the events in 2010 (*dashed vertical bar*)

A pictorial representation of these design options is in Fig. 32.1. The pooled method uses all available data, but if survival has improved over calendar time, the survival function will have been estimated from a mixture of patients given old and new treatments. The cohort approach has the clearest interpretation since it describes the survival experience of a particular cohort. However, using it to estimate 5-year survival will yield outdated estimates if survival has changed over the 20 years since members of the cohort were diagnosed. The period method will in many circumstances provide the best prediction of the current survival experience without explicitly modeling changes in survival over time (year of diagnosis). It is possible that the estimated survival might be inappropriate, if for instance a new treatment increases the hazard of dying in the first year but increases the proportion cured of the disease. More often the use of the most recent data to estimate the relevant hazard will mean that the period method will be favored. It has always been favored by demographers. It was explicitly introduced into epidemiology by Brenner and Gefeller (1996) and has been used by Brenner (2002) and by Sasieni et al. (2002) to study the long-term survival of cancer patients. Applying the period approach to data from the United States of America, Brenner (2002) estimated the 20-year relative survival for all types of cancer to be 51% compared to 40% using the cohort-based survival. The difference reflects the substantial improvement in survival over the past two decades.

32.4.2 Start and Endpoints

Survival analysis is the study of the time from an initiating event to a terminating event. Two aspects of event definitions are considered: (i) they cannot be defined using future data, and (ii) the study objective.

Event Definition The idea of walking backwards into the future is useful to decide what is an acceptable definition of an event. For instance, clinicians are fond of defining a patient as being in remission if he/she has been free of symptoms for a certain number of months (3 say). This is fine. What is not permissible from a probabilistic perspective is to then claim that remission started at the beginning of the 3-month period. As we walk backwards through time, we need to be able to see whether or not a patient is in remission without turning around to look into the future. The difficulty is that if someone has been symptom free for 2 months, we don't know whether or not he/she is in remission – that depends on what happens in the future. Practically, this causes problems in a survival analysis when there are patients in limbo: free from disease, but not for 3 months.

A light-hearted example of a poorly defined initiating event is given by the duration of pregnancy. It is impossible to be just 1 week pregnant! Since the duration of pregnancy is measured from a woman's last period but conception cannot occur until after ovulation (which is generally about 14 days after the previous period), 1 day after conception a woman is said to be 15 days pregnant.

Study Objective The study aim plays an important role in the choice of start and endpoints. When disease is not common in the target group, then death might not be a feasible endpoint: the size of sample required may be prohibitive, and so an earlier stage in the disease might be more appropriate. However, when disease is common among the target group, then death from any cause, sometimes called overall survival or all cause mortality, might be feasible.

There are benefits and drawbacks from choosing overall survival versus a cause-specific endpoint. Consider a study to examine survival in patients with a particular form of cancer (e.g., breast cancer). A drawback of overall survival is that it would dilute treatment effects by including death from causes that are not related to the cancer of interest, and so more data would be required to detect a difference than would be required using an endpoint of death from breast cancer. Indeed such primary endpoints are sometimes preferred (Cuzick 2008). An advantage of overall survival is that it avoids issues associated with cause-specific endpoints that arise from competing risks. For example, a meta-analysis of the early trials of radiotherapy and breast cancer showed that women treated with radiotherapy had lower rates of death from breast cancer but higher rates of death from cardiovascular disease (Cuzick et al. 1994). Later analyses showed that radiotherapy (particularly of the left breast) caused damage to the major blood vessels surrounding the heart. In this case, an analysis that focused solely on death from breast cancer and treated other events as censoring could be disastrously misleading. Similarly, an analysis that focused only on all-cause mortality would have missed the benefits and harms of radiotherapy. Understanding both has led to refinements in radiotherapy that maintained its therapeutic impact but minimized its adverse effects on the heart and major blood vessels.

32.4.3 Baseline Groups

Baseline groups are chosen for comparisons or as a way to standardize rates. The choice of baseline should depend on the study objectives and the nature of the cohort of interest. When studying mortality in a healthy cohort, it is usual to compare their survival experience to that of the general population, but when studying a cohort of very sick individuals or healthy individuals for an event that is not routinely registered, it may be desirable to compare their survival with a different control group. For instance, to assess whether a special residential environment helps to reduce suicide in schizophrenic patients, it would be better to compare them against patients cared for in the community than the general population. Similarly, when comparing relative survival in cancer patients by deprivation, one should preferably use deprivation-specific data on all-cause mortality in those without cancer. Some methods to compare survival of a cohort with a chosen baseline group are described in Sect. 32.6.2.

32.4.4 Choice of Design

Putting together chosen survival experience data, primary endpoints, and baseline groups into a suitable sampling schemes requires care. We review some common examples next that are also covered in more detail elsewhere in this handbook.

Matching A technique used in cohort studies to obtain a comparable survival curve is *matching* to identify patients from the baseline cohort, such as is done in case-control studies. Matching is usually undertaken once an event, such as the diagnosis of disease, has happened. If this event is the endpoint, such as in the time from birth to diagnosis, then the study has a period form. If the event is the start of the period of follow-up, such as in the time from diagnosis to death, then the study will have a cohort or pooled form. The basic idea is to match the cases to controls by using factors that are related to the hazard function. It is common to match on age and sex because the hazard function often increases with age, and men might have a different risk than women. However, the choice of variables used should depend on the study, as the following example demonstrates.

Example 32.8. Bone marrow transplant in childhood leukemia (cont.)
Matching was carried out at diagnosis of leukemia. Controls were selected from 397 ALL patients treated with chemotherapy. Matching was done on white blood cell count at diagnosis (0–10,000; 10,000–50,000; 50,000–100,000; >100,000/*cubic millimeter*), age at diagnosis (<1; 1–10; >10 years), immunophenotype (T-lineage; B-lineage), as well as clinical center and front-line chemotherapy protocol. Additionally, controls had to survive

in remission at least as long as the time from remission to transplant in the patient that they matched. Each of the 30 transplant patients was matched to between 1 and 7 controls. In all, there were 130 controls and no control was matched to more than 1 transplanted patient.

Sampling from the Risk Set Large cohort studies with long-term follow-up are extremely expensive. Studies requiring detailed analysis of food diaries or complicated analysis of blood, urine, or tissue can be prohibitively expensive. For this reason, many epidemiologists have set up cohort studies collecting questionnaires, sera, or urine and storing them for later use. The idea is to nest a case-control study within the cohort study (Langholz and Goldstein 1996; cf. chapter ▶Modern Epidemiological Study Designs of this handbook).

As is well known, in a matched case-control study, it is rarely efficient to collect more than about four controls per case (Breslow and Day 1980). So in a cohort study, one might wish to select a few "controls" from the cohort each time an event (case) occurs. Another approach is to select a small sub-cohort at the beginning and to supplement it with all the cases that develop during follow-up of the main cohort. There are a number of complications related to whether one can use controls selected for one case as controls for later cases (assuming that they are still at risk) and what happens if a control later becomes a case, but such nested case-control and case-cohort designs are extremely important in very large cohort studies looking at diet, genetics, or molecular measures of exposure.

The idea of the nested case-control design was first put forward by Thomas (1977) and was considered at length by Prentice (1986a) and Borgan and Langholz (1993). The case-cohort design was proposed by Prentice (1986b) and has been studied by Self and Prentice (1988) and by Chen and Lo (1999). More recent research has focused on how best to select controls (Langholz and Borgan 1995; Borgan and Olsen 1999). Chen (2002) discussed how to fit a Cox model to a study in which crude covariate information is available on the entire cohort and complete covariate information is available on a sample, but he assumed that the validation sample is chosen at random and it is not applicable to nested case-control designs.

Sampling Bias Finally, it is important to acknowledge sampling biases in the design before analyzing the data.

Example 32.4. Breast cancer screening (cont.)
Analysis of the difference in survival between screen-detected and symptomatic diagnosis is subject to two main sources of bias. Firstly, the initiating event is different (lead time bias). Secondly, slow growing tumors are more likely to be detected by screening (length bias). Both issues are discussed further in this handbook (chapter ▶Screening of this handbook).

Example 32.13. Immortal time bias
Suissa (2008) described observational studies from databases of general practitioner's prescription records that have shown significant beneficial effects of certain prescriptions. These studies ignored the issue that individuals who are exposed to the treatment necessarily survive until it is prescribed: before prescription, they are effectively immortal. Unless immortal time is acknowledged in the analysis, the treatment effect will be biased in favor of the prescription. For a similar reason, on average parents live longer than their children,

but this does not mean that you will live longer if you have children as an adult. It is because anyone who is a parent could not have died as an infant.

32.5 Descriptive Measures

Armed with data from a suitably designed study, the next stage is to summarize it. Some common approaches in survival analysis are first motivated by comparing them to common approaches for data without censoring or the usual univariate summaries. The survival analysis summaries are then discussed in detail.

32.5.1 Univariate Survival Analysis

When the data are not censored, certain univariate statistics and plots are often applied to summarize them. Possible replacements are presented in Table 32.1 and Fig. 32.2, and a more detailed description follows.

Table 32.1 Summary statistics for univariate analysis without censoring and possible replacements for survival data with censoring. The replacements marked * are obtained from Kaplan–Meier or life-table estimates of the survivor function. They are also shown in Fig. 32.2

Complete data	Survival data
Mean	Average rate
Histogram	Kaplan–Meier (KM) plot
Median	Median*
Interquartile range	Interquartile range*
% Improved (binary data)	%5-year survival*

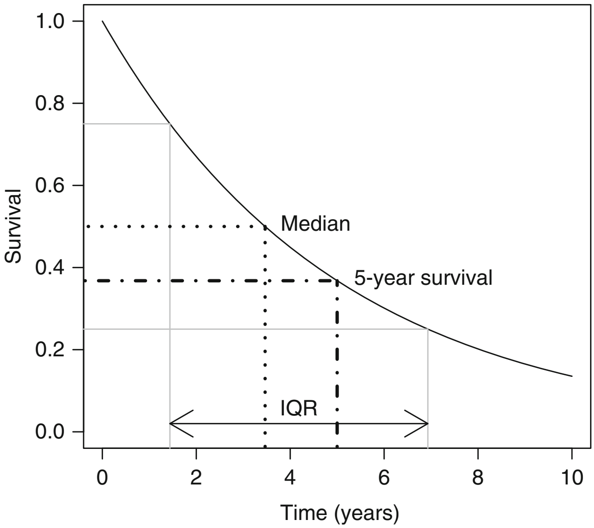

Fig. 32.2 A survival curve with the median, interquartile range (*IQR*), and 5-year survival statistics in Table 32.1 highlighted. Thus about half of the individuals survive more than 3.5 years (median), and a little over 35% survive at least 5 years (5-year survival). The survival for the middle 50% of individuals is between around 1.5–7.0 years (IQR)

In the presence of censoring, or when not everyone will experience the terminating event, the mean survival time may be impossible to estimate. However, a possible replacement is suggested by the fact that when there is no censoring, then the sample mean survival time is the inverse sample rate. This can be obtained when there is censoring.

Histograms are often used to show the spread of the data, but these do not transfer easily to survival data because of censoring. An equivalent way to show the data from a histogram is through a cumulative distribution function (*CDF*). This plot tends to be underused but can be more useful than a histogram, especially when different groups may be compared within the same plot. The survivor function is 1 minus the distribution function, and since it may be estimated (Kaplan–Meier), it can be used as replacement for the histogram.

If there are sufficient uncensored data, survival estimates provide a route to another summary of the location of a distribution, the median. They may also be used to gauge the spread of data through estimates of the interquartile range. Survival estimates are often obtained via Kaplan–Meier estimation, or life tables and these are covered in more detail in the following sections.

In some applications, the outcome is a binary indicator, perhaps denoting success or failure. A possible replacement for the success proportion with survival data is to fix the survival time to 5 years, say, and give an estimate of the proportion of cases that survived: the 5-year survival.

In the rest of this section, we consider how to estimate the survivor function to obtain some of the quantities and then discuss sensible ways to present the average rate.

32.5.2 Kaplan–Meier Survival Estimate

The product definition of the survival function in Sect. 32.3.2 leads naturally to the definition of the product-limit or Kaplan–Meier (1958) estimator of the survival function (see also Example 32.14).

Let $t_1 < t_2 < \ldots < t_n$ be distinct ordered event times observed in a cohort. Let d_j be the number of events at t_j and n_j the number in the cohort "at risk" of having an event observed at t_j. Then d_j/n_j will be a rough estimate of the probability of an event between t_{j-1} and t_j among those at risk at t_{j-1}. When the event of interest is death, once an individual has had an event, he/she is no longer at risk for further events. Similarly if an individual is only followed for 2 years, he/she is not at risk for an *observed* event beyond 2 years. More formally, the cumulative hazard between t_{j-1} and t_j is estimated by d_j/n_j, and $(n_j - d_j)/n_j$ estimates the probability of an individual at risk at t_{j-1} not dying by t_j. The Kaplan–Meier estimate of $S(t)$ is then the product over all t_j less than or equal to t of $(n_j - d_j)/n_j$. That is,

$$\hat{S}(t) = \prod_{t_j \le t} (n_j - d_j)/n_j = \prod_{t_j \le t} (1 - \hat{\lambda}_j).$$

So, in particular, the estimate at t_j is given by $(n_j - d_j)/n_j$ times the estimate at t_{j-1}.

Example 32.14. Cancer data from a clinical trial
To demonstrate the measures to summarize survival, we use the "cancer" data set provided by the statistical software Stata: There are 48 patients who received one of three different drugs, and the endpoint is death. Thirty-one patients died during follow-up.

A summary table of the data is shown in Table 32.2. Figure 32.3 presents a plot of the Kaplan–Meier survival estimates in each of the three arms.

Nelson–Aalen Cumulative Hazard Estimate Some authors prefer to present data in terms of the cumulative hazard function $\Lambda(t)$. The Nelson–Aalen estimator is given by

$$\hat{\Lambda}(t) = \sum_{t_j \le t} d_j/n_j = \sum_{t_j \le t} \hat{\lambda}_j .$$

In words, it is the sum of the estimated hazards at each event time. It is related to the Kaplan–Meier estimate because the Kaplan–Meier estimate uses the same hazard estimate $\hat{\lambda}_j$. The cumulative hazard can sometimes be a more useful way to assess

Table 32.2 Descriptive survival in the three treatment arms

	Survival at 1 year	Survival at 2 years	Median survival (years)	Mean annual mortality rate
Placebo ($n = 20$)	0.23	0	0.67	1.27
Drug 2 ($n = 14$)	0.85	0.21	1.83	0.34
Drug 3 ($n = 14$)	0.86	0.77	2.75	0.21

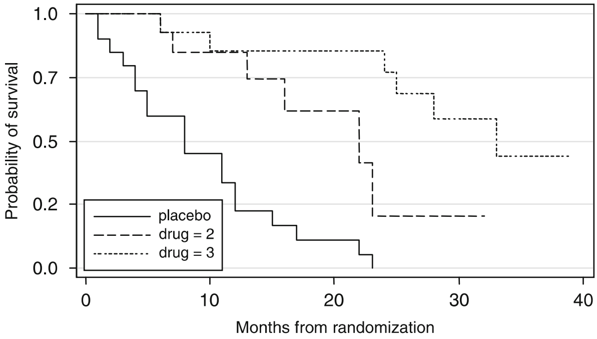

Fig. 32.3 Kaplan–Meier estimates of the survival of cancer patients over 3 years. The three estimates correspond to patients on different drugs. The chart shows an estimate of the probability of survival to each point on the x-axis. It starts at 1.0 on the y-axis because everyone is alive when they entered the trial. Given enough follow-up time, all the survival curves would end at zero; here they are plotted until the longest observation in each arm

how the hazard changes than the survival function. It is particularly useful when an individual may have more than one event.

Example 32.2. Skin cancer in organ transplant recipients (cont.)
The Nelson–Aalen cumulative hazard estimate was useful for this analysis because it was very common to get a second cancer after the first one. Around one in three developed at least one cancer per year following a first cancer, and almost one in six got more than one per year. This showed that regular surveillance was needed once a first skin cancer had been diagnosed.

32.5.3 Life Tables

We have seen that a survival function can be estimated by the product-limit or Kaplan–Meier estimate. Such an approach is standard for small and moderate cohorts. For larger cohorts and for aggregate data, it is more usual to estimate the hazard for a year at a time and to use the hazard function to estimate survival. Sometimes people calculate the person-years at risk in a given time period exactly and then use that as the denominator for calculating the rate. Often, however, the person-years at risk is approximated by multiplying the length of the interval by the mean of the number of people at risk at the beginning of the interval and the number at risk at the end of the interval. Formally one is assuming that on average, anyone who "drops out" or "enters" during the interval will have been at risk for half of the interval. Dividing the number of events in an interval by this estimate of the person-years leads to the life-table estimate of survival. The probability of surviving a long period is computed by multiplying the conditional probabilities of surviving each of the intervals constituting it. Suppose the conditional probabilities have been estimated in intervals of width one and that we wish to estimate the survival at time t such that j is the largest interval that is less than or equal to t. Then the $S(t)$ is estimated by the product of $(1 - p_i)$ for $i < j$ multiplied by $(1 - p_j)^{t-j}$. This method has an extremely long history being first devised in the seventeenth century by Edmund Halley to describe the mortality of the people of Breslau (Halley 1693). The probabilities p_i are calculated by the formula $d_i/(n_i - c_i/2)$ where n_i is the number at risk at the start of the ith interval, d_i is the number dying, and c_i is the number censoring during ith interval.

Whereas in clinical studies, it would be standard to base life tables on a group of patients followed from diagnosis to death; actuarial life tables are not constructed by observing a cohort of newborns until the last survivor dies. Rather they are based on estimates of probabilities of death, given survival to various ages, derived from the mortality experienced by the entire population over a few consecutive years. In that case, there is little point in noting the numbers censored in each interval; rather, one needs to keep track of the size of the risk set. The following fictitious example is provided to show the calculations involved (Table 32.3). Initially 2,456 patients are followed. In the first year, 543 (22%) die leaving 1,913 patients at the beginning of the second year. In the second year, 265 patients die and 22 are censored. In the third year, 934 new patients enter the study. (This could be due to transfer from

Table 32.3 Fictitious life table

Years from diagnosis	No. at start of interval	No. censored	No. of new patients in interval	Deaths	Conditional probability of death	Cumulative probability of survival
j	n_j	c_j		d_j	p_j	S_j
0	2,456	0	0	543	0.2211	1.0000
1	1,913	22	0	265	0.1393	0.7789
2	1,626	130	934	302	0.1489	0.6704
3	2,128	219	0	321	0.1590	0.5706
4	1,588	336	971	317	0.1664	0.4798
5	1,906	447	0	278	0.1652	0.4000

another hospital, and we assume that there is no information on the numbers treated from diagnosis in that hospital but that 934 who were diagnosed between 2 and 3 years earlier were transferred.) The conditional probability of dying in the third year is calculated as $302/(1{,}626 - 130/2 + 934/2) = 0.1489$. Thus the estimated probability of surviving until the beginning of year 4 is $(1-0.2211) * (1-0.1393) * (1 - 0.1489) = 0.5706$.

32.5.4 Standardizing Rates for Age

Since the rates of many diseases are highly age dependent, it may be misleading to present the crude disease rates. We consider three approaches to standardize the rates for age:

Directly Standardized Rate. The traditional approach (cf. chapter ▸Descriptive Studies of this handbook) takes a weighted average of the age-specific rates λ_i, with weights chosen to be proportional to the numbers p_{0i} in each age group in a standard population. This estimate ($\sum \lambda_i p_{0i} / \sum p_{0i}$) is known as the *directly standardized* rate. An alternative approach, indirect standardization is introduced in Sect. 32.6.2.

Cumulative Rate. Another approach is to use the cumulative rate up to some age such as 74 complete years (Day 1976). This has the advantage of dispensing with the selection of a standard population, and it is straightforward to convert from the cumulative rate to the cumulative risk. If the cumulative rate is 1 in x, then, to a very close approximation, the cumulative risk is 1 in $x + 0.5$ (because the cumulative risk, or survival function $\exp(-1/x)$, is mathematically approximately the same as $1/(x + 0.5)$).

Lifetime Risk. A third, less used, approach is to take a weighted sum of the age-specific rates using standard weights (corresponding to the probability of living to that age) so that the cumulative rate has the interpretation of the lifetime risk in a population with standard mortality rates (Sasieni and Adams 1999). An issue

Table 32.4 Cervical cancer rates in various populations around the world

	Age-standardized rate per 1,000 (world standard)	Cumulative rate (from birth) to age 74 per 1,000	Lifetime risk per 1,000
Cali, Colombia	49	50	71
Trujillo, Peru	55	58	77
USA (SEER)			
White	7	7	8
Black	12	12	15

Finland	4	5	6
England and Wales	12	12	13
New Zealand			
Maori	30	31	34
Non-Maori	12	12	13

that sometimes arises is that a single person can have multiple registrations, for example, one for breast cancer and another for colorectal cancer. When data on first registrations alone are not available, Sasieni et al. (2011) developed an adjustment.

Example 32.1. Rates of cervical cancer (cont.)
Table 32.4 extracted from Sasieni and Adams (1999) compares three measures of cervical cancer rates from various cancer registries for the years 1982–1989. The lifetime risk is calculated using all-cause mortality rates from England and Wales in 1992 as the standard. It is seen that the numerical difference between the various measures is not great, but the lifetime risk has perhaps the most natural interpretation.

The age-standardized rate is an average rate for the population (including those for whom the rate is essentially zero, e.g., children). It will not correspond to the crude rate unless the age distribution of the population is identical to that of the standard population. The cumulative rate to age 74 is more easily interpreted, but most people will think of it as a probability, and this is not quite correct – the difference will be particularly great when the cumulative rate is large (or in the presence of competing risks – see Sect. 32.8.2). The lifetime risk can be directly interpreted as the probability of being diagnosed with cervix cancer. It uses the hazard of all-cause mortality from a standard population and assumes that cervical cancer incidence rates are independent of mortality rates from other causes (see competing risks).

32.6 Comparison Between Groups

This section shows some methods to compare the survival experience of two or more groups, where the aim is to quantify the difference. The exponential distribution is first introduced as a way to make inferential statements. Subsequent sections comment on additional ways to compare the groups depending on the study's baseline comparison group.

32.6.1 Exponential Distribution

Model In many applications in epidemiology, it is reasonable to assume that the hazard function is constant over short intervals. The family of distributions with a constant hazard rate is known as the *exponential distribution*, and a distribution with a hazard function that is constant on intervals is known as a piecewise exponential distribution. The likelihood for such piecewise exponential models can be written quite simply and should be the basis for statistical analysis. Confidence intervals and inferential statements follow in the usual way.

Use with Aggregate Data The exponential distribution is often used to test for differences in aggregate data and in life tables. The model parameter is obtained by dividing the number of events in an interval by the number of person-years at risk, which is calculated by adding up the length of time that each individual was at risk within the interval. For instance, inference might be required for cancer incidence data given in 5-year age bands or for survival data given in terms of the number of whole years from diagnosis.

Checking the Assumption A simple way to check whether the constant hazard is reasonable is to use a Nelson–Aalen plot (Sect. 32.5.2) over the period thought to have a constant hazard. Since the model specifies that $\lambda(t) = \lambda$, we know that $\Lambda(t) = \lambda t$. If the exponential distribution is a reasonable approximation, then the Nelson–Aalen estimate of $\Lambda(t)$ should look like a straight line, with slope λ.

Poisson Approximation Although inference using the exponential distribution is relatively straightforward, a Poisson distribution is sometimes applied instead. This is a reasonable approach when one has a large number of individuals all of whom are at risk in an interval with a constant hazard λ per year, then the likelihood looks like a Poisson likelihood: the number of events observed will (to a close approximation) follow a Poisson distribution with mean λn, where n is the number of person-years at risk in the interval. The approximation will be good provided the number of individuals at risk in the interval is at least 10 times λn.

32.6.2 Standardized Mortality Ratios

The survival experience of a group of individuals relative to another group has been described using standardized mortality ratios for over 200 years (Keiding 1987), having first been described by English actuaries in the 1780s. The idea is to compare the expected number of deaths in two groups. We next describe standardized mortality ratios when a cohort is compared with an external baseline group such as the general population, then consider comparisons within a cohort, and provide a way to use the measure when the cohort are all healthy at the start of a study.

Standardization with External Baseline Groups are defined by age and sex and possibly the year of risk. For each group i, let λ_{0i} and n_{0i} denote the mortality rate and the number of person-years at risk in the reference population and λ_i and n_i be the corresponding quantities in the study cohort. The standardized mortality ratio (*SMR*) is defined as SMR $= \sum \lambda_i n_i / \sum \lambda_{0i} n_i$ and is equal to observed number of deaths in the study cohort divided by the expected number under the assumption that the reference population rates apply (cf. chapter ▸Descriptive Studies of this handbook).

Corresponding to the SMR, the indirectly standardized rate is the SMR times the standardized rate in the reference population: SMR $* \sum \lambda_{0i} n_{0i} / \sum n_{0i}$. Please note that the reference population does not serve as a "standard" population for the calculation of an SMR, that is, for the indirect standardization. Rather, the mortality rate of the reference population is standardized by the age distribution of the study cohort. This should be contrasted with the directly standardized rate: $\sum \lambda_i n_{0i} / \sum n_{0i}$. The latter is more widely used when the study cohort is very large but requires reasonable estimates of all the individual λ_i and should be avoided unless all the n_i are reasonably large.

Conditional Inference within a Cohort In cohort studies, one often wants to compare the number of events in two groups within a cohort. This is done by considering the observed number of events and the "expected" number of events in each group. The expected number is calculated as in the SMR by $\sum \lambda_{0i} n_i$. Statistical inference is usually based on the assumption of proportional hazards. That is, it is assumed that in each group, $\lambda_i = k\lambda_{0i}$ for all i. Suppose the observed and expected number of events are O_1 and E_1 in group 1 and O_2 and E_2 in group 2, respectively. Then, under the null hypothesis of equal hazards in the two groups ($\lambda = 1$), O_1 is distributed as a binomial sample from a population of size $O_1 + O_2$ with probability of $E_1/(E_1 + E_2)$. Hence the null hypothesis of no difference between the groups can be tested using an exact binomial test.

Example 32.5. Cohort of individual exposed to medicinal arsenic (cont.)
A comparison was made between the observed number of deaths from various causes (before the age of 85) and the expected number using age-, sex-, and calendar year-adjusted rates from England and Wales. Treating the cohort as a whole, SMRs were calculated for various causes of death (Table 32.5). There was a slight (and non-significant) deficit of death overall (suggesting that the cohort is slightly healthier than the population as a whole). The observed number of five deaths from bladder cancer was three times greater than expected and represented a significant increase compared to the general population.

Of the 5 bladder cancer deaths, 4 were in individuals with a cumulative dose of over 500 milligram (mg). The expected numbers were 0.83 for those exposed to less than 500 mg and 0.80 for those exposed to over 500 mg. Thus to test whether the risk was greater at the higher dose, one calculates the binomial probability of four or more "successes" out of five with a probability of 0.49 ($= 0.80/(0.80 + 0.83)$) each. The binomial probability is 0.18. Hence although the tendency was for the individuals who died from bladder cancer to have been exposed to a greater dose of arsenic, the association was not statistically significant.

Deaths in an Initially Disease-Free Cohort In most applications of the person-years method, it is simply a case of multiplying the number of years at risk by

Table 32.5 Mortality in a cohort of 478 individuals exposed to medicinal arsenic

	Observed number	Expected number	*SMR*	95% CI
All causes	188	209.1	0.90	0.77–1.03
All cancers	47	49.3	0.95	0.70–1.3
All circulatory diseases	97	106.5	0.91	0.74–1.1
Bladder cancer	5	1.6	3.07	1.01–7.3

SMR standardized mortality ratio; *CI* confidence interval

the population risk (mortality rate of a particular disease) and adding these to get an expected number of events (disease-specific deaths). Such estimates often overestimate the true mortality in a given study cohort because of what is known as "the healthy worker effect." Cohorts of individuals working in a particular occupation will often have low mortality rates for the first few years of follow-up simply because if they are working, then they are probably healthy. A particular problem arises in cancer screening studies in which one excludes anyone who already has cancer from the study. For such a cohort, it is not appropriate to simply apply the cancer-specific mortality rates because individuals are all cancer-free at entry. Instead one should explicitly model the probability of first getting cancer (using population incidence rates) and then dying from cancer (using cancer survival rates). Explicit formulae are given in Sasieni (2003), and the method is applied to evaluating colorectal cancer mortality in a cohort having colonoscopy by Dove-Edwin et al. (2005).

32.6.3 Comparisons That Use Matching

When the sample has been obtained by matching, such as in case-control studies, the Kaplan–Meier survival estimate is a useful way to compare the groups either directly or via a summary statistics from Table 32.1. With one-to-one matching, one could simply use the two Kaplan–Meier curves to obtain the statistics or plot the curves directly with standard error bars. If a variable number of "controls" are selected for each patient in the "special cohort," one needs to produce a weighted Kaplan–Meier curve. Here one simply weights each control by the inverse of the number of controls in the matched set so that each matched set of controls has weight 1. Estimation of the survival curve is straightforward, but estimation of its variance is more complicated (Winnett and Sasieni 2002).

Example 32.8. Bone marrow transplant in childhood leukemia (cont.)
Potential controls not matching to any transplanted patients tended to have better survival, although they also included patients who died before there was time for a transplant. Similarly, when there were multiple matching controls, their survival tended to be better. Thus, compared to all 397 controls, the matched sample of 130 controls had excellent survival for the first 6 months, but the survival curves crossed within 12 months of remission, and thereafter the smaller group had worse survival. After taking account of the variable number of controls, the weighted Nelson–Aalen estimate showed that the survival in transplant patients compared with that in those treated was even better (Fig. 32.4).

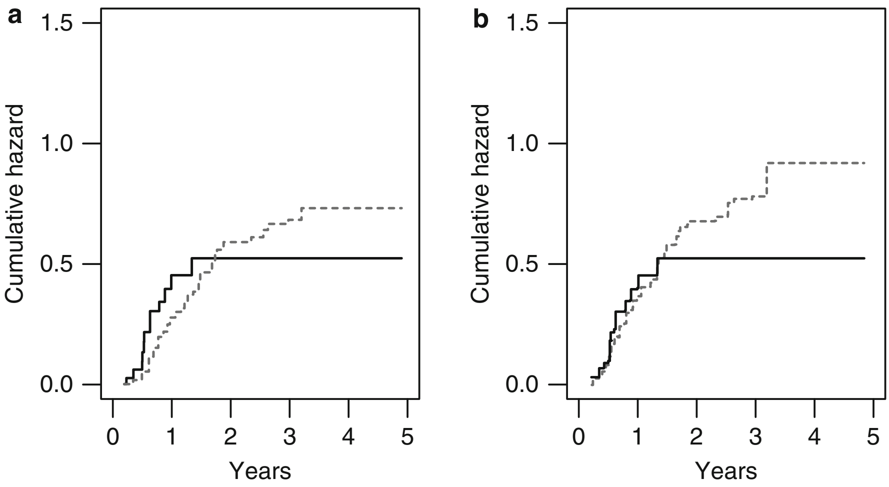

Fig. 32.4 Estimates of the cumulative hazard for the bone marrow transplant (BMT) patients (*solid lines*) and the conventionally treated (CT) patients (*dashed lines*). (**a**) Standard estimates based on 30 BMT and a matched group of 130 CT patients. (**b**) Standard estimate for the 30 BMT patients and weighted estimate for the 130 matched CT patients. In both cases, the CT patients have higher cumulative hazard beyond 2 years

32.6.4 Inference Without a Reference Population

The problem of comparing survival without the use of a reference population will be most relevant when the mortality of all groups in the study is substantially greater than that of the general population so that one can almost ignore the "background mortality." That is, one just compares the groups themselves.

A graphical solution is achieved by plotting the estimated survival function (using the Kaplan–Meier or the life-table approach) on a common set of axes. Comparison of survival at a fixed time (e.g., 3 years) can be made using Greenwood's formula for the variance of the survival estimate (Greenwood 1926). Greenwood's estimate is widely available in software packages, and a formula for calculating the estimated variance can be found in most texts on survival analysis. More sophisticated confidence bands, for the whole survival function, have been proposed by Hall and Wellner (1980).

Another useful summary of the survival in each group is the average event rate, which is estimated by dividing the number of events by the total person-years at risk. For instance, 12 deaths in a group of 100 patients who were followed for a total of 482 person-years would yield a rate of 12/482 or 2.5% per year. This simple approach is also amenable to hypothesis testing. Formally one is assuming a constant rate or exponential model, and the problem of testing between two groups is equivalent to testing for the equality of rate parameters in an exponential regression model.

Table 32.6 2×2 table formed at time T_j

	Die at T_j	Survive T_j	At risk at T_j
Group 1	d_{1j}	$n_{1j}–d_{1j}$	n_{1j}
Group 2	d_{2j}	$n_{2j}–d_{2j}$	n_{2j}

The test statistic most often used in medical statistics is a variant of the log-rank test first proposed by Mantel (1966). This is a test that is intended for use with censored survival data (including right-censoring and left-truncation) and which is most powerful when the proportional hazards model holds. The proportional hazards model is that the hazard in each group g is given by $\lambda_g(t) = \theta_g \lambda_0(t)$. In other words, the ratio of the hazard functions is constant over time. Readers, who are familiar with the Mantel–Haenszel test for a series of 2×2 tables, might like to know that the log-rank test for two groups is equivalent to the Mantel–Haenszel test applied to the set of 2×2 tables, one for each event time. Consider the situation at each event time T_j. Let d_{ij} be the number of events in group i at time T_j and n_{ij} the number at risk as illustrated in Table 32.6.

Although these 2×2 tables are not independent, they are conditionally independent (given the marginals), and the usual formula for the variance of the Mantel–Haenszel test statistic holds.

In epidemiology, it is often useful to be able to stratify the log-rank test so that a valid test can be obtained after adjusting for some other factor. Formally, the test assumes that within each stratum, proportional hazards hold with the same constants of proportionality: $\lambda_{gs}(t) = \theta_g \lambda_{0s}(t)$ for each stratum s and each group g.

Example 32.14. Cancer data from a clinical trial (cont.)
The log-rank statistic (which, under the null hypothesis of no differences in effect on survival between the three drugs, is asymptotically distributed as chi-squared with 2 degrees of freedom (df)) was 30.2 ($p < 0.0001$). Just comparing drugs 2 and 3, gave a log-rank of 3.4 (1 df, $p = 0.065$). However, it was noted that older patients fared worse – the log-rank test for age under 55 versus age over 55, stratified for treatment, had $p = 0.007$ – after stratifying on age, the difference between drugs 2 and 3 became more significant ($p = 0.03$).

32.6.5 Relative Survival

Ederer et al. (1961) proposed two methods of describing the relative survival of a group of cancer patients to that of a standard population. The idea is to divide the observed survival (as estimated by the Kaplan–Meier estimate) in one group of patients by their expected survival based on the experience of a reference group. A key question is how to estimate the expected survival. The Ederer I method simply uses the mean expected survival function: $S_\mathrm{e}(t) = \sum_{\{i=1,\dots,n\}} S_i(t)/n$ where $Si(t)$ is the probability of survival to time t for the ith individual based on the standard population. Here the mean is calculated based on all individuals in the cohort and does not take into account the different make-up of the cohort as individuals die (or are censored). By contrast, the Ederer II method takes the average hazard among those still at risk and converts that to a survival function (via the formula

$S(t) = \exp[-\Lambda(t)]$). The expected or conditional cumulative hazard function is estimated by

$$\Lambda_c(t) = \int_0^t \left\{ \sum Y_i(s)\lambda_i(s) \Big/ \sum Y_i(s) \right\} \mathrm{ds}, \tag{32.1}$$

where $\lambda_i(s)$ is the hazard function appropriate for the ith individual calculated from the reference population and $Y_i(s)$ is an indicator of whether the ith individual was at risk at time s. In the Ederer II method, the survival function does not correspond to the survival of an actual population but is a measure of the excess risk in a competing-risks model. Suppose the hazard in the study population is equal to the hazard in the reference population plus some excess, then the difference between the observed cumulative hazard and the conditional expected cumulative hazard will be equal to the cumulative excess hazard.

The difference between the two methods can be illustrated by reference to a group of cancer patients some of whom are aged 40–49 and some of whom are aged 80–89. In the Ederer I method, the 80- to 89-year-old patients will still have an impact on the relative survival after 10 years. In the Ederer II method, the older patients will have less and less impact on the relative survival as they die. So that, if after 6 years, there are no older patients still at risk, the hazards (both observed and expected) for 7–10 years will be based exclusively on the younger patients.

A slight variation on the Ederer II method was proposed by Hakulinen (1982). Instead of using an indicator of whether the ith individual was still at risk, he suggested using an estimate of whether the ith individual would still be at risk if she/he were subject to the survival of the reference population and the censoring from the study. That is, $Y_i(s)$ is replaced by $S_i(s)C_i(s)$ where $C_i(s)$ is an indicator of whether the ith individual would still have been under follow-up at time s. A problem with this approach is that it requires knowledge of the censoring times even of those individuals who are not censored. That is not a real problem if there is no loss to follow-up and the maximal follow-up time for an individual can be calculated, for instance, from his/her date of entry into the study. An advantage of Hakulinen's method over Ederer II is that the expected survival function can truly be interpreted as a survival function.

Application of these standard approaches is sometimes hampered by missing covariate data. However, statistical techniques to take this uncertainty into account are sometimes appropriate, and Nur et al. (2010) provide a tutorial.

Perme et al. (2012) have recently proposed another alternative. It uses an Ederer II relative survival-type comparison but with two adjustments. Firstly, the at-risk indicator $Y_i(s)$ is replaced by $Y_i(s)/S_i(s)$ in Eq. 32.1. Secondly, they also adjusted the Nelson–Aalen estimate for the group of cancer patients by weighting each event $N_i(s)$ (1 for event, 0 for no event) to be $N_i(s)/S_i(s)$, as well as weighting the at-risk indicator as just described. The idea is to recover the number of events and time at risk in the absence of death from other causes, under an assumption that the reweighting process is suitable. This idea is sometimes called inverse probability weighting. Roche et al. (2013) applied the method as well as the Ederer and the Hakulinen approaches to seven cancer types and compared estimates of 5-, 10-, and 15-year net survival estimates, finding little difference between them for 5-year survival but larger differences for 10- and 15-year survival.

32.7 Regression Analysis of Variables That Influence Survival

Regression models are important when there are several factors upon which the disease rates may depend. Chapter ▸Regression Methods for Epidemiological Analysis of this handbook gives a general introduction to regression models and also discusses some of those examined here. The first model reviewed in this section is Poisson regression. This approach is particularly useful when the mortality in the study population is of the same order of magnitude as that of a standard reference population. It is also sometimes used to make projections of future rates of disease. When considering a cohort of patients with a life-threatening disease, the background rate of mortality is often of little interest, or when studying events other than death, there may be no reference data available. Two sorts of regression model that are useful in these circumstances are also reviewed: accelerated failure time models that relate variables to the survival time and Cox and Aalen semi-parametric models that link variables to the hazard or rate function.

32.7.1 Poisson Regression

The basic observation for Poisson regression consists of numbers of events and numbers of person-years at risk together with a number of covariates. An observation could relate to a single individual (in which case the number of events would usually be 0 or 1), or it could be the sum of the observations from a number of individuals with common covariate values. The model assumes that the observed number of events follows a Poisson distribution with a particular mean given by the number of person-years at risk multiplied by the modeled disease rates. For mathematical simplicity, the usual regression model is multiplicative, that is, it is assumed that the logarithm of the hazard follows a linear regression model: $\ln(\lambda_i) = \sum_j x_{ij}\beta_j$. Such models can be fitted in many software packages. The observed numbers of events, O_i, are the values of the outcome variable, the x_{ij}'s are the covariate values, and the logarithms of person-years at risk p_i are given as offsets – their regression coefficient is forced to be one. In symbols, $E(O_i) = \exp\{\ln(p_i) + \sum_j x_{ij}\beta_j\}$.

In practice, it is often the case that the Poisson assumption is not appropriate. For whatever reasons, mortality and disease registry data often show greater variability than implied by the Poisson model. Various sophisticated solutions to the problem of "extra-Poisson variation" have been put forward, but simple solutions usually suffice. One approach assumes that the variance of O_i is directly proportional to (but not necessarily equal to) the expected value of O_i. Under that assumption, one can estimate the dispersion factor (the coefficient of proportionality), by dividing the Pearson chi-squared statistic for the "saturated model" (that is the model with the most terms in it or the one including all the explanatory variables) by the number of degrees of freedom (McCullagh and Nelder 1989). Inference proceeds by multiplying the model-based standard errors by the square-root of the dispersion factor. Although this quasi-likelihood approach often works well, it lacks a sound theoretical justification, and in practice, it may be difficult to define the saturated model. Another simple approach to dealing with extra-Poisson variation is to use the sandwich estimator of the variance instead of the model-based estimator (Huber 1967). The sandwich estimator, also known as the Huber estimator or even the robust estimator, is available in many statistical packages and provides valid asymptotic inference no matter what the true variance model (hence the name robust), provided the mean model is correct.

Example 32.3. Cervical cancer in England and Wales since 1950 (cont.)
The model used to explain changes in cervical cancer mortality rates during the second half of the twentieth century was

$$\begin{aligned}\ln(\text{rate}) = {} & f_1(\text{age}) + f_2(\text{cohort}) + f_{3a}(\text{year if age 20–49}) \\ & + f_{3b}(\text{year if age 50–69}) + f_{3c}(\text{year if age 70+})\ .\end{aligned}$$

Here the f's are functions that we estimate using cubic splines (f_1 and f_2) or step functions (f_{3a}, f_{3b}, and f_{3c}). Estimates of these functions are plotted in Fig. 32.5. Results summarizing the goodness of fit of this model compared to various sub-models are given in Table 32.7. The scaled deviance is the deviance divided by the dispersion factor from the full model. The dispersion factor is the Pearson chi-squared statistic divided by the degrees of freedom.

The model of a constant rate at all ages and at all times gives a hopelessly bad fit with a scaled deviance of over 40,000 on 671 degrees of freedom. Over 80% of the deviance can be explained simply by allowing the rates to vary with age, but the model still does not fit the data well. Nearly 80% of the remaining deviance (all but 1,194 of 5,789) can be explained by allowing the age-standardized rate to vary with birth cohort; and adding a main effect for period (year of death) leads only to a more modest improvement in the fit. The full model, with interactions between age and period, provides further improvements in the fit suggesting that the dominant factors are age and year of birth but that there have been significant changes over time and that these have not been the same across age groups. The accepted explanation for these age-specific period effects is the widespread use of screening in women age 20–64 from the mid-1980s (see Sasieni and Adams 1999). For instance, the relatively small period effect for ages 70+ can partly be explained by the fact that screening was only offered to women aged 20–64. This makes it unlikely to have had a large effect on mortality in older women, except possibly in recent times in which older women may have been screened several years earlier while still aged under 65 (cf. chapter ▶Screening of this handbook). Finally, note that even the "full" model (with 36 explanatory variables) still had considerable extra-Poisson variation – the dispersion factor was 1.74.

Poisson age–period–cohort models have been used to predict the future number of cases. This raises issues including whether it is better to project current trends or just use present rates and consideration of the most appropriate functional form of any projection. Møller et al. (2003) considered these and other aspects in an analysis of cancer projections against observations in Nordic countries. They found that projections were better than assuming current rates, and recommended certain types of projection. Their approach was used to make cancer incidence predictions in the UK to 2030 by Mistry et al. (2011). Some practical aspects implementing such models in the computer software Stata were described by Sasieni (2012).

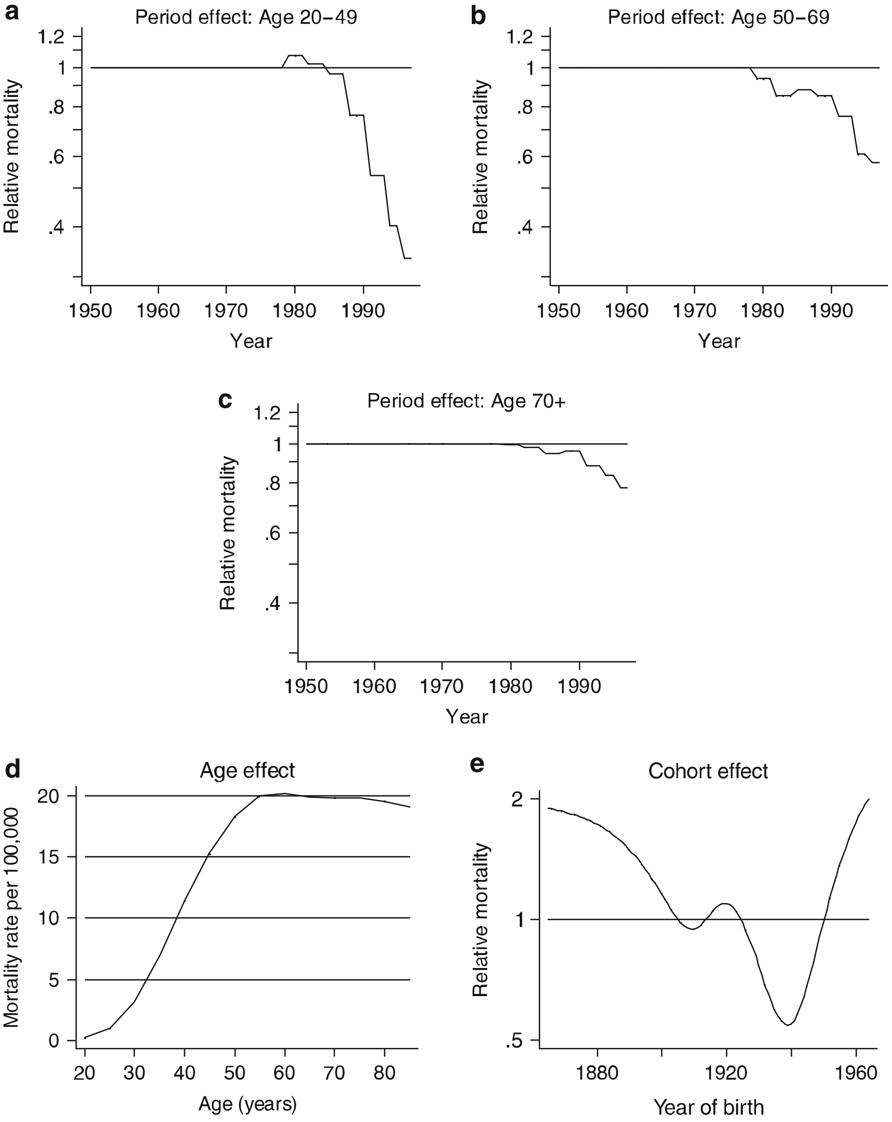

Fig. 32.5 Age, cohort, and age-specific period effects for cervical cancer mortality. The period effects are expressed as relative risks and are constrained to be 1.0 for 1950 to 1977. (**a**) Period effect for women aged 20–49; (**b**) Period effect for women aged 50–69; (**c**) Period effect for women aged 70+ (**d**) Age effect expressed as absolute rate for cohort born in 1905; (**e**) Cohort effect expressed as a relative risk

A common problem in using statistical software for Poisson regression is converting data on individuals including date of entry into the study, date of birth, date of exit and reason for exit (cause-specific death or censoring) into data suitable for Poisson regression: length of time at risk and number of events in

Table 32.7 Age–period–cohort modeling of cervical cancer mortality data from England and Wales

Model	Scaled deviance	Degrees of freedom	Chi-square/ df	Change in sc. deviance	Change in df
Null	41,288	671	95.66		
f_1(age)	5,789	665	14.71	35,499	6

f_1(age) + f_2(cohort)	1,194	656	3.10	4,595	9
f_1(age) + f_2(cohort) + f_3(period)	880	649	2.32	314	7
Full	648	635	1.74	232	14

Table 32.8 Example of how to code an individual for a Poisson model

Age group	Calendar year	Months at risk	Events
60–64	1986	7.5	0
60–64	1987	12	0
60–64	1988	10.5	0
65–69	1988	1.5	0
65–69	1989	12	0
65–69	1990	12	0
65–69	1991	12	0
65–69	1992	12	0
65–69	1993	10.5	0
70–74	1993	1.5	0
70–74	1994	12	0
70–74	1995	12	0
70–74	1996	12	0
70–74	1997	7.5	1

a number of risk groups. The situation can best be illustrated using a Lexis diagram (Keiding 1990; chapter ▸Descriptive Studies of this handbook). The horizontal axis is calendar time, the vertical axis is age, and individuals in the study can be represented by diagonal lines with slope 1. For instance, an individual could enter a study at age 62.5 in May 1986 and be followed until death in August 1997. Suppose population mortality rates are available in 5-year age bands (60–64, 65–69, 70–74, 75–79) for each calendar year. Then the individual's contributions to the various age groups and calendar years are as given in Table 32.8 (see also Fig. 32.6).

The conversion of individual data to age and calendar-year data is often referred to as person-years analysis and is fundamental to the analysis of large cohort studies. Programs exist in many software packages to facilitate the conversion of individual-level data (one record per person) to a format with a separate record for each individual in each risk stratum.

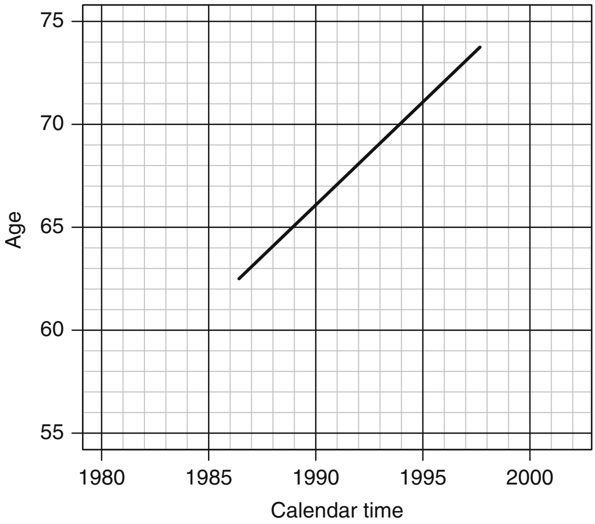

Fig. 32.6 Lexis diagram illustrating the experience of an individual, coded for a Poisson model in Table 32.8

32.7.2 Accelerated Failure Time Models

Most of the literature applying regression models to a function of the survival time assumes that the regression model is applied to the logarithm of the time. Such models are called "accelerated failure time models" because the effect of a covariate is to multiply the time scale on which events occur. It is as if the clock is made to run either slower or faster than usual. The simplest accelerated failure time model assumes that the survival times are exponential random variables, but other parametric models such as Weibull, gamma, and log-normal can also be used. For modeling all-cause adult mortality as a function of age, other distributions such as Gompertz or Makeham with hazards increasing exponentially with time are more appropriate. The book by Kalbfleisch and Prentice (2002) provides details of all these parametric distributions. All these regression models can be written as

$$\ln(T) = \beta_0 + \beta_1 Z_1 + \ldots + \beta_p Z_p + \varepsilon \, , \tag{32.2}$$

where $Z_1, \ldots, Z_p$ are covariates, $\beta_0, \ldots, \beta_p$ are regression parameters to be estimated, and ε is the random component distributed according to some model. (It should be noted that in this formulation, it is not ε but $\exp(\varepsilon)$ that has the named distribution.) A semi-parametric variant of this model uses the same formula (Eq. 32.2) but does not specify a parametric family for the distribution of ε. Parametric accelerated failure time models can be fitted using maximum likelihood estimation in a number of statistical packages. The semi-parametric model requires more advanced algorithms.

When using dummy covariates (i.e., Z_i is equal to 0 or 1), the regression parameters are easily interpreted: $\exp(\beta_i)$ is a multiplicative factor by which the "underlying" survival time is multiplied. If $\exp(\beta_i) = 3$, then on average individuals with $Z_i = 1$ take three times as long as individuals with $Z_i = 0$ to have the event of interest.

32.7.3 The Cox Model

Cox (1972) proposed modeling the conditional hazard as the product of an arbitrary baseline hazard $\lambda_0(t)$ and an exponential form that is linear in the covariates:

$$\lambda(t|Z_1, \ldots, Z_p) = \lambda_0(t) \exp\left(\beta_1 Z_1 + \ldots + \beta_p Z_p\right). \tag{32.3}$$

This model can be fitted quickly using most statistical software. We next comment on some aspects that might be important for applied epidemiology.

Relation to Other Models The restriction $\lambda_0(t) = \lambda_0$ leads to the exponential regression model (which is also an accelerated failure time model). Such a restriction will not generally be appropriate for problems in epidemiology where the underlying mortality rate is far from constant in time.

Taking $\lambda_0(t)$ to be the hazard from a reference population (i.e., discrete time) leads to the Poisson regression model (Breslow et al. 1983). Such modeling is particularly useful in epidemiology in which the goal may be to compare the survival of a study population to that of a reference population and to consider variables that affect the relative mortality. For this problem, Andersen et al. (1985) proposed a Cox-type model for the relative mortality replacing $\lambda_0(t)$ by the product of the individual-specific population mortality at time t, $\lambda_i^*(t)$, and an underlying relative mortality function, $\nu_0(t)$. They applied this model to patients with diabetes mellitus. Such a model may seem reasonable when studying a cohort at increased (or decreased) mortality from a number of causes, but the proportional excess mortality model (See 'Excess Risk' at the end of this section) may seem more appropriate when the cohort are at particular risk of certain causes of death and when that risk is unrelated to their underlying risk of death from other causes.

Censoring In the Cox model, there are three components to the data on each individual: the possibly censored failure time T; an indicator δ equal to 1 if T is a true failure time, 0 if it is censored; and $\vec{Z}$, the vector of explanatory variables. The model is flexible enough to incorporate explanatory variables that change value over the course of the study. The key censoring assumption is that the observation $(T = t, \delta = 0)$ tells us nothing more than that the true failure time is greater than t. When a study ends, some individuals will still be alive and will be censored. In such situations, it is necessary for survival to be independent of entry time for the above condition to be satisfied. Suppose for instance that early on after the introduction of a new type of surgery, only extremely sick patients are offered the new treatment but that once the hospital has 2 years experience in the technique, they offer it to relatively healthy patients too. If the results of all treated patients are studied 4 years after the introduction of the new technique, then patients censored in under 2 years may have been healthier at entry; thus if follow-up were continued for a further year, their survival in the third year might be better than that of patients entered in the first 2 years who survived 2 years. Thus the censoring time tells us something about the likely survival beyond the censoring time. In such circumstances, it is necessary to include "year of treatment" as an explanatory variable in the model.

We have discussed the effect of survival improving over calendar time when estimating survival rates, but when the duration of recruitment is short compared to the length of follow-up, such administrative censoring can usually be taken to be independent of survival. Other forms of censoring are more problematic. For instance, a patient who fails to attend a follow-up clinic might be too sick to get out of bed. So the fact that she/he was censored at t tells us more than simply that she/he was alive at t.

Relative Risk In the Cox model, $\lambda_0(t)$ is the hazard for an individual with $Z_i = 0$, $i = 1, \ldots, p$. Since all individuals with a $Z_i \neq 0$ are compared against $\lambda_0(t)$, it is called the baseline hazard. The model specifies that the hazard ratio between two individuals is constant over time. If one individual has covariates Z and other has covariates Z^*, then their hazard ratio is given by $\lambda_0(t|Z)/\lambda_0(t|Z^*) = \exp\{\beta(Z - Z^*)\}$, and it does not depend on the baseline hazard.

The relative risk is defined as the ratio of probabilities, that is, $\Pr(T < t|Z)/\Pr(T < t|Z^*)$. The hazard ratio will be a reasonable approximation of the relative risk provided that the event of interest is rare. To demonstrate, consider a hazard ratio of 2.0 and denote survival in the first individual to time t as S. Then the relative risk is $(1 - S^2)/(1 - S)$, or equivalently the relative risk of death in the other group will be $1 + S$ since $1 - S^2 = (1 + S)/(1 - S)$. Thus when the survival is 99% in one group, it will be 98.01% in the other group yielding a relative risk of 1.99, but when the survival in one group is 20%, it will be just 4% in the other group, yielding a relative risk of death of $0.96/0.80$ or 1.2.

Example 32.10. Testing a treatment for primary biliary cirrhosis (cont.)
Table 32.9 presents the results of fitting a Cox model to data from 216 patients with primary biliary cirrhosis in a clinical trial of azathioprine versus placebo (Christensen et al. 1985). The six variables were selected from an initial set of 25 partly using forward stepwise selection. An additional 32 patients were excluded because they had missing values of one or more of the six variables. The regression coefficients may be combined with their standard errors to obtain confidence intervals that rely on the asymptotic normality of the estimates. The positive coefficient associated with treatment implies that patients on the placebo (therapy = 1) had poorer prognosis than those on azathioprine (therapy = 0): the hazard of those on placebo is about 1.7 times greater than that of those on active treatment. Similarly, older patients had poorer prognosis. The hazard ratio associated with two patients aged 50 and 30 is $\exp[0.007\{\exp(3) - \exp(1)\}] = 1.13$. Notice, however, that the effect on survival is not fully described by the information in Table 32.9 because, without estimating the baseline hazard, one cannot translate the regression coefficients into effects on 5-year survival nor on median survival. Most statistical software for Cox regression will

Table 32.9 Cox model fitted to data from a clinical trial comparing the effects of azathioprine and placebo on the survival of 216 patients with primary biliary cirrhosis

Variable	Coding	$\hat{\beta}$	se($\hat{\beta}$)	exp($\hat{\beta}$)
Age	exp[(age in years − 20)/10]	0.007	0.0016	1.0
Albumin	serum value in gram per liter	−0.05	0.018	0.95
Bilirubin	$\log_{10}$ (serum concentration in micromole per liter)	2.51	0.32	12.3
Cholestasis	0 = no central cholestasis; 1 = yes	0.68	0.28	2.0
Cirrhosis	0 = no; 1 = yes	0.88	0.22	2.4
Therapy	0 = azathioprine; 1 = placebo	0.52	0.20	1.7

se standard error

also estimate the cumulative baseline hazard function $\Lambda_0(t)$ which is equal to the integral from 0 to t of $\lambda_0(u)$, and from this, one can calculate the estimated survival function for a given vector of covariates using the formula

$$\hat{S}(t|z) = \exp\{-\hat{\Lambda}_0(t)\exp(0.007\text{age} - 0.05\text{albumin} + 2.51\text{bilirubin} \\ + 0.68\text{cholestasi} + 0.88\text{cirrhosis} + 0.52\text{therapy})\}\ ,$$

where $\hat{\Lambda}_0$ is the estimate of Λ_0.

Stratified Model The basic model (32.3) has been generalized in various directions. A simple generalization is to permit different baseline hazard functions in each of a number of strata. The stratified Cox model assumes that, within each stratum, the proportional hazards assumption is justified and that the effect of the variable Z is the same in all strata:

$$\lambda(t|Z_1, \ldots, Z_p, \text{stratum } j) = \lambda_j(t)\exp\left(\beta_1 Z_1 + \ldots + \beta_p Z_p\right)\ . \qquad (32.4)$$

By incorporating constructed variables that are constant in some strata, the stratified model (32.4) can be used to model interactions between explanatory variables and strata. Suppose, for example, that one is stratifying by sex and including age as an explanatory variable. Let Z_1 = (age − 50) for men, = 0 for women; and let Z_2 = (age − 50) for women, = 0 for men. Then a model stratified on sex that includes Z_1, Z_2, and a treatment indicator Z_3 permits interactions between age and sex but assumes that the treatment acts proportionately on the hazards for any age–sex combination.

Link Functions Some epidemiologists like to use a different mathematical form of the explanatory variables in a Cox model, otherwise called a different link function. One version that is sometimes used is $\lambda(t|Z_1, \ldots, Z_p) = \lambda_0(t)(1 + \beta_1 Z_1 + \ldots + \beta_p Z_p)$. This is still a proportional hazards model, but the effect of different covariates is additive rather than multiplicative. For example if in model (32.3), being male infers a hazard ratio of 2 and being black infers a hazard ratio of 3, then being a black male infers a hazard ratio of 6 (= 2 × 3) relative to white females.

With the additive link, the hazard ratio for black males will be $1 + (2 - 1) + (3-1) = 4$. This form is useful when the variable is at a population level rather than an individual level, such as a percentage of the population exposed. For example, if there is a single term $Z_1(t)$ recording the proportion of individuals exposed to a factor at time t and exposure has a multiplicative effect on the individual hazard, then for a group of n-independent individuals, the appropriate hazard is $n\lambda_0(t)(1 + \beta_1 Z_1(t))$ where $\beta_1 \geq 0$ is the exposure effect. Duffy et al. (2007) considered this issue more generally.

Excess Risk When studying a cohort diagnosed with a particular disease or defined by exposure to a potential risk factor, it is often natural to model the excess mortality (or the excess cause-specific mortality). The reason is that we may assume that members of the cohort are subject to all the usual causes of death and that their "exposure" adds an independent route of death. For instance, patients with lymphoma might die from something unrelated or they might die of their lymphoma; the former will primarily be a function of age (mortality rises steeply with age), and the latter will largely depend on the time since their diagnosis. Gore et al. (1984) considered a variety of models for the analysis of survival in breast cancer patients. Sasieni (1996) showed how the Cox model could be applied to the excess mortality. The model was applied to nearly 1,000 patients with non-Hodgkins lymphoma. As one might have expected the effect of prognostic factors such as histology and stage were greater in the proportional excess model than in the usual Cox model (because these factors will not influence mortality from other causes). The model was also useful in showing that although there was still a deleterious effect of increasing age on the excess mortality, it was less than the effect estimated applying the Cox model to all-cause mortality.

32.7.4 Aalen Model

Aalen (1980, 1989, 1993) proposed an additive model for the conditional hazard function. His model is more general than the Cox model in that it has an unspecified function associated with each covariate. However (with two or more covariates), the Cox model is *not* a special case of the Aalen model. The Aalen model is that

$$\lambda(t|Z_1, \ldots, Z_p) = \lambda_0(t) + \lambda_1(t)Z_1 + \ldots + \lambda_p(t)Z_p\ , \tag{32.5}$$

where the functions $\lambda_0(t), \ldots, \lambda_p(t)$ are all unspecified and $\lambda_0(t)$ is the baseline hazard corresponding to an individual with $Z_i = 0, i = 1, \ldots, p$. It should be noted that if $\{Z_1, \ldots, Z_p\}$ is a set of dummy covariates for some factor, then the Aalen model is simply the non-parametric model allowing a different hazard function for each level of the factor. Biologically, the additive model may be interpreted in terms of excess risk. Such a model would be appropriate if each covariate contributed to a different route of death and these routes were independent of each other.

The fact that the Aalen model is so big (i.e., it has relative few constraints compared to a completely non-parametric model) is both to its advantage and its disadvantage. With no restriction on the relation between hazards over time, the model provides a description of the temporal influence of covariates. The Aalen model may be viewed as a one-step Taylor series approximation (i.e., a linear approximation) of an arbitrary $\lambda(t|Z_1, \ldots, Z_p)$ and will therefore provide a reasonable fit to any data provided the covariates have been centered and their effect is not too strong. For this reason, some suggest the use of the Aalen model as a diagnostic check in conjunction with the Cox model (Mau 1986; Henderson and Milner 1991). A disadvantage of the model is that the results cannot be presented in tabular form but require graphing of the estimated functions. It should also be noted that there is no restriction to prevent $\lambda_0(t) + \lambda_1(t)Z_1 + \ldots + \lambda_p(t)Z_p$ being negative (for some combination of covariate values), but a hazard function must be non-negative, so the model should not be applied to such covariate values.

The Aalen model has been used to model the excess mortality of cancer patients compared to that in the general population by Zahl (1996). He studied the long-term survival of men with colon cancer in Norway. A restriction of the Aalen model has been proposed by McKeague and Sasieni (1994). They suggested that some of the regression functions $\lambda_i(t)$ could be forced to be constant or a simple parametric function of time. Such a model allows parametric estimates of the constant additive effect of certain covariates. The special case $\lambda_0(t) + \beta_1 Z_1 + \ldots + \beta_p Z_p$, like the Cox model, has just one (baseline) hazard function to be estimated.

32.7.5 Using Regression Models to Adjust Survival Curves

When necessary, regression models can be used to adjust survival curves for confounding factors and thereby enable a more appropriate comparison to be made. To demonstrate, suppose we have a study designed to assess whether schizophrenic patients in a special residential environment were less likely to attempt suicide than patients cared for in the community. It might be impossible to set up a randomized study to carry out such a comparison. In this case, the statistical question is how to adjust the survival curve in patients cared for in the community so as to better reflect what one might have expected from the patients receiving residential care had they received usual care. One approach (Makuch 1982; Gail and Byar 1986) is to estimate the survival of each individual in the residential cohort using a model fitted to the standard cohort and to take the average of these survival estimates. For instance, if a Cox model is applied to the standard data with covariates Z_1 and Z_2 and yields estimates $\hat{\Lambda}(t)$ for the cumulative baseline hazard, $\hat{\beta}_1$ and $\hat{\beta}_2$, then the estimated survival curve for an individual with covariates z_{1i} and z_{2i} is

$$\hat{S}(t) = \exp\{-\hat{\Lambda}(t)\exp(\hat{\beta}_1 z_{1i} + \hat{\beta}_2 z_{2i})\} .$$

Example 32.7. Assessment of survival following liver transplantation (cont.)
Keiding et al. (1990) applied a Cox model to the English data with three covariates: ln(urea), ln(bilirubin), and an indicator for diuretic-responsive ascites. About 25% of the transplanted patients died within 2 months of transplant, but few patients died thereafter (the median follow-up was 6 months, the maximum was 3.5 years). This was quite similar to the "expected" survival based on the English data: the expected survival at 2 months was about 75% falling to about 60% by 6 months. The authors also compared the survival of their patients to that of primary biliary cirrhosis patients without transplant from an international trial of medical treatment. Once again, the expected survival was based on the results of fitting a Cox model. The expected survival based on the medically treated patients is similarly poor during the first 2 months but continues to decrease at a rapid rate so that the expected survival at 2 years is less than 20% compared with about 60% observed in the transplanted patients.

32.8 Further Extensions

In this necessarily brief overview of survival analysis, we focused attention on describing survival, comparing groups, and regression models. We end the chapter by commenting further on censoring, competing risks, and frailty.

32.8.1 Censoring and Truncation

Until now we have focused on *right-censoring*. The name comes from picturing a time line that runs left to right. The actual event time lies somewhere to the right of the censoring time, and information regarding what happens to the right of this time is censored. We have also discussed late-entry whereby some individuals do not join the study cohort at (their individual) time zero. Late entry is also sometimes called *left-truncation*. An example would arise in an epidemiological study of people living in a retirement community in which one was interested in factors influencing the age of death. In such a study, individuals only become eligible once they have moved to the retirement community. Some may move in at age 60, and others may not move there until they reach 80 (possibly following the death of a spouse). We observe how old individuals are when they join the community, but we do not know anything about individuals who die before they would have joined the community. If a woman joins at age 78, the fact that she lived to age 78 tells us nothing useful about events to the left of age 78 – had she died at age 76, she would not have been in the study. Both right-censoring and left-truncation can easily be accommodated by all the techniques that we have discussed thus far.

In epidemiology, one also has data that are subject to more extreme forms of censoring. The most extreme form arises from data on prevalence rates. In a cross-sectional study, one could survey whether individuals at different ages have or have not had some event in the past. For instance, one might be interested in age at menarche (and survey adolescent girls as to whether or not they have had their first period) or age at infection of a particular pathogen (and test for antibodies in blood). The assumption in such studies is that the event is not reversible and that the yes/no question will reduce the recall bias associated with asking people how long ago the event occurred. Such *current status* data are also referred to as (case I) *interval-censored* data. Here the age of the individual is the censoring time, and every individual is either left- or right-censored. Those who have not had the event are right-censored. But those who have are left-censored, that is, we know that their true event time lies somewhere to the left of the censoring time. Methods exist for analyzing prevalence data as reviewed by Keiding (1991). The classical problem is the non-parametric estimation of the survival function. The non-parametric maximum likelihood estimator is an extremely good estimator, and it can be estimated efficiently using the "pool adjacent violators algorithm" (Barlow et al. 1972). Testing for differences in survival based on interval-censored data was first discussed by Peto and Peto (1972). Several authors have considered regression models for prevalence data. Technically, fitting parametric regression models with prevalence data by maximum likelihood estimation presents no new problems (Odell et al. 1992). Semi-parametric models present more challenges (Huang 1996). The most widely studied are the Cox (proportional hazards) model and the proportional odds model. Essentially one can alternate between estimating the baseline hazard (or odds) for fixed values of the regression parameters and estimating the regression parameters for fixed value of the baseline function. Lin et al. (1998) proposed using the additive hazards model: $\lambda_0(t|Z) = \lambda_0(t) + \beta_1 Z_1(t) + \ldots + \beta_p Z_p(t)$ for current status data. They showed that the additive hazard model for current status data was equivalent to the usual Cox model for the event "observation made and observed to have died" with the covariate equal to minus the cumulative covariate from the additive hazard model (i.e., the integral from 0 to t of $-Z(s)$). The simple approach proposed by Lin et al. is not efficient and breaks down if the observation times are not independent of the covariates. Martinussen and Scheike (2002) showed how the additive hazard model could be fitted efficiently even in the presence of dependent observation times. Their method cannot simply be applied using standard Cox model software, but it is considerably simpler than efficient approaches to fitting the proportional hazards model to current status data. Groeneboom et al. (2010) proposed two estimators of the survivor function with interval-censoring, a so-called maximum smoothed likelihood estimator and a smoothed maximum likelihood estimator.

In other studies, individuals are screened or questioned periodically. In such studies, event times can be left- (the event happened before the first screen) or right-censored (the event happened after the last screen) or interval-censored (the event happened between two screens). This sort of data is sometimes called interval-censoring case 2 (Groeneboom and Wellner 1992) and sometimes *panel count* data. An added complication that is rarely considered is that the screening test may be less than 100% sensitive. In such circumstances, one should take into account the timing of all previous negative screens, not just the one immediately prior to the one that led to the detection of the event. For case 2 interval-censoring, the non-parametric maximum likelihood estimator of the survival function is harder to compute, but efficient algorithms exist (Groeneboom and Wellner 1992). Once again, testing has been considered (Zhang et al. 2001), and adaptation of the Cox model is possible

(Kooperberg and Clarkson 1997; Goetghebeur and Ryan 2000). A simple solution is to use conditional logistic regression to fit a proportional odds model (Rabinowitz et al. 2000). Rank estimation of a log-linear regression model has also been proposed (Li and Pu 2003). Practical issues such as how to deal with left-truncation in addition to interval-censoring and the effect of changes in disease incidence on the analysis are considered by Williamson et al. (2001).

A further complication arises when the initiating time is also possibly censored. For instance, one might be interested in the distribution of time from an infection to the development of symptomatic disease. It is likely that the time of infection will not be observed directly but will be interval-censored and the time of symptomatic disease may be right-censored. Such data are called *doubly-censored* (De Gruttola and Lagakos 1989).

Example 32.6. Blood transfusions and AIDS (cont.)
Each patient received blood over a period of time before HIV testing on donor blood was carried out, and so the time of infection was interval-censored. The time of infection was right-censored until symptoms were observed. Nearly one in six developed AIDS during follow-up, and a difference was observed between lightly and heavily treated patients.

Example 32.9. Skin cancer (cont.)
The time of metastasis was interval-censored and the time of death was right-censored. The authors used a Weibull model and looked at the effect of treatment, Breslow thickness, sex, site of the metastasis, and the time with stage II disease on survival post metastasis.

32.8.2 Competing Risks

Competing risks are nearly always present in survival analysis, but they may sometimes be dealt with by using an assumption about censoring or by using a comparative measure such as an excess hazard. It may also be possible to design a study with one or more risks removed. For example, one would not need to consider the competing risk of death from being run over by a bus for inhabitants of the Amazon jungle. Examples in epidemiology of when this may be useful are with a group of individuals that are relatively isolated and are therefore not exposed to some diseases or when a group is identified with genetic factors that protect against disease.

However, there are situations in which it is not possible to finesse the issue, and explicit modeling is required. A classic example is a three-state model in which patients start in remission and can either relapse or die while in remission (Fig. 32.7). One would certainly not wish to consider death as a source of independent censoring.

Whenever it is not possible to ignore the competing-risk problem, a common approach in epidemiology is to estimate the *cause-specific hazard* and from that the *cause-specific cumulative incidence*. Demographers and actuaries have traditionally called such quantities *crude*, meaning the joint function of times and causes; they contrast it with *net* for the marginals (integrating out the cause). An example of this setup is as follows.

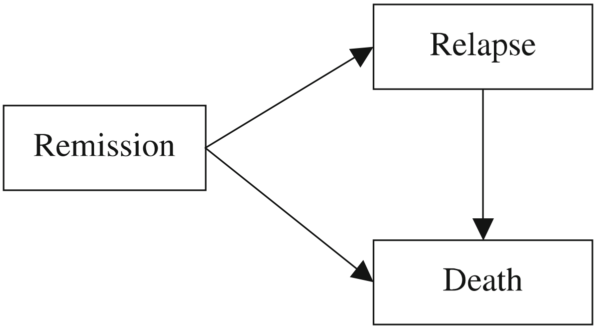

Fig. 32.7 Three-state model

Suppose individuals can die from one of K causes and that there is an additional process that (right) censors the data before they die. For example, individuals might be censored due to the end of follow-up in a clinical trial; we assume that the censoring is independent of mortality. The observed data on the ith individual consist of a survival time T_i and a cause indicator L_i with $L_i = 0$ if T_i is a censoring time. For cause $l \in \{0, 1, \ldots, K\}$, define the cause-specific hazard λ_l as one over Δ times the conditional probability of dying from cause l in the small interval between t and $t + \Delta$ conditional on surviving until time t: $\lambda_l = \Pr\{T < t + \Delta, L = l | T \geq t\}/\Delta$. The all-cause survival function S is defined in the usual way. The crude cumulative incidence function I_l for failures of type l is the probability that an individual will die from cause l by time t: $I_l(t) = \Pr\{T < t, L = l\}$. Let $\hat{S}$ denote the Kaplan–Meier estimator and d_{lj} and n_j the number of deaths of type l and the number at risk at time T_j, respectively. Note that $\hat{S}(T_{j-1})d_{lj}/n_j$ estimates probability of being alive at T_j times the conditional probability of dying from cause l between T_j and T_{j+1} given survival until T_j. Thus $I_l(t)$ can be estimated by $\sum_{\{j:T_j<t\}} \hat{S}(T_{j-1})d_{lj}/n_j$.

Example 32.15. Lung cancer trial

Lagakos (1978) tabulated and analyzed survival data from 194 patients with squamous cell carcinoma enrolled in a clinical trial. Of these, 83 had the event of local spread (cause 1), 44 had metastatic spread (cause 2), and 67 were censored (cause 0). An exponential model with constant cause-specific hazards was used, that is, where $\lambda_l(t) = \lambda_l$ for $l = 1, 2$ for all t. The main aim was to assess if three covariates were related to the survival: performance status (x_1, binary), treatment (x_2, binary), and age in years (x_3). They were included in the model via $\lambda_l = \exp(\beta_{l0} + \beta_{l1}x_1 + \beta_{l2}x_2 + \beta_{l3}x_3)$ for both $l = 1, 2$ causes, and the inferential problem was to assess whether $\beta_{lj} = 0$ for the $j = 1, 2, 3$ covariates. On the basis of the model fit, Lagakos found some evidence of a relationship between performance status and both causes but little for treatment or age. The data were reanalyzed in Crowder (2001), who first assessed whether the exponential model was justified. This was approached by considering a larger model in which the exponential form is a special case. He took $\lambda_l(t) = \phi_l \lambda_l^{\phi_l} t^{\phi_l - 1}$ where ϕ_1, ϕ_2 are additional parameters to be estimated, so that if $\phi_l = 1$, then the exponential model for cause l is obtained. Comparing the log-likelihood from this model (-35.21) with that from the exponential model (-45.57) yielded a log-likelihood ratio $\chi^2 = 2 \times (45.57 - 35.21) = 20.72$ on two degrees of freedom, so there was some evidence that the exponential model was not suitable ($p < 0.0001$). Crowder (2001) went on to consider further sub-models and tests of the covariates and ended up with similar conclusions to those in Lagakos (1978): the only important factor appeared to be performance status.

Further reading on competing risks is in textbooks from Crowder (2001, 2012).

32.8.3 Frailty

It is sometimes necessary to account for additional heterogeneity or lack of independence by allowing some individuals to be more "frail" than others. For instance, a standard life table assumes that all the variability within each cell can be explained by an exponential distribution, so that the hazard for each person i in a cell is the same λ for everyone. But, it might be more appropriate to suppose that the hazard for each person i is $u_i\lambda$, where $u_i \geq 0$ is the so-called frailty that has a distribution over the population. In other words, some individuals or groups are more likely to have the event than others. Allowing for frailty can make inference more robust but also changes the interpretation of observed trends. An example is where the rate of mortality is high at birth, then decreases during childhood and increases thereafter. A first interpretation might be that each infant faces a common hurdle to overcome in their first year of life. The alternative frailty interpretation is that some are more likely to die soon after birth than others, and once the frail babies have died, the healthy ones are still alive.

When the groups of individuals that might have the same frailty are specified in advance so that the hazard is $u_i\lambda_0(t)\exp(\beta_1 Z_1 + \ldots + \beta_p Z_p)$ for each individual in group i, where $\lambda_0(t)$ is an unknown baseline hazard function and $Z_1, \ldots, Z_p$ are known covariates, then a relatively popular extension of the Cox model to estimate the unknown parameters $\beta_1, \ldots, \beta_p$ allows a gamma frailty distribution with unit mean over the population (Clayton and Cuzick 1985). This model can be fitted in most statistical packages, which might explain part of its appeal. In Stata, it is fitted by the command `stcox` using the `shared` option to specify the groups. The gamma distribution is often justified because it is relatively flexible, but other frailty distributions that might be motivated from theoretical considerations have also been assessed, including the stable distribution. These are not currently available in Stata under a Cox model, for example, but when a parametric model is used instead then fitting the model is straightforward: the likelihood is written down, and a general-purpose optimization algorithm can be used to fit parameters.

Example 32.11. Infant mortality (cont.)
Moger and Aalen (2005) used a Weibull hazard and considered three possible parametric frailty distributions to account for common parents: (i) gamma, (ii) power variance function, and (iii) compound Poisson-gamma. All models had two parameters for the Weibull hazard. The first model had one parameter for the frailty distribution, so three in total; the second and third models had four and five parameters in total. The authors used standard routines in the statistical software S-PLUS to fit the models, based on derived likelihood functions. The log-likelihood value for model (i) was −4,865.0, for (ii) it was −4,861.9, and for (iii) it was −4,841.0. Model 3 fitted the data much better, for instance, the log-likelihood ratio

χ^2 for models 3 versus 2 was $2 \times (4{,}841.0 - 4{,}861.9) = 41.9$ on one degree of freedom, which is highly significant ($p < 0.0001$). A possible reason why the third model fitted the data best is that it allowed a proportion of the infants to be non-susceptible.

It might be of interest to estimate whether or not a frailty distribution improves a parametric survival model but without specifying the groups or a parametric frailty distribution. The non-parametric maximum likelihood estimate of the frailty distribution can be estimated using an expectation–maximization algorithm as described by Laird (1978) or by better algorithms mentioned in Crowder (2012).

Multivariate survival analysis is of the joint distribution of $K > 1$ survival times $t_1, \ldots, t_K$ for each unit. For the complete data setup, this is often approached via the multivariate normal distribution, but in survival analysis, one has to deal with censored data and so other techniques are called for, including the use of frailties. For instance, suppose there are two survival times of interest t_1 and t_2. Then one might model the hazard of these events for individual i as respectively $u_i\lambda_1$ and $u_i\lambda_2$, so that the survival times are said to be conditionally independent given u_i. The shared frailty $u_i \geq 0$ leads to positive dependence between the paired survival times. The gamma frailty Cox model mentioned above could be used for this setup. Another approach is to specify that the hazards are $u_{1i}\lambda_1$ and $u_{2i}\lambda_2$, where the frailties arise from a bivariate distribution. There are many more modeling possibilities, but applied work often uses parametric hazard models for λ_1 and λ_2, where a piecewise constant baseline hazard can be useful.

A wide variety of frailty models has been developed to account for aspects including familial relationships and sequences of lifetimes such as time between cancer diagnosis and relapse and then time from relapse to death or the time between skin melanomas. Some books that provide much more detail and focus on multivariate survival analysis are Hougaard (2000) and Crowder (2012); Therneau and Grambsch (2000) also have some material on frailty aspects.

32.9 Conclusions

Survival analysis is more closely associated with clinical medical research than with epidemiology, but there are a number of situations in which survival analysis is needed in epidemiological research. Some form of survival analysis will be required in any cohort study, and many of the more complicated designs used in modern epidemiology require quite sophisticated analytical techniques. In this chapter, we have presented a range of survival analysis tools covering a range of study designs. Before using these techniques, the reader is advised to consult an expert or to read a more complete text, but it is hoped that this chapter will help epidemiologists who come across survival analysis in the writing of others and those who think that they may need survival analysis in their own research.

The notions that events occur in time and that causes precede their effects are central to epidemiological research and the objective of understanding the causes of disease. Longitudinal studies are essential to epidemiology, and the complex evolution of risk factors, disease markers, and disease over time requires sophisticated statistical techniques.

33.1 Introduction

Factors contributing to the presence or absence of disease are not always easily determined or accurately measured. Consequently, epidemiologists are often faced with the task of inferring disease patterns using noisy or indirect measurements of risk factors or covariates. Problems of measurement arise for a number of reasons, including reliance on self-reported information, the use of records of suspect quality, intrinsic biological variability, sampling variability, and laboratory analysis error. Although the reasons for imprecise measurement are diverse, the inference problems they create share in common the structure that statistical models must be fit to data formulated in terms of well-defined but unobservable variables X, using information on measurements W that are less than perfectly correlated with X. Problems of this nature are called measurement error problems, and the statistical models and methods for analyzing such data are called measurement error models.

This chapter focuses on statistical issues related to the problems of fitting models relating a disease response variable Y to true predictors X and error-free predictors Z, given values of measurements W, in addition to Y and Z. Although disease status may also be subject to measurement error, attention is limited to measurement error in predictor variables. We further restrict attention to measurement error in continuous predictor variables. Categorical predictors are not immune from problems of ascertainment, but misclassification is a particular form of measurement error. Consequently, misclassification error is generally studied separately from measurement error; see chapter ▶Misclassification in this handbook.

A case-control study exhibiting measurement error was described in Karagas et al. (2002) and is briefly mentioned here to exemplify the notation. The purpose of the study was to assess the risk of bladder and two forms of non-melanoma skin cancer (Y's) to "true" arsenic exposure (X), adjusting for patient age (Z). True arsenic exposure was measured imprecisely through concentrations of arsenic in toenails (W).

This chapter is organized in three main sections. Section 33.2 defines basic concepts and models of measurement error and outlines the effects of ignoring measurement error on the results of standard statistical analyses. An important aspect of most measurement error problems is the inability to estimate parameters of interest given only the information contained in a sample of (Y, Z, W) values. Some features of the joint distribution of (Y, Z, X, W) must be known or estimated in order to estimate parameters of interest. Thus, additional data, depending on the type of error model, must often be collected. Consequently, it is important to include measurement error considerations when planning a study, both to enable application of a measurement error analysis of the data and to ensure validity of conclusions. Planning studies in the presence of measurement error is the topic of Sect. 33.3. Methods for the analysis of data measured with error differ according to the nature of the measurement error, the additional parameter-identifying information that is available, and the strength of the modeling assumptions appropriate for a particular problem. Section 33.4 describes a number of common approaches to the analysis of data measured with error, including simple, generally applicable bias-adjustment approaches, conditional likelihood, and full likelihood approaches.

This chapter is intended as an introduction to the topic. There are several books providing in-depth coverage of measurement error models. Fuller (1987) studies linear measurement error models. Carroll et al. (2006) provide detailed coverage of non-linear models as well as density estimation. Buonaccorsi (2010) describes additional methods for non-linear models and other topics including time series and misclassification. Gustafson (2004) covers measurement error from a Bayesian perspective with a focus on misclassification.

Other review articles addressing measurement error in epidemiology include Thürigen et al. (2000), Carroll (1998), Thomas et al. (1993) and Armstrong et al. (1992). Prior to the book by Fuller (1987), the literature on measurement error models was largely concerned with linear measurement error models and went under the name *errors-in-variables*. Chapter ▸Regression Methods for Epidemiological Analysis of this handbook presents additional topics in regression modeling.

33.2 Measurement Error and its Effects

This section presents the basic concepts and definitions used in the literature on non-linear measurement error models. The important distinction between differential and non-differential error is discussed first and is followed by a description of two important models for measurement error. The major effects of measurement error are described and illustrated in terms of multivariate normal regression models.

33.2.1 Differential and Non-Differential Error and Surrogate Variables

The error in W as a measurement of X is *non-differential* if the conditional distribution of Y given (Z, X, W) is the same as that of Y given (Z, X), that is, $f_{Y|ZXW} = f_{Y|ZX}$. When $f_{Y|ZXW} \neq f_{Y|ZX}$, the error is *differential*. The key feature of a non-differential measurement is that it contains no information for predicting Y in addition to the information already contained in Z and X. When $f_{Y|ZXW} = f_{Y|ZX}$, W is said to be a *surrogate* for X.

Many statistical methods in the literature on measurement error modeling are based on the assumption that W is a surrogate. It is important to understand this concept and to recognize when it is or is not an appropriate assumption. Non-differential error is plausible in many cases, but there are situations where it should not be assumed without careful consideration.

If measurement error is due solely to instrument or laboratory analysis error, then it can often be argued that the error is non-differential. However, in epidemiological applications, measurement error commonly has multiple sources, and instrument and laboratory analysis error are often minor components of the total measurement error. In these cases, it is not always clear whether measurement error is non-differential.

The potential for non-differential error is greater in case-control studies because covariate information ascertainment and exposure measurement follow disease response determination. In such studies, selective recall, or a tendency for cases to overestimate exposure, can induce dependencies between the response and the true exposure even after conditioning on true exposure.

A useful exercise for thinking about the plausibility of the assumption that W is a surrogate is to consider whether W would have been measured (or included in a regression model) had X been available. For example, suppose that the natural predictor X is defined as the temporal or spatial average value of a time-varying risk factor or spatially varying exposure (e.g., blood pressure, cholesterol, lead exposure, particulate matter exposure) and the observed W is a measurement at a single point in time or space. In such cases, it might be convincingly argued that the single measurement contributes little or no information in addition to that contained in the long-term average.

However, this line of reasoning is not foolproof. The surrogate status of W can depend on the particular model being fit to the data. For example, consider models where Z has two components; $Z = (Z_1, Z_2)$. It is possible to have $f_{Y|Z_1Z_2XW} = f_{Y|Z_1Z_2X}$ and $f_{Y|Z_1XW} \neq f_{Y|Z_1X}$. Thus, W is a surrogate in the full model including Z_1 and Z_2 but not in the reduced model including only Z_1. In other words, whether a variable is a surrogate or not depends on other variables in the model. A simple example illustrates this feature. Let $X \sim N(\mu_x, \sigma_x^2)$. Assume that $\epsilon_1, \epsilon_2, U_1$, and U_2 are mean zero normal random variables such that $X, \epsilon_1, \epsilon_2, U_1, U_2$ are mutually independent. Let $Z = X + \epsilon_1 + U_1$, $Y = \beta_1 + \beta_z Z + \beta_z X + \epsilon_2$ and $W = X + \epsilon_1 + U_2$. Then $E(Y|X) \neq E(Y|X, W)$ but $E(Y|Z, X, W) = E(Y|Z, X)$. The essential feature of this example is that the measurement error $W - X$ is correlated with the covariate Z. The presence or absence of Z in the model determines whether W is a surrogate or not. Such situations have the potential of arising in applications. For example, consider air pollution health effects studies. Suppose that X is the spatial average value of an air pollutant, W is the value measured at a single location, the components of Z include meteorological variables, and Y is a spatially aggregated measure of morbidity or mortality (all variables recorded daily, with X, W, and Z suitably lagged). If weather conditions influence both health and the measurement process (e.g., by influencing the spatial distribution of the pollutant), then it is possible that W would be a surrogate only for the full model containing Z.

With non-differential measurement error, it is possible to estimate parameters in the model relating the response to the true predictor using the measured predictor only, with minimal additional information on the error distribution, that is, it is not necessary to observe the true predictor. However, this is not generally possible with differential measurement error. In this case, it is necessary to have a validation subsample in which both the measured value and the true value are recorded. Data requirements are discussed more fully in Sect. 33.3. Much of the literature on measurement error models deals with the non-differential error, and hence that is the focus of this chapter. Problems with differential error are often better analyzed via techniques for missing data.

33.2.2 Error Models

The number of ways a surrogate W and predictor X can be related are countless. However, in practice, it is often possible to reduce most problems to one of two simple error structures. For understanding the effects of measurement error and the statistical methods for analyzing data measured with error, an understanding of the two simple error structures is generally sufficient.

33.2.2.1 Classical Error Model

The standard statistical model for the case in which W is a measurement of X in the usual sense is $W = X + U$, where U has mean zero and is independent of X. As explained in the preceding section, whether W is a surrogate or not depends on more than just the joint distribution of X and W. However, in the sometimes plausible case that the error U is independent of all other variables in a model, then it is non-differential and W is a surrogate. This is often called the classical error model. More precisely, it is an independent, unbiased, additive measurement error model. Because $E(W \mid X) = X$, W is said to be unbiased measurement of X.

Not all measuring methods produce unbiased measurements. However, it is often possible to calibrate a biased measurement resulting in an unbiased measurement. Error calibration is discussed later in greater detail.

33.2.2.2 Berkson Error Model

For the case of Berkson error, X varies around W and the accepted statistical model is $X = W + U$, where U has mean zero and is independent of W. For this model, $E(X \mid W) = W$, and W is called an unbiased Berkson predictor of X, or simply an unbiased predictor of X. The terminology results from the fact that the best squared-error predictor of X given W is $E(X \mid W) = W$.

Berkson (1950) describes a measurement error model which is superficially similar to the classical error model, but with very different statistical properties. He describes the error model for experimental situations in which the observed variable was controlled, hence the alternative name *controlled variable model*, and the error-free variable, X, varied around W. For example, suppose that an experimental design called for curing a material in a kiln at a specified temperature W, determined by thermostat setting. Although the thermostat is set to W, the actual temperature in the kiln, X, often varies randomly from W due to less-than-perfect thermostat control. For a properly calibrated thermostat, a reasonable assumption is that $E(X \mid W) = W$, which is the salient feature of a Berkson measurement (compare to an unbiased measurement for which $E(W \mid X) = X$).

Apart from experimental situations, in which W is truly a controlled variable, the unbiased Berkson error model seldom arises as a consequence of sampling design or direct measurement. However, like the classical error model, it is possible to calibrate a biased surrogate so that the calibrated measurement satisfies the assumptions of the Berkson error model.

33.2.2.3 Reduction to Unbiased Error Model

The utility of the classical and Berkson error structures is due to the fact that many error structures can be transformed to one or the other. Suppose that W^* is a surrogate for X. For the case that a linear model for the dependence of W^* on X is reasonable, that is, $W^* = \gamma_1 + \gamma_x X + U^*$, where U^* is independent of X, the transformed variable $W = (W^* - \gamma_1)/\gamma_x$ satisfies the classical error model $W = X + U$, where $U = U^*/\gamma_x$. In other words, W^* can be transformed into an independent, unbiased, additive measurement.

Alternatively, for the transformation $W = E(X \mid W^*)$, it follows that $X = W + U$, where $U = X - E(X \mid W^*)$ is uncorrelated with W. Thus, apart from the distinction between independence and zero correlation of the error U, any surrogate W^* can be transformed to an unbiased additive Berkson error structure.

Both types of calibration are useful. The transformation that maps an uncalibrated surrogate W^* into a classical error model is called *error calibration*. The transformation that maps W^* into a Berkson error model is called *regression calibration* (Carroll et al. 2006); see Tosteson et al. (1989) for an interesting application of regression calibration.

In theory, calibration reduces an arbitrary surrogate to a classical error measurement or a Berkson error measurement, explaining the attention given to these two unbiased error models. In practice, things are not so simple. Seldom are the parameters in the regression of W on X (error calibration) or in the regression of X on W (regression calibration) known, and these parameters have to be estimated, which is generally possible only if supplementary data are available for doing so. In these cases, there is yet another source of variability introduced by the estimation of the parameters in the chosen calibration function. This is estimator variability and should be accounted for in the estimation of standard errors of the estimators calculated from the calibrated data.

33.2.3 Measurement Error in the Normal Linear Model

We now consider the effects of measurement error in a simple linear regression model with normal variation. This model has limited use in epidemiology, but it is one of the few models in which the effects of measurement error can be explicitly derived and explained. Measurement error affects relative risk coefficients in much the same way as regression coefficients so that the insights gained from this simple model carry over to more useful epidemiological models.

Consider the multivariate normal formulation of the simple linear regression model,

$$\begin{pmatrix} Y \\ X \end{pmatrix} \sim \mathrm{N}\left\{ \begin{pmatrix} \beta_1 + \beta_x \mu_x \\ \mu_x \end{pmatrix}, \begin{pmatrix} \beta_x^2 \sigma_x^2 + \sigma_\epsilon^2 & \beta_x \sigma_x^2 \\ \beta_x \sigma_x^2 & \sigma_x^2 \end{pmatrix} \right\}. \tag{33.1}$$

If, as is assumed here, the substitute variable W is jointly normally distributed with (Y, X), then in the absence of additional assumptions on the relationship between W and (Y, X), the multivariate normal model for $(Y,\ X, W)$ is

$$\begin{pmatrix} Y \\ X \\ W \end{pmatrix} \sim \mathrm{N}\left\{ \begin{pmatrix} \beta_1 + \beta_x \mu_x \\ \mu_x \\ \mu_w \end{pmatrix}, \begin{pmatrix} \beta_x^2 \sigma_x^2 + \sigma_\epsilon^2 & \beta_x \sigma_x^2 & \beta_x \sigma_{xw} + \sigma_{\epsilon w} \\ \beta_x \sigma_x^2 & \sigma_x^2 & \sigma_{xw} \\ \beta_x \sigma_{xw} + \sigma_{\epsilon w} & \sigma_{xw} & \sigma_w^2 \end{pmatrix} \right\}, \tag{33.2}$$

where $\sigma_{xw} = \mathrm{Cov}(X, W)$ and $\sigma_{\epsilon w} = \mathrm{Cov}(\epsilon, W)$. In measurement error modeling, the available data consist of observations (Y, W) so that the relevant sampling model is the marginal distribution of $(Y,\ W)$.

We now describe biases that arise from the so-called *naive* analysis of the data, that is, the analysis of the observed data using the usual methods for error-free data. In this case, the naive analysis is least squares analysis of $\{(W_i, Y_i),\ \ i = 1, \ldots, n\}$ so that the naive analysis results in unbiased estimates of the parameters in the regression model for Y on W, or what we refer to as the *naive model*. Naive-model parameters are given in Table 33.1 for some particular error models.

33.2.3.1 Differential Error

For the case of a general measurement with possibly differential error, the naive estimator of slope is an unbiased estimator of $(\beta_x \sigma_{xw} + \sigma_{\epsilon w})/\sigma_w^2$ rather than β_x. Depending on the covariances between ϵ and W, and X and W, and the variance of W, the naive-model slope could be less than or greater than β_x, so that no general conclusions about bias are possible. Similarly, the residual variance of the naive regression could be either greater or less than the true model residual variance. It follows that for a general measurement W, the coefficient of determination for the naive analysis could be greater or less than for the true model. These results indicate the futility of trying to make generalizations about the effects of using a general measurement for X in a naive analysis.

33.2.3.2 Surrogate

For the multivariate normal model with $0 < \rho_{xw}^2 < 1$, W is a surrogate if and only if $\sigma_{\epsilon w} = 0$. With an arbitrary surrogate measurement, the naive estimator of slope unbiasedly estimates $\beta_x \sigma_{xw}/\sigma_w^2$. Depending on the covariance between X and W and the variance of W, the naive-model slope could be less or greater than β_x, so that again no general statements about bias in the regression parameters are possible. For an uncalibrated measurement, $E(W|X) = \gamma_0 + \gamma_x X$, $\sigma_{xw} = \mathrm{cov}(X, W) = \gamma_x \sigma_x^2$ and $\mathrm{Var}(X) = \gamma_x^2 \sigma_x^2 + \sigma_u^2$. In this case, the relative bias, $\sigma_{xw}/\sigma_w^2 = \gamma_x \sigma_x^2/(\gamma_x^2 \sigma_x^2 + \sigma_u^2)$, is bounded in absolute value by $1/|\gamma_x|$. For an uncalibrated Berkson measurement, $E(X|W) = \alpha_1 + \alpha_w W$, $\sigma_{xw} = \alpha_w \sigma_w^2$, and the relative bias is α_w. When W is a surrogate, the residual variance from the naive analysis is never less than the true model residual variance and is strictly greater except in the extreme case that X and W are perfectly correlated, $\rho_{xw}^2 = 1$. It follows that for an arbitrary surrogate, the coefficient of determination for the naive model is always less than or equal to that for the true model. The use of a surrogate always entails a loss of predictive power. The naive-model slope indicates that in order to recover β_x from an analysis of the observed data, only σ_{xw} would have to be known. A *validation study* in which bivariate observations (X, W) were obtained would provide the necessary information for estimating σ_{xw}.

33.2.3.3 Classical Error

If the surrogate, W, is an unbiased measurement, $E(W \mid X) = X$, and the classical error model holds, then $\mu_w = \mu_x$, $\sigma_{xw} = \sigma_x^2$, and $\sigma_w^2 = \sigma_x^2 + \sigma_u^2$. In this case, the naive slope estimator unbiasedly estimates $\beta_x \sigma_x^2/(\sigma_x^2 + \sigma_u^2)$. For this case, the sign ($\pm$) of $\beta_x \sigma_x^2/(\sigma_x^2 + \sigma_u^2)$ is always the same as the sign of β_x, and the inequality $\sigma_x^2/(\sigma_x^2 + \sigma_u^2)|\beta_x| \leq |\beta_x|$ shows that the naive estimator of slope is always biased toward 0. This type of bias is called *attenuation* or *attenuation toward the null*. The attenuation factor $\lambda = \sigma_x^2/(\sigma_x^2 + \sigma_u^2)$ is called the *reliability ratio*, and its inverse is called the *linear correction for attenuation*. In this case, the coefficient of determination is also attenuated toward zero, and the term attenuation is often used to describe both attenuation in the slope coefficient and the attenuation in the coefficient of determination. *Regression dilution* has also been used in the epidemiology literature to describe attenuation (MacMahon et al. 1990; Hughes 1993). In order to recover β_x from an analysis of the observed data, it would be sufficient to know σ_u^2. Either replicate measurements or validation data provide information for estimating the measurement error variance σ_u^2.

33.2.3.4 Berkson Error

With W a surrogate, the Berkson error model is embedded in the multivariate normal model by imposing the condition $E(X \mid W) = W$. In this case, $\mu_x = \mu_w, \sigma_{xw} = \sigma_w^2$ and $\sigma_x^2 = \sigma_w^2 + \sigma_u^2$. When W and X satisfy the unbiased Berkson error model, $X = W + U$, the naive estimator of slope is an unbiased estimator of β_x, that is, there is no bias. Thus, there is no bias in the naive regression parameter estimators, but there is an increase in the residual variance and a corresponding decrease in the model coefficient of determination. Even though no bias is introduced, there is still a penalty incurred with the use of Berkson predictors. However, with respect to valid inference on regression coefficients, the linear model is robust to Berkson errors. The practical importance of this robustness property is limited because the unbiased Berkson error model seldom is appropriate without regression calibration except in certain experimental settings as described previously.

33.2.3.5 Discussion

Measurement error is generally associated with attenuation, and as the Table 33.1 shows, attenuation in the coefficient of determination occurs with any surrogate measurement. However, attenuation in the regression slope is, in general, specific only to the classical error model. The fact that measurement-error-induced bias

Table 33.1 Table entries are slopes and residual variances of the linear model relating Y to W for the cases in which W is a differential measurement, a surrogate, an unbiased classical error measurement, an unbiased Berkson predictor, and the case of no error ($W = X$)

Error model	Slope	Residual variance
Differential	$\beta_x\left(\frac{\sigma_{xw}}{\sigma_w^2}\right)+\left(\frac{\sigma_{\epsilon w}}{\sigma_w^2}\right)$	$\sigma_\epsilon^2+\beta_x^2\sigma_x^2-\frac{(\sigma_{xw}\beta_x+\sigma_{\epsilon w})^2}{\sigma_w^2}$
Surrogate	$\beta_x\left(\frac{\sigma_{xw}}{\sigma_w^2}\right)$	$\sigma_\epsilon^2+\beta_x^2\sigma_x^2(1-\rho_{xw}^2)$
Classical	$\beta_x\left(\frac{\sigma_x^2}{\sigma_x^2+\sigma_u^2}\right)$	$\sigma_\epsilon^2+\beta_x^2\sigma_x^2\left(\frac{\sigma_u^2}{\sigma_x^2+\sigma_u^2}\right)$
Berkson	β_x	$\sigma_\epsilon^2+\beta_x^2\sigma_x^2\left(\frac{\sigma_u^2}{\sigma_x^2}\right)$
No error	β_x	σ_ϵ^2

depends critically on the type of measurement error underlies the importance of correct identification of the measurement error in applications. Incorrect specification of the measurement error component of a model can create problems as great as those caused by ignoring measurement error.

The increase in residual variance associated with surrogate measurements (including classical and Berkson) gives rise not only to a decrease in predictive power but also contributes to reduced power for testing. The non-centrality parameter for testing $H_0 : \beta_x = 0$ with surrogate measurements is $n\beta_x^2\sigma_x^2\rho_{xw}^2/\left\{\sigma_\epsilon^2+\beta_x^2\sigma_x^2\left(1-\rho_{xw}^2\right)\right\}$ which is less than the true-date non-centrality parameter, $n\beta_x^2\sigma_x^2/\sigma_\epsilon^2$, whenever $\rho_{xw}^2 < 1$. These expressions give rise to the equivalent-power sample size formula

$$n_w = n_x\left[\left\{\sigma_\epsilon^2+\beta_x^2\sigma_x^2\left(1-\rho_{xw}^2\right)\right\}/\left\{\sigma_\epsilon^2\rho_{xw}^2\right\}\right]\approx n_x/\rho_{xw}^2, \tag{33.3}$$

where n_w is the number of (W, Y) pairs required to give the same power as a sample of size n_x of (X, Y) pairs. The latter approximation is reasonable near the null value $\beta_x = 0$ (or more precisely, when $\beta_x^2\sigma_x^2\left(1-\rho_{xw}^2\right)$ is small).

The loss of power for testing is not always due to an increase in variability of the parameter estimates. For the classical error model, the variance of the naive estimator is *less than* the variance of the true-data estimator asymptotically if and only if $\beta_x^2\sigma_x^2/(\sigma_x^2+\sigma_u^2) < \sigma_\epsilon^2/\sigma_x^2$, which is possible when σ_ϵ^2 is large, or σ_u^2 is large, or $|\beta_x|$ is small. So relative to the case of no measurement error, classical errors can result in more precise estimates of the wrong (i.e., biased) quantity. This cannot occur with Berkson errors, for which asymptotically the variance of the naive estimator is never less than the variance of the true-data estimator.

The normal linear model also illustrates the need for additional information in measurement error models. For example, for the case of an arbitrary surrogate, the joint distribution of Y and W contains eight unknown parameters $(\beta_1,\ \beta_x,\ \mu_x,\ \mu_w,\ \sigma_x^2,\ \sigma_\epsilon^2,\ \sigma_{xw},\ \sigma_w^2)$, whereas a bivariate normal distribution is completely determined by only five parameters. This means that not all eight parameters can be estimated with data on (Y, W) alone. In particular, β_x is not estimable. However, from Table 33.1, it is apparent that if a consistent estimator of σ_{xw} can be constructed, say from validation data, then the method-of-moments estimator $\widehat{\beta}_x = \left(s_w^2/\widehat{\sigma}_{xw}\right)\widehat{\beta}_w$ is a consistent estimator of β_x, where $\widehat{\beta}_w$ is the least squares estimator of slope in the linear regression of Y on W, s_w^2 is the sample variance of W, and $\widehat{\sigma}_{xw}$ is the validation data estimator of σ_{xw}.

For the case of additive, unbiased, measurement error, the joint distribution of Y and W contains six unknown parameters $(\beta_1,\ \beta_x,\ \mu_x,\ \sigma_x^2,\ \sigma_\epsilon^2,\ \sigma_u^2)$, so that again not all of the parameters are identified. Once again, β_x is not estimable. However, if a consistent estimator of σ_u^2 can be constructed, say from either replicate measurements or validation data, then the method-of-moments estimator $\widehat{\beta}_x = \left\{s_w^2/\left(s_w^2 - \widehat{\sigma}_u^2\right)\right\}\widehat{\beta}_w$ is a consistent estimator of β_x, where $\widehat{\sigma}_u^2$ is the estimator of σ_u^2.

For the Berkson error model, there are also six unknown parameters in the joint distribution of Y and W, $(\beta_1,\ \beta_x,\ \mu_x,\ \sigma_x^2,\ \sigma_\epsilon^2,\ \sigma_w^2)$, so that again not all of the parameters are identified. The regression parameters β_1 and β_x are estimated unbiasedly by the intercept and slope estimators from the least squares regression of Y and W. However, without additional data, it is not possible to estimate σ_ϵ^2.

33.2.4 Multiple Linear Regression

The entries in Table 33.1 and the qualitative conclusions based on them generalize to the case of multiple linear regression with multiple predictors measured with error. For the Berkson error model, it remains the case that no bias in the regression parameter estimators results from the substitution of W for X, and the major effects of measurement error are those resulting from an increase in the residual variation.

For the classical measurement error model, there are important aspects of the problem that are not present in the simple linear regression model. When the model includes both covariates measured with error X and without error Z, it is possible for measurement error to bias the naive estimator of β_z as well as the naive estimator of β_x. Furthermore, attenuation in the coefficient of a variable measured with error is no longer a simple function of the variance of that variable and the measurement error variance. When there are multiple predictors measured with error, the bias in regression coefficients is a non-intuitive function of the measurement error covariance matrix and the true-predictor covariance matrix.

Suppose that the multiple linear regression model for Y given Z and X is $Y = \beta_1 + \beta_z^T Z + \beta_x^T X + \epsilon$. For the additive error model $W = X + U$, the naive estimator of the regression coefficients is estimating

$$\begin{pmatrix}\beta_{z*}\\ \beta_{x*}\end{pmatrix} = \begin{pmatrix}\sigma_{zz} & \sigma_{zx}\\ \sigma_{xz} & \sigma_{xx} + \sigma_{uu}\end{pmatrix}^{-1} \begin{pmatrix}\sigma_{zz} & \sigma_{zx}\\ \sigma_{xz} & \sigma_{xx}\end{pmatrix} \begin{pmatrix}\beta_z\\ \beta_x\end{pmatrix} \tag{33.4}$$

and not $(\beta_z^T, \beta_x^T)^T$. For the case of multiple predictors measured with error with no restrictions on the covariance matrices of the predictors or the measurement errors, bias in individual coefficients can take almost any form. Coefficients can be attenuated toward the null or inflated away from zero. The bias is not always multiplicative. The sign of coefficients can change, and zero coefficients can become non-zero (i.e., null predictors can appear to be significant). There is very little that can be said in general, and individual cases must be analyzed separately.

However, in the case of one variable measured with error, that is, X is a scalar, the attenuation factor in β_{x*} is $\lambda_1 = \sigma^2_{x|z}/(\sigma^2_{x|z} + \sigma^2_u)$ where $\sigma^2_{x|z}$ is the residual variance from the regression of X on Z, that is, $\beta_{x*} = \lambda_1\beta_x$. Because $\sigma^2_{x|z} \leq \sigma^2_x$, attenuation is accentuated relative to the case of no covariates when the covariates in the model are correlated with X, that is, $\lambda_1 \leq \lambda$ with strict inequality when $\sigma^2_{x|z} < \sigma^2_x$. Also, in the case of a single variable measured with error, $\beta_{z*} = \beta_z + (1 - \lambda_1)\beta_x\Gamma_z$, where Γ_z is the coefficient vector of Z in the regression of X on Z, that is, $E(X \mid Z) = \Gamma_1 + \Gamma_z^T Z$. Thus, measurement error in X can induce bias in the regression coefficients of Z. This has important implications for analysis of covariance models in which the continuous predictor is measured with error (Carroll 1989; Carroll et al. 1985).

The effects of measurement error on naive tests of hypotheses can be understood by exploiting the fact that in the classical error model, W is a surrogate. In this case, $E(Y|Z,W) = E\{E(Y|Z,X,W)|Z,W\} = E\{E(Y|Z,X)|Z,W\} = \beta_1 + \beta_z^T Z + \beta_x^T E(X|Z,W)$. With multivariate normality, $E(X|Z,W)$ is linear, say $E(X|Z,W) = \alpha_0 + \alpha_z^T Z + \alpha_w W$, and thus

$$E(Y|Z,W) = \beta_0 + \beta_x^T\alpha_0 + \left(\beta_z^T + \beta_x^T\alpha_z^T\right) Z + \beta_x^T\alpha_w^T W. \tag{33.5}$$

This expression holds for any surrogate W. Our summary of hypothesis testing in the presence of measurement error is appropriate for any surrogate variable model provided α_w^T is an invertible matrix, as it is for the classical error model. Suppose that the naive model is parameterized

$$E(Y|Z,W) = \gamma_0 + \gamma_z^T Z + \gamma_w^T W. \tag{33.6}$$

A comparison of (33.5) and (33.6) reveals the main effects of measurement error on hypothesis testing.

First note that $(\beta_z^T, \beta_x^T)^T = 0$ if and only if $(\gamma_z^T, \gamma_x^T)^T = 0$. This implies that the naive-model test that none of the predictors are useful for explaining variation in Y is valid in the sense of having the desired type I error rate. Further examination of (33.5) and (33.6) shows that $\gamma_z = 0$ is equivalent to $\beta_z = 0$, only if $\alpha_z\beta_x = 0$. It follows that the naive test of $H_0 : \beta_z = 0$ is valid only if X is unrelated to Y ($\beta_x = 0$) or if Z is unrelated to X ($\alpha_z = 0$). Finally, the fact that $\beta_x = 0$ is equivalent to $\alpha_w\beta_x = 0$ implies that the naive test of $H_0 : \beta_x = 0$ is valid. The naive tests that are valid, that is, those that maintain the type I error rate, will still suffer reduced power relative to the test based on the true data.

33.2.5 Non-Linear Regression

The effects of measurement error in non-linear models are much the same qualitatively as in the normal linear model. The use of a surrogate measurement generally results in reduced power for testing associations, produces parameter bias, and results in a model with less predictive power. However, the nature of the bias depends on the model, the type of parameter, and the error model. Generally, the more non-linear the model is, the less relevant are the results for the linear model. Parameters other than linear regression coefficients (e.g., polynomial coefficients, transformation parameters, and variance function parameters) have no counterpart in the normal linear model and the effect of measurement errors on such parameters must be studied on a case-by-case basis.

Regression coefficients in generalized linear models, including models of particular interest in epidemiology such as logistic regression and Poisson regression, are affected by measurement error in much the same manner as are linear model regression coefficients. This means that relative risks and odds ratios derived from logistic regressions models are affected by measurement error much the same as linear model regression coefficients (Rosner et al. 1989, 1990; Stefanski 1985; Stefanski and Carroll 1985). However, unlike the linear model, unbiased Berkson measurements generally produce biases in non-linear models, although they are often much less severe than biases resulting from classical measurement errors (for comparable ρ_{xw}). This fact forms the basis for the method known as *regression calibration* in which an unbiased Berkson predictor is estimated by a preliminary calibration analysis, and then the usual (naive) analysis is performed with $\widehat{E(X|W)}$ replacing X. This fact also explains why more attention is paid to the classical error model than to the Berkson error model.

The effects of classical measurement error on flexible regression models, for example, non-parametric regression, are not easily quantified, but there are general tendencies worth noting. Measurement error generally smooths out regression functions. Non-linear features of $E(Y|X)$ such as curvature of local extremes, points of non-differentiability, and discontinuities will generally be less pronounced or absent in $E(Y|W)$. For normal measurement error, $E(Y|W)$ is smooth whether $E(Y|X)$ is or is not, and local maxima and minima will be less extreme – measurement error tends to wear off the peaks and fill in the valleys. This can be seen in a simple parametric model. If $E(Y|X) = \beta_0 + \beta_1 X + \beta_2 X^2$ and (X, W) are jointly normal with $\mu_x = 0$, then $E(Y|W)$ is also quadratic with the quadratic coefficient attenuated by ρ_{xw}^4. The local extremes of the two regressions differ by $\beta_2 \sigma_x^2 (1 - \rho_{xw}^2)$ which is positive (negative) when $E(Y|X)$ is convex (concave). Finally, we note that monotonicity of regression functions can sometimes be affected by heavy-tailed measurement error (Hwang and Stefanski 1994).

The effects of classical measurement error on density estimation are qualitatively similar to that of non-parametric regressions. Modes are attenuated and regions of low density are inflated. Measurement error can mask multimodality in the true density and will inflate the tails of the distribution. Naive estimates of tail quantiles are generally more extreme than the corresponding true-data estimates.

33.2.6 Logistic Regression Example

This section closes with an empirical example illustrating the effects of measurement error in logistic regression, and the utility of the multivariate normal linear regression model results for approximating the effects of measurement error. The data used are a subset of the Framingham Heart Study data and are described in detail in Carroll et al. (2006). For these data, X is long-term average systolic blood pressure after transformation via ln(SBP-50), denoted TSBP. There are replicate measurements (W_1, W_2) for each of $n = 1,615$ subjects in the study. The true-data model is logistic regression of coronary heart disease (CHD) $(0, 1)$ on X and covariates (Z) including age, smoking status (SMOKE) $(0, 1)$, and cholesterol level (CHOL).

Assuming the classical error model for the replicate measurements, $W_j = X + U_j$, analysis of variance produces the estimate $\widehat{\sigma}_u^2 = 0.0126$. The average $\overline{W} = (W_1 + W_2)/2$ provides the best measurement of X with an error variance of $\sigma_U^2/2$ (with estimate 0.0063).

The three measurements, W_1, W_2 and $\overline{W}$, can be used to empirically demonstrate attenuation due to measurement error. The measurement error variances of W_1 and W_2 are equal and are twice as large the measurement error variance of $\overline{W}$. Thus, the attenuation in the regressions using W_1 and W_2 should be equal, whereas the regression using $\overline{W}$ should be less attenuated. Three naive logistic models,

$$\text{logit}\{\Pr(\text{CHD=1})\} = \beta_0 + \beta_{z_1}\text{AGE} + \beta_{z_2}\text{SMOKE} + \beta_{z_3}\text{CHOL} + \beta_x\text{TSBP},$$

were fit using each of the three measurements W_1, W_2, and $\overline{W}$. The estimates of the TSBP coefficient from the logistic regressions using W_1 and W_2 are both 1.5 (to one decimal place). The coefficient estimate from the fit using $\overline{W}$ is 1.7. The relative magnitudes of the coefficients $(1.5 < 1.7)$ are consistent with the anticipated effects of measurement error – greater attenuation associated with larger error variance. The multiple linear regression attenuation coefficient for a measurement with error variance σ^2 is $\lambda_1 = \sigma_{x|z}^2/(\sigma_{x|z}^2 + \sigma^2)$. Assuming that this applies approximately to the logistic model suggests that

$$1.7 \approx \frac{\sigma_{x|z}^2}{\sigma_{x|z}^2 + \sigma_u^2/2}\beta_x \qquad \text{and} \qquad 1.5 \approx \frac{\sigma_{x|z}^2}{\sigma_{x|z}^2 + \sigma_u^2}\beta_x.$$

Because β_x is unknown, these approximations cannot be checked directly. However, a check on their consistency is obtained by taking ratios leading to $1.13 = 1.7/1.5 \approx (\sigma_{x|z}^2 + \sigma_u^2)/(\sigma_{x|z}^2 + \sigma_u^2/2)$. Using the ANOVA estimate, $\widehat{\sigma}_u^2 = 0.0126$, and the mean squared error from the linear regression of $\overline{W}$ on AGE, SMOKE, and CHOL as an estimate of $\sigma_{\overline{w}|z}^2$, produces the estimate $\widehat{\sigma}_{x|z}^2 = \widehat{\sigma}_{\overline{w}|z}^2 - \widehat{\sigma}_u^2/2 = 0.0423 - 0.0063 = 0.0360$. Thus, $(\sigma_{x|z}^2 + \sigma_u^2)/(\sigma_{x|z}^2 + \sigma_u^2/2)$ is estimated to be $(0.0360 + 0.0126)/(0.0360 + 0.0063) = 1.15$. In other words, the attenuation in the logistic regression coefficients is consistent ($1.13 \approx 1.15$) with the attenuation predicted by the normal linear regression model result.

These basic statistics can also be used to calculate a simple bias-adjusted estimator as $\widehat{\beta}_x = 1.7(\widehat{\sigma}^2_{x|z} + \widehat{\sigma}^2_u/2)/\widehat{\sigma}^2_{x|z} = 1.7(0.0360 + 0.0063)/0.0360 = 2.0$, which is consistent with estimates reported by Carroll et al. (2006) obtained using a variety of measurement error estimation techniques. We do not recommend using linear model corrections for the logistic model because there are number of methods more suited to the task as described in Sect. 33.4. Our intent with this example is to demonstrate the general relevance of the easily derived theoretical results for linear regression to other generalized linear models.

The odds ratio for a Δ change in transformed systolic blood pressure is $\exp(\beta_x \Delta)$. With the naive analysis, this is estimated to be $\exp(1.7\Delta)$; the bias-corrected analysis produces the estimate $\exp(2.0\Delta)$. Therefore, the naive odds ratio is attenuated by approximately $\exp(-0.3\Delta)$. More generally, the naive (OR_N) and true (OR_T) odds ratios are related via $OR_N/OR_T = OR_T^{\lambda_1 - 1}$, where λ_1 is the attenuation factor in the naive estimate of β_x. The naive and true relative risks have approximately the same relationship under the same conditions (small risks) that justify approximating relative risks by odds ratios.

33.3 Planning Epidemiological Studies with Measurement Error

As the previous sections have established, exposure measurement error is common in epidemiological studies and, under certain assumptions, can be shown to have dramatic effects on the properties of relative risk estimates or other types of coefficients derived from epidemiological regression models. It is wise therefore to include measurement error considerations in the planning of a study, both to enable the application of a measurement error analysis at the conclusion of the study and to assure scientific validity.

In developing a useful plan, one must consider a number of important questions. To begin with, what are the scientific objectives of the study? Is the goal to identify a new risk factor for disease, perhaps for the first time, or is this a study to provide improved estimates of the quantitative impact of a known risk factor? Is prediction of future risks the ultimate goal? Do the measurement errors affect adjusting covariates as well? The answers to these questions will determine the possible responses to dealing with the measurement error in the design and analysis of the study, including the choice of a criterion for statistical optimality. It is even possible that no measurement error correction is needed to achieve the purposes of the study (Thiebaut et al. 2007), or in certain instances, absent other considerations such as cost, that *the most scientifically valid design would eliminate measurement error entirely.*

The nature of the measurement error should be carefully considered. For instance, is the measurement error non-differential? What is the evidence to support this conclusion? Especially in the study of complex phenomenon such as nutritional factors in disease, the non-differential assumption deserves scrutiny. For example, the diet "record" has often been used as the gold standard of nutritional intakes, but subsequent analyses have cast doubt on the non-differential measurement error associated with substituting monthly food frequency questionnaires (Kipnis et al. 1999). On the other hand, measurement errors due to validated scientific instrument errors may be more easily justified as non-differential.

Another thing to consider is the possible time dependency of exposure errors, and how this may affect the use of non-differential models. This often arises in case-control studies where exposures must be assessed retrospectively (cf. chapter ▸Case-Control Studies of this handbook). An interesting example occurs in a recent study of arsenic exposure where both drinking water and toenail measurements are available as personal exposure measures in a cancer case-control study (Karagas et al. 1998). Toenail concentrations give a biologically time-averaged measure of exposure, but the time scale is limited and the nail concentrations are influenced by individual metabolic processes. Drinking water concentrations may be free from possible confounding due to unrelated factors affecting metabolic pathways but could be less representative of average exposures over the time interval of interest. This kind of ambiguity is common in many epidemiological modeling situations and should indicate caution in the rote application of measurement error methods.

Depending on the type of non-differential error, different study plans may be required to identify the desired relative risk parameters. For instance, replicate measurements of an exposure variable may adequately identify the necessary variance parameters in a classical measurement error model. Under certain circumstances, an "instrumental" variable may provide the information needed to correct for measurement error. This type of reliability/validity data leads to identifiable relative risk regression parameters in classical or Berkson case error.

In more complex "surrogate" variable situations with non-differential error, an internal or external validation study may be necessary, where the "true" exposure measured without error is available for a subset or independent sample of subjects. These designs are also useful and appropriate for classical measurement error models but are essential in the case of surrogates which cannot be considered "unbiased." Internal validation studies have the capability of checking the non-differential assumption and thus are potentially more valuable. With external validation studies, there may be doubt as to whether the populations characterized by the validation and main study samples are comparable in the sense that the measurement error model is equivalent or "transportable" between the populations. The issue of whether an error model is transportable or not can arise with any type of measurement error (Table 33.2).

The considerations described above are summarized in the following table for some of the options that should be considered when planning a study in the presence of measurement error.

Because internal validation studies involve the observation of the true exposure and the health outcome for a portion of the sample, this design has a distinct

Table 33.2 Sampling plan characteristics for collecting validation data in epidemiological studies with measurement error of different types or properties

	Validation data			
Measurement error type/property	Replicates	Instrumental variables	External study	Internal study
Classical	Yes	Yes	Yes	Yes
Berkson	No	Yes	Yes	Yes
General surrogate	No	No	Yes	Yes
Differential	No	No	No	Yes

scientific appeal. However, relative costs will drive the choice of an optimal design. For instance, it may be the case that a classical additive error model applies and that replicate measures are easier or cheaper to get than true values. Depending on the relative impact on the optimality criterion used, the replicate design might be more cost-effective.

A number of approaches have been suggested and used for the design of epidemiological studies based on variables measured with error. These may be characterized broadly as sample size calculation methods, where the design decision to be made has to do mainly with the size of the main study in studies where the measurement error is known or can be ignored, and design approaches for studies using internal or external validation data where both the size of the main study and the validation sample must be chosen. In the sections that follow, we review both of these approaches.

33.3.1 Methods for Sample Size Calculations

Methods for sample size calculations are typically based on the operating characteristics of a simple hypothesis test. In the case of measurement error in a risk factor included in an epidemiological regression model, the null hypothesis is that the regression coefficient for the risk factor equals zero, implying no association between the exposure and the health outcome. For a specific alternative, one might calculate the power for a given sample size or, alternatively, the sample size required to achieve a given power.

It has been known for some time that the effect of measurement error is to reduce the power of the test for no association both in linear models (Cochran 1968) and 2×2 tables with non-differential misclassification (Fleiss 1981). This result has been extended to survival models (Prentice 1982) and to generalized linear models with non-differential exposure measurement error (Tosteson and Tsiatis 1988), including linear regression, logistic regression, and tests for association in 2×2 contingency tables. Using small relative risk approximations, it is possible to show that for all of these common models for epidemiological data, the ratio of the sample size required using the data measured without error to the sample size required using the error prone exposure is approximately $n_x/n_w \approx \rho^2_{xw}$, the square of the correlation between X and W; see also Eq. 33.3, Sect. 33.2.3. This relation provides a handy method for determining sample size requirements in the presence of measurement error as

$$n_w = n_x/\rho^2_{xw}. \tag{33.7}$$

If additional covariates Z are included in the calculation, a partial correlation can be used instead. The same formula has been used for sample size calculations based on regression models for prospective studies with log-linear risk functions and normal distributions for exposures and measurement error (McKeown-Eyssen and Tibshirani 1994) and case-control studies with conditionally normal exposures within the case and control groups (White et al. 1994). Recent developments have improved this approximation (Tosteson et al. 2003), but Formula (33.7) remains a useful tool for checking sample size requirements in studies with measurement error.

For generalized linear models (Tosteson and Tsiatis 1988) and survival models (Prentice 1982), it has been shown that optimal score test can be computed by replacing the error prone exposure variable W with $E[X|W]$, a technique that was later termed regression calibration (Carroll et al. 2006). Subsequent work extended these results to a more general form of the score test incorporating a non-parametric estimate of the measurement error distribution (Stefanski and Carroll 1990a). One implication of this result is that in common measurement error models, including normally distributed exposure errors and non-differential misclassification errors, the optimal test is computed simply by ignoring the measurement error and using the usual test based on W rather than X, the true exposure. However, the test will still suffer the loss of power implicit in Formula (33.7).

It is interesting to consider the effects of Berkson case errors on sample size calculations. The implication for analysis is somewhat different, in as much as regression coefficients are unbiased by Berkson case errors for linear models and to the first order for all generalized linear models. However, as applied to epidemiological research, there is no distinction with respect to the effects of this type of non-differential sample size calculations for simple regression models without confounders, and Formula (33.7) applies directly.

33.3.2 Planning for Reliability/Validation Data

In some epidemiological applications, collection of data for a measurement error correction will be planned, although this may be deemed unnecessary in some simple situations where the investigators only wish to demonstrate an association with an error-prone exposure and with no error in covariates or where the measurement errors are known. Information on the measurement error parameters can come from a number of possible designs, including replicate measurements, instrumental variables, external validation studies measuring the true and surrogate exposures (i.e., just X and W), or internal validation studies. A variety of statistical criteria can be used to optimize aspects of the design, most commonly the variance of the unbiased estimate of the relative risk for the exposure measured with error. Other criteria have included the power of tests of association, as in the previous section, and criteria based on the power of tests for null hypotheses other than no association (Spiegelman and Gray 1991).

To choose a design, it is usually necessary to have an estimate of the measurement error variance or other parameters. This may be difficult since validation data are needed to derive these estimates and will not yet have been collected at the time when the study is being planned. However, this dilemma is present in most practical design settings and can be overcome in a number of informal ways by deriving estimates from previous publications, pilot data, or theoretical considerations of the measurement error process. Certain sequential designs can be useful in this regard, and some suggestions are discussed here in the context of the design of internal validation studies.

In studies where a correction is planned for classical measurement error using replicates, the simple approach to sample size calculations may provide a guideline for choosing an appropriate number of replicates and a sample size by replacing ρ^2_{xw} with $\rho^2_{x\overline{w}}$, where $\overline{w}$ is the mean of the n_r replicates. Depending on the relative costs of replication and obtaining a study participant, these expressions may be used to find an optimal value for the overall sample size, n, and the number of replicates, n_r. For instrumental variables, a similar calculation can be made using a variation on the regression calibration procedure as applied to the score test for no association. In this case, the inflation in sample size for (33.7) is based on $\rho^2_{\widehat{x}x}$, where $\widehat{x} = E[X|W, T]$, the predicted value of the true exposure given the unbiased surrogate W and the instrumental variable T.

External and internal validation studies both involve a main study, with a sample size of n_1 and a validation study, with sample size of n_2. The external validation study involves an independent set of measurements of the true and surrogate exposures, whereas the internal validation study is based on a subset of the subjects in the main study. Both the size of the main study and the validation study must be specified. In the internal validation study, n_2 is by necessity less than or equal to n_1, with equality implying a fully validated design. In the external validation study, n_2 is not limited, but the impact of increasing the amount of validation data is more limited than in the internal validation study. This is because the fully validated internal validation study has no loss of power versus a study that has no measurement error, whereas the external validation study can only improve the power to the same as that of a study with measurement error where the measurement error parameters are known.

For common non-linear epidemiological regression analyses such as logistic regression, method for determining optimal values of n_1 and n_2 has typically involved specialized calculations (Spiegelman and Gray 1991; Stram et al. 1995). Less intractable expressions are available for linear discriminant models, not involving numerical integrations (Buonaccorsi 1988). The actual analysis of the data from the studies may be possible using approximations such as the regression calibration method requiring less sophisticated software (Spiegelman et al. 2001).

A variant on the internal validation study is designs which use surrogate exposures and outcomes as stratification variables to select a highly efficient validation sample. Cain and Breslow (1988) develop methods for case-control studies where surrogate variables were available during the design phase for cases and controls. Tosteson and Ware (1990) develop methods for studies where surrogates were available for both exposures and a binary outcome. These designs can be analyzed with ordinary logistic regression if that model is appropriate for the population data. Methods for improving the analysis of the designs and adapting them to other regression models have been proposed (Tosteson et al. 1994; Holcroft et al. 1997; Reilly 1996).

33.3.3 Examples and Applications

Much of the research on methods for planning studies with measurement error has been stimulated by applications from environmental, nutritional, and occupational epidemiology. Nevertheless, it is fair to say that published examples of studies designed with measurement error in mind are relatively rare, and the best source of case studies may be method papers such as those cited in this review. This may reflect a lack of convenient statistical software other than what individual researchers have been able to make available.

One example of a study using planning based on measurement error methods was provided by IJmker et al. (2006). The exposure of interest was the intensity of use of computers as measured by worker monitoring software, and the outcomes are musculoskeletal disorders. A web-based program for logistic regression based on the methods of Tosteson et al. (2003) was used to adjust the sample size for possible exposure measurement error.

Even without widely distributed software, some useful calculations can be quite simple, as shown above, and a more important factor in future applications of these methods will be proper education to raise the awareness among statisticians and epidemiologists of the importance of addressing the problem of measurement error in the planning phases of health research.

33.4 Measurement Error Models and Methods

33.4.1 Overview

This section describes several common methods for correcting biases induced by non-differential covariate measurement error. The focus is on non-linear regression models and the logistic model in particular, though all the methods apply to the linear model. The intent is to familiarize the reader with the central themes and key ideas that underlie the proposals and provide a contrast of the assumptions and types of data required to implement the procedures. The literature contains a very large number of proposals for measurement error correction in regression models, and the presentation here is necessarily focused. Texts that provide broad and detailed discussions of modern methods for handling measurement error include Carroll et al. (2006), Buonaccorsi (2010), and Gustafson (2004).

The starting point for all measurement error analyses is the disease model of interest relating the disease outcome Y to the true exposure(s) X and covariates Z and a measurement error model relating the mismeasured exposure W to (Z, X). Measurement error methods can be grouped according to whether they employ *functional* or *structural* modeling. Functional models make no assumptions on X, beyond what are made in the absence of measurement error, for example, $\sum_{i=1}^{n}(X_i - \overline{X})^2 > 0$ for simple linear regression (the use of the word *functional* here does not refer to the area of functional data analysis). Functional modeling is compelling because often there is little information in the data on the distribution of X. For this reason, much of the initial research in measurement error methods focused on functional modeling. Methods based on functional modeling can be divided into approximately consistent (remove most bias) and fully consistent methods (remove all bias as $n \rightarrow \infty$). Fully consistent methods for non-linear regression models often require assumptions on the distribution of the measurement error. Regression calibration and SIMEX are examples of approximately consistent methods while corrected scores, conditional scores, Tsiatis and Ma scores (Tsiatis and Ma 2004), and some instrumental variable (IV) methods are fully consistent for large classes of models. Each of these approaches is described below.

Structural models assume that the unobserved exposure X is random and require an exposure model for X, with the normal distribution as the default model. Bayesian and likelihood-based methods are used with structural models.

Note that the terms functional and structural refer to assumptions on X, not on the measurement error model. Functional modeling has the advantage of providing valid inference regardless of the distribution of X. On the other hand, structural modeling can result in large gains in efficiency and allows construction of likelihood ratio based confidence intervals that often have coverage probabilities closer to the nominal level than large sample normal theory intervals used with functional models. The choice between functional or structural modeling depends both on the assumptions one is willing to make and, in a few cases, the form of the model relating Y to (Z, X). The type and amount of data available also play a role. For example, validation data provides information on the distribution of X and may make structural modeling more palatable. The remainder of this chapter describes methods for correcting for measurement error. Functional methods are described first.

33.4.2 Regression Calibration

Regression calibration is a conceptually straightforward approach to bias reduction and has been successfully applied to a broad range of regression models. It is the default approach for the linear model. The method is fully consistent in linear models and log-linear models when the conditional variance of X given (Z, W) is constant. Regression calibration is approximately consistent in non-linear models. The method was first studied in the context of proportional hazards regression (Prentice 1982). Extensions to logistic regression and a general class of regression models were studied in Rosner et al. (1989, 1990) and Carroll and Stefanski (1990), respectively. A detailed and comprehensive discussion of regression calibration can be found in Carroll et al. (2006).

When the measurement error is non-differential, the induced disease model, or regression model, relating Y to the observed exposure W and covariates Z is $E[Y \mid Z, W] = E[E[Y \mid Z, X] \mid Z, W]$, that is, the induced disease model is obtained by regressing the true disease model on (Z, W). A consequence of the identity is that the form of the observed disease model depends on the conditional distribution of X given (Z, W). This distribution is typically not known, and even when known, evaluating the right-hand side of the identity can be difficult. For example, if the true disease model is logistic and the distribution of X conditional on (Z, W) is normal, there is no closed form expression for $E[Y \mid Z, W]$.

Regression calibration circumvents these problems by approximating the disease model relating Y to the observed covariates (Z, W). The approximation is obtained by replacing X with $E[X \mid Z, W]$ in the model relating Y to (Z, X). Because regression calibration provides a model for Y on (Z, W), the observed data can be used to assess the adequacy of the model.

To describe how to implement the method, it is useful to think of the approach as a method for imputing values for X. The idea is to estimate unobserved X with $X^* \equiv$ predicted value of X from the regression of X on (Z, W); see the discussion of Berkson error calibration in Sect. 33.2.2. Modeling and estimating the regression of X on (Z, W) requires additional data in the form of internal/external replicate observations, instrumental variables, or validation data; see the example below. The regression parameters in the true disease model are estimated by regressing Y on (Z, X^*). Note that X^* is the best estimate of X using the observed predictors (Z, W), best in the sense of minimizing mean square prediction error. To summarize, regression calibration estimation consists of two steps:

1. Model and estimate the regression of X on (Z, W) to obtain X^*.
2. Regress Y on (Z, X^*) to obtain regression parameter estimates.

A convenient feature of regression calibration is that standard software can often be used for estimation. However, standard errors for parameter estimates in Step 2 must account for the fact that X^* is estimated in Step 1, something standard software does not do. Bootstrap or asymptotic methods based on estimating equation theory are typically used; see Carroll et al. (2006) for details.

When (Z, X, W) is approximately jointly normal, or when X is strongly correlated with (Z, W), the regression of X on (Z, W) is approximately linear:

$$E[X \mid Z, W] \approx \mu_x + \sigma_{x|zw}\sigma_{zw}^{-1}\begin{pmatrix} Z - \mu_z \\ W - \mu_w \end{pmatrix}$$

where $\sigma_{x|zw}$ is the covariance of X with (Z, W) and σ_{zw} is the variance matrix of (Z, W). Implementing regression calibration using the linear approximation requires estimation of the calibration parameters μ_x, $\sigma_{x|zw}$, σ_{zw}, μ_w, and μ_z.

33.4.2.1 Example

We illustrate estimation of the calibration function when two replicate observations of X are available in the primary study (internal reliability data) and the error model is $W = X + \sigma_u U$. For ease of illustration, we assume there are no additional covariates Z. Let $\{W_{i1}, W_{i2}\}_{i=1}^{n}$ denote the replication data and suppose that $E[X_i \mid \overline{W}_i] \approx \mu_x + \sigma_{x|\overline{w}}\sigma_{\overline{w}}^{-1}(\overline{W}_i - \mu_w) = \mu_w + \frac{\sigma_{\overline{w}}^2 - \sigma_u^2/2}{\sigma_{\overline{w}}^2}(\overline{W}_i - \mu_w)$ where $\overline{W}_i = (W_{i1} + W_{i2})/2$, and the last equality follows from the form of the error model. Note that $\frac{\sigma_{\overline{w}}^2 - \sigma_u^2/2}{\sigma_{\overline{w}}^2}$ is the attenuation factor introduced in Sect. 33.2.3. The method-of-moments calibration parameter estimators are $\widehat{\mu}_w = \sum_{i=1}^{n} \overline{W}_i/n$, $\widehat{\sigma}_{\overline{w}}^2 = \sum_{i=1}^{n}(\overline{W}_i - \widehat{\mu}_w)^2/(n-1)$ and $\widehat{\sigma}^2 = \sum_{i=1}^{n}\sum_{j=1}^{2}(W_{ij} - \overline{W}_i)^2/n = \sum_{i=1}^{n}(W_{i1} - W_{i2})^2/2n$. The imputed value for X_i is $X_i^* = \widehat{\mu}_w + \frac{\widehat{\sigma_{\overline{w}}^2} - \widehat{\sigma_u^2}/2}{\widehat{\sigma_{\overline{w}}^2}}(\overline{W}_i - \widehat{\mu}_w)$.

For the Framingham data described in Sect. 33.2.6, recall that $\{W_{i1}, W_{i2}\}_{i=1}^{1{,}615}$ represented transformed systolic blood pressure measured for each subject at two separate exams. For these data, $\widehat{\sigma}_u^2 = 0.0126, \widehat{\sigma}_{\overline{w}}^2 = 0.0454$ and $\widehat{\mu}_w = 4.36$ so that the imputed measurement is $X_i^* = 4.36 + .86(\overline{W}_i - 4.36)$.

If the model relating Y to X is the simple linear regression model, ($Y = \beta_1 + \beta_x X + \epsilon$), regressing Y on X^* results in $\widehat{\beta}_x = \frac{\widehat{\sigma_{\overline{w}}^2}}{\widehat{\sigma_{\overline{w}}^2} - \widehat{\sigma_u^2}/2}\widehat{\beta}_{\overline{w}}$ where $\widehat{\beta}_{\overline{w}}$ is the naive estimator obtained from regressing Y on $\overline{W}$. Note for the linear model the regression calibration estimator coincides with the method-of-moments estimator given in Sect. 33.2 of this chapter.

Our illustration of calibration parameter estimation assumed exactly that two replicates were available for each X_i. This estimation scheme can be easily extended to an arbitrary number of replicates for each X_i (Carroll et al. 2006).

33.4.2.2 Additional Notes

Regression calibration can be ineffective in reducing bias in non-linear models when (a) the effect of X on Y is large, for example, large odds ratios in logistic regression, (b) the measurement error variance is large, and (c) the model relating Y to (Z, X) is not smooth. It is difficult to quantify what is meant by large in (a) and (b) because all three factors (a–c) can act together. Segmented regression is an example of a model where regression calibration fails due to lack of model smoothness (Küchenhoff and Carroll 1997). Segmented models relate Y to X using separate regression models on different segments along the range of X.

In logistic regression, the method has been found to be effective in a number of applications (Rosner et al. 1989, 1990; Carroll et al. 2006). Fearn et al. (2008) provide a recent epidemiological application of regression calibration. Extensions for regression calibration that are designed to address the potential pitfalls listed in (a)–(c) are given in Carroll and Stefanski (1990).

Regression calibration has been implemented for generalized linear models in STATA.

33.4.3 SIMEX

Simulation extrapolation (SIMEX) is a very broadly applicable method for bias correction and is the only method that provides a visual display of the effects of measurement error on regression parameter estimation. SIMEX is fully consistent for linear disease models and approximate for non-linear models. SIMEX is founded on the observation that bias in parameter estimation varies in a systematic way with the magnitude of the measurement error. Essentially, the method is to incrementally add measurement error to covariate W using computer-simulated random errors and then compute the corresponding regression parameter estimates (simulation step). The extrapolation step models the relation between the parameter estimates and the magnitude of the measurement errors. The SIMEX estimate is the extrapolation of this relation to the case of zero measurement error.

Details of the method are best understood in the context of the classical additive measurement error model. However, the method is not limited to this model. To describe the method, suppose $W_i = X_i + \sigma_u U_i$ for $i = 1, \ldots, n$ and for $s = 1, \ldots, B$, define $W_{is}(\lambda) = W_i + \sqrt{\lambda}\sigma_u U_{is}$ where $\lambda > 0$, and $\{U_{is}\}_{s=1}^{B}$ are i.i.d. computer-simulated standard normal variates. Note that the variance of the measurement error for the constructed measurement $W_{is}(\lambda)$ is $(1+\lambda)\sigma_u^2$, indicating that λ regulates the magnitude of the measurement error. Let $\widehat{\beta}_s(\lambda_j)$ denote the vector of regression parameter estimators obtained by regression of Y on $\{Z, W_s(\lambda_j)\}$ for $0 = \lambda_1 < \lambda_2 < \cdots < \lambda_M$. The value $\lambda_M = 2$ is recommended (Carroll et al. 2006). The notation explicitly indicates the dependence of the estimator on λ_j. Let $\widehat{\beta}(\lambda_j) = B^{-1}\sum_{s=1}^{B}\widehat{\beta}_s(\lambda_j)$. Here we are averaging over the B simulated samples to eliminate variability due to simulation, and empirical evidence suggests $B = 100$ is sufficient. Each component of the vector $\widehat{\beta}(\lambda)$ is then modeled as a function of λ, and the SIMEX estimator is the extrapolation of each model to $\lambda = -1$. Note that $\lambda = -1$ represents a measurement error variance of zero.

Consider, for example, estimation of β_x. The "observations" produced by the simulation $\{\widehat{\beta}_x(\lambda_j), \lambda_j\}_{j=1}^{M}$ are plotted and used to develop and fit an extrapolation model relating the dependent variable $\widehat{\beta}_x(\lambda)$ to the independent variable λ. In most applications, an adequate extrapolation model is provided by either the non-linear extrapolant function, $\widehat{\beta}_x(\lambda_j) \approx \gamma_1 + \frac{\gamma_2}{\gamma_3+\lambda}$, or a quadratic extrapolant function, $\widehat{\beta}_x(\lambda_j) \approx \gamma_1 + \gamma_2\lambda + \gamma_3\lambda^2$. The appropriate extrapolant function is fit to $\{\widehat{\beta}_x(\lambda_j), \lambda_j\}_{j=1}^{M}$ using ordinary least squares. It is worth noting that the non-linear extrapolant function can be difficult to fit numerically and details for doing so are given in Carroll et al. (2006).

33.4.3.1 Analytical Example

SIMEX was developed to understand and correct for the effects of covariate measurement error in non-linear disease models. However, it is instructive to consider the simple linear regression model to illustrate analytically the relation between $\widehat{\beta}(\lambda)$ and λ. In Sect. 33.2, the bias of the naive estimator was studied and it follows that $\widehat{\beta}_x(\lambda) = \frac{\beta_x \sigma_x^2}{\sigma_x^2 + \sigma_u^2(1+\lambda)} + O_p(n^{-\frac{1}{2}})$ where the symbol $O_p(n^{-\frac{1}{2}})$ denotes terms that are negligible for n large. Therefore, the non-linear extrapolant will result in a fully consistent estimator; $\widehat{\beta}_x(-1) = \frac{\beta_x \sigma_x^2}{\sigma_x^2 + \sigma_u^2(1+[-1])} + O_p(n^{-\frac{1}{2}}) = \beta_x + O_p(n^{-\frac{1}{2}})$.

33.4.3.2 Graphical Example

The Framingham data described in Sect. 33.2.6 are used here to graphically illustrate the SIMEX method. In that section, a logistic model was defined relating the probability of developing coronary heart disease to age, smoking status, cholesterol level, and a transformation of systolic blood pressure. Figure 33.1 depicts the effect of increasing amounts of measurement error on parameter estimates (log odds ratios) and the SIMEX extrapolation to the case of no measurement error. Note that the non-linear and quadratic extrapolants result in similar estimates.

33.4.3.3 Additional Notes

SIMEX has been implemented in the commercial statistical software package STATA and the free open source programming environment R as an R package (simex). Both implementations provide for different choices of the extrapolant function and provide estimates of standard error.

The SIMEX method was developed in a series of papers (Cook and Stefanski 1995; Stefanski and Cook 1995; Carroll et al. 1996) and is summarized in detail in Carroll et al. (2006). Recent epidemiological applications of the method include Kopecky et al. (2006), de Gramont et al. (2007), and Kottgen et al. (2007).

Further refinements and applications of the SIMEX method appear in a number of papers (Stefanski and Bay 1996; Lin and Carroll 1999; Wang et al. 1998; Li and Lin 2003; Kim and Gleser 2000; Kim et al. 2000; Holcomb 1999; Marcus and Elias 1998). Extensions to non-parametric regression are studied in Carroll et al. (1999a), Staudenmayer and Ruppert (2004), and Delaigle and Hall (2008). SIMEX has also been extended to measurement error in categorical covariates; see Küchenhoff et al. (2006).

33.4.4 Estimating Equations and Corrected Scores

Regression parameter estimators in non-linear models are defined implicitly through estimating equations (cf. chapter ▶Generalized Estimating Equations of this handbook). Estimating equations are often based on the likelihood *score*, that is, the derivative of the log-likelihood, or quasi-likelihood scores that only require assumptions on the first and second conditional moments of the disease model. The criterion of least squares also leads to parameter estimation based on estimating equations.

Corrected scores, conditional scores, and certain instrumental variable methods have been developed starting with estimating equations that define regression parameter estimates in the absence of measurement error. An estimating score is *unbiased* if it has expectation zero and is otherwise biased. Measurement error

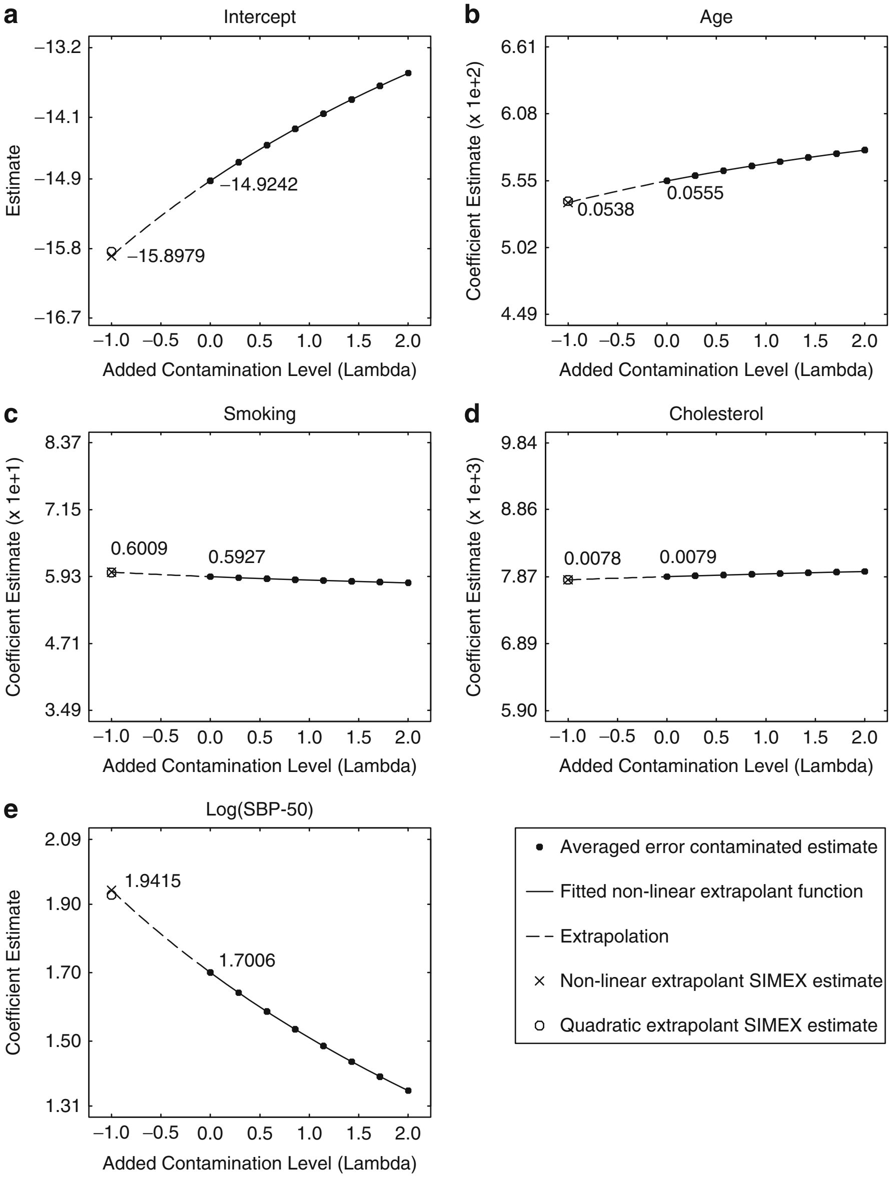

Fig. 33.1 SIMEX extrapolation plots for the Framingham data. Vertical axis scaling is ± two standard errors of the naive estimates

induces bias in estimating equations, which translates into bias in the parameter estimator. Modifying a score to remove bias produces estimators without bias.

To illustrate this concept, consider the no-intercept simple linear regression model with classical measurement error; $Y = \beta_x X + \epsilon$, $W = X + \sigma_u U$ and where X, ϵ, and U have mean zero. In the absence of measurement error, the least squares estimator for β_x solves $\sum_{i=1}^{n} \psi(Y_i, X_i; \beta_x) = 0$ where $\psi(Y_i, X_i; \beta_x) = (Y_i - \beta_x X_i)X_i$ is the least squares score. The score is unbiased: $E[\psi(Y_i, X_i; \beta_x)] = \beta_x \sigma_x^2 - \beta_x \sigma_x^2 = 0$. The score is no longer unbiased when W replaces X; $E[\psi(Y_i, W_i; \beta_x)] = \beta_x \sigma_x^2 - \beta_x(\sigma_x^2 + \sigma_u^2) \neq 0$ whenever $\sigma_u^2 > 0$ and $\beta_x \neq 0$.

Corrected scores are unbiased estimators of the score that would be used in the absence of measurement error. A corrected score $\psi^*(Y_i, W_i; \beta_x)$ satisfies $E[\psi^*(Y_i, W_i; \beta_x)] = \psi(Y_i, X_i; \beta_x)$ where the expectation is with respect to the measurement error distribution. Corrected scores were first defined in Stefanski (1989a) and Nakamura (1990). Note that corrected scores are unbiased whenever the original score is unbiased. This means that estimators obtained from corrected scores are fully consistent.

The corrected score for the simple linear no-intercept regression model is easily seen to be $\psi^*(Y_i, W_i; \beta_x) = \psi(Y_i, W_i; \beta_x) + \sigma_u^2 \beta_x$ resulting in the estimator $\widehat{\beta}_x = \sum_{i=1}^{n} Y_i W_i / (\sum_{i=1}^{n} W_i^2 - \sigma_u^2)$. In applications, an estimate of the measurement error variance replaces σ_u^2. Note that the corrected score estimator for the linear model is also the method-of-moments estimator.

For the linear model, the corrected score was identified without making an assumption on the distribution of the measurement error. For non-linear regression models, obtaining a corrected score generally requires specification of the measurement error distribution. Typically the normal distribution is assumed.

To illustrate the corrected score method for a non-linear model, consider Poisson regression with no intercept. The likelihood score in the absence of measurement error is $\psi(Y_i, X_i; \beta_x) = (Y_i - \exp\{\beta_x X_i\})X_i$. If we assume that the measurement error satisfies $U \sim N(0, 1)$, then $\psi^*(Y_i, W_i; \beta_x) = (Y_i - \exp\{\beta_x W_i - \beta_x^2 \sigma_u^2/2\})W_i + \beta_x \sigma_u^2 \exp\{\beta_x W_i - \beta_x^2 \sigma_u^2/2\})$ is the corrected score. Using results for the moment-generating function of a normal random variable, one can verify that $E[\psi^*(Y_i, W_i; \beta_x)] = (Y_i - \exp\{\beta_x X_i\})X_i$ where the expectation is with respect to the measurement error. The corrected score estimator $\widehat{\beta}_x$ solves $\sum_{i=1}^{n} \psi^*(Y_i, W_i; \widehat{\beta}_x) = 0$, and the solution must be obtained numerically for Poisson regression.

It is not always possible to obtain a corrected score (Stefanski 1989a). For example, the likelihood scores for logistic and probit regression do not admit a corrected score, except under certain restrictions (Buzas and Stefanski 1996c; Buzas 2009). Methods for obtaining corrected scores and approximately corrected scores for a general class of models via computer simulation have been recently studied (Novick and Stefanski 2002; Devanarayan and Stefanski 2002). Buonaccorsi (1996) describes another approach for correcting score functions in the presence of covariate measurement error that is equivalent to the corrected score approach for some disease models.

33.4.5 Conditional Scores

Conditional score estimation is the default method for logistic regression when the classical additive error model holds. The statistical theory of sufficient statistics and maximum likelihood underlie the derivation of conditional scores, and conditional score estimators retain certain optimality properties of likelihood estimators. Though we focus on logistic regression here, the method applies to a broader class of regression models, including Poisson and gamma regression. The method was derived in Stefanski and Carroll (1987). Construction of the conditional score estimator assumes that the measurement error is normally distributed. However, the estimator remains effective in reducing bias and is surprisingly efficient for modest departures from the normality assumption (Huang and Wang 2001). Derivation of conditional scores and consistency of estimators does not require an assumption on the distribution of X. Computing conditional score estimators requires an estimate of the measurement error variance.

The conditional score estimator for logistic regression is defined implicitly as the solution to estimating equations that are closely related to the maximum likelihood estimating equations used in the absence of measurement error. In the absence of measurement error, the maximum likelihood estimator of $(\beta_1, \beta_z, \beta_x)$ is defined implicitly as the solution to

$$\sum_{i=1}^{n} \{Y_i - F(\beta_1 + \beta_z Z_i + \beta_x X_i)\} \begin{pmatrix} 1 \\ Z_i \\ X_i \end{pmatrix} = 0,$$

where $F(v) = \{1 + \exp(-v)\}^{-1}$ is the logistic distribution function. The conditional score estimator is defined as the solution to the equations

$$\sum_{i=1}^{n} \{Y_i - F(\beta_1 + \beta_z Z_i + \beta_x \Delta_i)\} \begin{pmatrix} 1 \\ Z_i \\ \Delta_i \end{pmatrix} = 0$$

where $\Delta_i = W_i + (Y_i - \frac{1}{2})\widehat{\sigma}_u^2 \beta_x$ and $\widehat{\sigma}_u^2$ is an estimate of the measurement error variance. Conditional score estimation for logistic regression replaces the unobserved X_i with Δ_i. It can be shown that $E[Y \mid Z, \Delta] = F(\beta_1 + \beta_z Z + \beta_x \Delta)$, and it follows that the conditional score is unbiased. Because Δ depends on the parameter β_x, it is not possible to estimate $(\beta_1, \beta_z, \beta_x)$ using standard software by replacing X with Δ. Standard errors are computed using the sandwich estimator or bootstrap.

For models other than the logistic, the simple scheme of replacing X with Δ is not true generally, and conditional score estimating equations for Poisson and gamma regression is much more complicated.

The conditional score estimator for the logistic model compares favorably in terms of efficiency to the full maximum likelihood estimator that requires specification of an exposure model (Stefanski and Carroll 1990b). Sugar et al. (2007) derive the conditional score for the logistic model with a flexible exposure model.

Construction of a conditional score requires availability of a *sufficient statistic* for covariates measured with error. For some models, for example, logistic regression with a quadratic term in X, a sufficient statistic is not available and a conditional score does not exist. Tsiatis and Ma (2004) extend the conditional score approach by deriving estimating equations that retain certain optimality properties and are consistent regardless of the distribution for X. Their method is applicable to a broad class of disease models and essentially reproduces the conditional score method when there is a sufficient statistic. Computation of their estimator is non-trivial and the focus of current research.

33.4.6 Instrumental Variables

The methods described so far require additional data that allow estimation of the measurement error variance. Replicate observations and internal/external validation data are two sources of such additional information. Instrumental variables are another source of information that identify regression parameters in the presence of covariate measurement error. Instrumental variables (IV), denoted T, are additional measurements of X that satisfy three requirements; (i) T is non-differential, that is, $f_{Y|Z,X,T} = f_{Y|Z,X}$; (ii) T is correlated with X; and (iii) T is independent of $W - X$. Note that a replicate observation is an instrumental variable but an instrumental variable is not necessarily a replicate. It is possible to use an instrumental variable to estimate the measurement error variance and then use one of the above methods. Doing so can be inefficient, and IV methods typically do not directly estimate the measurement error variance.

Consider the cancer case-control study of arsenic exposure mentioned in Sect. 33.3. Two measurements of arsenic exposure are available for each case/control in the form of drinking water and toenail concentrations. Neither measure is an exact measure of long-term arsenic exposure (X). Taking toenail concentration to be an unbiased measurement of X, the drinking water concentration can serve as an instrumental variable.

Instrumental variable methods have been used in linear measurement error models since the 1940s, see Fuller (1987) for a good introduction. Instrumental variable methods for non-linear models were first studied in Amemiya (1985, 1990a, b). Extensions of regression calibration and conditional score methodology to instrumental variables are given in Carroll and Stefanski (1994), Stefanski and Buzas (1995), and Buzas and Stefanski (1996a, b). Hu and Schennach (2008) show that instrumental variables identify broad classes of regression models. In this regard, see also Carroll et al. (2004). Gustafson (2007) examines implications when the IV non-differential assumption (assumption (i) above) is mildly violated.

The essential idea underlying instrumental variable estimation can be understood by studying the simple linear model without intercept: $Y = \beta_x X + \epsilon$ and $W = X + \sigma_u U$. Then $Y = \beta_x W + \tilde{\epsilon}$ where $\tilde{\epsilon} = \epsilon - \beta_x \sigma_u U$, and it appears that Y and W follow a simple linear regression model. However, W and $\tilde{\epsilon}$ are correlated, violating a standard assumption in linear regression, and the least squares estimator for β_x is biased; see Sect. 33.2. The least squares estimating equation $\sum_{i=1}^{n}\{Y_i - \beta_x W_i\}W_i = 0$ is biased because W_i and $Y_i - \beta_x W_i$ are correlated. This suggests that an unbiased equation can be constructed by replacing W_i outside the brackets with a measurement uncorrelated with $Y_i - \beta_x W_i$. An IV T satisfies the requirement and the IV estimating equation $\sum_{i=1}^{n}\{Y_i - \beta_x W_i\}T_i = 0$ results in the consistent estimator $\widehat{\beta}_x = \sum_{i=1}^{n} Y_i T_i / \sum_{i=1}^{n} W_i T_i$. Non-zero correlation between X and T is required so that the denominator is not estimating zero. The key idea is that the score factors into two components where the first component $\{Y_i - \beta_x W_i\}$ has expectation zero and the second component T_i is uncorrelated with the first.

The method must be modified for non-linear problems. Logistic regression will be used to illustrate the modification. If we ignore measurement error, the estimating equations for logistic regression are

$$\sum_{i=1}^{n}\{Y_i - F(\beta_1 + \beta_z Z_i + \beta_x W_i)\}\begin{pmatrix}1\\ Z_i\\ W_i\end{pmatrix} = 0.$$

Unlike the linear case, for the logistic model and non-linear models generally, the first term in the estimating score, $\{Y_i - F(\beta_1 + \beta_z Z_i + \beta_x W_i)\}$, does not have expectation zero, so that replacing W_i with T_i outside the brackets in the above equation does not result in an estimator that reduces bias.

Define the logistic regression instrumental variable estimating equations

$$\sum_{i=1}^{n} h(Z_i, W_i, T_i)\{Y_i - F(\beta_1 + \beta_z Z_i + \beta_x W_i)\}\begin{pmatrix}1\\ Z_i\\ T_i\end{pmatrix} = 0$$

where $h(Z_i, W_i, T_i) = \sqrt{\frac{F'(\beta_1 + \beta_z Z_i + \beta_x T_i)}{F'(\beta_1 + \beta_z Z_i + \beta_x W_i)}}$ is a scalar-valued weight function and F' denotes the derivative of F. It can be shown the estimating equation is unbiased provided the distribution of the measurement error is symmetric, implying the estimator obtained from the equations is fully consistent. See Buzas (1997) for extensions to other disease models, including the Poisson and gamma models. Huang and Wang (2001) provide an alternative approach for the logistic model.

33.4.7 Likelihood Methods

Likelihood methods for estimation and inference are appealing because of optimality properties of maximum likelihood estimates and dependability of likelihood ratio confidence intervals. In the context of measurement error problems, the advantages of likelihood methods relative to functional methods have been studied in Schafer and Purdy (1996) and Küchenhoff and Carroll (1997). However, the advantageous properties are contingent on correct specification of the likelihood. As discussed below, this is often a difficult task in measurement error problems.

The likelihood for an observed data point (Y, W) conditional on Z is

$$f_{YW|Z} = \int f_{Y|Z,X,W} f_{W|Z,X} f_{X|Z} dx = \int f_{Y|Z,X} f_{W|Z,X} f_{X|Z} dx$$

where the second equality follows from the assumption of non-differential measurement error and W is possibly a vector containing replicates. The integral is replaced by a sum if X is a discrete random variable. The likelihood for the observed data is $\prod_{i=1}^{N} f_{Y_i,W_i|Z_i}$, and maximum likelihood estimates are obtained by maximizing the likelihood over all the unknown parameters in each of the three component distributions comprising the likelihood. In principle, the procedure is straightforward. However, there are several important points to be made.

1. The likelihood for the observed data requires *complete* distributional specification for the disease model $(f_{Y|Z,X})$, the error model $(f_{W|Z,X})$, and an exposure model $(f_{X|Z})$.
2. As was the case for functional models, estimation of parameters in the disease model generally requires, for all intents and purposes, observations that allow estimation of parameters in the error model, for example, replicate measurements.
3. When the exposure is modeled as a continuous random variable, for example, the normal distribution, the likelihood requires evaluation of an integral. For many applications, the integral cannot be evaluated analytically, and numerical methods must be used, typically Gaussian quadrature or Monte Carlo methods.
4. Finding the maximum of the likelihood is not always straightforward.

While the last two points must be addressed to implement the method, they are technical points and will not be discussed in detail. In principle, numerical integration followed by a maximization routine can be used, but this approach is often difficult to implement in practice; see Schafer (2002). Algorithms for computation and maximization of the likelihood in general regression models with exposure measurement error are given in Higdon and Schafer (2001) and Schafer (2002). Alternatively, a Bayesian formulation can be used to circumvent some of the computational difficulties; see Sect. 33.4.8. For the normal theory linear model and probit regression with normal distribution for the exposure model, the likelihood can be obtained analytically (Fuller 1987; Carroll et al. 1984; Schafer 1993). The analytical form of the likelihood for the probit model often provides an adequate approximation to the likelihood for the logistic model.

The first point above deserves discussion. None of the preceding methods required specification of an exposure model (functional methods). Here an exposure model is required. It is common to assume $X \mid Z \sim N(\alpha_1 + \alpha_x Z, \sigma^2_{x|z})$, but unless there are validation data, it is not possible to assess the adequacy of the exposure model using the data. Some models are robust to the normality assumption. For example, in the normal theory linear model, that is, when (Y, Z, X, W) is jointly normal, maximum likelihood estimators are fully consistent regardless of the distribution of X. For other disease models, the robustness to misspecification is not always clear-cut, but can be tested; see Huang et al. (2006) for a statistical test assessing the robustness of parameter estimates to the choice of distribution for X.

In a Bayesian framework, Richardson and Leblond (1997) show misspecification of the exposure model can affect estimation for logistic disease models.

Semi-parametric and flexible parametric modeling are two approaches that have been explored to address potential robustness issues in specifying an exposure model. Semi-parametric methods leave the exposure model unspecified, and the exposure model is essentially considered as another parameter that needs to be estimated. These models have the advantage of model robustness but may lack efficiency relative to the full likelihood, see Roeder et al. (1996), Schafer (2001), and Taupin (2001).

Flexible parametric exposure models typically use a mixture of normal densities to model the exposure distribution, as normal mixtures are capable of capturing moderately diversified features of distributions. Flexible parametric approaches have been studied in Küchenhoff and Carroll (1997), Carroll et al. (1999b), Schafer (2002), Gustafson et al. (2002), and Roy and Banerjee (2006). Guolo (2008) uses a skew-normal distribution to model the exposure in a case-control setting.

The likelihood can also be obtained conditional on both W and Z. In this case, the likelihood is

$$f_{Y|Z,W} = \int f_{Y|Z,X} f_{X|Z,W} dx$$

necessitating an exposure model relating X to W and Z. This form of the likelihood is natural for Berkson error models. In general, the choice of which likelihood to use is a matter of modeling convenience.

33.4.8 Bayesian Methods

Research and application of Bayesian methods (see also chapter ▶Bayesian Methods in Epidemiology of this handbook) in nearly all areas of statistics have greatly increased since the late 1980s with the advent of algorithms for sampling from posterior distributions. The field of measurement error is no exception.

Bayesian models are conceptually straightforward, and from an operational standpoint, Bayesian models can be considered an extension of likelihood models. A Bayesian model starts with the likelihood model, that is, disease, exposure, and error models, and adds a prior probability model to all unknown parameters in the likelihood. The posterior distribution for the unknown parameters is in principle obtained using Bayes theorem. The posterior distribution is the basis of inference in the Bayesian paradigm.

The Bayesian machinery can be applied to any data analytical setting where a likelihood is postulated, for example, covariate measurement error problems in multiple regression, logistic regression, survival analysis, non-parametric regression, and so on. While the Bayesian method is straightforward to describe and widely applicable, it is not necessarily straightforward to implement. Direct application of Bayes theorem typically requires evaluation of analytically and computationally intractable integrals.

Let $f_{Y|X,Z,\theta_Y}$, $f_{W|X,Z,\theta_W}$, and $f_{X|Z,\theta_X}$ denote the probability models for the outcome, error, and exposure where θ_Y, θ_W, and θ_X denote the unknown parameters in the respective models. A Bayesian analysis requires a prior probability distribution for the unknown parameters $\theta = (\theta_Y, \theta_W, \theta_X)$. Denote the prior density by f_θ. Usually the priors for θ_Y, θ_W, and θ_X are independent, so that $f_\theta = f_{\theta_Y} f_{\theta_W} f_{\theta_X}$.

Suppose the observable data consist of Y_i, W_{ij}, Z_i for $i = 1, \ldots n$ and $j = 1, \ldots, r_i$. The posterior distribution for the unobservable vector of covariates $X = (X_1, \ldots, X_n)$ and the model parameters θ is given by Bayes theorem:

$$f_{X,\theta|Y,W,Z} = \frac{\prod_{i=1}^{n} f_{Y_i|X_i,Z_i,\theta_Y} \prod_{j=1}^{r_i} f_{W_{ij}|X_i,Z_i,\theta_W} f_{X_i|Z_i,\theta} f_\theta}{\int\int \prod_{i=1}^{n} f_{Y_i|X_i,Z_i,\theta_Y} \prod_{j=1}^{r_i} f_{W_{ij}|X_i,Z_i,\theta_W} f_{X_i|Z_i,\theta} f_\theta dx d\theta}.$$

The integral in the denominator of the right-hand side is typically analytically intractable and of high dimension, with the latter issue rendering numerical integration techniques ineffective. Furthermore, we are interested in the marginal posterior distribution of θ, requiring another integration that is typically difficult to evaluate: $f_{\theta|Y,W,Z} = \int f_{X,\theta|Y,W,Z} dx$.

Evaluation of these integrals is circumvented using Markov chain Monte Carlo (MCMC) algorithms, with the Gibbs sampler and the Metropolis-Hastings algorithms, the most widely used variants (see chapter ▸Bayesian Methods in Epidemiology of this handbook). MCMC algorithms are able to sample from the posterior distribution $f_{X,\theta|Y,W,Z}$ without evaluating the integrals on the right-hand side. The marginal distribution $f_{\theta|Y,W,Z}$ can be estimated using only the sampled θ's. A detailed description of these algorithms is beyond the scope of this chapter. Carroll et al. (2006) and Gustafson (2004) provide details of implementing MCMC methods for covariate measurement error problems.

An important consideration when using MCMC methods is assessing convergence and mixing of the algorithm. Trace plots are often the best diagnostic tool for assessing convergence and mixing, though other diagnostic procedures have been developed. It is often helpful to compute several "chains," each starting in a different region of the parameter space, and noting whether the different chains end up in approximately the same region of the posterior distribution. Convergence and mixing of the separate chains are assessed visually using trace plots and quantitatively using Gelman and Rubin's R statistic. The example below illustrates the use of trace plots.

To illustrate the specification of commonly employed uninformative priors in a measurement error setting, consider the normal theory linear regression model:

$$\begin{aligned} Y \mid X, \theta_Y &\sim N(\beta_0 + \beta_x X, \sigma^2) \\ W \mid X, \theta_W &\sim N(X, \sigma_u^2) \\ X \mid \theta_X &\sim N(\mu_x, \sigma_x^2), \end{aligned}$$

where the distributions are independent. For this model, $\theta_Y = (\beta_0, \beta_x, \sigma^2)$, $\theta_W = \sigma_u^2$ and $\theta_X = (\mu_x, \sigma_x^2)$. Using independent normal prior distributions with mean zero and large variance for β_0, β_x, and μ_x, and independent inverse gamma distributions for the variance components σ^2, σ_u^2, and σ_x^2 allows for straightforward implementation of the Gibbs sampler, as these priors are conjugate for the normal theory model above. Using large variances for the normal distributions and appropriate shape and scale parameters for the inverse gamma distribution results in uninformative priors. Other choices of priors can also be used. For example, diffuse uniform priors for $(\beta_0, \beta_x, \mu_x, \sigma, \sigma_u, \sigma_x)$ are also commonly employed.

For most models, covariate measurement error renders some model parameters non-identified; see the discussion in Sect. 33.2.3. Additional data, such as replicate covariate measurements, instrumental variables, or validation data, can be used to identify model parameters. In the Bayesian framework, posterior distributions for non-identified parameters using proper priors still obtain. However, the posterior distributions of non-identified parameters will not converge to the true parameter values. Nevertheless, Gustafson (2005, 2009) recently studied the amount of information available for parameters in non-identified models and shows that in certain scenarios a moderate amount of prior information can lead to inferences that outperform inferences from identified models obtained by contracting (or expanding) the non-identified model.

33.4.8.1 Example

We return again to the Framingham data described in Sect. 33.2.6. Measurements of coronary heart disease, age, and three measurements of the logarithm of systolic blood pressure, denoted by Y, Z, W_1, W_2, and W_3, respectively, were obtained for $n = 1,615$ individuals. The log systolic blood pressure measurements are assumed to be replicates with additive normal measurement error, that is, $W_i = X_i + \sigma_u U_i, i = 1, 2, 3$ where $U_i \sim N(0, 1)$ are independent. For the Bayes fit, we assume $X \sim N(\mu_x, \sigma_x^2)$. Interest is in fitting the logistic regression model:

$$\text{logit}(E[Y \mid X, Z]) = \beta_0 + \beta_x X + \beta_z Z.$$

Having replicate measurements identifies all model parameters.

Four estimators were computed for comparison: the naive estimator that uses W_1 and Z as covariates, the Bayes, conditional score, and corrected score estimators (Buzas 2009). The Bayesian estimator used diffuse independent normal priors for each of β_0, β_x, β_z, and μ_x. Diffuse independent uniform priors were used for σ_x and σ_u. Three chains, each of length 10,000, were computed. The first 5,000 iterations were discarded, and the remaining samples thinned resulting in a sample of 1,000 from the posterior distribution. Convergence and mixing were very good; see the trace plots in Fig. 33.2. The plots show a stable mean and variance of the posterior samples and rapid movement through the posterior distribution. It is worth noting that if age and log systolic blood pressure were not centered and scaled during fitting, mixing was very slow for β_0 and β_x, requiring several hundred thousand iterations of the chain. Computations were done using WinBUGS software.

As seen in Table 33.3, the posterior mean and standard deviation from the Bayesian analysis are very similar to the estimates obtained from the conditional and corrected scores.

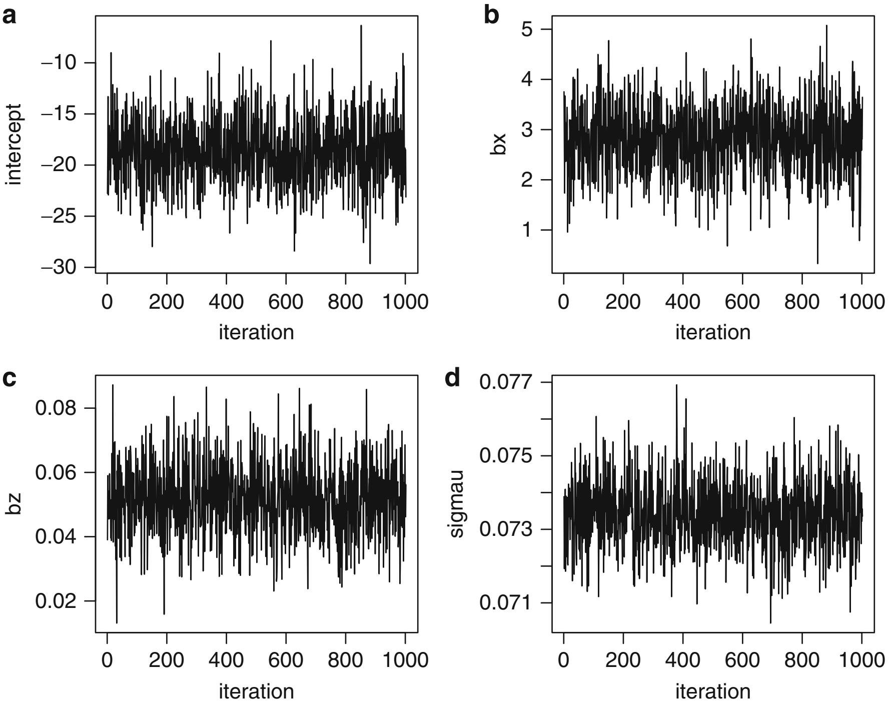

Fig. 33.2 Trace plots for the Framingham data

Table 33.3 Logistic parameter estimates for Framingham data

Covariate	Naive	Bayes	Conditional score	Corrected score
Intercept	−15.565 (2.624)	−18.655 (3.287)	−18.603 (3.288)	−18.614 (3.350)
Log blood pressure	2.161 (0.547)	2.806 (0.690)	2.817 (0.696)	2.835 (0.714)
Age	0.053 (0.010)	0.052 (0.011)	0.049 (0.011)	0.048 (0.010)

To summarize, advantages of Bayesian analyses include wide applicability, straightforward inference using posterior distributions, and the potential to handle complex and perhaps non-identified models. The disadvantages include potential sensitivity to priors and exposure models, the potential need to develop application-specific MCMC algorithms, and assessment of convergence of MCMC samplers. Note that more model complexity requires more checks on sensitivity of model assumptions.

33.4.8.2 Additional Notes

WinBUGS is currently the most widely used software package that implements MCMC algorithms. WinBUGS has a great deal of flexibility, and many types of outcome, exposure, error models, and priors can be specified. The syntax for WinBUGS is similar to that of R, though not identical. A strength of WinBUGS is that it is relatively simple to specify hierarchical Bayesian models using syntax analogous to mathematical notation one would use to specify these models on paper. Currently WinBUGS is free.

Perhaps the earliest paper to study covariate measurement error in epidemiology from a Bayesian perspective is Richardson and Gilks (1993). Examples of recent research into Bayesian methods for covariate measurement error in epidemiological settings are the following: Johnson et al. (2007) develop models in the setting of nutritional epidemiology for studying the effects of folate intake, measured imprecisely, of expectant mothers on gestational age. Sinha et al. (2010) provide a Bayesian analysis using semi-parametric models for both the disease and exposure models. Cheng and Crainiceanu (2009) develop an MCMC algorithm for survival data using non-parametric models for the baseline hazard and survival-exposure relation. They apply their method to the study of chronic kidney disease using an imprecise measure of baseline kidney function as a covariate. Li et al. (2007) use Bayesian methods in the context of estimating the effects of radiation exposure on thyroid disease. The problems in these papers share the feature that the models studied are complex, a quality Bayesian methods are often adept at handling.

33.4.9 Survival Analysis

The preceding discussion described general strategies applicable to a broad range of disease models. Survival data warrants its own section, as analysis of survival data with exposure measurement error using proportional hazards models presents some new issues (see also chapter ▶Exposure Assessment of this handbook). Of the methods presented, only SIMEX and Bayesian methods (when a likelihood is specified) can be applied without modification in the proportional hazards setting.

Many of the proposed methods for measurement error correction in proportional hazards models fall into one of two general strategies. The first strategy is to approximate the induced hazard and then use the approximated hazard in the partial likelihood equations. This strategy is analogous to the regression calibration approximation discussed earlier. The second strategy is to modify the partial likelihood estimating equations. Methods based on this strategy stem from the corrected and conditional score paradigms.

In the absence of measurement error, the proportional hazards model postulates a hazard function of the form $\lambda(t \mid Z, X) = \lambda_0(t) \exp(\beta_z^T Z + \beta_x X)$ where $\lambda_0(t)$ is an unspecified baseline hazard function. Estimation and inference for (β_x, β_z) are carried out through the partial likelihood function, as it does not depend on $\lambda_0(t)$.

Prentice (1982) has shown that when (Z, W) is observed, the induced hazard is $\lambda(t \mid Z, W) = \lambda_0(t) E[\exp(\beta_z^T Z + \beta_x X) \mid T \geq t, Z, W]$. The induced hazard requires a model for X conditional on $(T \geq t, Z, W)$. This is problematic because the distribution of T is left unspecified in proportional hazards models. However, when the disease is rare $\lambda(t \mid Z, W) \approx \lambda_0(t) E[\exp(\beta_z^T Z + \beta_x X) \mid Z, W]$ (Prentice 1982) and if we further assume that $X \mid Z, W$ is approximately normal with constant variance, then the induced hazard is proportional to

$\exp(\beta_z^T Z + \beta_x E[X \mid Z, W])$. In other words, regression calibration is appropriate in the proportional hazards setting when the disease is rare and $X \mid Z, W$ is approximately normal.

Modifications to the regression calibration algorithm have been developed for applications where the rare disease assumption is untenable; see Clayton (1991), Tsiatis et al. (1995), Wang et al. (1997) and Xie et al. (2001). Conditioning on $T \geq t$ cannot be ignored when the disease is not rare. The idea is to reestimate the calibration function $E[X \mid Z, W]$ in each risk set, that is, the set of individuals known to be at risk at time t. Clayton's proposal assumes that the calibration functions across risk sets have a common slope and his method can be applied provided one has an estimate of the measurement error variance. Xie et al. (2001) extend the idea to varying slopes across the risk sets and require replication (reliability data). Tsiatis et al. (1995) consider time-varying covariates and also allow for varying slopes across the risk sets.

When a validation subsample is available, it is possible to estimate the induced hazard non-parametrically, that is, without specifying a distribution for $X \mid (T \geq t, Z, W)$; see Zhou and Pepe (1995) and Zhou and Wang (2000) for the cases when the exposure is discrete and continuous, respectively.

The second strategy mentioned above avoids modeling the induced hazard and instead modifies the partial likelihood estimating equations. Methods based on the corrected score concept are explored in Nakamura (1992), Buzas (1998), Huang and Wang (2000), Augustin (2004), and Yi and Lawless (2007). The methods in Nakamura (1992) and Buzas (1998) assume the measurement error is normally distributed and only require an estimate of the measurement error variance. In contrast, the approach in Huang and Wang (2000) does not require assumptions on the measurement error distribution, but replicate observations on the mismeasured exposure are needed to compute the estimator. Each of the methods has been shown to be effective in reducing bias in parameter estimators. Tsiatis and Davidian (2001) extend conditional score methodology to the proportional hazards setting with covariates possibly time dependent. Song and Huang (2005) compare the conditional and corrected score approaches in small samples, generally noting the conditional score approach is superior.

33.5 Conclusions

Epidemiologists have long recognized the importance of addressing problems of measurement and ascertainment in the statistical analysis of epidemiological data. Much of the research in measurement error models has its origins in specific epidemiological applications, and this is reflected by many of the research papers cited in this review article. The importance of measurement error modeling to epidemiological research is on the rise, and that trend is likely to continue for the foreseeable future.

As the understanding of the etiology of disease increases, so too will the sophistication of the statistical models used to extract information from epidemiological data. Success in these modeling endeavors will depend on the ability to accurately model ever finer sources of variability in data, and measurement error is frequently one such non-negligible source of variation. Recent articles studying epidemiological applications with covariate measurement error bare out the increasing complexity of models studied.

This chapter provides an introduction to and a review of the literature on the problem of statistical inference in the presence of measurement error. Section 33.2 discussed the effects of measurement error in common epidemiological models. With the inevitable increase in the sophistication of models for epidemiological data, there will be a need to understand the effects of measurement error on parameter estimation in biologically based and physiologically based models of disease. The increasing ability to collect very detailed and precise information on subjects in validation samples (e.g., via continuous monitoring of biological processes, or genetic screening) means that consideration of measurement error at the design stage of a study will take on greater importance. Hence, the timely relevance of the issues and methods is discussed in Sect. 33.3. More elaborate modeling places greater demands on methods of estimation. Section 33.4 provided a summary and review of common approaches to estimation in the presence of measurement. Future research will necessarily have to accommodate more complex models and possibly multiple variates measured with correlated error.

34.1 Introduction

The problem of dealing with missing values is common throughout statistical work and is present whenever human subjects are enrolled. Respondents may refuse participation or may be unreachable. Patients in clinical and epidemiological studies may withdraw their initial consent without further explanation. Early work on missing values was largely concerned with algorithmic and computational solutions to the induced lack of balance or deviations from the intended study design (Afifi and Elashoff 1966; Hartley and Hocking 1971). More recently, general algorithms such as the Expectation–Maximization (EM) (Dempster et al. 1977) and data imputation and augmentation procedures (Rubin 1987; Tanner and Wong 1987), combined with powerful computing resources, have largely provided a solution to this aspect of the problem. There remains the very difficult and important question of assessing the impact of missing data on subsequent statistical inference. Conditions can be formulated, under which an analysis that proceeds as if the missing data are missing by design, that is, ignoring the missing value process, can provide valid answers to study questions. While such an approach is attractive from a pragmatic point of view, the difficulty is that such conditions can rarely be assumed to hold with full certainty. Indeed, assumptions will be required that cannot be assessed from the data under analysis. Hence in this setting there cannot be anything that could be termed a definitive analysis, and hence any analysis of preference is ideally to be supplemented with a so-called sensitivity analysis.

In Sect. 34.2, the key illustrative case study is introduced. Section 34.3 is devoted to an overview of the fundamental concepts of incomplete longitudinal or multivariate data, including a general framework within which missing data ideas can be developed as well as a modeling framework for both Gaussian and non-Gaussian outcomes, useful to further develop and illustrate practical strategies to deal with incomplete data. Simple methods that are often used but carry quite a bit of danger in them are discussed in Sect. 34.4. In Sect. 34.5, an overview of methods is provided which are valid when missingness is missing at random (MAR), that is, when the probability of dropout is allowed to depend on the observed measurements. Such methods can be used as a primary analysis. In this chapter, the focus will be primarily on incomplete outcomes. However, incomplete covariate data, perhaps in conjunction with incomplete outcome data, are relatively common too. It should be noted, therefore, that multiple imputation, discussed in Sect. 34.5.3, can nicely handle this type of missingness as well.

In Sect. 34.7, two approaches to modeling data with non-random dropout are considered: the selection model framework (Sect. 34.7.1) and the pattern-mixture modeling family (Sect. 34.7.3). The optimal place of such missing not at random (MNAR) models is within a sensitivity analysis. One can use different plausible models within one of the modeling frameworks or across both. In Sect. 34.7.5, local influence is considered, which is a sensitivity analysis tool that can be used within the selection model framework.

The case study that was introduced in Sect. 34.2 is analyzed and discussed throughout the chapter, by way of running example.

34.2 The Age-Related Macular Degeneration Trial

In this section, the age-related macular degeneration trial is introduced. These data arise from a randomized multi-centric clinical trial comparing an experimental treatment (interferon-α) with a corresponding placebo in the treatment of patients with age-related macular degeneration. Here, we focus on the comparison between placebo and the highest dose (six million units daily) of interferon-α, but the full results of this trial have been reported elsewhere (Pharmacological Therapy for Macular Degeneration Study Group 1997). Patients with macular degeneration progressively lose vision. In the trial, the patients' visual acuity was assessed at different time points (4, 12, 24, and 52 weeks) through patients' ability to read lines of letters on standardized vision charts. These charts display lines of five letters of decreasing size, which the patient must read from top (largest letters) to bottom (smallest letters). The patient's visual acuity is the total number of letters correctly read. In addition, one often refers to each line with at least four letters correctly read as a "line of vision".

An endpoint of interest in this trial was the visual acuity at 1 year (treated as a continuous endpoint). Table 34.1 shows the visual acuity recorded as the number of letters read (mean and standard error) by treatment group at baseline, and at the four measurement occasions after baseline. Another point of interest is whether the visual acuity increases or decreases compared to baseline. Accordingly, this dichotomous response variable is created. Table 34.2 displays the percentages of patients with such a decrease of visual acuity compared to baseline at all four time points, both overall and by treatment arm.

The original quasi-continuous outcome, visual acuity, as well as the binary indicator for increase or decrease in number of letters read compared to baseline will be analyzed throughout this chapter.

Let us now graphically explore these data. The average evolution describes how the mean profile for a number of relevant subpopulations (or the population as a whole) evolves over time. The individual profiles are displayed in Fig. 34.1, while the mean profiles of the visual acuity values per treatment arm, as well as their 95% confidence intervals, are plotted in Fig. 34.2.

The average profiles indicate a decrease over time, which seems equally strong for both groups since the profiles are nearly parallel. However, the average visual

Table 34.1 Age-related macular degeneration trial. Mean (standard error) of visual acuity at baseline, at 4, 12, 24, and 52 weeks according to randomized treatment group (placebo versus interferon-α)

Time point	Placebo	Interferon-α	Total
Baseline	55.3 (1.4)	54.6 (1.4)	55.0 (1.0)
4 weeks	54.0 (1.5)	50.9 (1.5)	52.5 (1.1)
12 weeks	52.9 (1.6)	48.7 (1.7)	50.8 (1.2)
24 weeks	49.3 (1.8)	45.5 (1.8)	47.5 (1.3)
1 year (52 weeks)	44.4 (1.8)	39.1 (1.9)	42.0 (1.3)

Table 34.2 Age-related macular degeneration trial. Percentage of patients with a decrease of visual acuity compared to baseline, at 4, 12, 24, and 52 weeks according to randomized treatment group (placebo versus interferon-α)

Time point	Placebo	Interferon-α	Total
4 weeks	65.2%	72.1%	68.6%
12 weeks	59.6%	73.6%	66.4%
24 weeks	65.8%	74.3%	69.8%
1 year (52 weeks)	77.5%	83.7%	80.3%

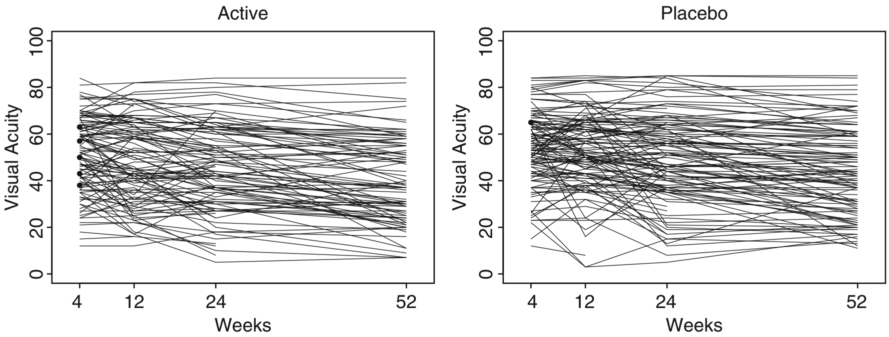

Fig. 34.1 Age-related macular degeneration trial. Individual profiles by treatment arm

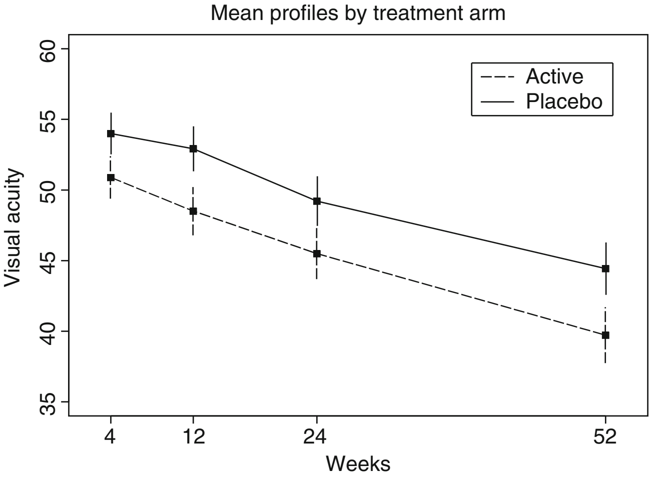

Fig. 34.2 Age-related macular degeneration trial. Mean profiles and 95% confidence intervals by treatment arm

acuity for the active group is overall smaller compared to the placebo group. As can be seen from the confidence intervals, these differences are clearly not significant at week 4 and 24, but might be for week 12 and 52. The individual profiles augment the averaged plot with a suggestion of the variability seen within the data.

Table 34.3 Age-related macular degeneration trial. Overview of missingness patterns and the frequencies with which they occur

Measurement occasion					
Week 4	Week 12	Week 24	Week 52	Number	%
Completers					
O	O	O	O	188	78.33
Dropouts					
O	O	O	M	24	10.00
O	O	M	M	8	3.33
O	M	M	M	6	2.50

Non-monotone missingness					
O	O	M	O	4	1.67
O	M	M	O	1	0.42
M	O	O	O	2	0.83
M	O	M	M	1	0.42

O observed, *M* missing

Thinning of the data towards the later study times suggests that trends at later times should be treated with caution. Indeed, an extra level of complexity is added whenever not all planned measurements are observed. This results in *incompleteness* or *missingness*. Another frequently encountered term is *dropout*, which refers to the case where all observations on a subject are obtained until a certain point in time, after which all measurements are missing. To simplify matters, we will largely focus on dropout, but a lot of the developments made are valid also for general types of missingness.

Regarding missingness in the ARMD data set, an overview of the different missingness patterns is given in Table 34.3. The missingness pattern shows at which of the scheduled time points the patient has an observation or a missing value. Clearly, both intermittent missingness as well as dropout occurs. It is observed that 188 of the 240 profiles are complete, which is a percentage of 78.33%, while 18.33% (44 subjects) drop out before the end of the study. Out of the latter group, 2.50% or six subjects have no follow-up measurements. The remaining 3.34%, representing eight subjects, have intermittent or non-monotone missing values. Although the group of dropouts is of considerable magnitude, the ones with intermittent missingness is much smaller. To be consistent throughout the analysis in this chapter, subjects with non-monotone profiles will not be taken into account. Further, neither will the subjects without any follow-up measurement be included in the analysis. Both reasons will become clear in the course of this chapter. This results in a data set of 226 of 240 subjects, or 94.17%.

One issue, resulting from dropout, is evidently a depletion of the study subjects. Of course, a decreasing sample size increases variability which, in turn, decreases precision. Note that the treatment might be a potential factor that could influence a patient's probability of dropping out. Although a large part of the scientist's study

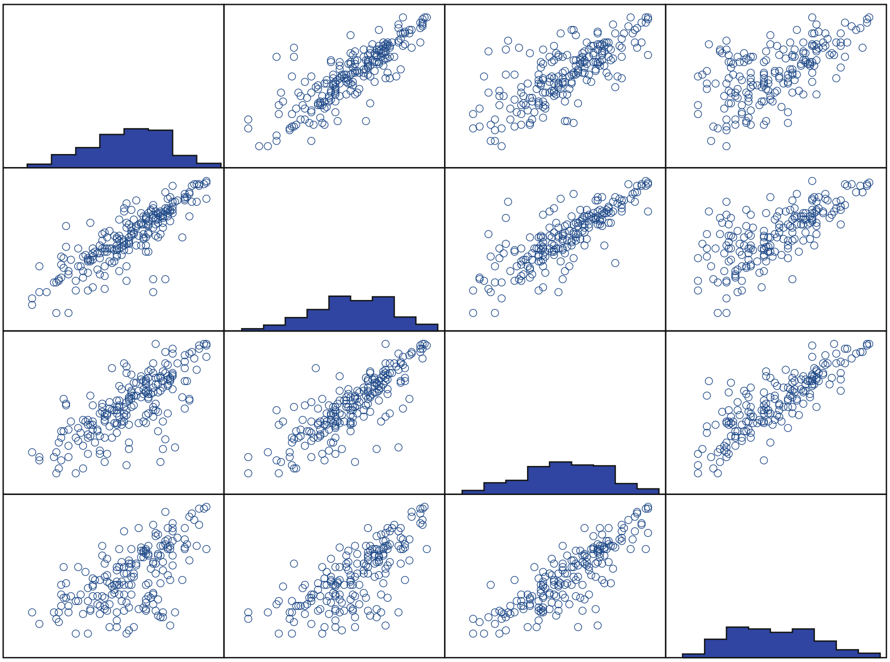

Fig. 34.3 Age-related macular degeneration trial. Scatter plot matrix for all four time points

interest will typically focus on the treatment effect, we should be aware that it is still a covariate and hence a design factor. Another question that will arise is whether dropout depends on observed or unobserved responses.

A different way of displaying several structural aspects is using a scatter plot matrix, such as in Fig. 34.3. The off-diagonal elements picture scatter plots of standardized residuals obtained from pairs of measurement occasions. The decay of correlation with time is studied by considering the evolution of the scatters with increasing distance to the main diagonal. Stationarity, on the other hand, implies that the scatter plots remain similar within diagonal bands *if measurement occasions are approximately equally spaced*. In addition to the scatter plots, we place histograms on the diagonal, capturing the variance structure. Features such as skewness, multimodality, and so forth, can then be graphically detected.

Further, the variance function is displayed in Fig. 34.4. The variance function is increasing non-linearly over time, and hence an unstructured variance model is a plausible starting point.

To gain further insight into the impact of dropout, it is useful to construct dropout-pattern-specific plots. Figure 34.5 displays the average profiles per dropout pattern, for both the interferon-α (active) and the placebo group.

This plot will be useful as a graphical start to a so-called pattern-mixture analysis, as described later in Sect. 34.7.3. The individual profiles plot, by definition

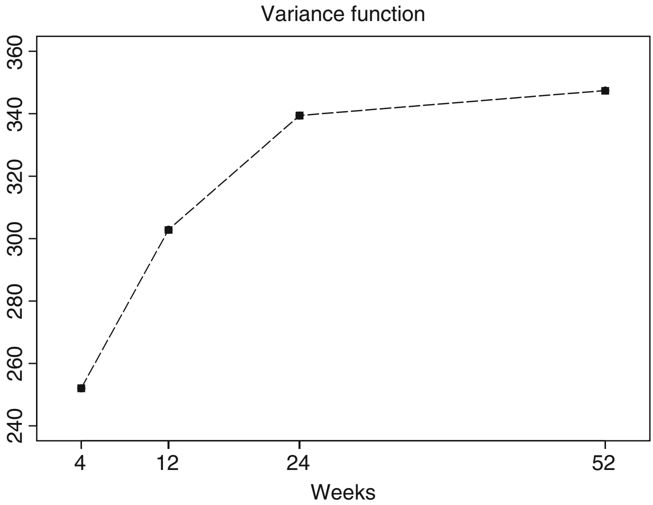

Fig. 34.4 Age-related macular degeneration trial. Variance function

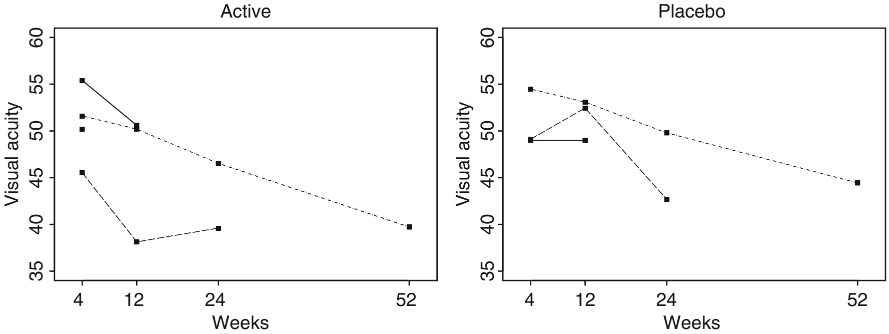

Fig. 34.5 Age-related macular degeneration trial. Mean profiles per pattern for both treatment arms

displaying all available data, has some intrinsic limitations and hence will not be considered. Indeed, as is the case with any individual data plot, it tends to be fairly busy. Further, if the same time axis is used for all profiles, also for those that drop out early, very little information can be extracted. In addition, the eye assigns more weight to the longer profiles, even though, they are considerably less frequent. In exploring the average profiles per pattern still care has to be taken for not overinterpreting the longer profiles and neglecting the shorter profiles.

Several observations can be made. In contrast to the average profile of the completers, the profiles of the incompleters do not show a linear trend (accept for the obvious case of two measurements). This implies that the impression from all patterns together may differ radically from a pattern-specific look. These conclusions seem to be consistent across treatment arms.

Another important observation is that those who drop out rather early, after week 12, increase from the start for the active group, and remain relatively stable for the placebo group. On the other hand patients who have the last measurement missing and are in the active group show a steep decrease between week 4 and 12, followed by a slight increase up to week 24. For the placebo group it is the other way around, the average profile increases a little from week 4–12, but decreases afterward. This implies that the average evolution is different for both treatment groups and also across the dropout patterns. Looked upon from the standpoint of dropout, this suggests that dropout will probably be related to the (observed) visual acuity values. Additionally, there is at least one important characteristic that makes dropout increase, namely, an unfavorable (downward) evolution of the visual acuity.

Arguably, careful modeling of these data, irrespective of the approach chosen, should reflect these features. We will consider the most important routes typically taken, starting from simple ad hoc methods, and then going to more principled methods, for which we first need to develop a formal but intuitively appealing framework.

34.3 Fundamental Concepts of Incomplete Multivariate Data

Data arising from epidemiological studies and biomedical research in general are often prone to incompleteness, or missingness. Since missingness usually occurs outside the control of the investigators, and may be related to the outcome of interest, it is generally necessary to address the process that governs this incompleteness. Only in special but important cases is it possible to ignore the missingness process.

In this section, we first introduce some general concepts of modeling incomplete data. Next, we discuss methods to model longitudinal or multivariate data both in the Gaussian and non-Gaussian setting, which capture the methodology necessary for the ARMD case study. For continuous measurements, the linear mixed model is used, whereas for non-Gaussian outcomes we distinguish between three model families: marginal, random-effects, and conditional models.

34.3.1 A Framework for Handling Missing Values

The nature of the missingness mechanism can affect the analysis of incomplete data and its resulting statistical inference. Therefore, we will introduce the terminology and notation necessary when modeling incomplete data, as well as the different missing data mechanisms.

Let the random vector $\vec{Y}$ correspond to the, possibly notional, complete set of measurements on a subject whether observed or not and suppose that its distribution depends on a vector of parameters $\vec{\theta}$. Let $\vec{R}$ be the associated missing value indicator, with distribution depending on parameter vector $\vec{\psi}$. In case missingness is restricted to dropout, we define D to be the occasion of dropout. For a particular realization of this pair $(\vec{y}, \vec{r})$, the elements of $\vec{r}$ take the values 1 and 0 indicating, respectively, whether the corresponding values of $\vec{y}$ are observed or not. When we are dealing with dropout the information in $\vec{r}$ can be summarized in a single variable: the first time at which a value is missing. Let $(\vec{y}_o, \vec{y}_m)$ denote the partition of $\vec{y}$ into the respective sets of observed and missing data. In what follows we will be attempting to fit and make inferences about models constructed for the pair $(\vec{y}, \vec{r})$ using only the observed data: $(\vec{y}_o, \vec{r})$. If $f(\vec{y}, \vec{r})$ is the joint distribution of the complete data, then the marginal distribution of the observed data, which forms the basis for model fitting, is

$$f(\vec{y}_o, \vec{r}) = \int f(\vec{y}, \vec{r})\dot{\vec{y}}_m. \tag{34.1}$$

Rubin's taxonomy (Rubin 1976; Little and Rubin 1987) of missing value processes is fundamental to modeling incomplete data. This classification essentially distinguishes settings in which important simplifications of this process are possible.

34.3.1.1 Missing Completely at Random (MCAR)

Under an MCAR mechanism the probability of an observation being missing is independent of the responses: $\mathrm{P}(\vec{R} = \vec{r} \mid \vec{y}) = \mathrm{P}(\vec{R} = \vec{r})$. The joint distribution of the *observed* data partitions as follows: $f(\vec{y}_o, \vec{r}) = f(\vec{y}_o; \vec{\theta})\mathrm{P}(\vec{r}; \vec{\psi})$. Under MCAR, the observed data can be analyzed as though the pattern of missing values was predetermined. In whatever way the data are analyzed, whether using a frequentist or likelihood procedure, the process generating the missing values can be ignored. For example, in this situation simple averages of the observed data at different times provide unbiased estimates of the underlying marginal profiles.

34.3.1.2 Missing at Random (MAR)

Under an MAR mechanism, the probability of an observation being missing is *conditionally* independent of the unobserved data, given the values of the observed data: $\mathrm{P}(\vec{R} = \vec{r} \mid \vec{y}) = \mathrm{P}(\vec{r} \mid \vec{y}_o)$, and again the joint distribution of the observed data can be partitioned:

$$f(\vec{y}_o, \vec{r}) = f(\vec{y}_o; \vec{\theta})\mathrm{P}(\vec{r} \mid \vec{y}_o; \vec{\psi}). \tag{34.2}$$

An example of random dropout occurs in a trial in which subjects are removed when their observed response drifts outside prescribed limits, Murray and Findlay (1988) describe an instance of this. We note that the handling of the MAR assumption is much easier with dropout than with more general missing value patterns.

No mention has been made of covariates and the dependence of missing value probabilities on these. According to Little (1995), the original intention was that MCAR should refer to the case in which the probability of a value being missing does not depend on the response *or* covariates, and suggests the term "covariate-dependent" missing value mechanism for the case where it depends on the latter.

This avoids the problem of having the class of mechanisms potentially changing with the addition and removal of covariates.

One can see the importance of the MAR assumption from an intuitive viewpoint. Essentially it states that once appropriate account is taken of what we have observed, there remains no dependence on unobservables, at least in terms of the probability model. We should as a consequence expect much of the missing value problem to disappear under the MAR mechanism and this is in fact the case. This can be shown more formally through consideration of the likelihood. The result (Eq. 34.2) implies that the joint log-likelihood for $\vec{\theta}$ and $\vec{\psi}$ partitions:

$$\ell(\vec{\theta}, \vec{\psi}; \vec{y}_o, \vec{r}) = \ell(\vec{\theta}; \vec{y}_o) + \ell(\vec{\psi}; \vec{r}).$$

Provided that $\vec{\theta}$ and $\vec{\psi}$ are not interdependent, information about the response model parameter $\vec{\theta}$ is contained wholly in $\ell(\vec{\theta}; \vec{y}_o)$, the log-likelihood of the observed response data. This is the log-likelihood function that is used when no account is taken of the missing value mechanism, hence for a likelihood analysis under the MAR assumption, the missing value mechanism is said to be *ignorable*. It should be noted that although the correct maximum likelihood estimates and likelihood ratio statistics will be generated by the use of $\ell(\vec{\theta}; \vec{y}_o)$, some care needs to be taken with the choice of appropriate sampling distribution in a frequentist analysis. For this the missing value mechanism is *not* ignorable, even under MAR (Kenward and Molenberghs 1998). In practice though there is little reason for worry since this just means that estimates of precision should be based on the observed rather than the expected information matrix. Additionally, it also has been shown how non-likelihood approaches can be developed for the MAR case (Robins et al. 1995, 1998; Fitzmaurice et al. 1995).

While the MAR assumption is particularly convenient in that it leads to considerable simplification in the issues surrounding the analysis of incomplete longitudinal data, it is rare in practice to be able to justify its adoption, and so in many situations the final class of missing value mechanisms applies.

34.3.1.3 Missing Not at Random (MNAR)

In this case neither MCAR nor MAR hold. Under MNAR, the probability of a measurement being missing depends on unobserved data. No simplification of the joint distribution is possible and inferences can only be made by making further assumptions, about which the observed data alone carry no information. Ideally the choice of such assumptions should be guided by external information, but the degree to which this is possible in practice varies greatly. In attempting to formulate models for the joint distribution of the response and dropout process, $f(\vec{y}, \vec{r})$, three main types of model have been used and these are defined by two possible factorizations of this distribution. The first, the *selection* model, is based on

$$f(\vec{y}, \vec{r}) = f(\vec{y})\mathrm{P}(\vec{r} \mid \vec{y}). \tag{34.3}$$

The second, the *pattern-mixture* model (PMM), uses

$$f(\vec{y}, \vec{r}) = f(\vec{y} \mid \vec{r})\mathrm{P}(\vec{r}). \tag{34.4}$$

The differences between these reversed factorizations are important in the MNAR case, and lead to quite different, but complementary, views of the missing value problem. Little (1995) and Hogan and Laird (1997) provide detailed reviews. The term "selection model" originates from the econometric literature (Heckman 1976) and it can be seen that a subject's missing values are "selected" through the probability model, given their measurements, whether observed or not. Rubin's classification is defined in the selection framework, and imposition of conditions on $\mathrm{P}(\vec{r} \mid \vec{y})$ determines to which of the three classes the model belongs in the frequentist sense. On the other hand, the pattern-mixture model allows a different response model for each pattern of missing values, the observed data being a mixture of these weighted by the probability of each missing value or dropout pattern. At first sight such a model is less appealing in terms of probability mechanisms for generating the data, but it has other important advantages. Recently it has been shown, for dropout, how the Rubin classification can be applied in the pattern-mixture framework as well (Molenberghs et al. 1998; Kenward et al. 2003).

Instead of using the selection or pattern-mixture model frameworks, the measurement and dropout process can be modeled jointly using a *shared-parameter* model (Wu and Carroll 1988; Wu and Bailey 1988, 1989; TenHave et al. 1998). In such a model the measurement and dropout process are assumed to be independent, conditional upon a certain set of shared parameters. This shared-parameter model is formulated by way of the following factorization:

$$f(\vec{y}, \vec{r}) = f(\vec{y} \mid \vec{b}_i)\mathrm{P}(\vec{r} \mid \vec{b}_i). \tag{34.5}$$

Here, $\vec{b}_i$ are shared parameters, often considered to be random effects and following a specific parametric distribution.

We will consider the first two approaches to modeling data with non-random dropout in Sects. 34.7.1 and 34.7.3.

These strategies used to analyze incomplete data are based on two choices. First, a choice has to be made regarding the modeling approach to the measurement sequence. The measurement model will depend on whether or not a full longitudinal analysis is done. In case focus is on the last observed measurement or on the last measurement occasion only, one typically opts for classical two- or multi-group comparisons (t test, Wilcoxon, etc.). In case a longitudinal analysis is deemed necessary, the choice made depends on the nature of the outcome. A variety of model both for Gaussian and non-Gaussian multivariate data will be discussed in Sect. 34.3.2.

Second, a choice has to be made regarding the modeling approach for the missingness process. Luckily, under certain assumptions this process can be ignored. Indeed, Rubin (1976) has shown that, under MAR and mild regularity conditions (parameters $\vec{\theta}$ and $\vec{\psi}$ are functionally independent), likelihood-based inference is valid when the missing data mechanism is ignored (see also Verbeke and Molenberghs 2000; Molenberghs and Kenward 2007). Practically speaking, the likelihood of interest is then based upon the factor $f(\vec{y}_i^o|\vec{\theta})$. This is called *ignorability*. The practical implication is that a software module with likelihood estimation facilities and with the ability to handle incompletely observed subjects manipulates the correct likelihood, providing valid parameter estimates and likelihood ratio values.

A few cautionary remarks are in place. First, when at least part of the scientific interest is directed toward the non-response process, obviously both processes need to be considered. Still, under MAR, both processes can be modeled and parameters estimated separately. Second, likelihood inference is often surrounded with references to the sampling distribution (e.g., to construct precision estimators and for statistical hypothesis tests; Kenward and Molenberghs 1998). However, the practical implication is that standard errors and associated tests, when based on the observed rather than the expected information matrix and given the parametric assumptions are correct, are valid. Third, it may be hard to fully rule out the operation of an MNAR mechanism. This point was brought up in the introduction and will be discussed further in Sect. 34.7. Fourth, an analysis can proceed only when a full longitudinal analysis is necessary, even when interest lies, for example, in a comparison between the two treatment groups at the last occasion. In the latter case, the fitted model can be used as the basis for inference at the last occasion.

Assume that $\vec{Y}_i$ is the n-dimensional response vector for subject i, containing the outcomes at n various measurement occasions, and $1 \leq i \leq N$, with N is the number of subjects. Note that in general, the number of measurements occasions can differ among patients, which would yield n_i instead of n. Further assume that incompleteness is due to dropout only, and that the first measurement Y_{i1} is obtained for everyone. Under the selection model framework, a possible model for the dropout process is based on a logistic regression for the probability of dropout at occasion j, given the subject is still in the study. We denote this probability by $g(\vec{h}_{ij}, y_{ij})$ in which $\vec{h}_{ij}$ is a vector containing all responses observed up to but not including occasion j, as well as relevant covariates. We then assume that $g(\vec{h}_{ij}, y_{ij})$ satisfies

$$\text{logit}\left[g(\vec{h}_{ij}, y_{ij})\right] = \text{logit}\left[\text{pr}\left(D_i = j|D_i \geq j, \vec{y}_i\right)\right] = \vec{h}_{ij}\vec{\psi} + \omega y_{ij}. \quad (34.6)$$

When ω equals zero, the dropout model is MAR, and all parameters can be estimated using standard software since the measurement model and the dropout model can then be fitted separately. If $\omega \neq 0$, the posited dropout process is MNAR. Model (34.6) provides the building blocks for the dropout process $f(d_i|\vec{y}_i, \vec{\psi})$. This model is often referred to as Diggle and Kenward's (1994) model. A review of this Diggle–Kenward model is provided in Sect. 34.7.1.

34.3.2 A Framework for Longitudinal or Multivariate Data

Let us now turn attention to standard model frameworks for longitudinal data, or multivariate data in general, which will be used to analyze the ARMD case study. First, the continuous case will be treated where the linear mixed model undoubtedly occupies the most prominent role. Then, we switch to the discrete setting, where important distinctions exist between three model families: the marginal, random-effects, and conditional model family. The mixed model parameters, both in the continuous and discrete cases, are usually estimated using maximum-likelihood-based methods, which implies that the results are valid under the MAR assumption. In contrast, generalized estimating equations, which is a commonly encountered marginal approach to non-Gaussian data, have a frequentist foundation. Consequently, this method is valid only under the MCAR assumption, necessitating the need for extensions. This will be discussed in Sects. 34.5.2 and 34.5.3. Note that even though Bayesian methodology is important, the focus in this is on likelihood- and frequentist-based methodology. An overview of Bayesian methodology can be found in Ibrahim and Molenberghs (2009).

Laird and Ware (1982) proposed, for continuous outcomes, likelihood-based mixed-effects models. A broad discussion of such models is provided in Verbeke and Molenberghs (2000). The general linear mixed effects model, perhaps with serial correlation, is the following:

$$\vec{Y}_i = X_i \vec{\beta} + Z_i \vec{b}_i + \vec{W}_i + \vec{\varepsilon}_i, \tag{34.7}$$

where $\vec{Y}_i$ is the n-dimensional response vector for subject i, $1 \le i \le N$, N is the number of subjects, X_i and Z_i are $(n \times p)$ and $(n \times q)$ known design matrices, $\vec{\beta}$ is the p-dimensional vector containing the fixed effects, $\vec{b}_i \sim N(\vec{0}, D)$ is the q-dimensional vector containing the random effects, $\vec{\varepsilon}_i \sim N(\vec{0}, \sigma^2 I_n)$ is a n-dimensional vector of measurement error components, and $\vec{b}_1, \ldots, \vec{b}_N, \vec{\varepsilon}_1, \ldots, \vec{\varepsilon}_N$ are assumed to be independent. Serial correlation is captured by the realization of a Gaussian stochastic process, $\vec{W}_i$, which is assumed to follow a $N(\vec{0}, \tau^2 H_i)$ law. The serial covariance matrix H_i only depends on i through the time points t_{ij} at which measurements are taken. The structure of the matrix H_i is determined through the autocorrelation function $\rho(t_{ij} - t_{ik})$. This function decreases such that $\rho(0) = 1$ and $\rho(+\infty) = 0$. Finally, D is a general $(q \times q)$ covariance matrix with (i, j) element $d_{ij} = d_{ji}$. Inference is based on the marginal distribution of the response $\vec{Y}_i$ which, after integrating over random effects, can be expressed as

$$\vec{Y}_i \sim N\left(X_i \vec{\beta}, Z_i D Z_i' + \Sigma_i\right). \tag{34.8}$$

Here, $\Sigma_i = \sigma^2 I_n + \tau^2 H_i$ is a $(n \times n)$ covariance matrix grouping the measurement error and serial components.

Two popular choices to capture serial correlation is by means of exponential or Gaussian decay. An exponential process is based on writing the correlation between two residuals at times t_{ij} and t_{ik} as

$$\mathrm{Corr}\left(t_{ij}, t_{ik}\right) = \exp\left(-\frac{|t_{ij} - t_{ik}|}{\phi}\right) = \rho^{|t_{ij}-t_{ik}|}, \tag{34.9}$$

($\phi > 0$), where $\rho = \exp(-1/\phi)$. The Gaussian counterpart is

$$\mathrm{Corr}\left(t_{ij}, t_{ik}\right) = \exp\left(-\frac{\left(t_{ij} - t_{ik}\right)^2}{\phi^2}\right) = \rho^{\left(t_{ij}-t_{ik}\right)^2}, \tag{34.10}$$

($\phi > 0$), $\rho = \exp(-1/\phi^2)$. It follows from Eq. 34.7 that, conditional on the random effect $\vec{b}_i$, $\vec{Y}_i$ is normally distributed with mean vector $X_i\vec{\beta} + Z_i\vec{b}_i$ and with covariance matrix Σ_i. Define $V_i = Z_i D Z_i' + \Sigma_i$, then the marginal distribution of $\vec{Y}_i$ is $\vec{Y}_i \sim N(X_i\vec{\beta}, V_i)$.

In a clinical-trial setting and in some epidemiological settings, one often has balanced data in the sense that the measurement occasions are common to all patients, as we assume here. In such a case, one often considers the random effects as nuisance parameters. The focus is then, for example, on the marginal compound-symmetry model rather than on the hierarchical random-intercepts model. Or, more generally, one considers $\Sigma_i = \Sigma$ to be unstructured and then no random effects are explicitly included. Especially when the number of patients is much larger than the number of measurement occasions within a patient, such an approach is useful. In an epidemiological setting however, one is often confronted with longer measurement sequences, perhaps also unequally spaced and/or of unequal length.

Whereas the linear mixed model is seen as a unifying parametric framework for Gaussian repeated measures (Verbeke and Molenberghs 2000), there are a variety of methods in common use in the non-Gaussian setting. Several authors, such as Diggle et al. (2002) and Aerts et al. (2002) distinguish between three such families. Still focusing on continuous outcomes, a marginal model is characterized by the specification of a marginal mean function

$$E\left(Y_{ij}|\vec{x}_{ij}\right) = \vec{x}_{ij}'\vec{\beta}, \tag{34.11}$$

whereas in a random-effects model we focus on the expectation, conditional upon the random-effects vector:

$$E\left(Y_{ij}|\vec{b}_i, \vec{x}_{ij}\right) = \vec{x}_{ij}'\vec{\beta} + \vec{z}_{ij}'\vec{b}_i. \tag{34.12}$$

Finally, a third family of models conditions a particular outcome on the other responses or a subset thereof. In particular, a simple first-order stationary transition model focuses on expectations of the form

$$E\left(Y_{ij}|Y_{i,j-1}, \ldots, Y_{i1}, \vec{x}_{ij}\right) = \vec{x}_{ij}'\vec{\beta} + \alpha Y_{i,j-1}. \tag{34.13}$$

In the linear mixed model case, random-effects models imply a simple marginal model. This is due to the elegant properties of the multivariate normal distribution. In particular, the expectation Eq. 34.11 follows from Eq. 34.12 by either (1) marginalizing over the random effects or by (2) conditioning upon the random-effects vector $\vec{b}_i = \vec{0}$. Hence, the fixed-effects parameters $\vec{\beta}$ have both a marginal as well as a hierarchical model interpretation. Finally, when a conditional model is expressed in terms of residuals rather than outcomes directly, it also leads to particular forms of the general linear mixed effects model.

Such a close connection between the model families does not exist when outcomes are of a non-normal type, such as binary, categorical, or discrete. We will consider each of the model families in turn and then point to some particular issues arising within them or when comparisons are made between them. We focus on the first two important subfamilies of models in turn, the marginal and random-effects models.

34.3.3 Marginal Models

In marginal models, the parameters characterize the marginal probabilities of a subset of the outcomes, without conditioning on the other outcomes. Thorough discussions on marginal modeling can be found in Diggle et al. (2002) and in Molenberghs and Verbeke (2005). Even though a variety of flexible full-likelihood models exist, maximum likelihood can be unattractive due to excessive computational requirements, especially when high-dimensional vectors of correlated data arise. As a consequence, alternative methods have been in demand. One such non-likelihood approach which is commonly used is *generalized estimating equations* (Liang and Zeger 1986) and will be discussed below.

Generalized Estimating Equations For clustered and repeated data, Liang and Zeger (1986) proposed so-called *generalized estimating equations* (GEE) which require only the correct specification of the univariate marginal distributions provided one is willing to adopt "working" assumptions about the association structure. They estimate the parameters associated with the expected value of an individual's vector of binary responses and phrase the working assumptions about the association between pairs of outcomes in terms of marginal correlations. The method combines estimating equations for the regression parameters $\vec{\beta}$ with moment-based estimating for the correlation parameters entering the working assumptions.

Let us now explain the GEE methodology a little further. The score equations to be solved when computing maximum likelihood estimates under a marginal generalized linear model (34.11) for non-Gaussian correlated outcomes are given by

$$\sum_{i=1}^{N} \frac{\partial \vec{\mu}_i}{\partial \vec{\beta}'} V_i^{-1} \left(\vec{y}_i - \vec{\mu}_i \right) = \vec{0}, \tag{34.14}$$

where $\vec{\mu}_i = E(\vec{y}_i)$ and V_i is the so-called working covariance matrix, that is, V_i approximates $\text{Var}(\vec{Y}_i)$, the true underlying covariance matrix for $\vec{Y}_i$. This working covariance matrix can be decomposed as $V_i = A_i^{1/2} R_i A_i^{1/2}$, in which $A_i^{1/2}$ is again the diagonal matrix with the marginal standard deviations of $\vec{Y}_i$ along the diagonal, and $R_i = \text{Corr}(\vec{Y}_i)$ is the correlation matrix. Usually, the marginal correlation matrix R_i contains a vector $\vec{\alpha}$, $R_i = R_i(\vec{\alpha})$ of unknown parameters which is replaced for practical purposes by a consistent estimate. Liang and Zeger (1986) dealt with this set of nuisance parameters $\vec{\alpha}$ by allowing for specification of an incorrect structure for R_i or so-called working correlation matrix. Assuming that the marginal mean $\vec{\mu}_i$ has been correctly specified as $h(\vec{\mu}_i) = X_i \vec{\beta}$, they further showed that, under mild regularity conditions, the estimator $\widehat{\vec{\beta}}$ obtained from solving Eq. 34.14 is asymptotically normally distributed with mean $\vec{\beta}$ and with covariance matrix

$$I_0^{-1} I_1 I_0^{-1}, \tag{34.15}$$

where

$$I_0 = \left(\sum_{i=1}^{N} \frac{\partial \vec{\mu}_i'}{\partial \vec{\beta}} V_i^{-1} \frac{\partial \vec{\mu}_i}{\partial \vec{\beta}'} \right), \tag{34.16}$$

$$I_1 = \left(\sum_{i=1}^{N} \frac{\partial \vec{\mu}_i'}{\partial \vec{\beta}} V_i^{-1} \text{Var}\left(\vec{y}_i\right) V_i^{-1} \frac{\partial \vec{\mu}_i}{\partial \vec{\beta}'} \right). \tag{34.17}$$

Consistent precision estimates can be obtained by replacing all unknown quantities in Eq. 34.15 by consistent parameter estimates. Observe that, when R_i is correctly specified, $\text{Var}(\vec{Y}_i) = V_i$ in Eq. 34.17, and thus $I_0 = I_1$. As a result, the expression for the covariance matrix (Eq. 34.15) reduces to I_0^{-1}, corresponding to full likelihood, that is, when the first and second moment assumptions are correct. Thus, when the working correlation structure is correctly specified, it reduces to full likelihood, although generally it differs from it.

On the other hand, when the working correlation structure differs strongly from the true underlying structure, there is no price to pay in terms of consistency of the asymptotic normality of $\widehat{\vec{\beta}}$, but such a poor choice may result in loss of efficiency. With incomplete data that arise under the MAR or MNAR assumption, an erroneously specified working correlation matrix may additionally lead to bias (Molenberghs and Kenward 2007).

Two further specifications are necessary before GEE is operational: $\text{Var}(\vec{Y}_i)$ on the one hand and $R_i(\vec{\alpha})$, with estimation of $\vec{\alpha}$ in particular, on the other hand. In practice, $\text{Var}(\vec{y}_i)$ in (34.15) is replaced by $(\vec{y}_i - \vec{\mu}_i)(\vec{y}_i - \vec{\mu}_i)'$, which is unbiased on the sole condition that the mean was again correctly specified. Second, one also needs estimates of the nuisance parameters of $\vec{\alpha}$. Liang and Zeger (1986) proposed moment-based estimates for the working correlation.

34.3.4 Random-Effects Models

Models with random effects are differentiated from marginal models by the inclusion of parameters which are specific to the cluster or subject. Unlike for correlated Gaussian outcomes, the parameters of the random effects and marginal models for correlated non-Gaussian data describe different types of effects of the covariates on the response probabilities (Neuhaus 1992). The choice between marginal and random-effects strategies should heavily depend on the scientific goals. Marginal models evaluate the overall risk as a function of covariates. With a random-effects approach, the response rates are modeled as a function of covariates and parameters, specific to a cluster or subject. In such models, interpretation of fixed-effect parameters is conditional on a constant level of the random-effects parameter. Marginal comparisons, on the other hand, make no use of within-cluster comparisons for cluster varying covariates and are therefore not useful to assess within-subject effects (Neuhaus et al. 1991).

While several non-equivalent random-effects models exist, one of the most popular is the *generalized linear mixed model* (Breslow and Clayton 1993) which is closely related to linear and non-linear mixed models, which is discussed in the following subsection.

Generalized Linear Mixed Models A general framework for mixed-effects models can be expressed as follows. Assume that $\vec{Y}_i$ (possibly appropriately transformed) satisfies

$$\vec{Y}_i | \vec{b}_i \sim F_i(\vec{\theta}, \vec{b}_i), \tag{34.18}$$

that is, conditional on $\vec{b}_i$, $\vec{Y}_i$ follows a prespecified distribution F_i, possibly depending on covariates, and parameterized through a vector $\vec{\theta}$ of unknown parameters, common to all subjects. Further, $\vec{b}_i$ is a q-dimensional vector of subject-specific parameters, called random effects, assumed to follow a so-called mixing distribution G which may depend on a vector $\vec{\psi}$ of unknown parameters, that is, $\vec{b}_i \sim G(\vec{\psi})$. The $\vec{b}_i$ reflect the between-unit heterogeneity in the population with respect to the distribution of $\vec{Y}_i$. In the presence of random effects, conditional independence is often assumed, under which the components Y_{ij} in $\vec{Y}_i$ are independent, conditional on $\vec{b}_i$. The distribution function F_i in Eq. 34.18 then becomes a product over the n independent elements in $\vec{Y}_i$.

In general, unless a fully Bayesian approach is followed, inference is based on the marginal model for $\vec{Y}_i$ which is obtained from integrating out the random effects, over their distribution $G(\vec{\psi})$. Let $f_i(\vec{y}_i|\vec{b}_i)$ and $g(\vec{b}_i)$ denote the density functions corresponding to the distributions F_i and G, respectively, then the marginal density function of $\vec{Y}_i$ equals

$$f_i(\vec{y}_i) = \int f_i\left(\vec{y}_i|\vec{b}_i\right) g(\vec{b}_i)\vec{b}_i, \tag{34.19}$$

which depends on the unknown parameters $\vec{\theta}$ and $\vec{\psi}$. Assuming independence of the units, estimates of $\widehat{\vec{\theta}}$ and $\widehat{\vec{\psi}}$ can be obtained from maximizing the likelihood function built from Eq. 34.19, and inferences immediately follow from classical maximum likelihood theory.

It is important to realize that the random-effects distribution G is crucial in the calculation of the marginal model (34.19). One often assumes G to be of a specific parametric form, such as a (multivariate) normal. Depending on F_i and G, the integration in Eq. 34.19 may or may not be possible analytically. Proposed solutions are based on Taylor series expansions of $f_i(\vec{y}_i|\vec{b}_i)$, or on numerical approximations of the integral, such as (adaptive) Gaussian quadrature. A general formulation of GLMM is as follows. Conditionally on random effects $\vec{b}_i$, it assumes that the elements Y_{ij} of $\vec{Y}_i$ are independent, with density function of the form

$$f\,(y|\theta_i,\phi) = \exp\left\{\phi^{-1}\left[y\theta_i - \psi(\theta_i)\right] + c(y,\phi)\right\},$$

with mean $E(Y_{ij}|\vec{b}_i)$ and variance $\mathrm{Var}(Y_{ij}|\vec{b}_i)$, and where, apart from a link function h, a linear regression model with parameters $\vec{\beta}$ and $\vec{b}_i$ is used for the mean, that is, $h(E(\vec{Y}_i|\vec{b}_i)) = X_i\vec{\beta} + Z_i\vec{b}_i$. Note that the linear mixed model is a special case, with identity link function. The random effects $\vec{b}_i$ are again assumed to be sampled from a (multivariate) normal distribution with mean $\vec{0}$ and covariance matrix D. When the link function is chosen to be of the logit form and the random effects are assumed to be normally distributed, the familiar logistic-linear GLMM follows.

There are at least two major differences in comparison to the linear mixed model discussed in the previous section. First, the marginal distribution of $\vec{Y}_i$ can no longer be calculated analytically, such that numerical approximations to the marginal density come into play, seriously complicating the computation of the maximum likelihood estimates of the parameters in the marginal model, i.e., $\vec{\beta}$, D, and the parameters in all Σ_i. A consequence is that the marginal covariance structure does not immediately follow from the model formulation, that is, it is not always clear in practice what assumptions a specific model implies with respect to the underlying variance function and the underlying correlation structure in the data.

A second important difference is with respect to the interpretation of the fixed effects $\vec{\beta}$. Under the linear model (34.7), $E(\vec{Y}_i)$ equals $X_i\vec{\beta}$, such that the fixed effects have a subject-specific as well as a population-averaged interpretation. Indeed, the elements in $\vec{\beta}$ reflect the effect of specific covariates, conditionally on the random effects $\vec{b}_i$, as well as marginalized over these random effects. Under non-linear mixed models, however, this does no longer hold in general. The fixed effects now only reflect the conditional effect of covariates, and the marginal effect is not easily obtained anymore as $E(\vec{Y}_i)$ which is given by

$$E(\vec{Y}_i) = \int \vec{y}_i \int f_i(\vec{y}_i|\vec{b}_i)g(\vec{b}_i)\mathrm{d}\vec{b}_i\mathrm{d}\vec{y}_i,$$

which, in general, is *not* of the form $h(E(Y_{ij}|\vec{b}_i = \vec{0})) = X_i\vec{\beta}$, that is, the link function of the conditional mean function evaluated in the zero random effects vector.

The non-linear nature of the model again implies that the marginal distribution of $\vec{y}_i$ is, in general, not easily obtained, such that model fitting requires approximation of the marginal density function. An exception to this occurs when the probit link is used. Further, as was also the case for non-linear mixed models, the parameters $\vec{\beta}$ have no marginal interpretation, except for some very particular models.

As an important example, consider the binomial model for binary data, with the logit canonical link function, and where the only random effects are intercepts b_i. It can then be shown that the marginal mean $\vec{\mu}_i = E(Y_{ij})$ satisfies $h(\vec{\mu}_i) \approx X_i\vec{\beta}^*$ with

$$\vec{\beta}^* = \left[c^2\text{Var}(b_i) + 1\right]^{-1/2}\vec{\beta}, \tag{34.20}$$

in which c equals $16\sqrt{3}/15\pi$. Hence, although the parameters $\vec{\beta}$ in the generalized linear mixed model have no marginal interpretation, they do show a strong relation to their marginal counterparts. Note that, as a consequence of this relation, larger covariate effects are obtained under the random-effects model in comparison to the marginal model.

34.4 Simple Ad Hoc Methods

Relatively simple methods that have been and still are in extensive use are valid when the measurement and missing data processes are independent and their parameters are separated, which is called the missing completely at random or MCAR assumption. Moreover, for some of these methods this assumption is necessary but not sufficient. It is important to realize that many of these methods are used also in situations where the MCAR assumption is not tenable. This should be seen as bad practice since it will often lead to biased estimates and invalid tests and hence to erroneous conclusions. Ample detail and illustrations of several problems are provided in Verbeke and Molenberghs (1997, Chap. 5).

Let us focus on two commonly used methods, complete case analysis and last observation carried forward (LOCF) analysis. The first one requires the strict MCAR assumption and is based on removing data, whereas LOCF requires even stronger and more unrealistic conditions to apply (Kenward and Molenberghs 2009). The LOCF method is discussed in the realm of single imputation techniques. For such single imputation methods, a single value is substituted for every "hole" in the data set and the resulting data set is analyzed as if it represented the true complete data. On the other hand, multiple imputation properly accounts for the uncertainty of imputation by multiply imputing the missing values given the observed ones (Rubin 1987; Schafer 1997). Additionally, it is valid under the less strict MAR assumption. The multiple imputation technique will be discussed in Sect. 34.5.3.

An often quoted advantage of the methods described below and related ones is that complete data software can be used. With the availability of such software like the SAS procedures GENMOD, MIXED, GLIMMIX, and NLMIXED, it is however no longer necessary to restrict oneself to complete data software, since they allow a likelihood-based ignorable analysis, using the data as they are, without deletion or imputation.

34.4.1 Complete Case Analysis

A complete case (CC) analysis includes only those cases for analysis, for which all measurements were recorded. This method has obvious advantages. It is very simple to describe and since the data structure is as would have resulted from a complete experiment, standard statistical software can be used. Further, since the entire estimation is done on the same subset of completers, there is a common basis for inference, unlike for the available case methods. Unfortunately, the method suffers from severe drawbacks. First, there is nearly always a substantial loss of information. For example, suppose there are 20 measurements, with 10% of missing data on each measurement. Suppose, further, that missingness on the different measurements is independent; then, the estimated percentage of incomplete observations is as high as 87%. The impact on precision and power is dramatic. Even though the reduction of the number of complete cases will be less dramatic in realistic settings where the missingness indicators are correlated, the effect just sketched will often undermine a complete case analysis. In addition, severe bias can result when the missingness mechanism is not MCAR. Indeed, should an estimator be consistent in the complete data problem, then the derived complete case analysis is consistent only if the missingness process is MCAR.

A simple partial check on the MCAR assumption is as follows (Little and Rubin 1987). Divide the observations on measurement j into two groups: (1) those subjects that are also observed on another measurement or set of measurements and (2) those missing on the other measurement(s). Should MCAR hold, then both groups should be random samples of the same population. Failure to reject equality of the distributional parameters of both samples increases the evidence for MCAR, but does not prove it.

34.4.2 Simple Forms of Imputation

An alternative way to obtain a data set on which complete data methods can be used is based on filling in rather than deletion. Commonly, the observed values are used to impute values for the missing observations. There are several ways to use the observed information. First, one can use information on the same subject (e.g., last observation carried forward). Second, information can be borrowed from other subjects (e.g., mean imputation). Finally, both within and between subject information can be used (e.g., conditional mean imputation, hot deck imputation). A standard reference is Little and Rubin (1987).

We will discuss the last observation carried forward method, which is the most commonly used single imputation technique.

Last Observation Carried Forward A method that has received a lot of attention (Siddiqui and Ali 1998; Mallinckrodt et al. 2003a,b) is last observation carried forward (LOCF). In the LOCF method, whenever a value is missing, the last observed value is substituted. The technique can be applied to both monotone and non-monotone missing data. It is typically applied to settings where incompleteness is due to attrition.

Very strong and often unrealistic assumptions have to be made to ensure validity of this method. First, one has to believe that a subjects' measurement stays at the same level from the moment of dropout onward (or during the period they are unobserved in the case of intermittent missingness). In a clinical trial setting, one might believe that the response profile *changes* as soon as a patient goes off treatment and even that it would flatten. However, the constant profile assumption is even stronger. Further, this method shares with other single imputation methods that it overestimates the precision by treating imputed and actually observed values on equal footing.

However, LOCF does not need to be seen as an imputation strategy. The situation in which the scientific question is in terms of the last observed measurement is often considered to be the real motivation for LOCF, though in some cases, the question defined as such may be perceived as having an unrealistic and ad hoc flavor. Clearly, measurements at (self-selected) dropout times are lumped together with measurements made at the (investigator defined) end of the study.

34.4.3 Discussion of Single Imputation Techniques

For review of other single imputation techniques we refer to Little and Rubin (1987) and Rubin (1987). They indicate great care has to be taken with these single imputations strategies. Dempster and Rubin (1983) write: "The idea of imputation is both seductive and dangerous. It is seductive because it can lull the user into the pleasurable state of believing that the data are complete after all, and it is dangerous because it lumps together situations where the problem is sufficiently minor that it can be legitimately handled in this way and situations where standard estimators applied to the real and imputed data have substantial biases." Indeed, all of these single imputation methods share the following pitfalls. First, since the imputation model could be wrong, the point estimates and comparisons of interest could be biased. Moreover, perhaps contrary to some common belief, such biases can be conservative (estimated effect is smaller in absolute value than the true one), but also liberal. Second, even for a correct imputation model, the uncertainty resulting from missingness is masked. Indeed, even when one is reasonably sure about the mean value the unknown observation *would have had*, the actual stochastic realization, depending on both the mean and error structures, is still unknown. Thus, the performance of imputation techniques is unreliable. In addition, these methods artificially increase the amount of information in the data by treating imputed and actually observed values on equal footing. This can lead to an artificially inflated precision. Finally, most methods require the MCAR assumption to hold while some even require additional and often unrealistically strong assumptions. Indeed, last observation carried forward requires the response to be unchanged until the end of the study.

34.5 Incomplete Data and MAR

As already pointed in Sect. 34.3.1, valid inference can be obtained under the MAR assumption through a likelihood-based analysis, without the need for modeling the dropout process. As a consequence, one can simply use, for example, linear or generalized linear mixed models as introduced in Sect. 34.3.2, without additional complication or effort. In this section, we will show there is no reason to use ad hoc methods when analysis valid under the MAR assumption can be implemented with standard software. Note that methods valid under MAR are also valid if data are MCAR, while the reverse does not hold.

34.5.1 Direct Likelihood

For longitudinal or multivariate data with missingness, a likelihood-based mixed-effects model only requires that the missing data are MAR. These mixed-effects models permit the inclusion of subjects with missing values at some time points (both dropout and intermittent missingness). For the continuous-outcome setting, this amounts to the general linear mixed model, introduced in Sect. 34.3.2, which can be viewed both in the marginal and hierarchical framework.

However, for the non-Gaussian case, such mixed-effects models are restricted to the random-effects model family. Here, we focus on the generalized linear mixed models, as also discussed in Sect. 34.3.2.

Such a likelihood-based MAR analysis is also termed likelihood-based ignorable analysis or direct-likelihood analysis. Obviously in such an analysis the observed data are used without deletion or imputation. In doing so, appropriate adjustments valid under MAR are made to parameters at times when data are incomplete, due to the within-patient correlation.

Settings in which the repeated measures are balanced, in the sense that a common set of measurement times is considered for all subjects, allow the a priori specification of a saturated model (e.g., full group by time interaction model for the fixed effects and unstructured variance-covariance matrix). For continuous outcomes, such a model specification is termed MMRM (mixed-model random missingness) by Mallinckrodt et al. (2001a, b). Thus, MMRM is a particular form of a linear mixed model, relevant for not only the clinical trials context, but also more generally for reasonably balanced studies with human subjects, and fitting within the ignorable likelihood paradigm.

Such a direct-likelihood approach is a very promising alternative for the often used simple methods described in Sect. 34.4.

34.5.2 Weighted Generalized Estimating Equations

For non-Gaussian outcomes in the marginal model framework, Liang and Zeger (1986) pointed out that inferences based on GEE, using the observed data are valid only under the strong assumption that the underlying missing-data process is MCAR. This is due to the fact that GEE is frequentist rather than likelihood based in nature. An exception is the situation where the working correlation structure happens to be correct, since then the estimating equations can be interpreted as likelihood equations. In general, however, the working correlation structure will not be correctly specified and hence, Robins et al. (1995) proposed a class of weighted estimating equations to allow for data which are MAR in case missingness is due to dropout.

The idea of weighted estimating equations (WGEE) is to weigh each subject's contribution in the GEEs by the inverse probability that a subject drops out at the time he or she dropped out. The incorporation of these weights reduces possible bias in the regression parameter estimates, $\hat{\vec{\beta}}$. Such a weight can be expressed as

$$\nu_{ij} \equiv P[D_i = j] = \prod_{k=2}^{j-1} (1 - P\left[R_{ik} = 0 | R_{i2} = \ldots = R_{i,k-1} = 1\right]) \\ \times P\left[R_{ij} = 0 | R_{i2} = \ldots = R_{i,j-1} = 1\right]^{I\{j \leq T\}},$$

where $j = 2, 3, \ldots, n+1$. Recall that we partitioned $\vec{Y}_i$ into the unobserved components $\vec{Y}_i^m$ and the observed components $\vec{Y}_i^o$. Similarly, we can make the same partition of $\vec{\mu}_i$ into $\vec{\mu}_i^m$ and $\vec{\mu}_i^o$. In the weighted GEE approach, the score equations to be solved when taking into account the correlation structure are:

$$S(\vec{\beta}) = \sum_{i=1}^{N} \frac{1}{\nu_{id}} \frac{\partial \vec{\mu}_i}{\partial \vec{\beta}'} \left(A_i^{1/2} R_i A_i^{1/2}\right)^{-1} \left(\vec{y}_i - \vec{\mu}_i\right) = \vec{0}, \tag{34.21}$$

where $\vec{y}_i(d)$ and $\vec{\mu}_i(d)$ are the first $d-1$ elements of $\vec{y}_i$ and $\vec{\mu}_i$ respectively. We define $\frac{\partial \vec{\mu}_i}{\partial \vec{\beta}'}(d)$ and $(A_i^{1/2} R_i A_i^{1/2})^{-1}(d)$ analogously, in line with the definitions of Robins et al. (1995).

34.5.3 Multiple Imputation

A well-known alternative method valid under the MAR assumption is multiple imputation (MI), which was introduced by Rubin (1978) and further discussed in Schafer (1999) and Little and Rubin (2002). The key idea of the procedure is to first replace each missing value with a set of M plausible values drawn from the conditional distribution of the unobserved outcomes, given the observed ones. This conditional distribution represents the uncertainty about the right value to impute. In this way, M imputed data sets are generated (imputation stage), which are then analyzed using standard complete data methods (analysis stage). Finally, the results from the M analyses have to be combined into a single one (pooling stage) by means of the method laid out in Rubin (1978), to produce inferences. To be valid, multiple imputation in its basic form requires the missingness mechanism to be MAR, even though versions under MNAR have been proposed (Rubin 1987; Molenberghs et al. 1997).

Thus, multiple imputation is valid under the same conditions as direct-likelihood, and therefore does not suffer from the problems encountered in most single imputation methods. However, there are a number of situations where multiple imputation is particularly useful. For example, when outcomes as well as covariates are missing then multiple imputation is a sensible route. The method is also useful when several analysis, perhaps conducted by different analysts, have to be done on the same set of incomplete data. In such a case, all analyses could start from the same set of multiply imputed sets of data and enhance comparability.

Let us discuss multiple imputation in a little more detail. In line with the notation in Sect. 34.3, suppose the parameter vector of the distribution of the response $\vec{Y}_i = (\vec{Y}_i^o, \vec{Y}_i^m)$ is denoted by $\vec{\theta} = (\vec{\beta}, \vec{\alpha})'$, in which $\vec{\beta}$ denotes the vector of fixed-effects parameters and $\vec{\alpha}$ the vector of covariance parameters. Multiple imputation uses the observed data $\vec{Y}^o$ to estimate the conditional distribution of $\vec{Y}^m$ given $\vec{Y}^o$. The missing data are sampled several times from this conditional distribution and augmented to the observed data. The resulting completed data are then used to estimate $\vec{\theta}$. If the distribution of $\vec{Y}_i = (\vec{Y}_i^o, \vec{Y}_i^m)$ were known, with parameter vector $\vec{\theta}$, then $\vec{Y}_i^m$ could be imputed by drawing a value of $\vec{Y}_i^m$ from the conditional distribution $f(\vec{y}_i^m | \vec{y}_i^o, \vec{\theta})$. The objective of the imputation phase is to sample from this true predictive distribution. However, $\vec{\theta}$ in the imputation model is unknown, and therefore needs to be estimated from the data first, say $\widehat{\vec{\theta}}$, after which $f(\vec{y}_i^m | \vec{y}_i^o, \widehat{\vec{\theta}})$ is used to impute the missing data. Precisely, this implies one first generates draws from the distribution of $\widehat{\vec{\theta}}$, thereby taking sampling uncertainty into account. Generally, the parameter vector in the imputation model differs from the parameter vector that governs the analysis model. Alternatively, a Bayesian approach, in which uncertainty about $\vec{\theta}$ is incorporated by means of some prior distribution for $\vec{\theta}$, can also be taken.

In the last phase of multiple imputation, the results of the analysis for the M imputed data sets are pooled into a single inference. The combined point estimate for the parameter of interest from the multiple imputation is simply the average of the M complete-data point estimates (Schafer 1999). Let $\vec{\theta}$ denote the parameter of interest, then the estimate and its estimated variance are given by:

$$\widehat{\vec{\theta}} \equiv \frac{1}{M}\sum_{m=1}^{M}\widehat{\vec{\theta}}^{m} \quad \text{and} \quad \widehat{\text{Var}}(\widehat{\vec{\theta}}) \equiv \vec{V} = \vec{W} + \left(\frac{M+1}{M}\right)\vec{B},$$

where

$$\vec{W} = \frac{\sum_{m=1}^{M}\vec{U}^{\,m}}{M} \quad \text{and} \quad \vec{B} = \frac{\sum_{m=1}^{M}(\widehat{\vec{\theta}}^{m} - \widehat{\vec{\theta}})(\widehat{\vec{\theta}}^{m} - \widehat{\vec{\theta}})'}{M-1},$$

with $\vec{W}$ denoting the average *within* imputation variance and $\vec{B}$ the *between* imputation variance (Rubin 1987).

As mentioned earlier, one can choose any complete data method to analyze the imputed data sets in the analysis stage of the MI method. This is particularly useful when interest lies in a marginal model for non-Gaussian outcomes. WGEE has been proposed as an alternative for GEE to be able to obtain valid inferences based on incomplete data under the MAR assumption. However, in WGEE, all subjects are given weights, which are calculated using the hypothesized dropout model. As a consequence, any misspecification of this dropout model will affect all subjects and thus all results. Therefore, we can consider MI combined with GEE at the analysis phase (MI-GEE). In essence, this method comes down to first using the predictive distribution of the unobserved outcomes given the observed ones and perhaps covariates. After this step, the missingness mechanism can be further ignored, provided we assume MAR. In these MI cases, a misspecification made in the imputation step will only effect the unobserved (i.e., imputed) but not the observed part of the data. Meng's (1994) results show that, as long as the imputation model is not grossly misspecified, this approach will perform well. Moreover, Beunckens et al. (2008) have proven that, even though WGEE is asymptotically unbiased, MI-GEE is less biased and more precise in small and moderate samples and MI-GEE is more robust to misspecification in either the imputation or measurement model.

34.6 Simple Methods and MAR Methods Applied to the ARMD Trial

Let us now apply the most often used simple methods which require the missingness mechanism to be MCAR, complete case analysis and last observation carried forward, as well as the following MAR methods to the age-related macular degeneration trial: direct-likelihood for Gaussian outcomes and when considering a random-effects model for non-Gaussian outcomes, and WGEE and MI-GEE when focus is on the marginal approach for non-Gaussian measurements.

Recall that there are 240 subjects, 188 of which have a complete follow-up. Note that of the 52 subjects with incomplete follow-up, 9 exhibit a non-monotone pattern. While this does not hamper direct-likelihood analysis, it is a challenge for WGEE. One way forward is to monotonize the missingness patterns by means of multiple imputation and then conduct WGEE, or to switch to MI-GEE altogether. However, to be consistent throughout the analysis, those subjects with non-monotone profiles will not be taken into account. Further, neither will the subjects without any follow-up measurement be included in the analysis, since at least one measurement should be taken. This results in a data set of 226 of 240 subjects, or 94.17%.

The original outcome is the visual acuity, that is the number of letters correctly read on a vision chart, which will be considered continuous. The dichotomous outcome is defined as increase or decrease in number of letters read compared with baseline. Both outcomes will be analyzed using the methods mentioned in the following text.

34.6.1 Analysis of the Continuous Outcome

We consider a multivariate normal model, with unconstrained time trend under placebo, a time-specific treatment effect, and an unstructured variance-covariance matrix. Let Y_{ij} be the visual acuity of subject $i = 1, \dots, 226$, at time point $j = 1, \dots, 4$, and T_i the treatment assignment for subject i, then the mean model takes the following form:

$$E(Y_{ij}) = \beta_{j1} + \beta_{j2} T_i.$$

Thus, this longitudinal model features a full treatment by time interaction with eight mean model parameters. The direct-likelihood analysis based on all observed data is contrasted with the simple CC and LOCF analyses.

Results of these three analyses are displayed in Table 34.4. From the parameter estimates, it is clear that the treatment effects are underestimated when considering the completers only. Whereas for all observed data treatment effect at week 12 and 52 are borderline significant, both turn insignificant when deleting subjects with missing values. For the LOCF analysis, going from week 4 to the end of the study, the underestimation of the treatment effect increases. Therefore, the effect at week 12 is borderline significant, but at week 52 it becomes insignificant. Once again, CC and LOCF miss important treatment differences, the most important one being that at week 52, the end of the study.

34.6.2 Analysis of the Binary Outcome

We now switch to the binary outcome, which indicates whether the number of letters correctly read at the follow-up occasion is higher or lower than the corresponding number of letters at baseline. Both marginal models and random-effects models are considered.

Table 34.4 Age-related macular degeneration trial. Parameter estimates (standard errors) for the linear mixed models, fitted to the continuous outcome visual acuity on the CC and LOCF population, and on the observed data (direct-likelihood). p-values are given for treatment effect at each of the four time points

Effect	Parameter	CC		LOCF		Observed data	
Parameter estimates (standard errors)							
Intercept 4	β_{11}	54.47	(1.54)	54.00	(1.47)	54.00	(1.47)
Intercept 12	β_{21}	53.08	(1.66)	53.03	(1.59)	53.01	(1.60)
Intercept 24	β_{31}	49.79	(1.80)	49.35	(1.72)	49.20	(1.74)
Intercept 52	β_{41}	44.43	(1.83)	44.59	(1.74)	43.99	(1.79)
Treatment effect 4	β_{12}	−2.87	(2.28)	−3.11	(2.10)	−3.11	(2.10)
Treatment effect 12	β_{22}	−2.89	(2.46)	−4.45	(2.27)	−4.54	(2.29)
Treatment effect 24	β_{32}	−3.27	(2.66)	−3.41	(2.45)	−3.60	(2.49)
Treatment effect 52	β_{42}	−4.71	(2.70)	−3.92	(2.48)	−5.18	(2.59)
p-values							
Treatment effect 4	β_{12}		0.211		0.140		0.140
Treatment effect 12	β_{22}		0.241		0.051		0.048
Treatment effect 24	β_{32}		0.220		0.165		0.150
Treatment effect 52	β_{42}		0.083		0.115		0.046

34.6.2.1 Marginal Models

In this section, a marginal model is used and in line with the previous section, we compare analyses performed on the completers only (CC), on the LOCF imputed data, as well as on the observed data. In all cases, standard GEE will be considered. For the observed, partially incomplete data, GEE is supplemented with WGEE and MI-GEE. Results of the GEE analyses are reported in Table 34.5. In all cases, we use the logit link, and the model takes the form

$$\text{logit}[P(Y_{ij} = 1 \mid T_i, t_j)] = \beta_{j1} + \beta_{j2} T_i, \tag{34.22}$$

with notational conventions as before, except that Y_{ij} is the indicator for whether or not letters of vision have been lost for subject i at time j, relative to baseline.

A working exchangeable correlation matrix is considered. For the WGEE analysis, the following weight model is assumed:

$$\begin{aligned} \text{logit}[P(D_i = j \mid D_i \geq j)] = \psi_0 &+ \psi_1 y_{i,j-1} + \psi_2 T_i \\ &+ \psi_{3,1} L_{1i} + \psi_{3,2} L_{2i} + \psi_{3,3} L_{3i} \\ &+ \psi_{4,1} I(t_j = 2) + \psi_{4,2} I(t_j = 3), \end{aligned}$$

where $y_{i,j-1}$ is the binary outcome at the previous time $t_{i,j-1} = t_{j-1}$, $L_{ki} = 1$ if the patient's eye lesion is of level $k = 1, \ldots, 4$ (since one dummy variable is redundant, only three are used), and $I(\cdot)$ is the indicator function. Parameter estimates, standard errors and p-values for the dropout model are given in Table 34.6. Covariates of importance are treatment assignment, the level of lesions at baseline, and time at which dropout occurs. For the latter covariates, there are three levels, since dropout can occur at times 2, 3, or 4. Hence, two indicator variables are included. Finally, the previous outcome does not have a significant impact, but will be kept in the model nevertheless.

When comparing parameter estimates across CC, LOCF, and observed data analyses, it is clear that LOCF has the effect of artificially increasing the correlation between measurements. The effect is mild in this case. The parameter estimates of the observed-data GEE are close to the LOCF results for earlier time points and close to CC for later time points. This is to be expected, as at the start of the study the LOCF and observed populations are virtually the same, with the same holding between CC and observed populations near the end of the study. Note also that the treatment effect under LOCF, especially at 12 weeks and after 1 year, is biased downward in comparison to the GEE analyses. Next, to properly use the information in the missingness process, WGEE or MI-GEE can be used. Two versions of MI-GEE are considered, that is, first the continuous outcome defined by the difference in numbers of letters correctly read compared with baseline is imputed whereafter the dichotomized version is analyzed, and second the binary outcome is imputed and analyzed.

In spite of there being no strong evidence for MAR, the results between GEE and WGEE differ quite a bit. It is noteworthy that at 12 weeks, a treatment effect

Table 34.5 Age-related macular degeneration trial. Parameter estimates (empirically corrected standard errors) for the marginal models: standard GEE on the CC and LOCF population and on the observed data. In the latter case, standard GEE, WGEE, and MI-GEE with imputation based on the continuous and binary outcome is used

				Observed data			
						Continuous	Binary
Effect	Parameter	CC	LOCF	Unweighted	WGEE	MI-GEE	MI-GEE
Parameter estimates (standard errors)

Table 34.6 Age-related macular degeneration trial. Parameter estimates (standard errors) and p-values for a logistic regression model to describe dropout

Effect	Parameter	Estimate (s.e.)	p-value
Intercept	ψ_0	0.13 (0.49)	0.7930
Previous outcome	ψ_1	0.04 (0.38)	0.9062
Treatment	ψ_2	−0.87 (0.37)	0.0185
Lesion level 1	ψ_{31}	−1.82 (0.49)	0.0002
Lesion level 2	ψ_{32}	−1.89 (0.52)	0.0003
Lesion level 3	ψ_{33}	−2.79 (0.72)	0.0001
Time 2	ψ_{41}	−1.73 (0.49)	0.0004
Time 3	ψ_{42}	−1.36 (0.44)	0.0019

is observed with WGEE which is borderline with the other marginal analyses. However, as mentioned before, the beneficial property of unbiasedness for WGEE is merely fulfilled for very large samples. On the other hand, MI-GEE produces only a small amount of bias in small samples, which is less compared to the bias of WGEE. Moreover, MI-GEE is robust against misspecification of the imputation and measurement model. Therefore, in real-life settings such as the age-related macular degeneration trial, we would opt to use MI-GEE instead of WGEE. Both versions of MI-GEE considered here show quite similar results. The standard errors are smaller compared to the ones estimated using WGEE. The treatment effect at week 12 detected by WGEE becomes borderline again in both MI-GEE analyses. Further, also the p-values at later time points are larger compared to WGEE.

34.6.2.2 Random-Effects Models

Let us now turn to a random-intercepts logistic model, in spirit to Eq. 34.22:

$$\text{logit}[P(Y_{ij} = 1 \mid T_i, t_j)] = \beta_{j1} + b_i + \beta_{j2} T_i, \tag{34.23}$$

with notation as before and $b_i \sim N(0, \tau^2)$. For the model fitting, numerical integration is used. Results are shown in Table 34.7.

We observe the usual relationship between the marginal parameters of Table 34.5 and their random-effects counterparts. Note also that the random-intercepts variance is largest under LOCF, underscoring again that this method artificially increases the association between measurements on the same subject. In this case, in contrast to the marginal models, both LOCF and CC, considerably overestimate the treatment effect at certain times, in particular at 4 and 24 weeks (unlike the continuous case). In conclusion, it is clear that CC and LOCF may differ from the direct-likelihood and weighted or MI-based GEE analyses. This underscores that the latter analyses are to be considered as candidates for primary analysis.

Table 34.7 Age-related macular degeneration trial. Parameter estimates (standard errors) for the random-intercept models: numerical-integration based fits on the CC and LOCF population, and on the observed data (direct-likelihood)

Effect	Parameter	CC	LOCF	Direct-lik.
Intercept 4	β_{11}	−1.73 (0.42)	−1.76 (0.40)	−1.64 (0.37)
Intercept 12	β_{21}	−1.53 (0.41)	−1.85 (0.40)	−1.75 (0.38)
Intercept 24	β_{31}	−1.93 (0.43)	−2.01 (0.41)	−1.85 (0.39)
Intercept 52	β_{41}	−2.74 (0.48)	−2.66 (0.44)	−2.76 (0.47)
Treatment 4	β_{12}	0.64 (0.54)	0.55 (0.53)	0.51 (0.49)
Treatment 12	β_{22}	0.81 (0.53)	1.04 (0.53)	1.02 (0.50)
Treatment 24	β_{32}	0.77 (0.55)	0.80 (0.53)	0.70 (0.51)

Random-intercept var.	τ^2	4.80 (1.17)	6.03 (1.33)	4.90 (1.14)

34.7 From MAR to Sensitivity Analysis

We have seen from previous sections that, if the MAR assumption is guaranteed to hold, a standard analysis will follow. This is certainly true for likelihood methods. Indeed, for example, a linear mixed model or a generalized linear mixed model fitted to incomplete data is valid, and it is as simple to conduct as it would be in contexts where data are complete.

The situation is a little different for the marginal GEE methods, since they need to be adjusted to the MAR case. Here, a mild extension of GEE to weighted GEE or a combination with multiple imputation comes to the rescue.

In conclusion, there are a number of tools available for correlated data which are easy to conduct and valid in the important MAR setting. As a consequence, there is little or no need for the simple methods such as complete case analysis or LOCF.

On the other hand though, in realistic settings, the reasons for missingness are varied and it is therefore hard to fully justify the MAR assumption as such. Moreover, since it is not possible to test for MNAR against MAR (Jansen et al. 2006; Molenberghs and Kenward 2007), one can never rule out the possibility of missing data to be MNAR. This implies that the need may exist to consider MNAR models. Nevertheless, ignorable analyses may provide reasonable stable results, even when the assumption of MAR is violated, in the sense that such analyses constrain the behavior of unseen data to be similar to that of the observed data (Mallinckrodt et al. 2001a, b).

While MNAR models are more general and explicitly incorporate the dropout mechanism, the inferences they produce are typically highly dependent on untestable and often implicit assumptions regarding the distribution of the unobserved measurements given the observed ones. The quality of the fit to the observed data does not reflect at all the appropriateness of the implied structure governing the unobserved data. This implies that a definite MNAR analysis does not exist.

Therefore, a sensible compromise between blindly shifting to MNAR models or ignoring them altogether is to make them a component of a sensitivity analysis. In this way we can explore the impact of deviations from the MAR assumption on the conclusions. In that sense, it is important to consider the effect on key parameters.

When the missingness mechanism is (assumed to be) MNAR, all frameworks have their advantages and disadvantages. However, in the case of pattern-mixture modeling it is clear which parts of the model are identifiable from the data, and which parts are completely assumption driven. On the other hand, selection models may be easier to conduct randomization-consistent inferences.

In this section we consider the full selection model proposed by Diggle and Kenward (1994). Next, an overview of different strategies to fit pattern-mixture models is provided. One route for sensitivity analysis is to explore the effect of different plausible models within one modeling framework. Another possibility is to consider pattern-mixture models as a complement to selection models (Thijs et al. 2002; Michiels et al. 2002). Finally, we discuss local influence, a sensitivity tool to explore the effect of (small) changes from the posited MAR model within the selection model framework.

34.7.1 Selection Models

Much of the early development of, and debate about, selection models appeared in the econometrics literature in which the tobit model (Heckman 1976) played a central role. This combines a marginal Gaussian regression model for the response, as might be used in the absence of missing data, with a Gaussian-based threshold model for the probability of a value being missing. Later on, selection models have been proposed for longitudinal data in the biometric and epidemiological setting.

For continuous outcomes, Diggle and Kenward (1994) proposed a full selection model which is valid under MNAR. In the discrete case, Molenberghs et al. (1997) considered a global odds ratio (Dale) model. Within the selection model framework, models have been proposed for non-monotone missingness as well (Baker et al. 1992; Jansen and Molenberghs 2008), and further a number of proposals have been made for non-Gaussian outcomes (Molenberghs and Verbeke 2005). Let us describe the Diggle and Kenward model for continuous longitudinal data in more detail, since we will apply this to the ARMD trial later on.

Diggle and Kenward Model for Continuous Longitudinal Data Diggle and Kenward (1994) proposed a model for longitudinal Gaussian data with non-random dropout, that is, the missingness mechanism was assumed to be MNAR, which combines the multivariate normal model for longitudinal Gaussian data with a logistic regression for dropout. To maximize the resulting likelihood, integration over the missing data is needed.

The likelihood contribution of the ith subject, based on the observed data $(\vec{y}_i^o, d_i)$, is proportional to the marginal density function

$$\begin{aligned} f(\vec{y}_i^o, d_i|\vec{\theta}, \vec{\psi}) &= \int f(\vec{y}_i, d_i|\vec{\theta}, \vec{\psi})\, d\vec{y}_i^m \\ &= \int f(\vec{y}_i|\vec{\theta}) f(d_i|\vec{y}_i, \vec{\psi})\, d\vec{y}_i^m, \end{aligned} \tag{34.24}$$

in which a marginal model for $\vec{Y}_i$ is combined with a model for the dropout process, conditional on the response – since we are considering the selection model framework – and where $\vec{\theta}$ and $\vec{\psi}$ are vectors of unknown parameters in the measurement model and dropout model, respectively.

Let $\vec{h}_{ij} = (y_{i1}, \ldots, y_{i,j-1})$ denote the observed history of subject i up to time $t_{i,j-1}$. The Diggle–Kenward model for the dropout process allows the conditional probability for dropout at occasion j, given that the subject was still observed at the previous occasion, to depend on the history $\vec{h}_{ij}$ and the possibly unobserved current outcome y_{ij}, but not on future outcomes $y_{ik}, k > j$. These conditional probabilities $P(D_i = j|D_i \geq j, \vec{h}_{ij}, y_{ij}, \vec{\psi})$ can now be used to calculate the probability of dropout at each occasion:

$$f(d_i|\vec{y}_i, \vec{\psi}) = P(D_i = d_i|\vec{y}_i, \vec{\psi}) = P(D_i = d_i|\vec{h}_{id_i}, y_{id_i}, \vec{\psi}) \tag{34.25}$$

$$= \begin{cases} P(D_i = d_i|D_i \geq d_i, \vec{h}_{id_i}, y_{id_i}, \vec{\psi}), & d_i = 2, \\ P(D_i = d_i|D_i \geq d_i, \vec{h}_{id_i}, y_{id_i}, \vec{\psi}) & \\ \qquad \times \prod_{j=2}^{d_i-1} \left[1 - P(D_i = j|D_i \geq j, \vec{h}_{ij}, y_{ij}, \vec{\psi})\right], & d_i = 3, \ldots, n, \\ \prod_{j=2}^{n} \left[1 - P(D_i = j|D_i \geq j, \vec{h}_{ij}, y_{ij}, \vec{\psi})\right], & d_i = n+1. \end{cases}$$

Diggle and Kenward (1994) combine a multivariate normal model for the measurement process with a logistic regression model for the dropout process. More specifically, the measurement model assumes that the vector $\vec{Y}_i$ of repeated measurements for the ith subject satisfies the linear regression model

$$\vec{Y}_i \sim N(\boldsymbol{X}_i\vec{\beta}, V_i), \qquad i = 1, \ldots, N, \tag{34.26}$$

in which $\vec{\beta}$ is a vector of population-averaged regression coefficients. The matrix V_i can be left unstructured or assumed to be of a specific form, such as resulting from a linear mixed model.

The logistic dropout model can, for example, take the form

$$\text{logit}\left[P(D_i = j \mid D_i \geq j, \vec{h}_{ij}, y_{ij}, \vec{\psi})\right] = \psi_0 + \psi_1 y_{i,j-1} + \psi_2 y_{ij}. \tag{34.27}$$

More general models can easily be constructed by including the complete history $\vec{h}_{ij} = (y_{i1}, \ldots, y_{i,j-1})$, as well as external covariates, in the above conditional dropout model. Note also that, strictly speaking, one could allow dropout at a specific occasion to be related to all future responses as well. However, this is rather counterintuitive in many cases. Moreover, including future outcomes seriously complicates the calculations since computation of the likelihood (Eq. 34.24) then requires evaluation of a possibly high-dimensional integral. Note also that special cases of the model (34.27) are obtained from setting $\psi_2 = 0$ or $\psi_1 = \psi_2 = 0$, respectively. In the first case, dropout is no longer allowed to depend on the current measurement, implying MAR. In the second case, dropout is independent of the outcome, which corresponds to MCAR. In both cases, all parameters can be estimated using standard software since the multivariate normal measurement model and the dropout model can then be fitted separately.

Diggle and Kenward (1994) obtained parameter and precision estimates by maximum likelihood. The likelihood involves marginalization over the unobserved outcomes $\vec{Y}_i^m$, for which subject-by-subject integration is required. Practically, this involves relatively tedious and computationally demanding forms of numerical integration. Diggle and Kenward (1994) used the Nelder and Mead simplex algorithm (Nelder and Mead 1965), whereas we will use the Newton-Raphson Ridge optimization method.

34.7.2 Selection Models Applied to the ARMD Trial

In this section, the visual acuity is first analyzed using the full selection model proposed by Diggle and Kenward (1994), discussed in Sect. 34.7.1. Apart from modeling the three missing data mechanisms MCAR, MAR, and MNAR, explicitly, an ignorable MAR analysis is also conducted in which the model for the response measurements only was fitted. For the measurement model, the linear mixed model was used, assuming again different intercepts and treatment effects for each of the four time points, next to an unstructured variance-covariance matrix. In the full selection models, the dropout is modeled by Eq. 34.27. Parameter estimates and corresponding standard errors of the fixed effects of the measurement model and of the dropout model parameters are given in Table 34.8. As expected, the parameter estimates and standard errors coincide for the ignorable direct-likelihood analysis and the selection models under MCAR and MAR, except for some numerical noise.

Since the main interest lies in the treatment effect at 1 year, the corresponding p-values are displayed in Table 34.8. In all four cases, this treatment effect is (borderline) significant.

Table 34.8 Age-related macular degeneration trial. Parameter estimates (standard errors) assuming ignorability, as well as explicitly modeling the missing data mechanism under MCAR, MAR, and MNAR assumptions, for all data

All subjects		Ignorable		MCAR		MAR		MNAR	
Effect	Parameters	Est.	(s.e.)	Est.	(s.e.)	Est.	(s.e.)	Est.	(s.e.)

Treatment 24	β_{32}	−3.60	(2.49)	−3.60	(2.46)	−3.60	(2.50)	−3.80	(2.50)
Treatment 52	β_{42}	−5.18	(2.59)	−5.18	(2.57)	−5.18	(2.62)	−5.71	(2.63)
Dropout model									
Intercept	ψ_0			−2.79	(0.17)	−1.86	(0.46)	−1.81	(0.47)
Previous	ψ_1					−0.020	(0.009)	0.016	(0.022)
Current	ψ_2							−0.042	(0.023)
−2 log-likelihood		6,488.7		6,782.7		6,778.4		6,775.9	
Treatment effect at 1 year	p-value	0.046		0.044		0.048		0.030	

Note that for the MNAR analysis, the estimates of the ψ_1 and ψ_2 parameter are more or less of the same magnitude, but with a different sign. This is in line with the argument of Molenberghs et al. (2001), stating that the dropout oftentimes depends on the increment $y_{ij} - y_{i,j-1}$. This is because two subsequent measurements are usually positively correlated. By rewriting the fitted dropout model in terms of the increment,

$$\text{logit}\left[\text{pr}(D_i = j | D_i \geq j, \vec{h}_{ij}, y_{ij}, \vec{\psi})\right] = -1.81 - 0.026 y_{i,j-1} - 0.042(y_{ij} - y_{i,j-1}),$$

we find that the probability of dropout increases with larger negative increments; that is, those patients who showed or would have shown a greater decrease in visual acuity from the previous visit are more likely to drop out.

34.7.3 Pattern-Mixture Models

Pattern-mixture models were introduced in Sect. 34.3.1 as one of the three major frameworks within which missing data models can be developed. In this section we provide a brief overview of such pattern-mixture models. More details can be found in Verbeke and Molenberghs (2000) and Molenberghs and Kenward (2007). Early references include Rubin (1978), who mentioned the concept of a sensitivity analysis within a fully Bayesian framework, Glynn et al. (1986), and Little and Rubin (1987). Important early development was provided by Little (1993, 1994, 1995).

Pattern-mixture models can be considered for their own sake to answer a particular scientific question. Further, several authors have contrasted selection models and pattern-mixture models. This is done either (1) to answer the same scientific question, such as marginal treatment effect or time evolution, based on these two rather different modeling strategies, or (2) to gain additional insight by supplementing the selection model results with those from a pattern-mixture approach.

Examples of pattern-mixture applications can be found in Verbeke et al. (2001a) or Michiels et al. (2002) for continuous outcomes, and Molenberghs et al. (1999) or Michiels et al. (1999) for categorical outcomes.

Recall that the pattern-mixture decomposition is given by Eq. 34.5. As a simple illustration consider a continuous response at three times of measurement which will be modeled using a trivariate Gaussian distribution. Assume that there may be dropout at time 2 or 3, and let the dropout indicator R take the values 1 and 2 to indicate that the last observation occurred at these times and 3 to indicate no dropout. Then, in the first instance, the model implies a different distribution for each time of dropout. We can write:

$$\vec{y} \mid r \sim N\left(\vec{\mu}^{(r)}; \vec{\Sigma}^{(r)}\right), \tag{34.28}$$

where

$$\vec{\mu}^{(r)} = \begin{bmatrix} \mu_1^{(r)} \\ \mu_2^{(r)} \\ \mu_3^{(r)} \end{bmatrix} \quad \text{and} \quad \vec{\Sigma}^{(r)} = \begin{bmatrix} \sigma_{11}^{(r)} & \sigma_{21}^{(r)} & \sigma_{31}^{(r)} \\ \sigma_{21}^{(r)} & \sigma_{22}^{(r)} & \sigma_{32}^{(r)} \\ \sigma_{31}^{(r)} & \sigma_{32}^{(r)} & \sigma_{33}^{(r)} \end{bmatrix},$$

for $r = 1, 2, 3$. Let $\mathrm{P}(r) = \pi_r$, then the marginal distribution of the response is a mixture of normals with, for example, mean

$$\vec{\mu} = \sum_{r=1}^{3} \pi_r \vec{\mu}^{(r)}.$$

However, although the π_r can be simply estimated from the observed proportions in each dropout group, only 16 of the 27 response parameters can be identified from the data without making further assumptions. These 16 comprise all the parameters from the completers plus those from the following two submodels. For $r = 2$

$$N\left(\begin{bmatrix} \mu_1^{(2)} \\ \mu_2^{(2)} \end{bmatrix}; \begin{bmatrix} \sigma_{11}^{(2)} & \sigma_{21}^{(2)} \\ \sigma_{31}^{(3)} & \sigma_{32}^{(3)} \end{bmatrix}\right),$$

and for $r = 1$: $N\left(\mu_1^{(2)}; \sigma_{11}^{(1)}\right)$. This is a *saturated* pattern-mixture model and the representation makes it very clear what information each dropout group provides, and consequently the assumptions that need to be made if we are to predict the behavior of the unobserved responses, and so obtain marginal models for the response. If the three sets of parameters $\vec{\mu}^{(r)}$ are simply equated, this implies MCAR. Progress can be made with less stringent restrictions however. In practice, choice of restrictions will need to be guided by the context. In addition, the form of the data will typically be more complex, requiring, for example, a more structured model for the response with the incorporation of covariates. Hence such models can be constructed in many ways.

An important issue is that pattern-mixture models are by construction under-identified, that is, over-specified. Little (1993, 1994) solves this problem through the use of identifying restrictions: inestimable parameters of the incomplete patterns are set equal to (functions of) the parameters describing the distribution of the completers. Identifying restrictions are not the only way to overcome under-identification, and we will discuss alternative approaches. Although some authors perceive this under-identification as a drawback, it can be an asset because it forces one to reflect on the assumptions made. Pattern-mixture models can serve important roles in sensitivity analysis.

Fitting pattern-mixture models can be approached in several ways. It is important to decide whether pattern-mixture and selection models are to be contrasted with one another or rather the pattern-mixture modeling is the central focus. In the latter case, it is natural to conduct an analysis, and preferably a sensitivity analysis, *within* the pattern-mixture family. Basically we will consider three strategies to deal with under-identification.

- *Strategy 1.* As mentioned before, Little (1993, 1994) advocated the use of identifying restrictions and presented a number of examples. A general framework for identifying restrictions is discussed in more detail in Thijs et al. (2002), with three special but important cases: *complete case missing values* (CCMV) (proposed by Little 1993), *neighboring case missing values* (NCMV), and *available case missing values* (ACMV). Note that ACMV is the natural counterpart of MAR in the pattern-mixture model framework (Molenberghs et al. 1998). This provides a way to compare ignorable selection models with their counterpart in the pattern-mixture setting. Kenward et al. (2003) focus on restrictions avoiding dependence of dropout on measurements made at future occasions.

  The procedure to apply identifying restrictions is discussed in full detail in Thijs et al. (2002). The key steps are as follows:

  1. Fit a model to the pattern-specific identifiable densities: $f_t(y_1, \ldots, y_t)$. This results in a set of parameter estimates, $\vec{\beta}_p$ say, for each pattern p.
  2. Select an identification method of choice (ACMV, CCMV, NCMV).
  3. Using this identification method, determine the conditional distributions of the unobserved outcomes, given the observed ones:
  $$f_t(y_{t+1}, \ldots, y_t | y_1, \ldots, y_t).$$
  4. Using standard multiple imputation methodology (Rubin 1987; Schafer 1997; Verbeke and Molenberghs 2000; Molenberghs and Kenward 2007), draw multiple imputations for the unobserved components, given the observed outcomes and the correct pattern-specific density.
  5. Analyze the multiply imputed data sets using the method of choice. This can be another pattern-mixture model, but also a selection model or any other desired model.
  6. Inferences can be conducted in the standard multiple imputation way.

- *Strategy 2.* As opposed to identifying restrictions, model simplification can be done in order to identify the parameters. The advantage is that the number of parameters decreases, which is desirable since the length of the parameter vector is a general issue with pattern-mixture models. Indeed, Hogan and Laird (1997) noted that in order to estimate the large number of parameters in general pattern-mixture models, one has to make the awkward requirement that each dropout pattern occurs sufficiently often. Broadly, we distinguish between two types of simplifications.
  - *Strategy 2a.* Trends can be restricted to functional forms supported by the information available within a pattern. For example, a linear or quadratic time trend is easily extrapolated beyond the last obtained measurement. One only needs to provide an ad hoc solution for the first or the first few patterns. In order to fit such models, one simply has to carry out a model building exercise within each of the patterns separately.

- *Strategy 2b.* Next, one can let the parameters vary across patterns in a controlled parametric way. Thus, rather than estimating a separate time trend within each pattern, one could for example assume that the time evolution within a pattern is unstructured, but parallel across patterns. This is effectuated by treating pattern as a covariate. The available data can be used to assess whether such simplifications are supported within the time ranges for which there is information.

Although the second strategy is computationally simple, it is important to note that there is a price to pay. Indeed, simplified models, qualified as *assumption rich* by Sheiner et al. (1997), also make untestable assumptions, just as in the selection model case. From a technical point of view, Strategy 2 only requires to either consider "pattern" as an extra covariate in the model, or to conduct an analysis "by pattern," such that a separate analysis is obtained for each of the dropout patterns. In the identifying restrictions setting on the other hand (Strategy 1), the assumptions are clear from the start. Precisely for these reasons it is stated in Thijs et al. (2002) that the use of simplified models is not the best strategy and can be rather dangerous as well.

Pattern-mixture models do not always automatically provide estimates and standard errors of marginal quantities of interest, such as overall treatment effect or overall time trend. Hogan and Laird (1997) provided a way to derive selection model quantities from the pattern-mixture model. Several authors have followed this idea to formally compare the conclusions from a selection model with the selection model parameters in a pattern-mixture model (Michiels et al. 1999; Verbeke et al. 2001a).

34.7.4 Pattern-Mixture Models Applied to the ARMD Trial

In this section, we consider the use of pattern-mixture models for the visual acuity outcome. Since there are four fixed time points in the ARMD trial, there are four patterns, going from only one observation available (Pattern 1) to all planned measurements observed (Pattern 4). These four patterns have subsample sizes 188, 24, 8, and 6, respectively. The corresponding pattern probabilities are $\vec{\pi}' = (0.832, 0.106, 0.035, 0.027)'$.

34.7.4.1 Strategy 1

First, we will apply Strategy 1 making use of CCMV, NCMV, and ACMV identification restrictions. In order to apply such identifying restrictions, one first needs to fit a model to the observed data. We will opt for a saturated model with parameters specific to each pattern. Next, for each of the three restrictions, multiple imputation is conducted, after which the same multivariate normal model as before is fitted to the imputed datasets. Finally, results are combined into a single one. The results for the three types of restrictions are shown in Table 34.9. From the estimates and associated standard errors, it is clear that there is little difference in conclusions between the strategies. The estimates for treatment effect

Table 34.9 Age-related macular degeneration trial. Parameter estimates (standard errors) and *p*-values resulting from the pattern-mixture model using identifying restrictions ACMV, CCMV, and NCMV

		ACMV	CCMV	NCMV
Effect	Parameter			
Parameter estimate (standard error)

Treatment 24	β_{32}	0.139	0.140	0.200
Treatment 52	β_{42}	0.065	0.069	0.101

and corresponding standard errors obtained under CCMV and NCMV restrictions are underestimated when comparing to ACMV.

Further, we observe that for all three strategies the *p*-value for the treatment effect at 1 year is above the significance level of 0.05, yet it is borderline significant for the ACMV restrictions – which is equivalent to MAR – in line with the conclusions drawn from the selection models in the previous section. The *p*-value is closest to significance and thus to the one from the selection models in case the NCMV restrictions are considered. The Diggle–Kenward MAR and MNAR selection models also show a borderline significant treatment effect, its *p*-value being below 0.05.

34.7.4.2 Strategy 2

To apply Strategy 2a, we have to fit the posited measurement model within each of the four patterns separately. For consistency reasons, again a saturated model will be considered. In Strategy 2b the measurement model reflects dependence on dropout by allowing the fixed effects as well as the covariance parameters to change with dropout pattern. This is done by including the interaction of all effects in the model with the pattern variable. Since in Strategy 2a we fit the same saturated model for each pattern, the result will be the same as obtained by Strategy 2b.

As mentioned above, this second strategy is not the best one to choose (Molenberghs and Kenward 2007). The strategy uses models that are sufficiently

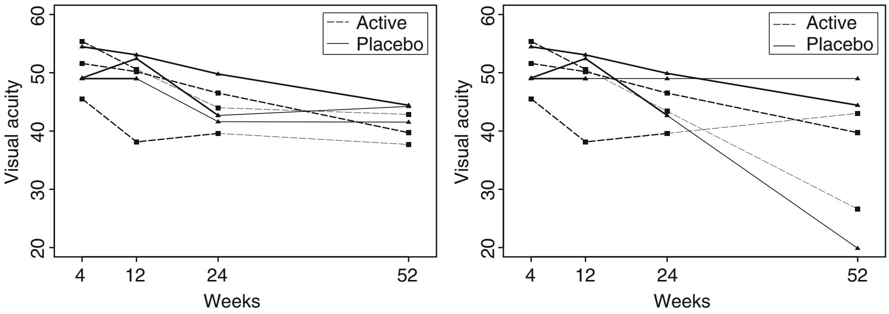

Fig. 34.6 Age-related macular degeneration trial. Mean profiles using ACMV restrictions (*left*) and extrapolation based on Strategy 2 (*right*), for dropout pattern 2–4, grouped per treatment arm

simple for extrapolations to be possible past the point of dropout within a particular pattern. Further, the results greatly depend on the extrapolations made, which may of course be highly inappropriate, especially as they are typically based on low-order polynomials. At the same time, the assumptions that these extrapolations imply concerning the dropout mechanisms are far from transparent. Let us illustrate this issue by comparing the extrapolations after applying Strategy 2 with the predicted means for each pattern obtained by the ACMV restriction from Strategy 1. We choose to consider the ACMV restriction due to its elegant property of being equivalent to MAR in the selection model framework. This is represented in Fig. 34.6. Bold line type is used for the range over which data are obtained for a particular pattern and extrapolation is indicated using thinner line type.

In all plots, the same mean response scale was retained, illustrating that the identifying restrictions strategies extrapolate much closer to the observed data mean response. Within both treatment arms there is a large difference between the extrapolation for pattern 2 and 3. The active treatment group shows a decline after dropout for pattern 2 in contrast to a rise after dropout for pattern 3. On the other hand, for the placebo group, pattern 2 remains stable after dropout, whereas pattern 3 shows a decrease after dropout. These findings suggest, again, that a more careful reflection on the extrapolation method is required.

34.7.5 Selection Models and Local Influence

Let us return to the Diggle and Kenward (1994) selection model, as described in Sect. 34.7.1, and consider the dropout model (34.27). When ω equals zero, the dropout model is random, and all parameters can be estimated using standard software since the measurement model for which we use a linear mixed model and the dropout model, assumed to follow a logistic regression, can then be fitted separately. If $\omega \neq 0$, the dropout process is assumed to be non-random.

Equation 34.6 is now used to construct the dropout process:

$$f(d_i|\vec{y}_i,\vec{\psi}) = \begin{cases} \prod_{j=2}^{n}\left[1-g\left(\vec{h}_{ij},y_{ij}\right)\right] & \text{for a complete sequence} \\ \prod_{j=2}^{d-1}\left[1-g\left(\vec{h}_{ij},y_{ij}\right)\right]g\left(\vec{h}_{id},y_{id}\right) & \text{for a dropout.} \end{cases} \tag{34.29}$$

Let us now shift attention to sensitivity and influence analysis issues. Whereas a global influence approach is based on case-deletion, a local influence-based sensitivity assessment of the relevant quantities, such as treatment effect or time evolution parameters, with respect to assumptions about the dropout model is based on the following perturbed version of Eq. 34.6:

$$\operatorname{logit}\left(g\left(\vec{h}_{ij},y_{ij}\right)\right) = \operatorname{logit}\left[\operatorname{pr}\left(D_i = j|D_i \geq j,\vec{y}_i\right)\right] = \vec{h}_{ij}\vec{\psi} + \omega_i y_{ij}, \tag{34.30}$$

$i = 1,\ldots,N$, in which different subjects give different weights to the response at time t_{ij} to predict dropout at time t_{ij}. If all ω_i equal zero, the model reduces to an MAR model. Hence Eq. 34.30 can be seen as an extension of the MAR model, which allows some individuals to drop out in a "less random" way ($|\omega_i|$ large) than others ($|\omega_i|$ small). It has to be noted that, even when ω_i is large, we still cannot conclude that the dropout model for these subjects is non-random. Rather, it is a way of pointing to subjects which, due to their strong influence, are able to distort the model parameters such that they can produce, for example, a dropout mechanism which is *seemingly* non-random. In reality, many different characteristics of such an individual's profile might be responsible for this effect. As mentioned earlier, such sensitivity has been alluded to by many authors, such as Laird (1994) and Rubin (1994).

Cook (1986) suggests that more confidence can be put in a model which is relatively stable under small modifications. The best known perturbation schemes are based on case-deletion (Cook and Weisberg 1982; Chatterjee and Hadi 1988) in which the effect is studied of completely removing cases from the analysis. They were introduced by Cook (1977, 1979) for the linear regression context. Denote the log-likelihood function, corresponding to measurement model (34.8) and dropout model (34.6), by

$$\ell(\vec{\gamma}) = \sum_{i=1}^{N}\ell_i(\vec{\gamma}), \tag{34.31}$$

in which $\ell_i(\vec{\gamma})$ is the contribution of the ith individual to the log-likelihood, and where $\vec{\gamma} = (\vec{\theta},\vec{\psi},\omega)$ is the s-dimensional vector, grouping the parameters of the measurement model and the dropout model. Further, we denote by

$$\ell_{(-i)}(\vec{\gamma}) \tag{34.32}$$

the log-likelihood function, where the contribution of the ith subject has been removed. Cook's distances are based on measuring the discrepancy between either the maximized likelihoods Eq. 34.31 and Eq. 34.32 or (subsets of) the estimated parameter vectors $\widehat{\vec{\gamma}}$ and $\widehat{\vec{\gamma}}_{(-i)}$, with obvious notation. Precisely, we will consider both

$$CD_{1i} = 2\left(\widehat{\ell} - \widehat{\ell}_{(-i)}\right) \tag{34.33}$$

as well as

$$CD_{2i}(\vec{\gamma}) = 2\left(\widehat{\vec{\gamma}} - \widehat{\vec{\gamma}}_{(-i)}\right)' \ddot{L}^{-1}\left(\widehat{\vec{\gamma}} - \widehat{\vec{\gamma}}_{(-i)}\right), \tag{34.34}$$

in which $\ddot{L}$ is the matrix of all second-order derivatives of $\ell(\vec{\gamma})$ with respect to $\vec{\gamma}$, evaluated at $\vec{\gamma} = \widehat{\vec{\gamma}}$. Formulation (34.34) easily allows to consider the global influence in a subvector of $\vec{\gamma}$, such as the dropout parameters $\vec{\psi}$, or the non-random parameter ω. This will be indicated using notation of the form $CD_{2i}(\vec{\psi})$, $CD_{2i}(\omega)$, etc.

In linear regression, global influence is conceptually simple, computationally straightforward, and well studied. The latter two of these features do not carry over to more general settings. To overcome these limitations, *local* influence methods have been suggested. The principle is to investigate how the results of an analysis are changed under infinitesimal perturbations of the model. In the framework of the linear mixed model, Beckman et al. (1987) used local influence to assess the effect of perturbing the error variances, the random-effects variances, and the response vector. In the same context, Lesaffre and Verbeke (1998) have shown that the local influence approach is also useful for the detection of influential subjects in a longitudinal data analysis. Moreover, since the resulting influence diagnostics can be expressed analytically, they often can be decomposed in interpretable components, which yield additional insights in the reasons why some subjects are more influential than others.

Verbeke et al. (2001a) studied the influence the non-randomness of dropout exerts on the model parameters. Let us briefly sketch the principles of local influence and then apply them to our MNAR problem.

We denote the log-likelihood function corresponding to model (34.30) by

$$\ell(\vec{\gamma}|\vec{\omega}) = \sum_{i=1}^{N} \ell_i(\vec{\gamma}|\omega_i), \tag{34.35}$$

in which $\ell_i(\vec{\gamma}|\omega_i)$ is the contribution of the ith individual to the log-likelihood, and where $\vec{\gamma} = (\vec{\theta}, \vec{\psi})$ is the s-dimensional vector, grouping the parameters of the measurement model and the dropout model, not including the $N \times 1$ vector $\vec{\omega} = (\omega_1, \omega_2, \ldots, \omega_N)'$ of weights defining the perturbation of the MAR model. Let $\widehat{\vec{\gamma}}$ be the maximum likelihood estimator for $\vec{\gamma}$, obtained by maximizing $\ell(\vec{\gamma}|\vec{\omega}_0)$, and let $\widehat{\vec{\gamma}}_\omega$ denote the maximum likelihood estimator for $\vec{\gamma}$ under $\ell(\vec{\gamma}|\vec{\omega})$. Cook (1986) proposed to measure the distance between $\widehat{\vec{\gamma}}_\omega$ and $\widehat{\vec{\gamma}}$ by the so-called likelihood displacement, defined by $LD(\vec{\omega}) = 2\left(\ell(\widehat{\vec{\gamma}}|\vec{\omega}_0) - \ell(\widehat{\vec{\gamma}}_\omega|\vec{\omega})\right)$. Since this quantity can only be depicted when $N = 2$, Cook (1986) proposed to look at local influence, i.e., at the normal curvatures $C_{\vec{h}}$ of $\vec{\xi}(\vec{\omega})$ in $\vec{\omega}_0$, in the direction of some N-dimensional vector $\vec{h}$ of unit length. It can be shown that a general form is given by

$$C_{\vec{h}}(\vec{\theta}) = -2\vec{h}'\left[\left.\frac{\partial^2 \ell_{i\omega}}{\partial\vec{\theta}\partial\omega_i}\right|_{\omega_i=0}\right]' \ddot{L}^{-1}(\vec{\theta})\left[\left.\frac{\partial^2 \ell_{i\omega}}{\partial\vec{\theta}\partial\omega_i}\right|_{\omega_i=0}\right]\vec{h}$$

$$C_{\vec{h}}(\vec{\psi}) = -2\vec{h}'\left[\left.\frac{\partial^2 \ell_{i\omega}}{\partial\vec{\psi}\partial\omega_i}\right|_{\omega_i=0}\right]' \ddot{L}^{-1}(\vec{\psi})\left[\left.\frac{\partial^2 \ell_{i\omega}}{\partial\vec{\psi}\partial\omega_i}\right|_{\omega_i=0}\right]\vec{h},$$

evaluated at $\vec{\gamma} = \widehat{\vec{\gamma}}$, where indeed the influence for the measurement and dropout model parameters split, since the second derivative matrix of the log-likelihood, $\ddot{L}$ is block-diagonal with blocks $\ddot{L}(\vec{\theta})$ and $\ddot{L}(\vec{\psi})$. Verbeke et al. (2001b) have decomposed local influence into meaningful and interpretable components.

34.7.6 Local Influence Applied to the ARMD Trial

Let us apply the local influence sensitivity tool to the ARMD trial. Figure 34.7 displays overall C_i and influences for subvectors $\vec{\theta}$, $\vec{\beta}$, $\vec{\alpha}$, and $\vec{\psi}$. In addition, the direction $\vec{h}_{\max}$, corresponding to maximal local influence, is given. The main emphasis should be put on the relative magnitudes. We observe that patients #10, #27, #28, #114, #139, and #154 have larger C_i values compared to other patients, which means they can be considered influential. Virtually the same picture holds for $C_i(\vec{\psi})$.

Turning attention to the influence on the measurement model, we see that for $C_i(\vec{\beta})$, there are no strikingly high peaks, whereas $C_i(\vec{\alpha})$ reveals two considerable peaks for patients #68 and #185. Note that both patients fail to have a high peak for the overall C_i. This is due to the fact that the scale for $C_i(\vec{\alpha})$ is relatively small, comparing to the overall C_i. Nevertheless, these patients can still be considered influential. Finally, the direction of maximum curvature reveals the same six influential patients as the overall C_i.

In Fig. 34.8, the individual profiles of the influential observations are highlighted. Let us take a closer look at these cases. The six patients, which are influencing the dropout model parameters, are those that drop out after the first measurement is taken at week 4. All of these patients are in the active treatment arm, except for #27. On the other hand, the two patients influential for the measurement model parameters stay in the study up to week 24 and have no observation for the last measurement occasion at 1 year. Patient # 68 received the active treatment, and his/her visual acuity decreases substantially after week 4, thereafter staying more or

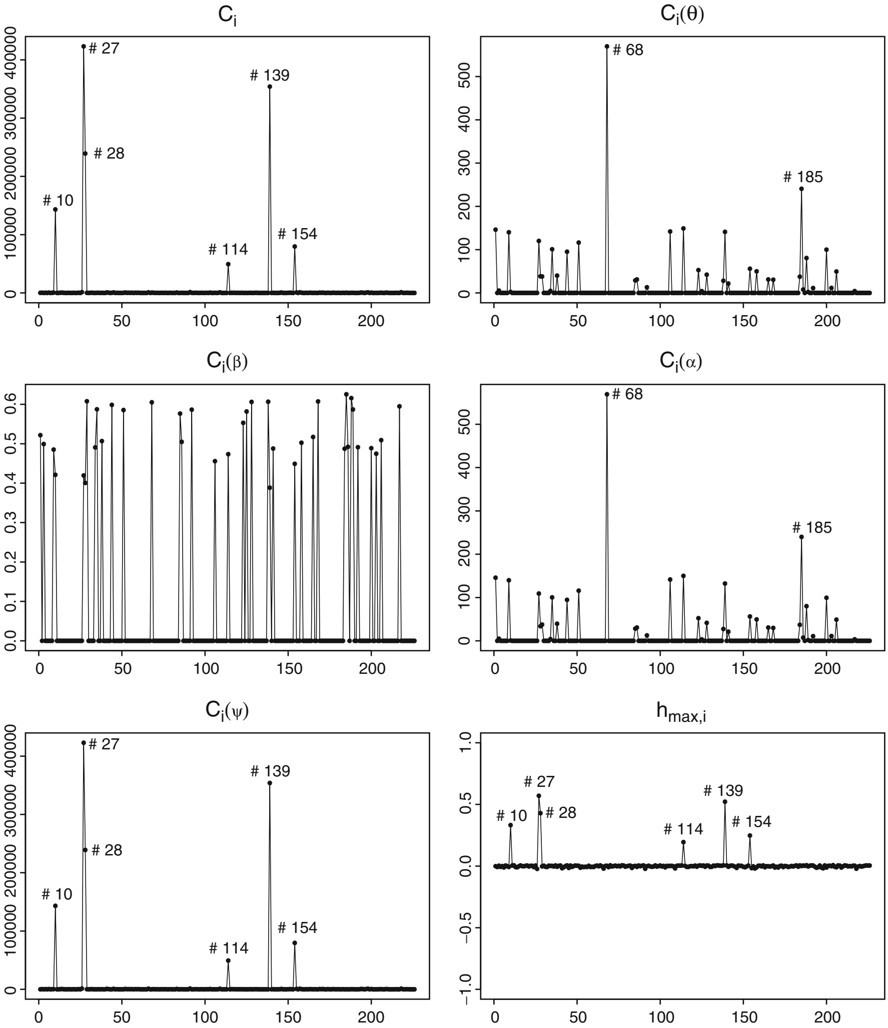

Fig. 34.7 Age-related macular degeneration trial. Index plots of C_i, $C_i(\vec{\theta})$, $C_i(\vec{\alpha})$, $C_i(\vec{\beta})$, $C_i(\vec{\psi})$ and of the components of the direction $\vec{h}_{\max,i}$ of maximal curvature

less level. Opposite, patient #185 is enrolled in the placebo treatment arm and his/her visual acuity increases after week 4, then sloping down a little after week 12.

It is interesting to consider an analysis without these influential observations. Therefore, we applied the selection model to three subsets of the data. The first subset was obtained by removing all the eight influential patients mentioned before. In the second subset of the data, patients #10, #27, #28, #114, #139, and #154 were removed, since these are overall the most influential ones. Finally, patients #68 and #185, who seemed to be influencing the measurement model the most, were

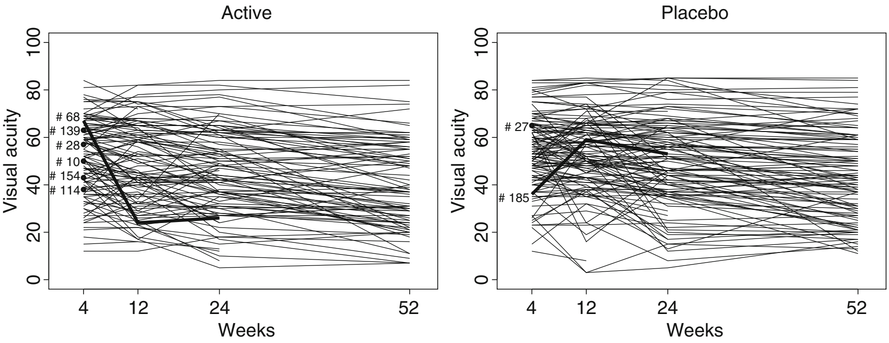

Fig. 34.8 Age-related macular degeneration trial. Individual profiles for both treatment arms, with influential subjects highlighted

removed, resulting in the third subset. The results of these analyses are shown in Table 34.10. We compare the results of the MAR and MNAR analyses.

After removing all influential patients (Set 1), the estimates of the dropout model parameters ψ_1 and ψ_2 are approximately the same, whereas the estimate of ψ_0 decreases from -1.86 to -1.90 under MAR, and from -1.81 to -1.85 under MNAR. The same can be seen after removing patients #10, #27, #28, # 114, #139, and #154, who have large overall C_i and $C(\vec{\psi})$ values (Set 2). Considering the treatment effect at 1 year, its estimate decreases from -5.18 to -5.45 under the MAR assumption, and from -5.71 to -6.12 under the MNAR assumption, resulting in a decrease of the p-value from 0.048 to 0.040 and from 0.030 to 0.021 under MAR and MNAR, respectively.

There is no impact on the likelihood ratio test for MAR against MNAR after removing all influential patients, the deviance G^2 only changes slightly from 2.5 to 2.6. If this likelihood ratio test would follow a standard χ^2_1-distribution, we would fail to reject the null hypothesis, which leads us to the MAR assumption. However, the test of MAR against MNAR is non-standard and it cannot be used as such (Rotnitzky et al. 2000; Jansen et al. 2006). Moreover, recall that one can never test for the assumption of MNAR versus MAR missingness.

Further, after removing the second set of influential patients, that is, patients #10, #27, #28, #114, #139, the estimate of the treatment effect at 1 year increases from -5.18 to -5.06 under the MAR analysis, yielding a slightly increased borderline p-value, whereas it decreases with 0.01 under the MNAR analysis and together with a decreased standard error the latter yields a small decrease in the p-value. The deviance G^2 for the likelihood ratio test for MAR against MNAR remains 2.5.

Finally, we perform the same analyses on the third set, with patients #68 and #185 removed. Both for the MAR and MNAR analysis, again the estimate of the treatment effect at 1 year decreases quite a lot, from -5.18 to -5.56 and from -5.71 to -6.09, respectively. Consequently, the p-value also drops down from 0.048 to 0.029 under

34.8 Conclusions

In this chapter, it has been shown that the use of simple methods, such as complete case analysis or last observation carried forward, at least require the missingness mechanism to be MCAR. Therefore, while historically very popular, these methods carry major drawbacks and can and ought to be replaced with more advanced methods. One such method is a likelihood-based ignorable analysis. It has a broad basis in the sense that it is valid under MAR and compatible with general strategies such as linear mixed models for Gaussian outcomes or generalized linear mixed models, within the random-effects model family, for non-Gaussian outcomes. These methods are simple to conduct as it would be in contexts where data are complete.

In the non-Gaussian setting, one often opts for a semi-parametric approach such as generalized estimating equations within the marginal model family. Since this method also requires the missingness to be MCAR, a reasonably straightforward modification is needed in order to make the method suitable for the MAR setting. Two alternatives have been considered in this chapter, that is, weighted generalized estimating equations and multiple-imputation-based generalized estimating equations. Both methods only require a little amount of programming which can be done using standard statistical software.

Thus, it has been made clear that a primary analysis should consist of methods which assume the missing data to be MAR instead of MCAR. On the other hand though, one can hardly ever rule out the possibility of missingness to be MNAR, which implies that the need may exist to consider MNAR models. Therefore, we have considered a full selection model proposed by Diggle and Kenward (1994) for Gaussian outcomes, as well as pattern-mixture models based on two strategies. Using the identifying restrictions strategy, a link exists between pattern-mixture models and selection models. Indeed, the ACMV identifying restriction is the pattern-mixture model equivalent of the MAR missingness assumption within the selection model framework. In addition, a comparison between the selection and pattern-mixture modeling approaches is useful to obtain additional insight into the data and/or to assess sensitivity.

Since MNAR models are based on assumptions regarding the unobserved outcomes, which are not verifiable from the available, observed data, one can never test the assumption of an MNAR model for or against MAR. This underscores that the conclusions drawn based on MNAR model are sensitive to the posited and unverifiable model assumptions. Consequently, in any incomplete data setting, there cannot be anything that could be called a definitive analysis and one should perform a sensitivity analysis. More confidence in the results can be gained if both models lead to similar conclusions. As seen in this chapter, this can be done not only within both the selection model and pattern-mixture model framework, but also across both frameworks. Further, we have discussed local influence, which is a sensitivity tool

Table 34.11 Age-related macular degeneration trial. Estimates, standard errors, and p-values for the treatment effect at 1 year for the ignorable direct-likelihood analysis, both Diggle–Kenward selection models assuming either MAR or MNAR, as well as the pattern-mixture model using ACMV restrictions

	Treatment at 1 year		
Model	Estimate	s.e.	p-value
Ignorable direct-likelihood	−5.18	2.59	0.047
Pattern-mixture model (ACMV)	−5.19	2.81	0.065
MAR selection model	−5.18	2.62	0.048
MNAR selection model	−5.71	2.63	0.030

that can be used within the selection model framework to detect (groups of) subjects which highly influence the obtained results.

All methods for analyzing incomplete data which are considered in this chapter are applied to the ARMD trial. In this way a broad sensitivity analysis is performed on this case study. For instance, let us focus on the treatment effect at 1 year obtained by the different methods, to assess the sensitivity of the modeling assumptions on the conclusions. A comparison of the estimates, standard errors, and p-values is provided in Table 34.11. Whereas the pattern-mixture model based on ACMV identifying restrictions shows a borderline (in)significant treatment effect at 1 year, it moves to borderline significant for the ignorable direct-likelihood analysis, which assumes MAR missingness, and the MAR Diggle–Kenward selection model, and its significance becomes more prominent in turning to the MNAR Diggle–Kenward selection model. In conclusion, the primary analysis, which ideally would be based on a model assuming MAR non-response, for instance, an ignorable direct-likelihood analysis as in this case, yields a borderline significant treatment effect at 1 year. To assess the sensitivity thereof, this primary analysis is extended with other MAR models under different modeling frameworks which clearly confirms this borderline significance. Expanding this sensitivity analysis by turning attention to MNAR models shows a decreased p-value thereby concluding a significant treatment effect at 1 year. Thus, a cautious conclusion is that there is some evidence for a treatment effect at the end of the study.

35.1 Introduction

Generalized linear models (GLMs) are a standard regression approach for analyzing univariate non-normal data. In their breakthrough paper, Nelder and Wedderburn (1972) have derived GLM as a unifying approach for fitting models with dependent variables that are count data or dichotomous. GLM is nicely summarized in chapter ▸Regression Methods for Epidemiological Analysis of this handbook, the great introductory text book of Dobson (2001) or the excellent monograph by McCullagh and Nelder (1989). Here, the user specifies a link function to relate the independent and the dependent variables. For example, in epidemiology, the standard choice for dichotomous dependent variables is the logit link function to model the mean structure, a model which is known for more than 50 years. Another advantage of the GLM approach in this situation is that the variance function does not need to be explicitly specified. It is automatically generated from the assumption that binary data are assumed to be Bernoulli distributed.

In many applications, however, observations are not independent, for example, when measurements are taken repeatedly from the same subject over time or when paired data are taken, for example, from the left and the right eye. Neglecting dependencies in such a situation can lead to false conclusions. Specifically, the precision of the results and thereby their significance is usually overestimated. If one aims at using standard estimation techniques like maximum likelihood (ML) or least squares in such correlated data situations, one needs to specify the complete multivariate distribution. This seems to be simple for paired data, where one has to additionally specify a single correlation coefficient in addition to the mean and the variance. However, if three observations are taken from the same subject over time, not only three pair-wise correlations need to be specified in addition to the link function and the variance function but also one third-order moment. And this complexity increases exponentially with the number of observations. The unfavorable characteristic of ML and other standard methods in such situations is that their desirable statistical properties like asymptotic normality of the estimators rely on the correct specification of the complete multivariate distribution.

An interesting approach that does not require correct specification of the entire distribution is the generalized estimating equations (GEE). The key feature of GEE is that only the mean structure is crucial, in that it needs to be correctly specified. Valid inference about regression coefficients is possible even if the variances and correlations are misspecified. Variances and correlations are not of primary interest and therefore considered nuisance. Of course, if the user is also interested in the associations between observations from the same cluster, he/she needs to correctly specify the means and the variances and correlations. However, all higher-order moments are of minor interest even in this situation. As there is no free lunch, this robustness property of GEE on the one hand comes at the cost of a loss of efficiency. On the other hand, the robustness property makes the GEE approach very interesting and relatively simple for applications. The GEE has been further developed in many different ways since its introduction in 1986 by Liang and Zeger (Liang and Zeger 1986;

Zeger and Liang 1986), and it is these extensions which make the approach very flexible.

The outline of this contribution is as follows. We describe several scenarios which are typical for GEE analysis and demonstrate the simplicity of GEE in an introductory example. We discuss the interpretability of GEE models. This is followed by an overview of standard GEE1 models, that is, GEE for the mean structure and the discussion of different working correlation structures that are available in standard software packages. We illustrate how sample size and power calculations may be performed using available software. Finally, we illustrate the use of GEE in a real data example. Technical details are banned to two appendices. Specifically, the GEE are derived as a combination of generalized least squares (GLS) and GLM in Appendix 2.

35.2 Areas of Application

A series of applications using GEE were published in the last 2 decades. The following introductory examples aim at giving a flavor of the different areas of application and scientific problems that were studied.

35.2.1 Cohort Study

In a longitudinal cohort study, human papilloma virus (HPV) detection was investigated in a group of pregnant women and a group of age-frequency matched non-pregnant women. The aim of the study was to clarify previous conflicting data concerning the detection of HPV infection in the pregnant versus the non-pregnant state while adjusting for other known risk factors of cervical cancer. To this end, 5 follow-ups at 3-month intervals were conducted. Here, the correlation between observations at different time points was considered nuisance (Ziegler et al. 2003).

35.2.2 Household Data

This example is unusual for aggregation within households. In general, correlation between household members living in the same household needs to be taken into account. This standard example will be considered in detail in the next section. Here, we consider a randomized trial, in which the functionality of two different types of smoke alarms with two different types of batteries was investigated in rural households (Yang et al. 2008). Specifically, alarm function and false alarms were tested 12 months after installation. Because several alarms were installed in a single household, correlation within households had to be taken into account. Specifically, correct alarms within a household are correlated. Furthermore, false alarms might be correlated if batteries have similar charge levels.

35.2.3 Clinical Epidemiology: Parallel Group Design with Repeated Measurements

In a double-blind placebo-controlled randomized multicenter trial, the edema-protective effect of a vasoactive drug was investigated in patients suffering from chronic venous insufficiency after decongestion of the legs (See Sect. 35.8). Two-hundred-thirty-one patients were randomly assigned to medical compression stockings plus SB-LOT (90 mg coumarin and 540 mg troxerutin per day) or medical compression stockings plus placebo for the first 4 weeks and SB-LOT or placebo for the second 12 weeks of the study. The primary efficacy endpoint was the lower leg volume measured. In total, patients were followed-up 5 times: 4, 6, 8, 12, and 16 weeks after starting the drug therapy. The primary analysis was a baseline-adjusted (visit 0) covariance analysis (ANCOVA) of the difference of the leg volume at the final visit minus the volume at baseline, that is, the time point of randomization for demonstrating a difference of the vasoactive drug when compared with placebo (Vanscheidt et al. 2002). A secondary analysis which aimed at detecting a difference in the slopes using GEE will be presented in Sect. 35.8.

35.2.4 Clinical Epidemiology: Crossover Study

In 2 × 2 crossover trials, patients receive both the active drug and the placebo, but the order is randomized (cf. chapter ▶Pharmacoepidemiology of this handbook). If there is no period effect, the standard analysis is the McNemar test investigating whether more subjects have given a preference to the active treatment. One alternative for analysis is the GEE approach in which treatment responses from both time points are analyzed jointly while at the same time taking into account the correlatedness of the responses (Diggle et al. 1994). 2 × 2 crossover trials can therefore be considered as longitudinal studies with two time points. The standard example for a 2×2 crossover study with binary endpoint has been provided by Jones and Kenward (2003). It consisted in safety data from a placebo-controlled bi-center trial on cerebrovascular deficiency. The primary endpoint of the study was whether the electrocardiogram as judged by a cardiologist was considered to be normal or abnormal. It will be used as example several times in this chapter and for the first time in Example 35.2.

35.2.5 Clinical Epidemiology: Laterality in Ophthalmological Studies

In the Blue Mountains Eye Study, a population-based cohort study, participants were investigated at baseline, after 5 and 10 years to determine whether local nutritional or ischemic factors are involved in cataract pathogenesis

(Tan et al. 2008). Specifically, the investigators assessed whether narrowed retinal vessel caliber predicted the long-term incidence of age-related cataract. Measurements were taken for both eyes so that two levels of nesting were present. The first level was caused by the time course and the second by the laterality, where both time course and laterality were considered nuisance.

35.2.6 Clinical Epidemiology: Local Correlation of Teeth in Dental Studies

In a placebo-controlled randomized clinical trial, the effect of a mouthrinse on gingivitis and tooth whitening was investigated (Hasturk et al. 2004). The first phase (1 month) was the experimental gingivitis phase and the second phase (5 months) was the oral hygiene phase, which included rinsing. Primary endpoints were chosen to reflect the gingival health and tooth whiteness. GEE were used to accommodate correlations between teeth from the same patient. The authors concluded that the fluoridated mouthrinse whitens teeth and reduces gingivitis.

35.2.7 Toxicological Litter Experiments

Ryan (1992) reanalyzed data from a developmental toxicity study in mice using GEE. The experiment included a control group and four groups exposed with different doses of diethylhexylphthalate (DEHP). Correlation between observations on the individual level arises from the litter. The authors concluded that the proportion of malformation in the offspring increased with dose. They also concluded that the intra-litter correlation was not constant.

35.2.8 Spatial Structure

In forest damage surveys, the state of tree, for example, the degree of defoliation, is measured in ordered categories. A typical survey uses a grid with rectangular meshes over a map in the survey area. For each grid point, damage states and covariates are measured for a fixed number of trees next to the grid point. A correct analysis needs to take into account the spatial correlation arising from neighboring effects among trees around the grid point (Fahrmeir and Pritscher 1996).

35.2.9 Diagnostic Tests

The evaluation of a new medical diagnostic test may focus on two different scientific questions.

Replacing a Test by a New One First, the new test may replace an existing one because of lower cost or higher validity. A related question would be the selection of the best test(s) from a bundle of new or established measurements. Of course, the tests are correlated in this setting, but the correlation is considered nuisance.

Using a New Test Supplementary to Existing Tests In the second situation, the new diagnostic test may be used supplementary to other new or established procedures. Here, only combinations of tests showing no or only a moderate correlation yield additional information. Subsequently, the association between tests is of primary interest in this setting (Martus et al. 2004).

35.2.10 Cluster of Individuals: Familial Aggregation

Genetic factors contribute to the etiology of many common diseases. While one goal of genetic epidemiological studies (cf. chapter ▶Statistical Methods in Genetic Epidemiology of this handbook) is to locate susceptibility genes for these complex diseases, it is important that strong evidence of familial aggregation be established at an early stage of research. GEE may be used for detecting familial aggregation and for investigating whether environmental or demographic factors influence these associations (Ziegler et al. 2000).

More generally, any cluster of individuals, including members of a household, children within a class at a school, or patients admitted to a general practitioner in a cluster randomized trial, yield correlated observations (cf. chapter ▶Cluster Randomized Trials of this handbook).

35.2.11 Summary

In all but the last two examples, the mean structure was of primary interest, while it was the association in the final two examples. Although the primary aim was the investigation of the mean structure in the first examples, the correlation within clusters should not be neglected for obtaining correct standard errors. With these various applications, we have shown that clustering between observations may arise from many different sources, including repeated measurements, households, or laterality. Cluster levels may be nested as demonstrated in the example from ophthalmology.

Correlations between sampling units, for example, the subjects in a household, the eyes of a subject, or the time point specific measurement, usually show a positive correlation (Cochran 1963). Examples of negative correlation are uncommon in epidemiology and biostatistics, but the examples given above encounter two. The first is related to litter experiments. Fetuses in a litter might be "competing" with respect to nutrition or other factors like space. The correlation typically depends on litter size, and it might be negative between fetuses according to fetus size. A similar example is the birthweight of human twins (Hanley et al. 2000). In the forest survey example, a spatial periodic variation can be observed (Baradat et al. 1996), and in some examples, it might be described by simple sine curves (Cochran 1963, pp. 218–219). The correlation between trees may therefore be negative. Simply speaking, a huge tree may show a negative correlation to the neighboring tree which might be small. The tree next to the small one may be big like the first tree, resulting in a positive correlation between the first and the third tree. In total, there might be a periodic correlation.

35.3 Introductory Example

In the previous section, we discussed many different areas of application for GEE. In this section, we demonstrate the effect of ignoring the correlation between sampling units. Using a simple example, we first assume that persons living in the same household are independent. Next, we consider a simple approach that allows to adjust for correlation by utilizing the sample size inflation factor (*SSIF*). This approach is, however, not entirely correct and cannot be easily generalized to more complex situations. Finally, we show that a simple GEE analysis yields very similar results as the *SSIF* approach. In contrast to the *SSIF* method, the GEE approach can be generalized easily and is very flexible.

Consider the raw data provided in Table 35.1. Clusters, that is, households, range in size from 1 to 7. Individuals in each of the 30 households were classified as to whether they had consulted a dentist in the past 12 months. A total of $N = 105$ subjects lived in the $n = 30$ households, giving an average household size of $T_a = 3.5$. Fifty-five persons (52.38%) consulted a dentist in the previous year. When we ignore the clustered nature of the data, we can easily estimate the standard error of the mean as usual by $\text{S.E.} = \hat{\sigma} \big/ \sqrt{N} = 0.0490$. The common asymptotic 95% confidence interval (CI) (chapter ▸Sample Size Determination in Epidemiological Studies of this handbook, Eq. 28.2) thus gives (42.78%–61.97%).

If subjects are correlated, the variability is altered. For example, when all subjects in a household either visit a dentist or do not visit a dentist, then the information from just one of the subjects living in the household is sufficient. By interviewing all household members, the sample size is just inflated but the additional subjects do not yield any additional information. If the correlation is not perfect but different from 0, interviewing more than one subject per household gives additional information but not as much as a subject from a new household. Still, there is some inflation in the sample size. If the correlation ϱ between all subjects in a household is identical

Table 35.1 Data on dentist visits for a cluster sample of 30 households

	Households																														Total
n_h	5	6	3	3	2	3	3	3	4	4	2	7	3	4	3	5	4	4	3	3	4	3	3	1	2	4	3	4	2	5	105
n_v	3	5	0	2	1	1	2	1	2	3	1	1	2	3	2	3	3	3	2	1	1	2	1	0	1	2	1	2	1	3	55

n_h number of subjects in household h, n_v number who had visited a dentist in the previous year (Modified from Cochran 1963; Hanley et al. 2000) and if the households are of equal size T, the *sample size inflation (SSIF)* can be shown to be (see Appendix 1)

$$SSIF = 1 + \varrho\,(T - 1)\,, \tag{35.1}$$

and the standard error of the mean correcting for the correlatedness of the data is S.E.$_{\cdot c} = \hat{\sigma}\sqrt{\widehat{SSIF}}\big/\sqrt{N}$ with $N = n\,T$. First, consider the extreme case $\varrho = 0$ of uncorrelated observations, then the *SSIF* equals 1, and no inflation occurs. If at the other extreme, $\varrho = 1$, the *SSIF* equals T, and no information is gained. If the cluster size varies, a simple approximation of T is through the average cluster size T_a.

In our example, the estimated Pearson correlation coefficient is $\hat{\varrho} = -0.07$, thus slightly negative. The *SSIF* is 0.825 so that the standard error corrected for correlation should be approximately S.E.$_{\cdot c} = \hat{\sigma}\sqrt{\widehat{SSIF}}\big/\sqrt{N} \approx 0.0446$, with (43.64%–61.14%) being the corresponding 95% CI. This CI is narrower than the CI ignoring the clustered nature of the data, which was 42.78%–61.97%.

Although the analysis using the *SSIF* is appealing and simple, it is not entirely correct because it relies on two assumptions. First, the correlations between all pairs of subjects living within a household need to be correctly specified. Here, we used the assumption that this correlation is identical. It may, however, vary between household members. For example, it is reasonable that children visit a dentist at least on an annual basis, while adults might not do so. Second, we used the average household size for calculating the SSIF. Household size was, however, not constant, and the degree of information between households of varying size may differ substantially.

In summary, there should be a simple robust approach, with robust meaning that it is valid irrespective of (a) the true correlation structure and (b) the cluster, that is, the household size. The independence estimating equation (IEE), a special and very simple type of GEE analysis, is able to accomplish both goals. If we employ the IEE, we assume that the subjects within a household are independent. As discussed before, this assumption does not hold, but by using a different variance estimator, the GEE approach "automatically" corrects for any misspecification of the variances and/or covariances. In the example, the IEE yield the same point estimate 52.38% for the proportion of subjects who visited a dentist in the previous year, the estimated standard error is 0.0436, and the corresponding 95% CI is given by (43.83%–60.93%). This CI is similar to the CI as obtained by the *SSIF* approach and about 2% narrower than the CI obtained by the naïve method.

IEE and GEE are implemented in various software packages, including SAS `PROC GENMOD`. The code for this simple example is

```
PROC GENMOD;
  CLASS household;
  MODEL visited = ;
  REPEATED SUBJECT = household /TYPE = ind;
run;
```

For application, data are arranged with one subject per row in a data matrix, `household` is a variable indicating the number of the household, and `visited` is a dichotomous variable being 1 if a subject visited a dentist and 0 otherwise. `TYPE = ind`, where `ind` is the abbreviation for "independent," is the option for calling the IEE.

35.4 Population-Averaged Interpretation

The GEE approach differs in fundamental conceptual ways from other models termed "state dependence" or "habit persistence" models. In state dependence models, also termed "conditional models," the response of an observation at time t may depend on responses within the same cluster, not only on some explanatory variables. In habit persistence models, also termed "binary choice models," which are commonly used in econometrics, a similar idea is followed. Here, however, latent variables are modeled which are interpreted as disposition or utility. In analogy to state dependence models, the utility at time point t may depend on the utility at other time points. Very popular in epidemiology are random effect models, where between-cluster variability is explicitly modeled and estimated. For a thorough discussion of these models, the reader may refer to the literature (see, for example, Fahrmeir and Tutz 1994; Lechner et al. 2008).

The GEE approach does not explicitly model between-cluster variation; instead, it focuses on the within-cluster similarity and then uses this estimated correlation to reestimate the regression parameters and to calculate standard errors. However, because the GEE approach does not explicitly model the between-cluster variation, the interpretation of the parameters is that of a population-averaged model, and this will be explained below using an example from Hanley et al. (2003) and Gail et al. (1984). To this end, consider a hypothetical study with extreme variation in the response probability from some clusters to others (Table 35.2). For simplicity, all clusters are of equal size, and exactly 50% of the subjects are exposed. Specifically, suppose that for half of the clusters the response proportion in unexposed subjects is 10%, while it is 50% in the exposed. For the other half of clusters, assume that 50% of the unexposed and 90% of the exposed subjects respond. The difference is 40 percentage points in both groups of clusters, and the odds ratio (*OR*) is 9.0. When the data are aggregated, the difference still is 40 percentage points, but the *OR* is as low as 5.4.

Table 35.2 Hypothetical data for illustrating the interpretation of generalized estimating equations

Clusters	Unexposed (response in %)	Exposed (response in %)	Difference (percentage points)	Odds ratio
1 to $n/2$	10	50	40	9.0
$n/2 + 1$ to n	50	90	40	9.0
Aggregated	30	70	40	5.4

The standard Cochran-Mantel-Haenszel type of analysis "recovers" the within-cluster *OR* of 9.0, as does a logistic regression, when an indicator variable is included for each cluster. Alternatively, one may fit a conditional logistic regression with cluster as stratum variable. However, the GEE approach yields an *OR* of 5.4 as for the aggregated data in Table 35.2. This *OR* of 5.4 contrasts the response probability for an exposed subject selected randomly from the *population* with the response probability for an unexposed subjected also selected randomly from the *population*. The random selection ignores the between-cluster variability and does not match on cluster. This *population-averaged* measure, from the marginal model used in the GEE approach, is specific to the mix of clusters studied. The *OR* of 9.0 contrasts the response probability for an exposed subject with the response probability for an unexposed subject *from the same cluster*, and it is therefore a *subject-specific model*. Both models have their own value, and the choice of the model depends on the interpretation required by the investigator.

35.5 Elements of a Generalized Estimating Equations (GEE) Analysis

The code piece shown at the end of Sect. 35.3 is a simple piece of code. In fact, the five lines already point to implicit assumptions that are made because some elements are not explicitly stated so that the default values are used. The user needs to explicitly or implicitly specify several components for fitting a GEE model. In detail, the following different elements (Box 35.1) need to be chosen by the researcher in any GEE software package (modified from Ballinger 2004; Stokes 1999):

Box 35.1. Important elements for a GEE analysis

1. *Specify the dependent variable.* Mandatory. The dependent variable may be of a type that is suitable for estimation in a GLM. For example, it may be continuous, categorical (ordered or unordered), or dichotomous.
2. *Specify the independent variable(s).* Mandatory but may be left blank. This specification includes coding of variables and modeling of interaction terms.
3. *Specify the link function.* Optional; default: identity link. The link function connects the dependent and the independent variables. For dichotomous dependent variables, the logit link or the probit link are standard choices.
4. *Specify the clustering variable.* Mandatory. The clustering variable indicates the clustering of the dependent variable in the data. Examples for cluster levels include household, family, or subject in case of repeated measurements or laterality.
5. *Specify the distribution of the dependent variable.* Optional; default: normal distribution. Here, the standard option is generally followed; for

example, the binomial distribution is often used for dichotomous variables. However, several choices are possible as will be explained below. The choice of the distribution determines the variance function.

6. *Specify the correlation structure.* Mandatory. Observations within clusters are correlated. The efficiency of estimates may be improved by choosing a correlation structure that is reasonable for the user and that is close to the true correlation structure. Different options for the correlation structure and standard choices will be discussed below.
7. *Specify the statistical tests to be calculated.* Optional; default: no complex statistical tests. In some applications, users are interested in testing more complex hypotheses, and test statistics may be formulated, for example, by contrasts.
8. *Specify the confidence intervals to be estimated.* Optional; default: no complex confidence intervals. In some applications, users are interested in estimating more complex confidence intervals. These can be formulated in some GEE software packages.

Example 35.1. Elements of GEE analysis for introductory example
For the introductory example from Sect. 35.3, data were prepared in a table as shown in Fig. 35.1, and we made the following choices: The dependent variables was `visited`, no independent variables were chosen so that `PROC GENMOD` fitted a model with a regression constant. No link function was specified. Since the identity link $f(x) = x$ is the default, a mean was estimated. Note that we did not choose the logit link although the dependent variable is dichotomous because the aim was to estimate a proportion, that is, the mean of 0–1 variables. The clustering variable was the household. This is indicated by the `REPEATED SUBJECT` statement. The distribution of the dependent variable and the variance function were not specified. Default distribution is the normal distribution in SAS, and the default variance estimator is the standard empirical variance. The option `TYPE = ind` indicates that the independence correlation was chosen, that is, observations were assumed to be uncorrelated. The correction for the within-household correlation was automatically done in `PROC GENMOD` by choosing the variance estimator of the GEE.

Example 35.2. Crossover study
The data from this 2 × 2 crossover example have been utilized for illustration in a series of papers and books on GEE (see, e.g., Jones and Kenward 2003). A total of 67 patients from one center have been treated with both placebo (A, Treat = 0) and an active drug (B, Treat = 1). The order AB or BA in which patients received the two treatments was randomized, and the time point variable is coded as Time = 1 if period 2 and Time = 0 if period 1. The endpoint was whether the electrocardiogram (ECG) was considered to be normal (ECG = 1) or abnormal (ECG = 0). The subject indicating variable is PID. The summary data are displayed in Table 35.3. Thirty-four patients first received the active drug, followed by placebo. Twenty-eight patients had a normal ECG in the first period, only 22 in the second. Four patients with treatment order AB had an abnormal ECG under placebo but a normal ECG when treated with the active drug. The same response pattern, that is, normal ECG for B, abnormal for A, was observed for 6 patients with treatment order BA. Only two patients had a normal ECG under placebo and an abnormal ECG under the active drug, and these two patients had treatment order AB.

	Household	PID	Visit
1	1	1	1
2	1	2	1
3	1	3	1
4	1	4	0
5	1	5	0
6	2	1	1
7	2	2	1
8	2	3	1
9	2	4	1
10	2	5	1
11	2	6	0
12	3	1	0
13	3	2	0
14	3	3	0
15	4	1	1
16	4	2	1
17	4	3	0
18	5	1	1
19	5	2	0

Fig. 35.1 Snapshot of household data from SAS. Displayed is a part of the 30 families. The variable `Household` indicates the household with values from 1 to 30. `PID` is the person identifier within a household, is consecutively numbered from 1 for every household. `Visit` equals 1 if the subject has seen a dentist in the last year, 0 otherwise

Table 35.3 Data from 2 × 2 crossover study

	Responses					Period	
Group	1 1	0 1	1 0	0 0	Total	1	2
BA	22	0	6	6	34	28	22
AB	18	4	2	9	33	20	22

A placebo, B active treatment, BA patients who first received the active treatment, followed by placebo, AB patients who first received placebo, followed by the active treatment (Data from Jones and Kenward 1989)

Subsequently, the important elements of a GEE analysis are:

1 *Dependent variable*: `ecg`.
2 *Independent variables*: `treat` and `time`.
3 *Link function*: The logit link is the natural choice (`LINK = logit`).
4 *Clustering variable*: `pid`.
5 *Distribution of the dependent variable*: Binomial (`DIST = bin`).

6 *Correlation structure*: The standard choice is the independent working correlation (`TYPE = ind`).
7 *Statistical tests to be calculated*: No specific test contrasts required.
8 *Confidence intervals to be estimated*: No specific confidence intervals required.

The SAS code for this example with the choices from above is:

```
PROC GENMOD;
  CLASS pid;
  MODEL ecg = treat time /DIST = bin LINK = logit;
  REPEATED SUBJECT = pid /TYPE = ind;
run;
```

35.6 The Working Correlation Matrix

In this section, we consider common choices of the working correlation matrix, and we illustrate the use of different working correlation matrices with data from the simple 2 × 2 crossover study of Example 35.2. Let the correlation between subjects t and t' of cluster i be $\varrho_{itt'} = \mathbb{C}orr(y_{it}, y_{it'})$. The elements $\varrho_{itt'}$ are summarized to the so-called working correlation matrix. This working correlation matrix need not be correctly specified. It is just used for improving efficiency. Specifically, the closer the *working correlation* is to the *true correlation*, the more efficient the estimates are. Throughout, we assume that different clusters are uncorrelated so that $\mathbb{C}orr(y_{it}, y_{jt'}) = 0$ for $i \neq j$.

Standard choices for working correlation matrices in standard software packages are

- Fixed
- Independent
- Exchangeable
- Autoregressive
- Stationary
- Stationary m-dependent
- Unstructured
- m-dependent

Below, we define the different choices and also consider several working correlation structures that are not standard in all packages.

Fixed Working Correlation Structure A correlation structure which is simple but rarely used in applications is the *fixed* or *user defined working correlation* structure (common abbreviations: FIX, FIXED, USER). Here, the researcher has to pre-specify the entire structure and all values of the correlation matrix. Because correlations between observations are typically unknown a priori in practice, the fixed working correlation structure is rarely used.

Independent Working Correlation Structure The simplest structure is the *independent working correlation* structure (common abbreviations: IND, INDE, INDEP). Here,

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ 0, & \text{if } t \neq t' \end{cases} .$$

No correlation parameter needs to be specified in this case, and the example correlation matrix is

$$\begin{pmatrix} 1 & & & \\ 0 & 1 & & \\ \vdots & \ddots & \ddots & \\ 0 & \cdots & 0 & 1 \end{pmatrix} .$$

This correlation structure reflects the situation in which one assumes that there is no correlation between responses in the same cluster.

Exchangeable Working Correlation Structure The *exchangeable working correlation* structure, also termed *compound symmetry working correlation* structure, is a natural choice in family studies, household studies, that is, in the case of cluster sampling (common abbreviations: EX, EXCH, CS). Here, one assumes that all correlations within a cluster are equal, that is,

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ \varrho, & \text{if } t \neq t' \end{cases} .$$

The correlation matrix has the form

$$\begin{pmatrix} 1 & & & \\ \varrho & 1 & & \\ \vdots & \ddots & \ddots & \\ \varrho & \cdots & \varrho & 1 \end{pmatrix} .$$

The number of parameters to be estimated is 1.

Although this working correlation structure assumes that all observations within a cluster have the same correlation, it is often a good choice even if the true correlation is not identical for all observations in a cluster and between clusters.

Autoregressive Working Correlation Structure A more reasonable working correlation structure than the m-dependent working correlation is the *autoregressive working correlation* (common abbreviations: AR, AR(1)). Specifically, autoregressive refers to the autoregressive model of order 1. The corresponding working correlation structure is given by

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ \varrho^{|t-t'|}, & \text{if } t \neq t' \end{cases} .$$

The correlation matrix thus has the form

$$\begin{pmatrix} 1 & & & \\ \varrho & 1 & & \\ \vdots & \ddots & \ddots & \\ \varrho^{T-1} & \cdots & \varrho & 1 \end{pmatrix} .$$

The number of parameters to be estimated is 1. This working correlation matrix reflects that all observations are correlated. However, there is an exponential decay of the correlation over time.

Stationary Working Correlation Structure Another working correlation structure that is of interest for use with longitudinal data is the *stationary working correlation* (common abbreviations: STA, STAT). Here, it is assumed that all measurements with a specific distance in time have equal correlations. Specifically, it is assumed that observations 1 and 3 have the same correlation as observations 2 and 4 or 5 and 7, and the general definition of the stationary working correlation is

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ \varrho_{|t-t'|}, & \text{if } t \neq t' \end{cases} .$$

The correlation matrix thus has the form

$$\begin{pmatrix} 1 & & & \\ \varrho & 1 & & \\ \vdots & \ddots & \ddots & \\ \varrho_{T-1} & \cdots & \varrho & 1 \end{pmatrix} ,$$

and the number of parameters to be estimated is $T - 1$.

Stationary *m*-Dependent Working Correlation Structure The general definition of the *m-dependent stationary working correlation* structure is

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ \varrho_{|t-t'|}, & \text{if } t \neq t' \text{ and } |t-t'| \leq m \\ 0, & \text{if } |t-t'| > m \end{cases} .$$

The most commonly used form is the 1-dependent working correlation, where adjacent observations are correlated with ϱ_1. All other observations are assumed to be uncorrelated. Its common abbreviation is MDEP(m), where m is a number for the depth. Unfortunately, this working correlation is called m-dependent working correlation structure in most software packages despite its stationarity.

Unstructured Working Correlation The final common working correlation does not make any assumption on a specific structure, and it is therefore called *unstructured working correlation* (common abbreviations: UN, UNSTR). It is defined as

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ \varrho_{tt'}, & \text{if } t \neq t' \end{cases},$$

and the correlation matrix has the form

$$\begin{pmatrix} 1 & & & \\ \varrho_{1,2} & 1 & & \\ \vdots & \ddots & \ddots & \\ \varrho_{1,T} & \cdots & \varrho_{T-1,T} & 1 \end{pmatrix}.$$

The number of parameters to be estimated is $T(T-1)/2$.

This correlation structure involves a large number of parameters that need to be estimated, and it is therefore useful only if there is a natural ordering of the observations within a cluster, for example, because of a longitudinal setting. Furthermore, cluster sizes should be similar because it is not reasonable to estimate a correlation coefficient from one or two pairs of observations. One ideal setting would be a longitudinal study with an equal number of follow-ups such as in the SB-LOT study of Sect. 35.2.3. Here, a natural ordering is given by the time points, and for all patients the same number of follow-ups was considered.

***m*-Dependent Working Correlation Structure** The *m-dependent working correlation* structure is not often used in applications. The assumption is that there is a band of different correlations. All correlations are truncated to zero after the m^{th} band. All other correlations equal the unstructured working correlation. The definition of the m-dependent correlation is

$$\mathbb{C}orr(y_{it}, y_{it'}) = \begin{cases} 1, & \text{if } t = t' \\ \varrho_{tt'}, & \text{if } t < t' \text{ and } |t - t'| \leq m \\ 0, & \text{if } |t - t'| > m \end{cases},$$

and the correlation matrix thus has the form

$$\begin{pmatrix} 1 & & & & & \\ \varrho_{1,2} & 1 & & & & \\ \vdots & \ddots & \ddots & & & \\ \varrho_{1,m} & & \ddots & 1 & & \\ & \ddots & & \ddots & \ddots & \\ \mathbf{0} & & \varrho_{T-m-1,T} & \cdots & \varrho_{T-1,T} & 1 \end{pmatrix} .$$

Nested Working Correlation Standard packages typically do not offer *nested correlation structures* as standard choice for a working correlation. In nested correlation structures, different levels of nesting are present. For example, in dental studies, teeth are nested within patients, and sites around a tooth are nested within teeth. A simple working correlation structure in this situation is

$$\mathbb{C}orr(y_{ie_1t}, y_{ie_2t'}) = \begin{cases} 1, & \text{if } t = t' \text{ and } e_1 = e_2 \\ \varrho_1, & \text{if } t = t' \text{ and } e_1 \neq e_2 \\ \varrho_2, & \text{if } t \neq t' \end{cases} .$$

Here, e_1, e_2 denote, for example, surfaces on the same tooth. Therefore, there might be a correlation ϱ_1 different from 0 between two surfaces e_1 and e_2 at the same tooth t. For $\boldsymbol{y}_i = (y_{i11}, y_{i21}, y_{i12}, y_{i22})'$, an example correlation matrix is given by

$$\begin{pmatrix} 1 & & & \\ \varrho_1 & 1 & & \\ \varrho_2 & \varrho_2 & 1 & \\ \varrho_2 & \varrho_2 & \varrho_1 & 1 \end{pmatrix} .$$

Nested correlation structures may also occur in repeated measurement studies. For example, repeated measurements are nested within a patient, and measurements of both eyes are nested within a measurement time point. As a consequence, there might thus be a correlation between the left and the right eye but also over time. Here, a combination of two different autoregressive structures seems to be appealing. Specifically,

$$\mathbb{C}orr(y_{ie_1t}, y_{ie_2t'}) = \begin{cases} 1, & \text{if } t = t' \text{ and } e_1 = e_2 \\ \varrho_1, & \text{if } t = t' \text{ and } e_1 \neq e_2 \\ \varrho_2^{|t-t'|}, & \text{if } t \neq t' \text{ and } e_1 = e_2 \\ \varrho_3^{|t-t'|}, & \text{if } t \neq t' \text{ and } e_1 \neq e_2 \end{cases}$$

might be an attractive choice in this situation because the correlation decreases over time. For measurements at the same eye, the correlation follows an AR(1) model and thus equals $\varrho_2^{|t-t'|}$. For different eyes at different time points, the correlation also decreases according to an AR(1) model but with a different correlation parameter $\varrho_3^{|t-t'|}$. A difficult choice in this example is the correlation for $t = t'$ and $e_1 \neq e_2$ which is different from 1 and therefore is not conform with the standard AR(1) model, where it should equal 1.

Example 35.3. Crossover study
Return to the data of the 2 × 2 crossover study from Example 35.2. To avoid the correlation between time points, we first analyze the data time point specific using a logistic regression model. Twenty-eight patients out of 34 receiving the active treatment had a normal ECG at the first time point, while only 20 out of 33 had a normal ECG at the first follow-up. At the second follow-up, 22 patients in both groups had a normal ECG. This time, 33 patients were in the active drug and 34 in the placebo group. For the time point specific analyses, the most reasonable choice is a logistic regression model which can be called in SAS using `PROC LOGISTIC`. The data have been named `jones` according to the first author of the book in which the example data have been provided (Jones and Kenward 2003). The model for the dependent variable `ecg` only includes the dummy-coded, that is, 0–1-coded treatment variable `treat`. Using a data step command like

```
if time = 2 then delete;
```

we have already deleted the second time point. The code for the logistic regression model is

```
PROC LOGISTIC DATA=jones;
MODEL ecg = treat;
run;
```

The log odds ratio (log *OR*) of the treatment effect is −1.1097, its standard error 0.5738, and the p-value 0.0531. The *OR* (95% CI in parenthesis) is 0.330 (0.107–1.015). Thus, there is a tendency for a superiority of the active treatment over placebo. But when only the first time point is considered, it is not significant at the 5% test level.
Similarly, when only the second time point is considered, the finding is not significant. Specifically, the *OR* (95% CI in parenthesis) is 0.917 (0.334–2.515), and the p-value is 0.8658.

With the GEE, the data from both time points can be combined and analyzed jointly. At the same time, the correlation between observations at time points 1 and 2 is adequately taken into account. This is not the case for the logistic regression. For the logistic regression model

```
PROC LOGISTIC DATA=jones;
MODEL ecg = time treat;
run;
```

which considers both the time point and the treatment effect but ignores the correlation of observations over time, the *OR* (95% CI) for the treatment effect is 0.571 (0.273–1.202), and the p-value 0.1403. The correlation between responses and the time point is slightly negative ($\hat{\varrho} = -0.0643$) as in the introductory example of Sect. 35.3. We can therefore expect an decrease of the p-value when the correlation is adequately taken into account by using the independent working correlation matrix.
As already indicated above, the distribution chosen is the binomial distribution. This leads to the option `dist = b` in `PROC GENMOD`. The link function is the logit link, indicated in the syntax through the option `link = logit`. The cluster variable is `pid`. It needs

to be used twice in the SAS code. First, it has to be declared as a class variable `CLASS pid`. Second, it has to be declared in the `REPEATED` statement. Unfortunately, SAS does not use a "cluster statement" but a "repeated statement." This statement has to be used even if the data are of a different clustered nature than repeated. For example, in dental studies, measurements between different teeth are commonly correlated, and the repeated subject variable is the patient. In the present example, there is indeed a repetition of the ECG measurement over time.

In the simplest case, the working correlation is assumed to be the independent working correlation, and the corresponding option is `TYPE = ind`. The SAS code therefore is

```
PROC GENMOD DATA=jones;
CLASS pid;
MODEL ecg = time treat /dist = b link = logit;
REPEATED SUBJECT = pid /TYPE = ind;
run;
```

This analysis results in a significant treatment effect, and the *OR* (95% CI) is 0.572 (0.362–0.904) with $p = 0.0167$.

The results are similar when the probit link is used. In the code given above, only the option `link = logit` needs to be replaced by `link = probit`. Here, the parameter estimates cannot be interpreted in terms of log *OR*s or *OR*s. The p-value is, however, very similar with $p = 0.0149$.

Because the correlation coefficient between the responses and the time point, that is, over time, is approximately -0.06, we can also estimate the GEE with a fixed working correlation. The SAS code is

```
PROC GENMOD DATA=jones;
  CLASS pid;
  MODEL ecg = time treat /dist = b link = logit;
  REPEATED SUBJECT = pid /TYPE = fixed( 1.00 -0.06
                                        -0.06  1.00 )
                                corrw;
run;
```

The option `TYPE = fixed` calls for a fixed, that is, pre-specified, working correlation matrix. This matrix is a 2 × 2 matrix because there are only two observations per subject in this example. The entries are 1s on the diagonal and -0.06 off the diagonal. The option `corrw` prints the working correlation matrix. The treatment effect is 0.5732 in this case, the 95% CI (0.3628–0.9057), and the p-value equals 0.0171.

Because the working correlation matrix is only of size 2 × 2, GEE working correlation structures yield the same estimated working correlation coefficient, when the correlation coefficient is estimated. Subsequently, the parameter estimates for the treatment effect are identical for these models. This means that the estimates for the exchangeable working correlation, the AR(1) working correlation, and the m-dependent working correlation all are equal. For example, the AR(1) working correlation model is estimated by

```
PROC GENMOD DATA=jones;
  CLASS pid;
  MODEL ecg = time treat /dist = b link = logit;
  REPEATED SUBJECT = pid /TYPE = exch corrw;
run;
```

This model gives an *OR* of 0.5661 with a 95% CI of (0.3588–0.8932). The p-value is 0.0145.

The estimated working correlation coefficient of this model is 0.64, thus extremely high for binary dependent data. The estimate of the working correlation coefficient is substantially different from the crude correlation coefficient of −0.06 which was estimated from the data by ignoring the treatment variable. Nevertheless, the parameter estimates of all models considered in this section were very similar which can be explained by theoretical findings (for references, see, e.g., Ziegler et al. 1998).

Finally, we note that the model considered so far does not include an interaction term between time point and treatment for measuring a carry-over effect. An interaction term can be added by simple using the product sign *.

```
PROC GENMOD DATA=jones;
  CLASS pid;
  MODEL ecg = time treat time * treat
                          /dist = b link = logit;
  REPEATED SUBJECT = pid /TYPE = ind;
run;
```

The p-value for the log *OR* of the carry-over effect appears to be 0.2962 in this example, thus not statistically significant at the 5% test level. Therefore, the carry-over effect is neglected in this model.

35.7 Sample Size Calculations

Sample size and power calculations are especially important for clinical epidemiological studies, where researchers aim at testing a specific pre-specified hypothesis. The simplest approach is to calculate the sample size by ignoring the clustered nature of the data, that is, perform the calculation as if observations were independent. Clustering can then be adjusted for by using the sample size inflation factor (Hsieh et al. 2003). An alternative approach is to use a sample size calculation approach specifically tailored for correlated response data, and a detailed review has been given by Dahmen and Ziegler (2004) (also see Davis 2002, pp. 310; for recent original work, see Ogungbenro et al. 2006; Tu et al. 2004). In a separate paper, we have presented a flexible SAS/IML macro called GEESIZE for sample size calculations (Dahmen et al. 2004) as an extension of the pioneering work by Rochon (1998). The macro is freely available from imbs-luebeck.de. The macro GEESIZE was validated by comparing the computed required sample size with results from closed formulae for two different parallel group study designs. Specifically, binary response variables with unequal cluster sizes were considered for testing a treatment effect, and rates of change in repeated measurements were validated (slope testing) for continuous outcome variables. Results from GEESIZE are also identical to those obtained by closed formulae for crossover designs. With GEESIZE, staggered entry and loss to follow-up can be dealt with, both leading to unequal cluster sizes. The theory underlying GEESIZE and all necessary formulae have been given by Dahmen et al. (2004). Here, we illustrate the use of GEESIZE by recalculating the sample size for the SB-LOT study from Sect. 35.2.3.

Example 35.4. Sample size calculation with GEESIZE
The SB-LOT study described in Sect. 35.2.3 forms the basis of this example. The aim is to demonstrate the edema-protective effect of a vasoactive drug in patients suffering from chronic venous insufficiency after decongestion of the legs. To this end, a double-blind two-arm placebo-controlled 1:1 randomized trial is planned with 5 equidistant follow-ups at weeks 0, 4, 8, 12, and 16 weeks after randomization. Patients either receive the active treatment, that is, medical compression stockings plus SB-LOT, or medical compression stockings plus placebo. The primary endpoint is the continuous variable lower leg volume.

In the original plan of the study, the primary endpoint was the difference of the lower leg volume after the end of the treatment period as compared with baseline. Sample size estimation was based on a standardized difference of 0.4 which was obtained from previous publications. At the one-sided 5% test level α and a power of 0.8 with a dropout rate of 20%, that is, early withdrawals for reasons not related to the efficacy, a sample size of 102 per group was planned (Vanscheidt et al. 2002).

For sample size calculations using GEE, additional assumptions are required. First, the primary hypothesis is now based on slope testing between treatments arms. The link function is the identity link (see _LINK_ in the example code), so that the mean of the dependent variable y_{it} of subject i at time point t given the covariates $\boldsymbol{x}_{it}$ is given by

$$\mathbb{E}(y_{it}|\boldsymbol{x}_{it}) = \mu_{it} = \beta_1 + \beta_2 x_i^{\text{Treat}} + \beta_3 x_{it}^{\text{Time}} + \beta_4 x_i^{\text{Treat}} \cdot x_{it}^{\text{Time}}$$

for the parameters of interest $\beta_1, \ldots, \beta_4$. Because the primary endpoint is quantitative, we use the normal distribution (see _VARI_ in the example code). There are five different time points in total, and the design matrix $\boldsymbol{X}_i$ of a subject i therefore has five rows. Each row consists in four columns: (1) the intercept, (2) the treatment effect is cluster constant and coded as $x_{it} = x_i = 1$ if active treatment, and 0 otherwise, (3) the time point with values from 0 to 4 (see _TIMES_ in the example code), and (4) the treatment by time interaction. The design matrix of a subject in the placebo and the control group are therefore (see _X_ in the example code)

$$\text{Placebo} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 2 & 0 \\ 1 & 0 & 3 & 0 \\ 1 & 0 & 4 & 0 \end{pmatrix}, \qquad \text{Treatment} = \begin{pmatrix} 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 \\ 1 & 1 & 2 & 2 \\ 1 & 1 & 3 & 3 \\ 1 & 1 & 4 & 4 \end{pmatrix}.$$

The hypothesis of interest is

$$H_0 : \beta_4 = 0 \quad \text{versus} \quad H_1 : \beta_4 > 0\,.$$

Because the general hypothesis consists in a single test, the test matrix H has a single row and is equal to $H = (0\;0\;0\;1)$ (see _H_ in the example code).

For the sample size calculation with GEESIZE, we utilize all follow-ups. We assume that no volume difference can be observed in the treatment group over time. However, we assume a linear decrease of the lower leg volume over time. Specifically, the lower leg volume at baseline is assumed to be 2,250 ml in both groups and linearly increases to 2,370 ml at the final follow-up in the placebo group (see _MU_ in the example code). We assume a common standard deviation of 300 ml. These assumptions are consistent with the standardized treatment difference of 0.4 from the published study. Furthermore, we assume a high correlation of $\varrho = 0.9$ (see _RHO_ in the example code) and an AR(1) as true correlation structure (see _PSI_ in the example code). The working correlation is assumed to be the identity matrix; this calculation is automatically carried out. If we assume no dropout, a 5% test level, and a power of 80%, we require 71 patients per group for testing the two-sided hypothesis which is the default in GEESIZE.

If we assume a monotone dropout of 5% for every follow-up, 5.5% of the sample is lost at time point 1, $0.0520 = (1 - 0.055)^2$ is lost at time point 2, $0.0491 = (1 - 0.055)^3$ at time point 3, and 0.0464 at time point 4. Subsequently, 79.75% of the sample is observed at the final follow-up. In the program, these percentages are summarized per group in the matrix _TAU_. Note that these calculations do not include staggered entry which is explained in detail in Dahmen et al. (2004). With these assumptions, we require 97 patients per group. This assumption corresponds to a drop out of approximately 20% at the end of the treatment period. In the original study plan, a one-sided hypothesis was formulated. For a comparison, we also calculate the required sample size using the one-sided hypothesis. If we assume no dropout, we require 56 patients per group, and with a monotone dropout of 5% per visit, we require 76 patients per group. Subsequently, the required sample size would have been lower for the GEE approach.

If the correlation drops, more patients are required. For example, if $\varrho = 0.8$ instead of 0.9, 148 patients would be required per group instead of 97. In contrast, 64 patients per group would be necessary at $\varrho = 0.95$.

35.8 Illustrative Data Analysis: GEE Analysis for a Parallel Group Design with Repeated Measurements: The SB-LOT Data

In this section, we consider the reanalysis of data from a parallel group randomized controlled trial with repeated measurements. The basic structure and design of this study has been described in Sect. 35.2.3. The primary aim of this study was to demonstrate an edema-protective effect of the vasoactive drug SB-LOT when compared with placebo. The primary analysis was a baseline-adjusted covariance analysis (ANCOVA) for the difference of the lower leg volume at the final visit minus the lower leg volume at baseline for demonstrating a difference of the vasoactive drug when compared with placebo (Vanscheidt et al. 2002). The secondary analysis, which will be presented here, aims at detecting a difference in the slopes by making use of the repeatedness nature of the data. Because the correlation between the measurements at different time points is considered nuisance, this reanalysis represents a typical setting for a GEE analysis.

35.8.1 Descriptive Statistics

In the double-blind placebo-controlled randomized multicenter SB-LOT trial, the primary efficacy endpoint was the lower leg volume measured by water plethysmometry. Patients were randomized to SB-LOT or placebo at baseline. In the first 4 weeks, all patients wore medical compression stockings. At the first follow-up, that is, 4 weeks after randomization, the stockings were discontinued in both treatment groups. Subsequently, the investigators expected an increase in the lower leg volume at subsequent follow-ups in the placebo group, while the lower leg volume was expected to be constant in the active treatment group SB-LOT (see Fig. 35.2). The additional follow-up times were 6, 8, 12, and 16 weeks after randomization. Thus, follow-ups were not equally spaced, and the number of patients is 113 per treatment group. Table 35.4 displays the lower leg volume (ml) in the course of the trial for these patients. The correlation between observations at different time points is high, and the crude correlation estimates are displayed in Table 35.5.

35.8.2 Standard GEE Analysis

For the GEE analysis, we use the lower leg volume at time t as dependent variable y_{it}. Because time points x_{it}^{Time} are not equally spaced in this study, they are

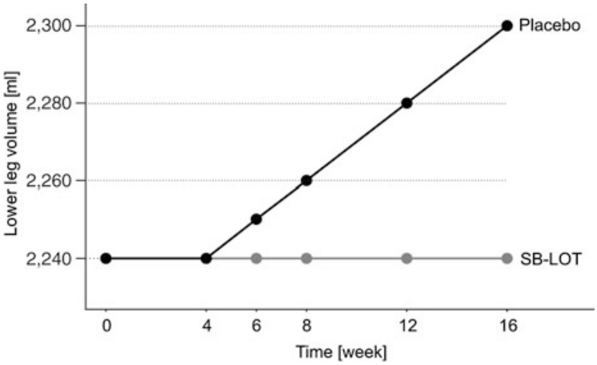

Fig. 35.2 Expected course of the trial. At randomization (week 0), both patients groups are expected to have identical lower leg volumes. Medical compression stockings are discontinued at week 4, and after week 4, the lower leg volume should increase linearly in the placebo group, while it should remain constant in the SB-LOT group

Week 12	0.9593	0.9973	0.9973	1.0000	0.9973
Week 16	0.9403	0.9971	0.9973	0.9973	1.0000

coded with values according to follow-up weeks starting with $t = 0$ for baseline. Treatment groups have been coded with 1 for placebo and 0 for SB-LOT, that is,

$$x_{it}^{\text{Treat}} = \begin{cases} 1, & \text{if placebo} \\ 0, & \text{if SB-LOT} \end{cases} .$$

Because of the continued use of medical compression stockings, the lower leg volume is expected to be equal after 4 weeks between both treatment arms (see Fig. 35.2). However, the slope should be different in subsequent weeks. Therefore, the model of interest for the mean structure is given by

$$\mathbb{E}(y_{it}) = \beta_1 + \beta_2 x_{it}^{\text{Treat}} + \beta_3 x_{it}^{\text{Time}} + \beta_4 x_{it}^{\text{Treat}} \cdot x_{it}^{\text{Time}}, \quad t = 4, 6, 8, 12, 16 . \quad (35.2)$$

Table 35.6 displays the result from the IEE analysis, and the example code is given below. In the example, `pid` is the person identification date, and the option `type3` requests Type III sum of squares. Because we are interested in slope testing, the parameter of interest Treatment × Time, that is, β_4, is

Table 35.6 Independence estimating equations (IEE) analysis for SB-LOT versus placebo

Parameter	Estimate	Std.Err.	95% CI		z	p

Treatment β_2	9.48	48.51	−85.60	104.56	0.20	0.8451
Time β_3	0.48	0.93	−1.34	2.31	0.52	0.6045
Treatment × Time β_4	2.51	1.27	0.02	5.00	1.97	0.0484

113 patients per group; *Std.Err.* robust standard error, *CI* confidence interval, z z-score (value of test statistic), p two-sided p-value

displayed in the last row of Table 35.6. Analogously to the ANCOVA model of Vanscheidt et al. (2002), the IEE shows an advantage for SB-LOT over placebo because the slope is significant at the 5% test level ($p = 0.0484$). In greater detail, the difference in the lower leg volume between SB-LOT and placebo increases by 2.51 ml per week, making a difference of 30 ml at the end of the observation period, that is, 12 weeks are discontinuation of medical compression stockings.

35.8.3 Different Working Correlation Structures

An interesting aspect is whether the model can be substantially improved by using a working correlation matrix which is not the identity matrix. Because measurements are repeated, the natural choice for a working correlation matrix would be an autoregressive working correlation of order 1. However, follow-ups are not equally spaced so that observations at time points 4 and 6 weeks are neighboring as well as observations at time points 8 and 12 weeks. An important assumption in standard GEE packages is that they assume equally spaced follow-ups. Subsequently, choosing AR(1) as working correlation for these data implies that the estimated correlation coefficient can hardly be interpreted. Nevertheless, the estimated working correlation may be used as weight for improving the model fit. Other working correlation matrices may be chosen as well, such as the 1-dependent working correlation or the exchangeable working correlation. The reader should note that even the use of the 1-dependent working correlation does not result in an easily interpretable correlation coefficient because the unequally spaced observations are used for estimating the correlation parameter. Again, the use of a working correlation coefficient might improve the fit, but an interpretation of the estimates is not intended in this example.

Table 35.7 displays the results of several GEE models with different working correlation structures for the slope coefficient β_4, and Table 35.8 gives the estimated

Table 35.7 GEE analysis using various working correlation structures for SB-LOT versus placebo. The parameter estimate (Est.) is the slope coefficient $\hat{\beta}_4$

Correlation	Est.	S.E.	95% CI		z	p	$\hat{\varrho}$

Week 12	0.9530	0.9924	0.9891	1.0000	0.9828
Week 16	0.9210	0.9568	0.9576	0.9828	1.0000

correlation coefficients for the unstructured working correlation model from the last row of Table 35.7. Estimates from the IEE and the exchangeable GEE are identical, and estimates from the autoregressive model AR(1) as well as the 1-dependent model are similar in contrast to the estimates from the unstructured working correlation model. The identity of the exchangeable GEE and the IEE can be explained by the theoretical findings of Mancl and Leroux (1996) and Wang and Carey (2003).

The results for the unstructured working correlation model are substantially different. For example, the parameter estimate of the slope coefficient does not agree with the findings of the descriptive statistics (Table 35.4). The results are not reliable, and this can be explained by the instability of the robust covariance matrix. Note that the term robustness refers to the model properties. However, the estimation aspect is a different one. The instability can be investigated by the condition of a covariance matrix which is the ratio of its largest and smallest eigenvalue, and it should not exceed 12.

35.9 Conclusions

In this section, we first discuss the aspect of efficiency of GEE to some extent. Second, we consider several generalizations of the GEE approach. First, the GEE approach does not rely on a correctly specified likelihood function. As there is no free lunch, this robustness property of GEE on the one hand comes at the cost of a loss of efficiency on the other as shown by Chaganty and Joe (2004). The loss in efficiency can be substantial. For example, if the robust variance estimator is used in the standard linear model for a two-arm parallel group study, the GEE variance is twice as large as the standard maximum-likelihood variance estimator; for details, see Ziegler (2011). Because the formulation and presentation of the general results is cumbersome, the reader may refer to Kauermann and Carroll (2001). Therefore, an important question is how the optimal choice of the working correlation matrix can be determined which leads to a minimal loss in efficiency. Furthermore, is it really the efficiency that drives the choice of the working correlation matrix? The simplest choice is the independent working correlation matrix leading to the IEE.

If possible, the investigator should choose a specific working correlation structure for both statistical and biological reasons (Ziegler and Vens 2010). While it is probably intuitive to the reader what is meant by biological plausibility, the statistical reasons for choosing a specific correlation matrix still need to be described. First, using several arguments, the IEE are recommended in clinical epidemiological studies when dropout is not too extreme (Dahmen and Ziegler 2004). Furthermore, as a simple guide, for cluster-type samples, including households or families, the exchangeable working correlation can be used. For longitudinal data, the AR(1) working correlation should be preferred over banded correlation structures (Wang and Carey 2003). Furthermore, m-dependent correlation structures are not biologically plausible. For weakly dependent dichotomous dependent variables, the IEE might be the working correlation structure of choice. An alternative statistical approach is to select the most reasonable working correlation matrix using standard model selection approaches, such as a modification of Akaike's information criterion (AIC), termed quasi-likelihood information criterion (QIC), or bootstrap stability estimates (Cui and Qian 2007; Hin and Wang 2009; Pan 2001a, b; Pan and Connett 2002).

The QIC can also be used for selecting the best mean structure. Alternative approaches for mean structure selection have been considered in several papers. Following the traditional significance testing way, Nuamah et al. (1996) presented an SAS macro for stepwise variable selection. A similar approach is followed by Cantoni (2004). For alternative approaches, the reader may refer to the literature (Pan 2001b; Pan and Connett 2002; Cantoni et al. 2005).

The variance estimator used in GEE is robust against misspecification of the true covariance matrix of the responses. However, it allows valid inferences only if the number of clusters is sufficiently large. In small samples, it has been shown that the null hypothesis is rejected more often than it should; the robust variance estimator is biased and too liberal. This is severe for a very small number of clusters ($n < 20$) but still a problem with as many as 50 clusters. It is worse for unequal cluster sizes than for equal cluster sizes and more extreme for more complex hypotheses. To overcome the liberality and biasedness, a series of modifications has been proposed (for overviews, see, e.g., Dahmen and Ziegler 2004, 2006).

The simple mean is strongly affected by an observation that is far from the rest of the data. In GEE analyses, parameter estimates can also be strongly influenced by outliers which may be clusters, a single cluster or even a single observation. Therefore, the change in parameter estimates is investigated in regression diagnostics if a single observation or a cluster is deleted from the analysis. Corresponding statistics are often called deletion diagnostics. Regression diagnostic techniques that are used in the linear model (Belsley et al. 1980; Cook and Weisberg 1982) or in GLM (Thomas and Cook 1989) can be generalized to the GEE (Vens and Ziegler 2012; Preisser and Perin 2007). Goodness of fit (GOF) statistics for the logistic GEE, including the well-known Tsiatis and Hosmer-Lemeshow type of GOF statistics, have been proposed in a series of different papers, and an excellent summary has been given by Evans and Li (2005).

Because of the clustered nature of the data, two scenarios can be distinguished: the investigation of residuals and deletion diagnostics for one observation and residuals and deletion diagnostics for an entire cluster. Residuals for GEE and the Cook statistic as deletion diagnostic for GEE have been introduced by Ziegler and Arminger (1996). We stress that we have defined the Cook statistic in a way that it does not rely on the correct specification of the covariance matrix. We therefore prefer our regression diagnostics over the definition by Hammill and Preisser (2006) and Venezuela et al. (2007) who use the usual maximum-likelihood-based approach for defining the Cook statistic.

Further regression diagnostics have been proposed, including perturbation methods (Jung 2008). Finally, we stress that the practical computation of the various regression diagnostics is computer time consuming. Therefore, a series of different algorithms has been proposed in recent years (Preisser and Perin 2007; Preisser et al. 2008; Wei and Fung 1999). Standard regression diagnostics are available only in a few standard packages, including a SAS/IML macro (Hammill and Preisser 2006) and `PROC GENMOD` (SAS ver. 9.2).

All analyses discussed so far are applicable to complete data sets or those where data are missing completely at random. This term describes the situation that missing data in the dependent variable y_{it} at time t does not depend on the value of the dependent variable $y_{it'}$ at any other time point t', $t \neq t'$. If, however, systematic differences between complete and incomplete clusters exist and if they are ignored, parameter estimates based on these naïve approaches may be biased and conclusions may be misleading (Rotnitzky and Wypij 1994); for a detailed discussion on missing data, see chapter ▶Missing Data of this handbook.

Although a series of approaches for dealing with missing data in the context of GEE have been proposed, they have rarely been applied in practice because they are hardly available in standard software. Much attention has been given to the situation where some data in the dependent variables from a cluster may be missing, and these are reviewed in Dahmen and Ziegler (2004).

Basically, three different techniques can be distinguished. The first is a two-step method for binary-dependent variables that applies the expectation maximization (EM) algorithm in the first step to obtain unrestricted estimates of multinomial probabilities (Fitzmaurice and Laird 1993). In the second step, the parameter vector of interest is estimated using the estimated response vectors. Two well-known semi-parametric alternatives are imputation methods (Paik 1997) and weighting methods (Robins et al. 1995). The concepts underlying these approaches are intuitive and appealing. Imputation methods replace missing data with estimated values so that a seemingly complete data set emerges. By contrast, weighting methods discard the incomplete data but weigh observations inversely proportional to the probability of observing a response. Imputation and weighting are different, in general, but they yield identical results under specific circumstances (Paik 1997).

Less emphasis has been put on missing covariates. As for missing data in the y, imputation approaches (Xie and Paik 1997a, b) and weighting methods are available (Robins et al. 1994).

In all previous sections, the aim was to consistently estimate the mean structure. The resulting estimating equations are termed GEE in this chapter, and they are usually named GEE1 in the literature. In some applications, the investigator is interested in the estimation of both the mean and the association structure. If both the mean and the association structure are of primary interest, the GEE considered in this chapter can be generalized, and they are usually termed GEE2. For the GEE2 approaches, the reader may refer to the literature (for detailed overviews, see, for example, Liang et al. 1992; Ziegler et al. 1998; Ziegler 2011).

Acknowledgements The author is grateful to Dr. Hans-Heinrich Henneicke-von Zepelin for making the SB-LOT data available and to Dr. Gerlinde Dahmen for analyzing the SB-LOT data.

Appendix 1: Sample Size Inflation Factor

In this appendix, the simple formula of Eq. 35.1 for the sample size inflation factor (SSIF) is derived. For simplicity, we denote $\boldsymbol{y}_i = (y_{i1}, \ldots, y_{iT})'$ for $i = 1, \ldots, n$. The $\boldsymbol{y}_i$ are assumed to be independently identically distributed with element-wise mean $\mathbb{E}(y_{it}) = \mu$, variances given by $\mathbb{V}ar(y_{it}) = \sigma^2$, and covariances given by $\mathbb{C}ov(y_{it}, y_{it'}) = \sigma_{xy}$ for $t = 1, \ldots, T$ and $t \neq t'$. Finally, we let $\mathbb{C}orr(y_{it}, y_{it'}) = \varrho_{xy} = \sigma_{xy} / \sigma^2$.

The simple mean estimator $\bar{y} = \frac{1}{nT} \sum_{i=1}^n \sum_{t=1}^T y_{it}$ is unbiased, and $\mathbb{V}ar(\bar{y})$ reduces to

$$\begin{aligned}
\mathbb{V}ar(\bar{y}) &= \tfrac{1}{n^2T^2} \sum_{i=1}^{n} \mathbb{V}ar\big(\textstyle\sum_{t=1}^T y_{it}\big) \\
&= \tfrac{1}{nT^2}\big(\textstyle\sum_{t=1}^T \mathbb{V}ar(y_{it}) + \tfrac{T(T-1)}{2} 2\mathbb{C}ov(y_{it}, y_{it'})\big) \\
&= \tfrac{1}{nT^2}\big(T\sigma^2 + T(T-1)\sigma_{xy}\big) = \tfrac{1}{nT^2}\big(T\sigma^2 + T(T-1)\sigma^2\varrho_{xy}\big) \\
&= \tfrac{\sigma^2}{nT}\big(1 + (T-1)\varrho_{xy}\big) = \frac{\sigma^2}{nT}\text{SSIF}
\end{aligned}$$

for $t \neq t'$.

Appendix 2: The Roots of the Generalized Estimating Equations (GEE) and Their Statistical Properties

In this section, we consider the roots of the GEE and the statistical properties of the estimator. This section may be ignored by readers who are not interested in technical details. First, we briefly discuss generalized least squares (GLS) and the resulting Aitken estimator, followed by feasible generalized least squares (FGLS). The Aitken estimator based on GLS or FGLS is restricted to continuous dependent variables but allows a general covariance structure. In contrast, the GLM is flexible with respect to the distribution of the responses. These might be continuous, dichotomous, or counts. However, the standard GLM does not allow for correlation between responses. The GEE can be considered a natural combination of both approaches. The GEE are formulated, and their properties are given.

A 2.1 Generalized Least Squares

First, consider the standard linear model for clustered data. Let n be the number of clusters $i = 1, \ldots, n$, and, for simplicity, assume that there are T observations per cluster. The method can easily be generalized to unequal cluster sizes T_i. For each y_{it}, a p dimensional vector of covariates $\boldsymbol{x}_{it}$ is available that possibly contains an intercept. Data are collected in column vectors $\boldsymbol{y}_i = (y_{i1}, \ldots, y_{iT})'$ and the $T \times p$ matrices $\boldsymbol{X}_i = (\boldsymbol{x}'_{i1}, \ldots, \boldsymbol{x}'_{iT})'$. In the context of GEE, the stacked matrix of the $\boldsymbol{X}_i$ is usually termed *X matrix* or *design matrix for the mean structure*, although it need not be a design matrix but may be any matrix of observations.

In this section, we consider modeling of the mean structure of y_{it} given $\boldsymbol{x}_{it}$, and the regression model should allow for correlation within clusters. In the linear model, such an approach is well-known under terms like Aitken estimator or feasible generalized least squares (FGLS). The respective linear model for the mean structure is given by

$$\mu_{it} = \mathbb{E}(y_{it}|\boldsymbol{X}_i) = \mathbb{E}(y_{it}|\boldsymbol{x}_{it}) = \boldsymbol{x}'_{it}\boldsymbol{\beta} = \beta_1 x_{i1t} + \beta_2 x_{i2t} + \ldots + \beta_p x_{ipt}\,, \quad (35.3)$$

where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$ is the unknown $p \times 1$ parameter vector of interest. The reader should note that Eq. 35.3 includes the assumption $\mathbb{E}(y_{it}|\boldsymbol{X}_i) = \mathbb{E}(y_{it}|\boldsymbol{x}_{it})$. This means that only the time point specific covariate $\boldsymbol{x}_{it}$ has an effect on the observation y_{it} at time point t. A possible effect of future or past observations is neglected. This assumption has been discussed in detail by Pepe and Anderson (1994) and Pan et al. (2002). Here, we only stress that this assumption is implicitly made in many GEE packages, and it might be violated in family studies. For example, parental smoking might well have an effect on the health status of the entire family, including the offspring.

In the following, we also assume that the covariance matrix of the vector $\boldsymbol{y}_i$ is correctly specified, known, and given by

$$\mathbb{C}ov(\boldsymbol{y}_i|\boldsymbol{X}_i) = \boldsymbol{\Sigma}_i \,. \tag{35.4}$$

Subsequently, the *generalized least squares (GLS) estimator* or *Aitken estimator* $\hat{\boldsymbol{\beta}}$ for $\boldsymbol{\beta}$ is given by

$$\hat{\boldsymbol{\beta}} = \left(\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\boldsymbol{X}\right)^{-1}\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\boldsymbol{y} = \left(\sum_{i=1}^{n}\boldsymbol{X}_i'\boldsymbol{\Sigma}_i^{-1}\boldsymbol{X}_i\right)^{-1}\sum_{i=1}^{n}\boldsymbol{X}_i'\boldsymbol{\Sigma}_i^{-1}\boldsymbol{y}_i \,, \tag{35.5}$$

where $\boldsymbol{X}$ and $\boldsymbol{y}$ are obtained by stacking $\boldsymbol{X}_i$ and $\boldsymbol{y}_i$, and $\boldsymbol{\Sigma}$ is the block diagonal matrix of the matrices $\boldsymbol{\Sigma}_i$. This estimator is based on the score function

$$\boldsymbol{u}(\boldsymbol{\beta}) = \frac{1}{n}\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}(\boldsymbol{y}-\boldsymbol{\mu}) = \frac{1}{n}\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}(\boldsymbol{y}-\boldsymbol{X}\boldsymbol{\beta})\,,$$

where $\boldsymbol{\mu}_i = (\mu_{i1},\ldots,\mu_{iT})' = \boldsymbol{X}_i\boldsymbol{\beta}$ and $\boldsymbol{\mu}$ is the stacked vector of the $\boldsymbol{\mu}_i$. An estimator $\hat{\boldsymbol{\beta}}$ is obtained by solving $\boldsymbol{u}(\hat{\boldsymbol{\beta}}) = \boldsymbol{0}$. The estimator $\hat{\boldsymbol{\beta}}$ is unbiased, and its covariance matrix is given by

$$\mathbb{V}ar\big(\hat{\boldsymbol{\beta}}\big) = \left(\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\boldsymbol{X}\right)^{-1} = \boldsymbol{A}^{-1}\,. \tag{35.6}$$

$\hat{\boldsymbol{\beta}}$ is the Gauss-Markov estimator, thus it has the smallest variance among all linear unbiased estimators. $\hat{\boldsymbol{\beta}}$ is finite normally distributed if $\boldsymbol{y}_i$ given $\boldsymbol{X}_i$ is normally distributed. If y_i given X_i is not normally distributed, $\hat{\beta}$ is asymptotically normal for $n \to \infty$. The matrix $\boldsymbol{A} = -\mathbb{E}(\partial\boldsymbol{u}(\boldsymbol{\beta})/\partial\boldsymbol{\beta})$ is the *Fisher information matrix.*

Now, we consider the case that estimation is based on the covariance matrix $\boldsymbol{\Sigma}_i$ which has been defined in Eq. 35.4 although

$$\mathbb{V}ar(\boldsymbol{y}_i|\boldsymbol{X}_i) = \boldsymbol{\Omega}_i \neq \boldsymbol{\Sigma}_i \tag{35.7}$$

holds. Equation 35.7 means that $\boldsymbol{\Omega}_i$ is the *true covariance matrix* and that the true covariance matrix is different from the *assumed covariance matrix* $\boldsymbol{\Sigma}_i$ which is used in the linear model. In this case, the estimator $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$ obtained by Eq. 35.5 remains consistent. The covariance matrix of Eq. 35.6 is, however, no longer appropriate as the assumed covariance matrix $\boldsymbol{\Sigma}_i$, that is, the assumed model, is different from the true one. Subsequently, conclusions-based tests or confidence intervals utilizing the covariance matrix from Eq. 35.6 might be wrong. Instead, one should use the covariance matrix

$$\mathbb{V}ar\big(\hat{\boldsymbol{\beta}}\big) = \left(\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\boldsymbol{X}\right)^{-1}\left(\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\boldsymbol{\Omega}\,\boldsymbol{\Sigma}^{-1}\boldsymbol{X}\right)\left(\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\boldsymbol{X}\right)^{-1} = \boldsymbol{A}^{-1}\boldsymbol{B}\boldsymbol{A}^{-1}\,, \tag{35.8}$$

where $\boldsymbol{\Omega}$ is a block diagonal matrix of $\boldsymbol{\Omega}_i$. This estimator is obtained from simple calculations using $\hat{\boldsymbol{\beta}}$ from Eq. 35.5 and using $\mathbb{V}ar(\boldsymbol{y}|\boldsymbol{X}) = \boldsymbol{\Omega}$. As before, $\hat{\boldsymbol{\beta}}$ is finite normally distributed for normally distributed $\boldsymbol{y}_i$. Otherwise, $\hat{\boldsymbol{\beta}}$ is asymptotically normal for $n \to \infty$. Furthermore, $\boldsymbol{A}^{-1}$ is the inverse Fisher information matrix.

$\boldsymbol{B}$ is termed the *outer product gradient (OPG)* because it can be derived as expected value of the outer product of the gradient $\boldsymbol{u}(\boldsymbol{\beta})$, that is, $\boldsymbol{B}(\boldsymbol{\beta}) = \mathbb{E}\big(\boldsymbol{u}(\boldsymbol{\beta})\boldsymbol{u}(\boldsymbol{\beta})'\big)$.

However, the true covariance matrix of $\hat{\boldsymbol{\beta}}$ is unknown because $\boldsymbol{\Omega}_i$ is unknown. It can, however, be consistently estimated by the so-called "robust estimator of variance" or "sandwich estimator". Here, $\boldsymbol{\Omega}_i$ is replaced by $\hat{\boldsymbol{\Omega}}_i = (\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}_i)(\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}_i)' = (\boldsymbol{y}_i - \boldsymbol{X}_i\hat{\boldsymbol{\beta}})(\boldsymbol{y}_i - \boldsymbol{X}_i\hat{\boldsymbol{\beta}})'$. $\hat{\boldsymbol{\Omega}}$ is the diagonal matrix of $\hat{\boldsymbol{\Omega}}_i$. Note that $\hat{\boldsymbol{\Omega}}_i$ is just a replacement for $\boldsymbol{\Omega}_i$, and $\boldsymbol{X}'\boldsymbol{\Sigma}^{-1}\hat{\boldsymbol{\Omega}}\boldsymbol{\Sigma}^{-1}\boldsymbol{X}$ is a consistent estimator of $\boldsymbol{B}$.

A 2.2 Feasible Generalized Least Squares

Instead of using a pre-specified covariance matrix $\boldsymbol{\Sigma}_i$, one can introduce a model $\boldsymbol{\Sigma}_i(\boldsymbol{\alpha})$ for the covariance matrix which depends on an additional parameter vector $\boldsymbol{\alpha}$. Simple models include an AR(1) structure in case of time-dependent data or an exchangeable structure for families. Given a specific simple structure, the parameter $\boldsymbol{\alpha}$ can be estimated in the first step. In the second step, $\hat{\boldsymbol{\beta}}$ is estimated using $\hat{\boldsymbol{\Sigma}}_i(\hat{\boldsymbol{\alpha}}_i)$. Of course, the structure for the covariance matrix may not involve too many different parameters, and not all covariance structures can be estimated. Only a part is identifiable, thus feasible. The resulting estimator is therefore called *feasible generalized least squares (FGLS) estimator*. A detailed discussion can be found in Greene's excellent textbook (Greene 1993).

A 2.3 Generalized Linear Model

In the linear model, we have been able to allow for within-cluster correlation. However, a linear model often is insufficient for modeling the mean and the variance structure of a problem. The GLM is a well-known alternative, allowing a more flexible modeling of the mean structure than the linear model. The mean structure is given by

$$\mu_{it} = \mathbb{E}(y_{it}|\boldsymbol{x}_{it}) = g(\boldsymbol{x}_{it}'\boldsymbol{\beta}),$$

where g is a non-linear *response function*; g^{-1} is the *link function*. The standard choice in epidemiology for dichotomous responses is the logit link function so that

$$\operatorname{logit}\mathbb{E}(y_{it}|\boldsymbol{x}_{it}) = \operatorname{logit}\mathbb{P}(y_{it}|\boldsymbol{x}_{it}) = \frac{\mathbb{P}(y_{it}|\boldsymbol{x}_{it})}{1 - \mathbb{P}(y_{it}|\boldsymbol{x}_{it})} = \boldsymbol{x}_{it}'\boldsymbol{\beta}\,,$$

which corresponds to the *expit response* function:

$$\mathbb{E}(y_{it}|\boldsymbol{x}_{it}) = \mathbb{P}(y_{it}|\boldsymbol{x}_{it}) = \operatorname{expit}(\boldsymbol{x}_{it}'\boldsymbol{\beta}) = \frac{\exp(\boldsymbol{x}_{it}'\boldsymbol{\beta})}{1 + \exp(\boldsymbol{x}_{it}'\boldsymbol{\beta})}\,.$$

Similarly, the log link is commonly used for count data.

If a distributional assumption for the responses is made, the variance function is automatically determined. In general, the variance $v_{it} = \mathbb{V}ar(y_{it}|\boldsymbol{x}_{it})$ is given by $v_{it} = h(\mu_{it}) \cdot \phi$. A common assumption for binary responses is the binomial distribution, yielding $v_{it} = \mu_{it}(1 - \mu_{it})$, thus $\phi = 1$. For count data, the standard choice is a Poisson distribution, where the mean and the variance are equal. Subsequently, $v_{it} = \mu_{it}$, and the parameter $\phi = 1$. In contrast, for the normal distribution, the variance is given by σ^2, thus independent of the mean. In this case, $v_{it} = 1 \cdot \phi = \sigma^2$ for $\phi = \sigma^2$.

If all observations y_{it} are independent, the parameter vector $\boldsymbol{\beta}$ can be estimated using standard maximum likelihood (ML). Specifically, the distributional assumption determines the score equations which are the first derivative of the log-likelihood function with respect to $\boldsymbol{\beta}$. For n-independent observations y_i, $i = 1, \ldots, n$, the score function has the form

$$\boldsymbol{u}(\boldsymbol{\beta}) = \frac{1}{n}\boldsymbol{D}'\boldsymbol{\Sigma}^{-1}(\boldsymbol{y} - \boldsymbol{\mu}) = \frac{1}{n}\sum_{i=1}^{n}\boldsymbol{D}_i'\boldsymbol{\Sigma}_i^{-1}(\boldsymbol{y}_i - \boldsymbol{\mu}_i)\,. \tag{35.9}$$

Here, $\boldsymbol{D}_i = \partial\boldsymbol{\mu}_i/\partial\boldsymbol{\beta}'$ is the matrix of first derivatives and $\boldsymbol{\Sigma}_i$ is the diagonal matrix of variances $\boldsymbol{\Sigma}_i = \text{diag}(v_{it})$. Subsequently, $\boldsymbol{D}$ is the stacked matrix of the $\boldsymbol{D}_i$ and $\hat{\cdot}$ indicates the estimates. In Eq. 35.9, the observations y_{it} are explicitly assumed to be independent because the variance matrix $\boldsymbol{\Sigma}_i$ is diagonal. The estimating equations $\boldsymbol{u}(\hat{\boldsymbol{\beta}}) = \boldsymbol{0}$ are therefore termed independence estimating equations (IEE). Except for the linear model, Eq. 35.9 generally has no closed formula solution, and the estimator is determined via iterative approaches like Fisher scoring or iterative re-weighted least squares (Dennis and Schnabel 1983). The estimator $\hat{\boldsymbol{\beta}}$ is asymptotically normal with mean $\boldsymbol{\beta}$ and covariance matrix $\mathbb{V}ar(\hat{\boldsymbol{\beta}}) = \left(\boldsymbol{D}'\boldsymbol{\Sigma}^{-1}\boldsymbol{D}\right)^{-1} = \boldsymbol{A}^{-1}$ which can be estimated consistently by

$$\widehat{\mathbb{V}ar}(\hat{\boldsymbol{\beta}}) = \left(\hat{\boldsymbol{D}}'\hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{D}}\right)^{-1} = \left(\sum_{i=1}^{n}\hat{\boldsymbol{D}}_i\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{D}}_i\right)^{-1}\,. \tag{35.10}$$

A 2.4 Generalized Estimating Equations: Formulation and Properties

In the last section, we assumed independence of observations y_{it} within cluster i. This assumption is most likely inadequate. The dependence was, however, only considered in the GLS and the FGLS models. We can now combine the Aitken estimator approach with the GLM method. If observations y_{it} within cluster i are correlated, then the true covariance matrix $\boldsymbol{\Omega}_i$ is not diagonal. Zeger et al. (1985) therefore proposed to use the robust estimator of variance $\boldsymbol{A}^{-1}\boldsymbol{B}\boldsymbol{A}^{-1}$ instead of the inverse Fisher information matrix $\boldsymbol{A}$:

$$\widehat{\mathbb{V}ar}(\hat{\boldsymbol{\beta}}) = \left(\hat{\boldsymbol{D}}'\hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{D}}\right)^{-1}\left(\hat{\boldsymbol{D}}'\hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{\Omega}}\hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{D}}\right)\left(\hat{\boldsymbol{D}}'\hat{\boldsymbol{\Sigma}}^{-1}\hat{\boldsymbol{D}}\right)^{-1} \tag{35.11}$$
$$= \left(\sum_{i=1}^{n}\hat{\boldsymbol{D}}_i'\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{D}}_i\right)^{-1}\left(\sum_{i=1}^{n}\hat{\boldsymbol{D}}_i'\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{\Omega}}_i\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{D}}_i\right)\left(\sum_{i=1}^{n}\hat{\boldsymbol{D}}_i'\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{D}}_i\right)^{-1}.$$

In contrast to Eq. 35.10, Eq. 35.11 is a consistent estimator of the covariance matrix of $\hat{\boldsymbol{\beta}}$ even if the correlations are dependent within a cluster. However, the estimator will not be very efficient in many cases because estimates are based on a model which assumes independence of observations. Liang and Zeger (1986) and Zeger and Liang (1986) proposed to increase the efficiency by a synthesis of FGLS and GLM. First, the mean structure μ_{it} and the variance function v_{it} are specified as in standard GLM. Second, a covariance matrix $\boldsymbol{\Sigma}_i$ that need not be a diagonal matrix is assumed as in FGLS. In practice, the covariance matrix is estimated in a first step, yielding $\hat{\boldsymbol{\Sigma}}_i$. This covariance matrix need not be correctly specified and is therefore termed "working covariance matrix." The resulting score function is given by

$$\boldsymbol{u}(\boldsymbol{\beta}) = \frac{1}{n}\boldsymbol{D}'\hat{\boldsymbol{\Sigma}}^{-1}\left(\boldsymbol{y}-\boldsymbol{\mu}\right) = \frac{1}{n}\sum_{i=1}^{n}\boldsymbol{D}_i'\hat{\boldsymbol{\Sigma}}_i^{-1}\left(\boldsymbol{y}_i-\boldsymbol{\mu}_i\right), \tag{35.12}$$

which needs to be set to $\mathbf{0}$ and solved for $\boldsymbol{\beta}$ to obtain the GEE estimator $\hat{\boldsymbol{\beta}}$. The working covariance matrix should be as close to the probably unknown true covariance matrix $\boldsymbol{\Omega}_i$. However, it is not the aim to have an interpretable covariance matrix. It is only used as weight for increasing the efficiency of the estimator.

The properties summarized in Box 35.2 hold for an estimator $\hat{\boldsymbol{\beta}}$ solving the GEE which are given by $\boldsymbol{u}(\hat{\boldsymbol{\beta}}) = \mathbf{0}$.

Box 35.2. Properties of the GEE estimator $\hat{\beta}$

1. *Existence.* There exists asymptotically a GEE estimator $\hat{\boldsymbol{\beta}}$ for the true parameter vector.
2. *Strong consistency.* The GEE estimator converges almost surely to the true parameter vector.
3. *Asymptotic unbiasedness.* The GEE estimator is asymptotically unbiased, that is, $\mathbb{E}(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta}$.
4. *Asymptotic normality.* The GEE estimator $\hat{\boldsymbol{\beta}}$ is asymptotically normal. More specifically, $\hat{\boldsymbol{\beta}}$ is asymptotically normally distributed with mean $\boldsymbol{\beta}$ and robust covariance matrix $\boldsymbol{A}^{-1}\boldsymbol{B}\boldsymbol{A}^{-1} = \boldsymbol{C}^{-1}$.
5. *Estimation of covariance matrix.* Strongly consistent estimators of the Fisher information matrix $\boldsymbol{A}$ and the OPG $\boldsymbol{B}$ are, for example, given by

$$\hat{\boldsymbol{A}}(\hat{\boldsymbol{\beta}}) = \frac{1}{n}\sum_{i=1}^{n}\hat{\boldsymbol{A}}_i = \frac{1}{n}\sum_{i=1}^{n}\left(\hat{\boldsymbol{D}}_i'\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{D}}_i\right) \quad \text{and}$$

$$\hat{\boldsymbol{B}}(\hat{\boldsymbol{\beta}}) = \frac{1}{n}\sum_{i=1}^{n}\hat{\boldsymbol{B}}_i = \frac{1}{n}\sum_{i=1}^{n}\left(\hat{\boldsymbol{D}}_i'\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{\Omega}}_i\hat{\boldsymbol{\Sigma}}_i^{-1}\hat{\boldsymbol{D}}_i\right),$$

where $\hat{\boldsymbol{D}}_i$, $\hat{\boldsymbol{\mu}}_i$, and $\hat{\boldsymbol{\Sigma}}_i$ are the estimators of $\boldsymbol{D}_i$, $\boldsymbol{\mu}_i$, and $\boldsymbol{\Sigma}_i$, respectively, and $\hat{\boldsymbol{\Omega}}_i = (\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}_i)(\boldsymbol{y}_i - \hat{\boldsymbol{\mu}}_i)'$.

6. *Efficiency.* If the working covariance matrix $\boldsymbol{\Sigma}_i$ is correctly specified, that is, if $\boldsymbol{\Sigma}_i = \boldsymbol{\Omega}_i$, then the GEE estimator $\hat{\boldsymbol{\beta}}$ of $\boldsymbol{\beta}$ is asymptotically efficient.

A few remarks are required after having formulated these strong statements. First, they are only valid under suitable regularity conditions. For example, necessary for the strong consistency is that the score function (35.12) is derived from a distribution belonging to the linear exponential family (Gourieroux et al. 1984). An important additional assumption is that the mean structure $\boldsymbol{\mu}_i = g(\boldsymbol{x}_i'\boldsymbol{\beta})$ is correctly specified. If it is misspecified, $\boldsymbol{\beta}$ cannot be consistently estimated, and $\hat{\boldsymbol{\beta}}$ does not converge to the true parameter vector $\boldsymbol{\beta}$. Furthermore, a covariance matrix $\boldsymbol{\Omega}_i$ needs to exist. Otherwise, estimation of the covariance would not be possible.

An interesting aspect is that the estimator is consistent, although a two-step approach is taken for estimation. To repeat, the working covariance matrix is estimated first. In the second step, the estimating equations for the mean structure are solved. In fact, it can be shown using properties 8.5 and 8.19 of Gourieroux and Monfort (1995) that the GEE estimator $\hat{\boldsymbol{\beta}}$ obtained in the two-step approach fulfills these assumptions. Alternatively, the proof can be obtained using the generalized method of moments (GMM) (Ziegler 1995).

Above, we have considered specifying a working covariance matrix. However, given the variance function, specification of a working correlation matrix is sufficient. In detail, both the mean μ_{it} and the variance v_{it} of y_{it} given $\boldsymbol{x}_{it}$ have been specified in the GLM. For GEE, the correct specification of the variance v_{it} is not required for consistent estimation of $\boldsymbol{\beta}$, and this is in contrast to GLM. However, with the specific choice of the variance according to a GLM, it is not necessary to specify the entire working covariance matrix. Instead, the standard decomposition

$$\varrho_{itt'} = \mathbb{C}orr(y_{it}, y_{it'}) = \frac{\mathbb{C}ov(y_{it}, y_{it'})}{\sqrt{\mathbb{V}ar(y_{it})\,\mathbb{V}ar(y_{it'})}} = \frac{\sigma_{itt'}}{\sqrt{v_{it}\,v_{it'}}}$$

can be used for simplification. Specifically, the working covariance matrix $\boldsymbol{\Sigma}_i$ can be obtained as

$$\boldsymbol{\Sigma}_i = \boldsymbol{V}_i^{1/2}\boldsymbol{R}_i\boldsymbol{V}_i^{1/2},$$

where $\boldsymbol{V}_i = \text{diag}(v_{it})$ is the diagonal matrix of variances v_{it} in cluster i, and $\boldsymbol{R}_i = \mathbb{C}orr(\boldsymbol{y}_i|\boldsymbol{X}_i)$ is the working correlation matrix of $\boldsymbol{y}_i$ given $\boldsymbol{X}_i$. $\boldsymbol{R}_i$ needs to be a positive definite correlation matrix that – in principle – should be as close to the true correlation matrix as possible.

36.1 Introduction

The use of meta-analyses in order to synthesize the evidence from epidemiological studies has become more and more popular recently. It has been estimated by Egger et al. (1998) that from articles retrieved by MEDLINE with the medical subject heading (MeSH) term "meta-analysis" some 33% reported results of a meta-analysis from randomized clinical trials and nearly the same proportion (27%) were from observational studies, including 12% papers in which the etiology of a disease was investigated. The remaining papers include methodological publications or review articles. Reasons for the popularity of meta-analyses are the growing information in the scientific literature and the need of timely decisions for risk assessment or in public health. Methods for meta-analyses in order to summarize or synthesize evidence from randomized controlled clinical trials have been continuously developed during the last years. In 1993, the Cochrane Collaboration was established as an international organization, which provides systematic reviews to evaluate healthcare interventions. They have published a handbook (Higgins and Green 2009) with detailed information on how to conduct systematic reviews of randomized clinical trials. While methods for meta-analyses of randomized clinical trials are now also summarized in several text books, for example, Sutton et al. (2000) and Whitehead (2002), and in a handbook by Egger et al. (2001a) and Dickersin (2002) argued that statistical methods for meta-analyses of epidemiological studies are still behind in comparison to the progress that has been made for randomized clinical trials. The use of meta-analyses for epidemiological research caused many controversial discussions; see, for example, Blettner et al. (1999), Berlin (1995), Greenland (1994), Feinstein (1995), Olkin (1994), Shapiro (1994a, b), or Weed (1997) for a detailed overview of the arguments. The most prominent arguments against meta-analyses are the fundamental issues of confounding, selection bias, as well as the large variety and heterogeneity of study designs and data collection procedures in epidemiological research. Despite these controversies, results from meta-analyses are often cited and used for decisions. They are often seen as the fundamentals for risk assessment. They are also performed to summarize the current state of knowledge often prior to designing new studies.

This chapter will first describe reasons for meta-analyses in epidemiological research and then illustrate how to perform a meta-analysis with the focus on meta-analysis of published data. Furthermore, network meta-analyses are introduced, which are a new methodological tool.

36.2 Reasons for Meta-Analysis in Epidemiology

One major issue in assessing causality in epidemiology is "consistency" as pointed out by Hill in 1965. The extent to which an observed association is similar in different studies, with different designs, using different methods of data collection and exposure assessment, by different investigators, and in different regions or countries is an essential criterion for causality. If different studies with inconsistent results are known, there is a need for understanding the differences. Reasons may be small sample sizes of individual studies (chance), different methods of exposure assessment (measurement errors), different statistical analyses (e.g., adjustment for confounding), or the use of different study populations (selection bias). Also, Thompson et al. (1997) showed that different baseline risks may cause heterogeneity. The goal of a meta-analysis is then to investigate whether the available evidence is consistent and/or to which degree inconsistent results can be explained by random variation or by systematic differences between design, setting, or analysis of the study as has been pointed out by Weed (2000).

Meta-analyses are often performed to obtain a combined estimator of the quantitative effect of the risk factor such as the relative risk (*RR*) or the odds ratio (OR). As single studies are often far too small to obtain reliable risk estimates, the combination of data of several studies may lead to more precise effect estimates and increased statistical power. This is mainly true if the exposure leads only to a small increase (or decrease) in risk or if the disease or the exposure of interest is rare. One example is the risk of developing lung cancer after the exposure to passive smoking where relative risk estimates in the order of 1.2 have been observed; see Boffetta (2002) for a summary of the epidemiological evidence. Another typical example is the association between childhood leukemia and exposure to electromagnetic fields. Meinert and Michaelis (1996) have performed a meta-analysis of the available case-control studies as the results of the investigations were inconsistent. Although many huge case-control studies have been performed in the last decade, in each single study, only a few children were categorized as "highly exposed." In most publications, a small but non-significant increase in risk was found, but no single study had enough power to exclude that there is no association between EMF exposure and childhood leukemia.

Sometimes, meta-analyses are also used to investigate more complex dose-response functions. For example, Tweedie and Mengersen (1995) investigated the dose-response relationship of exposure to passive smoking and lung cancer. A meta-analysis was also undertaken by Longnecker et al. (1988) to study the dose-response of alcohol consumption and breast cancer risk. However, results were limited as not enough data were present in several of the included publications. Interestingly, a large group of investigators led by Hamajima et al. (2002) has recently used individual patient data from 53 studies including nearly 60,000 cases for a reanalysis. It has been shown by Sauerbrei et al. (2001) in a critique that meta-analysis from aggregated data may be too limited to perform a dose-response analysis. A major limitation is that different categories are used in different publications. Thus, dose-response analyses are restricted to published values. Meta-analyses of published data have their main merits for exploring heterogeneity between studies and to provide crude quantitative estimates but probably less for investigating complex dose-response relationships.

36.3 Different Types of Overviews

Approaches for summarizing evidence include five different types of overviews: first, traditional narrative reviews that provide a qualitative but not a quantitative assessment of published results. Methods and guidelines for reviews have been recently published by Weed (1997).

Second, meta-analyses from literature (MAL) which are generally performed from freely available publications without the need of cooperation and without agreement of the authors from the original studies. They are comparable to a narrative review in many respects but include quantitative estimate(s) of the effect of interest. One recent example is a meta-analysis by Zeeger et al. (2003) of studies investigating some familial clustering of prostate cancer. Another meta-analysis has been recently published by Allam et al. (2003) on the association between Parkinson disease, smoking, and family history.

Third, meta-analyses with individual patient data (MAP) in which individual data from published and sometimes also unpublished studies are reanalyzed. Often, there is a close cooperation between the researcher performing the meta-analysis and the investigators of the individual studies. The new analysis may include specific inclusion criteria for patients and controls, new definition of the exposure and confounder variables, and new statistical modeling. This reanalysis may overcome some but not all of the problems of meta-analyses of published data (Blettner et al. 1999). They have been performed in epidemiological research for many years. One of the largest investigations of this form was a recent investigation on breast cancer and oral contraceptive use, where data from 54 case-control studies were pooled and reanalyzed (CGHFBC 1996). A further international collaboration led by Lubin and colleagues were set up to reanalyze data from 11 large cohort studies on lung cancer and radon among uranium miners. The reanalysis allowed a refined dose-response analysis and provided data for radiation protection issues. Pooled reanalyses are mostly performed by combining data from studies of the same type only. For example, Hung et al. (2003) reanalyzed data from all case-control studies in which the role of genetic polymorphisms for lung cancer in non-smokers was investigated. The role of diet for lung cancer was recently reviewed by Smith-Warner et al. (2002) in a qualitative and quantitative way by combining cohort studies. An overview of methodological aspects for a pooled analysis of data from cohort studies was published by Bennett (2003). There are methods under development which allow to combine individual and aggregate data. See, for example, the work by Riley et al. (2007) or Sutton et al. (2008).

Fourth, prospectively planned pooled meta-analyses of several studies in which pooling is already a part of the protocol. Data collection procedures, definitions of variables are as far as possible standardized for the individual studies. The statistical analysis has many similarities with the meta-analysis based on individual data. A major difference, however, is that joint planning of the data collection and analysis increase the homogeneity of the included data sets. However, in contrast to multicenter randomized clinical trials, important heterogeneity between the study centers still may exist. This heterogeneity may arise from differences in populations, in the relevant confounding variables (e.g., race may only be a confounder in some centers) and potentially differences in ascertainment of controls. For example, complete listings of population controls are available in some but not all countries. In the latter situation sometimes neighborhood controls are used. Mainly in occupational epidemiology, those studies are rather common, many of them were initiated by international bodies such as the International Agency for Research on Cancer (IARC) as the international pooled analysis by Boffetta et al. (1997) of cancer mortality among persons exposed to man-made mineral fiber. Another example for a prospectively planned pooled meta-analysis is given by a large brain tumor study initiated by the IARC including data from eight different countries (see Schlehofer et al. 1999).

Fifth, network meta-analyses which is a method that is increasingly used to estimate comparative effectiveness of treatments not compared directly in randomized controlled trials. This technique is introduced in more detail in Sect. 36.7.

Steinberg et al. (1997) compared the effort required and the results obtained of MAL and MAP with an application to ovarian cancer. Certainly, MAL are easier to perform, cheaper, and faster than MAP. Their credibility may be more questionable as discussed by many authors; see, for example, Blettner et al. (1999) or Egger et al. (1998). Statistical issues of pooling data from case-control studies have been investigated by Stukel et al. (2001) recently. The authors proposed a two-step approach and showed conditions under which the two-step approach gives similar results in comparison to the pooled analysis including all data. Here, the two-step approach implies to estimate first the odds ratio for each study in the usual way. Then in the second step, a combined estimator using either a fixed or random effects model is calculated.

36.4 Steps in Performing a Meta-Analysis

Each type of overview needs a clear study protocol that describes the research question and the design, including how studies are identified and selected, the statistical methods to use, and how the results will be reported. This protocol should also include the exact definition of the disease of interest, the risk factors, and the potential confounding variables that have to be considered. In accordance with Friedenreich (1993) and Jones (1992), the following steps are needed for a meta-analysis/pooled analysis.

Step 1. Define a clear and focused topic for the review: As for any other investigation, a clear protocol in which the research hypothesis, that is, the objectives of the meta-analysis are described, is mandatory. This protocol should include the exact definition of the disease of interest, the risk factors, and the potential confounding variables that have to be considered. The protocol should also include details on the steps that are described below, including specification of techniques for location of the studies, the statistical analysis, and the proposed publications.

Step 2. Establish inclusion and exclusion: It is important to define in advance which studies should be included into the meta-analysis. These criteria may include restrictions on the publication year as older studies may not be comparable to newer ones, on the design of the investigation, for example, to exclude ecological studies. Friedenreich (1994) has also proposed quality criteria to evaluate each study. Whether these criteria, however, should be used as inclusion criteria is discussed controversially. Another decision is whether studies that are only published as abstracts or internal communications should be included (Cook et al. 1993). A rule for the inclusion or exclusion of papers with repeated publication of the data is required. For example, for cohort studies, often several publications with different follow-up periods can be found. As one out of many examples, a German study among rubber workers by Straif et al. (1999, 2000) can be mentioned. In one paper, 11,633 workers were included, while the second paper is based on a subcohort of only 8,933 persons. Which results are more appropriate for the meta-analysis?

Step 3. Locate all studies (published and unpublished) that are relevant to the topic: Since the existence of electronic databases, retrieval of published studies has become much easier. Mainly systems like MEDLINE or CANCERLIT from the National Library of Medicine are valuable sources to locate publications. However, as Dickersin et al. (1994) showed for some examples as little as 50% of the publications were found by electronic searches. Therefore, there is a need to extend the search by manual checks of the reference lists of retrieved papers, monographs, books, and if possible by personal communications with researchers in the field. A clear goal of the search has to be to identify all relevant studies on the topic that meet the inclusion criteria. Egger et al. (2003) have pointed out that the completeness of the literature search is an important feature of the meta-analysis to avoid publication bias or selection bias. Of course, the publication should include the search strategies as well as the keywords and the databases used for electronic searches.

Step 4. Abstract information from the publications: The data collection step in a meta-analysis needs as much care as in other studies. In the meta-analysis, the unit of observation is the publication, and defined variables have to be abstracted from the publication (Stock 1995). In epidemiological studies, the key parameter is often the relative risk or odds ratio. Additionally, standard error, sample size, treatment of confounders, and other characteristics of the study design and data collection procedure need to be abstracted to assess the quality of the study. This is also important for subgroup analyses or for a sensitivity analysis. An abstract form has to be created before abstracting data. This form should be tested like other instruments in a pilot phase. Unfortunately, it may not always be possible to abstract the required estimates directly, for example, standard errors are not presented and have to be calculated based on confidence intervals (Greenland 1987). It may be necessary to contact the investigators to obtain further information if results are not published in sufficient detail. Abstracting and classification of study characteristics is the most time-consuming part of the meta-analysis. It has been recommended to blind the data abstractors, although some authors argue that blinding may not have a major influence on the results; for further discussion, see Berlin et al. (1997). Additionally, the rater may be acquainted with some of the studies and blinding cannot be performed. Another requirement is that two persons should perform the abstraction in parallel. When a meta-analysis with original data is performed, the major task is to obtain data from all project managers in a compatible way. Our experience shows that this is possible in principle but time consuming as data may not be available on modern electronic devices and often adaptations between database systems are required.

Step 5. Descriptive analysis: A first step in summarizing the results should be an extensive description of the single papers, including tabulation of relevant elements of each study, such as sample size, data collection procedures, confounder variables, means of statistical analysis, study design, publication year, performing year, geographical setting, etc. This request is also included in the guidelines for publications of meta-analysis that were published by Stroup et al. (2000).

Step 6. Statistical analysis: This includes the analysis of the heterogeneity of the study-specific effects, the calculation of a pooled estimate and the confidence interval as well as a sensitivity analysis. Details are given in the next section on statistical methods.

Step 7. Interpretation of the results: The importance of the sources and magnitude of different biases should be taken into account when interpreting the results. Combining several studies will often give small confidence intervals and suggest a false precision (Egger et al. 1998), but estimates may be biased. For clinical studies, Thompson (1994) has pointed out that the investigation of the heterogeneity between studies will generally give more insight than inspecting the confidence interval of the pooled estimate. This is even more true for a meta-analysis from epidemiological studies. Additionally, the possible effects of publication bias (see below) need to be considered carefully (Copas and Shi 2001).

Step 8. Publication: Guidelines for reporting meta-analyses of observational studies have been published by Stroup et al. (2000). More recently, a large group of methodologists and clinicians revised an existing guidance and checklist focused on the reporting of meta-analyses of randomized controlled trials named PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses, Moher et al. 2009). These guidelines are quite useful for preparing the publication and are also supported by most editors of major medical journals. Especially the detailed description of methods is required so that the analysis could be replicated by others.

36.5 Statistical Analysis

The statistical analysis of aggregated data from published studies was first developed in the fields of psychology and education (Glass 1977; Smith and Glass 1977). These methods have been adopted since the mid-1980s in medicine primarily for randomized clinical trials and are also used for epidemiological data. A recent overview may be found in the review by Sutton and Higgins (2008). We will give a brief outline of some issues of the analysis using an example based on a meta-analysis performed by Sillero-Arenas et al. (1992). This study was one of the first meta-analyses which tried to summarize quantitatively the association between hormone replacement therapy (HRT) and breast cancer in women. Sillero-Arenas et al. based their meta-analysis on 23 case-control and 13 cohort studies. The data extracted from their paper are given in Appendix A of this chapter.

The statistical analysis of MAP is more complex and not covered here.

36.5.1 Single Study Results

A first step of the statistical analysis is the description of the characteristics and the results of each study. Tabulations and simple graphical methods should be employed to visualize the results of the single studies. Plotting the odds ratios and their confidence intervals (so-called forest plot) is a simple way to spot obvious differences between the study results.

Figure 36.1 shows a forest plot of 36 studies investigating the association of HRT and breast cancer in women. Obviously there is a high variability of effects between studies present. Later we will describe how to account for heterogeneity of studies quantitatively.

36.5.2 Publication Bias

An important problem of meta-analysis is publication bias. This bias has received a lot of attention particularly in the area of clinical trials. Publication bias occurs when studies that have non-significant or negative results are published less frequently than positive studies. For randomized clinical trials, it has been shown that even with a computer-aided literature search not all of the relevant studies will be identified (Dickersin et al. 1994). In epidemiological studies, additional problems exist, because often a large number of variables will be collected as potential confounders (Blettner et al. 1999), but only significant or important results are mentioned in the abstract. Therefore, the respective publication may be overlooked for variables which are not mentioned in the abstract. Results of important variables may be published in additional papers, which have often not been planned in advance. In general, publication bias yields a non-negligible overestimation of the risk estimate. Consequently, publication bias should be investigated prior to further statistical analyses.

A simple graphical tool to detect publication bias is the so-called funnel plot. The basic idea is that studies which do not show an effect and which are not statistically significant are less likely to be published. If the sample size or alternatively the precision (i.e., the inverse of the variance) is plotted against the effect, a hole in lower left quadrant is expected. Figure 36.2 shows examples of funnel plots. The left

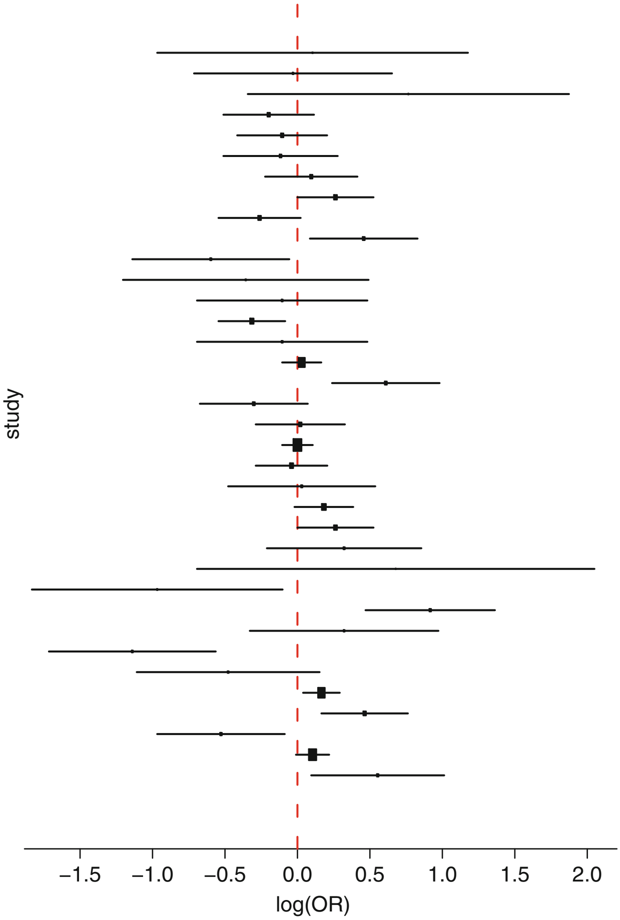

Fig. 36.1 Confidence interval plot of the breast cancer data

subplot of Fig. 36.2 shows a funnel plot with no indication of publication bias. The right subplot shows a so-called apparent hole in the lower left corner. In the case of the right subplot of Fig. 36.2, the presence of publication bias would be assumed.

Figure 36.3 shows a funnel plot for the breast cancer data. No apparent hole in the lower left corner is present. Thus, based on this figure, no publication bias would be assumed.

For a quantitative investigation of publication bias, several methods are available. This may be based on statistical tests; see, for example, Begg and Mazumdar (1994) or Schwarzer et al. (2002). A recent simulation study performed by Macaskill et al. (2001) favored the use of regression methods. The basic idea is to regress the estimated effect sizes $\hat{\theta}_i$ directly on the sample size or the inverse variance σ_i^{-2} as predictor. An alternative idea is to use Egger's regression test (Egger et al. 1997)

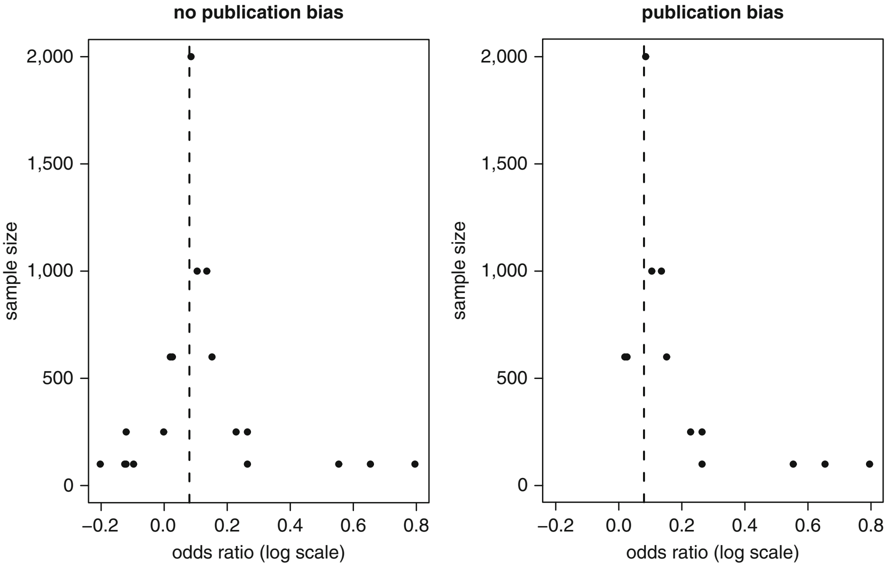

Fig. 36.2 Examples of funnel plots based on simulated data with (*right figure*) and without publication bias present (*left figure*). The *dotted line* shows the true effect

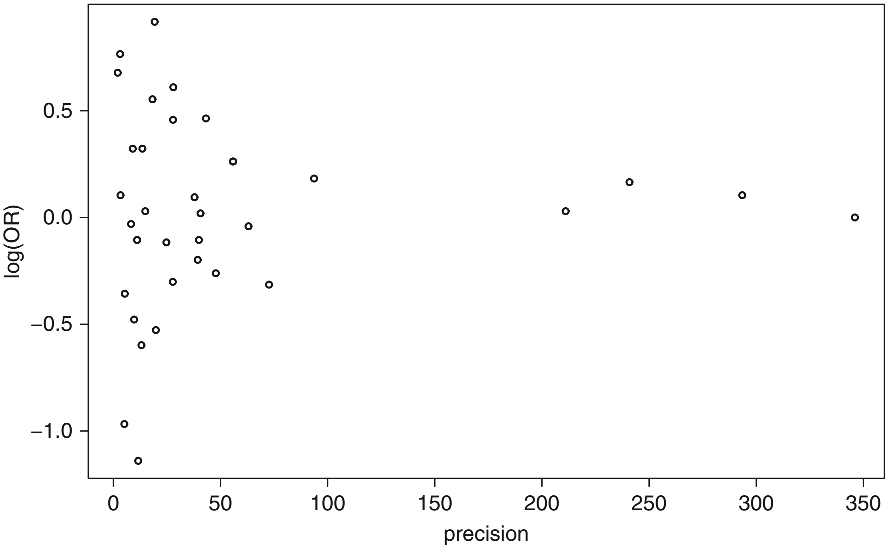

Fig. 36.3 Funnel plot of the breast cancer data

which uses standardized study-specific effects as dependent variable and the corresponding precision as an independent variable. Simulation studies by Macaskill et al. (2001) and by Peters et al. (2006) indicate that the method proposed by Macaskill is superior to Egger's method. Thus, our analysis is restricted to the method by Macaskill which leads to the following regression model

$$\hat{\theta}_i = \alpha + \beta \frac{1}{\sigma_i^2} + \epsilon_i, \quad i = 1, \ldots, k, \quad \epsilon_i \sim N(0, \sigma_i^2).$$

Here, the number of studies to be pooled is denoted by k. In this setting, it is assumed that the estimated treatment effects are independently normally distributed. With no publication bias present, the regression line should be parallel to the x-axis, that is, the slope should be zero. A non-zero slope would suggest an association between sample size or inverse variance, possibly due to publication bias. The estimated regression line in Fig. 36.4 shows no apparent slope. Likewise, the model output (not shown) does not indicate the presence of publication bias for the data at hand.

36.5.3 Estimation of a Summary Effect

Frequently, one of the aims of a meta-analysis is to provide an estimate of the overall effect of all studies combined. Methods for pooling depend on the data available. In general, a two-step procedure has to be applied. First, the risk estimates and

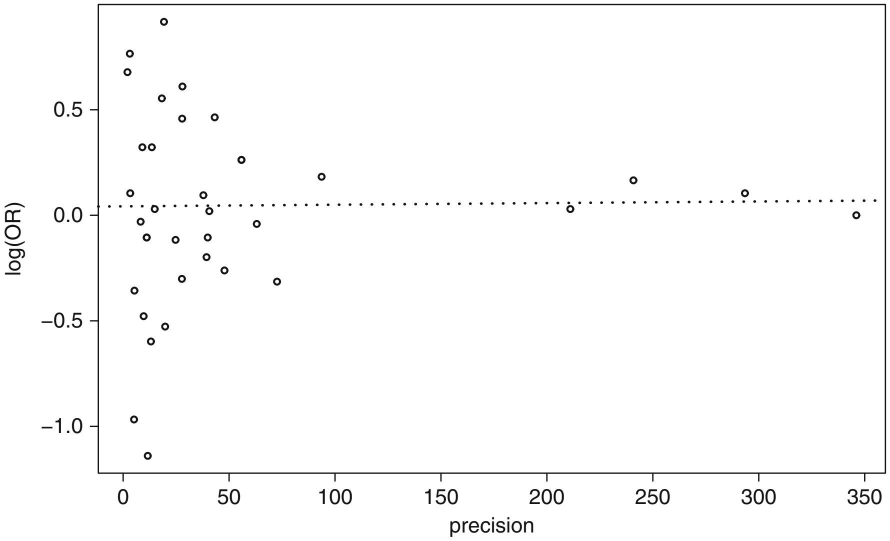

Fig. 36.4 Funnel regression plot of the breast cancer data

variances from each study have to be abstracted from publications or calculated if data are available. Then, a combined estimate is obtained as a (variance based) weighted average of the individual estimates. The methods for pooling based on the 2 × 2 table include the approaches by Mantel-Haenszel and Peto (see Pettiti 1994 for details). If data are not available in a 2 × 2 table, but as an estimate from a more complex model (such as an adjusted relative risk estimate), the Woolf approach can be adopted using the estimates and their (published or calculated) variance resulting from the regression model. This results in a weighted average of the log odds ratios $\hat{\theta}_i$ of the individual studies where the weights w_i are given by the inverse of the study-specific variance estimates $\hat{\sigma}_i^2$. For a discussion of risk measures, see chapter ▶Rates, Risks, Measures of Association and Impact of this handbook. Please note that the study-specific variance is assumed to be fixed and known, although they are based on estimates of the study-specific variances. As a result, the uncertainty associated with the estimation of σ_i^2 is ignored. Thus, in the following, the σ_i are treated as constants and the "hat" notation is omitted. The estimate of the summary effect of all studies is then given by

$$\begin{aligned} \hat{\theta} &= \frac{\sum_{i=1}^{k} w_i \hat{\theta}_i}{\sum_{i=1}^{k} w_i}, \\ w_i &= \frac{1}{\sigma_i^2}. \end{aligned}$$

The variance is given by

$$\operatorname{var}(\hat{\theta}) = \frac{1}{\sum_{i=1}^{k} \frac{1}{\sigma_i^2}}.$$

Applying this approach to the HRT data leads to a pooled risk estimate of 0.05598 with an estimated variance equal to 0.00051. Transforming this back to the original scale leads to an odds ratio of 1.058 with a 95% confidence interval of (1.012, 1.11). Thus, we would conclude combining all studies that there is a small harmful effect of hormone replacement therapy.

The major assumption here is that of a fixed model, that is, it is assumed that the underlying true exposure effect in each study is the same. The overall variation and, therefore, the confidence intervals will reflect only the random variation within each study but not any potential heterogeneity between the studies.

Figure 36.5 displays this idea. Whether pooling of the data is appropriate should be decided after investigating the heterogeneity of the study results. If the results vary substantially, no pooled estimator should be presented or only estimators for selected subgroups should be calculated (e.g., combining results from case-control studies only).

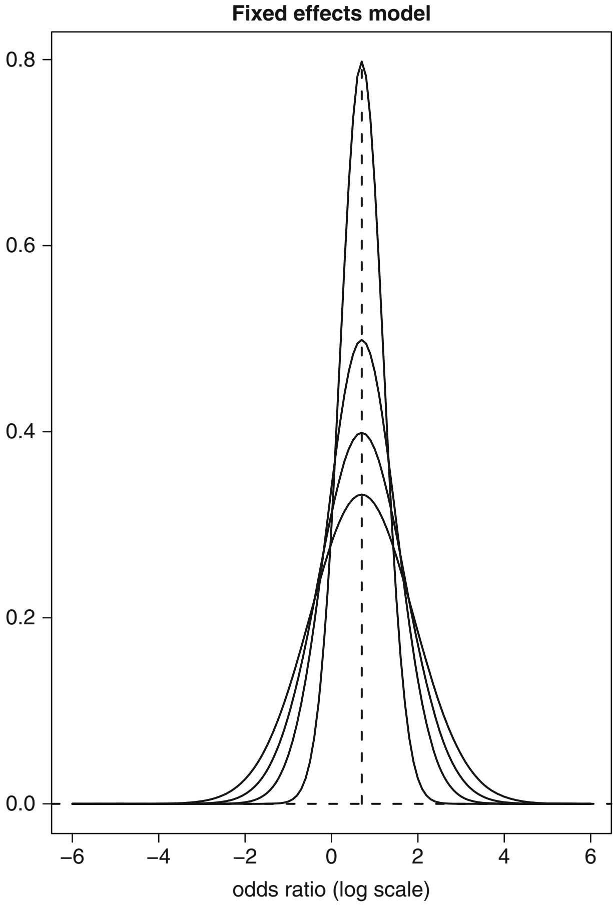

Fig. 36.5 Fixed effects model: common effect with different study variances

36.5.4 Heterogeneity

The investigation of heterogeneity between the different studies is a main task in each review or meta-analysis (Thompson 1994). For the quantitative assessment of heterogeneity, several statistical tests are available (Pettiti 1994; Paul and Donner 1989). A simple test for heterogeneity is based on the following test statistic:

$$\chi^2_{\text{het}} = \sum_{i=1}^{k} \frac{(\hat{\theta} - \hat{\theta}_i)^2}{\sigma_i^2} \sim \chi^2_{k-1} \qquad (36.1)$$

which under the null hypothesis of heterogeneity follows a χ^2 distribution with $k-1$ degrees of freedom. Hence, the null hypothesis is rejected if χ^2_{het} exceeds the $1-\alpha$

quantile of χ^2_{k-1} denoted as $\chi^2_{k-1,1-\alpha}$. For the data at hand, we clearly conclude that there is heterogeneity present ($\chi^2_{\text{het}} = 116.076$, df $=35$, p-value: 0.00000). Thus, using a combined estimate is at least questionable. Pooling the individual studies and performing this test can be done with any statistical package capable of weighted least squares regression. In part B of the Appendix of this chapter shows a SAS program which provides the results obtained so far. A major limitation of formal heterogeneity tests like the one presented before is, however, their low statistical power to detect any heterogeneity present.

A more powerful method is given by model-based approaches. A model-based approach has the advantage that it can be used to test specific alternatives and thus has a higher power to detect heterogeneity. So far, we considered the following simple fixed effects model:

$$\theta_i = \theta + \varepsilon_i, \quad i = 1, \ldots, k, \quad \varepsilon_i \sim N(0, \sigma_i^2).$$

Obviously, this model is not able to account for any heterogeneity, since deviations from θ_i and θ are assumed to be explained only by random error.

Thus, alternatively a random effects model should be considered. This model incorporates variation between studies. It is assumed that each study has its own (true) exposure effect and that there is a random distribution of these true exposure effects around a central effect. This idea is presented in Fig. 36.6. Frequently, it is assumed that the individual study effects follow a normal distribution with mean θ_i and variance σ_i^2 and the random distribution of the true effects is again a normal distribution with variance τ^2. In other words, the random effects model allows non-homogeneity between the effects of different studies. This leads to the following model:

$$\theta_i = \theta + b_i + \epsilon_i, \quad i = 1, \ldots, k, \quad b_i \sim N(0, \tau^2), \quad \epsilon_i \sim N(0, \sigma_i^2). \tag{36.2}$$

The observed effects from the different studies are used to estimate the parameters describing the fixed and random effects. This may be done using maximum-likelihood procedures. In the following sections, two further methods of estimating the heterogeneity variance in a random effects model are presented.

36.5.4.1 The Heterogeneity Variance Estimator Proposed by DerSimonian and Laird

The widely used approach by DerSimonian and Laird (1986) applies a method of moments to obtain an estimate of τ^2. Taking the expectation of (36.2) leads to $E(\theta_i) = \theta$ and calculating the variance leads to $\text{var}(\theta_i) = \text{var}(b_i) + \text{var}(\varepsilon_i) = \tau^2 + \sigma_i^2 = \sigma_i^{*^2}$ assuming that b_i and ϵ_i are independent. The heterogeneity variance τ^2 is unknown and has to be estimated from the data. The method by DerSimonian and Laird equates the heterogeneity test statistic (36.1) to its expected value. This expectation is calculated under the assumption of a random effects model and given

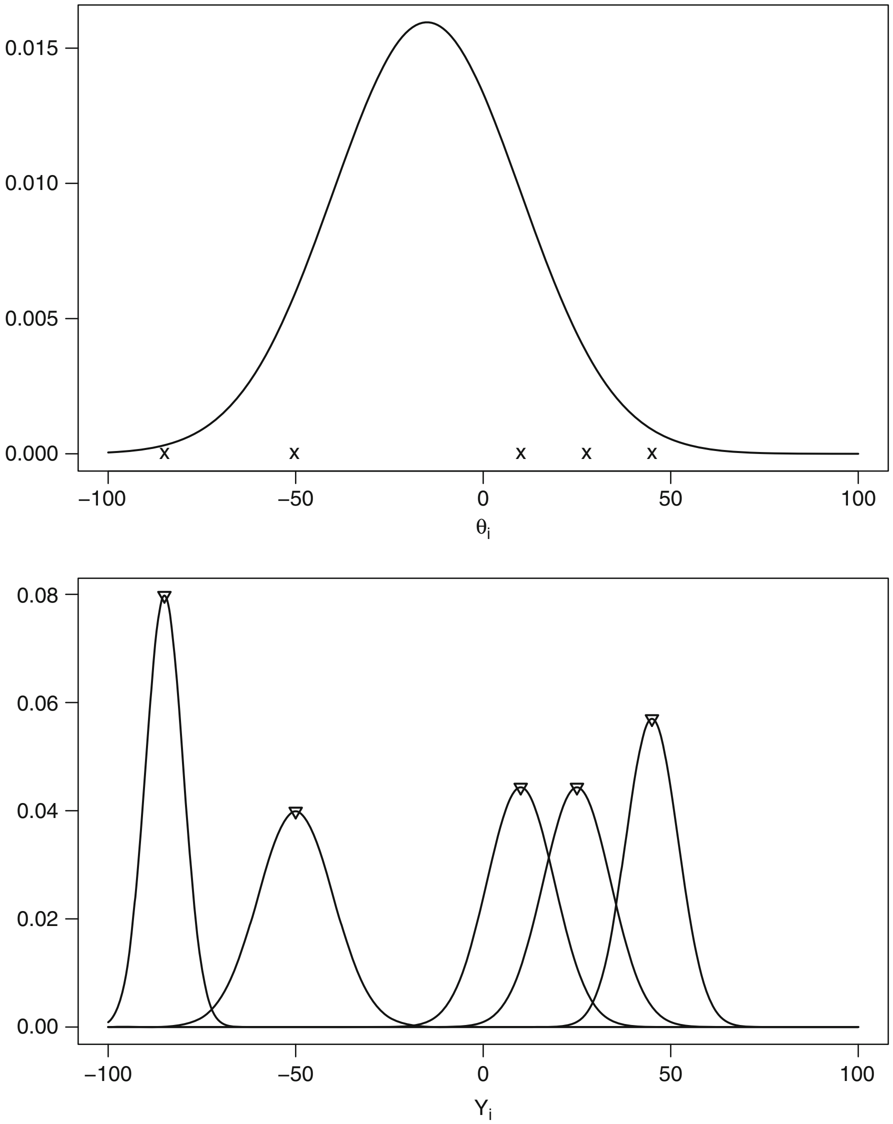

Fig. 36.6 Random effects model: variable effects drawn from a population of study effects

by $E(\chi^2_{\text{het}}) = k-1+\tau^2\left(\sum w_i - \frac{\sum w_i^2}{\sum w_i}\right)$. The weights w_i are those defined in (36.1). Equating χ^2_{het} to its expectation and solving for τ^2 gives

$$\hat{\tau}^2 = [\chi^2_{\text{het}} - (k-1)] / \left(\sum w_i - \frac{\sum w_i^2}{\sum w_i}\right).$$

In case $\chi^2_{\text{het}} < k-1$, the estimator $\hat{\tau}^2$ is truncated to zero. Thus, the pooled estimator $\hat{\theta}_{\text{DL}}$ under heterogeneity can be obtained as weighted average:

$$\hat{\theta}_{\text{DL}} = \frac{\sum_{i=1}^{k} w_i^* \hat{\theta}_i}{\sum_{i=1}^{k} w_i^*} \tag{36.3}$$

$$\text{with} \qquad w_i^* = \frac{1}{\sigma_i^{*2}} = \frac{1}{\hat{\tau}^2 + \sigma_i^2} \quad \text{we obtain} \tag{36.4}$$

$$\hat{\theta}_{\text{DL}} = \frac{\sum_{i=1}^{k} \hat{\theta}_i / (\hat{\tau}^2 + \sigma_i^2)}{\sum_{i=1}^{k} 1/(\hat{\tau}^2 + \sigma_i^2)}.$$

The variance of this estimator is given by:

$$\begin{aligned} \text{var}(\hat{\theta}_{\text{DL}}) &= \frac{1}{\sum_{i=1}^{k} \frac{1}{\sigma_i^{*2}}} \\ &= \frac{1}{\sum_{i=1}^{k} \frac{1}{\hat{\tau}^2 + \sigma_i^2}}. \end{aligned}$$

The between-study variance τ^2 can also be interpreted as a measure for the heterogeneity between studies. For our example, we obtain a pooled DerSimonian-Laird estimate of 0.0337 with heterogeneity variance equal to 0.0453. The variance of the pooled estimator is given by 0.0024. Transformed back to the original scale, we obtain an odds ratio of $OR = 1.034$ with 95% CI (0.939, 1.139). Based on this analysis, we would conclude that after adjusting for heterogeneity, this meta-analysis does not provide evidence for an association between HRT replacement therapy and breast cancer in women. It should be noted that within this approach, the study-specific variances are assumed to be known constants. This can lead to a considerable bias when pooling estimates using the DerSimonian-Laird estimator as demonstrated by Böhning et al. (2002).

36.5.4.2 Another Estimator of τ^2: The Simple Heterogeneity Variance Estimator

Sidik and Jonkman (2005) proposed a simple method for the estimation of the heterogeneity variance τ^2. As before, they consider a model as in (36.2) with $b_i \sim N(0, \tau^2)$. Now, for the purpose of their estimation method random effects model, they reparameterize the variance as

$$\text{var}(\hat{\theta}_i) = \tau^2 + \sigma_i^2 = \tau^2 \frac{\sigma_i^2 + \tau^2}{\tau^2} = \tau^2 (r_i + 1)$$

with $r_i = \sigma_i^2/\tau^2$. Then, the problem of estimating τ^2 is cast into the framework of simple linear regression:

$$E(\hat{\theta}) = X\theta$$
$$\text{var}(\hat{\theta}_1) = \tau^2 V.$$

Here, X is a vector of 1s with dimension $k \times 1$, and V is a diagonal matrix with elements $r_1 + 1, \ldots, r_k + 1$. In the framework of the usual weighted least squares, an estimator of θ is obtained as

$$\hat{\theta}_\nu = \frac{\sum_{i=1}^k \nu_i^{-1}\hat{\theta}_i}{\sum_{i=1}^k \nu_i^{-1}}$$

with $\nu_i = r_i + 1$. Please note that this is equivalent to (36.3) and (36.4). The advantage of casting the problem into the usual weighted least squares approach is that an estimator of τ^2 can be obtained as the usual weighted residual sum of squares as follows:

$$\hat{\tau}^2 = \frac{1}{k-1}\sum_{i=1}^{k} \nu_i^{-1}(\hat{\theta}_i - \hat{\theta}_\nu)^2. \tag{36.5}$$

Of course, an estimator of τ is needed to compute the ratios r_i of the within-study variance σ_i^2 and the between-study variance τ^2. Here, Sidik and Jonkman propose to use the empirical variance of the study-specific estimates $\hat{\theta}_i$

$$\hat{\tau}_0^2 = \frac{1}{k}\sum_{i=1}^{k}(\hat{\theta}_i - \bar{\theta})^2.$$

Plugging this into (36.5) leads to

$$\hat{\tau}_{SH}^2 = \frac{1}{k-1}\sum_{i=1}^{k} \hat{\nu}^{-1}(\hat{\theta}_i - \hat{\theta}_\nu)^2$$

with $\hat{\nu}_i = \hat{r}_i + 1$ and $\hat{r}_i = \sigma_i^2/\hat{\tau}_0^2$. Please note that this estimator is strictly positive in contrast to the DerSimonian-Laird estimator. This estimator will be referred to as the heterogeneity variance estimator SH. For the data at hand, an estimate of τ^2 equals 0.199.

36.5.4.3 Heterogeneity Variance Estimation by Likelihood-Based Methods

Besides the moment-based method by DerSimonian and Laird or the simple heterogeneity variance estimator, estimates of τ^2 can be obtained using likelihood-based methods. See, for example, the tutorials by Normand (1999) and van Houwelingen et al. (2002) for more details. The Appendix B and C of this chapter gives a SAS code to estimate the fixed and random effects models based on likelihood methods with the SAS program *proc mixed*. Estimates based on likelihood methods offer the advantage that they provide the option to formally test which model is appropriate for the data by applying the likelihood ratio test or penalized criteria such as the Bayesian information criterion (BIC). The BIC is obtained by the formula $\text{BIC} = -2 \times \log \text{Likelihood} + \log(k) \times q$ where q is the number of parameters in the model and k denotes the number of studies.

When using random effects models, another topic of interest is the form of the random effects' distribution. Besides a parametric distribution for the random effects, a discrete distribution may be assumed. Here, we suppose that the study-specific estimators $\hat{\theta}_1, \hat{\theta}_2, \ldots, \hat{\theta}_k$ are coming from q subpopulations $\theta_j, j = 1, \ldots, q$. Again, assuming that the effect of each individual study follows a normal distribution

$$f(\hat{\theta}_i, \theta_j, \sigma_i^2) = \frac{1}{\sqrt{2\pi\sigma_i^2}} e^{-\frac{(\hat{\theta}_i - \theta_j)^2}{2\sigma_i^2}}, \quad j = 1, \ldots, q,$$

we obtain a finite mixture model

$$f(\hat{\theta}_i, P) = \sum_{j=1}^{q} f(\hat{\theta}_i, \theta_j, \sigma_i^2) p_j .$$

The parameters of the distribution P

$$P \equiv \begin{bmatrix} \theta_1 & \ldots & \theta_q \\ p_1 & \ldots & p_q \end{bmatrix} \quad \text{with} \quad p_j \geq 0, \quad j = 1, \ldots, q,$$
$$p_1 + \cdots + p_q = 1,$$

need to be estimated from the data. The mixing weights p_j denote the a priori probability of an observation of belonging to a certain subpopulation with parameter θ_j. Please note that also the number of components q needs to be estimated as well. Estimation may be done with the program C.A.MAN (Schlattmann and Böhning 1993; Böhning et al. 1998) or more recently with the R package CAMAN (Schlattmann 2009). For the HRT data, we find a solution with three components which gives an acceptable fit to the data

```
weight:      0.2804 parameter:     -0.3365
weight:      0.5671 parameter:      0.0778
weight:      0.1524 parameter:      0.5446

Log-Likelihood at iterate :       -17.6306
```

Table 36.1 Model comparison for the breast cancer data

	Residual	Estimates (SE)			
Method	Hetero	Intercept	Het. ($\hat{\tau}^2$)	log Lik.	BIC
Fixed	None	0.056 (0.023)	–	−33.19	70.0
Mixed	Additive	0.027 (0.061)	0.086	−18.65	44.4
FM	Additive		0.079	−17.63	53.2

Here, the weights correspond to the mixing weights p_j, and the parameter corresponds to the subpopulation mean θ_j. These results imply that about 28% of the studies show a protective effect of HRT, whereas the majority of the studies show a harmful effect. About 57% of the studies show an increased log(risk) of 0.08, and 15% of the studies show a log(odds ratio) of 0.54. Thus, using a finite mixture model (FM), we find again considerable heterogeneity where the majority of studies find a harmful effect of hormone replacement therapy. It is noteworthy that a proportion of studies find a beneficial effect. Of course, this needs to be investigated further. One way to do this would be to classify the individual studies using the finite mixture model. Doing so, we find that, for example, study nine from the data given in the Appendix A belongs to this category. This is a case-control study for which no information about confounder adjustment is available. This would be a starting point for a sensitivity analysis. Table 36.1 gives an overview about the models fitted so far. These include the fixed effects model with a BIC value of 70.0, the mixed effects model using a normal distribution for the random effects with a BIC value of 44.4. The finite mixture model (FM) has a BIC value of 53.2. Thus, based on Table 36.1, it is quite obvious that a fixed effects model does not fit the data very well and that a random effects model should be used. Of course, the question remains which random effects model to choose for the analysis. Based on the BIC criterion given in Table 36.1, one would choose the parametric mixture model provided the assumption of a normal distribution of the random effects is justifiable. This can be investigated, for example, by a normal quantile-quantile plot of the estimated individual random effects given by the parametric model. For the data at hand, the assumption of normally distributed random effects appears reasonable; thus, we would choose the parametric mixture model.

36.5.4.4 Further Aspects of Heterogeneity

It should be noted that in general random effects models yield larger variance and confidence intervals than fixed effects models because a between-study component τ^2 is added to the variance. If the heterogeneity between the studies is large, τ^2 will dominate the weights and all studies will be weighted more equally (in the random effects model weight decreases for larger studies compared to the fixed effects model).

Furthermore, pooling in the presence of heterogeneity may be seriously misleading. Heterogeneity between studies warrants careful investigation of the sources of the differences. If there are a sufficient number of different studies available, further analyses, such as “meta-regression,” may be used to examine the sources of heterogeneity (Greenland 1987, 1994). One specific problem that occurs when binary endpoints are considered is that different risk measurements are used. While in case-control studies, an odds ratio is estimated, cohort studies yield an estimate for the relative risk. Although for studies in which rare events are investigated, odds ratios and relative risk estimates are very similar, this is not the case in studies where diseases with a higher prevalence are investigated. Odds ratio and relative risk differ and should not be combined. The problem that arises if studies with different designs are combined has not been well studied. We believe that no pooled estimate should be calculated combining data from case-control and cohort studies. There are many sources of heterogeneity, not only the size of risk estimates.

36.5.4.5 Meta-Regression

An important method for investigating heterogeneity is sensitivity analysis, for example, to calculate pooled estimators only for subgroups of studies (according to study type, quality of the study, period of publication, etc.) to investigate variations of the odds ratio. An extension of this approach is meta-regression as proposed by Greenland (1987); see also Thompson and Sharp (1999). The principal idea of meta-regression is once heterogeneity is detected to identify sources of heterogeneity by inclusion of known covariates.

For the breast cancer meta-analysis example a potential covariate is study type, case-control studies may show different results than cohort studies due to different exposure assessment. For our data, case-control studies are coded as $x_{i1} = 0$, and cohort studies are coded as $x_{i1} = 1$.

The fixed effect model is now

$$\theta_i = \beta_0 + \beta_1 x_{i1} + \epsilon_i, \quad \varepsilon_i \sim N(0, \sigma_i^2), \quad i = 1, \ldots, k.$$

Here, we find that cohort studies identify an association between HRT and breast cancer based on the regression equation $\hat{\theta}_i = 0.0015 + 0.145$ for a cohort study. Obviously, cohort studies come to results different form case-control studies. Clearly, after adjustment for covariates, the question remains if there is still residual heterogeneity present. Again, we can analyze the data using a random effects model in this case with a random intercept:

$$\theta_i = \beta_0 + \beta_1 x_{i1} + b_i + \epsilon_i, \quad b_i \sim N(0, \tau^2), \quad \varepsilon_i \sim N(0, \sigma_i^2).$$

For this model, the regression equation for the fixed effects gives now for a cohort study $\hat{\theta}_i = -0.009 + 0.1080$, and the corresponding heterogeneity variance is estimated as $\hat{\tau}^2 = 0.079$.

Table 36.2 compares fixed and random effects models for the HRT data. The table shows models with and without an estimate for the slope. Model selection can be based again on the BIC criterion. Apparently based on the BIC criterion, both fixed

Table 36.2 Comparison of fixed and random effects models

	Residual	Estimates (SE)				
Method	Hetero	Intercept	Slope	Het. ($\hat{\tau}^2$)	−log Lik.	BIC
Fixed	None	0.056 (0.023)	–	–	−33.85	70.0
Fixed	None	0.0014 (0.029)	0.145 (0.046)	–	−28.36	63.9
Mixed	Additive	0.027 (0.061)	–	0.086	−18.65	44.4
Mixed	Additive	−0.009 (0.072)	0.108 (0.126)	0.079	−18.25	47.3

effects models do not fit the data very well since their BIC values are considerably higher than those of the random effects models. Please note that if only the fixed effects models would be considered, this meta-analysis would show that cohort studies show a harmful effect. Comparing the mixed effects models in Table 36.2, the model with the covariate does not provide an improved fit of the data. The log-likelihood is only slightly larger, and penalizing the number of parameters leads to a larger BIC value for the mixed effect model with the covariate. Another interesting point is to compare the heterogeneity variance estimated by both models. Here, there is no substantial portion of heterogeneity explained by the covariate, since the heterogeneity variance is reduced to 0.079 from 0.086. From a statistical point of view, further covariates need to be identified and included into the model. From a public health point of view, the conclusion is perhaps less straightforward. Although inclusion of the covariate study type does not explain the heterogeneity of the studies very well, we find that cohort studies find a harmful effect. One might argue that although these results are far from perfect, they should not be ignored as absence of evidence does not imply evidence of absence. Looking back at these data in the light of the results from the woman health initiative (WHI) study (Rossouw et al. 2002), it becomes clear that caution is required in the analysis and interpretation of meta-analyses of observational studies. The major finding of the WHI study was that the group of subjects undergoing treatment with combined HRT in the form of Prempro (0.625 mg/day conjugated equine estrogens (CEE) +2.5 mg/day medroxyprogesterone acetate) was found to have increased risk of breast cancer (hazard ratio = 1.26, 95% CI: 1.00–1.59) and no apparent cardiac benefit. This is contradictory to the prior belief that HRT provides cardiovascular benefit. As a result, although several benefits were considered, these interim findings at 5 years were deemed sufficiently troubling to stop this arm of the trial at 5.2 years.

36.6 Interpretation of the Results of Meta-Analysis of Observational Studies

The example from above shows that the interpretation of the results of a meta-analysis should not only discuss the pooled estimator and the confidence interval but should focus on the examination of the heterogeneity between the results of the studies. Strength and weaknesses as well as potential bias should be discussed.

36.6.1 Bias

For epidemiological studies in general, the main problem is not the lack of precision and the random error but the fact that results may be distorted by different sources of bias or confounding; for a general overview of the problem of bias, see Hill and Kleinbaum (2000). That means that the standard error (or the size of the study) may not be the best indicator for the weight of a study. If more or better data are collected on a smaller amount of subjects, results may be more accurate than in a large study with insufficient information on the risk factors or on confounders. The assessment of bias in individual studies is therefore crucial for the overall interpretation.

The central problem of meta-analyses of clinical trials is publication bias that has already been a topic in a paper by Berlin et al. as early as 1989 and is still a topic of recent methodological investigations (see, e.g., Copas and Shi 2001). This bias has received a lot of attention particularly in the area of clinical trials. As mentioned in Sect. 36.5.2, publication bias yields in general a non-negligible overestimation of the risk estimate. However, as Morris (1994) has pointed out, there exist little systematic investigations of the magnitude of the problem for epidemiological studies. A major worry is that non-significant results are neither mentioned in the title nor in the abstract and publications and may be lost in the retrieval process.

36.6.2 Confounding

Another problem arises because different studies adjust for different confounding factors. It is well known that the estimated effect of a factor of interest is (strongly) influenced by the inclusion or exclusion of other factors, in the statistical model if these factors have an influence on the outcome and if they are correlated with the risk factor of interest. Combining estimates from several studies with different ways of adjusting for confounders yields biased results. Using literature data only, crude estimates may be available for some of the studies, model-based estimates for others. However, as the adjustment for confounders is an important issue for the assessment of an effect in each single study, it is obvious that combining these different estimates in a meta-analysis may not give meaningful results. It is necessary to use "similar" confounders in each study to adjust the estimated effect of interest in the single studies. In general, that would require a reanalysis of the single studies. Obviously, that requires the original data and a MAP is needed for this purpose.

36.6.3 Heterogeneity

In epidemiological research, different study designs are in use, and none of them can be considered as a gold standard as the randomized clinical trial for therapy studies. Therefore, it is necessary to evaluate the comparability of the single designs before summarizing the results. Often, case-control studies, cohort studies, and cross-sectional studies are used to investigate the same questions, and results of those studies need to be combined. Egger et al. (2001b) pointed out several examples in which results from case-control studies differ from those of cohort studies. For example, in a paper by Boyd et al. (1993), it was noted that cohort studies show no association between breast cancer and saturated fat intake, while the same meta-analysis using results from case-control studies only revealed an increased, statistically significant risk. Other reasons for heterogeneity may be different uses of data collection methods, different control selection (e.g., hospital vs. population controls), and differences in case ascertaining. Differences could be explored in a formal sensitivity analysis but also by graphical methods (funnel plot). However, meta-analyses from published data provide only limited information if the reasons for heterogeneity shall be investigated in depth.

The problem of heterogeneity can be well demonstrated with nearly any example of published meta-analysis. For example, Ursin et al. (1995) investigated the influence of the body mass index (BMI) on the development of premenopausal breast cancer. They included 23 studies of which 19 are case-control studies and 4 are cohort studies. Some of these studies were designed to investigate BMI as risk factor, others measured BMI as confounders in studies investigating other risk factors. It can only be speculated that the number of unpublished studies in which BMI was mainly considered as a confounder and did not show a strong influence on premenopausal breast cancer is non-negligible and that this issue may result in some bias. As is usual practice in epidemiological studies, relative risks were provided for several categories of BMI. To overcome this problem, the authors estimated a regression coefficient for the relative risk as a function of the BMI; however, several critical assumptions are necessary for this type of approach. The authors found severe heterogeneity across all studies combined (the p-value of a corresponding test was almost zero). An influence of the type of study (cohort study or case-control study) was apparent. Therefore, no overall summary is presented for case-control and cohort studies combined. One reason for the heterogeneity may be the variation in adjustment for confounders. Adjustment for confounders other than age was used only in 10 out of the 23 studies.

36.7 Network Meta-Analysis

Network meta-analyses are a recent development in meta-analyses, especially for randomized clinical trials, and are also referred to as multiple treatments meta-analyses. They are applied when the difference between two or more medical treatments should be investigated, but no or only few head-to-head comparison studies are available. In this situation, studies comparing the treatments of interest with a common comparator can be used for relative effect inferences. For example, there are randomized studies comparing treatment B versus standard treatment

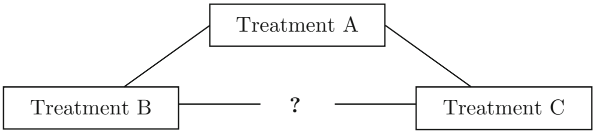

Fig. 36.7 Indirect comparison between treatment B and treatment C

A and furthermore randomized studies comparing treatment C versus treatment A (shown graphically in Fig. 36.7). A previously unresearched effect of treatment B versus treatment C can then be evaluated by an indirect comparison using the available studies.

36.7.1 Statistical Methods

In the setting of Fig. 36.7, let $\hat{\theta}_{BA}$ and $\hat{\theta}_{CA}$ be the estimated summary effects of the corresponding studies. These effects, for example, log odds ratios for binary outcome or differences in means for continuous data, can be combined in a network meta-analysis as follows:

$$\hat{\theta}_{BC} = \hat{\theta}_{BA} - \hat{\theta}_{CA}.$$

Extending this network, different paths for the same treatment comparison can also exist.

If further randomized studies were available comparing treatment D with treatments B and C, respectively (see Fig. 36.8), the effect θ_{BC} could be estimated on a second way:

$$\hat{\theta}_{BC} = \hat{\theta}_{BD} - \hat{\theta}_{CD}.$$

The network of different treatment comparisons can be arbitrarily extended to use all available evidence. Accordingly, several treatments can be compared simultaneously based on pairwise comparative or multiarm studies. If direct and indirect comparisons are included in a network meta-analysis, it is also named as mixed treatment comparisons (MTC) meta-analysis (Lu and Ades 2004). For example, Elliott and Meyer (2007a) investigated the effect of five antihypertensive drugs and placebo on incident diabetes mellitus based on 22 clinical trials with comparisons between two and three treatments. Figure 36.9 shows the network with the summary estimates for pairwise comparisons of traditional meta-analyses and each included study. None of these 22 trials performed a direct comparison between angiotensin-converting enzyme (ACE) inhibitors and angiontensin receptor blockers (ARB).
