Foreword to the Second Edition

Since 2005, when the first edition of the *Handbook of Epidemiology* was published, the English version of *Wikipedia* that was launched in 2001 has expanded from half a million articles and 1 gigabyte of text to about four million articles and 8 GB of text. A large number of articles deal with scientific and technical topics, including epidemiology and biostatistics. Has a stage been attained when the laborious task of compiling and editing books, particularly of an encyclopedic character, should be considered as not worth the effort, being outpaced by the swift mechanism of writing and updating texts online by volunteer authors?

Probably that stage will never be reached as different media fulfill different roles. Today there is room and need for handbooks occupying the territory between textbooks, with specific contents, perspectives, and targeted readership and all-encompassing encyclopedias of classical or “wiki” type in which the authors have freedom of approach provided they keep a presentation level allowing accessibility to a wide public. The *Handbook of Epidemiology* felicitously combines traits of both types of publications: it has the coverage expected from an up-to-date textbook of epidemiology and shows a variety of approaches by the different authors, who all share a style of presentation making each chapter well readable by epidemiologists and epidemiologists in training. More than a hundred scientifically distinguished authors have contributed to the book which benefits of their cumulated experience of at least five million person-hours of research and teaching. In this second edition, the total number of chapters has been substantially increased from 40 to 60. The sections of the book have been partly reorganized and their new headings neatly indicate the comprehensive coverage of the book: Concepts and Designs in Epidemiology; Methodological Approaches in Epidemiology; Statistical Methods in Epidemiology; Exposure-Oriented Epidemiology; Outcome-Oriented Epidemiology. The handbook is both a reference and a tool for several daily tasks: when writing a paper or reviewing articles and reports it helps checking the appropriateness and the implications of concepts and words, particularly if used in a non-standard way; when teaching and lecturing it may assist in preparing notes and visual aids. In addition going through individual chapters may provide a fresh look even at topics one is already familiar with (or thinks to be so).

As the name indicates, a handbook is designed to be “at hand,” on paper or electronically: I wish many in the epidemiological circles will have this *Handbook of Epidemiology* ready at hand for the consultation it fully deserves.

Florence, Italy Rodolfo Saracci

Foreword to the First Edition

When I was learning epidemiology nearly 50 years ago, there was barely one suitable textbook and a handful of specialized monographs to guide me. Information and ideas in journals were pretty sparse too. That all began to change about 25 years ago and soon we had a plethora of books to consider when deciding on something to recommend to students at every level from beginners to advanced postgraduates. This one is different from all the others. There has never been a single source of detailed descriptive accounts and informed discussions of all the essential aspects of practical epidemiology, written by experts and intended as a desk reference for mature epidemiologists who are in practice, probably already specializing in a particular field, but in need of current information and ideas about every aspect of the state of the art and science. Without a work like this, it is difficult to stay abreast of the times. A comprehensive current overview like this where each chapter is written by acknowledged experts chosen from a rich international pool of talent and expertise makes the task considerably easier.

It had been a rare privilege to receive and read the chapters as they have been written and sent to me through cyberspace. Each added to my enthusiasm for the project. I know and have a high regard for the authors of many of the chapters, and reading the chapters by those I did not know has given me a high regard for them too. The book has a logical framework and structure, proceeding from sections on concepts and methods and statistical methods to applications and fields of current research. I have learned a great deal from all of it, and furthermore I have enjoyed reading these accounts. I am confident that many others will do so too.

John M. Last
Emeritus Professor of Epidemiology
University of Ottawa, Canada

Preface to the Second Edition

The objective of this handbook is to provide a comprehensive overview of the field of epidemiology, bridging the gap between standard textbooks of epidemiology and publications for specialists with a narrow focus on specific areas. The handbook reviews the methodological approaches, statistical concepts, and important subject-matter topics pertinent to the field for which the reader seeks a detailed overview. It thus serves both as a first orientation for the interested reader and a starting point for an in-depth study of a specific area.

The handbook is intended as a reference source and a summarizing overview for professionals involved in health research, health reporting, health promotion, and health system administration. As a thorough guide through the major fields of epidemiology, it also provides a comprehensive resource for public health researchers, physicians, biostatisticians, epidemiologists, and executives in health services.

The first edition of this handbook, which appeared in 2005, was sold out much faster than expected. It had to be reprinted twice and received a subject index, which was missing in the first print. At that time we had already planned to work on a second, improved and expanded edition of the handbook, and we asked all authors for suggestions of further relevant topics to be covered by the handbook. The revision of the existing chapters started with an anonymous peer review of each chapter by authors of other chapters. It turned out that authors reviewed the chapters quite thoroughly making constructive suggestions for improvements and clarifications at the same time. This led to a careful revision of each chapter, several of which have undergone a fundamental renewal and update. We are very grateful to all authors for engaging in this fruitful process which helped to substantially improve the second edition. The second edition now covers several new topics in its 60 chapters, 20 more than the first edition, where topics are addressed that are usually only marginally represented in the specific literature or in standard textbooks, such as planning of epidemiological studies, data management, ethical aspects, practical fieldwork, epidemiology in developing countries, quality control, and good epidemiological practice.

The content of the handbook is arranged according to a new structure. It now contains five major parts ranging from concepts and designs (Part I), methodological approaches (Part II), statistical methods typically applied in epidemiological studies (Part III), various dimensions of disease determinants, i.e., exposures (Part IV), and major disease outcomes (Part V), where "exposure-oriented" and "outcome-oriented" epidemiology represent the two sides of the same coin. If the research question emphasizes disease determinants, the corresponding studies are usually classified as exposure-oriented. If, in contrast, a disease or another health-related event is the focus, we speak of "outcome-oriented" studies, in which risk factors for the specific disease are searched for. The above distinction is nevertheless somewhat arbitrary, as some research areas are not easily assigned to either category, e.g., molecular epidemiology, screening, clinical epidemiology, and infectious disease epidemiology.

In the following, we give an overview of the various chapters in the five parts, where every chapter of the handbook follows a similar structure. Each chapter stands on its own, giving an overview of the topic and the most important problems and approaches, which are supported by examples, practical applications, and illustrations. It serves as an introduction that allows one to enter a new field by addressing basic concepts and standard approaches, as well as recent advances and new perspectives. It thus also conveys more advanced knowledge for the reader who is familiar with the given topic by reflecting the state of the art and future prospects. Each chapter provides references both for the novice as well as for the advanced reader. Of course, some basic understanding of the concepts of probability, sampling distribution, estimation, and hypothesis testing will enable the reader to benefit from the statistical concepts primarily presented in Part III, and from the comprehensive discussion of empirical methods in the other parts.

After introducing the historical development of epidemiology at the beginning of **Part I**, the epistemological background and the conceptual building blocks of epidemiology such as models for causation and statistical ideas are described. The latter aspect is deepened with an overview of the various risk measures used in epidemiological studies. These measures depend on the type of data and the study design chosen to answer the research question: Descriptive studies provide the basic information for health reporting. Observational studies like cohort studies, case-control studies, and some modern study designs as well as experimental studies like intervention trials and cluster randomized trials, serve to examine associations and hypothesized causal relationships. The chapter on community-based health promotion builds the bridge between knowledge about the etiology of diseases and its application for prevention. Part I concludes with the implementation of classical epidemiological study designs using innovative internet-based approaches.

Part II of the handbook addresses the major methodological challenges faced by epidemiologists. These concern practical problems to be handled when conducting an epidemiological study such as key aspects of the planning of studies in general, their quality control, primary data collection, and exposure assessment. Further topics are major methodological issues that typically arise in observational studies such as the problem of misclassification, the two concepts of interaction and confounding as well as the problem of how to perform bias and sensitivity analyses. These more theoretical approaches are complemented by describing epidemiological methods for disease monitoring, surveillance and screening, where the latter aims at early detection of chronic diseases. Particular focus is on the problems related to health systems in developing countries and the resulting demands for epidemiological research as well as on the impact of the results of epidemiological studies on political decisions and the health system in developed countries. Part II closes with a discussion of human rights and responsibilities that have to be considered at the different stages of an epidemiological study.

The arsenal of statistical concepts and methods to be found in epidemiology is covered by **Part III**. It starts with a new general introduction into the basic statistical concepts that help to understand statistical thinking, where three complementing approaches to statistical inference are distinguished: the frequentist, the likelihood, and the Bayesian approach. Bayesian methods that try to integrate the evidence from the data with knowledge of the underlying scientific theory are introduced in a new chapter with emphasis on their application in epidemiological studies. The necessary steps during data management which are the prerequisites for any statistical analysis are now also described in the handbook in addition to another prerequisite, i.e., the sample size determination. Advanced techniques, such as fractional polynomials, are introduced for dose-effect analysis where exposures and/or outcomes are described by continuous variables. Since the relation between exposures and outcomes, which is the essence of epidemiology, is mostly represented by regression models, it is not surprising that the corresponding chapter is the longest in the handbook. Models where the outcome variables are in the form of a waiting time until a specific event, e.g., death, are discussed separately. Given that in practice data are often erroneous or missing, methods to handle the ensuing problems are presented in two chapters. The special problem of correlated data is accounted for in a new chapter on generalized estimating equations. Further issues in this statistical part of the handbook concern meta-analysis: the art of drawing joint conclusions from the results of several studies in order to put these conclusions on firmer ground; the analysis of spatial data where the values of the principal explanatory variable are geographical locations; and the analysis of genetic data, especially their high dimensionality, which requires specific methods for their analyses and directed acyclic graphs that play a major role under two different perspectives, i.e., to investigate the complex interplay in high-dimensional datasets and to capture causal interrelationships between determinants and potential outcomes.

Although each epidemiological study entails its own peculiarities and specific problems related to its design and realization, depending on the field of application, common features can be identified. Many important, partly classical, partly recent, applications of epidemiology of general interest to public health are defined by specific exposures. This exposure-oriented view on methods and design is taken in **Part IV**, which starts with the introduction of methods especially devoted to life course epidemiology. This new chapter is followed by the presentation of the main exposure-oriented fields such as social, occupational, environmental, nutritional, and reproductive epidemiology, but also more recent applications, such as the inclusion of molecular markers, are described. Clinical epidemiology and pharmacoepidemiology are growing areas where knowledge about the interplay between medical treatments and lifestyle factors and their joint effect on health outcomes is generated. Another exposure that is of special relevance with respect to the prevention of diseases is the individual's physical activity, which is discussed not only with respect to its public health relevance but also the current methodology to measure this exposure. A classical exposure with continuing interest to epidemiologists is ionizing radiation, where medical treatments add to occupational and environmental exposures. The specific methodological approaches to quantify these exposures are described in another new chapter.

Part V, the final part of this handbook, takes a disease-oriented perspective. It addresses specific methodological challenges to investigate prominent health outcomes and describes their epidemiology. The list of possible endpoints is almost endless. We selected ten disease groups because of their high public health relevance and/or their specific methodological challenges. These are infectious diseases, cardiovascular diseases, cancer, musculoskeletal disorders, and – newly included – overweight and obesity, asthma and allergies, dental diseases, digestive diseases, psychiatric disorders, and, last but not least, diabetes.

The editors are indebted to the knowledgeable experts for their valuable contributions, their enthusiastic support in producing this handbook, and their patience during the writing of the second edition, which took longer than we expected. We would like to thank Frauke Günther, Marc Suling, Claudia Börnhorst, and Angela Kammrad for their technical support. We are particularly grateful for the continuous and outstanding engagement of Regine Albrecht. Without her support, her patience with us and the contributors, and her remarkable autonomous management of the editorial work, this volume would not have been possible.

Preface to the First Edition

The objective of this book is to provide a comprehensive overview of the field of epidemiology, bridging the gap between standard textbooks of epidemiology and publications for specialists with a narrow focus on specific areas. It reviews the key issues, methodological approaches and statistical concepts pertinent to the field for which the reader seeks a detailed overview. It thus serves both as a first orientation for the interested reader and a starting point for an in-depth study of a specific area, as well as a quick reference and a summarizing overview for the expert.

The handbook is intended as a reference source for professionals involved in health research, health reporting, health promotion, and health system administration and related experts. It covers the major aspects of epidemiology and may be consulted as a thorough guide for specific topics. It is therefore of interest for public health researchers, physicians, biostatisticians, epidemiologists, and executives in health services.

The broad scope of the book is reflected by four major parts that facilitate an integration of epidemiological concepts and methods, statistical tools, applications, and epidemiological practice. The various facets are presented in 39 chapters and a general introduction to epidemiology. The latter provides the framework in which all other chapters are embedded and gives an overall picture of the whole handbook. It also highlights specific aspects and reveals the interwoven nature of the various research fields and disciplines related to epidemiology. The book covers topics that are usually missing from standard textbooks and that are only marginally represented in the specific literature, such as ethical aspects, practical fieldwork, health services research, epidemiology in developing countries, quality control, and good epidemiological practice. It also covers innovative areas, e.g., molecular and genetic epidemiology, modern study designs, and recent methodological developments.

Each chapter of the handbook serves as an introduction that allows one to enter a new field by addressing basic concepts, but without being too elementary. It also conveys more advanced knowledge and may thus be used as a reference source for the reader who is familiar with the given topic by reflecting the state of the art and future prospects. Of course, some basic understanding of the concepts of probability, sampling distribution, estimation, and hypothesis testing will help the reader to profit from the statistical concepts primarily presented in Part II and from the comprehensive discussion of empirical methods in the other parts. Each chapter is intended to stand on its own, giving an overview of the topic and the most important problems and approaches, which are supported by examples, practical applications, and illustrations. The basic concepts and knowledge, standard procedures and methods are presented, as well as recent advances and new perspectives. The handbook provides references both to introductory texts and to publications for the advanced reader.

The editors dedicate this handbook to Professor Eberhard Greiser, one of the pioneers of epidemiology in Germany. He is the founder of the Bremen Institute for Prevention Research and Social Medicine (BIPS), which is devoted to research into the causes and the prevention of disease. This institute, which started as a small enterprise dedicated to cardiovascular prevention, has grown to become one of the most highly regarded research institutes for epidemiology and public health in Germany. For almost 25 years Eberhard Greiser has been a leader in the field of epidemiology, committing his professional career to a critical appraisal of health practices for the benefit of us all. His major interests have been in pharmaceutical care and social medicine. In recognition of his contributions as a researcher and as a policy advisor to the advancement of the evolving field of epidemiology and public health in Germany we take his 65th birthday in November 2003 as an opportunity to acknowledge his efforts by editing this handbook.

The editors are indebted to knowledgeable experts for their valuable contributions and their enthusiastic support in producing this handbook. We thank all the colleagues who critically reviewed the chapters: Klaus Giersiepen, Cornelia Heitmann, Katrin Janhsen, Jürgen Kübler, Hermann Pohlabeln, Walter Schill, Jürgen Timm, and especially Klaus Krickeberg for his never-ending efforts. We also thank Heidi Asendorf, Thomas Behrens, Claudia Brünings-Kuppe, Andrea Eberle, Ronja Foraita, Andrea Gottlieb, Frauke Günther, Carola Lehmann, Anette Lübke, Ines Pelz, Jenny Peplies, Ursel Prote, Achim Reineke, Anke Suderburg, Nina Wawro, and Astrid Zierer for their technical support. Without the continuous and outstanding engagement of Regine Albrecht - her patience with us and the contributors and her remarkable autonomy - this volume would not have been possible. She has devoted many hours to our handbook over and above her other responsibilities as administrative assistant of the BIPS. Last but not least we are deeply grateful to Clemens Heine of Springer for his initiative, support, and advice in realizing this project and for his confidence in us.

June 2004

About the Editors

Wolfgang Ahrens Department of Epidemiological Methods and Etiologic Research, Leibniz Institute for Prevention Research and Epidemiology – BIPS Bremen, Germany

Wolfgang Ahrens is Professor for Epidemiological Methods at the Department of Mathematics and Computer Science of the University of Bremen since 2003. He is deputy director of the Leibniz Institute for Prevention Research and Epidemiology – BIPS, and head of the Department of Epidemiological Methods and Etiologic Research. Wolfgang Ahrens is an epidemiologist with considerable experience in leading population-based (inter)national multi-center studies involving primary data collection. His research focuses on epidemiological methods with particular emphasis on exposure assessment and the etiology and primary prevention of non-communicable diseases, especially cancer and nutrition- and lifestyle-related disorders. He coordinates two large European cohort studies of more than 16,000 children from eight countries, IDEFICS and I.Family, and he is member of the board of scientific directors of the German National Cohort including 200,000 German residents. He has published more than 220 international peer-reviewed papers and 16 book chapters. He has (co)authored three books, the most recent being a German textbook “Epidemiological Methods” (Springer 2012) and edited six books.

Iris Pigeot Department of Biometry and Data Management, Leibniz Institute for Prevention Research and Epidemiology – BIPS Bremen, Germany

Iris Pigeot is Professor of Statistics focused on Biometry and Methods in Epidemiology at the Department of Mathematics and Computer Science of the University of Bremen since 2001. She is Director of the Leibniz Institute for Prevention Research and Epidemiology – BIPS, and head of the Department of Biometry and Data Management. Her research activities focus on bioequivalence studies, graphical models, and genetic epidemiology. In recent years, she has widened the spectrum of her research to include the use of secondary data in the research of pharmaceutical drug safety as well as primary prevention and its evaluation, especially for childhood obesity. She received several teaching awards: the "Medal for Excellent Teaching" at the University of Dortmund in 1994, the "Award for Quality Teaching" at the University of Munich in 1996, and the "Berninghausen Award for Excellent Teaching and its Innovation" at the University of Bremen in 2008. In 2010, the IBS-DR awarded her the Susanne-Dahms medal for special accomplishments in the field of biometry.

Iris Pigeot and Wolfgang Ahrens are both editors of the book series "Epidemiology & Public Health" published by Springer (Heidelberg)

1.1 Scope

This chapter introduces the key concepts of epidemiology and summarizes their development. It highlights major areas of this discipline that are dealt with in detail in the chapters of this handbook and describes their interrelationship. The whole research area covered by the term "epidemiology" has been systemized in different ways and from various perspectives.

A first distinction differentiates between studies that are designed to evaluate the health effects of planned interventions and studies that are designed to just observe health-related characteristics and events in population groups. The first type of studies is called *experimental* because they introduce a certain measure to improve a health outcome of interest in a defined population. This measure is usually assigned to study subjects by random allocation and controlled by the investigator. Often experimental epidemiology is simply equated with randomized controlled trials. Clinical trials to study the efficacy of a treatment as, for example, a new drug, are a special type within this category. They are to be distinguished from trials of preventive interventions. The second type of studies, typically referred to as *observational*, studies situations as they present themselves without intervening. Such studies may describe the frequency or incidence of health outcomes or health determinants as well as their temporal or geographical variation. They may also be used to describe the natural history of a disease. If they aim to understand the etiology of a disease, they often exploit the so-called natural experiments in that they compare, for example, subjects exposed to a specific risk factor with non-exposed subjects. A typical example is the investigation of the influence of a risk factor like air pollution on a health outcome like asthma.

This gives rise to another, less clearly defined, classification of observational studies, that is, *explanatory* (or *analytical*) vs. *descriptive*. The objective of an explanatory study is to contribute to the search of causes for health-related events, in particular by isolating the effects of specific factors. The causality-oriented perspective distinguishes this type of studies from descriptive studies. In practice this distinction often corresponds to the use of different sources of data: In descriptive epidemiology often data are used that are routinely collected for various reasons, for example, for administrative purposes, whereas in explanatory or analytical epidemiology, data are usually collected for the study purpose itself. The term "descriptive epidemiology" covers the field of health reporting and is closely related to health statistics where reported data are usually stratified by time, place of residence, age, sex, and social position.

Observational epidemiology can also be divided into *exposure-oriented* and *outcome-oriented* epidemiology. These two research areas represent the two sides of the same coin. Insofar this distinction is more systematic rather than substantive. If the research question emphasizes disease determinants, for example, environmental or genetic factors, the corresponding studies usually are classified as exposure-oriented. If, in contrast, a disease or another health-related event like lung cancer or osteoarthritis is the focus, we speak of outcome-oriented studies in which risk factors for the specific disease are searched for.

After having introduced some common ways to classify the epidemiological research areas, we explain the definition of epidemiology, describe its scope, and illustrate its relations to adjacent research areas in Sect. 1.2. Section 1.3 gives a brief overview of the historical development of epidemiology and its applied areas. Section 1.4 provides an overview of the basic concepts related to the epidemiological study designs and describes specific applied research fields. Key concepts of statistical reasoning and major statistical methods are introduced in Sect. 1.5. Section 1.6 discusses "exposure-oriented" and "outcome-oriented" epidemiology and highlights some major research areas in both fields.

1.2 Epidemiology and Related Areas

Various disciplines contribute to the investigation of determinants of human health and disease, to the improvement of health care, and to the prevention of illness. These contributing disciplines stem from four major scientific areas, first from basic biomedical sciences such as biology, physiology, biochemistry, molecular genetics, and pathology; second from clinical sciences such as oncology, gynecology, orthopedics, obstetrics, cardiology, internal medicine, urology, radiology, and pharmacology; third from biostatistics and demography; and fourth from social and behavioral sciences as well as public health with epidemiology as its core.

1.2.1 Definition and Purpose of Epidemiology

One of the first definitions of epidemiology that was most frequently used at that time was given by MacMahon and Pugh (1970):

> Epidemiology is the study of the distribution and determinants of disease frequency in man.

This relatively simplistic definition was further developed later on as described below. The three components of this definition, that is, frequency, distribution, and determinants, embrace the basic principles and approaches in epidemiological research. The measurement of disease *frequency* relates to the quantification of disease occurrence in human populations. Such data are needed for further investigations of patterns of disease in subgroups of the population. This involves "… describing the *distribution* of health status in terms of age, sex, race, geography, etc., …" (MacMahon and Pugh 1970). The methods used to describe the distribution of diseases may be considered as a prerequisite to identify the *determinants* of human health and disease.

The above definition is based on two fundamental assumptions: first, the occurrence of diseases in populations is not a purely random process, and second, it is determined by causal and preventive factors (Hennekens and Buring 1987). As mentioned above, these factors have to be searched for systematically in populations defined by place, time, or otherwise. Different ecological models have been used to describe the interplay of these factors, which relate to host, agent,

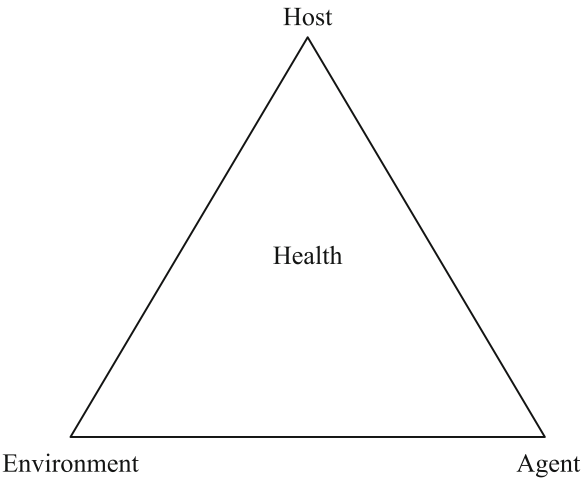

Fig. 1.1 The epidemiological triangle

and environment. Changing any of these three forces, which constitute the so-called epidemiological triangle (Fig. 1.1), will influence the balance among them and thereby increase or decrease the disease frequency (Mausner and Bahn 1974).

Thus, the search for etiological factors in the development of diseases and disorders is one of the main concerns of epidemiology. Complementary to the epidemiological triangle, the triad of time, place, and person is often used by epidemiologists to describe the distribution of diseases and their determinants. Determinants that influence health may consist of behavioral, cultural, social, psychological, biological, or physical factors. The determinants by time may relate to increase/decrease over the years, seasonal variations, or sudden changes of disease occurrence. Determinants by place can be characterized by country, climate zone, residence, and, more general, by geographical region. Personal determinants include age, sex, ethnic group, genetic traits, and individual behavior. Studying the interplay between time, place, and person helps to identify the etiological agent and the environmental factors as well as to describe the natural history of the disease, which then enables the epidemiologist to define targets for intervention with the purpose of disease prevention (Detels 2002). This widened perspective is reflected in a more comprehensive definition of epidemiology as given by Last (2001):

> The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control of health problems.

It has been further specified in the subsequent edition of the Dictionary of Epidemiology (Porta 2008):

> The study of the occurrence and distribution of health-related states or events in specified populations, including the study of the determinants influencing such states, and the application of this knowledge to control the health problems.

In this broader sense, health-related states or events include "diseases, causes of death, behaviors, reactions to preventive programs, and provision and use of health services," while determinants refer to "all the physical, biological, social, cultural, economic and behavioral factors that influence health" (Porta 2008). According to this widely accepted definition, the final aim of epidemiology is "to promote, protect, and restore health." Hence, the major goals of epidemiology may be defined from two overlapping perspectives. The first is a biomedical perspective looking primarily at the etiology of diseases and the disease process itself. This includes:

- The description of the disease spectrum, the syndromes of the disease, and the disease entities to learn about the various outcomes that may be caused by particular pathogens
- The description of the natural history, that is, the course of the disease to improve the diagnostic accuracy which is a major issue in clinical epidemiology
- The investigation of physiological or genetic variables in relation to influencing factors and disease outcomes to decide whether they are potential risk factors, disease markers, or indicators of early stages of disease
- The identification of factors that are responsible for the increase or decrease of disease risks in order to obtain the knowledge necessary for primary prevention
- The prediction of disease trends to facilitate the adaptation of the health services to future needs and to identify research priorities
- The clarification of disease transmission to control the spread of contagious diseases, for example, by targeted vaccination programs.

Achievement of these aims is the prerequisite for the second perspective, which defines the scope of epidemiology from a public health point of view. Especially in this respect, the statement as given in Box 1.1 was issued by the IEA (International Epidemiological Association) conference already in 1975.

Box 1.1. Statement by the IEA conference in 1975 (White and Henderson 1976)

"The discipline of epidemiology, together with the applied fields of economics, management sciences, and the social sciences, provide the essential quantitative and analytical methods, principles of logical inquiry, and rules for evidence for:

- . . .;
- Diagnosing, measuring, and projecting the health needs of community and populations;
- Determining health goals, objectives and priorities;
- Allocating and managing health care resources;
- Assessing intervention strategies and evaluating the impact of health services."

This list may be complemented by the provision of tools for investigating consequences of disease as unemployment, social deprivation, disablement, and death.

1.2.2 Epidemiology in Relation to Other Disciplines

Biomedical, clinical, and other related disciplines sometimes claim that epidemiology belongs to their particular research area. It is therefore not surprising that biometricians think of epidemiology as a part of biometry and physicians define epidemiology as a medical science. On the one hand, biometricians have in mind that epidemiology uses statistical methods to investigate the distribution of health-related entities in populations as opposed to handling single cases. This perspective on distributions of events, conditions, etc. is statistics by its very nature. On the other hand, physicians view epidemiology primarily from a substantive view on diseases and their treatment. In doing so, each of them may disregard central elements that constitute epidemiology.

Moreover, as described at the beginning, epidemiology overlaps with various other domains that provide their methods and knowledge to answer epidemiological questions. For example, measurement scales and instruments to assess subjective well-being developed by psychologists can be applied by epidemiologists to investigate the psychological effects of medical treatments in addition to classical clinical outcome parameters. Social sciences provide indicators and methods of field work that are useful in describing social inequality in health, in investigating social determinants of health, and in designing population-based prevention strategies. Other examples are methods and approaches from demography that are used to provide health reports, from population genetics to identify hereditary factors, and from molecular biology to search for precursors of diseases and factors of susceptibility.

Of course, epidemiology does not only borrow methods from other sciences but has also its own methodological core. This pertains in particular to the development and adaptation of study designs. It is also true for statistical methods. In most cases they can directly be applied to epidemiological data, but sometimes peculiarities in the data structure may call for the derivation of special methods to cope with these requirements. This is in particular the case in genetic epidemiology when, for example, gene-environment interactions have to be modeled.

The line of demarcation between epidemiology and related disciplines is often blurred. Let us take clinical medicine as an example. In clinical practice, a physician decides case by case to diagnose and treat individual patients. To achieve the optimal treatment for a given subject, he/she will classify this patient and then make use of knowledge on the group to which the person belongs. This knowledge may come from randomized clinical trials but also from (clinical) epidemiological studies. A randomized clinical trial is a special case of a randomized controlled trial (RCT). In a broad sense, an RCT is an epidemiological experiment in which subjects in a population are randomly allocated to groups, that is, a study group where intervention takes place and a control group without intervention. This reveals the link between clinical and epidemiological studies, where the latter focus on populations while clinical trials address highly selected groups of patients. Thus, it may be controversial whether randomized clinical trials for drug approval (i.e., phase III trials) are to be considered part of epidemiology, but it is clear that a follow-up concerned with safety aspects of drug utilization (the so-called phase IV studies) needs pharmaco-epidemiological approaches.

When discussing the delimitation of epidemiology, the complex area of public health plays an essential role. According to Last's definition (Last 2001) public health deals with the health needs of the population as a whole, in particular the prevention and treatment of disease. More explicitly, "Public health is one of the efforts organized by society to protect, promote, and restore the people's health. It is the combination of sciences, skills, and beliefs that is directed to the maintenance and improvement of the health of all the people through collective or social actions. (…) Public health … goals remain the same: to reduce the amount of disease, premature death, and disease-produced discomfort and disability in the population. Public health is thus a social institution, a discipline, and a practice" (Last 2001). The practice of public health is based on scientific knowledge of factors influencing health and disease, where epidemiology is, according to Detels and Breslow (2002), "the core science of public health and preventive medicine" that is complemented by biostatistics and "knowledge and strategies derived from biological, physical, social, and demographic sciences."

In conclusion, epidemiology cannot be reduced to a subdivision of one of the contributing sciences, but it should be considered as a multidisciplinary science laying the grounds of the applied field of public health.

1.3 Historical Development of Epidemiology

In the following we highlight some milestones of the historical development of epidemiology. For a more comprehensive description of the history of epidemiology, we refer to chapter ▸History of Epidemiological Methods and Concepts of this handbook.

1.3.1 Historical Background

The word "epidemic," that is, something that falls upon people (ἐπί upon; δῆμος people), which was in use in ancient Greece, reflected already one of the basic ideas of modern epidemiology, namely, to look at diseases on the level of *populations*, or *herds* as they also have been called, especially in the epidemiology of infectious diseases. The link with the search for *causes* of illness was present in early writings of the Egyptians, Jews, Greeks, and Romans (Bulloch 1938). Both Hippocrates (ca 460 – ca 375 BC) and Galen (129 or 230–200 or 201) advanced etiological theories. The first stressed atmospheric conditions and “miasmata” but considered nutrition and lifestyle as well (Hippocrates 400 BC). The second distinguished three causes of an “epidemic constitution” in a population: an atmospheric one, susceptibility, and lifestyle. The basic book by Coxe (1846) contains a classification of Galen’s writings including the subject “etiology.” For a survey on the various editions of Galen’s work and a biography, see the essay by Siegel (1968).

Regarding more specific observations, the influence of dust in quarries on chronic lung diseases was mentioned in a Roman text of the first century. Paracelsus in 1534 published the first treatise on *occupational diseases*, entitled “Von der Bergsucht oder Bergkranckheiten drey Bücher, inn dreyzehen Tractat verfast unnd beschriben worden” (“On miners’ diseases”); see his biography in English by Pagel (1982). Ramazzini (1713) conjectured that the relatively high incidence of breast cancer among nuns was due to celibacy. Sixty-two years later, Percival Pott (1775) was among the first ones to phrase a comparative observation in quantitative terms. He reported that scrotal cancer was very frequent among London chimney sweeps and that their death rate due to this disease was more than 200 times higher than that of other workers.

The most prominent early observational epidemiological study is that of John Snow on cholera in London in 1853. He was able to record the mortality by this disease in various places of residence which he characterized by type of water supply and sewage system. By comparing morbidity and mortality rates, he concluded that polluted water was indeed the cause of cholera (Snow 1855).

Parallel to this emergence of observational epidemiology, three more currents of epidemiological thinking have emerged during the centuries and have interacted with each other as well as with the former, namely, (1) the debate on *contagion* and *living causal agents*, (2) *descriptive* epidemiology in the classical sense of health statistics, and (3) *clinical trials*.

A contagion can be suspected from recording cases and their location in time, space, families, and the like. The possibility of its involvement in epidemics has therefore no doubt been considered since time immemorial; it was alluded to the early writings mentioned at the beginning. Nevertheless, Hippocrates and Galen did not admit it. It played an important role in the thinking about *variolation* and later on *vaccination* as introduced by Jenner in 1796 (Jenner 1798). The essay by Daniel Bernoulli on the impact of variolation (Bernoulli 1766) was the beginning of the theory of *mathematical modeling* of the spread of diseases.

By contrast to a contagion itself, the existence of *living* pathogens cannot be deduced from purely epidemiological observations, but the discussion around it has often been intermingled with that about contagion and has contributed much to epidemiological thinking. Fracastoro (1521) wrote about a *contagium animatum*. In the sequel the idea came up again and again in various forms, for example, in the writings of Snow. It culminated in the identification of specific parasites, fungi, bacteria, and viruses as agents in the period from, roughly, 1840 when Henle, after Arabian predecessors dating back to the ninth century, definitely showed that mites cause scabies, until 1984 when HIV was detected.

As far as we know, the term "epidemiology" first appeared in Madrid in 1802. From the late nineteenth century to about the middle of the twentieth, it was restricted to *epidemical infectious* diseases until it took its present meaning (see Sect. 1.2.1 and Greenwood 1932).

Descriptive epidemiology had various precursors, mainly in the form of church and military records on the one hand (Marshall and Tulloch 1838), and life tables on the other (Graunt 1662; Halley 1693). In the late eighteenth century, local medical statistics started to appear in many European cities and regions. They took a more systematic turn with the work of William Farr (1975). This lasted from 1837 when he was appointed to the General Register Office in London until his retirement in 1879. In particular, he developed classifications of diseases that led to the first International List of Causes of Death, to be adopted in 1893 by the International Statistical Institute. Farr took also part in the activities of the London Epidemiological Society, founded in 1850 with him and Snow as founding members and apparently the oldest learned society featuring the word "epidemiological" in its name.

Geographical epidemiology, that is, the presentation of health statistics in the form of maps, also started in the nineteenth century (Rupke 2000).

If we mean by a clinical trial a *planned*, *comparative*, and *quantitative* experiment on humans in order to learn something about the efficacy of a curative or preventive treatment in a clinical setting, James Lind is considered having done the first one. In 1747 he tried out six different supplements to the basic diet of 12 sailors suffering from scurvy and found that citrus fruits, and only these, cured the patients (Lind 1753). Later he also compared quinine to treat malaria with less well-defined control therapies (Lind 1771).

The first more or less rigorous trial of a preventive measure was performed by Jenner with 23 vaccinated people. For his trial he used what is now being called "historical controls," that is, he compared these vaccinated people with unvaccinated ones of the past who had not been specially selected beforehand for the purpose of the trial (Jenner 1798).

In the nineteenth century, some physicians began to think about the general principles of clinical trials and already emphasized probabilistic and statistical methods (Louis 1835; Bernard 1865). Some trials were done, for example, on the efficacy of bloodletting to treat pneumonia, but rigorous methods in the modern sense were established only after World War II, beginning in 1948 with the pioneer trial on the treatment of pulmonary tuberculosis by streptomycin as described in Hill (1962).

Let us conclude this all too short historical sketch with a few remarks on the history of applications of epidemiology:

Clinical trials have always been tied, by their very nature, to immediate applications as in the above-mentioned examples; hence we will not dwell on this further.

Observational epidemiology, including classical descriptive epidemiology, has led to hygienic measures. In fact, coming back to a concept of Galen (1951), one might define *hygiene* in a modern and general sense as applied observational epidemiology, its task being to diminish or to eliminate causal factors of any kind.

For example, the results of Snow's study on cholera found rapid applications in London but not in places like Hamburg where 8,600 people died in the cholera epidemic of 1892.

Hygiene was a matter of much debate and activity during the entire nineteenth century, although, before the identification of living pathogens, most measures taken were necessarily not directed against a known specific agent, with the exception of *meat inspection* for trichinae. This was made compulsory in Prussia in 1875 as proposed by Rudolf Virchow, one of the pioneers of modern hygiene and also an active politician (Ackerknecht 1953).

Hygienic activities generally had their epidemiological roots in the descriptive health statistics mentioned above. These statistics usually involved only factors like time, place of residence, sex, and age, but Virchow, for example, analyzed during the years 1854–1871 the mortality statistics for the city of Berlin and related mortality to social factors like poverty, crowded dwellings, and dangerous professions, thus becoming a forerunner of *social epidemiology*.

As a result of such reflections as well as of political pressure, large *sewage systems* were built in Europe and North America, the *refuse disposal* was re-organized, and the *water supply* improved. Other hygienic measures concerned the structure and functioning of *hospitals*, from reducing the number of patients per room and dispersing wards in the form of pavilions to antiseptic rules. The latter had mainly been inspired by more or less precise epidemiological observations on infections after the treatment of wounds and amputations (Tenon 1788; Simpson 1868–1869, 1869–1870; Ackerknecht 1967) and on puerperal fever (Gordon 1795; Holmes 1842–1843; Semmelweis 1861). *Nosocomial infections* are still a major public health problem and fighting them a major application of epidemiology.

1.3.2 Milestones in Epidemiological Research

The initiation of numerous epidemiological studies after the Second World War accelerated the research in this field and led to a systematic development of study designs and methods. In the following some exemplary studies are introduced that served as role models for the design and analysis of many subsequent investigations. It is not our intention to provide an exhaustive list of all major studies since that time, if at all feasible, but to exhibit some cornerstones marking the most important steps in the evolution of this science. Each of them had its own peculiarities with a high impact both on methods and epidemiological reasoning as well as on health policies.

The usefulness of descriptive study designs has been convincingly demonstrated by migrant studies comparing the incidence or mortality of a disease within a certain population between the country of origin and the new host country. Such observations offer an exceptional opportunity to distinguish between potential contributions of genetics and environment to the development of disease and thus make it possible to distinguish between the effects of nature and nurture. The most prominent examples are provided by investigations on Japanese migrants to Hawaii and California. For instance, the mortality from stomach cancer was much higher in Japan than among US inhabitants, whereas for colon cancer the relationship was reverse. Japanese migrants living in California had a mortality pattern that lay between these two populations. It was thus concluded that dietary and other lifestyle factors had a stronger impact than hereditary factors, which was further supported by the fact that the sons of Japanese immigrants in California had an even lower risk for stomach cancer and a still higher risk for cancer of the colon than their fathers (Buell and Dunn 1965).

One of the milestones in epidemiological research was the development of rigorous case-control designs, which facilitate the investigation of risk factors for chronic diseases with long induction periods. The most famous study of this type, although not the first one, is the study on smoking and lung cancer by Doll and Hill (1950). As early as in 1943, the German pathologist Schairer from the Scientific Institute for Research into the Hazards of Tobacco, Jena, published together with Schöniger a case-control study comparing 109 men and women deceased from lung cancer with 270 healthy male controls as well as with 318 men and women who died from other cancers with regard to their smoking habits (Schairer and Schöniger 1943). Judged by modern epidemiological standards, this study had several weaknesses; still, it showed a clear association of tobacco smoking and lung cancer. The case-control study by Doll and Hill was much more sophisticated in methodological terms. Over the whole period of investigation from 1948 to 1952, they recruited 1,357 male and 108 female patients with lung cancer from several hospitals in London and matched them with respect to age and sex to the same number of patients hospitalized for non-malignant conditions. For each patient, a smoking history was collected. Without going into detail here, these data supported a strong positive association between smoking and lung cancer. Despite the methodological concerns regarding case-control studies, Doll and Hill believed that smoking was responsible for the development of lung cancer. The study became a landmark that inspired future generations of epidemiologists to use this methodology (cf. chapter ▸Case-Control Studies of this handbook). It remains a model for the design and conduct of case-control studies until today, with excellent suggestions on how to reduce or eliminate selection, interview, and recall bias.

Because of the strong association observed in their case-control study, they initiated a cohort study of 20,000 male British physicians in 1951, known as the British Doctors' Study. These were followed over time to investigate the association between smoking and lung cancer prospectively. The authors compared mortality from lung cancer among those who never smoked with that among all smokers and with those who smoked various numbers of cigarettes per day (Doll and Hill 1954, 1964; Doll and Peto 1978).

Another, probably even more important cohort study was the Framingham Heart Study that was based on the population of Framingham, a small community in Massachusetts. The study was initiated in 1949 to yield insights into causes of cardiovascular diseases (CVD) (see chapter ▸Cardiovascular Health and Disease of this handbook). For this purpose, 5,127 participants free from coronary heart disease (CHD), 30 to 59 years of age, were examined and then observed for nearly 50 years to determine the rate of occurrence of new cases among persons free of disease at first observation (Dawber et al. 1951; Dawber 1980). The intensive biennial examination schedule, long-term continuity of follow-up and investigator involvement, and incorporation of new design components over its decade-long history have made this a uniquely rich source of data on risk factors for CVD. The study served as a reference and good example for many subsequent cohort studies in this field which adopted its methodology. In particular, analysis of the Framingham data led to the development of the perhaps most important modeling technique in epidemiology, the multiple logistic regression (Truett et al. 1967; see chapter ▶Regression Methods for Epidemiological Analysis of this handbook).

Two other leading examples of cohort studies conducted within a single population or for comparison of multiple populations to assess risk factors for cardiovascular events are the Whitehall Study of British civil servants (Rose and Shipley 1986; see also chapter ▶Occupational Epidemiology of this handbook) and the Seven Countries Study of factors accounting for differences in CHD rates between populations of Europe, Japan, and North America (Keys 1980; Kromhout et al. 1995; see chapter ▶Cardiovascular Health and Disease of this handbook).

In contrast to the above cohort studies that focused on cardiovascular diseases, the US Nurses' Health Study is an impressive example of a multipurpose cohort study. It recruited over 120,000 married female nurses, 30 to 55 years of age, in a mail survey in 1976. In this study, information on demographic, reproductive, medical, and lifestyle factors was obtained. Nurses were contacted every 2 years to assess outcomes that occurred during that interval and to update and to supplement the exposure information collected at baseline. Various exposure factors like the use of oral contraceptives, postmenopausal hormone therapy, and fat consumption were related to different outcomes such as cancer and cardiovascular disease (Lipnick et al. 1986; Willett et al. 1987; Stampfer et al. 1985). Recent results had an essential impact on the risk-benefit assessment of postmenopausal hormone therapy speaking against its use over extended periods (Chen et al. 2002).

Final the proof of a causal relationship is provided by experimental studies, namely, intervention trials. The most famous and largest intervention trial was the so-called Salk vaccine field trial in 1954 where nearly one million school children were randomly assigned to one of the two groups, a vaccination group that received the active vaccine and a comparison group receiving placebo. A 50% reduction of the incidence of paralytic poliomyelitis was observed in the vaccination group as compared to the placebo group. This gave the basis for the large-scale worldwide implementation of poliomyelitis vaccination programs for disease prevention.

In recent years, the accelerated developments in molecular biology were taken up by epidemiologists to measure markers of exposure, early biological effects, and host characteristics that influence response (susceptibility) in human cells, blood, tissue, and other material. These techniques augment the standard tools of epidemiology in the investigation of low-level risks, risks imposed by complex exposures, and the modification of risks by genetic factors. The use of such biomarkers of exposure and effect has led to a boom of the so-called molecular epidemiology (Schulte and Perera 1993; Rothman et al. 2012; Toniolo et al. 1997; chapter ▸Molecular Epidemiology of this handbook), a methodological approach with early origins. These developments were accompanied by the sequencing of the human genome and the advances in high-throughput genetic technologies that led to the rapid progress of genetic epidemiology (Khoury et al. 1993; chapter ▸Statistical Methods in Genetic Epidemiology of this handbook). The better understanding of genetic factors and their interaction with each other and with environmental factors in disease causation is a major challenge for future research. Here, large-scale studies, often accomplished by the pooling of several studies, paved the way for genome-wide association studies (GWAS) assessing genetic variants that entail increased disease risks.

1.3.3 Methodological Limits

The successes of epidemiology in identifying major risk factors of chronic diseases have been contrasted with more subtle risks that epidemiologists have seemingly discovered like the association between environmental tobacco smoke exposure and lung cancer. Such risks are difficult to determine and false alarms may result from chance findings. Thus it is not surprising that many studies showed conflicting evidence, that is, some studies seem to reveal a significant association with a suspected risk factor while others do not. The unreflected publication of such contradictory results in the lay press leads to opposing advice and thus to an increasing anxiety in the public. This has given rise to a controversial debate about the methodological weaknesses of epidemiology that culminated in the article “Epidemiology faces Its Limits” by Taubes (1995) and the discussions that it prompted.

In investigating low relative risks, say, below 2 or even below 1.5, the methodological shortcomings inherent in observational designs become more serious. Such studies are more prone to yield false positive or false negative findings due to the distorting effects of misclassification, bias, and confounding (see chapters ▸Misclassification, ▸Confounding and Interaction, ▸Sensitivity Analysis and Bias Analysis, and ▸Measurement Error of this handbook). For instance, the potential effect of environmental tobacco smoke (ETS) on lung cancer was denied because misclassification of only a few active smokers as non-smokers would result in relative risks that might explain all or most of the observed association between ETS and the risk of lung cancer in non-smokers (Lee and Forey 1996). Validation studies showed that this explanation was unlikely (Riboli et al. 1990; Wells et al. 1998). Thus, the numerous positive findings and the obvious biological plausibility of the exposure-disease relationship support the conclusion of a harmful effect of ETS (Boffetta et al. 1998; Chan-Yeung and Dimich-Ward 2003; IARC Monograph on ETS 2004). This example also illustrates that the investigation of low relative risks is not an academic exercise but may be of high public health relevance if a large segment of the population is exposed.

It is often believed that large-scale studies are needed to identify small risks since such studies result in narrower confidence intervals. However, a narrow confidence interval does not necessarily mean that the overwhelming effects of misclassification, bias, and confounding are adequately controlled by simply increasing the size of a study. Even sophisticated statistical analyses will never overcome serious deficiencies of the database. The fundamental quality of the data collected or provided for epidemiological purposes is therefore the cornerstone of any study and needs to be prioritized throughout its planning and conduct (see chapter ▶Quality Control and Good Epidemiological Practice of this handbook). In addition, the refinement of methods and measures involving all steps from study design over exposure and outcome assessment to the final data analysis, incorporating, for example, molecular markers, may help to push the edge of what can be achieved with epidemiology a little bit further.

Nevertheless a persistent problem is "The pressures to publish inconclusive results and the eagerness of the press to publicize them ..." (Taubes 1995). This pressure to publish positive findings that are of questionable validity imposes a particular demand on researchers not only to report and interpret study results carefully in peer-reviewed journals but also to communicate potential risks to the lay press in a comprehensible manner that accounts for potential limitations. Both authors and editors have to take care that the pressure to publish does not lead to a publication bias favoring positive findings and dismissing negative results.

1.4 Concepts, Methodological Approaches, and Applications

1.4.1 Concepts

Epidemiology may be considered as minor to physical sciences because it does not investigate the biological mechanism leading from exposure to disease as, for example, toxicology does. However, the ability of identifying modifiable conditions that contribute to health outcomes without identifying the biological mechanisms or the agent(s) that lead to these outcomes is a strength of epidemiology: It is not always necessary to wait until the underlying mechanism is completely understood in order to facilitate preventive action. This is illustrated by the historical examples of the improvements of environmental hygiene that led to a reduction of infectious diseases like cholera that was possible before the identification of *vibrio cholerae*.

What distinguishes epidemiology is its perspective on groups or populations rather than individuals. It is this demographic focus where statistical methods enter the field and provide the tools needed to compare different characteristics relating to disease occurrence between populations. Epidemiology is a comparative discipline that contrasts occurrence of diseases and characteristics between different time periods, different places, or different groups of persons. The comparison of groups is a central feature of epidemiology, be it the comparison of morbidity or mortality in populations with and without a certain exposure or the comparison of exposure between diseased subjects and a control group. Inclusion of an appropriate reference group (non-exposed or non-diseased) for comparison with the group of interest is a condition for causal inference.

In experimental studies efficient means are available to minimize the potential for bias. Due to the observational nature of the vast majority of epidemiological studies, bias and confounding are the major problems that may restrict the interpretation of the findings if not adequately taken into account (see chapters ▸Confounding and Interaction, ▸Sensitivity Analysis and Bias Analysis, and ▸Design and Planning of Epidemiological Studies of this handbook). Although possible associations are analyzed and reported on a group level, it is important to note that only data that provide the necessary information on an individual level allow the adequate consideration of confounding factors (see chapter ▸Descriptive Studies of this handbook).

Most epidemiological studies deal with mixed populations. On the one hand, the corresponding heterogeneity of covariables may threaten the internal validity of a study, because the inability to randomize study subjects in observational studies may impair the comparability between study groups due to confounding. On the other hand the observation of natural experiments in diverse groups of individuals enables epidemiologists to make statements about the real world and thus contributes to the external validity of the results. This population perspective enables the assessment of effectiveness of a treatment rather than its efficacy when evaluating interventions.

Due to practical limitations, it may not be feasible to obtain a representative sample of the whole population of interest in a given study. It may even be desired to investigate only defined subgroups of a population. Whatever the reason, a restriction on subgroups may not necessarily impair the meaning of the obtained results, but it may increase the internal validity of a study. Thus, it is a misconception that the cases always need to be representative of all persons with the disease and that the reference group always should be representative of the general non-diseased population. What is important is a precise definition of the population base, that is, in a case-control study, cases and controls need to originate from the same source population and the same inclusion/exclusion criteria need to be applied to both groups. This implies that the interpretation of study results has to consider possible limitations with respect to their generalizability beyond the source population.

Rarely a single positive study will provide sufficient evidence to justify an intervention. Limitations inherent in most observational studies require the consideration of alternative explanations of the findings and confirmation by independent evidence from other studies in different populations before preventive action can be recommended with sufficient certainty. The interpretation of negative studies deserves the same scrutiny as the interpretation of positive studies. Negative results should not hastily be interpreted to prove an absence of the association under investigation (Doll and Wald 1994). Besides chance, false-negative results may easily be due to a weak design and conduct of a given study, that is, absence of evidence is not evidence of absence (Altman and Bland 1995).

1.4.2 Study Designs

Epidemiological reasoning consists of three major steps. First, a statistical association between an explanatory characteristic (exposure) and the outcome of interest (disease) is assessed. Then, depending on the pattern of the association,

Table 1.1 Types of epidemiological studies

Type of study	Alternative name	Unit of study
Observational		
Ecological study	Correlational study	Populations
Cross-sectional study	Prevalence study; survey	Individuals
Case-control study	Case-referent study	Individuals
Cohort study	Follow-up study	Individuals
Experimental	*Intervention studies*	
Community trial	Community intervention study	Communities
Field trial	–	Healthy individuals
Randomized controlled trial	RCT	Individuals
Clinical trial	Therapeutic study[a]	Individual patients

[a] Clinical trials are included here since conceptually they are linked to epidemiology, although they are often not considered as epidemiological studies. Clinical trials have developed into a vast field of its own because of methodological reasons and their economic importance.

a hypothetical (biological) inference about the disease mechanism is formulated that can be refuted or confirmed by subsequent studies. Finally, when a plausible conjecture about the causal factor(s) leading to the outcome has been acknowledged, alteration or reduction of the putative cause and subsequent observation of the resulting disease frequency provide the verification or refutation of the presumed association.

In practice these three major steps are interwoven in an iterative process of hypothesis generation by descriptive and exploratory studies, statistical confirmation of the presumed association by analytical studies, and, if feasible, implementation and evaluation of intervention activities, that is, experimental studies. An overview of the different types of study and some common alternative names are given in Table 1.1.

A first observation of a presumed relation between exposure and disease is often done at the group level by correlating one group characteristic with an outcome, that is, in an attempt to relate differences in morbidity or mortality of population groups to differences in their local environment, culture, lifestyle, or other factors. Such correlational studies that are usually based on existing data (see chapter ▶Use of Health Registers of this handbook) are prone to the so-called ecological fallacy since the compared populations may differ in factors other than the ones of interest that are related to the disease. For a detailed discussion of this issue, we refer to the chapter ▶Descriptive Studies of this handbook. Nevertheless, ecological studies can provide clues to etiological factors and may serve as a gateway towards more detailed investigations. In subsequent analytical studies the investigator determines whether the relationship in question is also present among individuals, either by asking whether persons with the disease have the characteristic more frequently than those without the disease or by asking whether persons with the characteristic develop the disease more frequently than those not having it. The investigation of an association at the individual level is considered to be less vulnerable to be mixed up with the effect of a third common factor.

Studies that are primarily designed to describe the distribution of existing variables that can be used for the generation of broad hypotheses are often classified as descriptive studies (cf. chapter ▸Descriptive Studies of this handbook). Analytical studies examine an association, that is, the relationship between a risk factor and a disease in detail, and conduct a statistical test of the corresponding hypothesis. Typically the two main types of epidemiological studies, that is, case-control study and cohort study, belong to this category (see chapters ▸Cohort Studies and ▸Case-Control Studies of this handbook). However, a clear-cut distinction between analytical and descriptive study designs is not possible. A case-control study may be designed to explore associations of multiple exposures with a disease. Such “fishing expeditions” may better be characterized as descriptive rather than analytical studies. A cross-sectional study is descriptive when it surveys a community to determine the health status of its members. It is analytical when the association of an acute health event with a recent exposure is analyzed.

Cross-sectional studies provide descriptive data on prevalence of diseases useful for health-care planning. Prevalence data on risk factors from descriptive studies also help in planning an analytical study, for example, for sample size calculations. The design is particularly useful for investigating acute effects but has significant drawbacks in comparison to a longitudinal design because the temporal sequence between exposure and disease usually cannot be assessed with certainty, except for invariant characteristics like genetic polymorphisms. In addition, it cannot identify incident cases of a chronic disease (see chapter ▸Descriptive Studies of this handbook).

Both case-control and cohort studies are in some sense longitudinal because they incorporate the temporal dimension by relating exposure information to time periods that are prior to disease occurrence. These two study types – in particular when data are collected prospectively – are therefore more informative with respect to causal hypotheses than cross-sectional studies because they are less prone to the danger of “reverse causality” that may emerge when information on exposure and outcome relates to the same point in time. The best means to avoid this danger are prospective designs where the exposure data are collected prior to disease. Typically these are cohort studies, either concurrent or historical, as opposed to retrospective studies, that is, case-control studies where information on previous exposure is collected from diseased and non-diseased subjects. For further details of the strengths and weaknesses of the main observational designs, see chapter ▸Design and Planning of Epidemiological Studies of this handbook.

The different types of studies are arranged in Table 1.1 in ascending order according to their ability to support the causality of a supposed association. The criteria summarized by Hill (1965) have gained wide acceptance among epidemiologists as a checklist to assess the strength of the evidence for a causal relationship. However, an uncritical accumulation of items from such a list cannot replace the critical appraisal of the quality, strengths, and weaknesses of each study. The weight of evidence for a causal association depends in the first place on the type of study, with intervention studies providing the strongest evidence (Table 1.2)

Table 1.2 Reasoning in different types of epidemiological study

Study type	Reasoning
Ecological	Descriptive; association on group level may be used for development of broad hypotheses
Cross-sectional	Descriptive; individual association may be used for development and specification of hypotheses
Case-control	Increased prevalence of risk factor among diseased as compared to non-diseased may indicate a causal relationship
Cohort	Increased risk of disease among exposed as compared to non-exposed indicates a causal relationship
Intervention	Modification (reduction) of the incidence rate of the disease confirms a causal relationship

(see chapter ▶Intervention Trials of this handbook). The assessment of causality has then to be based on a critical judgment of evidence by conjecture and refutation (see chapter ▶Basic Concepts of this handbook for a discussion of this issue).

1.4.3 Collection of Data

Data are the foundation of any empirical study. It is fundamental to avoid any sort of systematic bias in the planning and conduct of an epidemiological study, be it information or selection bias. Errors that have been introduced during data collection can in most cases not be corrected later on. Exceptions from this rule are, for example, measurement instruments yielding distorted measurements where size and direction of the systematic error is known so that the individual measurement values can be calibrated accordingly. In other instances statistical methods are offered to cope with measurement error (see chapter ▶Measurement Error of this handbook). However, such later efforts are second choice and an optimal quality of the original data must be the primary goal. Selection bias may even be worse as it cannot be controlled for and may affect both the internal and the external validity of a study. Standardized procedures to ensure the quality of the original data to be collected for a given study are therefore crucial (see chapter ▶Quality Control and Good Epidemiological Practice of this handbook).

Original data will usually be collected by questionnaires, the main measurement instrument in epidemiology. Epidemiologists have neglected for a long time the potential in improving the methods for interviewing subjects in a highly standardized way and thus improving the validity and reliability of this central measurement tool. Only in the late 1990s, it has been recognized that major improvements in this area are not only necessary but also possible, for example, by adopting methodological developments from the social sciences (Olsen et al. 1998). Chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook is devoted to the basic principles and approaches in this field. Prior to the increased awareness related to data collection methods, the area of exposure assessment has developed into a flourishing research field that provided advanced tools and guidance for researchers (White et al. 2008; Kromhout 1994; Ahrens 1999; Nieuwenhuijsen 2003; chapter ▶Exposure Assessment of this handbook). Recent advances in molecular epidemiology have introduced new possibilities for exposure measurement that are now being used in addition to the classical questionnaires. However, since the suitability of biological markers for the retrospective assessment of exposure is limited due to the short half-life of most agents that can be examined in biological specimens, the use of interviews will retain its importance but will change its face. Computer-aided data collection with built-in plausibility checks – more and more being conducted in the form of telephone interviews or even by the Internet – will partially replace the traditional paper and pencil approach (see chapter ▶Internet-Based Epidemiology of this handbook).

Often it may not be feasible to collect primary data for the study purpose due to limited resources or because of the specific research question. In such cases, the epidemiologist can sometimes exploit existing databases such as registries (see chapter ▶Use of Health Registers of this handbook). Here, he/she usually has to face the problem that such "secondary" or "routine" data may have been collected for administrative or other purposes. Since such data are collected on a routine basis without the claim for subsequent systematic analyses, they may be of limited quality. Looking at these data from a research perspective thus often reveals inconsistencies that had not been noticed before. The degree of standardization that can be achieved in collection, documentation, and storage is particularly low if personnel of varying skills and levels of training is involved. Moreover, changes in procedures over time may introduce additional systematic variation. Measures for assessing the suitability and quality of the data and for careful data cleaning are therefore of special importance.

The scrutiny, time, and effort that need to be devoted to any data use - be it routine data or newly collected data - before they can be used for analysis are rarely addressed in standard textbooks of epidemiology and often neglected in study plans. This is also true for the coding of variables like diseases, pharmaceuticals, or job titles. They deserve special care with regard to training and quality assurance. Regardless of all efforts to ensure an optimal quality during data collection, a substantial input is needed to guarantee standardized and well-documented coding, processing, and storing of data (see chapter ▶Data Management in Epidemiology of this handbook). Residual errors that remain after all preceding steps need to be scrutinized and, if possible, corrected (see chapter ▶Quality Control and Good Epidemiological Practice of this handbook). Sufficient time has to be allocated for this work package that precedes the statistical analysis and publication of the study results. Finally, all data and study materials have to be stored and documented in a fashion that allows future use and/or sharing of the data or auditing of the study. Materials to be archived should not only include the electronic files of raw data and files for the analyses but also the study protocol, computer programs, the documentation of data processing and data correction, measurement protocols, and the final report. Both, during the conduct of the study as well as after its completion, materials and data have to be stored in a physically safe place with limited access to ensure safety and confidentiality even if the data have been anonymized.

1.4.4 Application of Epidemiological Knowledge

Epidemiological knowledge concerns *populations*. There are two ways to use this knowledge. The first is *group-oriented*: It consists in applying knowledge about a specific population directly to this population itself. This is part of *public health*. The conceptually simplest applications of this kind concern the planning of the health system (chapter ▸Health Services Research of this handbook) and of health strategies. For instance, epidemiological studies have shown that people exposed to inhaling asbestos fibers are prone to develop asbestosis and its sequels like cor pulmonale. We apply this knowledge to the entire population by prohibiting the use of asbestos.

The second path is taken when we are confronted with an individual person, typically in a clinical setting: We can then regard this person as a member of a population for which relevant epidemiological knowledge is available and deal with her or him accordingly. As an example, a physician confronted with a child suffering from medium dehydration due to acute diarrhea, knows from clinical trials that oral rehydration will normally be a very efficient treatment. Hence she/he will apply it in this particular case.

Clinical epidemiology plays a major role for the second path, where epidemiological knowledge is applied in all phases of clinical decision making, that is, in daily clinical practice, starting with diagnosis, passing to therapy, and culminating in prognosis and advice to the patient – including individual preventive measures.

1.4.4.1 Prevention

The first of the two preceding examples belongs to *population-based prevention* (see chapters ▸Intervention Trials, ▸Community-Based Health Promotion, and ▸Epidemiology in Developing Countries of this handbook). The underlying idea is to diminish the influence of risk factors identified by previous observational epidemiological studies. Risks of transmission of infectious diseases have long played a particular role in public health: Their influence was reduced by public hygiene in the classical sense. Applying observational epidemiology in order to diminish or eliminate risk factors has therefore been termed *hygiene* in a modern, general sense. Preventive measures in this context are sometimes themselves subject to an a posteriori evaluation which may bear on the one hand on the way they have been implemented and on the other hand on their effectiveness.

Population-based preventive measures can also be derived from results of experimental epidemiology. The most important applications of this kind are *vaccinations* performed systematically within a given population. They have to be subjected to rigorous efficacy trials before implementation. *Preventive drug treatments*, for example, against malaria or cardiovascular events, fall into the same category.

In many cases the target population itself is determined by a previous epidemiological study. For instance, dietary recommendations to reduce cardiovascular problems, and vaccinations against Hepatitis B, yellow fever, or influenza, are primarily given to people that were identified as being at *high risk* to contract the disease in question.

1.4.4.2 Screening

Population-based *treatments* as a measure of public health are conceivable but hardly ever implemented. There exists, however, a population-based application of epidemiology in the realm of *diagnosis*, namely, screening (see chapter ▸Screening of this handbook). Its purpose is to find yet unrecognized cases of disease or health defects by appropriate tests that can be rapidly executed within large population groups. The ultimate aim is mostly to allow a treatment at an early stage. Occasionally, screening was also performed in order to isolate infected people, for example, lepers. Classical examples of screening include mass X-ray examination to detect cases of pulmonary tuberculosis or breast cancer and cytological tests to identify cancer of the cervix uteri. Screening programs may concentrate on *high-risk groups* if it would be unfeasible, too expensive, or too dangerous to examine the entire original population. A striking example is the screening for pulmonary tuberculosis in Norway where most of the prevalent cases were found at an early stage by systematic X-ray examinations of only a small fraction of the population (Harstad et al. 2009).

1.4.4.3 Case Management

The concept of the *individual* risk of a person (see chapters ▸Rates, Risks, Measures of Association and Impact and ▸Cohort Studies of this handbook) that underlies the definition of risk groups represents a particular case of the second way of applications of epidemiology, that is, dealing with an individual person on the basis of epidemiological knowledge about populations which he/she is deemed to belong to. The most important application of this idea, however, is *clinical epidemiology* which was also called *statistics in clinical medicine*. It is the art of case management in the most general sense: diagnosis using the epidemiological characteristics of medical tests like sensitivity and specificity, treatment using the results of clinical trials, and prognosis for a specific case based again on relevant epidemiological studies. Chapter ▸Clinical Epidemiology and Evidence-Based Health Care of this handbook describes in detail fairly sophisticated procedures involving all aspects of case management including the opinion of the patient or his/her relatives and considerations of cost, secondary effects, and quality of life as elements entering the therapeutic decision.

1.4.4.4 Health Services

Health services research (HSR) is a vast and multiform field. It has no concise and generally accepted definition, but still there is a more or less general agreement about its essential ideas. Its purpose is to lay the general, scientific foundations for health policy in order to improve the health of people as much as possible under the constraints of society and nature (cf. chapter ▸Health Services Research of this handbook). The subjects of HSR are, in the first place, the underlying *structures*, that is, the basic elements concerned by questions of health and the relations between them; in the second place the *processes* of health-care delivery; and in the third place the *effects* of health services on the health of the general population.

On the methodological side, HSR means *analysis* and *evaluation* of all of these aspects. The tools are mainly coming from mathematics and statistics, economics, and sociology together with knowledge from clinical medicine and basic sciences like biology. Epidemiology plays a particularly important role. Evaluation implies *comparison*: comparison of different existing health-care systems and comparison of an existing one with theoretical, ideal systems in order to design a better one. The comparison of health-care systems of different countries has been a favorite subject. One of the main "factors" that distinguishes them is the way medical services are being paid for and the form of health insurance.

The basic elements are physicians, nurses and other personnel, hospitals, equipment, and money, but also the population served by the health system. Relations between these elements comprise *health needs* and *access to services* but also the *organization* of the health system.

Processes of health-care delivery may of course mean the usual clinical curative treatment of patients but also person- or community-based preventive actions including environmental measures, health education, or health strategies like the one that led to the eradication of smallpox.

Finally, the effects of health services, that is, the *output*, can be measured in many ways, for example, by morbidity and mortality, life expectancy, quality of life preserved or restored, and economic losses due to illness. However, the quantitative assessment of *effectiveness*, that is, the value of outputs relative to (usually monetary) inputs, is still in the limelight.

Epidemiology as a method serves two purposes. On the one hand, the results of epidemiological investigations enter the field as basic parameters. Some experimental epidemiological studies like intervention trials are even considered as *belonging* to health services research. On the other hand, many methods used in health services research that stem from mathematical statistics and whose goal is to study the influence of various factors on outcomes are formally the same as those employed in epidemiology. Given the importance and complexity of the subject, many different "approaches" and "models" have been proposed and tried out. Earlier ones were still fairly descriptive and static, focusing on the functioning of the health services or on health policy with a strong emphasis on the economic aspects. The input-output model where the effects of changes of essential inputs on the various outcomes of interest are studied, if possible in a quantitative way, is more recent. More than others it allows to a large extent a "modular" approach, separating from each other the investigation of different parts or levels of the health services.

1.4.5 Ethical Aspects

The protection of human rights is one of the most crucial aspects of all studies on humans. Although there are substantial differences between experimental and observational studies, they both have to face the challenging task to protect the privacy of all individuals taking part in a study. This also implies as a basic principle that study subjects are asked for their informed consent.

Another ethical angle of epidemiological research concerns the study quality. Poorly conducted research may lead to unsubstantiated and wrong decisions in clinical practice or policy making in public health and may thus cause harm to individuals but also to society as a whole. Therefore, guidelines such as the "Good Epidemiological Practice" provided by the International Epidemiological Association in 1998 have been prepared to maintain high study quality and to preserve human rights.

Of course, the four general principles of the Declaration of Helsinki (World Medical Association 2000) have to be followed, that is, autonomy (respect for individuals), beneficence (do good), non-maleficence (do no harm), and justice. These principles are of particular relevance in randomized controlled trials, where the intervention (or non-intervention) may involve negative consequences for participants.

Various recent developments in epidemiological research constitute a new challenge regarding ethical requirements. First, automated record linkage databases are now at least partly available that capture both exposure and outcome data on an individual level. Such databases have raised questions about confidentiality of patient's medical records, authorizing access to person-specific information, and their potential misuse. Second, the inclusion of molecular markers in epidemiological studies has led to a controversial debate on the potential benefit or harm of results gained by genetic and molecular epidemiological studies. This raises the following questions: Can knowledge on genetic markers be used in primary prevention programs? How should this knowledge be communicated to the study subjects who may be forced into the conflict between their individual "right to know" and their "right not to know?" A third driver of ethical questioning has been the discussion about integrity and conflict of interests, in particular when epidemiological studies are sponsored by interest groups or when the results are contradictory.

As a consequence, an increasing awareness that ethical conduct is essential to epidemiological research can be observed among epidemiologists. Thus, it is not surprising that now basic principles of integrity, honesty, truthfulness, fairness and equity, respect for people's autonomy, distributive justice, and doing good and not harm have become an integral part in the planning and conduct of epidemiological studies. Chapter ▶Ethical Aspects of Epidemiological Research of this handbook is devoted to all of these aspects.

1.5 Statistical Methods in Epidemiology

The statistical analysis of an empirical study relates to all its phases. It starts with the planning phase where ideally all details of the subsequent analysis should be laid down (see chapter ▶Design and Planning of Epidemiological Studies of this handbook). This concerns defining the variables to be collected and their scale; the methods how they should be summarized, for example, via means, rates, or odds; the appropriate statistical models to be used to capture the relationship between exposures and outcomes; the formulation of the research questions as statistical hypotheses; the calculation of the necessary sample size based on a given power or vice versa the power of the study based on a fixed sample size; and the appropriate techniques to check for robustness and sensitivity. It is crucial to have in mind that the study should be planned and carried out in such a way that its statistical analysis is able to answer the research questions we are interested in. If the analysis is not already adequately accounted for in the planning phase or if only a secondary analysis of already existing data can be done, the results will probably be of limited validity and interpretability.

1.5.1 Principles of Data Analysis

Having collected the data, the first step of a statistical analysis is devoted to the cleaning of the dataset. Questions to be answered are as follows: "Are the data free of measurement or coding errors?" "Are there differences between centers?" "Are the data biased, already edited, or modified in any way?" "Have data points been removed from the dataset?" "Are there outliers or internal inconsistencies in the dataset?" A sound and thorough descriptive analysis enables the investigator to inspect the data. Cross-checks based, for example, on the range of plausible values of the variables and cross tabulations of two or more variables have to be carried out to find internal inconsistencies and implausible data (see chapter ▶Data Management in Epidemiology of this handbook). Graphical representations such as scatterplots, boxplots, and stem-and-leaf diagrams help to detect outliers and irregularities. Calculating various summary statistics such as *mean* as compared to *median*, *standard deviation* as compared to *median absolute deviation from the median* is also reasonable to reveal deficiencies in the data. Special care has to be taken to deal with measurement errors and missing values. In both cases, special statistical techniques are available to cope with such data (see chapters ▶Measurement Error and ▶Missing Data of this handbook).

After having cleaned the dataset, descriptive measures such as cross tabulations, correlation coefficients or graphical representations like boxplots will help the epidemiologist to understand the structure of the data. Such summary statistics need, however, to be interpreted carefully. They are descriptive by their very nature and are not to be used to formulate statistical hypotheses that are subsequently investigated by a statistical significance test based on the same dataset.

In the next step parameters of interest such as relative risks or incidence rates should be estimated. The calculated point estimates should always be supplemented by their empirical measures of dispersion like standard deviations and by confidence intervals to get an idea about their stability and variation, respectively. In any case, confidence intervals are more informative than the corresponding significance tests. Whereas the latter just lead to a binary decision, a confidence interval also allows the assessment of the uncertainty of an observed measure and of its practical relevance. Nevertheless, if p-values are used for exploratory purposes, they can be considered as an objective measure to judge the meaning of an observed association without declaring it as "statistically significant" or "non-significant." In conclusion, Rothman and Greenland (1998, p. 6) put it as follows: "The notion of statistical significance has come to pervade epidemiological thinking, as well as that of other disciplines. Unfortunately, statistical hypothesis testing is a mode of analysis that offers less insight into epidemiological data than alternative methods that emphasize estimation of interpretable measures."

Despite the justified condemnation of the uncritical use of statistical significance tests, they are widely used in the close-to-final step of an analysis to confirm or reject postulated research hypotheses (cf. next section). More sophisticated techniques such as multivariate regression models are applied in order to describe the functional relationship between exposures and outcomes (see chapters ▶Analysis of Continuous Covariates and Dose-Effect Analysis and ▶Regression Methods for Epidemiological Analysis of this handbook). Such techniques are an important tool to analyze complex data; but as it is the case with statistical tests, their application may lead to erroneous results if carried out without appropriately accounting for the epidemiological context. This, of course, holds for any statistical method. Its blind use may be misleading with serious consequences in practice. Therefore, each statistical analysis should be accompanied by sensitivity analyses (cf. chapter ▶Sensitivity Analysis and Bias Analysis of this handbook) and checks for model robustness. Graphical tools such as residual plots, for instance, to test for the appropriateness of a chosen statistical model should also routinely be used.

The final step concerns the adequate reporting of the results and their careful interpretation. The latter has to be done in light of background information and subject-matter knowledge about the investigated research area.

1.5.2 Statistical Thinking

According to the definitions quoted in Sect. 1.2.1, epidemiology deals with the distribution and determinants of health-related phenomena in *populations* as opposed to looking at *individual* subjects or cases. Studying distributions and their determinants in populations in a quantitative way is the very essence of statistics. In this sense, epidemiology requires statistical thinking (for an introduction to statistical inference, see chapter ▶Statistical Inference and to Bayesian methods see chapter ▶Bayesian Methods in Epidemiology of this handbook) in the context of health including the emphasis on causal analysis as described in chapter ▶Basic Concepts and the manifold applications to be found all over in this handbook. However, this conception of epidemiology started to permeate the field relatively late, and, at the beginning, often unconsciously.

The traditional separation of statistics into its descriptive and its inferential component has existed in epidemiology, too, until the two merged conceptually though not structurally. The *descriptive* approaches, introduced by scientists like Farr (see Sect. 1.3.1), continue in the form of *health statistics*, *health yearbooks*, and similar summary statistics by major hospitals, research organizations, and various health administrations like national ministries of health and the World Health Organization, often illustrated by graphics. The visual representation of the geographical distribution of diseases has recently taken an upsurge with the advent of *geographical information systems* (chapter ▶Geographical Epidemiology).

Forerunners of the use of *inferential* statistics in various parts of epidemiology are also mentioned in Sect. 1.3.1. Thus, in the area of *clinical trials*, the efficacy of citrus fruit to cure scurvy was established by purely statistical reasoning. In the realm of *causal factors* for diseases, the discovery of water contamination as a factor for cholera still relied on quite rudimentary statistical arguments, whereas the influence of the presence of a doctor at childbirth on maternal mortality was confirmed by a quantitative argument coming close to a modern test of significance. The basic statistical idea of *comparing frequencies* in populations with different levels of factors (or "determinants") was already present in all of these early investigations. The same is true for statistics in the domain of *diagnosis* where statistical thinking expresses itself by concepts like *sensitivity* or *specificity* of a medical test. It seems that this was only recently conceived of as a branch of epidemiology on par with the others, indispensable in particular for developing areas like computer-aided diagnosis or telediagnosis.

A landmark of statistical thinking in epidemiology was the elaboration of the theory of *hypothesis testing* by Neyman and Pearson. No self-respecting physician writes any more a paper on health in a population without testing some hypotheses on the significance level 5% or without giving a p-value. Most of these hypotheses are about the efficacy of a curative treatment or, to a lesser degree, the etiology of an ailment, but the efficacy of preventive treatments and diagnostic problems is also addressed.

However, the underlying statistical thinking was often deficient. Non-acceptance of the alternative hypothesis was frequently regarded as acceptance of the null hypothesis. The meaning of an arbitrarily chosen significance level or of a p-value was not understood, and in particular several simultaneous trials or trials on several hypotheses were not handled correctly by confusing the significance level of each part of the study with the overall significance level, that is, by not adjusting the single significance levels for multiple testing. Other statistical procedures that usually provide more useful insights like *confidence bounds* were neglected. Above all, *causal interpretations* were often not clear or outright wrong, and hence erroneous practical conclusions were drawn. A statistical result in the form of a hypothesis accepted either by a test or by a correlation coefficient far from 0 was regarded as final evidence and not as one element that should lead to further investigations, usually of a biological nature.

Current statistical thinking expresses itself mainly in the study of the effect of several factors on a health phenomenon, be it a causal effect in etiological research (chapter ▸Basic Concepts of this handbook), a curative or preventive effect in clinical or intervention trials, or the effect of a judgment, for example, a medical test. Such effects are expressed in quantitative, statistical terms. Here, relations between the action of several factors as described by the concepts of interaction and confounding play a prominent role (chapter ▸Confounding and Interaction of this handbook). The use of modern statistical ideas and tools has thus allowed for a conceptual and practical *unification* of the many parts of epidemiology. The *same* statistical models and methods of analysis (see chapters of Part III (Statistical Methods in Epidemiology) of the handbook) are being used in all of them.

1.5.3 Multivariate Analysis

An epidemiological study typically involves a huge number of variables to be collected from the study participants, which implies a high-dimensional dataset that has to be appropriately analyzed to extract the essential information. This curse of dimensionality becomes especially serious in genetic or molecular epidemiological studies. In such situations, statistical methods are called for to reduce the dimensionality of the data and to reveal the underlying association structure. Various multivariate techniques are at hand depending on the structure of the data and the research aim. They can roughly be divided into two main groups. The first group covers methods to structure the dataset without distinguishing response and explanatory variables, whereas the second group provides techniques to model and test for postulated dependencies. Although these multivariate techniques seem to be quite appealing at a first glance, they are not a statistical panacea. Their major drawback is that they cannot be easily understood by the investigator which typically leads to a less deep understanding of the data. This "black box" phenomenon also implies that the interpretation and communication of the results is not as straightforward as it is when just showing some well-known risk measures supplemented by frequency tables. In addition, the various techniques may not lead to the same result, while each of them may be compatible with the observed data. Thus, a final decision on the underlying data structure should not be made without critically reflecting the results in light of the epidemiological context and of additional subject-matter knowledge as well as compared with simpler statistical analyses such as stratified analyses – perhaps restricted to some key variables – that hopefully support the results obtained from the multivariate analysis.

Multivariate analyses with the aim to structure the dataset comprise factor analysis, cluster, and discriminatory analysis. Factor analysis tries to collapse a large number of observed variables into a smaller number of possibly unobservable, that is, latent variables, so-called factors, for example, in the development of scoring systems. These factors represent correlated subgroups of the original set. They serve in addition to estimate the fundamental dimensions underlying the observed dataset. Cluster analysis simply aims at detecting highly interrelated subgroups of the dataset, for example, in the routine surveillance of a disease. Having detected certain subgroups, their common characteristics might be helpful, for example, to identify risk factors, prevention strategies, or therapeutic concepts. This is in contrast to discriminant analysis, which pertains to a known number of groups and aims to assign a subject to one of these groups (populations) based on certain characteristics of this subject while minimizing the probability of misclassification. As an example, a patient with a diagnosis of myocardial infarction has to be assigned to one of the two groups, one consisting of long-term survivors of such an event and the other consisting of short-term survivors. For this purpose, the physician may measure his/her systolic and diastolic blood pressure, heart rate, and mean arterial pressure and assess his/her stroke index. With these medical parameters the physician will be able to predict whether or not the patient will die within a short period of time. A detailed discussion of these techniques is beyond the scope of this handbook. Instead, we refer to classical textbooks in this field such as Dillon and Goldstein (1984); Everitt and Dunn (2001), and Giri (2004).

However, in line with the idea of epidemiology, epidemiologists are often not so much interested in detecting a structure in the dataset rather than in explaining the occurrence of some health outcome depending on potentially explanatory variables. Here, it is hardly sufficient to investigate the influence of a single variable on disease risk as most diseases are the result of the complex interplay of many different exposure variables. Although it is very helpful to look first at simple stratified 2 × 2 tables to account for confounders, such techniques become impractical if a large number of variables have to be accounted for, especially if the study population is small. In such situations, techniques are needed that allow the examination of the effect of several variables simultaneously not only for adjustment but also for prediction purposes.

This is realized by regression models that offer a wide variety of methods to capture the functional relationship between outcomes and explanatory variables (see chapter ►Regression Methods for Epidemiological Analysis of this handbook). Models with more than one explanatory variable are usually referred to as multiple regression models, multivariable, or multivariate models where the latter might also involve more than one outcome. Using such techniques one needs to keep in mind that a statistical model rests on assumptions like normality, variance homogeneity, independence, and linearity that have all to be checked carefully in a given data situation. The validity of the model depends on these assumptions which might not be fulfilled by the data. Various models are therefore available from which an adequate one has to be selected. This choice is partly based on the research question and the a priori epidemiological knowledge about the relevant variables and their measurement. Depending on the scale, continuous or discrete, linear or logistic regressions might then be used for modeling purposes. Even more complex techniques such as generalized linear models can be applied where the functional relationship is no longer assumed to be linear or generalized estimation equations if a correlation structure has to be accounted for (see chapters ►Analysis of Continuous Covariates and Dose-Effect Analysis, ►Regression Methods for Epidemiological Analysis, and ►Generalized Estimating Equations of this handbook). Once the type of regression model is determined, one has to decide which and how many variables should be included in the model. If variables are strongly correlated with each other, only one of them should be included if justified from a subject-matter point of view. Many software packages offer automatic selection strategies such as forward or backward selection, which usually lead to different models that are all consistent with the data at hand. An additional problem may occur due to the fact that the type of regression model will have an impact on the variables to be selected and vice versa. The resulting model may also fail to recognize effect modification or may be affected by peculiarities of this particular dataset that are of no general relevance.

Further extensions of simple regression models are, for example, time-series models that allow for time-dependent variation and correlation, Cox-type models to be applied in survival analysis (see chapter ►Survival Analysis of this handbook), and the so-called graphical chain models which try to capture even more complex association structures. One of their features is that they allow for indirect influences by incorporating so-called intermediate variables that simultaneously serve as explanatory and response variables. The interested reader is referred to Lauritzen and Wermuth (1989), Wermuth and Lauritzen (1990), Whittaker (1990), Lauritzen (1996), and Cox and Wermuth (1996). In particular, directed acyclic graphs (DAGs) are not only used for data-driven modeling of complex association structures, but they have also become increasingly popular to postulate causal relationships, where the data-driven modeling aspect of DAGs can at best assist to explore causal dependence networks. This results from the fact that, so far, a single DAG cannot accomplish probabilistic and causal interpretations simultaneously (see chapter ▸Directed Acyclic Graphs of this handbook).

1.5.4 Handling of Data Problems

Data are the basic elements of epidemiological investigation and information. In the form of values of predictor variables, they represent levels of factors (risk factors and covariates), which are the *determinants* of health-related states or events in the sense of the definition of epidemiology quoted in Sect. 1.2.1. As values of *response* (outcome) variables, they describe the health-related phenomena themselves. Measuring these values accurately is obviously fundamental for the conclusions to be drawn from an epidemiological study. The practical problems that arise when trying to do this are outlined in chapters ▸Design and Planning of Epidemiological Studies, ▸Quality Control and Good Epidemiological Practice, ▸Epidemiological Field Work in Population-Based Studies, and ▸Exposure Assessment of this handbook. However, even when taking great care and applying a rigorous quality control, some of the recorded data may still be erroneous and others may be missing. The question of how to handle these problems is the subject of chapters ▸Measurement Error and ▸Missing Data of this handbook.

Intuitively, it is clear that in both cases the approach to be taken depends on the particular situation, more precisely, on the type of *additional information* that may be available. We use this information either to correct or to supplement certain data individually or to correct the final results of the study.

Sometimes a naïve approach looks sensible for replacing a missing value or correcting a measurement error. Thus, if we know that the data at hand represent the size of a tumor in consecutive months, we may be tempted to replace a missing or obviously out-of-range value by an interpolated one. When monitoring maternal mortality in a developing country by studies carried out routinely on the basis of death registers, we may multiply the figures obtained by a factor that reflects the fact that many deaths in childbed are not recorded in these registers. This factor may be estimated beforehand by special studies where all such deaths were searched for, for example, by visits to the homes of diseased women and retrospective interviews. Even with such simple procedures, though, it is difficult to assess their impact on the *statistical quality* of a study, be it the power of a test or the width of a confidence interval.

The basic idea underlying the rigorous handling of measurement errors is to represent the *true* predictor variables that cannot be measured exactly via the so-called *surrogate* predictor variables that can be measured error free. The way a surrogate and a predictor are assumed to be related and the corresponding distributional assumptions form the so-called *measurement error model*. Several types of such models have been suggested and explored, the goal always being to get an idea about the magnitude of the effect on the statistical quality of the study if we correct the final results depending on the postulated model.

The general ideas that underlie methods for dealing with missing values are similar although the technical details are quite different. These methods are mainly based on jointly modeling the predictor and response variables and the missing value mechanism. This mechanism may or may not allow for imputation of a missing value.

1.5.5 Meta-Analysis

The use of meta-analyses to synthesize the evidence from epidemiological studies has become more and more popular. They can be considered as the quantitative parts of systematic reviews. Usually the main objective of a meta-analysis is the statistical combination of results from several studies that individually are not powerful enough to demonstrate a presumed effect. However, whereas it is always reasonable to review the literature and the published results on a certain topic systematically, the statistical combination of results from separate epidemiological studies may yield misleading results. Purely observational studies are in contrast to randomized clinical trials where differences in treatment effects between studies can mainly be attributed to random variation. Observational studies, however, may lead to different estimates of the same effect that can no longer be explained by chance alone, but that may be due to confounding and bias potentially inherent in each of them. Thus, the calculation of a combined measure of association based on heterogeneous estimates arising from different studies may lead to a biased estimate with spurious precision. Although it is possible to allow for heterogeneity in the statistical analysis by so-called random-effects models, their interpretation is often difficult. Inspecting the sources of heterogeneity and trying to explain it would therefore be a more sensible approach in most instances.

Nevertheless, a meta-analysis may be a reasonable way to integrate findings from different studies and to reveal an overall trend in the data. A meta-analysis of several studies to obtain an overall estimate of association, for instance, can be performed by pooling the original data or by calculating a combined measure of association based on the study-specific estimates. In both cases, it is important to retain the study as the unit of analysis. Ignoring this fact would lead to biased results since the between- and within study variations and the different sample sizes would then not be adequately accounted for in the statistical analysis.

Since the probable first application of formal methods to pool several studies by Pearson (1904), numerous sophisticated statistical methods have been developed that are reviewed in chapter ▸Meta-Analysis in Epidemiology of this handbook.

1.6 Research Areas

Epidemiology pursues three major objectives: (1) to describe the spectrum of diseases and their determinants, (2) to identify the causal factors of diseases, and (3) to apply this knowledge to prevention and public health practice.

1.6.1 Description of the Spectrum of Diseases

Describing the distribution of disease is an integral part of the planning and evaluation of health-care services. Often, information on possible exposures and disease outcomes has not been gathered with any specific hypothesis in mind but stems from routinely collected data. These descriptions serve two main purposes. First, they help in generating etiological hypotheses that may be investigated in detail by analytical studies. Second, descriptive data form the basis of health reports that provide important information for the planning of health systems, for example, by estimating the prevalence of diseases and by projecting temporal trends. The approaches used in descriptive epidemiology are presented in chapter ▸Descriptive Studies of this handbook.

Complementary descriptive information relates to the revelation of the natural history of diseases – one of the subjects of clinical epidemiology – that helps to improve diagnostic accuracy and therapeutic procedures in the clinical setting. The understanding of a disease process and its intermediate stages also gives important input for the definition of outcome variables, be it disease outcomes that are used in classical epidemiology or precursors of disease and preclinical stages that are relevant for screening or in molecular epidemiology studies.

1.6.2 Identification of Causes of Disease

A major part of current research in epidemiology is tied to the general methodological issues summarized in Sects. 1.4 and 1.5. These concern *any* kind of exposures (risk factors) and *any* kind of outcomes (health defects). After having described the basic ideas and the main procedures, the emphasis is now on more specific questions determined by a particular type of exposure (see chapters in Part IV (Exposure-Oriented Epidemiology) of this handbook) or a special kind of outcome (see chapters in Part V (Outcome-Oriented Epidemiology) of this handbook) or both. This distinction, however, is somewhat arbitrary, as some research areas are not easily assigned to either category as, for example, molecular epidemiology, clinical epidemiology, and infectious disease epidemiology.

1.6.2.1 Exposure-Oriented Research

The search for factors that cause a disease is a central feature of epidemiology. This is nicely illustrated by the famous investigation into the causes of cholera by John Snow, who identified the association of poor social and hygienic conditions, especially of the supply with contaminated water, with the disease which provided the basis for preventive action. Since that time, the investigation of hygienic conditions has been diversified by examining infectious agents, nutrition, pharmaceuticals, social conditions, or lifestyle factors as well as physical and chemical agents in the environment or at the workplace. A peculiarity is the investigation of genetic determinants by themselves and their interaction with the extraneous exposures mentioned above that requires special statistical methods for their analysis as outlined in chapter ▸Statistical Methods in Genetic Epidemiology of this handbook.

Nutrition belongs to the most frequently studied exposures and may serve as a model for both the methodological problems of exposure-oriented research and its potential for public health (cf. chapter ▸Nutritional Epidemiology of this handbook). There are only few health outcomes for which nutrition does not play a role in causation. A solid evidence base is required to guide action aiming at disease prevention and improvement of public health. Poor nutrition has direct effects on growth and normal development, as well as on the process of healthy aging. For example, 25% of cancer burden were estimated to be attributable to nutrition and obesity (Doll and Peto 2005). The effect of poor diet on chronic diseases is complex, for example, the role of micronutrients in maintaining optimal cell function and reducing the risk of cancer and cardiovascular disease. The accurate assessment of nutrient intake is a major challenge in observational studies, and available instruments are prone to bias and measurement error. Moreover, foods contain more than nutrients, and the way foods are prepared may enhance or reduce their harmful or beneficial effects on health. Because diet and behavior are complex and interrelated, it is important, both in the design and the interpretation of studies, to understand how this complexity may affect the results.

Accurate measurement of exposure is a particular problem in retrospective studies that exposure-oriented epidemiology is faced with. The use of biological markers of exposure and early effect has been proposed to reduce exposure misclassification. In a few cases, biomarker-based studies have led to important advances, as, for example, illustrated by the assessment of exposure to aflatoxins, enhanced sensitivity and specificity of assessment of past viral infections, and detection of protein and DNA adducts in workers exposed to reactive chemicals such as ethylene oxide. In other cases, however, several initially promising findings have not been confirmed by more sophisticated investigations. They include in particular the search for susceptibility to environmental carcinogens by looking at polymorphism for metabolic enzymes. The new opportunities offered by biomarkers to overcome some of the limitations of traditional approaches in epidemiology need to be assessed systematically. The measurement of biomarkers should be quality-controlled and validated. Sources of bias and confounding in molecular epidemiology studies have to be assessed with the same scruting as in other types of epidemiological studies.

Modern molecular techniques have made it possible to investigate exposure to genetic factors in the development or the course of diseases on a large scale (cf. chapter ▸Molecular Epidemiology of this handbook). Many diseases aggregate in families. Although some of the aggregation can be explained by shared risk factors among family members, it is plausible that a true genetic component exists for most human cancers and for the susceptibility to many infectious diseases. The knowledge of low-penetrance genes responsible for such susceptibility is still very limited, although research has focused on genes encoding for metabolic enzymes, DNA repair, cell-cycle control, and hormone receptors. In many studies only indirect evidence can be used since the suspected disease-related gene (candidate gene) is not directly observable. To locate or to identify susceptibility genes, genetic markers are used either in a so-called whole genome scan or in the investigation of candidate genes. The latter can be performed by linkage studies, where the common segregation of a marker and a disease is investigated in pedigrees; and by association studies, where it is investigated whether certain marker alleles of affected individuals are more or less frequent than in a randomly selected individual from the population. Both, population-based and family designs are complementary and play a central role in genetic epidemiological studies. In the case of low-penetrance genes, association studies have been successful in identifying genetic susceptibility factors. Given the lack of dependence of genetic markers from time of disease development, the case-control approach is particularly suitable for this type of investigation because their assessment is not prone to recall bias. More pronounced than in classical epidemiology, the three main complications in genetic epidemiology are dependencies, use of indirect evidence, and complex datasets.

1.6.2.2 Outcome-Oriented Research

Epidemiology in industrialized countries is nowadays dominated by research on chronic diseases, among them cardiovascular diseases, cancer, and metabolic, respiratory, digestive, psychiatric, and musculoskeletal disorders. Their epidemiology – especially the one of cancer – is characterized more than any other outcome-defined epidemiology by the abundance of observational studies to identify risk factors of all kind.

Cardiovascular diseases (cf. chapter ▸Cardiovascular Health and Disease of this handbook) have a multifactorial etiology and confounding effects are especially intriguing. For example, clustering of coronary heart diseases in families could be due both to genetic factors and to common dietary habits. High blood pressure and obesity play both the role of an outcome variable and of a risk factor. A typical feature of the epidemiology of cardiovascular diseases is marked by the decline of morbidity and mortality in some areas and population groups whose causes are manifold, including, for example, control of blood pressure and blood cholesterol as well as improved treatment regimens.

In many respects cancer epidemiology exemplifies the strengths and the weaknesses of the discipline at large. Although it is a relatively young discipline, it has been the key tool to demonstrate the causal role of important cancer risk factors, like smoking, human papilloma virus infections in cervical cancer, solar radiation in skin cancer, and obesity in many neoplasms (cf. chapter ▶Cancer Epidemiology of this handbook). Cancer epidemiology is an area in which innovative methodological approaches are developed as illustrated by the increasing use of biological and genetic markers pertaining to causal factors and early outcomes.

By comparison, the epidemiology of musculoskeletal disorders is still less developed. Already the definition of the various disorders and the distinction between them are still subject to debate. Case ascertainment is often tricky. In spite of the high prevalence of, for example, back pain or osteoarthritis and their enormous negative impact on quality of life, mortality caused by them is significantly lower than that by cancer or cardiovascular diseases. Even simple estimates of prevalence leave wide margins. Regarding established risk factors, we find, for instance, for osteoarthritis, and depending on its location, genetic factors, sex, obesity, heavy physical workload, and estrogen use. Not much more seems to be known although certain nutritional factors have been mentioned like red meat and alcohol (cf. chapter ▶Musculoskeletal Disorders of this handbook).

The investigation of infectious diseases is the most important historical root of epidemiology and is still of primary importance in developing countries. If a person suffers from a particular outcome like tuberculosis, the exposure "infection by the relevant microorganism," that is, by mycobacterium tuberculosis, must have been present by the very definition of the disease. However, it is not a sufficient condition for overt disease, and many analytical studies examine the influence of cofactors like social conditions, nutrition, and comorbidities regarded as risk factors for opportunistic infections. Purely descriptive health statistics, too, play a very important role in controlling infectious diseases. Related activities are general *epidemic surveillance*, *outbreak studies* by tracing possible carriers, and the search for infectious sources like salmonella as sources of food poisoning or the various origins of *nosocomial* illness. The most specific features of the epidemiology of infectious diseases are *mathematical modeling* and *prevention by immunization*. Modeling has to be understood in the sense of population dynamics. What is being modeled is typically the temporal development of the incidence or prevalence of the disease in question. The model, be it deterministic or stochastic, describes the mechanism of the infection. It depends on specific parameters like contact frequencies between infected and susceptible subjects and curing rates. It is interesting to note that with the discovery of the infectious cycle of malaria, Ronald Ross, also designed and analyzed a mathematical model for it that led him to conceive the *threshold principle* (Bailey 1975; Diekmann and Heesterbeek 2000). The prevention of infectious diseases can in principle be done in three ways: by acting on cofactors of the type mentioned above; by interfering with the infectious process via hygiene, separation of susceptible persons from carriers or vectors, and elimination of vectors; or by raising the immunity of susceptible people by various measures like preventive drug treatment, the main method of immunization being a vaccination, though. The effect of a vaccination in a population can be modeled in its turn, which leads in particular to the basic epidemiological concept of *herd immunity* (chapter ▶Infectious Disease Epidemiology of this handbook).

2.1 Introduction

Epidemiology emerged as a scientific discipline in the seventeenth century when the conditions became ripe for collecting, analyzing, and interpreting population data. Population comparative studies were performed in the eighteenth century. Since then, a body of methods and concepts needed to perform population studies has been developed, refined, and theorized. It constitutes the genuine core of the scientific discipline known today as epidemiology. I identify four phases in the evolution of these epidemiological methods and concepts. During the preformal phase (seventeenth to nineteenth century), there was no theory guiding the implementation of population studies. During the early phase (1900–1945), study designs were segregated, ways of dealing with non-comparability were developed and applied, epidemiology became an academic discipline, and epidemiological textbooks were published. In the third phase, classic epidemiology (1945–1980), study designs were refined, and the measurement of effects, confounding effects, interactions, and biases were formalized. The latest phase, modern epidemiology (since 1980), has been characterized by an integration of methods and concepts into a theoretical corpus that comprises study designs, measures of event occurrences and effects, confounding effects, interactions, biases, and causal inferences. There are indications that a new phase is dawning, characterized by refinements in conceptual domains such as the assessment of confounding effects, biases, and of complex interactions.

2.1.1 Note About Terminology and References

I use risk, rate, and odds, followed by “ratio” or “difference,” as defined by Elandt-Johnson (1975), to describe measures of effect. Two measures of disease occurrence are either divided (ratio) or subtracted (difference). The usage of these terms has varied substantially across time and place (Zhang et al. 2004). The resulting dilemma for the historian is between using the terms as found in the historical documents and using the modern terminology throughout. I used to let the terminology vary across historical periods in order to be consistent with the terms used in the historical documents I was describing until I realized that, besides those with some advanced epidemiological training, most students were confused by the multiplicity of terms used to define the same concept. I now prefer to stick to the modern terminology. For example, I don’t use the terms retrospective and prospective studies to characterize, respectively, case-control and cohort studies even though the former terms have been used for decades before being abandoned (Vandenbroucke 1991; Doll 1991). But I do qualify as “cohort” a German study published in 1913, that is, about half a century before the term was proposed as a synonym of prospective study. Substituting the ancient with the modern terminology may sometimes make the text sound anachronistic, but it also highlights the continuity in the evolution of epidemiological methods and concepts over the last three centuries.

Years of birth and death of scientists and philosophers, whose names are mentioned in this chapter, were only provided when both dates were potentially available.

For research and teaching purposes only, most papers cited in this article can be downloaded from the People's Epidemiology Library (www.epidemiology.ch/history/PeopleEpidemiologyLibrary.html).

2.2 A Historical Definition of Epidemiology

Epidemiology is a combination of Greek terms meaning, literally, the science (logos) of what falls upon (epi) the people (demos), or the science of epidemics. It was originally baptized as such, to characterize the study of epidemics of mostly infectious diseases (Villalba 1803). The name also implies that the need for epidemiology started with the first epidemics. When did the first epidemics occur?

2.2.1 Genesis and Evolution of Epidemics in Agrarian Societies

There are good reasons to believe that epidemics were not a major issue in foraging societies, which subsisted by hunting, gathering, and fishing and did not produce food. They consisted of small, mobile bands, usually less than 50 people, without domesticated animals (except for dogs in the latest period before the Neolithic). No infectious disease could become recurrent in these small, nomadic clans because a contagious and lethal disease would either wipe out the clan or be interrupted when the clan moved away from the outbreak, leaving its sick and dead behind. Data on prehistoric and contemporary foragers support the idea that no recurring epidemics existed before 10,000 BCE: a convenient transition date between foraging and agrarian societies.

Two conditions were needed for recurring epidemics to occur (McNeill 1977). For one, large domesticated animals living closely enough with humans had to provide an opportunity for some animal parasites, such as the agents of tuberculosis, measles, flu, smallpox, and so on, to adapt to the human organism. Secondly, a population pool of at least 500,000 people was necessary for a parasite to permanently subsist within a population and cyclically emerge when the pool of susceptible subjects is reconstituted. Early agrarian civilizations were therefore most likely free of epidemics since these two conditions were supposedly first met in Sumer, Mesopotamia, around 2000 BCE. The plagues that afflicted the Egyptians in the Book of Exodus may have occurred between 1000 BCE and 500 BCE. It is generally accepted that since then, epidemics of new (i.e., neolithic or later) infectious diseases disseminated throughout the globe until all the population basins were connected. At that stage, local epidemics evolved into world pandemics (McNeill 1977).

Data from China between 243 BCE and 1911 CE provide a glimpse into the evolution of the intensity of outbreaks during the past 2,000 years (Morabia 2009).

In China, the frequency of outbreaks has been proportional to the size of the population. The burden of epidemics increased exponentially after 1100 and continued unabated until the nineteenth century (Morabia 2009). It is probable that the evolution of epidemics was similar in Europe and in China, which were the two most populated areas in the Old World. Except maybe for the huge death toll of the Black Death epidemic during the fourteenth century, which affected European populations but maybe not China, there are indications that epidemics also grew in intensity between 1,000 and 1,800 CE in European countries, such as Britain (Creighton 1894).

Thus, historical evidence suggests that pre-epidemiology medical systems across continents failed, by and large, to understand and control the evolution of infectious diseases. Why?

2.2.2 Why Pre-Epidemiology Medical Systems Failed to Understand Epidemics

For about 4,000 years, since the emergence of medicine as a profession (Porter 1997), premodern doctors have had the ambitious aim of understanding the complex and unique set of causes responsible for the occurrence of *each specific case* of disease. They had a holistic vision of health and disease based on the belief that the body and the universe coexisted in precarious equilibrium. A disequilibrium meant disease. Factors that could precipitate disease were so numerous that each case had its own set of causes, and no two cases were alike. Except when it came to describe qualitatively the frequency of symptoms and signs among the sick, doctors focused exclusively on the individual patient and therefore could not view – and were probably not interested in – the pattern of disease occurring at the population level. Their clinical practice confronted them with the individual consequences of epidemics but not with their population effects. They were not conceptually equipped to study the causes of diseases and to assess the efficacy of treatments. From this point of view, Hippocratic medicine is a form of ancient holistic medicine.

The idea that each individual case is different subsisted until well into the nineteenth century. When cholera broke out in New York in 1832, the apothecary Horace Bartley (dates unknown) described each case admitted to a local hospital separately, without attempting to group them in any way. Doctors prescribed different treatments to each patient, hoping that one would work. But this trial-and-error approach could not succeed (Bartley 1832). Had they grouped and compared the patients by treatment received, they would have found that camphor, peppermint, mercury, and sulfur worked half of the time given that the lethality of cholera is about 50%. In reality, not a single one of these treatments was effective.

Prescribing a different treatment to each patient was compatible with the dominant theory of the early nineteenth century regarding disease causation. It was believed that diseases were due to some form of air pollution. The putrefaction of organic matters, such as human excrements, garbage, and dead animal bodies, which abounded in the streets of poor and working class neighborhoods, was thought to release toxic gases, sickening those who inhaled them. But the miasma theory required a second condition to explain why not everyone was being affected: miasma produced disease solely among people who were predisposed to it because of their constitution or because, in their individual context, body fluids were in disequilibrium. In other words, each case of disease was unique and needed to be treated in a specific way. Most people in medicine and public health, including both doctors and social reformers, largely adhered to this multifactorial theory, which was in line with the holistic beliefs of the past. It was therefore not a surprise that the late Hippocratic concept of miasma subsisted for over 2,500 years.

In the nineteenth century, the success of the miasma theory was based on its apparent ability to guide public health action. It implied that reducing poverty, cleaning streets, improving housing, and draining dirt and excrement by creating a proper sewage system would prevent disease. And it did. Cleaning lice prevented typhus; exterminating rats prevented plague; avoiding fecal pollution prevented typhoid and cholera. The apparent successes of the miasma theory blinded its supporters from its flaws, which were not discovered until scientists tested their hypotheses using population comparative studies.

2.3 Epidemics Since Epidemiology

2.3.1 Plague Surveillance

The first known analysis of population data to describe patterns of epidemics focused on the plague, which, since the fourteenth century, was a recurring scourge in most European countries. No one knew what caused it. Religious and superstitious reasons were often invoked. Even though its contagious nature was highly debated among scholars, people behaved as if it was: authorities sealed to death the sick and their families in their houses, and the upper class had formed a safe habit of fleeing to the countryside when the disease was lurking in their town.

In 1662, John Graunt (1620–1674) published an analysis of the trends in mortality from the London plague, based on the Bills of Mortality, which were the ancestors of our current death certificates. Graunt observed that there was regularity and predictability in the trends of deaths from causes other than plague. Plague, however, made “sudden jumps” in frequency, which was more consistent with an environmental origin than with a disorder originating from the “constitution of human bodies” (Graunt 1662). Graunt did not mention astrologic or divine factors. The last outbreak of plague in London occurred in 1665, shortly after Graunt’s publication. The exact reasons for the interruption of the plague cycle are unknown, but it is reasonable to believe that once population evidence clearly showed that plague was caused by an environmental factor that cyclically came and went, authorities began to enforce ship quarantines and cordon sanitaires on Europe eastern borders more rigorously and more effectively than in the past.

2.3.2 Nineteenth-Century Population Sciences

Graunt was a pioneer. After him, we know of only few attempts to analyze and interpret population data before the nineteenth century, in which new population sciences such as economics, evolutionary biology, sociology, demography, anthropology, statistics, and epidemiology surged. All these new sciences were built on the premise that there were issues that could only be studied using groups of people (populations) as the unit of analysis. Consider Thomas Malthus's (1766–1834) theory of societal implosions, Charles Darwin's (1809–1882) theory of natural selection, or Karl Marx's (1818–1883) theory of profit. They can only be explained in terms of populations.

2.3.3 Contagionism

Those who first used population studies were inclined to adhere to modern theories of disease causation, which singled out necessary and sufficient causes: if the cause was unique and the same for all, it was logical to compare groups of people who were exposed to it with those that were not. In contrast, the miasma theory was incompatible with population studies: if disease stemmed from a different set of causes in each person, there is no sense in grouping distinct individuals, just as one would not group apples and pears and call them the same fruit.

Thus, causal hypotheses based on the theory of contagionism, aka the germ theory of disease causation, could be tested using population studies. Even though no organism had yet been linked to a specific disease, contagionism had its minority of followers, one of whom was John Snow. Indeed, what Snow had in mind when he compared the frequency of cholera deaths among clients of the Southwark and Vauxhall, who pumped cholera-contaminated water, with those of the Lambeth companies, who pumped cleaner water, was simply that the postulated cholera germ present in the water was the necessary and sufficient cause. To avoid criticism from miasmatists, Snow was happy to report that both groups of clients were comparable in terms of exposure to air pollution.

The irony is that these cholera outbreaks in London would have remained localized if the sanitarians had not washed the streets of London into the Thames in the midst of the epidemic, creating optimal conditions for local outbreaks to be disseminated to the whole city (Johnson 2006).

Snow's investigation of the 1854 epidemic of cholera in South London does not correspond with any of the modern epidemiological designs. Snow's investigation consisted in categorizing the cholera deaths into clients of the Southwark and Vauxhall or of the Lambeth companies. He did not know the total number of clients supplied by each of the two companies in the districts in which he had enumerated and located the cholera deaths. He therefore used the total number of London houses supplied by the two companies in 1853 (40,046 and 26,107, respectively) as denominator for the company-specific numbers of deaths. Snow's work is nonetheless a large-scale use of both population thinking (i.e., a ratio of deaths over houses) and group comparison (i.e., clients of the Lambeth vs. Southwark and Vauxhall).

2.4 Preformal Epidemiology

Preformal epidemiology refers to the phase during which investigations combining population thinking and group comparisons were performed spontaneously, without guidance from an underlying theory. Epidemiology was not a *formal* scientific discipline yet.

I have argued previously that there could not be any form of epidemiology before the seventeenth century when population data regarding health-related issues became available (Morabia 2004, 2013). Soon after, however, group comparisons were conceived. William Petty (1623–1687), the English author of *Political Arithmetic,* and an early advocate of population data collection, imagined that he could challenge his colleagues in the Royal College of Physicians by asking questions such as whether they took as much medicine and remedies as "the like number of men of other societies," whether 1,000 patients of the best physicians would experience the same mortality rate as 1,000 patients of places where there dwell no physicians, whether 100 patients sick with acute diseases who used physicians would experience the same mortality rate as 100 patients who used no doctors and relied on chance only (Petty 1927, pp. 169–170). Each of these questions can only be answered by group comparison.

A group comparison involving purposefully collected data was conducted by James Lind (1716–1794) on the HMS Salisbury in 1747. Of the six pairs of scorbutic seamen receiving different treatments, those who received lemons and oranges were the only ones to be rapidly cured (Lind 1753). This small trial produced valid results where innumerous trial-and-error attempts to use different sorts of treatments, one patient at a time, had failed.

The other pioneering preformal epidemiological works have been abundantly described. This includes the work of the medical quantitativists in eighteenth century United Kingdom (Troehler 2000), Pierre Louis's (1787–1872) demonstration of the inefficacy of bloodletting as a treatment of pneumonia (Morabia 1996; Louis 1836), Ignaz Semmelweis's (1818–1865) 1848 intervention in Vienna in which he forced his interns to disinfect their hands before attending parturient women (Carter 1983), and John Snow's (1813–1858) work discussed above (Vinten-Johansen et al. 2003; Snow 1855, 1936).

A definition of epidemiol in contrast, the role of preformal epidemiologists in the investigation of outbreaks of infectious diseases has been understated (Morabia 1998). Epidemiologists were commonly called to investigate local outbreaks of diseases such as typhoid fever. In this activity, they could not rely on bacteriological evidence because bacteriology was still in its infancy in the late nineteenth century, and laboratories were not universally available. Using essentially survey and surveillance data, group comparisons, and detective skills, epidemiologists were able to show, for instance, that oysters could be the culprit of local outbreaks of typhoid fever (Morabia and Hardy 2005; Hardy 1999) and that cow's milk or condensed milk could cause fatal diarrhea in babies (Morabia et al. 2013).

Preformal epidemiological studies are characterized by the identification of a single causative factor. They come from people who were contagionists or believed that treatment had to be determined according to characteristics of the diseases, (e.g., scurvy, pneumonia, and cholera) and not by the unique constitution of individuals. These modern thinkers were few in number yet achieved a lot. There is not much knowledge about prevention or treatment that we credit pre-twentieth century science with but a great deal of it has been generated by preformal epidemiologists.

It is striking that Lind, Louis, Semmelweis, and Snow's conclusions were met with tremendous skepticism during their lifetime (Vandenbroucke et al. 1991). The main obstacle was the lack of agreement on whether or not groups were meaningful entities and, if they were, whether the groups in those studies were comparable or not. Critics saw a strong potential for what we now call confounding effects in the preformal epidemiological studies. Preformal epidemiologists were not methodologically and conceptually equipped to address these criticisms. A theory of group comparison was badly needed to support the design of stronger studies.

An important episode related to the history of the concept of interaction occurred during the nineteenth century. The German hygienist Max von Pettenkofer (1818–1901) attempted to reconcile miasmatism and contagionism into a theory of cholera origin, stating that the cholera germ had to be modified by its migration across porous soils in order to become a pathogenic miasma (von Pettenkofer 1869). Von Pettenkofer was trying to reconcile the old and new ways of thinking since interactions were at the core of holistic medicine and germs were a perfect case of monocausation. He failed under dramatic conditions mainly because he did not test his theory using group comparison (Morabia 2007a).

A definition of preformal epidemiology is provided in the description of the aims of the London Epidemiological Society was instituted in 1850: "the study of Epidemic and Endemic Diseases, with special reference to the investigation of (a) the various external or physical agencies and the different conditions of life which favour their development or influence their character; and (b) the sanitary and hygienic measures best fitted to check, mitigate, or prevent them. (...) While the chief object of the other medical societies of the metropolis is the investigation of the physiological, pathological, and therapeutic relations of diseases, that of the Epidemiological Society is specially the study of their etiological or causal relations, and the influences of locality, climate and season, diet and occupation, etc., on their rise, dissemination, and continuance. Diseases are looked at not so much in detail as in the aggregate; not in individual cases, but in groups and successions of cases; and not in one place only, but over wide and varied areas of observation. It is as a branch of Natural History rather than of technical medicine that the Society seeks to render the knowledge of epidemics and endemics more accurate and complete." (Anonymous 1876)

2.5 Early Epidemiology

Early epidemiology corresponds to the phase during which elements of an epidemiological theory were produced, epidemiology became an academic discipline, and epidemiological textbooks became available.

2.5.1 Population Thinking

2.5.1.1 Risk Versus Rate

In Snow and Louis's work, the occurrence of events in their studied population was expressed in a way that today looks naive. Snow used a ratio of cholera deaths over client houses. Louis used simple proportions. William Farr (1807–1883) who had a more mathematical mind than Snow and Louis, however, felt the need to formally distinguish risk and rates when trying to explain why cholera excited more terror than tuberculosis even though one had a 50% chance of surviving cholera vs. almost no chance of surviving tuberculosis (Farr 1838). The median survival time after diagnosis was 7 days for cholera and 2 years for tuberculosis. It was more frightful to have a 50% chance of death within the following few days than to be sure to die within the next 2 years. Risks were 46% over 7 days for cholera vs. 100% over 2 years for tuberculosis. What was needed was a measure that expressed the speed at which a disease killed. This was the rate. Farr expressed the risk by unit of time: 47% over 7 days became 47 per 100 per week, and 100% over 2 years became about 1.0 per 100 per week. The mortality rate from tuberculosis was about one fiftieth of that from cholera, reflecting the reasonable terror cholera excited in populations.

2.5.1.2 The Typhoid Vaccine Controversy

The concepts of risk and rate were further refined when Austin Bradford Hill (1897–1991) showed that it could be computed using person-times in the denominator. Hill's clarification occurred at the end of a long controversy between an army commission and a British team made of an epidemiologist, Major Greenwood (1880–1947), and a statistician, Udny Yule (1871–1951). Both groups diverged on the mode of analyzing the data from the antityphoid vaccine campaigns conducted in the British army (Susser 1977). Soldiers were inoculated at different points in time after the beginning of the campaign. The army commission wanted to define every soldier as inoculated, as long as they were inoculated by the end of the campaign. By doing so, on the one hand, they attributed some non-inoculated time free of disease to the vaccine, making it look better than it really was. Greenwood and Yule, on the other hand, wanted to define the inoculated as those solely inoculated at baseline, considering those inoculated later during the campaign as non-inoculated. In doing so, they made non-inoculation look better since inoculated-disease free time was analyzed as non-inoculated. Incidentally, both approaches showed a protective effect of the vaccine. But Hill extended the two ideas to a more accurate measure, showing that one could avoid the limitations of both approaches by computing person-times and allocating the follow-up period fairly into inoculated and non-inoculated time (Hill 1939).

2.5.2 Group Comparisons

Early epidemiologists invented the basic study designs currently used by epidemiologists.

2.5.2.1 Weinberg and Lane-Claypon Historical Cohort Study

The historical cohort study performed by Wilhelm Weinberg (1862–1937), in Germany, remains, by current standards, an impressive endeavor. Many people in public health had begun to worry by 1900 that the improved survival observed among tuberculosis people, probably due to a combination of better nutrition and isolation in sanatoria, would lead to a wide dissemination of the disease, which ultimately could jeopardize the "quality of the race." This mode of thinking was called eugenics in England and the USA, and racial hygiene in Germany. Weinberg performed his study to determine whether tuberculosis could threaten, in the long run, the average population health. Weinberg wanted to assess the fertility of the tuberculous and the survival of their offspring. He knew, however, that he could not address these questions in a cross-sectional survey since the only cases would be people who had survived after having contracted tuberculosis. These may be different from those who had died from tuberculosis. To enumerate all the cases occurring in the population, he realized that he had to follow people from birth. He therefore conceived an astute way of linking population and death registries of his state, Baden-Württemberg, and generated two cohorts: one comprising all the children (n = 18,052) of all the people who had died from tuberculosis between 1873 and 1889 and another cohort all the children (n = 7,574) of a sample of the people who had died from other causes during the same period. His study showed that those with tuberculosis had fewer children than those without tuberculosis and that their children died at a younger age (Weinberg 1913; Morabia and Guthold 2007). Weinberg concluded that tuberculosis was not a threat for the German race.

Weinberg's historical cohort study was published slightly after a much smaller one by Janet Lane-Claypon (1877–1967) in Berlin. Using the registry of a family planning clinic, she was able to show that breastfed infants grew up faster than infants fed with bottled milk (Winkelstein Jr. 2004).

2.5.2.2 Frost's Generational Cohort

Another ice-breaking historical cohort was conducted in the USA by Wade Hampton Frost (1880–1938) (Frost 1933). Frost's method of constructing the cohorts was novel. Starting with a survey of 556 persons living in 132 families from a small town in Tennessee, he identified, by interview, another 238 former members of the family who were dead or living. Altogether, they represented almost 10,000 person-years.

He then categorized the person-times according to the history of family contact with pulmonary tuberculosis. He found, as Weinberg before him, that the rate of tuberculosis infection was twice as high among those with a family contact as among those without such contact.

2.5.2.3 Goldberger and the Missed Nobel Prize

Another outstanding epidemiological work of the period was conducted by Joseph Goldberger (1874–1929) and Edgar Sydenstricker (1881–1936) in South Carolina (Goldberger et al. 1920). In an attempt to separate the effect of diet from that of income in the etiology of pellagra, they surveyed cotton mill workers and their families and followed them during the summer, monitoring the cases of pellagra. They found that lack of diversified diet was the culprit, and it was the consequence of insufficient income and a lack of access to affordable fresh food forcing the pellagrous-prone families to subsist predominantly on corn. Goldberger should have been awarded a Nobel Prize in 1929 as part of a series of awards related to the discovery of vitamins, but he died that same year.

2.5.2.4 Case-Control Studies

Early epidemiologists conducted case-control studies. The one reported in 1926 by Janet Lane-Claypon stands out as a remarkable and innovative project for its design and magnitude (Lane-Claypon 1926; Morabia 2010; Press and Pharoah 2010). She compared 500 hospitalized breast cancer patients with 500 control subjects, hospitalized for non-cancerous illnesses. All were interviewed the same way. The study showed that breast cancer patients had fewer children than the control subjects, even though, from a modern perspective, both groups were hyperfertile, with an average of 3.5 children among the breast cancer patients and 5.5 children among the control subjects. In this study, Lane-Claypon mentioned that cases may recall their past exposure differently than the controls, a potential threat to the validity of case-control studies now known as recall bias (Lane-Claypon 1926).

Most case-control studies subsequent to the 1926 study but prior to 1945 demonstrated a growing understanding of the strengths and pitfalls of case-control studies. In 1928, Lombard and Doehring matched each of their cancer records with the record of an "individual without cancer, of the same sex and approximately the same age" (Lombard and Doering 1928). The 1931 study by Wainwright (1931) reanalyzed by Press and Pharoah (2010) replicated Lane-Claypon's 1926 study. In 1933, Stocks and Karn filled two full pages of the *Annals of Eugenics*, describing their matched case and control selection, stating in particular that "the control series is not a random sample, but is made to conform to the case series, which is a random sample of a cancerous population" (Stocks and Karn 1933). At least three case-control studies were published before 1945 about the determinants of ischemic heart disease and hypertension (Johnson 1929; Glendy et al. 1937; English et al. 1940). They all provided detail about the comparability of the controls to the cases.

The 1939 (Mueller 1939a, b) and 1943 (Schairer and Schoeniger 1943, 2001) German studies on smoking and lung cancer had designs below the standard of their time (Morabia 2012, 2013b). Mueller described 86 cases of lung cancer at length, some deceased and some alive, only to say that they were compared with "the same number of healthy men of the same age" (Mueller 1939b). Schairer and Schoeniger compared 93 deceased cases of lung cancer, 226 deceased cases of other cancers, and 270 "controls," all men (Schairer and Schoeniger 1943, 2001). They mentioned only that the controls were men from Jena, "aged 53 and 54 years," and that 270 out of the 700 invited returned satisfactorily filled questionnaires. These studies marked a regression in quality and rigor relative to the pre-Nazi German epidemiology of Weinberg (Morabia and Guthold 2007; Weinberg 1913).

2.5.3 Concepts

2.5.3.1 Confounded Effects as an Artifact

Epidemiologists of the first half of the twentieth century searched for formal ways to address the criticism of non-comparability (Morabia 2007b, 2011). They implemented new techniques such as random allocation of treatment (Therapeutic Trial Committee of the Medical Research Council 1934) and restriction of the study sample (Goldberger et al. 1920). They improved the epidemiological study designs with historical cohort studies (Weinberg 1913; Winkelstein Jr. 2004) and case-control studies (Lane-Claypon 1926; Lombard and Doering 1928; Johnson 1929; Stocks and Karn 1933; Glendy et al. 1937; English et al. 1940). Analytical techniques were used to "standardize" compared risks and rates (Goldberger et al. 1920; Weinberg 1913) and used exposure propensity score equation (Lane-Claypon 1926). All of these efforts had the same objective: to design studies and analyze data in ways that purposefully optimized comparability of exposure to potential alternate causes of the studied outcome.

Surprisingly, the first definition of the concept we refer to today as "confounding" did not follow from this line of efforts of balancing the effects of multiple independent causes across groups.

2.5.3.2 The Pooling Bias

In 1903, G. Udny Yule, the Cambridge statistician, gave an early description of a form of bias, or "fallacy", which could lead to spurious associations (Yule 1903). He showed that there were situations in which pooling strata could provoke the appearance of associations which did not correspond to the effect observed within each stratum. The same fallacy was independently described 36 years later by Major Greenwood, the first Professor of Epidemiology at the London School of Hygiene and Tropical Medicine (Greenwood 1935), (pp. 84–85), and 40 years later by Austin Bradford Hill (Hill 1939), (pp. 125–127). Yule, Greenwood, and Hill warned analysts against the dangers of pooling data. They understood that group non-comparability after pooling strata was the underlying problem but did not describe the fallacy as a major source of bias in population studies and did not suggest computing weighted averages of the stratum-specific effects to bypass the fallacy.

2.5.3.3 Randomization

During this period randomized controlled trials were conducted. Under the conceptual leadership of Hill, the Medical Research Council (MRC) of the UK conducted a trial to assess the efficacy of serotherapy in the treatment of pneumonia (Therapeutic Trial Committee of the Medical Research Council 1934). Patients were allocated to either serum rich in antipneumonia antibodies, or rest. They were randomized by alternate allocation, with every other patient receiving serotherapy. However, the allocation procedures were too transparent for the clinicians who seemed to have had a tendency of preferentially giving serotherapy to younger patients with better prognoses. This flaw led later experimenters to conceal the randomization procedures (Chalmers 2002), as in the randomized control trial conducted by Joseph Asbury Bell in 1941 (Chalmers 2010). This student of Frost tested the efficacy of a pertussis vaccine.

2.5.4 Early Epidemiology

The early epidemiology phase lasted up until 1945. Early epidemiologists comprised Weinberg, Lane-Claypon, Frost, Greenwood, Hill, Goldberger, Sydenstricker, and Bell. They conducted the first historical cohort studies, case-control studies, and randomized controlled trials. They identified ways to improve comparability in observational studies.

Epidemiology became academic. Frost was appointed first American Professor of Epidemiology, after having been "Resident Lecturer" since 1919. Greenwood became the first Professor of Epidemiology in the UK in 1928. Epidemiology was defined, but the definition was evolving rapidly. Frost's first definition reflected his own training as a public health officer: epidemiology was the study of the natural history and the causes of infectious diseases. In 1924, Frost expanded the definition to include tuberculosis and "mass phenomena of such non-infectious diseases such as scurvy," but he excluded the "so-called constitutional diseases such as arteriosclerosis or nephritis" (Comstock 2004). In 1935, Greenwood further expanded the definition to include "any disease" which manifested itself as a "mass phenomenon" (Greenwood 1935).

In 1935, Greenwood published a textbook of epidemiology, although there is some controversy surrounding its qualification as a "first" textbook (Bracken 2003). In 1941, Frost published a large article, entitled Epidemiology, which reads like the outline of a more extensive textbook (Frost 1941).

2.6 Classic Epidemiology

2.6.1 Tobacco and Lung Cancer Before Epidemiology

The uptake of cigarette smoking in Western societies throughout the first half of the twentieth century remains a puzzling public health phenomena. In less than 50 years, a majority of men became chronic smokers. At the time, most of the public only saw cigarettes as a benign product, at worst (i.e., what can a little bit of smoke do to your lungs?), and, at best, a product that kept them healthy, as Marlene Dietrich (1901–1992) is famously known to have claimed. Still, some researchers suspected that it could have deleterious effects on human health. By the end of the 1920s, the Argentinean Angel Roffo (1882–1947) had hypothesized, supported by laboratory and animal experiments, that tobacco could cause cancers (Proctor 2006). In 1938, the statistician Raymond Pearl (1879–1940) reported a 10-year shorter life expectancy of heavy smokers vs. light or non-smokers on the basis of a life table analysis of 6,813 white males (Pearl 1938). Thoracic surgeons in particular were surprised by the rise in lung cancer patients, a very rare occurrence until 1900. In 1939, Alton Ochsner (1896–1981) and Michael DeBakey (1908–2008), in a report of 79 cases of lung cancer, mentioned “smoking” as “undoubtedly a source of chronic irritation of the bronchial mucosa” and therefore a possible cause of lung cancer (Ochsner and DeBakey 1939). They provided, however, no data on the smoking habits of their cases and had no control group. They actually attenuated this statement in their second series of 129 cases published in 1947. Having shown that 75% of the subjects smoked, they enigmatically concluded that smoking habits “seemed of no particular significance in this particular series” (Ochsner et al. 1947). Once again, they had no control series.

In the background, incidences of lung cancer were soaring. Medical societies were debating whether it was real or “only apparent” because of improved diagnosis due to the invention of x-rays (Medical Research Council 1952). On the basis of the San Francisco Cancer Survey, Frederick Hoffman, in 1931, had already concluded that tobacco caused cancer of the lung (Hoffman 1931), but his results, further confirmed by the two German studies of 1939 and 1943, had little impact on the debates. It is unclear how much researchers in the UK and the USA knew about these studies before the war. However, given the favorable political climate surrounding cigarettes and in the light of the obstacles encountered in the publication process of much better studies immediately after the war, it is unlikely that these studies could have weighed in the balance of the pros and cons about the carcinogenic effect of tobacco.

New evidence was provided by case-control studies published in 1950 in the USA (Wynder and Graham 1950; Levin et al. 1950) and in the UK (Doll and Hill 1950). Richard Doll (1912–2005) and Austin Bradford Hill’s studies represented major methodological developments compared to the pre-World War II epidemiology.

2.6.2 Group Comparisons

2.6.2.1 Case-Control Studies

Doll and Hill compared 647 male cases of lung cancer recruited from 20 hospitals in London with 647 male controls, who were patients admitted to these same hospitals for non-cancer conditions (Doll and Hill 1950). They were all interviewed about their past smoking habits, including duration, date of starting and quitting, amount smoked, and type of tobacco.

The prevalence of smoking was 99.7% among cases and 95.8% among controls. Even when one considered the amount smoked, differences were not startling. But because the study was population-based, Doll and Hill were able to divide, within age categories, the number of cases in the study, by the size of the Greater London population represented by the controls. For example, if 10% of the controls were light smokers, they assumed that 10% of the male residents of Greater London were light smokers at the time of the study. Dividing the number of light smoker cases by whichever number, 10% of the male population provided an approximation of the mortality rate of light smokers. The mortality rate of a category of smokers further divided by the mortality rate of non-smokers would represent a "ratio," which Doll and Hill thought approximated the corresponding "relative risk" (Doll and Hill 1950, p. 491). For example, in the age group 45–54, smokers of 15–21 cigarettes per day had 20 times the risk of lung cancer as non-smokers; those smoking 50 cigarettes per day had a relative risk of 55.6.

Thus, Doll and Hill performed a case-control study as a way to estimate risks and relative risks. They did not use odds ratios, which became the preferential way of approximating risk ratios in case-control studies rapidly after.

2.6.2.2 Cohort Studies

One year after their case-control study was published, Doll and Hill began the British Doctors Study. They had decided to perform a "prospective study" because they thought that "if there was any undetected flaw" in case-control (they used the term "retrospective") studies, "it would be exposed only by some entirely new approach" (Doll and Hill 1954). They sent a very short questionnaire to the 59,600 doctors of the United Kingdom about their smoking habits. They got 40,564 valid answers from doctors (34,445 men and 6,192 women) and started tracking their dates and causes of death beginning on November 1, 1951. Their preliminary report in 1954 (Doll and Hill 1954) indicated that the "standardized rates from cancer of the lung for 1,000 men aged 45–75 years in relation to the most recent amount of tobacco smoked" were very similar when "estimated from (a) the "backward" inquiry into the history of patients with cancer of the lung and other diseases in London and (b) from the present "forward" inquiry into the mortality of doctors" (Doll and Hill 1954). In modern terminology, Doll and Hill's cohort and case-control studies had provided very similar rate ratios for the association between cigarette smoking and lung cancer.

The British Doctors Study was followed by other larger cohort studies in the United States. The American Cancer Society (ACS)'s "Hammond and Horn Study" was launched in January 1952. Its leaders, E. Cuyler Hammond (1912–1986) and Daniel Horn (1916–1992), had conceived a convenient way to rapidly involve 200,000 Americans (Hammond and Horn 1958a, b). They recruited ACS members and their relatives and friends. The study confirmed that smoking had a stronger association with lung cancer than with coronary artery disease yet also demonstrated that, in terms of excess deaths, many more smokers died of coronary artery disease than of lung cancer (Hammond and Horn 1958b). In 1953, Harold Dorn (1906–1963) launched an even larger cohort study than that of the ACS. The US Veteran's cohort study enrolled 300,000 male holders of active life insurance policies from the Veteran Administration (Dorn 1959).

2.6.2.3 Cornfield's Rare Disease Assumption

Jerome Cornfield (1912–1979) has made key contributions to epidemiological methods and concepts. His biography has yet to be written. In 1951, he demonstrated that the risk ratio could be approximated by the ratio of the odds of exposure in cases over the odds of exposure in controls derived from a case-control study (Cornfield 1951). In doing so, Cornfield provided the solution to one of the main obstacles to recognizing case-control studies as valid for assessing causal associations. Before Doll and Hill's case-control studies were only viewed as able to determine whether cases had experienced different exposures than controls (Lane-Claypon 1926; Lombard and Doering 1928). This was an indirect answer to the causal question: does exposure impact the risk of disease? Doll and Hill had assumed that the controls were representative of all residents in the Great London to compute "ratios." Cornfield perceived that, using Bayes theorem, it was possible to transform a conditional probability of exposure derived from case-control studies, into a conditional probability of disease, which was the causal question. The Bayesian derivation of the probabilities themselves required an estimate of the rate of the outcome, say a disease, in the studied population, information that case-control studies did not provide. Nonetheless, using Bayes theorem, the ratio of conditional odds of exposure in cases and controls, approximated a ratio of conditional probabilities of disease in exposed vs. non-exposed, that is, a risk ratio, given that the rate of the disease in the population was low. This key condition for the odds ratio (a term not used by Cornfield) to approximate the risk ratio is known today as the "rare disease assumption." Using data from a case-control study of smoking and lung cancer by Robert Schrek (dates unknown) and coauthors (Schrek et al. 1950), Cornfield demonstrated that the rate ratio of lung cancer could be approximated by the ratio of the odds of exposure since the annual prevalence of lung cancer in the population was only 15.5 per 100,000. Cornfield also added the caveat that, for this approximation to be valid, cases and controls had to be representative of all cases and of all people free of disease in the target population.

2.6.3 Concepts

2.6.3.1 Confounding

The classic concept of confounding is paradoxically unrelated to the work of early epidemiologists but has its roots in a controversy about the statistical assessment of interaction (Vandenbroucke 2004). The British statistician Edward H. Simpson explored whether the interaction term could be left out of a mathematical model if the stratum-specific odds ratios were similar (Simpson 1951). His conclusion, known today as Simpson's paradox, was that this was possible only if there was no third variable related to outcome among the non-exposed, and to exposure among the non-outcomes. This paradox became the basis for the classic definition of a confounding variable, or confounder, probably through the work of sociologist Leslie Kish (1910–2000), who linked the paradox with the qualifier "confounding" (Kish 1959; Vandenbroucke 2004).

In 1959, Nathan Mantel (1919–2002) and William Haenszel (1910–1998) published their influential estimates of the adjusted odds ratio (Mantel and Haenszel 1959). They did not use the words odds ratio, or any form of the term "confound," but the paper was about computing an average estimate of the odds ratio across strata of a confounding variable.

The qualifier confounding, as well as variations of Simpson's paradox, appears in the epidemiological literature from 1970 on (MacMahon and Pugh 1970; Susser 1973). The hypothetical examples provided in textbooks illustrated situations in which the odds ratio and the rate ratio were homogeneous across the strata of a confounder but different from when strata were pooled to compute a single crude odds ratio. These examples were identical to those given by Yule, Greenwood, and Hill in the previous phase of epidemiology history, but no explicit reference to these early epidemiologists was made (Morabia 2011).

2.6.3.2 Interaction

Hammond has made many insightful contributions to epidemiological methods and concepts. Along with Dorn, he had conceived the first cohort study sponsored by the American Cancer Society. In his book chapter on *Causes and Effect* (Hammond 1955), Hammond had assembled a list of characteristics that a causal association could satisfy which is very similar to the list published 10 years later by Hill (1965).

But Hammond, teaming up with Irving Selikoff (1915–1992), also paved the way for a modern and quantitative assessment of interactions (Hammond et al. 1979). Selikoff had pioneered the research on the health effects of asbestos for which he had assembled a large cohort of insulators and other asbestos workers, all of whom were exposed to asbestos. To serve as unexposed comparison, Hammond selected within the ACS cohort study blue-collar workers exposed to dust and fumes. Comparing asbestos workers with the ACS cohort, they were able to show that smoking and asbestos both caused lung cancer in terms of mortality rate differences and rate ratios but that their joint rate difference was much larger than the sum of their individual rate differences. They concluded that the presence of a "synergistic effect" meant that "a young person who is so strongly addicted to cigarette smoking that he cannot break the habit or is unwilling to do so would be particularly well advised not to enter a trade involving exposure to asbestos dust."

2.6.3.3 Bias

The origin of the classic theory of selection bias is justly attributed to Joseph Berkson (1899–1982), a statistician at the Mayo Clinic. In the 1940s, Berkson had worked out a mathematical example, which aimed to illustrate how comparative studies based on autopsy records could generate spurious associations strictly on the basis of the selection probabilities of the diseases. He had been prompted to this by a 1929 publication of Raymond Pearl (1879–1940), a Johns Hopkins statistician, which suggested that tuberculosis protected against cancer since it was less commonly found at autopsy among people who had died from cancer than among those who had died from other causes (Pearl 1929b). Berkson showed mathematically that the bias was unavoidable under Pearl's study design (Berkson 1946). His point was that if the cases had disease A (e.g., cancer), controls had disease B (e.g., coronary heart disease), and the "exposure" was disease C (e.g., tuberculosis), the simple mix of conditional probabilities of admission for exposed and non-exposed cases and controls would generate a biased effect. Later, Berkson, a skeptic of the tobacco-lung cancer association, attempted to generalize the domain of application of his selection bias from autopsy studies to all types of case-control and cohort studies (Berkson 1955). Berkson's theoretical demonstration became the model for selection bias in epidemiology training, even though it has proved extremely difficult to illustrate the bias empirically (Roberts et al. 1978).

2.6.3.4 Misclassification Bias

The foundation for a classic definition of misclassification bias was also established in the 1950s. In 1954, Ernst Wynder (1922–1999) et al. had reported that circumcision of the husband protected the wife from cervical cancer (Wynder et al. 1954). A few years later, in 1958, Lilienfeld and Graham challenged the validity of the information wives could provide about their husband prepuce coverage (Lilienfeld and Graham 1958). They supported their argument by showing that even men were inaccurate about their own circumcision status. In a comparison of self-reported circumcision statuses of 192 men with the clinical evaluation of a doctor, Lilienfeld and Graham found that 56% of the self-reports were a false negative and 18% were a false positive. A debate followed on the impact of misclassification of exposure on the estimation of effects (Diamond and Lilienfeld 1962a, b; Keys and Kihlberg 1963). The terms of the debate were clarified by Newell (1962). Later, Copeland et al. (1977) summarized the impact of non-differential and differential misclassification on measures of effects and provided ways to correct for the bias when the misclassification magnitude (e.g., sensitivity and specificity) was known.

2.6.3.5 Classification of Biases

The 1950s, 1960s, and 1970s saw a proliferation of biases that could occur at any level of an epidemiological study. David Sackett took a stab at a bias typology. Having identified 35 sources of biases, he classified them according to whether they occurred in the design, sample selection, conduct, measurements, analysis, or interpretation of a study (Sackett 1979). Classic epidemiology textbooks do not go beyond mentioning different sources of bias.

2.6.4 Classic Epidemiology

The classic definition, popularized by Last's *Dictionary of Epidemiology*, states that epidemiology is "the study of the distribution and the determinants of health-related states of events in specified populations, and the application of this study to control health problems" (Last 2001). The definition weaves descriptive epidemiology ("distribution"), analytical epidemiology ("determinants"), and public health ("application") together.

Textbooks flourished, written by leading researchers (Morris 1957; MacMahon et al. 1960; MacMahon and Pugh 1970; Susser 1973; Lilienfeld 1976).

The symbolic achievement of classic epidemiology was the publication of the 1964 US Surgeon General report, *Smoking and Health* (The Surgeon General's Advisory Committee 1964). The report had been prepared by a committee comprising only people that had been unanimously proposed or tolerated by the tobacco industry. It relied essentially on epidemiological evidence and concluded that there was a causal link between cigarette smoking and lung cancer in men.

2.7 Modern Epidemiology

2.7.1 Population Thinking

2.7.1.1 Estimability and Estimation

Miettinen's "Estimability and Estimation in Case-Referent Studies" (Miettinen 1976) most likely marks the transition from classic to modern epidemiology for two reasons: (1) it explicated the link between risk and rate, respectively, baptized cumulative incidence and incidence density; (2) it unified the two major epidemiological study designs in generalizing the link between cohort and case-control studies. The core of Miettinen's model is depicted in the now historical (one could even say "cult") Fig. 2.1 of Miettinen 1976 (see also Fig. 2.1 in this chapter).

2.7.1.2 Risk and Rate

The way Miettinen approaches risk and rate strikes me to be analogous to the way William Farr described them about 150 years earlier. Farr said that prognosis could be predicted "with certainty," as a rate, in populations, and predicted with risks as "probabilities," in individual patients (Farr 1838). Miettinen wrote, "for populations it is desired to learn about rates," and "for individuals the concern is with risks (for various time periods)" (Miettinen 1976). Miettinen extended Farr's description by deriving the mathematical relationship between rates and risks. Dividing the number of incident cases by the number of person-times for a very short period of time provided an instantaneous risk, called "incidence density." Summing or integrating the instantaneous risks over a longer period of time provided a cumulated risk, called "cumulative incidence.'' Four years later, Morgenstern, Kleinbaum, and Kupper translated this theory in simpler terms and applied examples (Morgenstern et al. 1980).

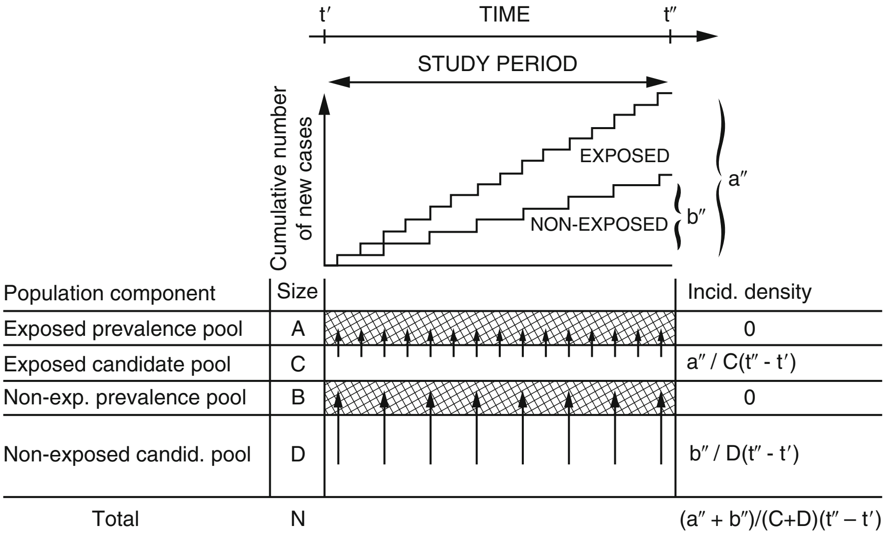

Fig. 2.1 Static population (e.g., a particular age group) over the time span of a case-referent study based on *incident* cases. The sizes of the different component populations remain static, but there is turnover of membership in each compartment. The *arrows* indicate occurrences of new cases, i.e., transitions from the candidate pools to the prevalence pools. Note that the incidence densities are zero in each of the prevalence pools and that the incident cases are referred to the follow-up experiences in the candidate pools only. Also note that the incidence density ratio is (a″/b″)/(C/D), with a″/b″ and C/D estimable from the (incident) cases and referents, respectively, regardless of the levels of incidence or prevalence (Source: Miettinen 1976)

2.7.2 Group Comparison

2.7.2.1 Rare Disease Assumption Revisited

In "Estimability and Estimation in Case-Referent Studies," Miettinen described the assumption formulated by Cornfield in 1951 according to which the odds ratio could approximate the risk ratio *only if* the disease was rare and the target population as "overly superficial and restrictive" (Miettinen 1976). It depended, Miettinen argued, on the way controls were selected from hypothetical underlying cohorts of exposed and non-exposed at-risk subjects. The "rare disease assumption" was appropriate in situations in which the controls were sampled from subjects who had not developed the outcome by the end of the risk period, that is, after all the cases had been identified. "No rare disease assumption was however required" for the situation in which the controls were sampled from the whole cohorts at baseline, or from the people still at risk of the outcome by the time the case was recruited into the study. Actually, the odds ratio could potentially be estimated to be exactly the same as the risk ratio when controls were sampled from the base and exactly the same as the rate ratio when controls were sampled concurrently to the cases, however common the disease was. These elements of Miettinen's paper were further explicated by Greenland and Thomas (1982) and by Greenland et al. (1986).

2.7.3 Concepts

Modern epidemiologists refined the concepts of confounding, interaction, and bias.

2.7.3.1 Confounding

The notion of a confounder as an additional variable brought epidemiologists to specify, in the late 1970s and early 1980s, that, in addition to the two properties already formulated by Simpson (being associated with exposure in the population, and associated with the outcome among the unexposed), the third variable should not mediate the relation of exposure to outcome (Greenland and Neutra 1980; Rothman 1977; Miettinen and Cook 1981). Otherwise, the approach to the concept had not changed substantially between Yule's expression of confounding as, "a fallacy caused by the mixing of records [i.e., strata]" (Yule 1903), and Rothman's "On the simplest level, confounding may be considered as a mixing of effects" (Rothman 1986, p. 89).

The classic definition of confounding had weaknesses. It was derived from the relation of additional variables to exposure and outcome and not from the characteristics of the studied association, such as non-comparability. A variable could meet the classic definition and not be a confounder (Greenland and Robins 1986). Matching for a confounder had different implications in cohort and case-control studies (Miettinen and Cook 1981; Kupper et al. 1981). Screening for confounding by comparing the stratum-specific and the pooled effects could lead to different conclusions based on whether one used risk ratios, risk differences, or odds ratios (Miettinen and Cook 1981).

Of note, one of the rare empirical examples of strong confounded associations was published in Lancet, in 1982. The paper reported a 12-fold higher risk of Kaposi's sarcoma in homosexual men who had used aphrodisiac poppers 500 times or more in their life compared to those who used them less than 500 times (Marmor et al. 1982; Morabia 1995). It was first believed that the confounder was HIV, but the HIV-Kaposi's sarcoma association itself was confounded by a herpes virus associated with multiple partner intercourses connected to the frequent usage of poppers and exposure to HIV (Moore and Chang 1995).

Departure from the fallacy-based definition of confounded effects was initiated in a 1986 paper by Greenland and Robins, which made the potential outcome approach conceived by Splawa-Neyman (1990) and developed by Rubin (1974) widely accessible to epidemiologists (Greenland and Robins 1986). Their potential outcome model was confined to deterministic risks (i.e., risks that can equal only 0 or 1), and the explication was based on the four "causal" types described by Copas (1973): "doomed," "exposure causative," "exposure preventive," and "immune." Each causal type was characterized by two different outcomes (whether exposed or non-exposed) and each led to a different causal explanation. There were therefore two causal explanations for each observed effect *in an individual*. In group comparisons, however, the proportion of doomed and immune could be balanced and the causal effect partially or completely identified. The observed effect was however confounded when the doomed and/or immune causal types were not balanced across the compared groups (Greenland and Robins 1986). This theory of confounding derived from potential outcome contrasts was generalized from randomized to observational studies (Rubin 1990; Hernan and Robins 2006). It was also compatible with a fallacy-based definition since non-exchangeable groups differ on variables that meet the three criteria of confounding variables.

The foundations, contributions, and segues of the Greenland and Robins 1986 paper were recently reviewed by its authors (Greenland and Robins 2009). From a broader historical perspective, "identifiability, exchangeability, and confounding" marks the transition from a definition of confounded effects based on effect mixes, to a theory of group comparability.

In later developments, it was shown that comparability could be achieved by standardization, stratification, inverse probability weighting, and other techniques beyond randomization (Hernan and Robins 2006) and that connections could be drawn between potential outcome models, directed acyclic graphs and structural equations (Hernan et al. 2004; Greenland et al. 1999; Pearl 1995, 2000; Greenland and Brumback 2002). These new ways of analyzing data produced results of practical value (Cole et al. 2003; Hernan et al. 2000).

2.7.3.2 Interaction

Much thought has been invested in the concept of interaction by modern epidemiologists. A Medline search of the American Journal of Epidemiology and the International Journal of Epidemiology (started in 1972) showed that the term "interaction" was practically never used other than to describe infectious processes before Rothman's landmark 1974 paper (Rothman 1974). Since then, textbooks have provided a theory of how to assess, quantify, and test for interactions on multiplicative or additive scales (Kleinbaum et al. 1982; Rothman and Greenland 1998; Szklo and Nieto 2000; Templeton 2000; Susser et al. 2006).

Interaction is what glued components together in Rothman's causal pie (Rothman 1976) since a cause is not complete as long as one of its components is missing. Additional developments of the theory of interaction included the case-only studies (Yang et al. 1997) and the role of parallelism in assessing synergy (Darroch 1997). There are ongoing attempts to integrate the concept of interaction to causal models as was done for confounded effects (Vanderweele and Robins 2007).

2.7.3.3 Bias

The modern theory of bias went beyond Sackett's typology. Modern epidemiologists found that all biases fell under two broad categories, selection biases and misclassification biases. Most textbooks followed thereafter, in the dichotomization of bias sources (Miettinen 1985; Kleinbaum et al. 1982; Rothman 1986).

In 1977, Copeland et al. summarized the state of knowledge with respect to misclassification bias for associations involving two binary variables. The rule was that the bias would tend to underestimate the true effect if the degree of misclassification was similar in the compared groups, that is, if it was non-differential, but that it could either underestimate or overestimate the true effect if the information from one group was more misclassified than that from another.

Selection bias was thought for a while to be similar to confounded effects except that the confounder was measured (Rothman 1986). It was however later shown that confounding was attributable to exposure and outcome having a common "cause," while selection bias was due to exposure and outcome having a common "effect" (Hernan et al. 2004).

2.7.4 Modern Epidemiology

The definition of epidemiology provided in the most influential textbook of the phase states that "the ultimate goal of most epidemiological research is the elaboration of causes that can explain patterns of disease occurrence" (Rothman and Greenland 1998, p. 29).

Many textbooks have translated the modern epidemiological credo in their own ways (Kleinbaum et al. 1982; Rothman 1986; Rothman and Greenland 1998; Rothman et al. 2008; Szklo and Nieto 2000). Characteristically, one third of the textbook entitled *Modern Epidemiology* is dedicated to the application of the methods to specific domains of research such as nutritional, environmental, genetic, and clinical epidemiology (Rothman et al. 2008). This reflects a process of differentiation of field of expertise among epidemiologists associated with a flurry of specialized epidemiological textbooks.

In my view, the main contribution of modern epidemiology has been the assembly, homogenization, and unification of the diverse elements of theory existing about measures of disease occurrence, study design, confounding, interaction, and bias.

Building on the classic epidemiology tradition, modern epidemiology has continued to focus on isolating single causes of often complex, mostly non-communicable diseases, with apparently declining return. Modern epidemiology has been criticized for being "prisoner to the proximate" (McMichael 1999) focusing on a single level of organization (Susser and Susser 1996) favoring point vs. life course exposures (Kuh and Shlomo 2004) and neglecting complexity in favor of parsimony (Schwartz and Susser 2006).

2.8 Causal Inference

Historically, the combination of population thinking and group comparison has allowed epidemiologists to solve causal questions that were beyond the reach of holism and clinical management of single patients. It is therefore irrelevant to look for epidemiological modes of causal inferences prior to the emergence of population thinking in the seventeenth century. The lack of valid inferences related to health determinants, prevention, or treatment is obvious in the Hippocratic treatises as well as throughout the ancient medical literature (Morabia 2004).

The Scottish philosopher David Hume (1711–1776) in the eighteenth century. Hume proposed a set of "rules by which to judge of causes and effects" in situations in which the connection was not obvious, and in particular, when the cause was not deterministically followed by the effect (Hume 1978). These rules were logical criteria which one would expect to characterize a causal relation. For instance, the cause had to precede the effect; the effect intensity had to vary with the intensity of its cause; effects had specific causes and causes had specific effects; and analogous effects had to have analogous causes (Morabia 1991). But Hume's rules were not meant to be applied to evidence generated from group comparisons. They were therefore not directly relevant for epidemiology.

In a 1955 chapter of a book about smoking and health, E Cuyler Hammond listed a series of criteria to rule out the role of a "third factor" when attempting to relate a cause to its probabilistic effect (Hammond 1955).

All trained epidemiologists are familiar with Austin Bradford Hill's synthesis of the epidemiological approach to causality (Hill 1965). It had been preceded by a rich and international discussion among epidemiologists (Blackburn and Labarthe 2012). In contrast to Hume's rules, Hill's list of "viewpoints" applies specifically to evidence generated from group comparisons. It specified that, except for the cause preceding the effect, none of the criteria was indispensable. Hill also stressed that it was meaningless to combine criteria into scores because an association was not more likely to be causal if it met more criteria. Hill also explicitly mentioned that statistical tests were irrelevant for causal inference. It is of note that Hill did not use the term "criteria" at all but referred to "aspects," "features," "characteristics" of associations, or "viewpoints" from which we should study associations "before we cry causation."

Hill's synthesis has remained the major reference for causal inference in epidemiology. His paper was *not* replaced by later attempts to enrich it (Susser 1977) or supplanted by attempts to restrict causal inferences to observations obtained deductively rather than inductively (Buck 1975; Rothman 1988).

Causal inference is about synthesizing all we know at a given point in time, beyond the epidemiological results. Concluding that the human papilloma virus caused cervical cancer involves more than the epidemiological association of the virus and the disease (Muñoz et al. 1992). It incorporates the knowledge about the virus and about carcinogenic process derived from laboratory experiments. Causal inference goes beyond the strict context of epidemiological methods and concepts.

2.9 Epistemology of Epidemiology

To write this history of epidemiological methods and concepts, I used a mode of framing the evolution of scientific discipline referred to as "genetic epistemology" by Jean Piaget (1896–1980) (Piaget 1970; Morabia 2004). The idea is that scientific disciplines are in continual construction, formalization, and organization. Their methods and concepts are commonsensical when the discipline first appears but become increasingly theoretical and abstract as the discipline acquires experience and addresses questions of increasingly complex nature (Piaget 1970).

This work relies therefore on the premises that the methods and concepts that eventually formed epidemiology (a) had a history, which started with commonsensical comparisons and observations, (b) evolved as more abstract and formal with more rigorous methods and overarching concepts, and (c) are still evolving today. To trace this history, I have used the four phases (preformal, early, classic, and modern) previously identified in the history of epidemiological methods and concepts (Morabia 2004). I summarize here how each method and concept evolved across the four phases.

Population thinking. Risk and rate were used intuitively from Graunt to Snow to describe cumulative or instantaneous occurrences of health events. Farr distinguished them theoretically, and Miettinen, 150 years later, showed how risks could be derived from rates. The distinction and relationships between prevalence and incidence have been progressively worked across early, classic, and modern epidemiology.

Group comparison, before the twentieth century, lacked directionality and did not provide for group comparability. From 1900 on, study designs were refined, and techniques for reaching comparability were invented and used. In the 1950s, it was understood that cohort and case-control studies were mathematically linked. Later, it was shown that both designs could be conceptualized as different ways of sampling the same underlying cohorts.

Confounding was first expressed as a commonsensical issue of group non-comparability, later as an uncontrolled fallacy, then as a controllable fallacy resulting in confounded effects, and, more recently, as an issue of group non-comparability of potential outcome types. This latest development tied together the seemingly disconnected phases of the history of confounding as it established that group non-comparability was the essence of confounding, and that statistical fallacy was one of its consequences.

Interaction belonged initially to an early form of complex thinking, in which multiple causes had to be combined for an effect to occur. The classic concept of interaction has restricted the usage of the term to situations in which the combined effects of multiple causes are not the simple combination of their individual effects. Further theoretical developments have been hindered by the complexity of the subject and the difficulty of proving the empirical importance of interactions.

Bias was viewed as a collection of errors occurring at different levels of the epidemiological investigation until a consensus emerged that most biases could stem from selection or misclassification.

2.10 Conclusions

This review of the historical contribution of epidemiology to health knowledge indicates that epidemiology is characterized by the combination of population thinking and group comparisons aimed at discovering the determinants of human health, assessing the efficacy and side effects of treatments, and assessing the efficacy of screening. The set of methods (study designs) and concepts (measures of disease occurrence, confounding, interaction, and bias) have evolved since the seventeenth century and are therefore relatively novel (Morabia 2013a)

In this evolution, we can identify four phases characterized by qualitative leaps in formalization and abstraction of methods and concepts. After a preformal phase, in which epidemiology was discovered intuitively by scientists, and mostly physicians, epidemiology has gone through an early, a classic, and a modern phase.

The next phase in the evolution of epidemiological methods and concepts does not belong in this review, but it can be stated with confidence that the discipline is evolving and that a new phase is dawning.

3.1 Introduction

Epidemiology is the science that focuses on the occurrence of disease in its broadest sense, with the fundamental aim to understand and to control its causes. This chapter deals with the conceptual building blocks of epidemiology. First, we offer a model for causation, from which a variety of insights relevant to epidemiological understanding emerge. We then discuss the basis by which we attempt to infer that an identified factor is indeed a cause of disease; the guidelines lead us through a rapid review of modern scientific philosophy. The remainder of the chapter deals with epidemiological fundamentals of measurement, including the measurement of disease and the measurement of causal effects. More detailed discussion can be found in many textbooks; the present material follows the viewpoints, terminology, and development in Modern Epidemiology, 3rd edition (Rothman et al. 2008).

3.2 Causation and Causal Inference

3.2.1 A General Model of Causation

While useful in everyday life, ordinary concepts of causation are too primitive to serve well as the basis for scientific theories. This shortcoming may be especially true in the health and social sciences, in which typical causes are neither necessary nor sufficient to bring about effects of interest. Hence, as has long been recognized, there is a need to develop a more refined conceptual model that can serve as a starting point in discussions of causation. In particular, such a model should facilitate problems of multifactorial causation, confounding, interdependence of effects, direct and indirect effects, levels of causation, and systems or webs of causation (MacMahon and Pugh 1967, 1970; Susser 1973). This section describes one starting point, the sufficient-component cause model (or sufficient-cause model), which has proven useful in elucidating certain concepts in individual mechanisms of causation. Later, we will discuss causal models better suited for population studies of causation in the absence of mechanistic theories.

To begin, we need to define *cause*. For our purposes, we can define a cause of a specific disease event as an antecedent event, condition, or characteristic that was necessary for the occurrence of a specific instance of the disease at the moment it occurred, given that other conditions are fixed. In other words, a cause of a disease event is an event, condition, or characteristic that preceded the disease event and without which the disease event either would not have occurred at all or would not have occurred until some later time. With this definition, it may be that no specific event, condition, or characteristic is sufficient by itself to produce disease. This definition, then, does not define a complete causal mechanism but only a component of it.

A common characteristic of the concept of causation that we develop early in life is the assumption of a one-to-one correspondence between the observed cause and effect. Each cause is seen as necessary *and* sufficient in itself to produce the effect. Thus, the flick of a light switch appears to be the singular cause that makes the lights go on. There are less evident causes, however, that also operate to produce the effect: The need for an unspent bulb in the light fixture, wiring from the switch to the bulb, and voltage to produce a current when the circuit is closed. To achieve the effect of turning on the light, each of these is equally as important as moving the switch because absence of any of these components of the causal constellation will prevent the effect.

For many people, the roots of early causal thinking persist and become manifest in attempts to find single causes as explanations for observed phenomena. But experience and reflection should easily persuade us that the cause of any effect must consist of a constellation of components that act in concert (Mill 1843). A "sufficient cause," which means a complete causal mechanism, can be defined as a set of minimal conditions and events that inevitably produce disease; "minimal" implies that all of the conditions or events are necessary (Mackie 1965). In disease etiology, the completion of a sufficient cause may be considered equivalent to the onset of disease. (Onset here refers to the onset of the earliest stage of the disease process, rather than the onset of signs or symptoms.) For biological effects, most and sometimes all of the components of a sufficient cause are unknown (Rothman 1976).

For example, tobacco smoking is a cause of lung cancer, but by itself, it is not a sufficient cause. First, the term *smoking* is too imprecise to be used in a causal description. One must specify the type of smoke (e.g., cigarette, cigar, pipe), whether it is filtered or unfiltered, the manner and frequency of inhalation, and the onset and duration of smoking. More important, smoking, even defined explicitly, will not cause cancer in everyone. So who are those who are "susceptible" to the effects of smoking? Or, to put it in other terms, what are the other components of the causal constellation that act with smoking to produce lung cancer?

When causal components remain unknown, we are inclined to assign an equal risk to all individuals whose causal status for some components is known and identical. Thus, men who are heavy cigarette smokers are said to have approximately a 10% lifetime risk of developing lung cancer. Some interpret this statement to mean that all men would be subject to a 10% probability of lung cancer if they were to become heavy smokers, as if the outcome, aside from smoking, were purely a matter of chance. In contrast, we view the assignment of equal risks as reflecting nothing more than assigning to everyone within a specific category, in this case male heavy smokers, the average of the individual risks for people in that category. In the classical view, these risks are either one or zero, according to whether the individual will or will not get lung cancer.

We cannot measure the individual risks, and assigning the average value to everyone in the category reflects nothing more than our ignorance about the determinants of lung cancer that interact with cigarette smoke. It is apparent from epidemiological data that some people can engage in chain smoking for many decades without developing lung cancer. Others are or will become "primed" by unknown circumstances and need only to add cigarette smoke to the nearly sufficient constellation of causes to initiate lung cancer. In our ignorance of these hidden

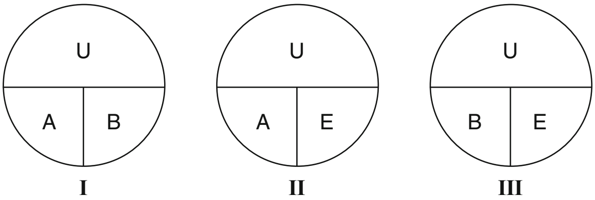

Fig. 3.1 Three sufficient causes of a disease

causal components, the best we can do in assessing risk is to classify people according to measured causal risk indicators and then assign the average risk observed within a class to persons within the class. As knowledge expands, the risk estimates assigned to people will depart from average according to the presence or absence of other factors that affect the risk.

For example, we now know that smokers with substantial asbestos exposure are at higher risk of lung cancer than those who lack asbestos exposure. Consequently, with adequate data, we could assign different risks to heavy smokers based on their asbestos exposure. Within categories of asbestos exposure, the average risks would be assigned to all heavy smokers until other risk factors are identified.

Figure 3.1 provides a schematic diagram of sufficient causes in a hypothetical individual. Each constellation of component causes represented in Fig. 3.1 is minimally sufficient to produce the disease; that is, there is no redundant or extraneous component cause – each one is a necessary part of that specific causal mechanism. A specific component cause may play a role in one, two, or all three of the causal mechanisms pictured.

Figure 3.1 does not depict aspects of the causal process such as prevention, sequence, or timing of action of the component causes, dose, and other complexities. These aspects of the causal process must be accommodated in the model by an appropriate definition of each causal component. Thus, if the disease is lung cancer and the factor E represents cigarette smoking, it might be defined more explicitly as smoking at least two packs a day of unfiltered cigarettes for at least 20 years. If the outcome is smallpox, which is completely prevented by immunization, U could represent "unimmunized." More generally, preventive effects of a factor C can be represented by placing its complement "no C" within sufficient causes.

3.2.2 Strength of Effects

We will call the set of conditions necessary and sufficient for a factor to produce disease the *causal complement* of the factor. Thus, the condition "(A and U) or (B and U)" is the causal complement of E in the above example. The strength of a factor's effect on a population depends on the relative prevalence of its causal complement. This dependence of the effects of a specific component cause on the prevalence of its causal complement has nothing to do with the biological mechanism of the component's action, since the component is an equal partner in each mechanism in which it appears. Nevertheless, a factor will appear to have a strong effect if its causal complement is common. Conversely, a factor with a rare causal complement will appear to have a weak effect.

In epidemiology, the strength of a factor's effect is usually measured by the change in disease frequency produced by introducing the factor into a population. This change may be measured in absolute or relative terms. In either case, the strength of an effect may have tremendous public health significance, but it may have little biological significance. The reason is that given a specific causal mechanism, *any* of the component causes can have strong or weak effects. The actual identity of the constituent components of the cause amount to the biology of causation, whereas the strength of a factor's effect depends on the time-specific distribution of its causal complements in the population. Over a span of time, the strength of the effect of a given factor on the occurrence of a given disease may change, because the prevalence of its causal complements in various mechanisms may also change. The causal mechanisms in which the factor and its complements act could remain unchanged, however.

3.2.3 Interaction Among Causes

Two component causes acting in the same sufficient cause may be thought of as interacting biologically to produce disease. Indeed, one may define biological interaction as the participation of two component causes in the same sufficient cause. Such interaction is also known as causal coaction or joint action. The joint action of the two component causes does not have to be simultaneous action: One component cause could act many years before the other, but it would have to leave some effect that interacts with the later component.

For example, suppose a traumatic injury to the head leads to a permanent disturbance in equilibrium. Many years later, the faulty equilibrium may lead to a fall while walking on an icy path, causing a broken hip. The causal mechanism for the broken hip includes the traumatic injury to the head as a component cause, along with its consequence of a disturbed equilibrium. The causal mechanism also includes the walk along the icy path. These two component causes have interacted with one another, although their time of action is many years apart. They also would interact with the other component causes, such as the type of footwear, the absence of a handhold, and any other conditions that were necessary to the causal mechanism of the fall and the broken hip that resulted.

The degree of observable interaction between two specific component causes depends on how many different sufficient causes produce disease, and the proportion of cases that occur through sufficient causes in which the two component causes both play some role. For example, in Fig. 3.2, suppose that G were only a hypothetical substance that did not actually exist. Consequently, no disease would occur from sufficient cause II, because it depends on an action by G, and factors B and F would act only through the distinct mechanisms represented by sufficient causes I and III. Thus, B and F would be biologically independent. Now suppose G is present; then B and F would interact biologically. Furthermore, if C is completely

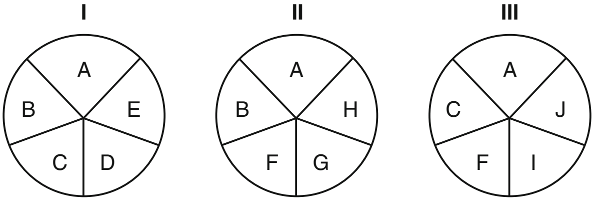

Fig. 3.2 Another example of three sufficient causes of a disease

absent, then cases will occur only when factors B and F act together in the mechanism represented by sufficient cause II. Thus, the extent or apparent strength of biological interaction between two factors is dependent on the prevalence of other factors.

3.2.4 Proportion of Disease Due to Specific Causes

In Fig. 3.1, assuming that the three sufficient causes in the diagram are the only ones operating, what fraction of disease is caused by U? The answer is all of it; without U, there is no disease. U is considered a "necessary cause." What fraction is due to E? E causes disease through two mechanisms, I and II, and all disease arising through either of these two mechanisms is due to E. This is not to say that all disease is due to U alone or that a fraction of disease is due to E alone; no component cause acts alone. Rather, these factors interact with their complementary factors to produce disease.

There is a tendency to think that the sum of the fractions of disease attributable to each of the causes of the disease should be 100%. For example, in their widely cited work, *The Causes of Cancer*, Doll and Peto created a table giving their estimates of the fraction of all cancers caused by various agents; the total for the fractions was nearly 100% (Doll and Peto 1981, Table 20). Although they acknowledged that any case could be caused by more than one agent, which would mean that the attributable fractions would not sum to 100%, they referred to this situation as a "difficulty" and an "anomaly." It is, however, neither a difficulty nor an anomaly but simply a consequence of allowing for the fact that no event has a single agent as the cause. The fraction of disease that can be attributed to each of the causes of disease in all the causal mechanisms actually has no upper limit: For cancer, or any disease, the upper limit for the total of the fraction of disease attributable to all the component causes of all the causal mechanisms that produce it is not 100% but infinity. Only the fraction of disease attributable to a single component cause cannot exceed 100%.

3.2.5 Induction Period and Latent Period

The diagram of causes in Fig. 3.2 also provides a model for conceptualizing the *induction period,* which may be defined as the period of time from causal action until disease occurrence. If, in sufficient cause I, the sequence of action of the causes is A, B, C, D, and E, and we are studying the effect of B, which, let us assume, acts at a narrowly defined point in time, disease does not occur immediately after B acts. It occurs only after the sequence is completed, so there will be a delay while C, D, and finally E act. When E acts, disease occurs. The interval between the action of B and the disease occurrence is the induction time for the effect of B.

In the example given earlier of an equilibrium disorder leading to a later fall and hip injury, the induction time between the occurrence of the equilibrium disorder and the later hip injury might be very long. In an individual instance, we would not know the exact length of an induction period, since we cannot be sure of the causal mechanism that produces disease in an individual instance, nor when all the relevant component causes acted. We can characterize the induction period relating the action of a component cause to the occurrence of disease in general, however, by accumulating data for many individuals. A clear example of a lengthy induction time is the cause-effect relation between exposure of a female fetus to diethylstilbestrol (DES) and the subsequent development of clear cell adenocarcinoma of the vagina. The cancer usually occurs between the ages of 15 and 30. Since the causal exposure to DES occurs early in pregnancy, there is an induction time of about 15–30 years for the carcinogenic action of DES. During this time, other causes presumably are operating; some evidence suggests that hormonal action during adolescence may be part of the mechanism (Rothman 1981).

It is incorrect to characterize a disease itself as having a lengthy or brief induction time. The induction time can be conceptualized only in relation to a specific component cause. Thus, we say that the induction time relating DES to clear cell carcinoma of the vagina is 15–30 years, but we cannot say that 15–30 years is the induction time for clear cell carcinoma in general. Since each component cause in any causal mechanism can act at a time different from the other component causes, each can have its own induction time. For the component cause that acts last, the induction time equals zero. If another component cause of clear cell carcinoma of the vagina that acts during adolescence were identified, it would have a much shorter induction time for its carcinogenic action than DES. Thus, induction time characterizes a specific cause-effect pair rather than just the effect.

Disease, once initiated, will not necessarily be apparent. The time interval between disease occurrence and detection has been termed the *latent* period (Rothman 1981), although others have used this term interchangeably with induction period. The latent period can be reduced by improved methods of disease detection. The induction period, on the other hand, cannot be reduced by early detection of disease, since disease occurrence marks the end of the induction period. Earlier detection of disease, however, may reduce the apparent induction period (the time between causal action and disease detection), since the time when disease is detected, as a practical matter, is usually used to mark the time of disease occurrence. Thus, diseases such as slow-growing cancers may appear to have long induction periods with respect to many causes because they have long latent periods. The latent period, unlike the induction period, is a characteristic of the disease and the detection effort applied to the person with the disease.

Although it is not possible to reduce the induction period proper by earlier detection of disease, it may be possible to observe intermediate stages of a causal mechanism. The increased interest in biomarkers such as DNA adducts is an example of attempting to focus on causes more proximal to the disease occurrence. Such biomarkers may reflect the effects of earlier acting agents on the organism.

Some agents may have a causal action by shortening the induction time of other agents. Suppose that exposure to factor A leads to epilepsy after an interval of 10 years, on the average. It may be that exposure to a drug, B, would shorten this interval to 2 years. Is B acting as a catalyst or as a cause of epilepsy? The answer is both: A catalyst *is* a cause. Without B, the occurrence of epilepsy comes 8 years later than it comes with B, so we can say that B causes the onset of the early epilepsy. It is not sufficient to argue that the epilepsy would have occurred anyway. First, it would not have occurred at that time, and the time of occurrence is part of our definition of an event. Second, epilepsy will occur later only if the individual survives an additional 8 years, which is not certain. Agent B not only determines when the epilepsy occurs, it can determine whether it occurs. Thus, we should call any agent that acts as a catalyst of a causal mechanism, speeding up an induction period for other agents, as a cause in its own right. Similarly, any agent that postpones the onset of an event, drawing out the induction period for another agent, is a preventive. It should not be too surprising to equate postponement to prevention: We routinely use such an equation when we employ the euphemism that we prevent death, which actually can only be postponed. What we prevent is death at a given time, in favor of death at a later time.

3.2.6 Philosophy of Scientific Inference

Modern science began to emerge around the sixteenth and seventeenth centuries, when the knowledge demands of emerging technologies (such as artillery and transoceanic navigation) stimulated inquiry into the origins of knowledge. An early codification of the scientific method was Francis Bacon's *Novum Organum,* published in 1620, which presented an *inductivist* view of science. In this philosophy, scientific reasoning is said to depend on making generalizations, or inductions, from observations to general laws of nature; the observations are said to induce the formulation of a natural law in the mind of the scientist. Thus, an inductivist would have said that Jenner's observation of lack of smallpox among milkmaids induced in Jenner's mind the theory that cowpox (common among milkmaids) conferred immunity to smallpox. Inductivist philosophy reached a pinnacle of sorts in the canons of John Stuart Mill (1843), which evolved into inferential criteria that are still in use today.

Inductivist philosophy was a great step forward from the medieval scholasticism that preceded it, for at least it demanded that a scientist make careful observations of people and nature, rather than appeal to faith, ancient texts, or authorities. Nonetheless, by the eighteenth century, the Scottish philosopher David Hume had described a disturbing deficiency in inductivism: An inductive argument carried no logical force; instead, such an argument represented nothing more than an *assumption* that certain events would in the future follow in the same pattern as they had in the past. Thus, to argue that cowpox caused immunity to smallpox because no one got smallpox after having cowpox corresponded to an unjustified assumption that the pattern observed so far (no smallpox after cowpox) will continue into the future. Hume pointed out that, even for the most reasonable sounding of such assumptions, there was no logic or force of necessity behind the inductive argument.

Causal inference based on mere coincidence of events constitutes a logical fallacy known as *post hoc ergo propter hoc* (Latin for "after this therefore on account of this"). This fallacy is exemplified by the inference that the crowing of a rooster is necessary for the sun to rise because sunrise is always preceded by the crowing. The *post hoc* fallacy is a special case of a more general logical fallacy known as the *fallacy of affirming the consequent*. This fallacy of confirmation takes the following general form: "We know that if H is true, B must be true; and we know that B is true; therefore H must be true." This fallacy is used routinely by scientists in interpreting data. It is used, for example, when one argues as follows: "if sewer service causes heart disease, then heart disease rates should be highest where sewer service is available; heart disease rates are indeed highest where sewer service is available; therefore, sewer service causes heart disease." Here, H is the hypothesis "sewer service causes heart disease" and B is the observation "heart disease rates are highest where sewer service is available." The argument is of course logically unsound, as demonstrated by the fact that we can imagine many ways in which the premises could be true but the conclusion false; for example, economic development could lead to both sewer service and elevated heart disease rates, without any effect of the latter on the former.

3.2.7 Refutationism

Many philosophers and scientists from Hume's time forward attempted to set out a firm logical basis for scientific reasoning. In the 1920s, most notable among these was the school of logical positivists, who sought a logic for science that could lead inevitably to correct scientific conclusions, in much the way rigorous logic can lead inevitably to correct conclusions in mathematics. Other philosophers and scientists, however, had started to suspect that scientific hypotheses can never be proven or established as true in any logical sense. For example, a number of philosophers noted that scientific statements can only be found to be consistent with observation but cannot be proven or disproven in any "airtight" logical or mathematical sense (Duhem 1906, transl. 1954; Popper 1934, transl. 1959; Quine 1951). This fact is sometimes called the problem of *non-identification* or *underdetermination* of theories by observations (Curd and Cover 1998). In particular, available observations are always consistent with several hypotheses that themselves are mutually inconsistent, which explains why (as Hume noted) scientific theories cannot be logically proven. In particular, consistency between a hypothesis and observations is no proof of the hypothesis, because we can always invent alternative hypotheses that are just as consistent with the observations.

In contrast, a valid observation that is inconsistent with a hypothesis implies that the hypothesis as stated is false and so refutes the hypothesis. If you wring the rooster's neck before it crows and the sun still rises, you have disproved that the rooster's crowing is a necessary cause of sunrise. Or consider a hypothetical research program to learn the boiling point of water (Magee 1985). A scientist who boils water in an open flask and repeatedly measures the boiling point at 100°C will never, no matter how many confirmatory repetitions are involved, prove that 100°C is always the boiling point. On the other hand, merely one attempt to boil the water in a closed flask or at high altitude will refute the proposition that water always boils at 100°C.

According to Popper, science advances by a process of elimination that he called "conjecture and refutation." Scientists form hypotheses based on intuition, conjecture, and previous experience. Good scientists use deductive logic to infer predictions from the hypothesis and then compare observations with the predictions. Hypotheses whose predictions agree with observations are confirmed (Popper used the term "corroborated") only in the sense that they can continue to be used as explanations of natural phenomena. At any time, however, they may be refuted by further observations and might be replaced by other hypotheses that are more consistent with the observations. This view of scientific inference is sometimes called *refutationism* or *falsificationism.* Refutationists consider induction to be a psychologic crutch: Repeated observations did not in fact induce the formulation of a natural law, but only the belief that such a law has been found. For a refutationist, only the psychologic comfort provided by induction explains why it still has advocates.

One way to rescue the concept of induction from the stigma of pure delusion is to resurrect it as a psychologic phenomenon, as Hume and Popper claimed it was, but one that plays a legitimate role in hypothesis formation. The philosophy of conjecture and refutation places no constraints on the origin of conjectures. Even delusions are permitted as hypotheses, and therefore inductively inspired hypotheses, however psychological, are valid starting points for scientific evaluation. This concession does not admit a logical role for induction in confirming scientific hypotheses, but it allows the process of induction to play a part, along with imagination, in the scientific cycle of conjecture and refutation.

The philosophy of conjecture and refutation has profound implications for the methodology of science. The popular concept of a scientist doggedly assembling evidence to support a favorite thesis is objectionable from the standpoint of refutationist philosophy because it encourages scientists to consider their own pet theories as their intellectual property, to be confirmed, proven, and, when all the evidence is in, cast in stone and defended as natural law. Such attitudes hinder critical evaluation, interchange, and progress. The approach of conjecture and refutation, in contrast, encourages scientists to consider multiple hypotheses and to seek crucial tests that decide between competing hypotheses by falsifying one of them. Because falsification of one or more theories is the goal, there is incentive to depersonalize the theories. Criticism leveled at a theory need not be seen as criticism of the person who proposed it. It has been suggested that the reason why certain fields of science advance rapidly while others languish is that the rapidly advancing fields are propelled by scientists who are busy constructing and testing competing hypotheses; the other fields, in contrast, “are sick by comparison, because they have forgotten the necessity for alternative hypotheses and disproof” (Platt 1964).

The refutationist model of science has a number of valuable lessons for research conduct, especially of the need to seek alternative explanations for observations, rather than focus on the chimera of seeking scientific “proof” for some favored theory. Nonetheless, it is vulnerable to several criticisms (Pearce 1990), most notable among them being that observations (or some would say their interpretations) are themselves laden with theory (sometimes called the *Duhem-Quine thesis*; Curd and Cover 1998). Thus, observations can never provide the sort of definitive refutations that are the hallmark of popular accounts of refutationism. For example, there may be uncontrolled and even unimagined biases that have made our refutational observations invalid; to claim refutation is to assume as true the unprovable theory that no such bias exists. In other words, theories are underdetermined by observations, but refutations are theory-laden and thus also underdetermined. The net result is that logical certainty about either the truth or falsity of an internally consistent theory is impossible (Quine 1951).

3.2.8 Bayesianism

There is another philosophy of inference that, like refutationism, holds an objective view of scientific truth and a view of knowledge as tentative or uncertain but which focuses on evaluation of knowledge rather than truth. Like refutationism, the modern form of this philosophy evolved from the writings of eighteenth century British philosophers, but the focal arguments first appeared in a pivotal essay by Bayes (1763), and hence the philosophy is usually referred to as Bayesianism (Howson and Urbach 1993). Like refutationism, it did not reach a complete expression until after World War I, most notably in the writings of Ramsey (1931) and DeFinetti (1937), and, like refutationism, it did not begin to appear in epidemiology until the 1970s (see, e.g., Cornfield 1976).

The central problem addressed by Bayesianism is the following: In classical logic, a deductive argument can provide you no information about the truth or falsity of a scientific hypothesis unless you can be 100% certain about the truth of the premises of the argument. Consider the logical argument called *modus tollens*: “If H implies B, and B is false, then H must be false.” This argument is logically valid, but the conclusion follows only on the assumptions that the premises “H implies B” and “B is false” are true statements. If these premises are statements about the physical world, we cannot possibly know them to be correct with 100% certainty, since all observations are subject to error. Furthermore, the claim that “H implies B” will often depend on its own chain of deductions, each with its own premises of which we cannot be certain.

For example, if H is "television viewing causes homicides" and B is "homicide rates are highest where televisions are most common," the first premise used in modus tollens to test the hypothesis that television viewing causes homicides will be "If television viewing causes homicides, homicide rates are highest where televisions are most common." The validity of this premise is doubtful – after all, even if television does cause homicides, homicide rates may be low where televisions are common because of socioeconomic advantages in those areas.

Continuing to reason in this fashion, we could arrive at a more pessimistic state than even Hume imagined: Not only is induction without logical foundation, but *deduction* has no scientific utility because we cannot ensure the validity of all the premises. The Bayesian answer to this problem is partial, in that it makes a severe demand on the scientist and puts a severe limitation on the results. It says roughly this: If you can assign a degree of certainty, or personal probability, to the premises of your valid argument, you may use any and all the rules of probability theory to derive a certainty for the conclusion, and this certainty will be a logically valid consequence of your original certainties. The catch is that your concluding certainty, or *posterior probability*, may heavily depend on what you used as initial certainties, or *prior probabilities*. And, if those initial certainties are not those of a colleague, that colleague may very well assign a different certainty to the conclusion than you derived.

Because the posterior probabilities emanating from a Bayesian inference depend on the person supplying the initial certainties, and so may vary across individuals, the inferences are said to be *subjective*. This subjectivity of Bayesian inference is often mistaken for a subjective treatment of truth. Not only is such a view of Bayesianism incorrect, but it is diametrically opposed to Bayesian philosophy. The Bayesian approach represents a constructive attempt to deal with the dilemma that scientific laws and facts should not be treated as known with certainty, whereas classical deductive logic yields conclusions only when some law, fact, or connection is asserted with 100% certainty.

A common criticism of Bayesian philosophy is that it diverts attention away from the classical goals of science, such as the discovery of how the world works, toward psychological states of mind called "certainties," "subjective probabilities," or "degrees of belief" (Popper 1959). This criticism fails, however, to recognize the importance of a scientist's state of mind in determining what theories to test and what tests to apply.

Most epidemiologists desire some interval estimate or evaluation of the likely range for an effect in light of available data. This estimate must inevitably be derived in the face of considerable uncertainty about methodological details and various events that led to the available data and can be extremely sensitive to the reasoning used in its derivation. Psychological investigations have found that most people, including scientists, reason poorly in general and especially poorly in the face of uncertainty (Kahnemann et al. 1982; Gilovich et al. 2002). Bayesian philosophy provides a methodology for such reasoning and in particular provides many warnings against being overly certain about one's conclusions:

> Such warnings are echoed in refutationist philosophy. As Peter Medawar put it,
> I cannot give any scientist of any age better advice than this: the intensity of the conviction that a hypothesis is true has no bearing on whether it is true or not (Medawar 1979).

We would only add that intensity of conviction that a hypothesis is false has no bearing on whether it is false or not.

3.2.9 Impossibility of Proof

Vigorous debate is a characteristic of modern scientific philosophy, no less in epidemiology than in other areas (Rothman 1988). Perhaps the most important common thread that emerges from the debated philosophies is Hume's legacy that proof is impossible in empirical science. This simple fact is especially important to epidemiologists, who often face the criticism that proof is impossible in epidemiology, with the implication that it is possible in other scientific disciplines. Such criticism may stem from a view that experiments are the definitive source of scientific knowledge. Such a view is mistaken on at least two counts. First, the non-experimental nature of a science does not preclude impressive scientific discoveries; the myriad examples include plate tectonics, the evolution of species, planets orbiting other stars, and the effects of cigarette smoking on human health. Even when they are possible, experiments (including randomized trials) do not provide anything approaching proof and in fact may be controversial, contradictory, or irreproducible. The cold-fusion debacle demonstrates well that neither physical nor experimental science is immune to such problems (Taubes 1993).

Some experimental scientists hold that epidemiological relations are only suggestive and believe that detailed laboratory study of mechanisms within single individuals can reveal cause-effect relations with certainty. This view overlooks the fact that *all* relations are suggestive in exactly the manner discussed by Hume: Even the most careful and detailed mechanistic dissection of individual events cannot provide more than associations, albeit at a finer level. Laboratory studies often involve a degree of observer control that cannot be approached in epidemiology; it is only this control, not the level of observation, that can strengthen the inferences from laboratory studies. And again, such control is no guarantee against error.

All of the fruits of scientific work, in epidemiology or other disciplines, are at best only tentative formulations of a description of nature, even when the work itself is carried out without mistakes. The tentativeness of our knowledge does not prevent practical applications, but it should keep us skeptical and critical, not only of everyone else's work, but of our own as well. Avoidance of dogmatism or absolute certainty, along with judicious application of common sense, is arguably the most important and least controversial hallmark of the scientific enterprise (Haack 2003).

3.2.10 Causal Inference in Epidemiology

Biological knowledge about epidemiological hypotheses is often scant, making the hypotheses themselves at times little more than vague statements of causal association between exposure and disease, such as "smoking causes cardiovascular disease." These vague hypotheses have only vague consequences that can be difficult to test. To cope with this vagueness, epidemiologists usually focus on testing the negation of the causal hypothesis, that is, the null hypothesis that the exposure does *not* have a causal relation to disease. Then, any observed association can potentially refute the hypothesis, subject to the assumption (auxiliary hypothesis) that biases are absent.

If the causal mechanism is stated specifically enough, epidemiological observations can provide crucial tests of competing non-null causal hypotheses. For example, when toxic shock syndrome was first studied, there were two competing hypotheses about the origin of the toxin. Under one hypothesis, the toxin was a chemical in the tampon, so that women using tampons were exposed to the toxin directly from the tampon. Under the other hypothesis, the tampon acted as a culture medium for Staphylococci that produced the toxin. Both hypotheses explained the relation of toxic shock occurrence to tampon use. The two hypotheses, however, lead to opposite predictions about the relation between the frequency of changing tampons and the risk of toxic shock. Under the hypothesis of a chemical intoxication, more frequent changing of the tampon would lead to more exposure to the toxin and possible absorption of a greater overall dose. This hypothesis predicted that women who changed tampons more frequently would have a higher risk than women who changed tampons infrequently. The culture-medium hypothesis predicts that the women who change tampons frequently would have a lower risk than those who leave the tampon in for longer periods, because a short duration of use for each tampon would prevent the staphylococci from multiplying enough to produce a damaging dose of toxin. Thus, epidemiological research, which showed that infrequent changing of tampons was associated with the risk of toxic shock, refuted the chemical theory.

Another example of a theory easily tested by epidemiological data related to the finding that women who took replacement estrogen therapy were at a considerably higher risk for endometrial cancer. Horwitz and Feinstein (1978) conjectured a competing theory to explain the association: They proposed that women taking estrogen experienced symptoms such as bleeding that induced them to consult a physician. The resulting diagnostic workup led to the detection of endometrial cancer at an earlier stage in these women, as compared with women not taking estrogens. Many epidemiological observations could have been and were used to evaluate these competing hypotheses. The causal theory predicted that the risk of endometrial cancer would tend to increase with increasing use (dose, frequency, and duration) of estrogens, as for other carcinogenic exposures. The detection bias theory, on the other hand, predicted that women who had used estrogens only for a short while would have the greatest risk, since the symptoms related to estrogen use that led to the medical consultation tend to appear soon after use begins. Because the association of recent estrogen use and endometrial cancer was the same in both long-term and short-term estrogen users, the detection bias theory was refuted as an explanation for all but a small fraction of endometrial cancer cases occurring after estrogen use. (Refutation of the detection bias theory also depended on many other observations. Especially important was the theory's implication that there must be a large reservoir of undetected endometrial cancer in the typical population of women to account for the much greater rate observed in estrogen users.)

The endometrial cancer example illustrates a critical point in understanding the process of causal inference in epidemiological studies: Many of the hypotheses being evaluated in the interpretation of epidemiological studies are non-causal hypotheses, in the sense of involving no causal connection between the study exposure and the disease. For example, hypotheses that amount to explanations of how specific types of bias could have led to an association between exposure and disease are the usual alternatives to the primary study hypothesis that the epidemiologist needs to consider in drawing inferences. Much of the interpretation of epidemiological studies amounts to the testing of such non-causal explanations for observed associations.

3.2.11 Causal Criteria

In practice, how do epidemiologists separate out the causal from the non-causal explanations? Despite philosophic criticisms of inductive inference, inductively-oriented causal criteria have commonly been used to make such inferences. If a set of necessary and sufficient causal criteria could be used to distinguish causal from non-causal relations in epidemiological studies, the job of the scientist would be eased considerably. With such criteria, all the concerns about the logic or lack thereof in causal inference could be forgotten: It would only be necessary to consult the checklist of criteria to see if a relation were causal. We know from philosophy that a set of sufficient criteria does not exist. Nevertheless, lists of causal criteria have become popular, possibly because they seem to provide a road map through complicated territory.

Hill (1965) proposed a famous set of considerations for use in making causal inferences, which he took care not to label as "criteria." Hill's set can be seen as expanding on considerations in the landmark Surgeon General's report on Smoking and Health (1964), which in turn were anticipated by the inductive canons of Mill (1843) and discussions given by Hume. Hill suggested that the following aspects of an association be considered in attempting to distinguish causal from non-causal associations: (1) strength, (2) consistency, (3) specificity, (4) temporality, (5) biological gradient, (6) plausibility, (7) coherence, (8) experimental evidence, and (9) analogy.

Hill recognized that (apart from temporality) there is no necessary or sufficient criterion for determining whether an observed association is causal and emphasized due caution in application of his considerations (Phillips and Goodman 2004). His caution accords with the views of Hume, Popper, and others that causal inferences cannot attain the certainty of logical deductions. Although some epidemiologists have argued that it is detrimental to cloud the inferential process by considering checklist criteria (Lanes and Poole 1984), a moderate approach seeks to transform informal considerations like Hill's into deductive tests of causal hypotheses (Maclure 1985; Weed 1986; Susser 1991; Weiss 2002). Such an approach avoids the temptation to use causal criteria simply to buttress pet theories at hand and instead allows epidemiologists to focus on evaluating competing causal theories using crucial observations.

3.3 Measures of Disease Frequency

A central task in epidemiological research is to quantify the occurrence of disease in populations. We discuss here four basic measures of disease occurrence. *Incidence times* are simply the times at which new disease occurs among population members. *Incidence rate* measures the occurrence of new disease per unit of person-time. *Incidence proportion* measures the proportion of people who develop new disease during a specified period of time. *Prevalence*, a measure of status rather than of newly occurring disease, measures the proportion of people who have disease at a specific time.

3.3.1 Incidence Time

In attempting to measure the frequency of disease occurrence in a population, it is insufficient merely to record the number of people or even the proportion of the population that is affected. It is also necessary to take into account the time elapsed before disease occurs as well as the period of time during which events are counted. Consider the frequency of death. Since all people are eventually affected, the time from birth to death becomes the determining factor in the rate of occurrence of death. If, on average, death comes earlier to the members of one population than to members of another population, it is natural to say that the first population has a higher death rate than the second.

In an epidemiological study, we may measure the time of events in an individual's life relative to any one of several reference events. Using age, for example, the reference event is birth, but we might instead use the start of a treatment or the start of an exposure as the reference event. The reference event may be unique to each person, as it is with birth, or it may be identical for all persons, as with calendar time. The time of the reference event determines the time origin or *zero time* for measuring time of events.

Given an outcome event or "incident" of interest, a person's *incidence time* for this outcome is defined as the time span from zero time to the time at which the event occurs if it occurs. A man who experienced his first myocardial infarction (MI) in 1990 at age 50 has an incidence time of 1,990 in (Western) calendar time and an incidence time of 50 in age time. A person's incidence time is undefined if that person never experiences the event. (There is a useful convention that classifies such a person as having an unspecified incidence time that is known to exceed the last time the person could have experienced the event. Under this convention, a woman who had a hysterectomy in 1990 without ever having had endometrial cancer is classified as having an endometrial cancer incidence time greater than 1990.)

3.3.2 Incidence Rate

Epidemiologists often study events that are not inevitable or that may not occur during the period of observation. In such situations, the set of incidence times for a specific event in a population will not all be defined or observed, and another incidence measure must be sought. Ideally, such a measure would take into account the number of individuals in a population that become ill as well as the length of time contributed by all persons during the period they were in the population and events are counted.

Consider any population and a risk period over which we want to measure incidence in this population. Every member of the population experiences a specific amount of time in the population over the risk period; the sum of these times over all population members is called the total *person-time* at risk over the period. Person-time should be distinguished from clock time in that it is a summation of time that occurs simultaneously for many people, whereas clock time is not. Person-time represents the observational experience in which disease onsets can be observed. The number of new cases of disease divided by the person-time is the *incidence rate* of the population over the period:

$$\text{Incidence rate} = \frac{\text{no. disease onsets}}{\sum\limits_{\text{persons}} \text{time at risk for getting disease}}.$$

When the risk period is of fixed length Δt, the total person-time at risk over the period is equal to the average size of the population over the period, $\overline{N}$, times the length of the period, Δt. If we denote the incident number by A, it follows that the person-time rate equals $A/(\overline{N} \times \Delta t)$. This formulation makes clear that the incidence rate has units of inverse time (per year, per month, per day, etc.). The units attached to an incidence rate can be written as year^{-1}, month^{-1}, or day^{-1}.

It is an important principle that the only events eligible to be counted in the numerator of an incidence rate are those that occur to persons who are contributing time to the denominator of the incidence rate at the time that the disease onset occurs. Likewise, only time contributed by persons eligible to be counted in the numerator if they suffer an event should be counted in the denominator. The time contributed by each person to the denominator is sometimes known as the "time at risk," that is, time at risk of an event occurring. Analogously, the people who contribute time to the denominator of an incidence rate are referred to as the "population at risk."

Incidence rates often include only the first occurrence of disease onset as an eligible event for the numerator of the rate. For the many diseases that are irreversible states, such as diabetes, multiple sclerosis, cirrhosis, or death, there is at most only one onset that a person can experience. For some diseases that do recur, such as rhinitis, we may simply wish to measure the incidence of “first” occurrence, even though the disease can occur repeatedly. For other diseases, such as cancer or heart disease, the first occurrence is often of greater interest for study than subsequent occurrences in the same individual. Therefore, it is typical that the events in the numerator of an incidence rate correspond to the first occurrence of a particular disease, even in those instances in which it is possible for an individual to have more than one occurrence.

When the events tallied in the numerator of an incidence rate are first occurrences of disease, then the time contributed by each individual who develops the disease should terminate with the onset of disease. The reason is that the individual is no longer eligible to experience the event (the first occurrence can only occur once per individual), so there is no more information to obtain from continued observation of that individual. Thus, each individual who experiences the event should contribute time to the denominator up until the occurrence of the event but not afterward. Furthermore, for the study of first occurrences, the number of disease onsets in the numerator of the incidence rate is also a count of people experiencing the event, since only one event can occur per person.

An epidemiologist who wishes to study both first and subsequent occurrences of disease may decide not to distinguish between first and later occurrences and simply count all the events that occur among the population under observation. If so, then the time accumulated in the denominator of the rate would not cease with the occurrence of the event, since an additional event might occur in the same individual. Usually, however, there is enough of a biological distinction between first and subsequent occurrences to warrant measuring them separately. One approach is to define the “population at risk” differently for each occurrence of the event: The population at risk for the first event would consist of individuals who have not experienced the disease before; the population at risk for the second event, or first recurrence, would be limited to those who have experienced the event once and only once, etc. A given individual should contribute time to the denominator of the incidence rate for first events only until the time that the disease first occurs. At that point, the individual should cease contributing time to the denominator of that rate and should now begin to contribute time to the denominator of the rate measuring the second occurrence. If and when there is a second event, the individual should stop contributing time to the rate measuring the second occurrence and begin to contribute to the denominator of the rate measuring the third occurrence and so forth. In effect, measuring the rate for the sequence of events amounts to conducting a separate study for first events, second events, third events, and so forth, each with its own population at risk and distinct events.

3.3.3 Closed and Open Populations

Conceptually, we can imagine the person-time experience of two distinct types of populations, the *closed population* and the *open population*. A closed population adds no new members over time, and loses members only to death, whereas an

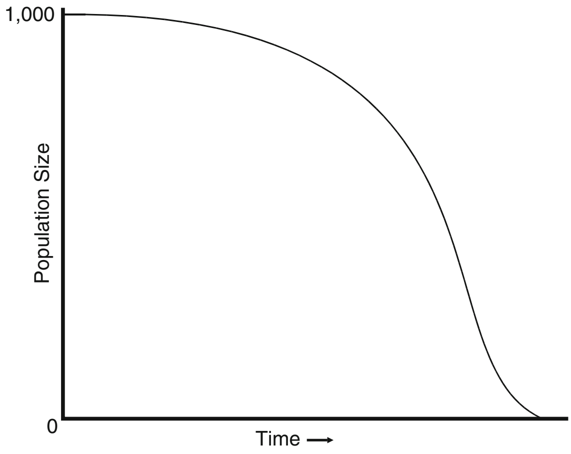

Fig. 3.3 Size of a closed population of 1,000 people, by time

open population may gain members over time through immigration or birth, or lose members who are still alive through emigration. (Some demographers and ecologists use a broader definition of closed population in which births (but not immigration or emigration) are allowed.) Suppose we graph the survival experience of a closed population of 1,000 people. Since death eventually claims everyone, after a period of sufficient time, the original 1,000 will have dwindled to zero. A graph of the size of the population with time might approximate that in Fig. 3.3.

The curve slopes downward because as the 1,000 individuals in the population die, the population at risk of death is reduced. The population is closed in the sense that we consider the fate of only the 1,000 individuals present at time zero. The person-time experience of these 1,000 individuals is represented by the area under the curve in the diagram. As each individual dies, the curve notches downward; that individual no longer contributes to the person-time denominator of the death (mortality) rate. Each individual's contribution is exactly equal to the length of time that individual is followed from start to finish; in this example, since the entire population is followed until death, the finish is the individual's death. In other instances, the contribution to the person-time experience would continue until either the onset of disease or some arbitrary cut-off time for observation, whichever came sooner.

Suppose we added up the total person-time experience of this closed population of 1,000 and obtained a total of 75,000 person-years. The death rate would be $(1{,}000/75{,}000)\times\text{year}^{-1}$ since the 75,000 person-years represent the experience of all 1,000 people until their deaths. Furthermore, if time is measured from start of follow-up, the average death time in this closed population would be 75,000 person-years/1,000 persons = 75 years, which is the inverse of the death rate.

A closed population facing a constant death rate would decline in size exponentially (which is what is meant by the term "exponential decay"). In practice, however, death rates for a closed population change with time, since the population is aging as time progresses. Consequently, the decay curve of a closed human population is never exponential. *Life-table* methodology is a procedure by which the death rate (or disease rate) of a closed population is evaluated within successive small age or time intervals, so that the age or time dependence of mortality can be elucidated. Even with such methods, it can be difficult to distinguish any age-related effects from those related to other time axes, since each individual's age increases directly with an increase along any other time axis. For example, a person's age increases with increasing duration of employment, increasing calendar time, and increasing time from start of follow-up.

An open population differs from a closed population in that individual contributions need not begin at the same time. Instead, the population at risk is open to new members who become eligible with passing time. People can enter a population open in calendar time through various mechanisms. Some are born into it; others migrate into it. For a population of people of a specific age, individuals can become eligible to enter the population by aging into it. Similarly, individuals can exit from the person-time observational experience defining a given incidence rate by dying, aging out of a defined age group, emigrating, or by becoming diseased (the latter method of exiting applies only if first bouts of a disease are being studied).

3.3.4 Steady State

If the number of people entering a population is balanced by the number exiting the population in any period of time within levels of age, sex, and other determinants of risk, the population is said to be *stationary*, or in a *steady state.* Steady state is a property that can occur only in open populations, not closed populations. It is, however, possible to have a population in steady state in which no immigration or emigration is occurring; this situation would occur if births perfectly balanced deaths in the population. The graph of the size of an open population in steady state is simply a horizontal line. People are continually entering and leaving the population in a way that might be diagrammed as shown in Fig. 3.4.

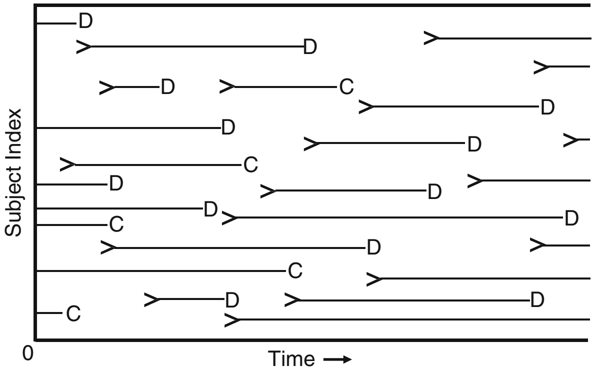

Fig. 3.4 Composition of an open population in approximate steady state, by time. > indicates entry into the population, D indicates disease onset, and C indicates exit from the population without disease

In the diagram, the symbol > represents a person entering the population, a line segment represents their person-time experience, and the termination of a line segment represents the end of their experience. A terminal D indicates that the experience ended because of disease onset, and a terminal C indicates that the experience ended for other reasons. In theory, any time interval will provide a good estimate of the incidence rate in a stationary population. The value of incidence will be the ratio of the number of cases of disease onset, indicated by D, to the area depicting the product of population × time. Because this ratio is equivalent to the density of disease onsets in the observational area, the incidence rate has also been referred to as *incidence density* (Miettinen 1976). The measure has also been called the *person-time rate, force of morbidity* (or *force of mortality* in reference to deaths), *hazard rate*, and *disease intensity*, although the latter three terms are more commonly used to refer to the theoretical limit approached by an incidence rate as the time interval is narrowed toward zero.

3.3.5 Interpretation of an Incidence Rate

The numerical portion of an incidence rate has a lower bound of zero but has no upper bound; it has the mathematical range for the ratio of two non-negative quantities, in this case the number of events in the numerator and the person-time in the denominator. At first, it may seem surprising that an incidence rate can exceed the value of 1.0, which would seem to indicate that more than 100% of a population is affected. It is true that at most, only 100% of persons in a population can get a disease, but the incidence rate does not measure the proportion of a population with illness and in fact is not a proportion at all. Recall that incidence rate is measured in units of the reciprocal of time. Among 100 people, no more than 100 deaths can occur, but those 100 deaths can occur in 10,000 person-years, in 1,000 person-years, in 100 person-years, or even in 1 person-year (if the 100 deaths occur after an average of 3.65 days each). An incidence rate of 100 cases (or deaths) per 1 person-year might be expressed as

$$100\frac{\text{cases}}{\text{person-year}}.$$

It might also be expressed as

$$10,000\frac{\text{cases}}{\text{person-century}}\text{ or}$$

$$8.33\frac{\text{cases}}{\text{person-month}}\text{ or}$$

$$1.92\frac{\text{cases}}{\text{person-week}}\text{ or}$$

$$0.27 \frac{\text{cases}}{\text{person-day}}.$$

The numerical value of an incidence rate in itself has no interpretability because it depends on the arbitrary selection of the time unit. It is thus essential in presenting incidence rates to give the appropriate time units, either as in the examples given above or as in 8.33 month^{-1} or 1.92 week^{-1}. Although the measure of time in the denominator of an incidence rate is often taken in terms of years, one can have units of years in the denominator regardless of whether the observations were collected over 1 year of time, over 2 week of time, or over 10 years of time.

The reciprocal of time is an awkward concept that does not provide an intuitive grasp of an incidence rate. The measure does, however, have a close connection to more interpretable measures of occurrence in closed populations. Referring back to Fig. 3.3, one can see that the area under the curve is equal to $N \times T$, where N is the number of people starting out in the closed population and T is the average time until death. Equivalently, the area under the curve in Fig. 3.3 is equal to the area of a rectangle with height N and width T. Since T is the average time until death for the N people, the total person-time experience is $N \times T$. The time-averaged death rate when the follow-up for the closed population is complete is $N/(N \times T) = 1/T$; that is, the death rate equals the reciprocal of the average time until death.

More generally, in a stationary population with no migration, the crude incidence rate of an inevitable outcome such as death will equal the reciprocal of the average time until the outcome. The time until the outcome is sometimes referred to as the "waiting time" until the event occurs (Morrison 1979). Thus, in a stationary population with no migration, a death rate of 0.04 year^{-1} would translate to an average time until death of 25 years.

If the outcome of interest is not death but either disease onset or death from a specific cause, the waiting time interpretation must be modified slightly: The waiting time is the average time until disease onset, assuming that a person is not at risk of other causes of death, or other events that remove one from risk of the outcome of interest. That is, the waiting time must be redefined to account for *competing risks*, that is, events that "compete" with the outcome of interest to remove persons from the population at risk.

Unfortunately, the interpretation of incidence rates as the inverse of the average "waiting time" will usually not be valid unless the incidence rate is calculated for a stationary population with no migration (no immigration or emigration) or a closed population with complete follow-up. For example, the death rate for the United States in 1977 was 0.0088 year^{-1}; in a steady state, this rate would correspond to a mean life span, or expectation of life, of 114 years. Other analyses, however, indicate that the actual expectation of life in 1977 was 73 years (Alho 1992). The discrepancy is due to immigration and to the lack of a steady state. Note that the no-migration assumption cannot hold within specific age groups, for people are always "migrating" in and out of age groups as they age.

While the notion of incidence is a central one in epidemiology, it cannot capture all aspects of disease occurrence. Consider that a rate of 1 case/(100 years) $= 0.01\ \text{year}^{-1}$

could be obtained by following 100 people for an average of 1 year and observing 1 case but could also be obtained by following two people for 50 years and observing 1 case, a very different scenario. To distinguish these situations, concepts that directly incorporate the notion of follow-up time and risk are needed.

3.3.6 Incidence Proportions and Survival Proportions

For a given interval of time, we can divide the number of new cases of disease occurring during that interval by the population size. If we measure the population size at the start of the interval and no one enters the population (immigrates) or leaves alive (emigrates) after the start of the interval, such a measure becomes the proportion of people who become cases during the time interval among those who were in the population at the start of the interval. We call this quantity the incidence *proportion*, which may also be defined as the proportion of a closed population at risk that becomes diseased within a given period of time. This quantity is often called the "cumulative incidence" (Miettinen 1976), but the term "cumulative incidence" is also used for another quantity we will discuss below. A more traditional term for incidence proportion is "attack rate," but we reserve the term "rate" for person-time incidence rates.

If *risk* is defined as the probability of an individual developing disease in a specified time interval, then incidence proportion is a measure, or estimate, of average risk. Although this concept of risk applies only to individuals and incidence proportion to populations, incidence proportion is sometimes called "risk". "Average risk" is a more accurate synonym, one that we will sometimes use.

Like any proportion, the value of an incidence proportion ranges from zero to one and is dimensionless. It is uninterpretable, however, without specification of the time period to which it applies. An incidence proportion of death of 3% means something very different when it refers to a 40-year period than when it refers to a 40-day period.

A useful complementary measure to the incidence proportion is the *survival proportion*, which may be defined as the proportion of a closed population at risk that does *not* become diseased within a given period of time. If R and S denote the incidence and survival proportions, we have that $S = 1 - R$ and $R = 1 - S$. Another measure that is commonly used is the *incidence odds*, defined as $R/S = R/(1-R)$, the ratio of the proportion getting the disease to the proportion not getting the disease. If R is small, $S \doteq 1$ and $R/S \doteq R$; that is, the incidence odds will approximate the incidence proportion when both quantities are small. Otherwise, because $S < 1$, the incidence odds will be greater than the incidence proportion.

Under certain conditions, there is a very simple relation between the incidence proportion and the incidence rate of a non-recurrent event. Consider a closed population over an interval t_0 to t_1 and let $\Delta t = t_1 - t_0$ be the length of the interval. If N is the size of the population at t_0, and A is the number of disease onsets over the interval, then the incidence and survival proportions over the interval are $R = A/N$ and $S = (N - A)/N$. Now suppose the size of the population at risk declines only slightly over the interval. Then $N - A \doteq N$, $S \doteq 1$, and so $R/S \doteq R$. Furthermore, the average size of the population at risk will be approximately N, and so the total person-time at risk over the interval will be approximately $N\Delta t$. Thus, the incidence rate (I) over the interval will be approximately $A/N\Delta t$, and we obtain

$$R = A/N = (A/N\Delta t)\Delta t \doteq I\Delta t \doteq R/S.$$

In words, the incidence proportion, incidence odds, and the quantity $I\Delta t$ will all approximate one another if the population at risk declines only slightly over the interval. We can make this approximation hold to within an accuracy of $1/N$ by making Δt so short that no more than one person leaves the population at risk over the interval. Thus, given a sufficiently short time interval, one can simply multiply the incidence rate by the time period to approximate the incidence proportion. This approximation offers another interpretation for the incidence rate: It can be viewed as the limiting value of the ratio of the average risk to the time period for the risk as the duration of the time period approaches zero.

A specific type of incidence proportion is the *case fatality rate*, or *case fatality ratio*, which is the incidence proportion of death among those who develop an illness (it is therefore not a rate in our sense but a proportion). The time period for measuring the case fatality rate is often unstated, but it is always better to specify it.

3.3.7 Prevalence

Unlike incidence measures, which focus on events, *prevalence* focuses on disease status. Prevalence may be defined as the proportion of a population that has disease at a specific point in time. The terms *point prevalence*, *prevalence proportion*, and *prevalence rate* are sometimes used to mean the same thing. The *prevalence pool* is the subset of the population with the disease. An individual who dies with or from disease is removed from the prevalence pool; consequently, death from an illness decreases prevalence. Diseases with large incidence rates may have low prevalences if they are rapidly fatal. People may also exit the prevalence pool by recovering from disease or emigrating from the population.

Recall that a stationary population has an equal number of people entering and exiting during any unit of time. Suppose that both the population at risk and the prevalence pool are stationary and that everyone is either at risk or has the disease. Then the number of people entering the prevalence pool in any time period will be balanced by the number exiting from it:

$$\text{Inflow (to prevalence pool)} = \text{outflow (from prevalence pool).}$$

People can enter the prevalence pool from the non-diseased population and by immigration from another population. Suppose there is no immigration into or emigration from the prevalence pool, so that no one enters or leaves the pool except by disease onset, death, or recovery. If the size of the population is N and the size of the prevalence pool is P, then the size of the population at risk that "feeds" the prevalence pool will be $N - P$. Also, during any time interval of length Δt, the number of people who enter the prevalence pool will be

$$I(N - P)\Delta t,$$

where I is the incidence rate, and the outflow from the prevalence pool will be

$$I' P \Delta t,$$

where I' represents the incidence rate of exiting from the prevalence pool, that is, the number who exit divided by the person-time experience of those in the prevalence pool.

3.3.8 Prevalence, Incidence, and Mean Duration

Earlier, we mentioned that, in the absence of migration, the reciprocal of an incidence rate in a stationary population equals the mean time spent in the population before the incident event. Therefore, in the absence of migration and in a stationary population, the reciprocal of I' will be the mean duration of the disease, $\overline{D}$, which is the mean time until death or recovery. It follows that

$$\text{inflow} = I(N - P)\Delta t = \text{outflow} = (1/\overline{D})P\Delta t$$

which yields

$$\frac{P}{N - P} = I \times \overline{D}.$$

$P/(N - P)$ is the ratio of diseased to non-diseased people in the population or equivalently, the ratio of the prevalence proportion to its complement (1 − prevalence proportion). (We could call those who are non-diseased healthy except that we mean they do not have a specific illness, which doesn't imply an absence of all illness.) The ratio $P/(N - P)$ is called the *prevalence odds*; it is the odds of having a disease relative to not having the disease. As shown above, the prevalence odds equals the incidence rate times the mean duration of illness. If the prevalence is small, say less than 0.1, then

$$\text{Prevalence proportion} \doteq I \times \overline{D}$$

since the prevalence proportion will approximate the prevalence odds for small values of prevalence. More generally (Freeman and Hutichison 1980), under the assumption of stationarity and no migration in or out of the prevalence pool,

$$\text{Prevalence proportion} = \frac{I \times \overline{D}}{1 + I \times \overline{D}}$$

which can be obtained from the above expression for the prevalence odds, $P/(N - P)$.

Like the incidence proportion, the prevalence proportion is dimensionless, with a range of zero to one. The above equations are in accord with these requirements, because in each of them, the incidence rate, with a dimensionality of the reciprocal of time, is multiplied by the mean duration of illness, which has the dimensionality of time, giving a dimensionless product.

Furthermore, the product $I \times \overline{D}$ has the range of zero to infinity, which corresponds to the range of prevalence odds, whereas the expression

$$\frac{I \times \overline{D}}{1 + I \times \overline{D}}$$

is always in the range zero to one, corresponding to the range of a proportion.

Unfortunately, the above formulas have limited practical utility because of the no-migration assumption and because they do not apply to age-specific prevalence (Miettinen 1976). If we consider the prevalence pool of, say, diabetics age 60–64, we can see that this pool experiences considerable immigration from younger diabetics aging into the pool and considerable emigration from members aging out of the pool. Under such conditions, we require more elaborate formulas that give prevalence as a function of age-specific incidence, duration, and other population parameters (Preston 1987; Keiding 1991; Alho 1992).

3.3.9 Utility of Prevalence in Etiological Research

Seldom is prevalence of direct interest in etiological applications of epidemiological research. Since prevalence reflects both the incidence rate and the probability of surviving with disease, studies of prevalence, or studies based on prevalent cases, yield associations that reflect the determinants of survival with disease just as much as the causes of disease. The study of prevalence can be misleading in the paradoxical situation in which better survival from a disease and therefore a higher prevalence follows from the action of preventive agents that mitigate the disease once it occurs. In such a situation, the preventive agent may be positively associated with the prevalence of disease and so be misconstrued as a causative agent.

Nevertheless, for one class of diseases, namely, congenital malformations, prevalence is usually employed. The proportion of babies born with some malformation is a prevalence proportion, not an incidence rate. The incidence of malformations refers to the occurrence of the malformations among the susceptible populations of embryos. Many malformations lead to early embryonic or fetal death that is classified, if recognized, as a miscarriage rather than a birth. Thus, malformed babies at birth represent only those individuals who survived long enough with their malformations to be recorded as a birth. This is indeed a prevalence measure, the reference point in time being the moment of birth. The measure classifies the population of newborns as to their disease status, malformed or not, at the time of birth. This example illustrates that the time reference for a prevalence need not be a common point in calendar time: It can be a point on another time scale, such as an individual's life span.

It would be more useful and desirable to study the incidence than the prevalence of congenital malformations; as already noted, studying prevalence makes it impossible to distinguish the effects of agents that increase the incidence rate from the effects of agents that increase survival with the disease once the disease occurs. Unfortunately, it is seldom possible to measure the incidence rate of malformations, since the population at risk, young embryos, is difficult to ascertain, and learning the occurrence and timing of the malformations among the embryos is equally problematic. Consequently, in this area of research, incident cases are not usually studied, with most investigators settling for the theoretically less desirable but much more practical study of prevalence at birth.

Prevalence is sometimes used to measure the occurrence of non-lethal degenerative diseases with no clear moment of onset. It is also used in seroprevalence studies of the incidence of infection, especially when the infection has a long asymptomatic (silent) phase that can only be detected by serum testing (such as HIV infection). In these and other situations, prevalence is measured simply for convenience, and inferences are made about incidence by using assumptions about the duration of illness. Of course, in epidemiological applications outside of etiological research, such as planning for and managing health resources and facilities, health economics, and other public health activities, prevalence may be a more relevant measure than incidence.

Although prevalence is generally of lesser interest than incidence for etiological research, in many public health applications prevalence is of primary interest. The reason is that the disease burden in a population is often more closely related to prevalence than to incidence. For example, a factor that has no effect on asthma incidence but which prolongs the duration of asthmatic episodes would increase the disease burden, as reflected in the need for medication, the utilization of inpatient or emergency medical services, and number of outpatient visits.

3.4 Measures of Effect

Epidemiologists use the term *effect* in two senses. In one sense, any case of a given disease may be the effect of a given cause. *Effect* is used in this way to mean the endpoint of a causal mechanism, identifying the type of outcome that a cause produces. For example, we may say that HIV infection is an effect of sharing needles for drug use. This use of the term *effect* merely identifies HIV infection as one consequence of the activity of sharing needles. Other effects of the exposure, such as Hepatitis B infection, are also possible.

In a more particular and quantitative sense, an *effect* is also the amount of change in a population's disease frequency caused by a specific factor. If disease frequency is measured in terms of incidence rate or proportion, then the effect is the change in incidence rate or proportion brought about by a particular factor. We might say that for drug users, the effect of sharing needles, compared with not sharing needles, is to increase the average risk of HIV infection from 0.001 in 1 year to 0.01 in 1 year. Although it is customary to use the definite article in referring to this second type of effect ("the" effect of sharing needles), it is not meant to imply that this is a unique effect of sharing needles. An increase in risk for Hepatitis or other diseases remains possible, and the increase in risk of HIV infection may differ across populations and time.

In epidemiology, it is customary to refer to potential causal characteristics as *exposures*. Thus, "exposure" can refer to a behavior (such as needle sharing), a treatment (such as an educational program about hazards of needle sharing), a trait (such as genotype), or an exposure in the ordinary sense (such as injection of contaminated blood).

Population effects are most commonly expressed as effects on incidence rates or incidence proportions, but other measures based on the incidence times or prevalences may also be used. Epidemiological analyses that focus on survival time until death or recurrence of disease are examples of analyses that measure effects on incidence times. *Absolute effects* are differences in incidence rates, incidence proportions, prevalences, or incidence times. *Relative effects* involve ratios of these measures.

3.4.1 Simple Effect Measures

Consider a cohort followed over a specific time interval – say 1996–2000, or age 50–69. If we can imagine the experience of this cohort over the same interval under two different conditions – say, "exposed" and "unexposed" – then we can ask what the incidence rate of any outcome would be under the two conditions. Thus, we might consider a cohort of smokers and an exposure that consisted of mailing to each cohort member a brochure of current smoking cessation programs in their county of residence. We could then ask what the lung cancer incidence rate would be in this cohort if we carry out this treatment and what it would be if we did not carry out this treatment. The difference between the two rates we call the absolute effect of our mailing program on the incidence rate, or the *causal rate difference*. To be brief, we might refer to the causal rate difference as the excess rate due to the program (which would be negative if the program prevented some lung cancers).

In a parallel manner, we may ask what the incidence proportion would be if we carry out this treatment and what it would be if we do not carry out this treatment. The difference of the two proportions we call the absolute effect of our treatment on the incidence proportions, or *causal risk difference* or excess risk for short. Also in a parallel fashion, the difference in the average lung-cancer-free years of life lived over the interval under the treated and untreated conditions is another absolute effect of treatment.

To illustrate the above measures in symbolic form, suppose we have a closed cohort of size N at the start of a fixed time interval and that anyone alive without the disease is at risk of the disease. Further, suppose that if every member of the cohort gets exposed throughout the interval, A_1 cases will occur and the total time at risk will be T_1, but if no member of the same cohort is exposed during the interval, A_0 cases will occur and the total time at risk will be T_0. Then the causal rate difference will be

$$\frac{A_1}{T_1} - \frac{A_0}{T_0},$$

the causal risk difference will be

$$\frac{A_1}{N} - \frac{A_0}{N},$$

and the causal difference in average disease-free time will be

$$\frac{T_1}{N} - \frac{T_0}{N}.$$

Each of these measures compares disease occurrence by taking differences and so are called difference measures, or absolute measures.

More commonly, effect measures are defined by taking ratios. Examples of such ratio (or relative) measures are the *causal rate ratio*

$$\frac{A_1/T_1}{A_0/T_0} = \frac{I_1}{I_0},$$

where $I_j = A_j/T_j$ is the incidence rate under condition j ($1 =$ exposed, $0 =$ unexposed); the *causal risk ratio*

$$\frac{A_1/N}{A_0/N} = \frac{A_1}{A_0} = \frac{R_1}{R_0},$$

where $R_j = A_j/N$ is the incidence proportion (average risk) under condition j; and the *causal ratio of disease-free time*,

$$\frac{T_1/N}{T_0/N} = \frac{T_1}{T_0}.$$

The rate ratio and risk ratio are often called relative risk measures. The three ratio measures are related by the simple formula

$$\frac{R_1}{R_0} = \frac{R_1 N}{R_0 N} = \frac{A_1}{A_0} = \frac{I_1}{I_0}\frac{T_1}{T_0},$$

which follows from the fact that the number of cases equals the disease rate times the time at risk. A fourth relative risk measure can be constructed from the incidence odds. If we write $S_1 = 1 - R_1$ and $S_0 = 1 - R_0$, the *causal odds ratio* is then

$$\frac{R_1/S_1}{R_0/S_0} = \frac{A_1/(N - A_1)}{A_0/(N - A_0)}.$$

The definitions of effect just given are sometimes called *counterfactual* or *potential-outcome* definitions. Such definitions may be traced back to the writings of Hume but received little attention from scientists until the twentieth century (see Lewis 1973; Rubin 1990 for early references in philosophy and statistics, respectively). The definitions are often called "counterfactual" because at least one of the two circumstances in the definitions must be contrary to fact: The cohort may be exposed or "treated" (e.g., every member sent a mailing) or untreated (no one sent a mailing); if the cohort is treated, then the untreated condition will be counterfactual, and if it is untreated, then the treated condition will be counterfactual. Both conditions may be counterfactual: If only part of the cohort is sent the mailing, both conditions in the definitions will be contrary to this fact. Nonetheless, one of the two conditions compared may be the actual treatment received by the population, in which case the outcome under that treatment is not counterfactual. Hence, the term "potential-outcome" better captures the nature of the comparisons, which are between outcomes that could have occurred (depending on the treatment given), and one of which may have occurred.

Potential-outcome comparisons amount to thought experiments, useful for conceptualizing what is meant by causal effects. In practice, actual estimation of causal effects involves circumstances that only simulate counterfactual thought experiments, as explained below. Although some authors have objected to counterfactual causal concepts on philosophical grounds, it turns out that such concepts directly parallel concepts found in graphical and structural-equation models of causality (Pearl 2009; Greenland and Brumback 2002).

An important feature of potential-outcome definitions of effect is that they involve two distinct conditions: an index condition, which usually involves some exposure or treatment, and a reference condition against which this exposure of treatment will be evaluated – such as no treatment. To ask for "the" effect of exposure is meaningless without reference to some other condition. In the above example, the effect of one mailing is only defined in reference to no mailings. We could have instead asked about the effect of one mailing relative to four mailings; this is a very different comparison than one versus no mailing.

3.4.2 Effect-Measure Modification

Suppose we divide our cohort into two or more distinct categories, or strata. In each stratum, we can construct an effect measure of our choosing. These stratum-specific effect measures may or may not equal one another. Rarely would we have any reason to suppose that they do equal one another. If indeed they are not equal, we say that the effect measure is *heterogeneous*, *modified*, or *varies* across strata. If they are equal, we say that the measure is *homogeneous*, *uniform*, or *constant* across strata.

A major point about effect-measure modification is that, if effects are present, it will usually be the case that only one or none of the effect measures discussed above will be uniform across strata. In fact, if the exposure has any effect on an occurrence measure, at most one of the ratio or difference measures of effect can be uniform across strata. As an example, suppose among males the average risk would be 0.50 if exposure was present but would be 0.20 if exposure was absent, whereas among females, the average risk would be 0.10 if exposure was present but would be 0.04 if exposure was absent. Then the causal risk difference for males is $0.50-0.20 = 0.30$, five times the female difference of $0.10 - 0.04 = 0.06$. In contrast, for both sexes, the causal risk ratio is $0.50/0.20 = 0.10/0.04 = 2.5$. Now suppose we change this example to make the differences uniform, say by making the exposed male risk 0.26 instead of 0.50. Then both differences would be 0.06, but the male risk ratio would be $0.26/0.20 = 1.3$, much less than the female risk ratio of 2.5.

3.4.3 Relative Versus Absolute Measures

As mentioned above, we refer to differences in incidence rates, incidence proportions, prevalences, or incidence times as absolute measures. Relative effect measures are based on the ratio of an absolute effect measure to a baseline measure of occurrence. Analogous measures are used routinely whenever change or growth is measured. For example, suppose that an investment of a sum of money has yielded a gain of $1,000 in 1 year. Knowing the gain might be useful in itself for some purposes, but the absolute increase in value does not reveal by itself how effective the investment was. If the initial investment was $5,000 and grew to $6,000 in 1 year, then we could judge the investment by relating the absolute gain, $6,000–$5,000, to the initial amount. That is, we take the $1,000 gain and divide it by the $5,000 of the original principal, obtaining 20% as the relative gain. The relative gain puts the absolute gain into a perspective that reveals how effective the investment was.

Because the magnitude of the relative effect depends on the magnitude of the baseline occurrence, the same absolute effect in two populations can correspond to greatly differing relative effects (Peacock 1971). Conversely, the same relative effects for two populations could correspond to greatly differing absolute effects.

3.4.4 Attributable Fractions

Although the potential-outcome approach to effects has provided the foundation for extensive statistical and philosophical developments in causal analysis, it takes no account of the mechanisms that produce effects. Suppose that all sufficient causes of a particular disease were divided into two sets, those that contain a specific cause (exposure) and those that do not, and that the exposure is never preventive. This situation is summarized in Fig. 3.5.

C and C′ may represent many different combinations of causal components. Each of the two sets of sufficient causes represents a theoretically large variety of causal

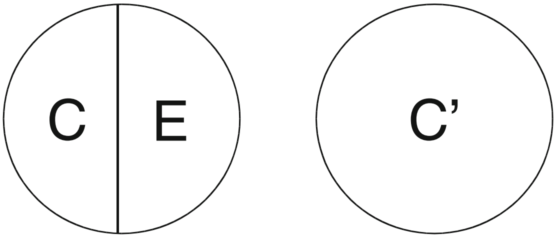

Fig. 3.5 Two types of sufficient causes of a disease

mechanisms for disease, perhaps as many as one distinct mechanism for every case that occurs. Disease can occur either with or without E, the exposure of interest. The causal mechanisms are grouped in the diagram according to whether or not they contain the exposure. We say that the exposure E causes disease if a sufficient cause that contains E gets completed. Thus, we say that exposure can cause disease if exposure will cause disease under at least some set of conditions C.

Perhaps the most straightforward way to quantify the effect of the exposure would be to estimate the numbers of cases that were caused by E. This number is not estimable from ordinary incidence data, because the observation of an exposed case does not reveal the mechanism that caused the case. In particular, people who have the exposure can develop the disease from a mechanism that does not include the exposure. For example, a smoker may develop lung cancer through some mechanism that does not involve smoking (e.g., one involving asbestos or radiation exposure). For such lung cancer cases, their smoking was incidental; it did not contribute to the cancer causation. There is currently no way to tell which exposures are responsible for a given case. Therefore, exposed cases include some cases of disease caused by the exposure, if the exposure is indeed a cause, and some cases of disease that occur through mechanisms that do not involve the exposure.

The observed incidence rate or proportion among the exposed reflects the incidence of cases in both sets of sufficient causes represented in Fig. 3.5. The incidence of sufficient causes containing E could be found by subtracting the incidence of the sufficient causes that lack E. Unfortunately, the latter incidence cannot be estimated if we cannot distinguish cases for which exposure played an etiological role from cases for which exposure was irrelevant (Greenland and Robins 1988). Thus, if I_1 is the incidence rate of disease in a population when exposure is present, and I_0 is the rate in that population when exposure is absent, the rate difference $I_1 - I_0$ does not necessarily equal the rate of disease with the exposure as a component cause.

To see the source of this difficulty, imagine a cohort in which, for every member, the causal complement of exposure, C, will be completed before the sufficient cause C′ is completed. If the cohort is unexposed, every case of disease must be attributable to the cause C′. But, if the cohort is exposed from start of follow-up, every case of disease occurs when C is completed (E being already present), so every case of disease must be attributable to the sufficient cause containing C and E. Thus, the incidence rate of cases caused by exposure is I_1 when exposure is present, not $I_1 - I_0$.

Several other measures have often been incorrectly interpreted as the fraction of cases caused by exposure, or etiological fraction. One such measure is the *rate fraction*,

$$\frac{I_1 - I_0}{I_1} = \frac{I_1/I_0 - 1}{I_1/I_0} = \frac{IR - 1}{IR},$$

also known as the *relative excess rate,* in which IR denotes the incidence rate ratio. The preceding example shows that the rate fraction is generally *not* equal to the fraction of cases in which exposure played a role in the disease etiology, for in the example, the latter fraction is 100%. Another fractional measure is $(A_1 - A_0)/A_1$, the excess caseload due to exposure, which has been called the *excess fraction* (Greenland and Robins 1988). The preceding example shows that this measure may be far less than the etiological fraction, for in the example, the latter fraction is 100%, regardless of A_0.

There has been much confusion in the epidemiological literature over the definition and interpretation of terms related to the above concepts. The term "attributable risk" has, at one time or another, been used to refer to the risk difference, the rate fraction, the etiological fraction, and the excess fraction. The terms "etiological fraction," "attributable fraction," and "attributable proportion" have each been used to refer to the etiological fraction at one time, the excess fraction at others, and the rate fraction at still other times.

In a closed cohort, the fraction of the exposed incidence proportion $R_1 = A_1/N$ that is attributable to exposure is exactly equal to the excess fraction:

$$\frac{R_1 - R_0}{R_1} = \frac{A_1/N - A_0/N}{A_1/N} = \frac{A_1 - A_0}{A_1},$$

where $R_0 = A_0/N$ is what the incidence proportion would be with no exposure. An equivalent formula for the excess fraction is

$$\frac{R_1 - R_0}{R_1} = \frac{R_1/R_0 - 1}{R_1/R_0} = \frac{RR - 1}{RR},$$

where RR is the causal risk ratio. The rate fraction is often mistakenly equated with either the etiological fraction or the excess fraction. To see that it is not equal to the excess fraction, let T_1 and T_0 represent the total time at risk that would be experienced by the cohort under exposure and non-exposure during the interval of interest. The rate fraction $(I_1 - I_0)/I_1$ then equals

$$\frac{A_1/T_1 - A_0/T_0}{A_1/T_1}.$$

If exposure has any effect, and if the disease removes people from further risk (as when the disease is irreversible), then T_1 will be less than T_0. The last expression cannot equal the excess fraction $(A_1 - A_0)/A_1$ if $T_1 \neq T_0$, although if the exposure effect on total time at risk is small, T_1 will be close to T_0 and so the rate fraction will approximate the excess fraction. Although the excess fraction and rate fraction for an uncommon disease will usually be close to one another, for reasons outlined above, both may be much less than the etiological fraction (Greenland and Robins 1988). This discrepancy leads to some serious issues in policy and legal settings, in which the etiological fraction corresponds to the probability of causation (PC), that is, the probability that the disease of a randomly selected case had exposure as a component cause. In these settings, an estimate of the excess fraction or rate fraction in the exposed is often presented as an estimate of PC. Unfortunately, the excess fraction and rate fraction can be considerably different from the PC, even if the disease is rare; hence, such presentations are misleading (Greenland 1999; Greenland and Robins 2000).

For convenience, we refer to the family of fractional measures, including the etiological, excess, and rate fractions as "attributable fractions" as in Rothman et al. (2008). This term was originally introduced by Ouellet et al. (1979) and Deubner et al. (1980). These fractions are also often called "attributable risk percent" (Cole and MacMahon 1971; Koepsell and Weiss 2003) or "attributable risk," although the latter term is also used to denote the risk difference (MacMahon and Pugh 1970; Koepsell and Weiss 2003). These measures were intended for use with exposures that have a net causal effect; they become negative and hence difficult to interpret with a net preventive effect. One simple approach for dealing with preventive exposures is to interchange the exposed and unexposed quantities in the above formulas, interchanging I_1 with I_0, P_1 with P_0, A_1 with A_0, and T_1 with T_0. The resulting measures have been called *preventable fractions* and are easily interpreted. For example, $(A_0 - A_1)/A_0 = (R_0 - R_1)/R_0 = 1 - R_1/R_0 = 1 - RR$ is the fraction of the caseload under non-exposure that could be prevented by exposure.

3.4.5 Population Attributable Fractions and Impact Fractions

One often sees in the literature a definition of "population attributable risk" or "population attributable fraction" as the reduction in incidence that would be achieved if the population had been entirely unexposed, compared with its current (actual) exposure pattern. One should recognize that this concept, due to Levin (1953), is just a special case of the definition of attributable fraction based on exposure pattern. In particular, it is a comparison of the incidence (either rate or number of cases, which must be kept distinct) under the observed pattern of exposure, and the incidence under a counterfactual pattern in which exposure or treatment is entirely absent from the population. A more general concept is the "impact fraction" (Morgenstern and Bursic 1982), which is a comparison of incidence under the observed exposure pattern and incidence under a counterfactual pattern in which exposure is only partially removed from the population. Again, this is a special case of our definition of attributable fraction based on exposure pattern.

3.4.6 Estimation of Effects

Effects are defined in reference to a *single*, enumerable population, under two distinct conditions. Such definitions require that one can meaningfully describe each condition for the one population. Consider, for example, the "effect" of sex (male versus female) on heart disease. For these words to have content, we must be able to imagine a cohort of men, their heart disease incidence, and what their incidence would have been had the very same men been women instead. The apparent ludicrousness of this demand reveals the vague meaning of sex effect. To reach a reasonable level of scientific precision, sex effect could be replaced by more precise mechanistic concepts, such as hormonal effects and effects of other sex-associated factors. With such concepts, we can imagine what it means for the men to have their exposure changed: hormone treatments, sex-change operations, and so on.

The single population in an effect definition can only be observed under one of the two conditions in the definition (and sometimes neither). This leads to the problem of effect *estimation*, which is to predict accurately what the magnitude of disease occurrence would have been in the single population under conditions that did not in fact occur (counterfactual conditions). For example, we may have observed $I_1 = 50$ deaths/100,000 person-years in a target cohort of smokers over a 10-year follow-up and ask what rate reduction would have been achieved had these smokers quit at the start of follow-up. Here, we observed a rate I_1 and are asking about I_0, the rate that would have occurred under complete smoking cessation.

Since I_0 is not observed, we must predict what it would have been. To do so, we would want to refer to outside data such as data from a cohort that was not part of the target cohort. From these data, we would construct a prediction of I_0. The point we wish to emphasize here is that neither the outside cohort nor the prediction derived from it are part of the effect measure: They are only ingredients in our estimation process. This point is overlooked by effect definitions that refer to two separate "exposed" and "unexposed" populations. Such definitions confuse the concept of effect with the concept of *association*.

3.4.7 Measures of Association

A measure of association, as opposed to a measure of effect, is a contrast between occurrence measures in two different populations or in a single population at two different times. For example, if we took the ratio of cancer incidence rates among males and females in Canada, it would not be an effect measure, because its two component rates refer to different groups of people. We describe the rate ratio as a *measure of association*; in this example, it is a measure of the association of gender with cancer incidence in Canada. As another example, we could contrast the incidence rate of dental caries in a community in the year before and in the third year after the introduction of fluoridation of the water supply. If we take the difference of the rates in these before and after periods, this difference is not an effect measure, because its two component rates refer to two different populations, one before fluoridation and one after. There may be considerable or even complete overlap in the persons present in the before and after periods; nonetheless, the experiences compared refer to different time periods. The rate difference is a measure of the association of fluoridation with dental caries incidence in the community, but it is not an effect measure.

All observable epidemiological contrasts between occurrence measures should be considered measures of association, rather than effect measures, because all epidemiological measures that contrast two or more observed occurrence measures must involve some differences in persons or time between the measures; we cannot observe a single population undergoing two mutually exclusive exposures (e.g., smoking, not smoking) at the same time. It is only as a thought experiment that we can imagine a comparison among potential outcomes, because by definition, at least one (and possibly both) occurrence measures being compared will be counterfactual and hence unobserved for the population. Nonetheless, if we can obtain estimates of occurrence measures in that population under those two events or states, either by direct observation or by a prediction from data outside the population, we can estimate effect measures.

The more difficult issue is whether the imagined effect measure is a well-defined contrast for a single person or population. To imagine an effect, we must imagine a single population that could have theoretically experienced either of two contrasting events or states (e.g., smoking and not smoking) as possible alternative histories (Greenland 2002, 2005; Hernán 2005). This challenge may be minor for medical treatments and similar interventions, for usually, it is no trouble to imagine a treated person as having been untreated instead and vice-versa. The situation is far different when discussing personal characteristics. For example, when talking of sex effects, it is at least highly ambiguous to talk of what would have happened to a woman had she been a man instead, since it leaves open too many crucial details. Does "being a man instead" mean a sex-change operation? If so, the effect under study is really that of the operation. Or does "being a man instead" mean merely using men's hairstyle and clothing well enough to be mistaken for a man? If so, the effect under study is really that of effective change in appearance.

3.5 Confounding

In the preceding example of dental caries, it is tempting to ascribe any and all of a decline in incidence following fluoridation to the act of fluoridation itself. Let us analyze what such an inference translates into in terms of measures of effect and association. The *effect* we wish to measure is that which fluoridation had on the rate; to measure this effect, we must contrast the actual rate under fluoridation with the rate that would have occurred *in the same time period* had fluoridation *not* been introduced. We cannot observe the latter rate, for it is counterfactual. Thus, we substitute in its place, or exchange, the rate in the time period before fluoridation.

In doing so, we substitute a measure of association (the rate difference before and after fluoridation) for what we are really interested in (the causal rate difference between rates without and with fluoridation in the post-fluoridation time period).

This substitution will be misleading to the extent that the rate before fluoridation does not equal and so should not be exchanged with the counterfactual rate (i.e., the rate that would have occurred in the post-fluoridation period if fluoridation had not been introduced). If the two are not equal, then the measure of association we are using will not equal the measure of effect we are substituting it for. In such a circumstance, we say that our measure of association is *confounded* (for our desired measure of effect). Other ways of expressing the same idea is that the before-after rate difference is confounded for the causal rate difference or that *confounding* is present in the before-after difference (Greenland and Robins 1986). On the other hand, if the rate before fluoridation does equal the counterfactual rate, so that the measure of association equals our desired measure of effect, we say that the before-after difference is unconfounded or that no confounding is present in this difference.

The preceding definitions apply to ratios as well as differences. Because ratios and differences contrast the same underlying quantities, confounding of a ratio measure implies confounding of the corresponding difference measure and vice versa: If the value substituted for the counterfactual rate or risk does not equal that rate or risk, both the ratio and difference will be confounded.

The above definitions also extend immediately to situations in which the contrasted quantities are average risks, incidence times, or prevalences. For example, one could wish to estimate the impact of fluoridation on caries prevalence 3 years after fluoridation began. Here, the needed but unobserved counterfactual is what the caries prevalence would have been 3 years after fluoridation began had fluoridation not begun; for it, we might substitute the prevalence of caries at the time fluoridation began. It is possible (though perhaps rare in practice) for there to be confounding for one effect measure and not another if the two effect measures derive from different underlying occurrence measures. For example, there could in theory be confounding of the rate ratio but not the risk ratio.

One point of confusion in the literature is the failure to recognize that odds are risk-based measures, and hence odds ratios will be confounded under exactly the same circumstances as risk ratios (Miettinen and Cook 1981; Greenland and Robins 1986; Greenland 1987). The confusion arises because of the peculiarity that the causal odds ratio for a whole cohort can be closer to the null than any stratum-specific causal odds ratio. Such non-collapsibility of the causal odds ratio is usually confused with confounding, even though it has nothing to do with the latter phenomenon (Greenland et al. 1999).

Consider again the fluoridation example. Suppose that, within the year after fluoridation began, dental hygiene education programs were implemented in some of the schools in the community. If these programs were effective, then (other things being equal) some reduction in caries incidence would have occurred as a consequence of the programs. Thus, even if fluoridation had not begun, the caries incidence would have declined in the post-fluoridation time period. In other words, the programs alone would have caused the counterfactual rate in our effect measure to be lower than the pre-fluoridation rate that substitutes for it. As a result, the measure of association (which is the before-after rate difference) must be larger than the desired measure of effect (the causal rate difference). In this situation, we say the programs *confounded* the measure of association or that the program effects are confounded with the fluoridation effect in the measure of association. We also say that the programs are *confounders* of the association and that the association is confounded by the programs.

Confounders are factors (exposures, interventions, treatments, etc.) that explain or produce confounding. In the present example, the programs explain why the before-after association overstates the fluoridation effect: The before-after risk difference or ratio includes the effects of programs as well as the effects of fluoridation. More generally, a confounder explains a discrepancy between the desired but unobservable counterfactual risk or rate (which the exposed would have had, had they been unexposed) and the unexposed risk or rate that was its substitute. In order for a factor to explain some of this discrepancy, and thus confound, it must be capable of affecting or at least predicting the risk or rate in the unexposed (reference) group. In the above example, we assumed that the presence of the dental hygiene programs in the years after fluoridation accounted for some of the discrepancy between the before-fluoridation rate and the (counterfactual) rate that would have occurred 3 years after fluoridation if fluoridation had not been introduced.

A large portion of epidemiological methods are concerned with avoiding or adjusting (controlling) for confounding. Such methods inevitably rely on the gathering and proper use of confounder measurements. The most fundamental adjustment methods rely on the notion of *stratification* on confounders. If we make our comparisons within specific levels of a confounder, those comparisons cannot be confounded by that confounder. For example, we could limit our before-after fluoridation comparisons to schools in states in which no dental-hygiene program was introduced. In such schools, program introductions could not have had an effect (because no program was present), and so any decline following fluoridation could not be explained by effects of programs in those schools.

3.6 Selection Bias

Selection biases are distortions that result from procedures used to select subjects and from factors that influence study participation. The common element of such biases is that the relation between exposure and disease is different for those who participate and those who should be theoretically eligible for study, including those who do not participate. The result is that associations observed in the study represent a mix of forces determining participation as well as forces determining disease.

3.6.1 Self-Selection Bias

One form of such bias is self-selection bias. When the Centers for Disease Control (CDC) investigated subsequent leukemia incidence among troops who had been present at the Smoky Atomic Test in Nevada (Caldwell et al. 1980), 76% of the troops identified as members of that cohort had known outcomes. Of this 76%, 82% were traced by the investigators, but the other 18% contacted the investigators on their own initiative in response to publicity about the investigation. This self-referral of subjects is ordinarily considered a threat to validity, since the reasons for self-referral may be associated with the outcome under study (Criqui et al. 1979). In the Smoky study, there were four leukemia cases among the $0.18 \times 0.76 = 15\%$ of cohort members who referred themselves and four among the $0.82 \times 0.76 = 62\%$ of cohort members traced by the investigators, for a total of eight cases among the 76% of the cohort with known outcomes. These data indicate that self-selection bias was a small but real problem in the Smoky study. If the 24% of the cohort with unknown outcomes had a leukemia incidence like that of the subjects traced by the investigators, we should expect that only $4(24/62) = 1.5$ or about 1 or 2 cases occurred among this 24%, for a total of only 9 or 10 cases in the entire cohort. If, however, we assumed that the 24% with unknown outcomes had a leukemia incidence like that of subjects with known outcomes, we would calculate that $8(24/76) = 2.5$ or about 2 or 3 cases occurred among this 24%, for a total of 10 or 11 cases in the entire cohort.

Self-selection can also occur before subjects are identified for study. For example, it is routine to find that the mortality of active workers is less than that of the population as a whole (McMichael 1976; Fox and Collier 1976). This “healthy-worker effect” presumably derives from a screening process, perhaps largely self-selection, that allows relatively healthy people to become or remain workers, whereas those who remain unemployed, retired, disabled, or otherwise out of the active worker population are as a group less healthy (Wang and Miettinen 1982).

3.6.2 Diagnostic Bias

Another type of selection bias occurring before subjects are identified for study is diagnostic bias (Sackett 1979). When the relation between oral contraceptives and venous thromboembolism was first investigated with case-control studies of hospitalized patients, there was a concern that some of the women had been hospitalized with a diagnosis of venous thromboembolism because their physicians suspected a relation between this disease and oral contraceptives and had known about oral contraceptive use in patients who presented with suggestive symptoms (Sartwell et al. 1969). A study of hospitalized patients with thromboembolism could lead to an exaggerated estimate of the effect of oral contraceptives on thromboembolism if the hospitalization and determination of the diagnosis were influenced by the history of oral contraceptive use.

3.7 Information Bias

Once the subjects to be compared have been identified, the information to be compared must be obtained. Bias in evaluating an effect can occur from errors in obtaining the needed information. Information bias can occur whenever there are errors in the measurement of subjects, but the consequences of the errors are different depending on whether the distribution of errors for one variable (e.g., exposure or disease) depends on the actual value of other variables.

For discrete variables (variables with only a countable number of possible values, such as indicators for sex), measurement error is usually called classification error or misclassification. Classification error that depends on the values of other variables is referred to as *differential misclassification*. Classification error that does not depend on the values of other variables is referred to as *non-differential misclassification*.

3.7.1 Differential Misclassification

Suppose a cohort study were undertaken to compare incidence rates of emphysema among smokers and non-smokers. Emphysema is a disease that may go undiagnosed without unusual medical attention. If smokers, because of concern about health-related effects of smoking or as a consequence of other health effects of smoking (such as bronchitis), seek medical attention to a greater degree than non-smokers, then emphysema might be diagnosed more frequently among smokers than among non-smokers simply as a consequence of the greater medical attention. Unless steps were taken to ensure comparable follow-up, an information bias would result: A spurious excess of emphysema incidence would be found among smokers compared with non-smokers that is unrelated to any biological effect of smoking. This is an example of differential misclassification, since the underdiagnosis of emphysema, a classification error, occurs more frequently for non-smokers than for smokers. Sackett (1979) has described it as a diagnostic bias, but unlike the diagnostic bias in the studies of oral contraceptives and thromboembolism described earlier, it is not a selection bias, since it occurs among subjects already included in the study. Nevertheless, the similarities between some selection biases and differential misclassification biases are worth noting.

In case-control studies of congenital malformations, the etiological information may be obtained at interview from mothers. The case mothers have recently given birth to a malformed baby, whereas the vast majority of control mothers have recently given birth to an apparently healthy baby. Another variety of differential misclassification, referred to as recall bias, can result if the mothers of malformed infants recall exposures more thoroughly than mothers of healthy infants. It is supposed that the birth of a malformed infant serves as a stimulus to a mother to recall all events that might have played some role in the unfortunate outcome. Presumably, such women will remember exposures such as infectious disease, trauma, and drugs more accurately than mothers of healthy infants, who have not had a comparable stimulus. Consequently, information on such exposures will be ascertained more frequently from mothers of malformed babies, and an apparent effect, unrelated to any biological effect, will result from this recall bias. Recall bias is a possibility in any case-control study that uses an anamnestic response, since the cases and controls by definition are people who differ with respect to their disease experience, and this difference may affect recall. Klemetti and Saxen (1967) found that the amount of time lapsed between the exposure and the recall was an important indicator of the accuracy of recall; studies in which the average time since exposure was different for interviewed cases and controls could thus suffer a differential misclassification.

The bias that is caused by differential misclassification can either exaggerate or underestimate an effect. In each of the examples above, the misclassification serves to exaggerate the effects under study, but examples to the contrary can also be found. Because of the relatively unpredictable effects of differential misclassification, some investigators go through elaborate procedures to ensure that the misclassification will be non-differential, such as blinding of exposure evaluations with respect to outcome status. Unfortunately, even in situations when blinding is accomplished or in cohort studies in which disease outcomes have not yet occurred, collapsing continuous or categorical exposure data into fewer categories can induce differential misclassification (Wacholder 1991; Flegal et al. 1991).

3.7.2 Non-Differential Misclassification

Non-differential exposure or disease misclassification occurs when the proportion of subjects misclassified on exposure does not depend on disease status or when the proportion of subjects misclassified on disease does not depend on exposure. Under certain conditions, any bias introduced by such non-differential misclassification of a binary exposure or disease is predictable in direction, namely, toward the null value (Newell 1962; Keys and Kihlberg 1963; Gullen et al. 1968; Copeland et al. 1977). Contrary to popular misconceptions, however, non-differential exposure or disease misclassification can sometimes produce bias away from the null (Walker and Blettner 1985; Dosemeci et al. 1990; Chavance et al. 1992; Kristensen 1992). For example, when both exposure and disease are non-differentially misclassified but the classification errors are dependent, it is possible to obtain bias away from the null (Chavance et al. 1992; Kristensen 1992), and the simple bias relations just given will no longer apply. Dependent errors can arise easily in many situations, such as in studies in which exposure and disease status are both determined from interviews.

Because the bias from independent non-differential misclassification of a dichotomous exposure is always in the direction of the null value, historically it has not been a great source of concern to epidemiologists, who have generally considered it more acceptable to underestimate effects than to overestimate effects. Nevertheless, such misclassification is a serious problem: The bias it introduces may account for certain discrepancies among epidemiological studies. Many studies ascertain information in a way that guarantees substantial misclassification, and many studies use classification schemes that can mask effects in a manner identical to non-differential misclassification.

Suppose aspirin transiently reduces risk of myocardial infarction. The word transiently implies a brief induction period. Any study that considered as exposure aspirin use outside of a narrow time interval before the occurrence of a myocardial infarction would be misclassifying aspirin use: There is relevant use of aspirin, and there is use of aspirin that is irrelevant because it does not allow the exposure to act causally under the causal hypothesis with its specified induction period. Many studies ask about "ever use" (use at any time during an individual's life) of drugs or other exposures. Such cumulative indices over an individual's lifetime inevitably augment possibly relevant exposure with irrelevant exposure and can thus introduce a bias toward the null value through non-differential misclassification.

Note that for a binary exposure variable with non-differential misclassification and independent classification errors, the direction of bias will be toward the null value, but if the exposure variable has more than two categories, one or more of those categories may manifest bias away from the null (Dosemeci et al. 1990). For example, suppose exposure had three levels, 0, 1, and 2, with risk increasing as level increased, and we wished to measure the effect of exposure at levels 1 and 2 relative to 0. If there was misclassification only between levels 1 and 2, the measures of effect for these two levels of exposure would be biased toward each other, and therefore the estimation for level 1 versus 0 would be biased away from the null (Walker and Blettner 1985).

In cohort studies in which there are disease categories with few subjects, investigators are occasionally tempted to combine outcome categories to increase the number of subjects in each analysis, thereby gaining precision. This collapsing of categories can obscure effects on more narrowly defined disease categories. For example, Smithells and Shepard (1978) investigated the teratogenicity of the drug Bendectin, a drug indicated for nausea of pregnancy. Because only 35 babies in their cohort study were born with a malformation, their analysis was focused on the single outcome, "malformation." But no teratogen causes all malformations; if such an analysis fails to find an effect, the failure may simply be the result of the grouping of many malformations not related to Bendectin with those that are. In fact, despite the authors' claim that "their study provides substantial evidence that Bendectin is not teratogenic in man," their data indicated a strong (though imprecise) relation between Bendectin and cardiac malformations. Unwarranted assurances of a lack of effect can easily emerge from studies in which a wide range of etiologically unrelated outcomes are grouped.

Non-differential exposure and disease misclassification is a greater concern in interpreting studies that seem to indicate the absence of an effect. Consequently, in studies that indicate little or no effect, it is crucial for the researchers to consider the problem of non-differential misclassification to determine to what extent a real effect might have been obscured. On the other hand, in studies that describe a strong non-zero effect, preoccupation with non-differential exposure and disease misclassification is rarely warranted, provided that the errors are independent.

Occasionally, critics of a study will argue that poor exposure data or a poor disease classification invalidates the results. This argument is incorrect, however, if the results indicate a non-zero effect and one can be sure that the classification errors produced bias toward the null, since the bias will be in the direction of underestimating the effect.

The importance of appreciating the likely direction of bias was illustrated by the interpretation of a study on spermicides and birth defects (Jick et al. 1981a, b). This study reported an increased prevalence of several types of congenital disorder among women who were identified as having filled a prescription for spermicides during a specified interval before the birth. The exposure information was only a rough correlate of the actual use of spermicides during a theoretically relevant time period, but the misclassification that resulted was in all probability non-differential and independent of errors in outcome ascertainment, because prescription information was recorded on a computer log before the outcome was known. One of the criticisms raised about the study was that inaccuracies in the exposure information cast doubt on the validity of the findings (Felarca et al. 1981; Oakley 1982). Whatever bias was present on this account, however, would not likely have led to an underestimation of any real effect, so this criticism is inappropriate (Jick et al. 1981b).

Generally speaking, it is incorrect to dismiss a study reporting an effect simply because there is substantial non-differential misclassification of exposure, since an estimate of effect without the misclassification could be even greater, provided that the misclassification probabilities apply uniformly to all subjects. Thus, the implications of non-differential misclassification depend heavily on whether the study is perceived as “positive” or “negative.” Emphasis on measurement instead of on a qualitative description of study results lessens the likelihood for misinterpretation, but even so, it is important to bear in mind the direction and likely magnitude of a bias.

3.7.3 Misclassification of Confounders

If a confounding variable is misclassified, the ability to control confounding in the analysis is hampered (Greenland 1980; Savitz and Baron 1989; Brenner 1993; Marshall and Hastrup 1996; Marshall et al. 1999). While independent non-differential misclassification of exposure or disease usually biases study results in the direction of the null hypothesis, independent non-differential misclassification of a confounding variable will usually reduce the degree to which confounding can be controlled and thus can cause a bias in either direction, depending on the direction of the confounding. For this reason, misclassification of confounding factors can be a serious problem.

If the confounding is strong and the exposure-disease relation is weak or zero, misclassification of the confounding factor can lead to extremely misleading results. For example, a strong causal relation between smoking and bladder cancer, coupled with a strong association between smoking and coffee drinking, makes smoking a strong confounder of any possible relation between coffee drinking and bladder cancer. Since the control of confounding by smoking depends on accurate smoking information, and since some misclassification of the relevant smoking information is inevitable no matter how smoking is measured, some residual confounding is inevitable (Morrison et al. 1982). The problem of residual confounding would be even worse if the only available information on smoking were a simple dichotomy such as "ever smoked" versus "never smoked," since the lack of detailed specification of smoking prohibits adequate control of confounding. The resulting confounding is especially troublesome because to many investigators and readers, it may appear that confounding by smoking has been controlled.

3.8 Conclusion

Epidemiology is concerned with making inferences about the distribution and causes of disease and health in human populations. One should bear in mind that these inferences, like any scientific inference, can never be drawn with complete certainty and will often be highly tentative in light of unresolved validity issues, such as uncontrolled confounding. The uncertainties stemming from validity issues cannot always be addressed by statistical methods; hence, the process of epidemiological inference is a more complicated process than statistical inference. Epidemiological inference is further complicated by subtleties that arise when quantifying and measuring population effects, such as the distinction between number of individuals harmed by an exposure and the excess caseload produced by an exposure. These subtleties also cannot be addressed using ordinary statistical theory, and yet they can be of crucial importance in attempts to employ epidemiological results in decision-making contexts. The proper conduct and interpretation of epidemiological research and its application in public health requires mastery of epidemiological concepts and methods that are outlined in this chapter and elucidated further in the subsequent chapters of this handbook.

4.1 Introduction

A major aim of epidemiological research is to measure disease occurrence in relation to various characteristics such as exposure to environmental, occupational, or lifestyle risk factors, genetic traits, or other features. In this chapter, various measures will be considered that quantify disease occurrence, associations between disease occurrence and these characteristics, as well as their consequences in terms of both disease risk and impact at the population level. As a common practice, the generic term exposure will be used throughout the chapter to denote such characteristics. Emphasis will be placed on measures based on occurrence of new disease cases, referred to as disease incidence. Measures based on disease prevalence, i.e., considering newly occurring and previously existing disease cases as a whole, will be considered more briefly.

We will first define the basic measure of disease incidence, namely, the incidence rate, from which other measures considered in this chapter can be derived. These other measures, namely, measures of disease risk, measures of association between exposure and disease risk (e.g., relative risk), and measures of impact of exposure-disease associations (e.g., attributable risk), will be considered successively. Additional points will be made regarding standardized incidence rates and measures based on prevalence.

4.2 Incidence and Hazard Rates

4.2.1 Definition

The incidence rate of a given disease is the number of persons observed to develop the disease (number of incident cases) among subjects at risk of developing the disease in the source population over a chosen time period or age interval. Incidence rates are not interpretable as probabilities. While they have a lower bound of zero, they have no upper bound. Units of incidence rates are reciprocals of person-time, such as reciprocals of person-years or multiples of person-years (e.g., 100,000 person-years). For instance, if 10 cases develop from the follow-up of 20 subjects and for a total follow-up time of 5 years, the incidence rate is $10/100 = 0.1$ cases per person-year (assuming an instantaneous event with immediate recovery and all 20 subjects being at risk until the end of the observation period).

Usually, incidence rates are assessed over relatively short time periods compared with the time scale for disease development, e.g., intervals of 5-years for chronic diseases with an extended period of susceptibility such as many cancers.

Synonyms for incidence rate are average incidence rate, force of morbidity, person-time rate, or incidence density (Miettinen 1976) with the last term reflecting the interpretation of an incidence rate as the density of incident case occurrences in an accumulated amount of person-time (Morgenstern et al. 1980). Mortality rates (overall or cause-specific) can be regarded as special cases of incidence rates, the outcome considered being death rather than disease occurrence.

Incidence rates can be regarded as estimates of a limiting theoretical quantity, namely, the hazard rate, $h(t)$, also called the incidence intensity or force of morbidity. The hazard rate at time t, $h(t)$, is the instantaneous rate of developing the disease of interest in an arbitrarily short interval Δ around time t, provided the subject is still at risk at time t (i.e., has not fallen ill before time t). Technically, it has the following mathematical definition:

$$h(t) = \text{limit}_{\Delta \downarrow 0} \Delta^{-1} \Pr(t \le T < t + \Delta | t \le T), \tag{4.1}$$

where T is the time period for the development of the disease considered and Pr denotes probability. Indeed, for time intervals in which the hazard rate can be assumed constant, the incidence rate as defined above represents a valid estimate of the hazard rate. Thus, this result applies when piecewise constant hazard rates are assumed, which can be regarded as realistic in many applications, especially when reasonably short time intervals are used, and leads to convenient estimating procedures, e.g., based on the Poisson model.

Strictly speaking, incidence and hazard rates do not coincide. Hazard rates are formally defined as theoretical functions of time whereas incidence rates are defined directly as estimates and constitute valid estimates of hazard rates under certain assumptions (see above). For the sake of simplicity, however, we will use the terms incidence rates and hazard rates as synonyms in the remainder of this chapter unless a clear distinction is needed.

4.2.2 Estimability and Basic Principles of Estimation

From the definitions above, it ensues that individual follow-up data are needed to obtain incidence rates or estimate hazard rates. Alternatively, in the absence of individual follow-up data, person-time at risk can be estimated as the time period width times the population size at midpoint. Such estimation makes the assumption that individuals who disappear from being at risk, either because they succumb or because they move in or out, do so evenly across the time interval. Thus, population data such as registry data can be used to estimate incidence rates as long as an exhaustive census of incident cases can be obtained.

Among the main designs considered in Part I (Concepts and Designs in Epidemiology) of this handbook, the cohort design (cf. chapter ▸Cohort Studies of this handbook) is the ideal design to obtain incidence or hazard rates for various levels or profiles of exposure, i.e., exposure-specific incidence or hazard rates. This is because follow-up is available on subjects with various profiles of exposure. In many applications, obtaining exposure-specific incidence rates is not trivial, however. Indeed, multiple exposures are often considered, some with several exposed levels and some continuous. Moreover, it may be necessary to account for confounders or effect modifiers. Hence, estimation often requires modeling. Methods of inference based on regression models are considered in detail in Part III (Statistical Methods in Epidemiology) of this handbook, particularly chapter ▶Regression Methods for Epidemiological Analysis.

Case-control data (cf. chapter ▶Case-Control Studies of this handbook) pose a more difficult problem than cohort data because case-control data alone are not sufficient to yield incidence or hazard rates. Indeed, they provide data on the distributions of exposure respectively in diseased subjects (cases) and non-diseased subjects (controls) for the disease under study, which can be used to estimate odds ratios (see Sect. 4.4) but are not sufficient to estimate exposure-specific incidence rates. However, it is possible to arrive at exposure-specific incidence rates from case-control data if case-control data are complemented by either follow-up or population data, which happens for nested or population-based case-control studies. In a nested case-control study, the cases and controls are selected from a follow-up study. In a population-based case-control study, they are selected from a specified population in which an effort is made to identify all incident cases diagnosed during a fixed time interval, usually in a grouped form (e.g., number of cases and number of subjects by age group). In both situations, full information on exposure is obtained only for cases and controls. Additionally, complementary information on composite incidence (i.e., counts of events and person-time) can be sought from the follow-up or population data. By combining this information with odds ratio estimates, exposure-specific incidence rates can be obtained. This has long been recognized (Cornfield 1951, 1956; MacMahon 1962; Miettinen 1974, 1976; Neutra and Drolette 1978) and is a consequence of the relation (Miettinen 1974; Gail et al. 1989):

$$h_0 = h^*(1 - AR), \tag{4.2}$$

where AR is the attributable risk in the population for all exposures considered, a quantity estimable from case-control data (see Sect. 4.5); h_0 is the baseline incidence rate, i.e., the incidence rate for subjects at the reference (unexposed) level of all exposures considered; and h^* is the composite or average incidence rate in the population that includes unexposed subjects and subjects at various levels of all exposures (i.e., with various profiles of exposure). The composite incidence rate h^* can be estimated from the complementary follow-up or population data. Equation 4.2 simply states that the incidence rate for unexposed subjects is equal to the proportion of the average incidence rate in the population that is not associated with any of the exposures considered. Equation 4.2 can be specialized to various subgroups or strata defined by categories of age, sex, or geographical location such as region or center, on which incidence rates are assumed constant. From the baseline rate h_0, incidence rates for all levels or profiles of exposure can be derived using odds ratio estimates, provided odds ratio estimates are reasonable estimates of incidence rate ratios as in the case of a rare disease (see Sect. 4.4). Consequently, exposure-specific incidence rates can be obtained from case-control data as long as they are complemented by follow-up or population data that can be used to estimate average incidence rates.

Example 4.1.
Exposure-specific incidence rates of breast cancer were obtained based on age as well as family history in first-degree relatives, reproductive history (i.e., age at menarche and age at first live birth), and history of benign disease from the Breast Cancer Detection and Demonstration Project (BCDDP). The BCDDP combined the prospective follow-up of 284,780 women over 5 years and a nested case-control study (Gail et al. 1989) with about 3,000 cases and 3,000 controls. For each 5-year age group from ages 35 to 79 years, composite incidence rates were obtained from the follow-up data. In age groups 40–44 and 45–49 years, 162 and 249 new cases of breast cancer developed from the follow-up of 79,526.4 and 88,660.7 person-years, yielding composite incidence rates of 203.7 and 280.8 per 10^5 person-years, respectively. For all women less than 50 years of age, the attributable risk for family history, reproductive history, and history of benign breast disease was estimated at 0.4771 from the nested case-control data (see Sect. 4.5). By applying Eq. 4.2, baseline incidence rates for women at the reference level of all these factors were $203.7 \times (1 - 0.4771) = 106.5$ and $280.8 \times (1 - 0.4771) = 146.8$ per 10^5 person-years, respectively. For a nulliparous woman of age 40, with menarche at age 12, one previous biopsy for benign breast disease, and no history of breast-cancer in her first-degree relatives, the corresponding odds ratio was estimated at 2.89 from logistic regression analysis of the nested case-control data (see Sect. 4.4.6.3), yielding an exposure-specific incidence rate of $106.5 \times 2.89 = 307.8$ per 10^5 person-years. For a 45-year-old woman with the same exposure profile, the corresponding exposure-specific incidence rate was $146.8 \times 2.89 = 424.3$ per 10^5 person-years.

Finally, cross-sectional data cannot provide any assessment of incidence rates but instead will yield estimates of disease prevalence proportions as discussed in Sect. 4.6 of this chapter.

4.2.3 Relation with Other Measures

The reason why exposure-specific incidence or hazard rates are central quantities is that, once they are available, most other quantities described in this chapter can be obtained from them, namely, measures of disease risk, measures of association between exposure and disease risk, and measures of exposure impact in terms of new disease burden at the population level. However, it should be noted that measures of impact as well as some measures of association (i.e., odds ratios) can be estimated from case-control data alone without relying on exposure-specific incidence rates (see Sects. 4.3 and 4.4). Moreover, cross-sectional data can yield estimates of measures of association and impact with respect to disease prevalence (see Sect. 4.6).

4.3 Measures of Disease Risk

4.3.1 Definition

Disease risk is defined as the probability that an individual who is initially disease-free will develop a given disease over a specified time or age interval (e.g., 1 year or lifetime). Of all incidence and risk measures, this measure is probably the one most familiar and interpretable to consumers of health data.

If the interval starting at time a_1 and ending just before time a_2, i.e., $[a_1, a_2)$, is considered, disease risk can be written formally as

$$\pi(a_1, a_2) = \int_{a_1}^{a_2} h(a)\{S(a)/S(a_1)\}da. \tag{4.3}$$

In Eq. 4.3, $h(a)$ denotes the disease hazard rate at time or age a (see Sect. 4.2). The function $S(\cdot)$, with $(\cdot)$ an arbitrary argument, is the survival function, so that $S(a)$ denotes the probability of still being disease-free at time at age a and $S(a)/S(a_1)$ denotes the conditional probability of staying disease-free up to time or age a for an individual who is free of disease at the beginning of the interval $[a_1, a_2)$. Equation 4.3 integrates over the interval $[a_1, a_2)$ the instantaneous incidence rate of developing disease at time or age a for subjects still at risk of developing the disease (i.e., subjects still disease-free). Because the survival function $S(\cdot)$ can be written as a function of the disease hazard rate through

$$S(a_2)/S(a_1) = \exp\left\{-\int_{a_1}^{a_2} h(a)da\right\}, \tag{4.4}$$

disease risk is also a function of the disease hazard rate.

By specifying the functions $h(\cdot)$ and $S(\cdot)$, various quantities can be obtained that measure disease risk in different contexts. First, the time scale on which these functions as well as disease risk are defined corresponds to two specific uses of risk. In most applications, the relevant time scale is age, since disease incidence is influenced by age in most applications. Note that by considering the age interval $[0, a_2)$, one obtains lifetime disease risk up to age a_2. However, in clinical epidemiology settings, risk refers to the occurrence of an event, such as relapse or death in subjects already presenting with the disease of interest. In this context, the relevant time scale becomes time from disease diagnosis or, possibly, time from some other disease-related event, such as a surgical resection of a tumor or occurrence of a first myocardial infarction.

Second, risk definition may or may not account for individual exposure profiles. If no risk factors are considered in the estimation of the disease hazard rate, the corresponding measure of disease risk defines the average or composite risk over the entire population that includes subjects with various exposure profiles. This measure, also called cumulative incidence (Miettinen 1976), may be of value at the population level. However, the main usefulness of risk is in quantifying an individual's predicted probability of developing disease depending on the individual's exposure profile. Thus, estimates of exposure-specific disease hazard rate have to be available for such exposure-specific risk (also called individualized or absolute risk) to be estimated.

Third, the consideration of competing risks and the corresponding definition of the survival function $S(\cdot)$ yields two separate definitions of risk. Indeed, although risk is defined with respect to the occurrence of a given disease, subjects can die from other causes (i.e., competing risks), which obviously precludes disease occurrence. The first option is to define $S(a)$ as the theoretical probability of being disease-free at time or age a if other causes of death (competing risks) were eliminated yielding a measure of disease risk in a setting with no competing risks. This measure may not be of much practical value. Moreover, unless unverifiable assumptions regarding incidence of the disease of interest and deaths from other causes can be made, for instance, assuming that they occur independently, the function $S(\cdot)$ will not be estimable. For these reasons, it is more feasible to define $S(a)$ as the probability that an individual will be alive and disease-free at age a as the second option, yielding a more practical definition of disease risk as the probability of developing disease in the presence of competing causes of death (see Sect. 4.3.5).

From the definition of disease risk above, it appears that disease risk depends on the incidence rate of disease in the population considered and can also be influenced by the strength of the relationship between exposures and disease if individual risk is considered. One consequence is that risk estimates may not be portable from one population to another, as incidence rates may vary widely among populations that are separated in time and location or even among subgroups of populations, possibly because of differing genetic patterns or differing exposure to unknown risk factors. Additionally, competing causes of death (competing risks) may have different patterns among different populations, which might also influence values of disease risk.

4.3.2 Range

Disease risk is a probability and therefore lies between 0 and 1 and is dimensionless. A value of 0 while theoretically possible would correspond to very special cases such as a purely genetic disease for an individual not carrying the disease gene. A value of 1 would be even more unusual and might again correspond to a genetic disease with a penetrance of 1 for a gene carrier, but, even in this case, the value should be less than 1 if competing risks are accounted for.

4.3.3 Synonyms

Beside the term "disease risk," "absolute risk" or "absolute cause-specific risk" have been used by several authors (Dupont 1989; Benichou and Gail 1990a, 1995; Benichou 2000a; Langholz and Borgan 1997). Alternative terms include "individualized risk" (Gail et al. 1989), "individual risk" (Spiegelman et al. 1994), "crude probability" (Chiang 1968), "crude incidence" (Korn and Dorey 1992), "cumulative incidence" (Gray 1988; Miettinen 1976), "cumulative incidence risk" (Miettinen 1974), and "absolute incidence risk" (Miettinen 1976).

The term "cumulative risk" refers to the quantity $\int_{a_1}^{a_2} h(a)da$ and approximates disease risk closely in the case where disease is rare.

The term "attack rate" defines the risk of developing a communicable disease during a local outbreak and for the duration of the epidemic or the time during which primary cases occur (MacMahon and Pugh 1970, Chap. 5; Rothman and Greenland 1998, Chap. 27).

The term “floating absolute risk,” introduced by Easton et al. (1991), refers to a concept different from disease risk. It was derived to remedy the standard problem that measures of association such as ratios of rates, risks, or odds are estimated in reference to a baseline group, which causes their estimates for different levels of exposure to be correlated and may lead to lack of precision if the baseline group is small. The authors proposed a procedure to obtain estimates unaffected by these problems and used the term “floating absolute risk” to indicate that standard errors were not estimated in reference to an arbitrary baseline group.

4.3.4 Interpretation and Usefulness

Overall or average risks provide results such as “one in nine women will develop breast cancer at some time during her life” (American Cancer Society 1992), which are of no direct use in quantifying the risk of women with given exposure profiles and no direct help in deciding on preventive treatment or surveillance measures.

Upon taking individual exposure profiles into account, resulting individual disease risk estimates become useful in providing an individual measure of the probability of disease occurrence and can therefore be useful in counseling. They are well suited to predicting risk for an individual, unlike measures of association that quantify the increase in the probability of disease occurrence relative to subjects at the baseline level of exposure, but do not quantify that probability itself.

Individual risk has been used as a tool for individual counseling in breast cancer (Benichou et al. 1996; Gail and Benichou 1994; Hoskins et al. 1995). Indeed, a woman’s decision to take a preventive treatment such as tamoxifen (Fisher et al. 1998; Wu and Brown 2003) or even undergo prophylactic mastectomy (Hartman et al. 2001; Lynch et al. 2001) depends on her awareness of the medical options, on personal preferences, and on individual risk. A woman may have several risk factors, but if her individual risk of developing breast cancer over the next 10 years is small, she may be reassured and she may be well advised simply to embark on a program of surveillance. Conversely, she may be very concerned about her absolute risk over a longer time period, such as 30 years, and she may decide to use prophylactic medical treatment or even undergo prophylactic mastectomy if her absolute risk is very high.

Estimates of individual risk of breast cancer are available based on age, family history, reproductive history and history of benign disease (Gail et al. 1989; Costantino et al. 1999) and were originally derived from the BCDDP that combined a follow-up study and a nested case-control study (Gail et al. 1989). This example illustrates that not only exposures or risk factors per se (such as family history) may be used to obtain individual risk estimates but also markers of risk such as benign breast disease which are known to be associated with an increase in disease risk and may reflect some premalignant stage. In the same fashion, it has been suggested to improve existing individual risk estimates of breast cancer by incorporating mammographic density, a risk marker known to be associated with increased breast cancer risk (Benichou et al. 1997). In the cardiovascular field, individual risk estimates of developing myocardial infarction, developing coronary heart disease, dying from coronary heart disease, developing stroke, developing cardiovascular disease, and dying from cardiovascular disease were derived from the Framingham heart and Framingham offspring cohort studies. These estimates are based on age, sex, HDL, LDL, and total cholesterol levels, smoking status, blood pressure, and diabetes history (Anderson et al. 1991).

Individual risk is also useful in designing and interpreting trials of interventions to prevent the occurrence of a disease. At the design stage, disease risk may be used for sample size calculations because the sample sizes required for these studies depend importantly on the risk of developing the disease during the period of study and the expected distribution of exposure profiles in the study sample (Anderson et al. 1992). Disease risk has also been used to define eligibility criteria in such studies. For example, women were enrolled in a preventive trial to decide whether the drug tamoxifen can reduce the risk of developing breast cancer (Fisher et al. 1998). Because tamoxifen is a potentially toxic drug and because it was to be administered to a healthy population, it was decided to restrict eligibility to women with somewhat elevated absolute risks of breast cancer. All women over age 59 as well as younger women whose absolute risks were estimated to equal or exceed that of a typical 60-year-old woman were eligible to participate (Fisher et al. 1998). Individual risk has been used to interpret results of this trial through a risk-benefit analysis in order to help define which women are more likely to benefit from using tamoxifen. Women were identified who had a decrease in breast cancer risk and other events such as hip fracture from using tamoxifen surpassing the tamoxifen-induced increase in other events such as endometrial cancer, pulmonary embolism, or deep vein thrombosis (Gail et al. 1999).

Disease risk can also be important in decisions affecting public health. For example, in order to estimate the absolute reduction in lung cancer incidence that might result from measures to reduce exposure to radon, one could categorize a general population into subgroups based on age, sex, smoking, status and current radon exposure levels and then estimate the absolute reduction in lung cancer incidence that would result from lowering radon levels in each subgroup (Benichou and Gail 1990a; Gail 1975). Such an analysis would complement estimation of population attributable risk or generalized impact fractions (see Sect. 4.5).

The concept of risk is also useful in clinical epidemiology as a measure of the individualized probability of an adverse event, such as a recurrence or death in diseased subjects. In that context, risk depends on factors that are predictive of recurrence or death, rather than on factors influencing the risk of incident disease, and the time scale of interest is usually time from diagnosis or from surgery rather than age. It can serve as a useful tool to help define individual patient management, and, for instance, the absolute risk of recurrence in the next 3 years might be an important element in deciding whether to prescribe an aggressive and potentially toxic treatment regimen (Benichou and Gail 1990a; Korn and Dorey 1992).

4.3.5 Properties

Two main points need to be emphasized. First, as is evident from its definition, disease risk can only be estimated and interpreted in reference to a specified age or time interval. One might be interested in short time spans (e.g., 5 years) or long time spans (e.g., 30 years). Of course, disease risk increases as the time span increases. Sometimes, the time span is variable such as in lifetime risk.

Disease risk can be influenced strongly by the intensity of competing risks (typically competing causes of death, see above). Disease risk varies inversely as a function of death rates from other causes.

4.3.6 Estimability

It follows from its definition that disease risk is estimable as long as hazard rates for the disease (or event) of interest are estimable. Therefore, disease risk is directly estimable from cohort data, but case-control data have to be complemented with follow-up or population data in order to obtain the necessary complementary information on incidence rates (see Sect. 4.2).

It has been argued above (see Sect. 4.3.1) that disease risk is a more useful measure when it takes into account competing risks, i.e., the possibility for an individual to die of an unrelated disease before developing the disease (or disease-related event) of interest. In this setting, disease risk is defined as the probability of disease occurrence *in the presence* of competing risks, which is more relevant for individual predictions and other applications discussed above than the underlying (or "net" or "latent") probability of disease occurrence *in the absence* of competing risks. Moreover, disease risk is identifiable without any unverifiable competing risk assumptions in this setting, such as the assumption that competing risks act independently of the cause of interest because, as Prentice et al. (1978) emphasize, all functions of the disease hazard rates are estimable. Death rates from other causes can be estimated either internally from the study data or from external sources such as vital statistics.

Example 4.1. (Continued)
In order to obtain estimates of breast cancer risk in the presence of competing risks, Gail et al. (1989) used United States (US) mortality rates from year 1979 for all causes except breast cancer to estimate the competing risks with more precision than from the BCDDP follow-up data. In age groups 40–44 and 45–49 years, these death rates were 153.0 and 248.6 per 10^5 person-years, respectively, hence of the same order of magnitude as breast cancer incidence rates. In older age groups, these death rates were much higher than breast cancer incidence rates, thus strongly influencing breast cancer risk estimates for age intervals including these age groups. For instance, death rates from causes other than breast cancer were 1,017.7 and 2,419.8 per 10^5 person-years in age groups 65–69 and 70–74 years, respectively, whereas average incidence rates of breast cancer were 356.1 and 307.8 per 10^5 person-years in these age groups, respectively.

4.3.7 Estimation from Cohort Studies

Estimation of disease risk rests on estimating disease incidence and hazard rates, a topic also addressed in Part III (Statistical Methods in Epidemiology) of this handbook. Several approaches have been worked out fully for disease risk estimation. A brief review of these approaches is given here starting with average risk estimates that do not take exposure profiles into account and continuing with exposure-specific estimates.

4.3.7.1 Estimates of Average Disease Risk

The density or exponential method (Miettinen 1976; Kleinbaum et al. 1982, Chap. 6; Rothman and Greenland 1998, Chap. 3) relies on subdividing the time or age scale in successive time or age intervals $I_1,\ldots, I_i,\ldots, I_I$ (e.g., 1- or 5-year intervals) on which the rate of disease incidence is assumed constant (i.e., piecewise constant). Disease risk over time or age interval $[a_1, a_2)$, i.e., the probability for an individual to experience disease occurrence over interval $[a_1, a_2)$ is taken as one minus the probability of staying disease-free through the successive intervals included in $[a_1, a_2)$. Assuming that disease is rare on each of the successive intervals considered, disease risk can be estimated as

$$\hat{\pi}(a_1, a_2) = 1 - \exp\left(-\sum_i \hat{h}_i \Delta_i\right). \tag{4.5}$$

The sum is taken over all intervals included in $[a_1, a_2)$. Notation Δ_i denotes the width of interval i, whereas $\hat{h}_i$ denotes the incidence rate in interval i, obtained as the ratio of the number of incident cases over the person-time accumulated during follow-up in that interval.

While Eq. 4.5 is simple to apply, its validity depends on several assumptions. The assumption that disease incidence is constant over each time or age interval considered makes it a parametric approach. However, if intervals are small enough, this will not amount to a strong assumption. Moreover, it relies on the assumption that disease incidence is small on each interval. If this is not the case, a more complicated formula will be needed. Finally, this approach ignores competing risks.

Benichou and Gail (1990a) generalized this approach by lifting the condition on small incidence on each interval and allowing competing risks to be taken into account. They derived a generalized expression for the estimate of disease risk over time or age interval $[a_1, a_2)$ as

$$\hat{\pi}(a_1, a_2) = \sum_i \frac{\hat{h}_{1i}}{\hat{h}_{1i} + \hat{h}_{2i}} \left[1 - \exp\left\{-(\hat{h}_{1i} + \hat{h}_{2i})\Delta_i\right\}\right] A(i), \tag{4.6}$$

with $A(i) = \prod_{j<i} \exp\left\{-(\hat{h}_{1j} + \hat{h}_{2j})\Delta_j\right\}$.

In Eq. 4.6, the sum is taken over all intervals included in $[a_1, a_2)$, Δ_i denotes the width of interval i, $\hat{h}_{1i}$ denotes the disease incidence rate in interval i, $\hat{h}_{2i}$ the death rate from other causes in interval i, and the product in $A(i)$ is taken over time intervals in $[a_1, a_2)$ from the first one to the one just preceding interval i. Death rates can be obtained in a similar fashion as disease incidence rates. It should be noted that disease risk can be estimated for a much longer duration than the actual follow-up of individuals in the study if age is the time scale (open cohort) provided there is no secular trend in disease incidence.

Variance estimates were derived by Benichou and Gail (1990a). Moreover, based on simulations of a closed cohort, they found that resulting confidence intervals have satisfactory coverage, especially with the log transformation, and observed little or no bias on risk estimates with a sufficient number of intervals even when disease incidence varied sharply with time.

The actuarial method or life table method (Cutler and Ederer 1958; Elveback 1958; Fleiss et al. 1976; Kleinbaum et al. 1982, Chap. 6; Rothman and Greenland 1998, Chap. 3) shares similarities with the density method, although it was derived from a less parametric viewpoint. As with the density method, time is split into intervals. In each time interval i, the probability for an individual who is disease-free at the beginning of the interval to stay disease-free throughout the interval is estimated. Disease risk is obtained as one minus the estimated probability of staying disease-free throughout the successive time intervals included in $[a_1, a_2)$ as

$$\hat{\pi}(a_1, a_2) = 1 - \prod_i \frac{(n_i - w_i/2 - d_i)}{(n_i - w_i/2)}, \tag{4.7}$$

where the product is taken over all intervals included in $[a_1, a_2)$, n_i denotes the number of disease-free subjects at the beginning of interval i, d_i the number of incident cases occurring in interval i, and w_i the number of subjects either lost to follow-up or dying from other causes (competing risks) in interval i. The actuarial approach is most appropriate when grouped data are available and the actual follow-up of each individual in each interval is not known. The person-years of follow-up for subjects lost to follow-up or affected with competing risks in interval i is not used directly but, if one assumes that the mean withdrawal time occurs at the midpoint of the interval, then the denominator in each product term of Eq. 4.7 can be regarded as the effective number of persons at risk of developing the disease in the corresponding interval. Namely, it represents the number of disease-free persons that would be expected to produce d_i incident cases if all persons could be followed for the entire interval (Elandt-Johnson 1977; Kleinbaum et al. 1982, Chap. 6; Littell 1952). The actuarial method can be regarded as a refinement of the simple cumulative method (Kleinbaum et al. 1982, Chap. 6) that ignores quantity w_i and simply estimates disease risk as the number of individuals who contract the disease divided by the total number in the cohort or exposure subgroup of interest. The actuarial method is preferable to this direct method because, in practice, it is rare that a large enough cohort can be followed over a long enough time to reliably estimate the risk of disease by this simple method. Moreover, the simple cumulative method cannot handle the case when subjects are followed for varying lengths of time, which often occurs because subjects can be enrolled at different times whereas the follow-up ends at the same time for all subjects.

As shown by several authors (Cutler and Ederer 1958; Fleiss et al. 1976), the actuarial method results in biased estimates of risk even in the unlikely and most favorable event (in terms of bias) of all withdrawals occurring at the interval midpoints. Alternative approaches based on different choices of the quantity to subtract from n_i (i.e., choices different from $w_i/2$) are not subject to less bias, however (Elandt-Johnson 1977). The problem can be best handled by using narrow intervals, but this is done at the expense of a larger random error (i.e., less precise estimates of risk).

Compared to the density method (Eqs. 4.5 and 4.6), the actuarial method has the advantage of not requiring knowledge of individual follow-up times in each interval but only knowledge of the number at risk at the beginning of the interval and the number of withdrawals. The density method could be used, however, without knowledge of follow-up time by assigning a follow-up time of half the interval width to subjects who are lost to follow-up, develop disease or die from other causes, in an analogous fashion as with the actuarial method (Benichou and Gail 1990a). The actuarial method requires neither the assumption of constant incidence rate nor rarity of disease incidence on all time intervals. However, bias is less of a problem with the density than the actuarial method and the density method applies naturally to open cohorts and extends easily to risk estimates that take exposure profiles into account (see below).

When individual follow-up times are all known, a fully non-parametric risk estimate can be obtained in the spirit of the Kaplan–Meier estimate of survival (Kaplan and Meier 1958; see also chapter ▸Survival Analysis of this handbook). Disease risk is estimated through summation on all distinct times in $[a_1, a_2)$ at which new disease cases occur (Aalen and Johansen 1978; Kay and Schumacher 1983; Gray 1988; Matthews 1988; Keiding and Andersen 1989; Benichou and Gail 1990a; Korn and Dorey 1992). Corresponding variance estimates were derived (Aalen 1978; Aalen and Johansen 1978; Keiding and Andersen 1989; Benichou and Gail 1990a; Korn and Dorey 1992) from which confidence intervals can be obtained, based on the log transformation as suggested by Benichou and Gail (1990a) and Keiding and Andersen (1989) or based on the approach of Dorey and Korn (1987).

Upon comparing the generalized density method (see Eq. 4.6) and the non-parametric method, Benichou and Gail (1990a) showed that the loss of efficiency of the non-parametric method is small compared to the density method. Moreover, the non-parametric method yields little bias in risk estimates as well nearly nominal coverage for confidence intervals of risk with the log transformation. Nominal coverage refers to the theoretical probability of a confidence interval to cover the true parameter and may be assessed using simulations (i.e., a 95% confidence interval will be said to have nominal coverage if it does include the true parameter value in 95% of the cases). Hence, properties of the generalized density and non-parametric methods agree closely. However, the generalized density method has the advantage of simplicity of computation and is better suited to open cohorts.

4.3.7.2 Estimates of Exposure-Specific Disease Risk

In order to obtain risk estimates that depend on exposure profiles, the cohort could be subdivided into subcohorts based on exposure levels and the methods above applied to these subcohorts. However, this approach would be impractical because it would yield risk estimates with very low precision. In order to remedy this problem, a natural approach to incorporate exposures is to model incidence rates through regression models.

Benichou and Gail (1990a) proposed a direct extension of the generalized density method (Eq. 4.6). This extension is based on assuming that the disease hazard rate on each time or age interval i is the product of a constant baseline hazard rate for subjects at the reference level of exposure in interval i and a function of the various exposures. The corresponding parameters, i.e., baseline hazard rates and hazard ratio parameters for exposure, can be jointly estimated by maximizing the piecewise exponential likelihood, which is equivalent to the usual Poisson likelihood for the analysis of cohort data (Holford 1980; Laird and Oliver 1981). Corresponding variance estimates are available (Benichou and Gail 1990a). In simulations, risk estimates appeared subject to little bias, variance estimates were also little biased, and coverage of confidence intervals was nearly nominal, except for the exposure profiles with very few subjects (Benichou and Gail 1990a). Other parametric approaches were considered to obtain risk estimates of cardiovascular events from the Framingham studies (Anderson et al. 1991). Semi-parametric estimators of risk were also derived (Benichou and Gail 1990a). In contrast with the previous approach where a piecewise exponential or Poisson distribution is assumed, the baseline disease hazard rate is expressed as an unspecified function of time or age rather than a constant, which corresponds to the semi-parametric Cox regression model (Cox 1972). Risk estimates are obtained as functions of the partial likelihood estimates (Cox 1975) of hazard ratio parameters and related Nelson-Aalen estimates of cumulative baseline hazard rates (Borgan 1998). From results in Tsiatis (1981) and Andersen and Gill (1982) on the joint distribution of these parameter estimates, Benichou and Gail (1990a) derived an asymptotic variance estimator.

Regression based methods appear well suited for estimating exposure-specific disease risk and are therefore useful for the purpose of individual prediction. Compared to the semi-parametric approach, the generalized density method appears easier to implement while providing a good compromise between bias and precision.

4.3.8 Estimation from Population-Based or Nested Case-Control Studies

As discussed above, whereas disease risk is directly estimable from cohort data, case-control data have to be complemented with follow-up or population data in order to obtain the necessary information on incidence rates. If such complementary data are available, exposure-specific incidence rates and exposure-specific disease risk can be estimated. All approaches proposed in the literature rely on regression methods.

4.3.8.1 The Hybrid Approach

This approach relies on the assumption of piecewise constant incidence rates and on Eq. 4.2 to obtain baseline incidence rates in strata defined by factors such as age, sex, race, or geographical area (see Sect. 4.2.2). Odds ratio estimates are then combined with baseline incidence rates to arrive at exposure-specific incidence rates (see Sect. 4.2.2). Applying Eq. 4.6 to these rates and death rates from competing causes, disease risk estimates can be obtained for desired time intervals. This approach has been used in practice to obtain individual risks of breast cancer by Gail et al. (1989) (see Example 4.1 below). Resulting disease risk estimates can be termed estimates of individual breast cancer risk since they depend on age and individual exposure profile (216 profiles were considered overall). The approach can be seen as a multivariate extension of earlier work by Miettinen (1974). It has been termed a hybrid approach (Benichou 2000a) since it relies on two models, namely, the piecewise exponential model that underlies the density method (i.e., constant incidence by age group) and the logistic model used to obtain odds ratio estimates from the nested case-control data (see Sect. 4.4.6.3). It can be applied to population-based case-control data with no individual follow-up of subjects in a similar manner as to nested case-control data, as discussed and illustrated for bladder cancer by Benichou and Wacholder (1994) (see Example 4.2 below).

Variance estimators for risk estimates are complex since exposure-specific incidence rate estimates involve odds ratio parameters obtained through logistic regression from the case-control data and counts of incident cases from the follow-up or population data. Estimators of variances and covariances of age- and exposure-specific incidence rates that take into account all sources of variability have been fully worked out for various sampling schemes regarding control selection in the general case (Benichou and Gail 1990a) and specifically to account for the special features of the BCDDP data (Benichou and Gail 1995). Simulations tailored to the BCDDP data showed a small upward bias in risk estimates due to the small upward bias incurred by using odds ratios to estimate hazard ratios when the rare-disease assumption appeared questionable. Variance estimates had very little bias and yielded confidence intervals with near nominal coverage. Coverage was improved with the logit transformation.

Example 4.1. (Continued)

Applying Eq. 4.6 to exposure-specific incidence rates of breast cancer estimated from the BCDDP data (see Sect. 4.2.2) and death rates from other causes estimated from US mortality data (see Sect. 4.3.6), risk estimates of breast cancer can be obtained. For instance, the 10-year risk of developing breast cancer between ages 40 and 50 years for a woman initially free of breast cancer at age 40 years and with the exposure profile considered in Sect. 4.2.2 (i.e., nulliparous woman with menarche at age 12 years, one previous biopsy for benign breast disease, and no history of breast cancer in her first-degree relatives) is obtained as a sum of 2 terms. The first term, $\hat{\pi}_1$, corresponding to age interval 40–44, is obtained from Eq. 4.6 as

$$\begin{aligned}\hat{\pi}_1 = &\frac{307.8 \times 10^{-5}}{307.8 \times 10^{-5} + 153.0 \times 10^{-5}}\\ &\times \left[1 - \exp\left\{-5(307.8 \times 10^{-5} + 153.0 \times 10^{-5})\right\}\right] = 0.0152.\end{aligned}$$

The second term, $\hat{\pi}_2$, corresponding to age interval 45–49, is obtained from Eq. 4.6 as the product of the probability of developing breast cancer in age interval 45–49 times the probability of having stayed free of breast cancer and not died from other causes in age interval 40–44:

$$\begin{aligned}\hat{\pi}_2 = & \frac{424.3 \times 10^{-5}}{424.3 \times 10^{-5} + 248.6 \times 10^{-5}} \\ & \times \left[1 - \exp\left\{-5(424.3 \times 10^{-5} + 248.6 \times 10^{-5})\right\}\right] \\ & \times \exp\left\{-5(307.8 \times 10^{-5} + 153.0 \times 10^{-5})\right\} = 0.0204.\end{aligned}$$

Thus, the 10-year risk of developing breast cancer is obtained as the sum $0.0152+0.0204 = 0.0356$, or 3.6%. The corresponding 95% confidence interval based on taking all sources of variability into account can be estimated as 3.0–4.2% through computations described in Benichou and Gail (1995). Breast cancer risk estimates can be obtained for all age intervals in the range 20–80 years and all 216 exposure profiles including the profile considered above. This whole approach to individual breast cancer risk estimation is known as the "Gail model" and has enjoyed widespread use in individual counseling, and in designing, and interpreting prevention trials. Practical implementation has been greatly facilitated by the development of graphs (Benichou et al. 1996) as well as a computer program (Benichou 1993a) and its modified version that is available on the US National Cancer Institute web site at http://bcra.nci.nih.gov/brc/ accessed 12 May 2004.

Example 4.2.
In the year 1978, incident cases of bladder cancer were identified through ten cancer registries in the Unites States. For instance, 32 incident cases were identified among white males aged 45–64 years whose population numbered 97,420 individuals. Assuming that this population remained constant throughout the year 1978, these data yielded an average incidence rate of 32.8 per 10^5 person-years. The National Bladder Cancer Study was a population-based case-control study conducted at the ten cancer registries. Incident cases aged 21–84 years were selected from the registries. Controls aged 21–84 years were selected from telephone sampling or Health Care Financing Administration rosters and frequency-matched to cases on geographical area, age, and sex. Based on case-control data from two states (Utah and New Jersey) and one large city (Atlanta), odds ratios were estimated for smoking status (never smoker, ex-smoker, current light smoker, current heavy smoker) and occupational exposure to carcinogens (yes, no) using logistic regression (see Sect. 4.4.6.3). Moreover, the attributable risk for smoking and occupational exposure was estimated for white males in each of the nine strata resulting from the three areas and three age groups (i.e., 21–44, 45–64 and 65+ years) (see Sect. 4.5.1). Among white males aged 45–64 years in Utah, it was estimated at 54.0%, yielding a baseline incidence rate of $32.8 \times (1 - 0.540) = 15.1$ per 10^5 person-years. The odds ratios for current heavy smokers ($\geq$20 cigarettes per day) and occupational exposure were estimated at 2.9 and 1.6. Hence, among white males aged 45–64 years in Utah, exposure-specific incidence rates were estimated at $15.1 \times 1.6 = 24.1$ per 10^5 person-years for never smokers with a history of occupational exposure and $15.1 \times 2.9 \times 1.6 = 69.8$ per 10^5 person-years for current heavy smokers with a history of occupational exposure assuming a multiplicative effect of smoking and occupational exposure (and allowing for rounding error). From these exposure-specific incidence rates, estimates of the risk of bladder cancer over specified age intervals could be derived, using Eq. 4.6.

4.3.8.2 Other Parametric Approaches

A pseudo-likelihood approach also relying on the assumption on piecewise constant incidence (i.e., piecewise exponential model) has been proposed as an alternative to the hybrid approach (Benichou and Wacholder 1994). In each stratum separately, observed distributions of exposure in the cases and controls are applied to counts of incident cases and person-time to obtain respective expected numbers of incident cases and of person-time per stratum and exposure level. Then, baseline incidence rates and hazard ratios are jointly estimated from these expected quantities under a piecewise exponential model. Joint estimation proceeds from maximizing the likelihood corresponding to this model. Since this likelihood includes expected rather than observed counts, it is termed a pseudo-likelihood. Thus, the procedure includes two steps. In the first step, expected numbers of incident cases and person-time per exposure and stratum are calculated. Then, the parameters of interest (i.e., stratum-specific baseline incidence rates and hazard ratios) are estimated from these expected counts through maximizing a pseudo-likelihood. This approach is easy to implement, as was illustrated on population-based case-control data of bladder cancer.

Example 4.2. (Continued)
Among white males aged 45–64 years and in all other strata separately, observed proportions of cases (respectively controls) with given joint level of smoking and occupational exposure among the eight (four times two) joint levels considered were applied to counts of incident cases (respectively person-time) to obtain expected counts by stratum and joint exposure level. Namely, the products of the counts by the observed proportions were formed. Using these expected counts, a pseudo-likelihood based on the piecewise exponential model was maximized yielding estimates of relative hazards and stratum-specific baseline incidence rates. For instance, the baseline incidence rate for white males aged 45–64 years in Utah was estimated at 13.7 per 10^5 person-years, and relative hazards for current heavy smoking and occupational exposure were estimated at 2.9 and 1.5, respectively. Hence, among white males aged 45–64 years in Utah, exposure-specific incidence rates were estimated at $13.7 \times 1.5 = 20.6$ per 10^5 person-years for never smokers with a history of occupational exposure and $13.7 \times 2.9 \times 1.5 = 61.9$ per 10^5 person-years for current heavy smokers with a history of occupational exposure, still assuming a multiplicative effect of smoking and occupational exposure (and allowing for rounding error).

A full likelihood approach has also been proposed based on the piecewise exponential model (Benichou and Wacholder 1994). All parameters (i.e., baseline rates, hazard ratios, and conditional probabilities for the distribution of exposure in the cases and controls) are estimated jointly through maximizing a likelihood involving all parameters. This approach may prove intractable in practice except in simple situations with few exposure levels considered. A full likelihood approach based on the logistic model (Greenland 1981) appears much easier to implement. Baseline incidence rates are obtained by simply adding to the stratum parameter estimates from the logistic model a term corresponding to the logarithm of the ratio of sampling fractions among cases and controls in the stratum (Greenland 1981; Prentice and Pyke 1979; also similar to discussion of Eq. 4.11 in Sect. 4.4.6.3).

Example 4.2. (Continued)
Although it required the estimation of 60 additional parameters relative to the pseudo-likelihood approach, the full likelihood approach based on the piecewise exponential model could be implemented. The 60 additional parameters described the conditional probabilities of exposure (smoking and occupational exposure) in the cases and controls for all nine strata. For instance, the baseline incidence rate for white males aged 45–64 years in Utah

was estimated at 13.9 per 10^5 person-years, and relative hazards for current heavy smoking and occupational exposure were estimated at 2.9 and 1.6, respectively. Hence, among white males aged 45–64 years in Utah, exposure-specific incidence rates were estimated at $13.9 \times 1.6 = 22.2$ per 10^5 person-years for never smokers with a history of occupational exposure and $13.9 \times 2.9 \times 1.6 = 64.1$ per 10^5 person-years for current heavy smokers with a history of occupational exposure still assuming a multiplicative effect of smoking and occupational exposure (and allowing for rounding error).

Upon comparing the pseudo-likelihood, full likelihood and hybrid approach on population-based case-control data of bladder cancer, Benichou and Wacholder (1994) noted that the hybrid approach seemed to be less efficient for incidence rate estimation than the other two approaches, which were themselves equally efficient. They discussed other advantages of the pseudo-likelihood and full likelihood approaches. Namely, these approaches allow direct estimation of hazard ratios rather than odds ratios. Furthermore, the pseudo-likelihood approach and the full likelihood approach (in its version relying on the piecewise exponential model) can be applied to more general regression models, e.g., models with an additive form using hazard rate difference parameters rather than hazard ratio parameters (see Sects. 4.4.4 and 4.4.6.4). Finally, all three approaches require that cases and controls be selected completely at random and that incident cases or at least a known proportion of them (i.e., known sampling fraction) be fully identified.

4.3.8.3 Semi-Parametric Approach

In nested case-control studies, controls are usually individually matched to cases on time. Namely, for each case, one (or several) control(s) is (are) selected among subjects with the same age and length of follow-up in the cohort as the case (Breslow et al. 1983; Liddell et al. 1977; Mantel 1973; see also chapter ▸Modern Epidemiological Study Designs of this handbook).

The three parametric approaches described in Sects. 4.3.8.1 and 4.3.8.2 do not apply readily to this context of individual time matching of controls to cases. Langholz and Borgan (1997) developed a semi-parametric approach to handle this case. Their approach can be regarded as an extension of the semi-parametric approach for cohort studies described above (see Sect. 4.3.7.2). Incidence rates are expressed as the product of baseline incidence rates of an unspecified form times a function of the covariates representing the hazard ratio (Cox 1972). Hazard ratio parameter estimates are obtained from maximizing the partial likelihood of the Cox model for nested case-control data (Oakes 1981; Prentice and Breslow 1978). Risk estimates are obtained by combining partial likelihood hazard ratio parameter estimates and corresponding cumulative hazard estimates.

A direct comparison of the semi-parametric approach with the parametric approaches presented in Sects. 4.3.8.1 and 4.3.8.2 is not possible because the semi-parametric approach applies only to time-matched data, which the parametric approaches cannot handle. The semi-parametric approach requires observation of individual follow-up time of each subject in the original cohort in order to form the risk sets for each failure time and enable control selection. It is therefore potentially less widely applicable than the parametric approaches.

4.3.9 Final Notes and Additional References

General problems of definition of disease risk, interpretation and usefulness, properties, estimation, and special problems have been reviewed in detail (Benichou 2000a). Special problems include accounting for continuous or time-dependent exposure, estimation of disease risk from two-stage case-control data, and validation procedures for disease risk estimates. Finally, an important challenge is to increase awareness of the proper interpretation and use of disease risk in practice and develop general software for easier implementation.

4.4 Measures of Association

4.4.1 Definitions and General Points

Measures of association have a long history and have been reviewed in many textbooks. They assess the strength of associations between one or several exposures and the risk of developing a given disease. Thus, they are useful in etiological research to assess and quantify associations between potential risk (or protective) factors and disease risk. The question addressed is whether and to what degree a given exposure is associated with occurrence of the disease of interest. In fact, this is the primary question that most epidemiological studies are trying to answer.

Depending on the available data, measures of association may be based on disease rates, disease risks, or even disease odds, i.e., $\pi/(1-\pi)$, with π denoting disease risk. They contrast rates, risks, or odds for subjects with various levels of exposure, e.g., risks or rates of developing breast cancer for 40-year-old women with or without a personal history of benign breast disease. They can be expressed in terms of ratios or differences of risks or rates among subjects exposed and non-exposed to given factors or among subjects with various levels of exposure.

Measures of association can be defined for categorical or continuous exposures. For categorical exposures, any two exposure levels can be contrasted using the measures of association defined below. However, it is convenient to define a reference level to which any exposure level can be contrasted. This choice is sometimes natural (e.g., non-smokers in assessing the association of smoking with disease occurrence) but can be more problematic if the exposure considered is of continuous nature, where a range of low exposures may be considered potentially inconsequential. The choice of a reference range is important for interpreting results. It should be wide enough for estimates of measures of association to be reasonably precise. However, it should not be so wide that it compromises meaningful interpretation of the results, which depend critically on the homogeneity of the reference level. For continuous exposures, measures of association can also be expressed per unit of exposure, e.g., for each additional gram of daily alcohol consumption. The reference level may then be a precise value such as no daily alcohol consumption or a range of values such as less than 10 g of daily alcohol consumption.

4.4.2 Usefulness and Interpretation

When computing a measure of association, it is usually assumed that the relationship being captured has the potential to be causal and efforts are taken to remove the impact of confounders from the quantity. Section 4.4.6 provides a summary of techniques for adjustment for confounders. Nonetheless, except for the special case of randomized studies, most investigators retain the word "association" rather than "effect" when describing the relationship between exposure and outcome to emphasize the possibility that unknown confounders may still influence the relationship.

Rothman and Greenland (chapter ▶Basic Concepts of this handbook) take efforts to differentiate the concepts of effect and association, and adopt the framework of *counterfactuals*, popular in the field of economics (Wooldridge 2001), to define the term *effect size*. They then define "measure of association" as computed to compare two actual populations. Hence, the distinction is one of a true causal concept versus one that may be subject to the confounding of the true effect arising from the population mix of characteristics at hand. These definitions are more precise and serve as reminders of the true nature of causality. We will retain the less precise but more common terminology where "measure of association" refers to either or both concepts. We also note that the discussion here is limited to measures of association with a *binary* (i.e., coded as 1 = present, 0 = absent) or event *count* (number of events) outcome. In many situations, classification into disease versus no disease is not clear-cut. For example, the definition of an abnormal lipid profile has undergone frequent change. In such cases, using measures based on continuous outcomes may be a better choice. We comment on relationships between measures of association for continuous and categorical outcomes in Sect. 4.4.6.2.

When choosing a measure of association, the primary goal is interpretability and familiarity to consumers of the information. Another guideline is that the measure of association should allow as simple a description of the association as possible. For example, it has been empirically observed that risk ratios are more likely than risk differences to remain constant across subpopulations with different risk levels (Breslow and Day 1980, Chap. 2), hence simplifying description of the association of the exposure with the outcome. Breslow and Day (1980, Chap. 2), also point out that ratios can be converted to differences by taking the logarithm of the risk or rate.

Definitions and properties of measures of association as well as relations among them are reviewed below for measures based on ratios and measures based on differences. Then, estimability of these measures from cohort and case-control designs and general points regarding estimation of these measures are considered, including an overview of techniques to adjust for confounders. More details regarding inference, namely, estimating these measures and assessing the statistical

Table 4.1 Measures of association discussed in this chapter (GLM = generalized linear model; see Sect. 4.4.6)

Measure	Lower limit	Upper limit	Null value	Definition	Link function in GLM
Rate ratio (*HR*)	0	$+\infty$	1	$h_E/h_{\bar{E}}$	Log
Risk ratio (*RR*)	0	$+\infty$	1	$\pi_E/\pi_{\bar{E}}$	Log
Odds ratio (*OR*)	0	$+\infty$	1	$[\pi_E/(1\text{-}\ \pi_E)]/[\pi_{\bar{E}}\ /(1\text{-}\pi_{\bar{E}})]$	Logit
Rate difference	$-\infty$	$+\infty$	0	$h_E - h_{\bar{E}}$	Identity
Risk difference	-1	$+1$	0	$\pi_E\text{-}\ \pi_{\bar{E}}$	Identity

significance of apparent associations, will be presented in Part III (Statistical Methods in Epidemiology) of this handbook.

The above Table 4.1 provides an overview of measures of association discussed in this chapter.

4.4.3 Measures Based on Ratios

4.4.3.1 General Properties

Ratio-based measures of association are particularly appropriate when the effect of the exposure is multiplicative, which means there is a similar percent increase or decrease associated with exposure in rate, risk, or odds across exposure subgroups. As noted above, effects have often been observed to be multiplicative, leading to ratios providing a simple description of the association (e.g., see Breslow and Day 1980, Chap. 2). Ratio measures are dimensionless and range from zero to infinity, with one designating no association of the exposure with the outcome. When the outcome is death or disease, and the ratio has the rate, risk or odds of the outcome with the exposed group in the numerator, a value less than one indicates a protective effect of exposure. The exposure is then referred to as a protective factor. When the ratio in this setup is greater than one, there is greater disease occurrence with exposure, and the exposure is then referred to as a risk factor.

It can be shown that numerically, the odds ratio falls the furthest from the null, and the risk ratio the closest, with the rate ratio in between. For example, from the below Table 4.2, based on a fictitious data from a cohort study for a disease that is not rare, we would obtain a risk ratio $\widehat{RR} = 0.3/0.1 = 3.00$ and an odds ratio $\widehat{OR} = [(30)(90)]/[(10)(70)] = 3.86$. If we assume a constant hazard rate, so that the risk for each group is $1 - \exp(-hT)$, with T being the follow-up time for each subject, we have the rate ratio $\widehat{HR} = \ln(1-0.3)/\ln(1-0.1) = 3.39$ (calculations described in Sect. 4.4.6.1). Hence, $1 < \widehat{RR} < \widehat{HR} < \widehat{OR}$.

The difference in magnitude between the above ratio measures is important to keep in mind when interpreting them for diseases or outcomes that are not rare. For rare outcomes, the values of the three ratio measures tend to be close. Ratios become differences on the logarithmic scale, and estimation and inference often take place on the log scale, where zero indicates no association.

Table 4.2 Data from fictitious cohort study

	Exposed	Unexposed
Diseased	30	10
Non-diseased	70	90

4.4.3.2 Rate Ratios

As the name implies, the rate ratio is the ratio between the rate of disease among those exposed and those not exposed or $h_E/h_{\bar{E}}$. Conceptually, the rate ratio is identical to a hazard ratio HR. The latter term tends to be used when time dependence of the rate is emphasized, as the hazard rate is a function that may depend on time. The situation of a constant rate ratio over time is referred to as *proportional hazards*. The proportional hazard assumption is often made in the analysis of rates (see below). Theoretically, the hazard ratio at a given time point is the limiting value of the rate ratio as the time interval around the point becomes very short, just as the hazard rate is the limiting quantity for incidence rate (see Sect. 4.2). The rate ratio has also been called the *Incidence Density Ratio* (Kleinbaum et al. 1982, Chap. 8). It may be noted that the rate ratio is attenuated by less than perfect specificity of the outcome criteria, but relatively unaffected by less than perfect sensitivity, especially when the rate is low, as long as the sensitivity is unaffected by exposure. In other words, if cases are equally missed in the exposed and unexposed groups, the rate ratio is relatively unaffected. However, if non-cases are considered cases, the ratio will be lower than if diagnostic criteria identified only true cases. Even in the fictitious example above with high incidence rates, 80% sensitivity leads to a slightly attenuated rate ratio of 3.29 from

$$\widehat{HR} = \ln[1 - (0.80)(0.3)]/\ln[1 - (0.80)(0.1)) = 3.29$$

(as compared to the correct rate ratio of 3.39 from Table 4.2), while 80% specificity leads to a severely biased rate ratio of

$$\widehat{HR} = \ln[0.80(1 - 0.3)]/\ln[0.80(1 - 0.1)] = 1.77.$$

Rate ratios are extremely useful because of the ease of estimating them in many contexts. They refer to population dynamics, and are not as easily interpretable on the individual level. It has been argued, however, that rate ratios make more sense than risk ratios (see Sect. 4.4.3.3) when the period subjects are at risk is longer than the observation period (Kleinbaum et al. 1982, Chap. 8). Numerically, the rate ratio is further from the null than the risk ratio. When rates are low, the similarity of risk and rate leads to rate ratios being close to risk ratios, as discussed in Sect. 4.4.3.3. Some investigators tend to refer to rate ratios as relative risks, creating some confusion in terminology. Further considerations of how the rate ratio relates to other ratio-based measures of association are offered by Rothman and Greenland (1998, p. 50).

4.4.3.3 Risk Ratios

The risk ratio, relative risk, or ratio of risks of disease among those exposed π_E and those not exposed $\pi_{\bar{E}}$, $RR = \pi_E/\pi_{\bar{E}}$, has been viewed as the gold standard among measures of association for many years. It is eminently interpretable on the individual level as a given-fold increase in risk of disease. Like other ratio-based measures, it tends to be more stable than the risk difference across population groups at widely different risk. However, similar to rate ratios and odds ratios (introduced in Sect. 4.4.3.4), the risk ratio can be viewed as misleading in the public eye when the risk among both the unexposed and the exposed is very low, yet many-fold increased by exposure. Another disadvantage of the risk ratio is its asymmetry with respect to the definition of an event, so that the risk ratio for not having an event, $(1 - \pi_E)/(1 - \pi_{\bar{E}})$, cannot be directly computed from the risk ratio for having an event. For example, knowing that the risk ratio for an event $RR = 3.00$, the scenario $\pi_E = 0.3$, $\pi_{\bar{E}} = 0.1$ results in $(1 - \pi_E)/(1 - \pi_{\bar{E}}) = 0.7/0.9 = 0.78$, while the scenario $\pi_E = 0.6$, $\pi_{\bar{E}} = 0.2$, which represents the same risk ratio of 3.00, results in $(1-\pi_E)/(1-\pi_{\bar{E}}) = 0.4/0.8 = 0.50$. The risk ratio depends on the length of the time interval considered because risk itself refers to a specific interval (see Sect. 4.3). In the literature, the term relative risk is often used to denote the rate ratio as well as the risk ratio, creating some confusion. Therefore, we will avoid the term "relative risk" in the following. Numerically, the risk ratio is closer to the null than the rate ratio for the same data (see Sect. 4.4.3.1).

Cornfield et al. (1959), in the smoking versus lung cancer debate, derived several theoretical properties of the risk ratio, which have further supported its use. In this debate, Cornfield, along with Doll and Hill, argued against strong opposition from R.A. Fisher and Joseph Berkson that the association was causal and not likely due to unmeasured confounders, such as a genetic predisposition to both smoke and contract lung cancer. First of all, Cornfield et al. (1959) turned attenuation of the risk ratio due to lack of specificity of the outcome into an advantage, by noting that the ratio will become stronger as the disease subtype affected by the exposure is honed. Second, Cornfield et al. demonstrated that if a confounder is to explain the outcome with exposure risk ratio $RR > 1$, that confounder has to have risk ratio at least *RR*, and in addition, the prevalence of the confounder must be at least *RR* times greater among the exposed than among the unexposed. Lin et al. (1998) presented more general formulas that confirm Cornfield et al.'s assertions under assumptions of no interaction between the confounder and exposure. These theoretical results have led investigators to reason that high risk ratios (say above 1.4; Siemiatycki et al. 1988) are not likely to be explained by uncontrolled confounding.

4.4.3.4 Odds Ratios

For several reasons, the odds ratio has emerged as the most popular measure of association. The odds ratio is the ratio of odds, $OR = [\pi_E/(1 - \pi_E)]/[\pi_{\bar{E}}/(1 - \pi_{\bar{E}})]$. Historically, the odds ratio was considered an approximation to the risk ratio obtainable from case-control studies. The reason for this is that the probabilities of being sampled into case and control groups cancel in the calculation of the odds ratio, as long as sampling is independent of exposure status. Furthermore, when π_E and $\pi_{\bar{E}}$ are small, the ratio $(1 - \pi_{\bar{E}})/(1 - \pi_E)$ has little influence on the odds ratio, making it approximately equal to the risk ratio $\pi_E/\pi_{\bar{E}}$. The assumption of small π_E and $\pi_{\bar{E}}$ is referred to as the *rare-disease assumption.* Kleinbaum et al. (1982) have pointed out that in a case-control study of a stable population with incident cases and controls being representative of non-cases, the odds ratio is the rate ratio. Numerically, the odds ratio is the furthest from the null of the three ratio measures considered here.

More recently, the odds ratio has gained status as an association measure in its own right and is often applied in cohort studies and clinical trials, as well as in case-control studies. This is due to many desirable properties of the odds ratio. First of all, focusing on risk rather than odds may be a matter of convention rather than a preference based on fundamental principles, and using the same measure across settings has the advantage of consistency and makes comparisons and meta-analyses easy. In contrast to the risk ratio, the odds ratio is symmetric so that the odds ratio for disease is the inverse of the odds ratio for no disease. Furthermore, the odds ratio based on exposure probabilities equals the odds ratio based on disease probabilities, a fact that follows from Bayes' theorem (e.g., Cornfield 1951; Miettinen 1974; Neutra and Drolette 1978) or directly from consideration of how cases and controls are sampled. The disease and exposure odds ratios are sometimes referred to as *prospective* and *retrospective odds ratios*, respectively. Finally, odds ratios from both case-control and cohort studies are estimable by logistic regression, which has become the most popular approach to regression analysis with binary outcomes (see Sect. 4.4.6.3).

Some investigators feel that the risk ratio is more directly interpretable than the odds ratio and have developed methods for converting odds ratios into risk ratios for situations when risks are not low (Zhang and Yu 1998).

One disadvantage of odds ratios is that the crude odds ratio differs from an odds ratio conditional on (adjusted for) another factor that is related to the outcome, even when that factor is unrelated to the exposure, i.e. not a confounder (Miettinen and Cook 1981). This problem, referred to as non-collapsibility does not occur for risk ratios and risk differences. Non-collapsibility is related to the modeling considerations of cluster specific and marginal logistic models, and to the well-known difference between matched and unmatched odds ratio estimates, both discussed in Sect. 4.4.6.3.

4.4.4 Measures Based on Differences

4.4.4.1 General Properties

Difference-based measures lead to simple models when effects are additive (e.g., see Breslow and Day 1980, Chap. 2), which means that the exposure leads to a similar absolute increase or decrease in rate or risk across subgroups. The difference in odds is very rarely used and not addressed here. As noted above, additive relationships are less common in practice, except on the logarithmic scale, when they are equivalent to ratio measures. However, difference measures may be more understandable to the public when the outcome is rare, and relate directly to measures of impact discussed below (see Sect. 4.5).

The numerical ranges of difference measures depend on their component parts. The rate difference ranges from minus to plus infinity, while the risk difference is bounded between minus and plus one. The situation of no association is reflected by a difference measure of zero. When the measure is formed as the rate or risk among the exposed minus that among the non-exposed, a positive value indicates that the exposure is a risk factor, while a negative value indicates that it is a protective factor. It can be shown that the risk difference over a given time period falls numerically nearer to the null than does the rate difference expressed per the same period as the unit. For example, Table 4.2 yields a risk difference of $0.30 - 0.10 = 0.20$, while the rate difference is $-\ln(0.70) + \ln(0.90) = 0.25$. However, they will be close for rare outcomes. In contrast to ratio measures, difference measures are always attenuated by less than perfect sensitivity (i.e., missed cases), but the rate difference is unaffected by less than perfect specificity. The risk difference is also relatively unaffected when risk is low. In the fictitious example above, if the sensitivity of the test used to detect disease is 80%, the rate difference is $-\ln[1 - (0.80)(0.3)] + \ln[1 - (0.80)(0.1)] = 0.19$, but if the specificity is 80%, the rate difference remains at 0.25.

4.4.4.2 Rate Differences

The rate difference is defined as $h_E - h_{\bar{E}}$ and has been commonly employed to compare mortality rates and other demographic rates between countries, time periods, and/or regions. In such comparisons, the two rates being compared are often *directly standardized* (see Sect. 4.6) to the age and sex distribution of a standard population chosen, e.g., as the population of a given country in a given census year.

For the special case of a dichotomous exposure, the rate difference, i.e., the difference between the incidence rates in the exposed and unexposed subjects has been termed “excess incidence” (Berkson 1958; MacMahon and Pugh 1970; Mausner and Bahn 1974), “excess risk” (Schlesselman 1982), “Berkson’s simple difference” (Walter 1976), “incidence density difference” (Miettinen 1976), or even “attributable risk” (Markush 1977; Schlesselman 1982), which may have caused some confusion.

4.4.4.3 Risk Differences

The risk difference $\pi_E - \pi_{\bar{E}}$ is parallel to the rate difference discussed in Sect. 4.4.4.2, and similar considerations apply. Due to the upper and lower limits of plus, minus one on risk, but not on rate, risk differences are more difficult to model than rate differences.

4.4.5 Estimability

Because exposure-specific incidence rates and risks can be obtained from cohort data, all measures of association considered (based on ratios or differences) can be obtained as well. This is also true of case-control data complemented by follow-up or population data (see Sects. 4.2 and 4.3). Case-control data alone allow estimation of odds ratios thanks to the identity between disease and exposure odds ratios (see Sect. 4.4.3.4) that extends to the logistic regression framework. Prentice and Pyke 1979 showed that the unconditional logistic model (see also Breslow and Day 1980, Chap. 6) applies to case-control data as long as the intercept is disregarded (see Sect. 4.4.6.3). Interestingly, time-matched case-control studies allow estimation of hazard rates (e.g., see Miettinen 1976; Greenland and Thomas 1982; Prentice and Breslow 1978).

4.4.6 Estimation

The most popular measures of association have a long history of methods for estimation and statistical inference. Some traditional approaches have the advantage of being applicable in small samples. Traditional methods adjust for confounders by *direct standardization* (see Sect. 4.6.1) of the rates or risks involved, prior to computation of the measure of association, or by *stratification*, where association measures are computed separately for subgroups and then combined. For measures based on the difference of rates or risks, direct standardization and stratification can be identical, if the same weights are chosen (Kahn and Sempos 1989). Generally, however, direct standardization uses predetermined weights chosen for external validity, while *optimal* or *efficient* weights are chosen with stratification. Efficient weights make the standard error of the combined estimator as small as possible. *Regression adjustment* is a form of stratification, which provides more flexibility, but most often relies on large sample size for inference.

In modern epidemiology, measures of association are most often estimated from regression analysis. Such methods tend to require large sample sizes, in particular when based on *generalized linear models* (often abbreviated *GLM*). In this context, the ratio, difference, or other association measures arise from the regression coefficient of the exposure indicator, and different measures of association result depending on the transformation applied to the mean of the outcome variable. Note that the mean of an event count over a unit time interval is the rate, and the mean of a binary outcome is the risk. For example, a model may use the logarithm of the rate ($\ln(h)$) or risk ($\ln(\pi)$) as the outcome to be able to estimate ratio measures of association.

The function applied to the rate or risk in a regression analysis is referred to as the *link function* in the framework of generalized linear models underlying such analyses (see McCullagh and Nelder (1989) and Palta (2003) for theory and practical application). For example, linear regression would regress the risk or rate directly on exposure without any transformation, which is referred to as using the *identity link*. When the exposure is the only predictor in such a model, all link functions fit equally well and simply represent different ways to characterize the association. However, when several exposures or confounders are involved, or if the exposure is measured as a continuous or ordinal variable, some link functions and not others may require interaction or non-linear terms to improve the fit. The considerations in choosing the link function parallel those for choosing a measure of association as multiplicative or additive and as computed from rates, risks, or odds, discussed above (see Table 4.1).

Both traditional and regression estimation is briefly overviewed below, with more details provided in chapters ▸Regression Methods for Epidemiological Analysis and ▸Survival Analysis of this handbook.

4.4.6.1 Estimation and Adjustment for Confounding of Rate Ratios

Estimation of the rate or hazard ratio between exposed and non-exposed individuals can be based either on event counts (overall or in subgroups and/or subintervals of time) or on the time to event for each individual, where the time for subjects without events are entered as time to end of follow-up and are referred to as being *censored* (see chapter ▸Survival Analysis of this handbook).

In the first case, estimation can proceed directly by forming ratios of interest or by modeling the number of events on exposure by a generalized linear model. When ratios are formed directly as the ratio of the number of cases D_E divided by the person time at risk t_E, i.e., D_E/t_E, in those exposed and $D_{\bar{E}}/t_{\bar{E}}$ in those unexposed, the 95% confidence interval of the resulting rate ratio $HR = D_E/t_E/D_{\bar{E}}/t_{\bar{E}}$ is obtained as (Rothman and Greenland 1998, page 238)

$$[\exp(\ln(\widehat{HR}) - 1.96(1/D_E + 1/D_{\bar{E}})^{1/2}), \exp(\ln(\widehat{\mathrm{HR}}) + 1.96(1/D_E + 1/D_{\bar{E}})^{1/2})].$$

In either case, it is often necessary to adjust for confounding factors, including age and sex. When rate ratios are formed directly, the rates are generally adjusted by direct standardization (see Sect. 4.6.1) or by use of the *standardized mortality (*or *morbidity* or *incidence) ratio SMR* or *SIR* (see Sect. 4.6.1). The SMR and SIR have found wide application in investigations of the potential health effects of occupational exposures.

A common regression approach to estimating rate ratios requires information on event count and person time at risk for each subgroup, time interval and exposure level of interest. To obtain rate ratios from the regression requires that the logarithm of the mean number of events be modeled. This is referred to in the generalized linear model framework as using a *log link* function. The resulting regression equation is

$$\ln(h_i) = -\ln(t_i) + \beta_0 + \beta_E E_i + \beta_1 X_{1i} + \beta_2 X_{2i} + \ldots \qquad (4.8)$$

where the subscript i indicates subject, $i = 1, \ldots. n$, and E_i is an indicator that equals 0 for the unexposed and 1 for the exposed. In this equation, β_0 is the logarithm of the rate per time unit for the unexposed with confounder values, $X_1, X_2, \ldots = 0$. Care should be taken to center confounders so that this intercept is meaningful. The quantity $\ln(t_i)$ is referred to as the offset and allows event counts over different size denominators to be used as the outcome variable. In the case when disease rates in a population are modeled, t_i are population sizes. The rate ratio for exposure adjusted for confounders $X_1, X_2, \ldots$ is obtained as exp (β_E). Differences in rate ratios across levels of X can easily be accommodated by the inclusion of interaction terms in the model. Inferences on the rate ratio follow from the standard error of the estimate $\hat{\beta}_E$ of β_E, which is approximately normally distributed with reasonable large sample sizes, so that a 95% confidence interval for the rate ratio is

$$\left[\exp\left(\hat{\beta}_E - 1.96\text{se}(\hat{\beta}_E)\right); \left(\exp(\hat{\beta}_E + 1.96\text{se}(\hat{\beta}_E)\right)\right].$$

The standard errors se$(\hat{\beta}_E)$ can be obtained from maximum-likelihood theory, assuming that the counts follow a *Poisson* or *negative binomial distribution.* The variance of the Poisson distribution equals the rate, while the negative binomial distribution allows for the variance being larger than the rate.

There are also several approaches available in most statistical software packages to adjust standard errors for so-called overdispersion. Overdispersion refers to variability in rates being larger than expected from a Poisson count process. For example, events may cluster in time, or there may be unmeasured characteristics of the population influencing the rate, so that the overall count arises from a mixture of different rates. An example of overdispersion (Palta 2003) arises in overall cancer rates because different cancers predominate for different ages and genders. One of the approaches to adjusting for overdispersion is to use a *robust* or *sandwich* estimator of the standard error of $\hat{\beta}_E$ available in software packages, such as PROC GENMOD in SAS (1999) that fit *generalized estimating equations* (Liang and Zeger 1986).

When the data consist of times to event for individuals, the rate ratio or hazard ratio can be estimated by techniques designed for *survival analysis* (e.g., see Hosmer and Lemeshow 1999 and chapter ▸Survival Analysis of this handbook).

Most parametrically specified survival distributions (i.e., distributions $S(t) = 1 - F(t)$, where F is the distribution of time to event) lead to hazard ratios $h_E(t)/h_{\bar{E}}(t)$ that vary over time. When the hazard ratio remains constant, this is referred to as proportional hazards. This property holds when the time to event follows the *exponential distribution*, so that the probability of avoiding an event up to time t is given by $S(t) = \exp(-ht)$ where h is a constant hazard rate and for the *Weibull distribution* $S(t) = \exp[(-ht)^{\gamma}]$ as long as γ is the same for the exposed and non-exposed groups. Models are sometimes fit that assume that the exponential distribution holds over short intervals, i.e., piecewise constant hazard rate. In these models, the hazard ratio is constant across short intervals but can be allowed to change over time. An exponential distribution for time to event leads to the Poisson distribution for number of events in a given time period.

In the situation of proportional hazards, estimation of the hazard ratio can proceed without specifying the actual survival distribution via the *Cox model*, where estimation is based on so-called partial likelihood (Cox 1972). The reason this works is that the actual level of the hazard rate cancels out; similarly to how the offset becomes part of the intercept in the regression model given by Eq. 4.8 above.

Table 4.3 Notation for a generic 2 × 2 table from cohort or case-control study

	Exposed	Unexposed
Diseased	a	b
Non-diseased	c	d

4.4.6.2 Estimation and Adjustment for Confounding for Risk Ratios

In a cohort study with a fixed follow-up time, the risk ratio can be estimated in a straightforward manner. From a 2×2 table (see Table 4.3) with cells *a, b, c, d,* where a is the number diseased and exposed, b is the number diseased and unexposed, c the number non-diseased and exposed, and d the number non-diseased and unexposed, the risk ratio is estimated by $\widehat{RR} = \{a/(a + c)\}/\{b/(b + d)\}$.

Statistical inference can be based on the approximate standard error (Katz et al. 1978) which can be estimated as $\mathrm{se}(\ln(\widehat{RR})) = \{a/(a+c)+d/b(b+d)\}^{1/2}$. In cases where follow-up time is not fixed, the risk ratio can be calculated from the individual risks estimated from the incidence rate or hazard rate. However, this is rarely done, as investigators tend to prefer the hazard ratio as the measure of association in such situations. The risk ratio can be estimated from case-control studies only when the ratio of sampling probabilities of cases and controls is known or by using the odds ratio (see Sect. 4.4.6.3) as an approximation.

Although standardization can be used either as direct standardization to adjust risks before forming ratios or as indirect standardization to compute the SMR (see Sect. 4.6.1) from risks in a reference population, it is often more appropriate to apply stratified analyses to adjust the risk ratio for confounders (see also Sect. 4.6.1). For example, a study of cancer risk in individuals exposed or not exposed to a risk factor may be stratified into age groups, or a study investigating outcomes in neonates may be stratified by birth weight. Stratum-specific risk ratio estimates can be calculated and then be combined for instance by the popular Mantel–Haenszel estimator that is known to have good properties. It is given by

$$\widehat{RR}_{\mathrm{MH}} = \sum (a_i(b_i + d_i)/n_i) \Big/ \sum (b_i(a_i + c_i)/n_i),$$

where the sums are across strata and n_i is the number of subjects in stratum i. This estimator is stable in small samples but has a larger standard error than the corresponding estimator from regression modeling. Formulas for the standard error are provided by Breslow and Day (1987) and Rothman and Greenland (1998).

From regression analysis, the risk ratio can be obtained as $\exp(\beta_E)$ from fitting the binary or *binomial* (grouped binary events) outcome to the model:

$$\ln(\pi_i) = \beta_0 + \beta_E E_i + \beta_1 X_{1i} + \ldots \tag{4.9}$$

This is a generalized linear model with error distribution reflecting each binary outcome being independent with variance $\pi_i(1 - \pi_i)$ and log link. Clearly, the log link is not ideal, as $\pi_i > 1$ can result from some exposure-confounder combinations. Nonetheless, this model tends to be reasonable with low risks. Maximum likelihood or generalized estimating equation fitting automatically provides large sample inference, with or without adjustment for deviations from the binomial error structure by robust standard errors. Deviations from binomial structure may result from clustering or correlation between events within subgroups or from multiple events per person (e.g., cavities in teeth when teeth are individually counted).

Another option for the link function when modeling the risk by a generalized linear model is the so-called complementary log-log link resulting in the model:

$$\ln(-\ln(1-\pi_i)) = \beta_0 + \beta_E E_i + \beta_1 X_{1i} + \ldots . \tag{4.10}$$

This model has the advantage of always estimating risks to be in the range 0–1. However, $\exp(\beta_E)$ is the rate ratio rather than the risk ratio.

4.4.6.3 Estimation and Adjustment for Confounding for Odds Ratios

In the traditional setting, the odds ratio in an unmatched case-control or cohort study is estimated from a 2×2 table (see Table 4.3) as $\widehat{OR} = ad/bc$. Inference can be based on exact methods, which historically were difficult to implement, but are now available in most statistical software packages, such as the SAS procedure PROC FREQ. With the exact approach, the confidence interval for the odds ratio is obtained from the *non-central hypergeometric distribution*. Over the years, many approximations to this interval have been developed, the most accurate of which is the *Cornfield approximation* (Cornfield 1956). Another, less accurate method is based on the approximate standard error of $\ln(\widehat{OR})$ known as the Woolf (1955) or *logit method*, where $\text{se}(\ln(\widehat{OR}))$ is calculated as $(1/a + 1/b + 1/c + 1/d)^{1/2}$. The logit method takes its name from being related to an approximation used for fitting logistic regression. Although the approximation has limited use for reporting final study results, it is useful to have an explicit approximation of the standard error for study planning purposes.

Stratified methods for estimating the odds ratio either build on taking a weighted average of the stratum specific log odds ratios, using the inverses of the logit method standard errors for each stratum as the weights, or using the Mantel-Haenszel stratified odds ratio estimator (Mantel and Haenszel 1959),

$$\widehat{OR}_{\text{MH}} = \left(\sum a_i c_i / n_i\right) \Big/ \left(\sum b_i d_i / n_i\right),$$

where the sums are across strata with tables as depicted in Table 4.3 for each stratum and n_i is the number of subjects in stratum i. This odds ratio estimator has been shown to have excellent properties even when strata are very small (Birch 1964; Breslow 1981; Breslow and Day 1980, Chaps. 4–5; Landis et al. 1978, 2000; Greenland 1987; Robins and Greenland 1989). The confidence interval for a stratified odds ratio can be obtained by exact methods or by the approximation of Miettinen (1976) where $\text{se}(\ln(\widehat{OR}))$ is calculated as $\ln(\widehat{OR}_{\text{MH}})/\chi_{\text{MH}}$. Here χ_{MH} is the square root of the *Mantel–Haenszel stratified chi-square test* used to test the null hypothesis that the odds ratio equals one (Mantel and Haenszel 1959). This test statistic is computed as

$$\chi^2_{\mathrm{MH}} = \Sigma[a_i - (a_i + b_i)(a_i + c_i)/n_i]^2/[(a_i + b_i)(a_i + c_i)(d_i + b_i)(d_i + c_i)/(n_i^2(n_i - 1))].$$

The 95% confidence interval for the odds ratio is then given by

$$[\exp(\ln(\widehat{OR}) - 1.96(\ln(\widehat{OR}_{\mathrm{MH}})/\chi_{\mathrm{MH}}), \exp(\ln(\widehat{OR}) + 1.96(\ln(\widehat{OR}_{\mathrm{MH}})/\chi_{\mathrm{MH}}))].$$

A special case of stratification occurs when data are pair matched, such that each case is matched to a control, e.g., based on kinship or neighborhood. In this case, the Mantel–Haenszel odds ratio estimator becomes m_{++}/m_{--} , where m_{++} is the number of pairs (matched sets) where both the case and the control are exposed, and m_{--} is the number of pairs where neither is exposed. Breslow and Day (1980, Chap. 7) provide additional formulas for the situation when several controls are matched to each case. Confidence intervals can again be obtained by exact formulas (Breslow and Day 1980, Chap. 7). It is well known that although matched studies are not technically confounded by the factors matched on because cases and controls are balanced on these, odds ratios based on the matched formula are larger than odds ratios not taking the matching into account. This is an example of the point made above regarding the non-collapsibility of odds ratios in Sect. 4.4.3.4. We discuss this phenomenon further in the logistic model framework below.

Increasingly, logistic regression is used for the estimation of odds ratios from clinical trials, cohort and case-control studies. Logistic regression fits the equation

$$\ln(\pi_i/(1 - \pi_i)) = \beta_0 + \beta_E E_i + \beta_1 X_{1i} + \ldots \tag{4.11}$$

with E_i denoting the exposure status and X_{1i}, $X_{2i}, \ldots$ the confounder variables of individual i. For a cohort study, β_0 is $\ln(\pi_i/(1 - \pi_\iota))$ for an unexposed individual with all confounders equal to 0. For such a person, then, the risk of disease $\pi_i = \exp(\beta_0)/[1 + \exp(\beta_0)]$. In a case-control study, the intercept in Eq. 4.11 is $\beta_0 = \beta_{0,\mathrm{cohort}} + \ln(P_1/P_0)$, with P_1 and P_0 the probabilities for being sampled into the study for cases and controls, respectively. We see again that risk can be estimated from a case-control study only when the sampling scheme of cases and controls is known. The odds ratio for exposure, adjusted for confounders, is $\exp(\beta_E)$.

In the generalized linear model framework, Eq. 4.11 is said to use the *logit link*, where the logit function is defined as $g(\pi) = \ln(\pi/(1 - \pi))$. The logit link is the one that follows most naturally from the mathematical formulation of the binomial distribution (McCullagh and Nelder 1989) and is referred to as the *canonical link*, whereas the log is the canonical link for rates. Just as for other generalized linear models, maximum-likelihood-based and robust standard errors are available, with the latter taking into account clustering of events. It should be noted, however, that generalizations of logistic regression to the longitudinal or clustered setting by generalized estimating equations (GEE) do not work for case-control studies

(Neuhaus and Jewell 1990; for a general introduction to GEE see e.g. chapter ►Generalized Estimating Equations of this handbook).

One point that has received considerable attention for clustered or matched data is the difference in estimated odds ratios between so-called marginal logistic models usually fit via GEE and so-called cluster specific models that explicitly model random intercepts for each cluster or matched set (Neuhaus et al. 1991). This difference is another manifestation of the non-collapsibility of odds ratios, mentioned in Sect. 4.4.3.4, and arises even when there is no confounding by cluster-specific factors (see, e.g., Hanley et al. 2003). Some further insight into this problem can be generated by realizing that logistic regression arises from dichotomizing a continuous underlying latent variable with a logistic distribution (conditional on covariates). The logistic regression coefficients depend on the standard deviation of that continuous latent variable, and the difference between marginal and cluster specific coefficients is a reflection of inherently choosing the dependence to be on overall versus within cluster standard deviations, respectively (Palta et al. 1997; Palta and Lin 1999). General problems of using standard deviation units of outcomes have been pointed out (Greenland et al. 1986) and are inherent and unavoidable in the use of logistic regression for clustered data.

Matched data can also be analyzed by *conditional logistic regression* that fits the model

$$\ln(\pi_{ji}/(1-\pi_{ji})) = \beta_{0j} + \beta_E E_{ji} + \beta_1 X_{1ji} + \ldots \tag{4.12}$$

for individual i in the matched set j. Estimation of β_E and β_1, ... is based on algorithms that compare individuals only within and not between matched sets. For example, for matched pairs, estimation is based on differences in exposure and confounders. Equation 4.12 is a cluster-specific model but differs from random effects models in the fact that the intercepts β_{0j} can reflect true confounders, while intercepts in the random effects models are assumed to be independent of risk factors. The algorithms for conditional logistic regression do not actually estimate the matched set-specific intercepts β_{0j} that cancel out. All variables that do not vary within matched sets are automatically absorbed into β_{0j} although interactions of such variables with those that vary within set can be included in the model. While the conditional logistic regression model is usually fit by large sample methods, such as maximum likelihood, so-called exact procedures have also become available (e.g., Mehta et al. 2000). Again, taking matching into account in the analysis results in larger coefficients than those of the unmatched model (4.11). When all matching variables are explicit (such as age and sex), they can be directly entered as covariates in Eq. 4.11.

4.4.6.4 Estimation and Adjustment for Confounding for Rate Differences

Regression estimation of the rate difference with and without adjustment for confounders can be done in the generalized linear model framework by specifying the identity link function, resulting in linear regression of the rates with variance arising from the Poisson distribution. Overdispersion can be handled the same way as for ratios. However, unequal time intervals cannot be as easily accommodated with the identity link. Instead, weighted ordinary regression of observed rates can be employed, where inverse variance weights automatically account for the interval length (Breslow and Day 1987, Chap. 4).

4.5 Measures of Impact

Measures of impact are used to assess the contribution of one or several exposures to the occurrence of incident cases at the population level. Thus, they are useful in public health to weigh the impact of exposure on the burden of disease occurrence and assess potential prevention programs aimed at reducing or eliminating exposure in the population. They are sometimes referred to as measures of *potential* impact to convey the notion that the true impact at the population level may be different from that reflected by these measures except under very specific conditions (see Sect. 4.5.1.4). The most commonly used measure of impact is the attributable risk. This measure is presented in some detail below. Then, other measures are briefly described. Table 4.4 provides an overview of measures of impact discussed in this chapter.

4.5.1 Attributable Risk

4.5.1.1 Definition

The term "attributable risk" (*AR*) was initially introduced by Levin in 1953 as a measure to quantify the impact of smoking on lung cancer occurrence. Gradually, it has become a widely used measure to assess the consequences of an association between an exposure and a disease at the population level. It is defined as the following ratio:

$$AR = \{\Pr(D) - \Pr(D|\overline{E})\}/\Pr(D). \tag{4.13}$$

The numerator contrasts the probability of disease, $\Pr(D)$, in the population, which may have some exposed, E, and some unexposed, $\overline{E}$, individuals, with the hypothetical probability of disease in the same population but with all exposure eliminated $\Pr(D|\overline{E})$. Thus, it measures the additional probability of disease in the population that is associated with the presence of an exposure in the population, and *AR* measures the corresponding proportion. Probabilities in Eq. 4.13 will usually refer to disease risk although, depending on the context, they may be replaced with incidence rates.

Unlike measures of association (see Sect. 4.4), *AR* depends both on the strength of the association between exposure and disease and the prevalence of exposure in the population, p_E. This can be seen, for instance, through rewriting *AR* from Eq. 4.13. Upon expressing $\Pr(D)$ as

$$\Pr(D|E)p_E + \Pr(D|\overline{E})p_{\bar{E}} \text{ with } p_{\bar{E}} = 1 - p_E,$$

both in the numerator and the denominator, and noting that

$$\Pr(D|E) = \text{RR} \times \Pr(D|\overline{E}),$$

the term $\Pr(D|\overline{E})$ cancels out and AR is obtained as (Cole and MacMahon 1971; Miettinen 1974)

$$AR = \{p_E(RR - 1)\}/\{1 + p_E(RR - 1)\}, \tag{4.14}$$

a function of both the prevalence of exposure in the population, p_E, and the rate ratio or relative risk, RR.

An alternative formulation underscores this joint dependency in yet another manner. Again, upon expressing $\Pr(D)$ as

$$\Pr(D|E)p_E + \Pr(D|\overline{E})p_{\bar{E}} \text{ with } p_{\bar{E}} = 1 - p_E$$

and noting that

$$\Pr(D|E) = \text{RR} \times \Pr(D|\overline{E}),$$

the numerator in Eq. 4.13 can be rewritten as

$$p_E \Pr(D|E) - p_E \Pr(D|E)/RR.$$

From using Bayes' theorem to express $\Pr(D|E)$ as $\Pr(E|D)\Pr(D)/p_E$, it then becomes equal to

$$\Pr(D)p_{E|D}(1 - 1/RR),$$

after simple algebra. This yields (Miettinen 1974)

$$AR = p_{E|D}(RR - 1)/RR, \tag{4.15}$$

a function of the prevalence of exposure in diseased individuals, $p_{E|D}$, and the rate ratio or relative risk, RR.

A high relative risk can correspond to a low or high AR depending on the prevalence of exposure, which leads to widely different public health consequences. One implication is that, portability is not a usual property of AR, as the prevalence of exposure may vary widely among populations that are separated in time or location. This is in contrast with measures of association such as the relative risk or rate ratio which are more portable from one population to another, as the strength of the association between disease and exposure might vary little among populations (unless strong interactions with environmental or genetic factors are present). However, portability of RR can be questioned as well in the case of imperfect specificity of exposure assessment, since misclassification of non-exposed subjects as exposed will bias RR toward unity, which will affect differentially RR estimates in various populations depending on their exposure prevalence. This is not a problem with AR, which is not affected by imperfect specificity of exposure assessment.

Table 4.4 Measures of impact discussed in this chapter

Measures	Range	Definition[a]	Usual interpretation (s)[b]
Attributable risk (*AR*)	$-\infty$ to 1 0 to 1 for risk factor	1. $\{\Pr(D) - \Pr(D\|\overline{E})\}/\Pr(D)$ 2. $\{p_E(RR-1)\}/\{1 + p_E(RR-1)\}$ 3. $p_{E\|D}(RR-1)/RR$	Proportion of disease cases in the population attributable to exposure Proportion of disease cases in the population potentially preventable by eliminating exposure
Attributable risk among the exposed (AR_E)	$-\infty$ to 1 0 to 1 for risk factor	1. $\{\Pr(D\|E) - \Pr(D\|\overline{E})\}/\Pr(D\|E)$ 2. $(RR - 1)/RR$	Proportion of disease cases among the exposed attributable to exposure
Sequential attributable risk	0 to 1 for risk factor	Contributions of a given exposure to the joint attributable risk to several exposures for a given order of exposures	Proportion of disease cases in the population potentially preventable by eliminating a given exposure when several exposures are removed in a given sequence
Partial attributable risk	0 to 1 for risk factor	Average contribution of a given exposure to the joint attributable risk to several exposures over all possible exposure orders	Average proportion of disease cases in the population potentially preventable by eliminating a given exposure when several exposures are removed in sequence over all possible orders of removal
Prevented (preventable) fraction (PF)	$-\infty$ to 1 0 to 1 for protective factor	1. $\{\Pr(D\|\overline{E}) - \Pr(D)\}/\Pr(D\|\overline{E})$ 2. $p_E(1 - RR)$	Proportion of disease cases averted ("prevented fraction") in relation to the presence of a protective exposure or intervention in the population Proportion of cases that could be potentially averted ("preventable fraction") if a protective exposure or intervention were introduced de novo in the population

Generalized impact fraction	$-\infty$ to 1 0 to 1 for risk factor and modified distribution with lowering of exposure	$\{\Pr(D) - \Pr^*(D)\}/\Pr(D)$	Proportion of disease cases potentially averted (fractional reduction of disease occurrence) from changing the current distribution of exposure in the population to some modified distribution
Person-years of life lost (PYLL)	$\geq$0 for risk factor (person-years)	Difference between current life expectancy and life expectancy with exposure removed at the population level	Person-time of life lost at the population level attributable to exposure
Average potential years of life lost (PYLL)	$\geq$0 for risk factor (years)	Average difference per exposed person between current life expectancy and life expectancy with exposure removed	Average loss of life expectancy per person attributable to exposure

[a] $\Pr(D)$, $\Pr(D|\overline{E})$, $\Pr(D|E)$, and $\Pr^*(D)$ denote probabilities of disease (disease risks), namely, the overall probability of disease in the population, the probability of disease in the population with all exposure eliminated, the probability of disease among exposed individuals, and the overall probability of disease under a modified distribution of exposure, respectively. Alternatively, they may refer to disease rates depending on the context. The terms p_E and $p_{E|D}$ respectively refer to the overall exposure prevalence in the population and the exposure prevalence in the diseased individuals. The term *RR* refers to risk or rate ratios for exposed relative to unexposed individuals.

[b] Interpretations subject to conditions (see text, e.g., Sect. 4.5.1.4)

4.5.1.2 Range

When the exposure considered is a risk factor ($RR > 1$), it follows from the above definition that AR lies between 0 and 1. Therefore, it is very often expressed as a percentage. AR increases both with the strength of the association between exposure and disease measured by RR and with the prevalence of exposure in the population. A prevalence of 1 (or 100%) yields a value of AR equal to the attributable risk among the exposed, i.e., $(RR - 1)/RR$. AR approaches 1 for an infinitely high RR provided the exposure is present in the population (i.e., non-null prevalence of exposure).

AR takes a null value when either there is no association between exposure and disease ($RR = 1$) or there are no exposed subjects. Negative AR values are obtained for a protective exposure ($RR < 1$). In this case, AR varies between 0 and $-\infty$, a scale on which AR lacks a meaningful interpretation. One solution is to reverse the coding of exposure (i.e., interchange exposed and unexposed categories) to go back to the situation of a positive AR, sometimes called the preventable fraction in this case (Benichou 2000c; Greenland 1987; Last 1983). Alternatively, one can consider a different parameter, namely, the prevented fraction (see Sect. 4.5.4).

4.5.1.3 Synonyms

Some confusion in the terminology arises from the reported use of as many as 16 different terms in the literature to denote attributable risk (Gefeller 1990, 1995). However, a literature search by Uter and Pfahlberg (1999) found some consistency in terminology usage, with "attributable risk" and "population attributable risk" (MacMahon and Pugh 1970) the most commonly used terms by far, followed by "etiological fraction" (Miettinen 1974). Other popular terms include "attributable risk percentage" (Cole and MacMahon 1971), "fraction of etiology" (Miettinen 1974), and "attributable fraction" (Greenland and Robins 1988; Last 1983; Ouellet et al. 1979; Rothman and Greenland 1998, Chap. 4).

Moreover, additional confusion may originate in the use by some authors (MacMahon and Pugh 1970; Markush 1977; Schlesselman 1982) of the term "attributable risk" to denote a measure of association, the excess incidence, that is the difference between the incidence rates in exposed and unexposed subjects (see Sect. 4.4.4.2). Context will usually help the readers detect this less common use.

4.5.1.4 Interpretation and Usefulness

While measures of association such as the rate ratio and relative risk are used to establish an association in etiological research, AR has a public health interpretation as a measure of the disease burden attributable or at least related to one or several exposures. Consequently, AR is used to assess the potential impact of prevention programs aimed at eliminating exposure from the population. It is often thought of as the fraction of disease that could be eliminated if exposure could be totally removed from the population.

However, this interpretation can be misleading because, for it to be strictly correct, the three following conditions have to be met (Walter 1976). First, estimation of AR has to be unbiased (see Sect. 4.5.1.7). Second, exposure has to be causal rather than merely associated with the disease. Third, elimination of exposure has to be without any effect on the distribution of other risk factors. Indeed, as it might be difficult to alter the level of exposure to one factor independently of other risk factors, the resulting change in disease load might be different from the *AR* estimate. For these reasons, various authors elect to use weaker definitions of *AR*, such as the proportion of disease that can be related or linked, rather than attributable, to exposure (Miettinen 1974).

A fundamental problem regarding causality has been discussed by Greenland and Robins (1988) and Robins and Greenland (1989) who considered the proportion of disease cases for which exposure played an etiological role, i.e., cases for which exposure was a component cause of disease occurrence. They termed this quantity the etiological fraction and argued that it was a more relevant measure of impact than *AR*. Rothman and Greenland (1998, Chap. 4) argued that *AR* and the etiological fractions are different quantities using logical reasoning regarding causality and the fact that disease occurrence may require several component causal factors rather than one. The main problem with the etiological fraction is that it is usually impossible to distinguish exposed cases for whom exposure played an etiological role from those where exposure was irrelevant. As a consequence, estimating the etiological fraction will typically require non-identifiable biological assumptions about exposure actions and interactions to be estimable (Cox 1984, 1985; Robins and Greenland 1989; Seiler 1987). Thus, despite its limitations, *AR* remains a useful measure to assess the potential impact of exposure at the population level and can serve as a suitable guide in practice to assess and compare various prevention strategies.

Several authors have considered an interpretation of *AR* in terms of etiological research. The argument is that if an *AR* estimate is available for several risk factors jointly, then its complement to 1, $1 - AR$, must represent a gauge of the proportion of disease cases not explained by the risk factors used in estimating *AR*. Hence, $1 - AR$ would represent the proportion of cases attributable to other (possibly unknown) risk factors. For instance, it was estimated that the *AR* of breast cancer was 41% for late age at first birth, nulliparity, family history of breast cancer, and higher socioeconomic status, which suggested that at least 59% of cases had to be attributable to other risk factors (Madigan et al. 1995). A similar type of reasoning was used in several well-known reports of estimated percentages of cancer death or incidence attributable to various established cancer risk factors (e.g., smoking, diet, occupational exposure to carcinogens…). Some of these reports conveyed the impression that little remained unexplained by factors other than the main established preventable risk factors and that cancer was a mostly preventable illness (Colditz et al. 1996, 1997; Doll and Peto 1981; Henderson et al. 1991; Ames et al. 1995). Such interpretation has to be taken with great caution since *AR*s for different risk factors may add to more than 100% because multiple exposures are usually possible (e.g., smoking and occupational exposure to asbestos). Moreover, this interpretation can be refuted on the basis of logical arguments regarding the fact that disease occurrence may require more than one causal factor (see Rothman and Greenland 1998, Chap. 2). Furthermore, one can note that once a new risk factor is considered, the joint unexposed reference category changes from lack of exposure to all previously considered risk factors to lack of exposure to those risk factors *and* the new risk factor (Begg 2001). Because of this change in the reference category, the *AR* for the new risk factor may surpass the quantity $1-AR$ for previously considered risk factors. Thus, while it is useful to know that only 41% of breast cancer cases can be attributed to four established risk factors in the above example, it is entirely conceivable that new risk factors of breast cancer may be elicited which yield an *AR* of more than 59% by themselves in the above example.

4.5.1.5 Properties

AR has two main properties. First, *AR* values greatly depend on the definition of the reference level for exposure (unexposed or baseline level). A more stringent definition of the reference level corresponds to a larger proportion of subjects exposed, and, as one keeps depleting the reference category from subjects with higher levels of risk, *AR* values and estimates keep rising. This property has a major impact on *AR* estimates as was illustrated by Benichou (1991) and Wacholder et al. (1994). For instance, Benichou (1991) found that the *AR* estimate of esophageal cancer for an alcohol consumption greater or equal to 80 g/day (reference level of $0-79$ g/day) was 38% in the Ille-et-Vilaine district of France and increased dramatically to 70% for an alcohol consumption greater or equal to 40 g/day (i.e., using the more restrictive reference level $0-39$ g/day) (see Example 4.3 below). This property plays a role whenever studying a continuous exposure with a continuous gradient of risk and when there is no obvious choice of threshold. Therefore, *AR* estimates must be reported with reference to a clearly defined baseline level in order to be validly interpreted.

Example 4.3.

A case-control study of esophageal cancer conducted in the Ille-et-Vilaine district of France included 200 cases and 775 controls selected by simple random sampling from electoral lists (Tuyns et al. 1977). The assessment of associations between alcohol consumption and smoking with esophageal cancer has been the focus of detailed illustration by Breslow and Day (1980) who presented various approaches to odds ratio estimation with or without adjustment for age. As in previous work (Benichou 1991), four levels of alcohol consumption (0–39, 40–79, 80–119, and 120+ g/day) are considered here as well as three levels of smoking (0–9, 10–29, 30+ g/day) and three age groups (25–44, 45–54, 55+ years). There were 29, 75, 51, and 45 cases with respective alcohol consumptions of 0–39, 40–79, 80–119, and 120+ g/day. Corresponding numbers of controls were 386, 280, 87, and 22, respectively. The first reference level considered, 0–79 g/day, included 104 cases and 666 controls, leaving 96 cases and 109 controls in the exposed (i.e., 80+ g/day) category (see Table 4.5). The corresponding crude (unadjusted) odds ratio was estimated as $(96 \times 666)/(104 \times 109) = 5.6$ (see Sect. 4.4.6.3). Using methods described below (see Sects. 4.5.1.6 and 4.5.1.7), the crude *AR* estimate was 39.5% for alcohol consumption, and the age- and smoking-adjusted *AR* estimates were close to 38%. The second reference level considered, $0-39$ g/day, was more restrictive and included only 29 cases and 286 controls, leaving 171 cases and 489 controls in the exposed (i.e., 40+ g/day) category (see Table 4.5). The corresponding crude odds ratio was estimated as $(171 \times 386)/(29 \times 389) = 5.9$ (see Sect. 4.4.6.3). Using methods described below (see Sects. 4.5.1.6 and 4.5.1.7), the crude *AR* estimate was 70.9%, and adjusted *AR* estimates were in the range 70–72%. The marked increase mainly resulted from the much higher proportion of subjects exposed with the more restrictive definition of the reference category (63% instead of 14% of exposed controls).

Table 4.5 Numbers of cases and controls in the reference and exposed categories of daily alcohol consumption according to two definitions of the reference category – data from a case-control study of esophageal cancer (From Tuyns et al. 1977)

More restrictive definition of reference category (0–39 g/day)				Less restrictive definition of reference category (0–79 g/day)			
	Reference category (0–39 g/day)	Exposed category (40+ g/day)	Total		Reference category (0–79 g/day)	Exposed category (80+ g/day)	Total
Cases	29	171	200	Cases	104	96	200
Controls	386	389	775	Controls	666	109	775
Total	315	660	975	Total	770	205	975

The second main property is distributivity. If several exposed categories are considered instead of just one, then the sum of the category-specific *AR*s equals the overall *AR* calculated from combining those exposed categories into a single one, regardless of the number and the divisions of the original categories (Benichou 1991; Wacholder et al. 1994; Walter 1976), provided the reference category remains the same. This property applies strictly to crude *AR* estimates and to adjusted *AR* estimates calculated on the basis of a saturated model including all possible interactions (Benichou 1991). It applies approximately to adjusted estimates not based on a saturated model (Wacholder et al. 1994). Thus, if an overall *AR* estimate is the focus of interest, there is no need to break the exposed category into several mutually exclusive categories, even in the presence of a gradient of risk with increasing level of exposure. Of course, if the impact of a partial removal of exposure is the question of interest, retaining detailed information on the exposed categories will be necessary (Greenland 2001).

Example 4.3. (Continued)
For the more restrictive definition of the reference category of daily alcohol consumption (0–39 g/day), the crude *AR* was estimated at 70.9%. The separate contributions of categories 40–79, 80–119, and 120+ g/day were 27.0%, 22.2%, and 21.7%, summing to the same value 70.9%. Similarly, for the less restrictive definition of the reference category (0–79 g/day), the crude *AR* was estimated at 39.5% and the separate contributions of categories 80–119 g/day and 120+ g/day were 18.7% and 20.8%, summing to the same value 39.5%.

4.5.1.6 Estimability and Basic Principles of Estimation

AR can be estimated from cohort studies since all quantities in Eqs. 4.13, 4.14, and 4.15 are directly estimable from cohort studies. *AR* estimates can differ depending on whether rate ratios, risk ratios, or odds ratios are used but will be numerically close for rare diseases. For case-control studies, exposure-specific incidence rates or risks are not available unless data are complemented with follow-up or population-based data (see Sect. 4.2.2). Thus, one has to rely on odds ratio estimates, use Eq. 4.14, and estimate p_E from the proportion exposed in the controls, making the rare-disease assumption also involved in estimating odds ratios rather than relative risks. For crude *AR* estimation, the estimate of the odds ratio is taken as ad/bc and that of p_E as $c/(c+d)$, where, as in Sect. 4.4, a, b, c, and d, respectively, denote the numbers of exposed cases, unexposed cases, exposed controls, and unexposed controls. Alternatively, one can use Eq. 4.15, in which the quantity $p_{E|D}$ can be directly estimated from the diseased individuals (cases) as $a/(a+b)$ and *RR* can be estimated from the odds ratio again as ad/bc. Using either equation, the resulting point estimate is given by $(ad - bc)/\{d(a+b)\}$.

Variance estimates of crude *AR* estimates are based on applying the delta method (Rao 1965). For instance, an estimate of the variance for case-control data is given by the quantity

$$\mathrm{var}(\widehat{AR}) = b(c+d)\{ad(c+d) + bc(a+b)\}/\{d^3(a+b)^3\}.$$

Various $(1-\alpha)\%$ confidence intervals for *AR* have been proposed that can be applied to all epidemiological designs once point, and variance estimates are obtained. They include standard confidence intervals for *AR* based on the untransformed *AR* point estimate, namely

$$\widehat{AR} \pm z_{1-\alpha/2}\mathrm{se}(\widehat{AR});$$

AR confidence intervals based on the log-transformed variable $\ln(1-AR)$, namely,

$$1-(1-\widehat{AR})\left\lfloor \exp\left\{\pm z_{1-\alpha/2}\mathrm{se}(\widehat{AR})/(1-\widehat{AR})\right\}\right\rfloor \text{ (Walter 1975);}$$

as well as confidence intervals based on the logit-transformed variable $\ln\{AR/(1-AR)\}$, namely,

$$\left\{1+\left\{(1-\widehat{AR})/\widehat{AR}\right\}\left(\exp\left[\pm z_{1-\alpha/2}\mathrm{se}(\widehat{AR})\Big/\left\{\widehat{AR}(1-\widehat{AR})\right\}\right]\right)\right\}^{-1}$$

(Leung and Kupper 1981).

In the previous formulae, $z_{1-\alpha/2}$ denotes the $(1-\alpha/2)$th percentile of the standard normal distribution, $\widehat{AR}$ denotes the *AR* point estimate, and $\mathrm{se}(\widehat{AR})$ denotes its corresponding standard error estimate. Whittemore (1982) noted that the log transformation yields a wider interval than the standard interval for $AR > 0$. Leung and Kupper (1981) showed that the interval based on the logit transform is narrower than the standard interval for values of *AR* strictly between 0.21 and 0.79, whereas the reverse holds outside this range for positive values of *AR*. While the coverage probabilities of these intervals have been studied in some specific situations and partial comparisons have been made, no general studies have been performed to determine their relative merits in terms of coverage probability.

Detailed reviews of estimability and basic estimation of *AR* for various epidemiological designs can be found in Walter (1976) and Benichou (2000b, 2001) who provide explicit formulae for $\widehat{AR}$ and $\mathrm{se}(\widehat{AR})$ for cohort and case-control designs.

Example 4.3. (Continued)
For the more restrictive definition of the reference category of daily alcohol consumption (0–79 g/day), the crude *AR* estimate was obtained as

$$(171 \times 386 - 29 \times 389)/(386 \times 200) = 0.709$$

or 70.9%. Its variance was estimated as

$$29 \times 775 \times (171 \times 386 \times 775 + 29 \times 389 \times 200)/(386^3 \times 200^3) = 0.00261,$$

yielding a standard error estimate of 0.051 or 5.1%. The corresponding 95% confidence intervals for AR are given by 60.9–80.9% (no transformation), 58.9–79.4% (log transformation), and 60.0–79.8% (logit transformation), very similar to each other in this example.

4.5.1.7 Adjusted Estimation

As is the case for measures of association, unadjusted (or crude or marginal) AR estimates may be inconsistent (Miettinen 1974; Walter 1976, 1980, 1983). The precise conditions under which adjusted AR estimates that take into account the distribution and effect of other factors will differ from unadjusted AR estimates that fail to do so were worked out by Walter (1980). If E and X are two dichotomous factors taking levels 0 and 1, and if one is interested in estimating the AR for exposure E, then the following applies. The adjusted and unadjusted AR estimates coincide (i.e., the crude AR estimate is unbiased) if and only if (a) E and X are such that $\Pr(E = 0, X = 0) \times \Pr(E = 1, X = 1) = \Pr(E = 0, X = 1) \times \Pr(E = 1, X = 0)$, which amounts to the independence of their distributions or (b) exposure to X alone does not increase disease risk, namely, $\Pr(D|E = 0, X = 1) = \Pr(D|E = 0, X = 0)$. When considering one (or several) polychotomous factor(s) X forming J levels ($J > 2$), conditions (a) and (b) can be extended to a set of analogous sufficient conditions. Condition (a) translates into a set of $J(J-1)/2$ conditions for all pairs of levels j and j' of X, amounting to an independent distribution of E and all factors in X. Condition (b) translates into a set of $J - 1$ conditions stating that in the absence of exposure to E, exposure to any of the other factors in X, alone or in combination, does not increase disease risk.

The extent of bias varies according to the severity of the departure from conditions (a) and (b) above. Although no systematic numerical study of the bias of unadjusted AR estimates has been performed, Walter (1980) provided a revealing example of a case-control study assessing the association between alcohol, smoking, and oral cancer. In that study, severe positive bias was observed for crude AR estimates, with a very large difference between crude and adjusted AR estimates both for smoking (51.3% vs. 30.6%, a 20.7 difference in percentage points and 68% relative difference in AR estimates) and alcohol (52.2% vs. 37.0%, a 15.2% absolute difference and 48% relative difference). Thus, the prudent approach must be to adjust for factors that are suspected or known to act as confounders in a similar fashion as for estimating measures of associations.

Two simple adjusted estimation approaches discussed in the literature are inconsistent. The first approach was presented by Walter (1976) and is based on a factorization of the crude risk ratio into two components similar to those in Miettinen's earlier derivation (Miettinen 1972). In this approach, a crude AR estimate is obtained under the assumption of no association between exposure and disease (i.e., values of RR or the odds ratio are taken equal to 1 separately for each level of confounding). This term reflects the *AR* only due to confounding factors since it is obtained under the assumption that disease and exposure are not associated. By subtracting this term from the crude *AR* estimate that ignores confounding factors and thus reflects the impact of both exposure and confounding factors, what remains is an estimate of the *AR* for exposure adjusted for confounding (Walter 1976). The second approach is based on using Eq. 4.14 and plugging in a common adjusted *RR* estimate (odds ratio estimate in case-control studies), along with an estimate of p_E (Cole and MacMahon 1971; Morgenstern and Bursic 1982). Both approaches, while intuitively appealing, were shown to be inconsistent (Ejigou 1979; Greenland and Morgenstern 1983; Morgenstern and Bursic 1982), and, accordingly, very severe bias was exhibited in simulations of cross-sectional and cohort designs (Gefeller 1995).

By contrast, two adjusted approaches based on stratification yield valid estimates. The Mantel–Haenszel approach consists in plugging-in an estimate of the common adjusted *RR* (odds ratio in case-control studies) and an estimate of the prevalence of exposure in diseased individuals, $p_{E|D}$, in Eq. 4.15 in order to obtain an adjusted estimate of *AR* (Greenland 1984, 1987; Kuritz and Landis 1987, 1988a, b). In doing so, it is possible to adjust for one or more polychotomous factors forming J levels or strata. While several choices are available for a common adjusted *RR* or odds ratio estimator, a usual choice is to use a Mantel–Haenszel estimator of *RR* in cohort studies (Kleinbaum et al. 1982, Chaps. 9 and 17; Landis et al. 2000; Rothman and Greenland 1998, Chaps. 15–16; Tarone 1981) or odds ratio in case-control studies (Breslow and Day 1980, Chaps. 4–5; Kleinbaum et al. 1982, Chaps. 9, 17; Landis et al. 2000; Mantel and Haenszel 1959; Rothman and Greenland 1998, Chaps. 15–16) (see Sect. 4.4.6). For this reason, the term “Mantel–Haenszel approach” has been proposed to denote this approach to adjusted *AR* estimation (Benichou 1991). When there is no interaction between exposure and factors adjusted for, Mantel–Haenszel type estimators of *RR* or odds ratio have favorable properties, as they combine lack of (or very small) bias even for sparse data (e.g., individually matched case-control data) and good efficiency except in extreme circumstances (Birch 1964; Breslow 1981; Breslow and Day 1980, Chaps. 4–5; Landis et al. 1978, 2000). Moreover, variance estimators are consistent even for sparse data (“dually consistent” variance estimators) (Greenland 1987; Robins and Greenland 1989). Simulation studies of cohort and case-control designs (Gefeller 1992; Greenland 1987; Kuritz and Landis 1988a, b) showed that adjusted *AR* estimates are little affected by small-sample bias when there is no interaction between exposure and adjustment factors but can be misleading if such interaction is present.

Example 4.3. (Continued)
In order to control for age and smoking, nine strata (joint categories) of smoking × age have to be considered. The Mantel–Haenszel odds ratio estimate can be calculated from quantities a_j, b_j, c_j, and d_j that respectively denote the numbers of exposed cases, unexposed cases, exposed controls, and unexposed controls in stratum j, using the methods in Sect. 4.4.6.3. With the more restrictive definition of the reference category for daily alcohol consumption, the Mantel–Haenszel odds ratio was estimated at 6.2, thus

slightly higher than the crude odds ratio of 5.9. Combined with an observed proportion of exposed cases of $171/200 = 0.855$, this resulted in an adjusted *AR* estimate of $0.855\times(6.2-1)/6.2 = 0.716$ or 71.6% using Eq. 4.15 (allowing for rounding error), slightly higher than the crude *AR* estimate of 70.9%. The corresponding estimate of the standard error was 5.1%.

The weighted-sum approach also allows adjustment for one or more polychotomous factors forming J levels or strata. The *AR* is written as a weighted sum over all strata of stratum-specific *AR*s, i.e., $\sum_{j=1}^{J} w_j AR_j$ (Walter 1976; Whittemore 1982, 1983). Using crude estimates of AR_j separately within each stratum j and setting weights w_j as proportions of diseased individuals (cases) yields an asymptotically unbiased estimator of *AR*, which can be seen to be a maximum-likelihood estimator (Whittemore 1982). This choice of weights defines the "case-load method." The weighted-sum approach does not require the assumption of a common relative risk or odds ratio. Instead, the relative risks or odds ratios are estimated separately for each adjustment level with no restrictions placed on them, corresponding to a fully saturated model for exposure and adjustment factors (i.e., a model with all interaction terms present). From these separate relative risk or odds ratio estimates, separate *AR* estimates are obtained for each level of adjustment. Thus, the weighted-sum approach not only accounts for confounding but also for interaction. Simulation studies of cohort and case-control designs (Gefeller 1992; Kuritz and Landis 1988a, b; Whittemore 1982) show that the weighted-sum approach can be affected by small sample bias, sometimes severely. It should be avoided when analyzing sparse data and should not be used altogether for analyzing individually matched case-control data.

Example 4.3. (Continued)
As with the Mantel–Haenszel approach, nine strata (joint categories) of smoking × age have to be considered in order to control for age and smoking. In each stratum separately, an *AR* estimate is calculated using the methods for crude *AR* estimation (see Sect. 4.5.1.6). For instance, among heavy smokers (30+ g/day) in age group 65+ years, there were 15 exposed cases, 5 unexposed cases, 4 exposed controls, and 6 unexposed controls, yielding an odds ratio estimate of 4.5 and an *AR* estimate of 58.3%. The corresponding weight was $20/200 = 0.1$, so that the contribution of this stratum to the overall adjusted *AR* was 5.8%. Summing the contributions of all nine strata yielded an adjusted *AR* estimate of 70.0%, thus lower than both the crude and Mantel–Haenszel adjusted *AR* estimates. The corresponding standard error estimate was 5.8%, higher than the standard error estimate from the Mantel–Haenszel approach because fewer assumptions were made. Namely, the odds ratio was not assumed common to all strata, so that nine separate odds ratios had to be estimated (one for each stratum) rather than a single common odds ratio from all strata. To circumvent the problem of empty cells, the standard error estimate was obtained after assigning the value 0.5 to all zero cells.

A natural alternative to generalize these approaches is to use adjustment procedures based on regression models, in order to take advantage of their flexible and unified approach to efficient parameter estimation and hypothesis testing. Regression models allow one to take into account adjustment factors as well as interaction of exposures with some or all adjustment factors. This approach was first used by Walter (1976), Sturmans et al. (1977), and Fleiss (1979) followed by

Deubner et al. (1980) and Greenland (1987). The full generality and flexibility of the regression approach was exploited by Bruzzi et al. (1985) who developed a general *AR* estimate based on rewriting *AR* as

$$1 - \sum_{j=1}^{J} \sum_{i=0}^{I} \rho_{ij} RR_{i|j}^{-1}.$$

Quantities ρ_{ij} represent the proportion of diseased individuals with level i of exposure ($i = 0$ at the reference level, $i = 1, \ldots, I$ for exposed levels) and j of confounding and can be estimated from cohort or case-control data (or cross-sectional survey data) using the observed proportions. The quantity $RR_{i|j}^{-1}$ represents the inverse of the rate ratio, risk ratio, or odds ratio depending on the context, for level i of exposure at level j of confounding. It can be estimated from regression models (see Sect. 4.4), both for cohort and case-control data (as well as cross-sectional data), which allows confounding and interactions to be accounted for. Hence, this regression-based approach to *AR* estimation allows control for confounding and interaction and can be used for the main epidemiological designs. Depending on the design, conditional or unconditional logistic, log-linear or Poisson models can be used. Variance estimators were developed based on an extension of the delta method to implicitly related random variables in order to take into account the variability in estimates of terms ρ_{ij} and $RR_{i|j}^{-1}$ as well as their correlations (Basu and Landis 1995; Benichou and Gail 1989, 1990b). This regression approach includes the crude and two stratification approaches as special cases and offers additional options (Benichou 1991). The unadjusted approach corresponds to models for $RR_{i|j}^{-1}$ with exposure only. The Mantel–Haenszel approach corresponds to models with exposure and confounding factors but no interaction terms between exposure and adjustment factors. The weighted-sum approach corresponds to fully saturated models with all interaction terms between exposure and confounding factors. Intermediate models are possible, for instance, models allowing for interaction between exposure and only one confounder, or models in which the main effects of some confounders are not modeled in a saturated way.

Example 4.3. (Continued)
Still considering the more restrictive definition of the reference category for daily alcohol consumption, an unconditional logistic model (see Sect. 4.4.6.3) with two parameters, one general intercept and one parameter for elevated alcohol consumption, was fit, ignoring smoking and age. The resulting unadjusted odds ratio estimate was 5.9 as in Sect. 4.5.1.6. The formula above for $1 - AR$ reduced to a single sum with two terms ($i = 0, 1$) corresponding to unexposed and exposed categories, respectively. The resulting unadjusted *AR* estimate was 70.9% (standard error estimate of 5.1), identical to the crude *AR* estimate in Sect. 4.5.1.6. Adding eight terms for smoking and age in the logistic model increased the fit significantly ($p < 0.001$, likelihood ratio test) and yielded an adjusted odds ratio estimate of 6.3, slightly higher than the Mantel–Haenszel odds ratio estimate of 6.2 (see above). This resulted in an adjusted *AR* estimate of 71.9%, slightly higher than the corresponding Mantel–Haenszel *AR* estimate of 71.6%, and with a slightly lower standard error estimate of 5.0%. Adding two terms for interactions of smoking with alcohol consumption (thus

allowing for different odds ratio estimates depending on smoking level) resulted in a decreased *AR* estimate of 70.3% (with a higher standard error estimate of 5.4% because of the additional parameters estimated). Adding six more terms allowed for all two-by-two interactions between alcohol consumption and joint age × smoking level and yielded a fully saturated model. Thus, nine odds ratios for alcohol consumption were estimated (one for each stratum) as with the weighted-sum approach. This resulted in little change as regards *AR*, with an *AR* estimate of 70.0%, identical to the *AR* estimate with the weighted-sum approach, which precisely corresponds to a fully saturated model. The corresponding standard error estimate was increased to 5.6% due to the estimation of additional parameters.

A modification of Bruzzi et al.'s approach was developed by Greenland and Drescher (1993) in order to obtain full maximum-likelihood estimates of *AR*. The modification consists in estimating the quantities ρ_{ij} from the regression model rather than simply relying on the observed proportions of cases. The two model-based approaches seem to differ very little numerically (Greenland and Drescher 1993). Greenland and Drescher's approach might be more efficient in small samples although no difference was observed in simulations of the case-control design even for samples of 100 cases and 100 controls (Greenland and Drescher 1993). It might be less robust to model misspecification, however, as it relies more heavily on the *RR* or odds ratio model used. Finally, it does not apply to the conditional logistic model, and if that model is to be used (notably, in case-control studies with individual matching), the original approach of Bruzzi et al. is the only possible choice.

Detailed reviews of adjusted *AR* estimation (Benichou 1991, 2001; Coughlin et al. 1994; Gefeller 1992) are available. Alternative methods to obtain estimates of variance and confidence intervals for *AR* have been developed either based on re-sampling techniques (Gefeller 1992; Greenland 1992; Kahn et al. 1998; Kooperberg and Petitti 1991; Llorca and Delgado-Rodriguez 2000; Uter and Pfahlberg 1999) or on quadratic equations (Lui 2001a, b, 2003).

4.5.1.8 Final Notes and Additional References

General problems of *AR* definition, interpretation, and usefulness as well as properties have been reviewed in detail (Benichou 2000b; Gefeller 1992; Miettinen 1974; Rockhill et al. 1998a, b; Walter 1976). Special issues were reviewed by Benichou (2000b, 2001). They include estimation of *AR* for risk factors with multiple levels of exposure or with a continuous form, multiple risk factors, recurrent disease events, and disease classification with more than two categories. They also include assessing the consequences of exposure misclassification on *AR* estimates. Specific software for attributable risk estimation (Kahn et al. 1998; Mezzetti et al. 1996) as well as a simplified approach to confidence interval estimation (Daly 1998) have been developed to facilitate implementation of methods for attributable risk estimation. Finally, much remains to be done to promote proper use and interpretation of *AR* as illustrated in a literature review (Uter and Pfahlberg 2001).

4.5.2 Attributable Risk Among the Exposed

The attributable risk in the exposed (AR_E) or attributable fraction in the exposed is defined as the following ratio (Cole and MacMahon 1971; Levin 1953; MacMahon and Pugh 1970; Miettinen 1974):

$$AR_E = \left\{\Pr(D|E) - \Pr(D|\overline{E})\right\} / \Pr(D|E), \tag{4.16}$$

where $\Pr(D|E)$ is the probability of disease in the exposed individuals (E) and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same subjects but with all exposure eliminated. Depending on the context, these probabilities will refer to disease risk or may be replaced with incidence rates (see Sect. 4.5.1). AR_E can be rewritten as

$$AR_E = (RR - 1)/RR, \tag{4.17}$$

where RR denotes the risk or rate ratio. Following Greenland and Robins (1988), Rothman and Greenland (1998, Chap. 4) proposed to use the terms "excess fraction" for the definition of AR_E based on risks or risk ratios and "rate fraction" for the definition of AR_E based on rates or rate ratios.

Like AR, AR_E lies between 0 and 1 when exposures considered are risk factors ($RR > 1$) with a maximal limiting value of 1, is equal to zero in the absence of association between exposure and disease ($RR = 1$), and is negative for protective exposures ($RR < 1$).

As for AR, AR_E has an interpretation as a measure of the disease burden attributable or at least related to one or several exposures among the exposed subjects. Consequently, AR_E could be used to assess the potential impact of prevention programs aimed at eliminating exposure from the population. These interpretations are subject to the same limitations as corresponding interpretations for AR, however (see Sect. 4.5.1.4). Moreover, AR_E does not have a clear public health interpretation because it does not depend on the exposure prevalence but only on the risk or rate ratio of which it is merely a one-to-one transformation. For the assessment of the relative impact of several exposures, AR_E will not be an appropriate measure since AR_E for different exposures refers to different groups of subjects in the population (i.e., subjects exposed to each given exposure).

AR_E being a one-to-one function of RR, issues of estimability, and estimation for AR_E are similar to those for RR. They depend on whether rates or risks are considered. For case-control studies, odds ratios can be used. Greenland (1987) specifically derived adjusted point estimates and confidence intervals for AR_E based on the Mantel–Haenszel approach.

4.5.3 Sequential and Partial Attributable Risks

Upon considering multiple exposures, separate ARs can be estimated for each exposure as well as the overall AR for all exposures jointly. Except in very special circumstances worked out by Walter (1983) (i.e., lack of joint exposure or additive effects of exposures on disease risk or rate), the sum of separate *AR* estimates over all exposures considered will not equal the overall *AR* estimate.

Because this property is somewhat counterintuitive and generates misinterpretations, three alternative approaches have been suggested: one based on considering variance decomposition methods (Begg et al. 1998) rather than estimating *AR*, one based on estimating assigned share or probability of causation of a given exposure with relevance in litigation procedures for individuals with multiple exposures (Cox 1984, 1985; Lagakos and Mosteller 1986; Seiler 1987; Seiler and Scott 1987; Benichou 1993b; McElduff et al. 2002), and one based on an extension of the concept of *AR* (Eide and Gefeller 1995; Land et al. 2001). This last approach relies on partitioning techniques (Gefeller et al. 1998; Land and Gefeller 1997) and keeps with the framework of *AR* estimation by introducing the sequential *AR* that generalizes the concept of *AR*. The principle is to define an order among the exposures considered. Then, the contribution of each exposure is assessed sequentially according to that order. The contribution of the first exposure considered is calculated as the standard *AR* for that exposure separately. The contribution of the second exposure is obtained as the difference between the joint *AR* estimate for the first two exposures and the separate *AR* estimate for the first exposure, the contribution of the third exposure is obtained as the difference between the joint *AR* estimates for the first three and first two exposures, etc. Thus, a multidimensional vector consisting of contributions of each separate exposure is obtained.

These contributions are meaningful in terms of potential prevention programs that consider successive rather than simultaneous elimination of exposures from the population. Indeed, each step yields the additional contribution of the elimination of a given exposure once higher-ranked exposures are eliminated. At some point, additional contributions may become very small, indicating that there is not much point in considering extra steps. By construction, these contributions sum to the overall *AR* for all exposures jointly, which constitutes an appealing property. Of course, separate vectors of contributions are obtained for different orders. Meaningful orders depend on practical possibilities in implementing potential prevention programs in a given population. Average contributions can be calculated for each given exposure by calculating the mean of contributions corresponding to that exposure over all possible orders. These average contributions have been termed partial attributable risks (Eide and Gefeller 1995) and represent another potentially useful measure. Methods for visualizing sequential and partial *AR*s are provided by Eide and Heuch (2001). An illustration is given by Fig. 4.1. A detailed review of properties, interpretation, and variants of sequential and partial *AR*s was provided by Land et al. (2001).

Example 4.3. (Continued)
Smoking is also a known risk factor of esophageal cancer, so it is important to estimate the impact of smoking and the joint impact of smoking and alcohol consumption on esophageal cancer in addition to that of alcohol consumption alone. Using the first category (i.e., 0–9 g/day) as the reference level of smoking, there were 78 cases in the reference level of smoking, 122 cases in the exposed level (i.e., 10+ g/day), 447 controls in the reference level, and 328 controls in the exposed level. From these data, the crude odds ratio estimate for smoking at least 10 g/day was 2.1, and the crude *AR* estimate for smoking at least 10 g/day was 32.4%. Moreover, there were 9 cases and 252 controls in the joint

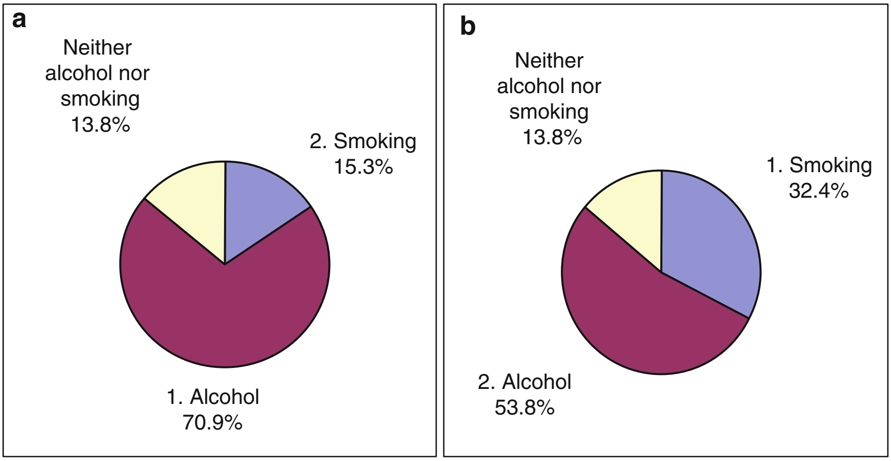

Fig. 4.1 Sequential attributable risk estimates for elevated alcohol consumption (80+ g/day) and heavy smoking (10+ g/day) for two different orders of removal (*left panel* (**a**): alcohol, then smoking; *right panel* (**b**): smoking, then alcohol) – case-control data on esophageal cancer (Tuyns et al. 1977; cf. Example 4.3)

reference level of alcohol consumption and smoking (i.e., 0–39 g/day of alcohol and 0–9 g/day of tobacco), which yielded a crude joint odds ratio estimate of 10.2 and a crude joint *AR* estimate for drinking at least 40 g/day of alcohol or smoking at least 10 g/day of tobacco of 86.2%.

Furthermore, the crude *AR* estimate for alcohol consumption of at least 40 g/day was estimated at 70.9% in Sect. 4.5.1.6. Hence, considering the first order of risk factor removal (i.e., eliminating alcohol consumption above 39 g/day followed by eliminating smoking above 9 g/day) yields sequential *AR* estimates of 70.9% for elevated daily alcohol consumption and 86.2% − 70.9% = 15.3 percentage points for heavy smoking so that, once elevated alcohol consumption is eliminated, the additional impact of eliminating heavy smoking appears rather limited (Fig. 4.1a). Considering the second order (i.e., eliminating heavy smoking first) yields sequential *AR* estimates of 32.4% for heavy smoking and 86.2% − 32.4% = 53.8 percentage points for elevated alcohol consumption so that, once heavy smoking is eliminated, the additional impact of eliminating elevated alcohol consumption remains major (Fig. 4.1b). A summary of these results is provided by partial *AR*s for elevated alcohol consumption and heavy smoking, with estimated values of 62.4% and 23.9%, respectively, again reflecting the higher impact of elevated alcohol consumption on esophageal cancer.

4.5.4 Preventable and Prevented Fractions

When considering a protective exposure or intervention, an appropriate alternative to *AR* is the preventable or prevented fraction (*PF*) defined as the ratio (Miettinen 1974):

$$PF = \left\{\Pr(D|\overline{E}) - \Pr(D)\right\} / \Pr(D|\overline{E}),$$

where $\Pr(D)$ is the probability of disease in the population, which may have some exposed (E) and some unexposed ($\overline{E}$) individuals, and $\Pr(D|\overline{E})$ is the hypothetical probability of disease in the same population but with all (protective) exposure eliminated. Depending on the context, these probabilities will refer to disease risk or may be replaced with incidence rates (see sections above). *PF* can be rewritten as

$$PF = p_E(1 - RR), \tag{4.19}$$

a function of both the prevalence of exposure, p_E, and the risk or rate ratio, *RR*. Thus, a strong association between exposure and disease may correspond to a high or low value of *PF* depending on the prevalence of exposure, as for *AR*. Moreover, portability is not a typical property of *PF*, as for *AR*. As for *AR* again, it may be useful to compare *PF* estimates among population subgroups to target prevention efforts to specific subgroups with a potentially high impact (as measured by the *PF*).

For a protective factor ($RR < 1$), *PF* lies between 0 and 1 and increases with the prevalence of exposure and the strength of the association between exposure and disease.

PF measures the impact of an association between a protective exposure and disease at the population level. It has a public health interpretation as the proportion of disease cases averted ("prevented fraction") in relation to the presence of a protective exposure or intervention in the population, among the totality of cases that would have developed in the absence of that factor or intervention in the population. In this case, it is useful to assess prevention programs a posteriori. Alternatively, it can be used to assess prevention programs a priori by measuring the proportion of cases that could be potentially averted ("preventable fraction") if a protective exposure or intervention was introduced de novo in the population (Gargiullo et al. 1995). These interpretations are subject to the same limitations as corresponding interpretations for *AR*, however (see Sect. 4.5.1.4).

PF and *AR* are mathematically related through (Walter 1976)

$$1 - PF = 1/(1 - AR). \tag{4.20}$$

From Eq. 4.20, it appears that, for a protective factor, *PF* estimates will usually differ from *AR* estimates obtained by reversing the coding of exposure. This follows from the respective definitions of *AR* and *PF*. While *AR*, with reverse coding, measures the potential reduction in disease occurrence that could be achieved if all subjects in the current population became exposed, *PF* measures the reduction in disease occurrence obtained from introducing exposure at the current prevalence in a formally unexposed population (Benichou 2000c).

In view of Eq. 4.20, estimability and estimation issues are similar for *AR* and *PF*. Specific *PF* adjusted point and confidence interval estimates were derived using the Mantel–Haenszel approach (Greenland 1987) and weighted-sum approaches (Gargiullo et al. 1995).

4.5.5 Generalized Impact Fraction

The generalized impact fraction (*GIF*) or generalized attributable fraction was introduced by Walter (1980) and Morgenstern and Bursic (1982) as the ratio

$$GIF = \{\Pr(D) - \Pr^*(D)\}/\Pr(D), \tag{4.21}$$

where $\Pr(D)$ and $\Pr^*(D)$, respectively, denote the probability of disease under the current distribution of exposure and under a modified distribution of exposure. As for *AR* and *PF*, these probabilities denote risks or can be replaced by incidence rates depending on the context.

The generalized impact fraction not only depends on the association between exposure and disease as well as the current distribution (rather than just the prevalence) of exposure but also on the target distribution of exposure considered that will yield $\Pr^*(D)$. It is a general measure of impact that includes *AR* and *PF* as special cases. *AR* contrasts the current distribution of exposure with a modified distribution defined by the absence of exposure. Conversely, *PF* contrasts a distribution defined by the absence of exposure with the current distribution of exposure (prevented fraction) or target distribution of exposure (preventable fraction).

The generalized impact fraction can be interpreted as the fractional reduction of disease occurrence that would result from changing the current distribution of exposure in the population to some modified distribution. Thus, it can be used to assess prevention programs or interventions, targeting all subjects or subjects at specified levels, and aimed at modifying or shifting the exposure distribution (reducing exposure) but not necessarily eliminating exposure. For instance, heavy smokers could be specifically targeted by interventions rather than all smokers. The special *AR* case corresponds to the complete elimination of exposure by considering a modified distribution putting unit mass on the lowest risk configuration and can be used to assess interventions aimed at eliminating (rather than reducing) exposure. Alternatively, the general impact fraction could be used to assess the increase in disease occurrence as a result of exposure changes in the population, such as the increase in breast cancer incidence as a result of delayed childbearing (Kleinbaum et al. 1982, Chap. 9). Such interpretations are subject to the same limitations as for *AR* and *PF* (see Sect. 4.5.1.4).

The generalized impact fraction has been used, for instance, by Lubin and Boice (1989) who considered the impact on lung cancer of a modification in the distribution of radon exposure consisting in truncating the current distribution at various thresholds and by Wahrendorf (1987) who examined the impact of various changes in dietary habits on colorectal and stomach cancers.

Issues of estimability are similar to those for *AR* and *PF*. Methods to estimate the generalized impact fraction are similar to methods for estimating *AR* and *PF*. However, unlike for *AR* or *PF*, it might be useful to retain the continuous nature of exposures to define the modification of the distribution considered (for instance, a shift in the distribution), and extensions of methods for estimating *AR* for continuous factors (Benichou and Gail 1990b) are relevant in this context. Drescher and Becher (1997) proposed extending model-based approaches of Bruzzi et al. (1985) and Greenland and Drescher (1993) to estimate the generalized impact fraction in case-control studies and considered continuous as well as categorical exposures.

4.5.6 Person-Years of Life Lost

Person-years of life lost (or potential years of life lost, PYLL) for a given cause of death is a measure defined as the difference between current life expectancy of the population and potential life expectancy with the cause of death eliminated (Smith 1998). For instance, one may be interested in PYLL due to prostate cancer in men, breast cancer in women, or cancer as a whole (all sites) in men and women. Methods for estimating PYLL rely on calculating cause-deleted life tables. Total PYLL at the population level or average PYLL per person may be estimated. As an example, a recent report from the Surveillance, Epidemiology, and End Results (SEER) estimated that 8.4 million years of life overall were lost due to cancer in the US population (both sexes, all races) in the year 2001, with an average value of potential years of life lost per person of 15.1 years. Corresponding numbers were 779,900 years overall and 18.8 years on average for breast cancer in women and 275,200 years overall and 9.0 years on average for prostate cancer in men (Ries et al. 2004).

PYLL represents an assessment of the impact of a given disease. Thus, it is not directly interpretable as a measure of exposure impact, except perhaps for diseases with a dominating risk factor, such as asbestos exposure for mesothelioma or human papilloma virus for cervical cancer.

However, it is possible to obtain a corresponding measure of the impact of a given exposure by converting PYLL due to a particular cause of death to PYLL due to a particular exposure. Estimation of an exposure-specific PYLL is obtained through applying an *AR* estimate for that exposure to the disease-specific PYLL, namely, calculating the product PYLL times *AR*, which yields the fraction of PYLL attributable to exposure. In this process, several causes of deaths may have to be considered. For instance, the fractions of PYLL for mesothelioma and lung cancer would need to be added in order to obtain the overall PYLL for asbestos exposure. In contrast with *AR* that provides a measure of exposure impact as a fraction of disease incidence (or death), such calculations of PYLL will provide a measure of exposure impact on the life expectancy scale. As for *AR*, the impact of a given exposure on the PYLL scale will depend on the prevalence of exposure in the population and strength of association between exposure and disease(s). Moreover, it will depend critically on the age distribution of exposure-associated diseases and their severity, i.e. case fatality.

4.6 Other Topics

4.6.1 Standardization of Risks and Rates

Risks and rates can usually not be directly compared between countries, regions, or time periods because of differences in age structure. For example, an older population may appear to have higher rates of certain cancers, not because of the presence of risk factors but because of the higher age itself. This is a form of confounding. In the tradition of demography, so-called standardization is applied to reported rates and risks to adjust for differences in age and possibly other confounders. Direct standardization is the most commonly used technique. It proceeds by forming a weighted average of age-specific rates or risks, where the weights reflect a known population structure. This structure is typically chosen as that of a country in a given census year, the so-called standard population. A directly standardized rate can be written:

$$SR = \Sigma n_j^S h_j / \Sigma n_j^S = \Sigma w_j^S h_j, \tag{4.22}$$

where n_j^S is the number of individuals in age group j in the standard population, h_j are age specific rates in the population under study, and w_j^S are weights such that $\Sigma w_j^S = 1$. A standardized risk can be computed in the same manner. Since the weights are fixed and not estimated, the variance of the estimated standardized rate is

$$\text{var}(\Sigma w_j^S h_j) = \Sigma (w_j^S)^2 h_j, \tag{4.23}$$

based on the Poisson assumption for the age specific rates. For risks, the binomial assumption may be used for the age-specific risks.

When age-specific rates or risks are not available in the exposed population under study, so-called indirect standardization may be used. This technique is less common but requires knowledge only of the age distribution, and not the age-specific rates, in the population under study. The approach is particularly useful if the exposed cohort is relatively small and the age-specific incidence or mortality rates thus are unstable. The term is somewhat of a misnomer, as the technique in effect employs direct standardization of the rates in the unexposed (reference) to the exposed population where the age distribution of the exposed group is the standard. The *indirect* step serves only to project back to a rate standardized to the unexposed reference population. The indirectly standardized rate is obtained by $(SMR)(CR^O)$, where *SMR* is the *standardized mortality* or *morbidity ratio* (see below) and CR^O is the *crude* (i.e., original overall) rate in a reference population that provides stratum-specific rates.

The standardized mortality or morbidity ratio is a ratio between observed and expected event counts, where the expected count is based on age-specific rates or risks in a reference population, which is a non-exposed or general population group. Then, the standardized mortality (or morbidity or incidence) ratio

$$SMR\ or\ SIR = D_E/E_0 = \Sigma n_j h_j / \Sigma n_j h_{0j},$$

where D_E is the number of events in the exposed and E_0 is the expected number of events obtained from the rates h_{0j} in the unexposed applied to the sample composition of the exposed. The *SMR* can also be rewritten as a weighted average of sex- and age-specific (say) rate ratios h_j/h_{0j} with weights $w_j = n_j h_{0j}$. It can be shown that these weights minimize the standard error of the weighted average (Breslow and Day 1987, Chap. 2) as long as the rates in the reference population are assumed to be known rather than estimated. Stratified analyses as discussed above, on the other hand, choose weights that minimize the standard errors when the rates are estimated among both the exposed and the unexposed. The *SMR* has the advantage that age- and sex-specific rates are not needed for the exposed group.

The denominator of the *SMR* is generally obtained from age- and sex-specific rates in the entire regional population. This allows the random variation of the denominator to be considered to be none, and confidence intervals can be based on the estimate $1/D_E^{1/2}$ for the standard error of ln(*SMR*). This standard error computation also assumes that the events among the exposed are uncorrelated (do not cluster) or, more specifically, that the event count follows a Poisson distribution.

It may be noted that directly standardized rates are based on a choice of standard population to generate weights. While the weights used for the *SMR* result from the composition of the comparison group and do not involve a true standard population, the weights used in direct standardization are external as they result from information outside the samples being compared. In principle, the latter weights are similar to survey weights applied in, e.g., the National Health and Nutrition Examination Survey (NHANES), where the sample must be standardized to the US population to account for the methodology used in drawing it. While improving external validity, weights from direct standardization and survey weights always result in loss of statistical efficiency, i.e., standard errors will be larger than for crude or non-weighted rates and risks. In contrast, many of the methods to adjust for confounding discussed in Sect. 4.4 are internal to the specific comparison and designed to optimize statistical efficiency.

4.6.2 Measures Based on Prevalence

Prevalence is the number of cases either at a given point in time (point prevalence) or over a time period (period prevalence) divided by the population size. Prevalence can be easier to obtain than incidence. For example, a population survey can determine how many individuals in a population suffer from a given illness or health condition at a point in time.

Measures of association based on prevalence parallel those for risk (for point prevalence) or incidence rates (for period prevalence). For example, one can form prevalence ratios, prevalence differences, and prevalence odds ratios. Measures of impact based on prevalence can also be obtained.

Prevalence and the measures of association based on it are useful entities for health policy planning and for determining the level of services needed for individuals with a given health condition in the population. It is usually considered less useful for studying the etiology of a disease. The reason for this is that under certain assumptions, prevalence of a disease equals its incidence multiplied by its duration (Kleinbaum et al. 1982, Chap. 8). These assumptions are that the population is stable and that both the incidence and prevalence remain constant. Under more general conditions, prevalence still reflects both incidence and duration but in a more complex manner. For a potentially fatal or incurable disease, duration means survival, and the exposures that increase incidence may reduce or increase survival and hence the association of an exposure with prevalence may be very different than its association with incidence. On the other hand, when a disease or condition can be of limited duration due to recovery or cure, and its duration is maintained by the same exposures that caused it, prevalence can be more meaningful than incidence. For example, it is conceivable that weight gain in a person may have caused hypertension, and when the person loses the same amount of weight, she/he moves out of being hypertensive. In this latter case, the prevalence ratio between the percentages with hypertension in those exposed and unexposed to the risk factor captures the increase in the risk of living with the condition caused by the exposure, while the incidence ratio captures only part of the etiological association.

4.7 Conclusions

Disease frequency is measured through the computation of incidence rates or estimation of disease risk. Both measures are directly accessible from cohort data. They can be obtained from case-control data only if they are complemented by follow-up or population data. Using regression techniques, methods are available to derive incidence rates or risk estimates specific to a given exposure profile. Exposure-specific risk estimates are useful in individual prediction.

A wide variety of options and techniques are available for measuring association. The odds ratio is presently the most often used measure of association for both cohort and case-control studies. Adjustment for confounding is key in all analyses of observational studies and can be pursued by standardization, stratification, and by regression techniques. The flexibility of the latter, especially in the generalized linear model framework, and availability of computer software, has made it widely applied in the last several years.

Several measures are available to assess the impact of an exposure in terms of the occurrence of new disease cases at the population level, among which the attributable risk is the most commonly used. Several approaches have been developed to derive adjusted estimates of the attributable risk from case-control as well as cohort data, either based on stratification or on more flexible regression techniques. The concept of attributable risk has been extended to handle preventive exposures, multiple exposures, as well as assessing the impact of various modifications of the exposure distribution rather than the mere elimination of exposure.

5.1 Introduction

We begin by setting out some definitions in descriptive epidemiology, the sources of data from which such studies arise and provide a brief outline of the sections that comprise this chapter.

5.1.1 Definitions

A distinction has traditionally been drawn between “descriptive” and “analytical” epidemiology, and their characteristics as “hypothesis generating” or “hypothesis testing,” respectively, have been taught to generations of students. This distinction may perhaps reflect the part separation of the distribution from the causes of disease, as in the current dictionary definition of epidemiology (Porta 2008):

> The study of the occurrence and distribution of health-related states or events in specified populations, including the study of the determinants influencing such states, and the application of this knowledge to control the health problems.

Describing the distribution of disease is an integral part of the planning and evaluation of health-care services, but, in the context of investigative epidemiology, the distinction is an arbitrary one. There are no real differences in the concepts, methods, or deductive processes between descriptive and analytical epidemiology, for example, between the information conveyed by the observations of an association between the risk of liver cancer and being engaged in a specific occupation, or having markers of infection by a certain virus. Both may tell us something about the cause of liver cancer. Only the sources of information differ. In the former case, it has derived from some routine source (a dataset or register maintained for general disease surveillance purposes or even for unrelated administrative reasons). These sources include information on possible exposures or disease outcomes that have not been collected with the testing of any specific hypothesis in mind. It is this use of routinely collected data that characterizes descriptive studies.

Descriptive epidemiology is certainly not synonymous with ecological studies of groups, as suggested by some authors (Estève et al. 1994), since most “descriptive” studies have information on distribution and levels of several exposure variables for individual members of the population studied. In their classic textbook, MacMahon and Trichopoulos (1996) liken this phase of epidemiological investigation to the early questions in the parlor game “20 questions” – using generally available information to focus down the field of inquiry to one that may need expensive ad hoc study. But the variables available in routine data sources are no less “exposures” from the point of view of methodology, or deductive reasoning, than are those measured by questionnaire, physical examination, or biochemical tests. The fact that some “exposures” may be remote from the molecular mechanisms involved in disease etiology is a familiar one when considering “cause” of disease, especially from a public health perspective of devising appropriate methods of prevention. “Cause” is a relative concept that only has meaning in epidemiology terms of its removal being associated with a diminished risk of the disease, and, in this context, it is just as relevant to improve educational levels in a population as a means of reducing infection by HIV as it is to identify the mechanisms by which the virus enters the host cell.

"Exposures" in descriptive epidemiology are those characteristics of individuals that are present in the preexisting datasets available for study. The most commonly available are personal characteristics, the so-called "demographic" variables, systematically collected by vital statistics and health-care institutions. They include birth date (or age), sex, address (current place of residence), birthplace, race/ethnic group, marital status, religion, occupation, and education. From sources within the health sector, there may be much more detail on diagnostic and therapeutic interventions, while community surveys may include information on health determinants, such as tobacco and alcohol use, weight, height, and blood pressure.

Disease outcomes may be in terms of incident cases (from disease registers), deaths (vital statistics), episodes of morbidity (utilization statistics from health services), or prevalence of, especially, chronic conditions from population surveys.

Information on "exposure" and "outcome" for the same individual may be taken from a single source (e.g., a disease register or population survey), or it may be necessary to perform record linkage between different sources to obtain exposure and outcome information on individuals in the population under study.

5.1.2 Sources of Data

There is a wide variety of sources of information that can be drawn upon for information on exposure and disease outcome. They are of two broad types: systems based on populations, containing data collected through personal interviews or examinations, and systems based on records, containing data collected from vital and medical records. They include:

- Census data or population registers
- Medical birth registries (health events related to pregnancy and birth)
- Vital statistics (especially death certificate data)
- Disease registers, recording new cases of specific diseases in defined populations (such as registries that collect information on diagnoses of cancer, insulin-managed diabetes mellitus, etc.)
- Notification systems (especially for infectious diseases)
- Hospital activity statistics, especially on admissions/discharges from hospital, including diagnosis
- Primary care contacts
- Diagnostic services (pathology)
- Community surveys (e.g., those carried out by the National Center for Health Statistics in the USA (Curtin et al. 2012))

Some of these are described in chapters ►Use of Health Registers and ►Emergency and Disaster Health Surveillance of this handbook.

5.1.3 Outline of the Chapter

The chapter comprises four parts, beginning with an introduction of the most important measurements in descriptive epidemiology in Sect. 5.2. Since these are primarily concerned with risk or burden of disease in a single population, appropriate methods for comparisons between populations – the hallmark of epidemiology – are presented in Sect. 5.3. Section 5.4 illustrates how these tools can be applied in the study designs familiar to epidemiologists, with a special emphasis on ecological studies, while Sect. 5.5 provides a series of examples, illustrating the principles of descriptive studies.

5.2 Measurement

5.2.1 Incidence

Incidence is the number of new cases occurring. It can be expressed as an absolute number of cases or in relation to the size of the population at risk and time during which the cases occur, as an incidence rate (cf. chapter ▸Rates, Risks, Measures of Association and Impact of this handbook). Incidence requires definition of the moment at which the disease "begins," when an individual becomes a new "case." While this may be relatively straightforward for many infectious diseases, for most acute and chronic diseases, the time of onset is less clear cut and is by convention considered to be the time of diagnosis. This is necessarily a somewhat arbitrary point in time and dependent upon local circumstances. Incidence may refer to the number of new disease events or to the number of individuals affected. The distinction is important where the same individual may have more than one event of the same disease, during the period of observation (e.g., common infections and accidents).

Incidence data are available from disease registers as well as from notification systems for infectious diseases. Disease registers are part of a surveillance system for various diseases, and an accurate registration from a notification of disease events depends upon the patient seeking medical advice, the correct diagnosis being made, and notification of it being made to the public health authorities. Completeness is very variable but probably higher for serious or highly contagious diseases. Registers have been more important, and successful, for cancer than for any other condition. This is because of the serious nature of most cancers, which means that, except in certain low-resource countries with limited access to medical care and concepts, the vast majority of those affected will present for diagnosis (and treatment, if available). As a result, enumeration of incident cases of cancer is relatively easy in comparison with other diseases, and this has permitted the establishment of a worldwide network of cancer registries, providing data on defined populations (Parkin 2006). Incidence data from cancer registries worldwide that meet defined criteria regarding completeness and validity are published at 5-year intervals in the *Cancer Incidence in Five Continents* series. The latest volume (9th) contains comparable incidence information from 225 registries in 60 countries, mainly over the period 1998–2002 (Curado et al. 2007).

Other sources of information on incidence include:

(a) Retrospective or prospective surveys for incident cases of a particular disease. The approach is similar to ongoing registers, except that it is limited in time.
(b) Community surveys. General morbidity surveys record all cases of disease appearing in a sample of the community, for example, at primary care level, during a period of time. They are most efficient for relatively common conditions.
(c) Hospital activity statistics. These summarize hospital admissions. Such statistics are usually *event*-based, so there may be multiple admissions for the same disease event. The number of hospitalizations is also affected by the facilities available, admissions policies, and social factors. It may be difficult to define the population at risk, unless national-level data can be compiled.

Incidence rates are of particular value in the study of disease etiology, since they are informative about the risk of developing the disease in different population groups.

5.2.2 Prevalence

Prevalence is the number or, more usually, the proportion of a population that has the disease at a given point in time (Rothman and Greenland 1998; cf. chapter ▸Rates, Risks, Measures of Association and Impact of this handbook). For many diseases (e.g., hypertension, diabetes), prevalence usefully describes the number of individuals requiring care and may be useful in planning health services. Prevalence is proportional to the incidence of the disease and its duration (and when both are constant, then **P**revalence = **I**ncidence × **D**uration). In the absence of useful data on incidence or mortality, prevalence may be used to compare the risk of disease between populations, although this has clear drawbacks, not least because prevalence is related also to the mean duration of the disease. The mean duration may simply reflect the availability of screening and treatment strategies, allowing prolonged survival. For some chronic diseases, what to consider as the moment of cure (after which an individual is no longer a "case") is a problem when trying to calculate comparable indices of prevalence between populations (Bray et al. 2013). Population surveys are a common source of information on prevalence of the more common conditions or complaints, including those that may exist in asymptomatic form, and therefore remain unrecognized in a clinical setting.

A less commonly used measure is *period prevalence*, which is the sum of all cases of the disease that have existed during a given period divided by the average population at risk during the period. It has been used for studying mental illness, where the exact time of onset is difficult to define and when it may be difficult to know whether the condition was present at a particular point in time.

5.2.3 Case Fatality/Survival

Case fatality is a measure of the severity of a disease. It is the proportion of cases of a particular disease that are fatal within a specified time. *Survival* is proportion of cases that do not die in a given interval after diagnosis (and is equal to *1-fatality*). The survival time is defined as the time that elapsed between diagnosis and death. Computation of survival depends upon follow-up of diagnosed patients for deaths or withdrawal from observation. There are two related approaches to the estimation of survival: the Kaplan-Meier and actuarial, or life-table, methods. The former (Kaplan and Meier 1958) is particularly useful when exact survival times are available, since smooth estimates of survival as a function of time since diagnosis can be obtained. The actuarial method requires a life-table with survival times grouped usually into intervals that permit the calculation of the cumulative probability of survival at time t_i from the conditional probabilities of survival during consecutive intervals of follow-up time up to and including t_i (Cutler and Ederer 1958; Ederer et al. 1961). Information from all cases is used in the estimation of survival, including those withdrawn due their follow-up ending owing to closure of study and those who are lost to follow-up before the termination. In both cases, follow-up is censored before the time of the outcome event, usually the death of the patient. "Observed survival" is influenced not only by mortality from the disease of interest but also by deaths from other causes. If these deaths can be identified, they can be treated as withdrawals, and the "corrected survival" (also referred to as "net survival") calculated. Alternatively, allowance for deaths due to causes other than the disease under study is made by calculation of "relative survival" (Ederer et al. 1961). This makes use of an appropriate population life-table to estimate expected numbers of deaths. The issue of competing risks is discussed in detail in chapter ▸Rates, Risks, Measures of Association and Impact of this handbook. For comparisons between different populations, age standardization of survival is necessary (see Sect. 5.3.1.1).

For a more detailed description of survival analysis, see chapter ▸Survival Analysis of this handbook.

5.2.4 Mortality

Mortality is the number of deaths occurring in a population and is the product of the incidence and the fatality of the disease.

Mortality statistics derive from the information on death certificates, collected by civil registration systems recording vital events (births, marriages, deaths). The responsible authority varies between countries, but usually the first level of data collection and processing is the municipality or province, with collation of national statistics being the responsibility of the Ministry of Health or the Interior Ministry. Death certificates record information on the person dying, and the cause of death, as certified, usually by a medical practitioner. The International Classification of Diseases (ICD) provides a uniform system of nomenclature and coding and a recommended format for the death certificate (WHO (World Health Organization) 1992). Mortality statistics are produced according to the underlying cause of death; this may not equate with the presence of a particular disease. Although the ICD contains a set of rules and guidelines that allow the underlying cause to be selected in a uniform manner, interpretation of the concept probably varies considerably, for example, when death occurs from pneumonia in a person previously diagnosed as having cancer. Comprehensive mortality statistics thus require that diagnostic data are available on decedents, which are transferred in a logical, standardized fashion to death certificates, which are then accurately and consistently coded, compiled, and analyzed.

It is well known that mortality data may be deficient both in completeness of ascertainment and in the validity of the recorded cause of death (Alderson 1981). A huge number of studies of the validity of cause-of-death statements in vital statistics data have been carried out. These compare cause of death entered on the death certificate with a reference diagnosis, which may be derived from autopsy reports (e.g., Heasman and Lipworth 1966), detailed clinical records (Puffer and Wynne-Griffith 1967), or cancer registry data (Percy et al. 1981). They reveal that the degree of accuracy of the stated cause of death declines as the degree of precision in the diagnosis increases. Despite the problems, mortality data remain an extremely valuable source of information on disease burden and a useful proxy for risk of disease in many circumstances. A major advantage is in their widespread availability. According to *World Health Statistics 2012* (WHO 2012), only 34 countries (representing 15% of the global population) produce high-quality cause-of-death data (predominantly in Europe and the Americas), while countries representing almost two-thirds of the world population produce lower-quality cause-of-death data, with the remaining 74 countries – mainly low-resource countries – lack such data altogether. National-level statistics are collated and made available by the WHO (2012); however, the fact of publication by national and international authorities is not a guarantee of data quality. For some countries, or time periods, coverage of the population is manifestly incomplete, and the so-called mortality rates produced are implausibly low. The WHO Statistical Information System (WHOSIS) (now incorporated into the Global Health Observatory (GHO)) publishes tables of estimated coverage and completeness of mortality statistics in their database (Mathers et al. 2005). As well as deficiencies in these, quality of cause-of-death information may be poor. This can sometimes be predicted when a substantial proportion of certificates are completed by non-medical practitioners. (WHO formerly published a useful table in "World Health Statistics Annual" (WHO 1998) giving – for a few countries at least – the relevant percentage.) Otherwise, quality of data must be judged from indicators such as the proportion of deaths coded to *Senility and Ill Defined Conditions*.

The mortality rate – the number of deaths in relation to the population at risk, in a specified period of time – provides an indicator of the average risk to the *population* of dying from a given cause (while fatality represents the probability that an *individual* with the disease will die from it). Mortality rates are the most useful measure of the impact or burden of disease in a population. They are probably equally often used as a convenient proxy measure of the risk of acquiring the disease (incidence) when comparing different groups, because of their availability, although such use introduces the assumption of equal survival/fatality in the populations being compared.

The *infant mortality rate* is a widely used indicator of the level of health and development. It is calculated as the number of deaths in children aged less than one, during a given year, divided by the number of live births in the same year. Other similar indicators include the fetal death rate, stillbirth or late fetal death rate, perinatal mortality rate, neonatal mortality rate, and postneonatal mortality rate. These data may be collected by household survey, rather than the vital statistics system, especially in developing countries (United Nations 1984).

5.2.5 Person-Years of Life Lost

The concept of person-years of life lost (PYLL) was introduced over 50 years ago (Dempsey 1947) in order to refine the traditional mortality rates, by providing a weighting for deaths occurring at different ages. These methods started to become more widely used from the late 1970s in health services planning (Murray and Axtell 1974). There are many variations in the calculations used (summarized by Murray 1994). There are four variants of "normal" lifespan against which to compare premature death. The simplest is to choose a fixed value for the potential limit where ages ranging from 60 to 85 have been used. *Potential years of life lost* are calculated as

$$\sum_{x=0}^{L} d_x (L - x)$$

where d_x is the number of deaths at age x and L is the potential limit to life. This method gives no importance to deaths over the upper limit. To avoid this, calculating the *expected years of life lost*, using the expectation of life at the age of death (e_x), derived from an appropriate life-table, seems a better solution:

$$\sum_{x=0}^{l} d_x e_x$$

where l is the last age group and e_x is the expectation of life at each age. The expectation of life (e_x) may be taken from a period life-table or, more appropriately, be cohort-specific. This method is not suitable, however, for comparing between populations with different expectations of life. For this purpose, a standard expectation of life (e_x^*), taken from some ideal standard population, should be used. The calculated indicator then becomes the *standard expected years of life lost*. Another variation is to give different weights to years of life lost at different ages. The rationale is that the economic, or social, "value" of individuals varies with their age.

In addition, discounting may be used to give decreasing weights to the life years saved over time, admitting that life years in the future are valued less highly than at present (Das Gupta et al. 1972; Layard and Glaister 1994).

The approach has been taken a step further, with the development of indices that take into account non-fatal health outcomes of disease, such as *quality-adjusted life years (lost)* (*QALYs*) or *disability-adjusted life years (lost)* (*DALYs*) (Murray 1994; Morrow and Bryant 1995). Essentially, these admit that, between onset of a disease and death or recovery, there is a spectrum of morbidity, which can be quantified in terms of its duration and severity. Three elements are needed in calculating these indices, therefore: the incidence of the disease, its mean duration or, equivalently, survival probability, and a measure of life "quality" in between onset and end of disease. The problem in using these indices lies in ascribing values to quality of life, or level of disability, since both are subjective and will vary with time since diagnosis and in different cultural and socioeconomic settings. Nevertheless, the estimation of DALYs for different conditions worldwide has been widely used by the World Health Organization (WHO) as a means of establishing priorities for health-care programs (WHO 2000). The calculation involves summing the standard expected years of life lost (using a standard model life-table with expectation at life at birth being 82.5 for females and 80 for males), with the time lived between onset and death in different disability classes having a severity weighting between 0 and 1. Some examples of long-term disease and injury sequelae falling into each class are given in Table 5.1; the full list can be found in WHO (2008). Both an age weighting function and a discount rate (of 3% per year) are applied (Murray and Lopez 1996). The International Agency for Research on Cancer (IARC) has recently proposed a framework (Soerjomataram et al. 2012a) to estimate DALYs due to cancer in 184 countries (Soerjomataram et al. 2012b).

5.2.6 Rates of Disease

Although the dimensions of a health problem may be expressed by the absolute numbers of events e.g., the numbers of cases of infectious diseases, including AIDS, reported through WHO's surveillance data (WHO 2012), comparisons between population groups require that the number of events is related to the size of the population in which they occur, by the calculation of rates or proportions. "Rate," as the name implies, incorporates a time dimension – the number of events occurring in a defined population during a defined time period. The term rate is often used interchangeably with *risk*, although the risk of disease is a probability, or proportion, and describes the accumulation of the effect of rates over a given period of time. Ideally, we would estimate a rate by ascertaining, for every individual in the population, the risk of being diagnosed or dying at a given age and specific point in time. This *instantaneous rate* requires that the designated period of time is infinitely small, approaching zero. In practice, the average rate of occurrence of new cases or deaths in a sufficiently large population is calculated for a sufficiently long time period. In this formulation, the denominator is the underlying *person-time at risk* in

Table 5.1 Disability classes for the Global Burden of Disease study, with examples of long-term disease and injury sequelae falling into each class (WHO 2008)

Disability class	Severity weights	Conditions
I	0.00–0.02	Stunting due to malnutrition, schistosomiasis infection, long-term scarring due to burns (less than 20% of body)
II	0.02–0.12	Amputated finger, asthma case, edentulism, mastectomy, severe anemia, stress incontinence
III	0.12–0.24	Angina, HIV not progressed to AIDS, infertility, alcohol dependence and problem use, low vision (<6/18, >3/60), rheumatoid arthritis
IV	0.24–0.36	Amputated arm, congestive heart failure, deafness, drug dependence, Parkinson disease, tuberculosis
V	0.36–0.50	Bipolar affective disorder, mild mental retardation, neurological sequelae of malaria, recto-vaginal fistula
VI	0.50–0.70	AIDS cases not on antiretroviral drugs, Alzheimer and other dementias, blindness, Down syndrome
VII	0.70–1.00	Active psychosis, severe depression, severe migraine, quadriplegia, terminal stage cancer

which the cases or deaths in the numerator arose. Prevalence and survival, as defined above, are proportions (or percentages), not rates, as there is no time dimension, although the term "rate" is frequently appended.

5.2.7 Population at Risk

For the denominators of proportions, such as prevalence and survival, the population at risk comprises the number of individuals at a point in time. When rates are calculated, the time period of observation also needs to be specified. The denominator is calculated as units of person-time (Last 2001), whereby each person in the study population contributes one person-year for each year of observation before disease develops or the person is lost to follow-up. In prospective cohort studies, the individuals can be followed up until the end of the study, and summation of the varying lengths of individual follow-up accurately represents the person-time at risk of disease. However, in descriptive epidemiology, information on the population-at-risk is not usually available at the individual level, unless there is an accurate population register. It is usually necessary to approximate person-years at risk using cross-sectional population data from national statistical organizations. The estimation of the denominator, a summation of the midyear estimates for each of the years under consideration, is thus dependent on both the availability and completeness of demographic information on the population under study.

In most developing and developed countries, 10-yearly population censuses provide basic population estimates by age, sex, and census year, and statistical offices often produce estimates for intercensal years, based on rates of birth, death,

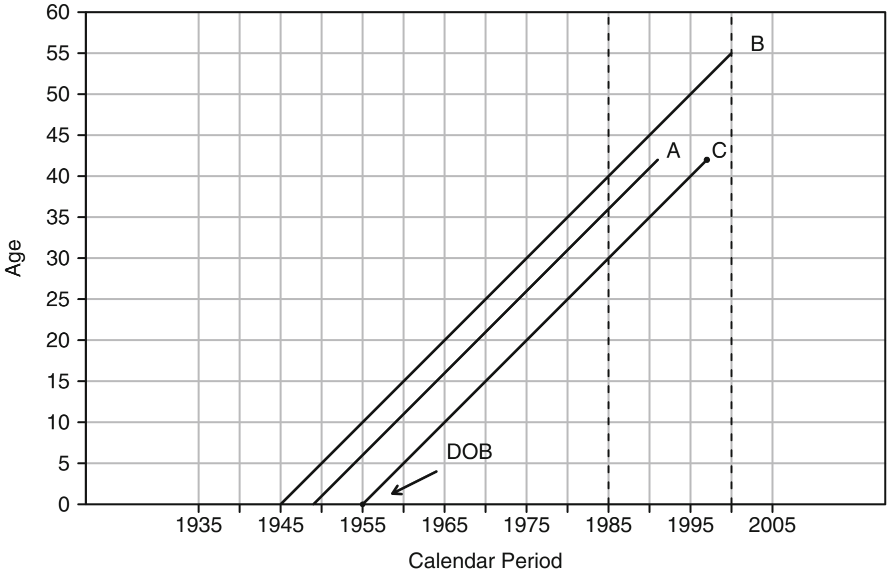

Fig. 5.1 The modern Lexis diagram depicting three subjects under observation between 1985 and 2000. Subject *A* is lost to follow-up aged 42 in 1991, *B* is alive at the end of follow-up (end of 2000), and *C* has the outcome of interest at the age of 42 in 1997 – the date of birth (*DOB*) can be ascertained for *C* by period – age = 1955, and his/her "life journey" represented by the diagonal line from *DOB* to 1997

and migration. The approximation assumes there is stability in the underlying population, as individuals traverse the age-time plane represented by the well-known Lexis diagram (Fig. 5.1). The German demographer Lexis (1875) described this graphical representation of the life history of subjects according to birth cohort (the abscissa) and age (the ordinate). The modern interpretation of the Lexis diagram displays subjects arranged by calendar year of event and age at time of event on the same unit scale, with each cell corresponding to a year of birth, the diagonal tracing the experience of subjects born in the same year, who are under observation until either the end of follow-up; the event of interest occurs; or they are lost to follow-up. In the commonly tabulated system used for vital rates, a synthetic birth cohort over a 10-year range is derived from the combined experience of a 5-year age group over 5 years of occurrence. Approximate cohorts are identified by their central year of birth and overlap each other by exactly 5 years. Given a steady state of demographic gains and losses, where the number of individuals in a designated period entering an age group equals the number that leave, the method can be considered to provide adequate estimates of the person-time at risk in most circumstances. For diseases that are relatively rare (of low prevalence), the estimate is not unduly biased by the fact that the numerator is a subset of the denominator.

It should be recalled that the number of units of person-time does not represent a number of independent observations. One hundred person-years of observation may result from 100 persons being followed for 1 year each or from 20 people under observation for 5 years.

Population at risk should, ideally, only include those persons who are potentially susceptible to the disease being studied. Sometimes, this is taken into account in the denominator, for example, in studying occupational diseases (where only those in the relevant occupation are at risk), and in infectious disease epidemiology, where a large proportion of the population is immune.

5.3 Comparisons Between Populations

In descriptive studies, comparisons between two or more populations are usually based on rates that account for the person-time at risk in each group using mid-year population estimates. The summary measure is estimated by stratifying on some well-known factor to remove its effect as a potential confounder. Comparisons of disease risk as a rule must take into account the effects of age, given its influence on both the disease process and the exposure of interest across groups.

The graphical representation of age-specific rates in a particular population describes how risk evolves with age. In comparing age-disease curves in two (or more) populations, it is a useful point of departure, often alerting the researcher to anomalies in the data or to certain hypotheses that warrant further investigation. Standard methods exist for comparing rates in two or more populations. The simple techniques include the comparison of rates based on age standardization and stratification methods that pool the age-specific rates to obtain a weighted ratio (Mantel and Haenszel 1959). In the presence of heterogeneity in the age-specific rates, pooling or standardization may not provide a satisfactory measure of relative risk, and visual inspections together with statistical tests that look for departures from the assumption of proportionality (homogeneity) should be investigated (Estève et al. 1994).

Greater flexibility and a more unified framework is a prerequisite when dealing with a series of population comparisons, and, given most diseases are multifactorial, the analysis must consider the association between numerous factors on disease risk while adjusting for several potential confounders. Statistical models offer quantitative and comparable estimates of disease risk based on objective criteria for choosing the best description of the data and whether observed variations are real or due to chance. Some methods for the analysis of two groups and multiple groups are briefly described below.

5.3.1 Comparisons Between Two Groups

5.3.1.1 Standardization

The Direct Method Crude rates can be thought of as a weighted sum of age-specific rates that render *biased* comparisons between populations if the weights that represent the size of each age stratum are different in each population compared. The age-standardized rate is the summary rate that would have been observed, given the schedule of age-specific rates, in a population with the age composition of some reference population, called the *standard*. The calculation of the standardized rate is an example of *direct standardization*, whereby the observed age-specific rates in each group are applied to the *same* standard, that is, the same age-specific weights. Age groups are indexed by the subscript i, d_i is the number of cases, y_i is the number of person-time at risk (frequently obtained by multiplying population estimates based on those at risk by the length of the observation period), and w_i is the proportion of persons or *weight* of age group i in the chosen standard population. The age-standardized rate (*ASR*) is given by

$$ASR = \sum_i d_i w_i / y_i .$$

The main criticism of the technique stems from the need to select an arbitrary standard population. The most widely used reference for global comparisons is the world standard, as proposed by Segi (1960) on the basis of the pooled population of 46 countries and modified for the first volume of *Cancer Incidence in Five Continents* by Doll et al. (1966). Although this does not really resemble the age structure of the current population of the world (so that *ASR*s will rarely be similar to crude rates), this is of little importance, since it is the *ratio* of *ASR*s (the standardized rate ratio), an estimate of relative risk between populations, that is the focus of interest. This has been shown to be quite insensitive to the choice of standard (Bray et al. 2002; Gillum 2002).

Another form of direct standardization involves the cumulative risk, defined as the probability that an individual will develop the disease in question during a certain age span, in the absence of other competing causes of death. The age span over which the risk is accumulated must be specified. The age ranges 0–64 and 0–74 are generally used and attempt to give two representations of the lifetime risk of developing the disease. Other age ranges may be more appropriate for more specific needs, such as investigating childhood diseases. If the cumulative risk using the above age ranges is less than 10%, as is the case for relatively rare diseases, it can be approximated very well by the cumulative rate (cf. chapter ▸Rates, Risks, Measures of Association and Impact of this handbook).

The cumulative rate is the summation of the age-specific rates over each year of age from birth to a defined upper age limit. As age-specific incidence rates are typically computed for 5-year age intervals, the cumulative rate is then five times the sum of the age-specific rates calculated over the 5-year age groups, assuming the age-specific rates are the same for all ages within the 5-year age stratum. The cumulative rate from 0 to 74 is given by

$$5 \sum_{i=1}^{15} d_i / y_i .$$

The precise mathematical relationship between the cumulative rate and the cumulative risk (Day 1992) is

$$\text{cumulative risk} = 1 - \exp(-\text{cumulative rate}).$$

The cumulative rate has several advantages over age-standardized rates. Firstly, the predicament of choosing an arbitrary reference population is irrelevant. Secondly, as an approximation to the cumulative risk, it has a greater intuitive appeal and is more directly interpretable as a measurement of lifetime risk, assuming no other causes of death are in operation.

The Indirect Method An alternative form of age standardization, known as the *indirect method*, involves calculating the ratio of the total number of cases *observed* in the population of interest, $O = \sum_i d_i$, to the number of cases which would be *expected*, E, if the age-specific risks of some reference population applied. The expected number of cases in a study population is given by

$$E = \sum_i m_i y_i$$

where the m_i are age-specific rates for the reference population and y_i the number of persons in age class i in the population of interest. The ratio is termed the standardized mortality ratio (SMR) when deaths and mortality rates are used; the terms "standardized incidence ratio" (SIR) or "standardized morbidity ratio" are used for incidence data. Expressed as a percentage, the calculation is

$$SMR \text{ (or } SIR) = \frac{O}{E} \times 100.$$

There are two ways in which the reference population can be chosen. If the aim is to compare several populations with a specific reference population, then it would be sensible to choose a reference population with relatively large numbers of observed cases, since this increases the precision of the reference rates. A second strategy would be to create a pooled population from those to be compared; this has the advantage of increasing the precision of the reference rates and is analogous to comparing the observed rate in each population with that expected if the true age-specific risks were identical in all of the populations. Whichever approach is taken, it is important to realize that the *SMR*s of the individual populations can only be compared with the reference population. In addition, the *SMR* for population A compared with population B is *not* the inverse of the *SMR* for B compared with A.

Both direct and indirect standardization can give a reasonable summary of a multiplicative effect and are normally close in practice. Indirect standardization however requires a further assumption of uniformity of the effect – the *SMR* has optimal statistical properties only if the force of incidence in the population of interest is *proportional* to that of the reference.

Direct standardization is preferred for statistical reasons, given that a ratio of *SMR*s for two comparison groups may in some instances misrepresent the underlying stratum-specific ratios (Breslow and Day 1987). The risk ratio of two directly standardized rates (based on the same standard) has an associated confidence interval based on either exact variance calculations (Rothman and Greenland 1998) or a close approximation given by Smith (1987). As already mentioned, heterogeneity in the age-specific rates may render the relative risk estimate invalid.

5.3.1.2 Stratification: The Mantel-Haenszel (MH) Estimate

The standardized rate ratio is not a very efficient estimator of relative risk, since the weightings for the age strata are entirely arbitrary. More efficient summary measures assume uniformity across strata. The common rate ratio ρ for population 1 compared with population 0 is $\rho = \lambda_{1i}/\lambda_{0i}$. This relation can be written as $\lambda_{1i} = \lambda_{0i} \cdot \rho$ or, in the form of a *log-linear model*, as

$$\ln(\lambda_{1i}) = \ln(\lambda_{0i}) + \ln(\rho)\,.$$

This is sometimes called the *multiplicative model*.

The Mantel-Haenszel (MH) estimate of the common rate ratio ρ is simply the weighted average of the ratio of the age-specific rates:

$$\hat{\rho} = \frac{\sum\limits_i \frac{d_{1i}\, y_{0i}}{y_{\cdot i}}}{\sum\limits_i \frac{d_{0i}\, y_{1i}}{y_{\cdot i}}}$$

where $\cdot$ denotes summation over the index it replaces.

The Cochran-Mantel-Haenszel (CMH) test tests the hypothesis $\rho \neq 1$ against the null hypothesis $\rho = 1$ (Cochran 1954), for example, whether the force of incidence is identical in the two populations being compared ($\rho = 1$). However, the CMH test is valid only if the age-specific rate ratios are approximately proportional, that is, $\rho_i \approx \rho$. Therefore, it is important to check this assumption. Several such tests are described by Breslow (1984); one method involves comparing the numbers of cases observed and expected under the assumption of proportionality, while another tests the same null hypothesis against the specific alternative of a trend (increasing or decreasing) in the age-specific rate ratios. The different hypotheses which can be tested and their corresponding alternative hypotheses are shown in Table 5.2 and Fig. 5.2 below. More details and the required formulae can be found in Estève et al. (1994).

Table 5.2 Null hypotheses and corresponding alternatives for the common rate ratio ρ

H_0 (null hypothesis)	H_a (alternative hypothesis)
$\rho = 1$	$\rho \neq 1$, test for a common rate ratio (i.e., assumes proportionality)
$\rho_i = \rho$	ρ_i unrestricted, test for heterogeneity in the ρ_i
$\rho_i = \rho$	$\rho_i = \rho \times f(i)$, test for trend in the ρ_i with the age values i

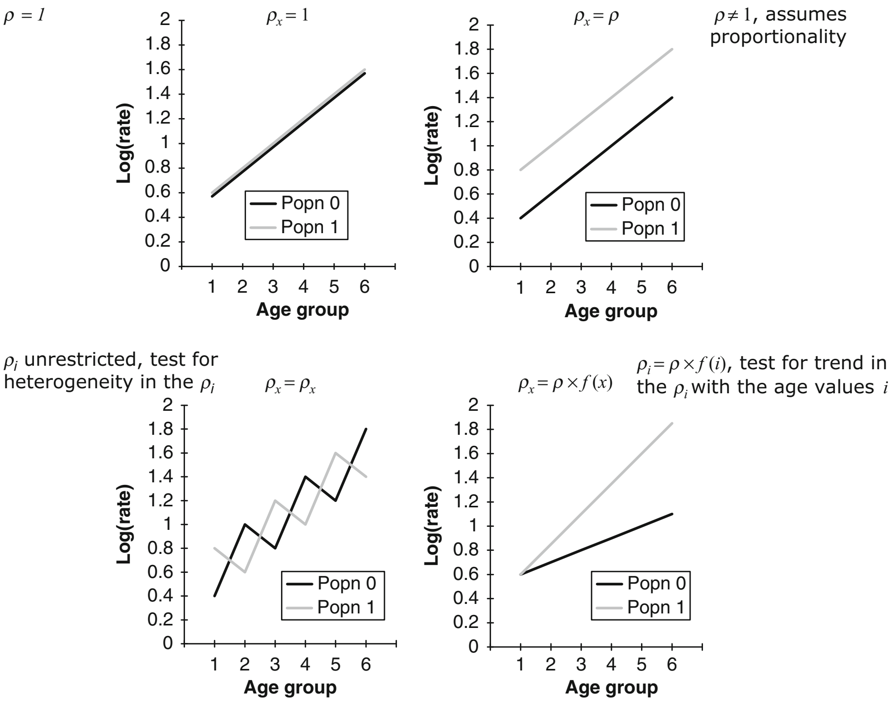

Fig. 5.2 Graphical representation of the null hypotheses and alternatives described in Table 5.2

5.3.2 Comparisons Between Multiple Groups

In practice, when comparing multiple populations, the simple methods above offer some serious limitations. Generally, a series of pairwise comparisons may yield spurious significant results due to multiple testing and is therefore not appropriate. In indirect standardization, the choosing of the age-specific risks of one population as a reference over several others is inconsistent: the *ratio* of population 1 relative to population 0 is not the inverse of the *ratio* of the population 0 relative to population 1.

In most studies, there are a number of confounders that require examination and possible adjustment, other than age. The Mantel-Haenszel estimates may be extended to adjust simultaneously for several confounders, but we may not have sufficient data to simultaneously consider many strata. In addition, it is not possible to classify an explanatory variable as an exposure or a confounder using this method, and a separate analysis is required to obtain rate ratios for each exposure adjusted for the confounders.

A regression model provides a uniform framework for estimating the magnitude of the effect of interest, testing whether the effect is uniform across subgroups of the populations (effect modification), whether the effects of potential confounders may account for the effect, and whether a particular model is given a parsimonious but adequate description of the observed data.

Further details on appropriate regression models as well as the techniques and strategies required in statistical modeling are described in chapters ▶Regression Methods for Epidemiological Analysis and ▶Survival Analysis of this handbook. A particular model that attempts to quantify trends in rates over time as a function of age, period of event, and year of birth is described in detail in Sect. 5.5.3.3 of this chapter.

5.4 Study Designs in Descriptive Epidemiology

5.4.1 Data on Individuals

Investigation of observed associations between exposure variables, and disease outcome in individuals, may be investigated using cohort (prospective) (cf. chapter ▶Cohort Studies of this handbook), case-control (retrospective) (cf. chapter ▶Case-Control Studies), and cross-sectional study designs.

5.4.1.1 Cohort Designs

The basic descriptive epidemiological study involves a comparison of disease rates in individuals categorized according to exposure variables that have been obtained from "routine" data sources and relate to personal (demographic) characteristics, place (of residence, birth, diagnosis), and time (of birth, of diagnosis). The focus is on the risk in one exposure group, relative to another. Relative risks may be approximated by the ratio of disease rates, with person-years at risk estimated from census data (or population registers, if available). The simplest way to adjust for the major confounders (especially age) is by standardization of the rates used for the rate ratios (Sect. 5.3.1.1). The idea of comparing summary rates for two populations seems appealing since we would hope to describe the differences between the two as a simple ratio. However, this simple description would only be appropriate if the proportional differences in age-specific rates were constant across all age groups, that is, if the assumption of proportionality holds (see Sect. 5.3.1.2). The multiplicative model presented in Sect. 5.3.1.2 is important in descriptive cancer epidemiology, since the aim is generally to estimate ρ and its statistical significance (Breslow 1984; Estève et al. 1994).

Alternatives to the rate ratios of age-standardized rates are the Mantel-Haenszel estimate (MH) introduced in Sect. 5.3.1.2, which has been shown to be particularly robust, and the internal standardization method of maximum likelihood (ML), which has optimal statistical properties (Breslow and Day 1975). Providing the assumption of proportionality of the ratio of the age-specific rates in the two groups is valid, the values obtained from the three methods should be close.

An alternative method of comparison is to calculate the standardized incidence ratio (SIR) for the populations being compared to a reference population

(Sect. 5.3.1.1 "The Indirect Method"). This indirect standardization is often preferred to direct standardization to increase statistical precision for rare diseases or small populations. As already mentioned in Sect. 5.3.2, when more than one confounding variable (age) is present, the adjustment methods discussed above are not suitable, and it is more efficient to use standard log-linear modeling methods (Kaldor et al. 1990; Kirkwood and Sterne 2003). When the population-at-risk in each cell of the cross-classification is available, it is assumed that the number of cases or deaths per cell has a Poisson distribution, with mean value proportional to the number of person-years at risk, and that the logarithm of the rate is a linear function of the classification variables. Poisson regression provides adjusted relative risk estimates for each population group, with reference to an appropriate standard. Even when age is the only confounding variable, statistical modeling has advantages over standardization and related techniques in relative risk estimates with greater numerical stability (Breslow and Day 1987).

5.4.1.2 Case-Control Comparisons

Very often, in descriptive studies, the information on the cases/deaths is more detailed, in terms of variables of interest, than that on the population at risk. For example, the case file may include information on occupation, socioeconomic status, or details about date of immigration, while the population-at-risk cannot be categorized in such detail. Analysis has to rely entirely on the numerator data, that is, on proportionate incidence or mortality data. Comparison of proportions between different case series via the proportionate mortality ratio (*PMR*) or proportionate incidence ratio (*PIR*) is generally, implicitly at least, an attempt to approximate the relative risk or ratio of rates. Confounding by age (as a result of different age structures of the case series being compared) can be removed by indirect standardization techniques, with the fraction of deaths or of cases due to specific causes in the reference series as the standard (Breslow and Day 1987). Proportionate methods are, however, relative measures, and the *PMR* for a specific disease (age standardized) is close in value to the ratio of the *SMR* for the disease, to the *SMR* for all causes (Kupper et al. 1978).

Odds ratios provide a better estimate of relative risk than the ratio of proportions, in most circumstances (Miettinen and Wang 1981). Odds ratios are estimated by case-control comparisons, comparing exposure status among the cases of the disease of interest, and cases/deaths of other (control) diseases. Unconditional logistic regression or stratified analyses are performed to obtain maximum likelihood estimates of the odds ratios (Breslow and Day 1980). The odds ratio values based on logistic regression are heavily dependent on the choice of the controls: if the risk for the subjects used as controls is unrelated to exposure, the estimates from the logistic model for the effects of exposure closely approximate those which would be obtained using Poisson regression with denominator populations.

These methods have been widely used in the study of disease risk by social status and occupation (Logan 1982) and in migrant populations (Marmot et al. 1984; Kaldor et al. 1990).

5.4.1.3 Cross-Sectional Studies

In contrast to longitudinal studies, for which observations of cause and effect represent different points in time, cross-sectional studies *simultaneously* observe exposure status and outcome status at a single point in time or over a short period in the life of members of a sample population. The analysis proceeds by determining the prevalence "rates" in exposed and non-exposed persons or, according to level of exposure, commonly using data from complete population surveys to correlate putative etiological factors with outcome.

Cross-sectional studies are relevant to public health planning, in that they may provide information on the care requirements of a population at a given point in time. In the context of investigative inquiries, they can be considered advantageous to more complex designs in measuring the association between diseases of slow inception and long duration, where the time of onset is difficult to establish, such as osteoarthritis or certain mental disorders, and exposures that endure over a prolonged time period, for example, HLA antigens or air pollution levels. They are simpler, quicker, and more economical than cohort (longitudinal studies), as no follow-up of individuals is required. In addition, the sample may be more representative of the target population as they are based on a sample of the general population.

There are however two major drawbacks to cross-sectional studies. Firstly, it is difficult to establish whether the temporal sequence is from that of exposure to outcome or vice versa. Are individuals, for instance, in lower socioeconomic groups more likely to develop mental disorders, or is it that mental illness triggers a series of events that relegates persons from a wide spectrum of socioeconomic groups to a lower status at the time of measurement? Thus, it is important to consider the possibility of reverse causation – whereby exposure status is in part a consequence of disease; the association obtained in a cross-sectional study may be wholly different from that obtained at time of the disease origin. Secondly, as it is usually not possible to determine incidence in cross-sectional studies, the use of prevalence as a proxy of frequency may distort the exposure-disease relationship as, by definition, the prevalence measure will include a larger number of cases with a long duration of disease relative to incidence. Hence, persons who die or recover quickly tend to be less likely to be included as a prevalent case than persons with long-lasting disease.

In descriptive studies, measures of exposure and outcome are taken directly from existing survey datasets. These include general purpose datasets, such as that derived from the General Lifestyle Survey in the UK (Office for National Statistics 2012), a multipurpose continuous survey which collects information on a range of topics, including health and the use of health services from people living in private households in Great Britain. Other datasets, more specific to health topics, include the National Health Interview Survey (NHIS) and National Health and Nutrition Examination Survey (NHANES) carried out by the National Center for Health Statistics (CDC 2012) in the USA.

The analysis proceeds by classifying exposure and outcome status dichotomously in a contingency table. A *prevalence rate ratio* can be calculated as the ratio of the prevalence of the outcome in those exposed to the putative risk factor compared with those not exposed or, where the level of exposure varies by intensity, test for a trend in outcome by exposure category. A case-control approach to the analysis can also be taken, whereby the *odds ratio* is calculated, although it is important to appreciate that the two ratios are not equivalent and only approximate each other when the prevalence and odds are small and the disease is rare (cross-sectional studies however require relatively common outcomes). Confounding is an important bias (cf. chapter ▸Confounding and Interaction of this handbook), and multivariate techniques such as logistic regression (estimating odds ratios) and proportional hazards models (estimating prevalence rate ratios) can be used when the outcome is, for example, the presence or absence of disease.

5.4.2 Ecological Studies

5.4.2.1 Main Characteristics

The characteristic of ecological studies is that *exposure* and *outcome* are measured on *populations/groups*, rather than on individuals. The units of observation may be populations defined by place of residence (counties, regions, districts, etc.); by personal characteristics, such as race, religion, or socioeconomic status; or by time (birth cohorts). Usually, these studies are descriptive, in that they exploit preexisting sources of information, rather than data collected to investigate a specific hypothesis. Thus, the outcome (disease) data are the likes of mortality rates, incidence rates, or prevalence data from health surveys. Exposure information may be from sources such as household/community surveys, environmental measurements, or commercial sources (data on production or sales). Exposure is expressed as an aggregate (summary) measure such as population mean, median, and proportion based on observations from individuals within the group. Exposure data may also be some environmental measurement (e.g., of air pollution, ambient temperature). The essential difference from most epidemiological study designs is that there is no information on the joint distribution of exposure and outcome in the individuals *within* the populations being studied. Table 5.3 shows two populations (A and B). In studies in which data on individuals are available, the numbers in the individual cells of each table are known, and we may calculate relative risks or odds ratios for each (and combine the results from the two strata). However, in an ecological study, only the values in the margins of each table (with n_{EA} denoting the number of exposed and $n_{\bar{E}A}$ the number of non-exposed subjects in population A and n_{DA} denoting the number of diseased and $n_{\bar{D}A}$ the number of non-diseased subjects in population A, analogously for population B) are known, so that we have simply prevalence of exposure, and disease incidence or prevalence, for populations A and B.

Ecological studies may be used to generate (or test) etiological hypotheses and to evaluate interventions at the population level.

The main problem, as described below, is that ecological designs are usually being employed to make such inferences (concerning cause/prevention) about individuals, based upon observations using groups. Such interpretations are prey to

Table 5.3 Ecological study: comparison of prevalence of exposure and outcome in two populations A and B

	A				B		
	Diseased	Non-diseased	Total		Diseased	Non-diseased	Total
Exposed	?	?	n_{EA}	Exposed	?	?	n_{EB}
Non-exposed	?	?	$n_{\bar{E}A}$	Non-exposed	?	?	$n_{\bar{E}B}$
Total	n_{DA}	$n_{\bar{D}A}$		Total	n_{DB}	$n_{\bar{D}B}$	

Prevalence of exposure in A = $\frac{n_{EA}}{n_{EA}+n_{\bar{E}A}}$

Prevalence of exposure in B = $\frac{n_{EB}}{n_{EB}+n_{\bar{E}B}}$

Rate of disease in A = $\frac{n_{DA}}{n_{DA}+n_{\bar{D}A}}$

Rate of disease in B = $\frac{n_{DB}}{n_{DB}+n_{\bar{D}B}}$

a variety of artifacts, referred to collectively as “the ecological fallacy” (Piantadosi et al. 1988). However, ecological studies may have particular value when some characteristic of the group (rather than the sum of individuals within it) is important in determining outcome, so that ecological designs are more appropriate than studies of individuals within the groups (see Sect. 5.4.2.4). Similarly, ecological studies may be used to evaluate the effect of population-level interventions, especially if the interest is in the effect at group rather than individual level. Thus, the relationship between exercise and mortality from cardiovascular disease may be known from individual-based studies, but the effectiveness of an educational program on the topic in influencing disease rates might choose an ecological design to capture the combined effect at group and individual level.

5.4.2.2 Types of Design

Exploratory Ecological Studies The term “exploratory ecological study” has sometimes been used to describe the comparison of disease rates between populations defined, for example, by place of residence, ethnic group, birthplace, or birth cohort (Estève et al. 1994; Morgenstern 1982). In fact, it is hard to understand the justification for the use of the term “ecological” for such studies. They compare disease risk among individuals characterized by various exposure variables (such as place of residence, or birthplace, or period of birth) and as such, differ only in the source of information, from cohort studies using questionnaires or biological measurements, comparing disease rates according to exposure type or level (occupational groups, smoking status, etc.). Probably, the term should be reserved for comparisons between groups in which “exposure” has not been measured but is simply assumed from some sort of a priori knowledge or guesswork. This is the basis of many studies carried out with quite sophisticated laboratory methods, where the subjects comprise some sort of sample (usually by no means random) from populations believed to be at high/medium/low exposure of something. Another version would be studies in which exposure is not measured, and may not even be defined, but is assumed to have some underlying spatial or temporal distribution; the purpose of the analysis is to see if disease risk in the population groups studied has,

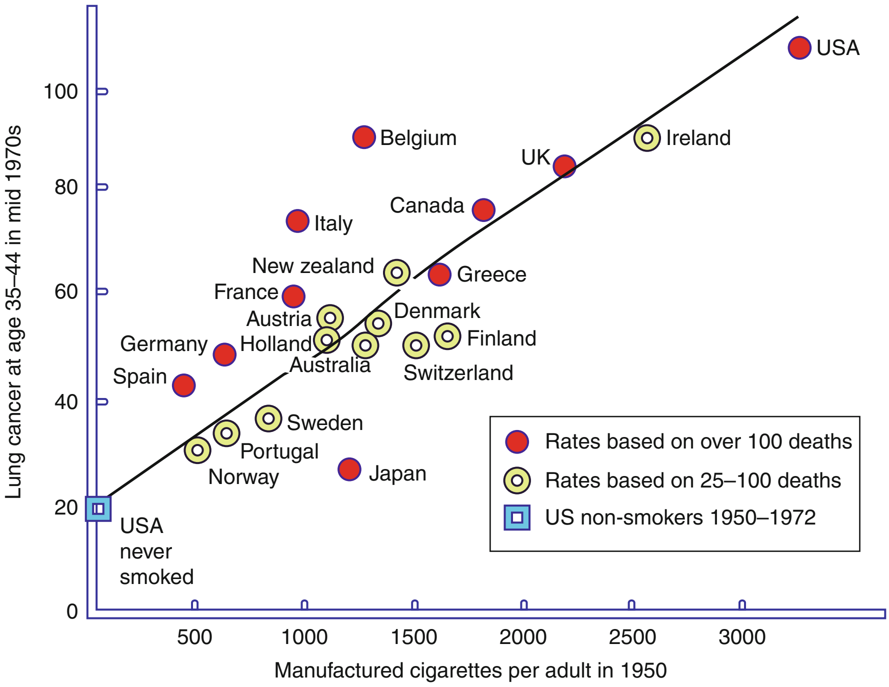

Fig. 5.3 International correlation between manufactured cigarette consumption per adult in 1950 while one particular generation was entering adult life (in 1950), and lung cancer rates in that generation enters middle age (in the mid-1970s)

too. This includes studies of geographical clustering and of spatial autocorrelation (cf. chapter ►Geographical Epidemiology of this handbook).

Multigroup Comparison Ecological Study This is the most commonly used study design. For several populations (usually geographical regions), outcome (disease) levels (prevalence, rates) are compared with exposure (means, proportions) variables of interest. An example is given by the early studies suggesting the importance of blood lipids in the etiology of ischemic heart disease. Coronary heart disease rates were compared with plasma cholesterol and dietary fat intake in different populations (McGill 1968). Figure 5.3 shows a well-known example from Doll and Peto (1981), relating lung cancer mortality to consumption of manufactured cigarettes.

Time Trend Ecological Studies A single population is studied, but is cut up into *groups* corresponding to different time periods. The objective of the study is to determine whether the time trend in outcome (disease rates) corresponds to time trend in exposure.

Multiple Group Time-Trend Ecological Studies These are a mixture of multi-group and time trend designs. Change in exposure and outcome over time is compared for several populations. Dwyer and Hetzel (1980) compared time trends in coronary heart disease mortality in three countries in relation to changes in major risk factors. The advantage of this design is that it is less subject to confounding than with a single population, that is, the unmeasured factor, related to both exposure and outcome (change in disease), is unlikely in several different populations but quite possible in one.

5.4.2.3 Analytical Methods

The simplest level of analysis is to plot the disease rate and indicator of exposure for each population on a scattergram and to calculate a correlation coefficient. This merely indicates the level (strength and direction) of association between the parameters; it does not necessarily imply that the exposure variables predict outcome, rather that other influencing factors (confounders) are likely to have been well controlled in the ecological grouping. Moreover, the correlation coefficients may be quite biased, especially if the groups for study have been chosen on the basis of their level of exposure.

More usually, interest lies in quantifying the magnitude of the effect to be expected from different levels of exposure, and regression of group-specific disease rates (Y) on group-specific exposure prevalence (x) is the method employed. The simple linear model ($Y = \alpha + \beta x + \varepsilon$ with ε denoting an error term) is typically used. An estimate of the effect of exposure (at the individual level) can be derived from the regression results (Beral et al. 1979). The relative risk is the ratio of the disease rate (Y) in an exposed population ($x = 1$) divided by the rate in an non-exposed population ($x = 0$). Assuming the above linear model for Y, this results in

$$RR = \frac{\alpha + \beta * 1}{\alpha + \beta * 0} = \frac{\alpha + \beta}{\alpha} = 1 + \frac{\beta}{\alpha}.$$

If a log-linear model is fitted, such that $\ln(Y) = \alpha + \beta x + \varepsilon$, then the estimate of relative risk can be derived as $\exp(\hat{\beta})$. For more details on regression models, we refer to chapter ▶Regression Methods for Epidemiological Analysis of this handbook.

These equations assume that the groups studied are perfectly homogenous for exposure and that the relationship modeled (prediction of disease rate) is valid at both extremes of exposure (nil or total), a situation that is rarely observed in practice. Homogeneity of exposure is unlikely, of course, and the summary statistics (means, medians) have large and unknown error terms. Trying to mitigate the problem by studying small population gives rise to different technical problems (measurement error, migration) and a larger variance of estimated disease rates.

In the situation where the rates in the different populations being compared have different precision (due to varying size), weighted regression is frequently used, to give more emphasis to the larger units. The usual weighting applied is the inverse of the variance, although maximum likelihood methods (taking into account variation in rates that would be expected by chance) may be more appropriate (Pocock et al. 1981).

Time Lagging It is reasonable to take exposure date from an earlier period than that for the outcome (disease). Varying the interval to obtain the best fit (e.g., correlation) has been used to provide information on the possible induction period between exposure and disease. Rose (1982) found that the correlation between serum cholesterol and coronary heart disease mortality in men aged 40–59 in seven countries was maximal when the interval between the two measures was 15 years.

5.4.2.4 Advantages of Ecological Studies

There are several advantages to ecological study designs:

- They are very economical, since they use existing data on exposure and outcome, with no costs involved in collection.
- They are very rapid, even compared with case-control studies, where time is needed for recruitment, for example, for investigating suspect clusters.
- Very large numbers can be studied, so that *small* increases in risk can be investigated. Small risks affecting large numbers of people are important from a public health point of view.
- They may – and ideally do – include populations with a very wide range of exposure level (more than can be found in a single population used for conventional cohort or case-control studies). For example, the range of variation in dietary fat intake in a single population may be too small to demonstrate the differences in risk at different levels (Prentice and Sheppard 1990).
- They may be the only practical analytical approach to investigating the effects of an exposure that is *relatively constant* in a population but differs *between* populations, for example, exposure to external environment (air, radiation, water).
- In many circumstances, individual measures of exposure are difficult or impossible to obtain. This is often the case in studies of diet and disease, since collection of individual food records is difficult, may not reflect habitual intake, and does not allow for individual variability in metabolic response to a given diet. 24-hour dietary recalls, although of little value in the study of dietary exposures in individuals, may, when averaged for a population, provide a useful indicator of exposure for ecological analysis. The same principles apply to average exposures to air pollution, trace elements in soil/water, and so on.
- There may be interest in "contextual effects," that is, group or community level effects, rather than inferences about individual exposure-outcome. This is particularly important in communicable disease epidemiology, where models of transmission have a group component, for example, transmission of vector-borne diseases will be dependent upon the prevalence of carriers in the population (Koopman and Longini 1994). Ecological studies are relevant in examining the effects of policy, laws, and social processes where contextual as well as individual effects are relevant to the outcome.

5.4.2.5 Disadvantages of Ecological Studies

The above advantages have to be contrasted with several disadvantages, not only from a technical perspective.

Technical Disadvantages

- *Data Problems*

  The data on exposure are obtained from existing sources, usually not compiled for the purpose for which they are being used, and may in consequence lead to a somewhat inaccurate estimator of the relevant exposure. Thus, data based on production, sales, or food disappearance give only an approximate guide to actual exposure, even at the group level. If the data are from a sample of the population, this may be unrepresentative of the group. The outcome (disease) variables are subject to similar concerns. Data quality may differ between the populations, due, for example, to varying completeness of death registration. Lack of comparability may also result from changes in disease classification or coding over time. A further concern is the accuracy of person-years at risk for group data. This is an issue for all types of descriptive study, where person-years at risk are estimated from cross-sectional counts, rather than longitudinal observation of individuals. Moreover, migration of populations will make comparisons over time difficult since cases of disease may not be exactly from the exposed population. This problem is compounded if migration is related to the presence of the disease studied. A solution commonly adopted is simply to assert that the populations studied are "stable," without having any objective evidence to that effect.

  Misclassification of exposure within the groups being studied may have surprising consequences. Even when non-differential (unrelated to outcome), the bias in estimated risk of exposure may be away from the null value – the opposite to the familiar situation in individual-based studies (Brenner et al. 1992).
- *Availability of Data*

  The number of variables available for the populations studied is quite limited. There is little scope for any adjustment for possible confounding (limited though this is in ecological studies).
- *Problem of Induction Period*

  It is reasonable to assume that there is some delay between exposure and outcome and that both should not be measured at the same time. It is not difficult to find published studies in which the exposure measures postdate those of outcome. Some time lag should be included (e.g., Fig. 5.3), but this involves assumptions, possibly arbitrary, as to the appropriate mean interval to use. Furthermore, exposure information may not be available for the relatively distant past, and, when it is, the population in the units of analysis will comprise different individuals, if exposure and outcome measures are far apart in time.
- *Ecological Fallacy*

  This is the main problem when inferences about individual exposure-outcome associations are being inferred from observations at the group level (Piantadosi et al. 1988). In this instance, the assumption being made is that the single measure

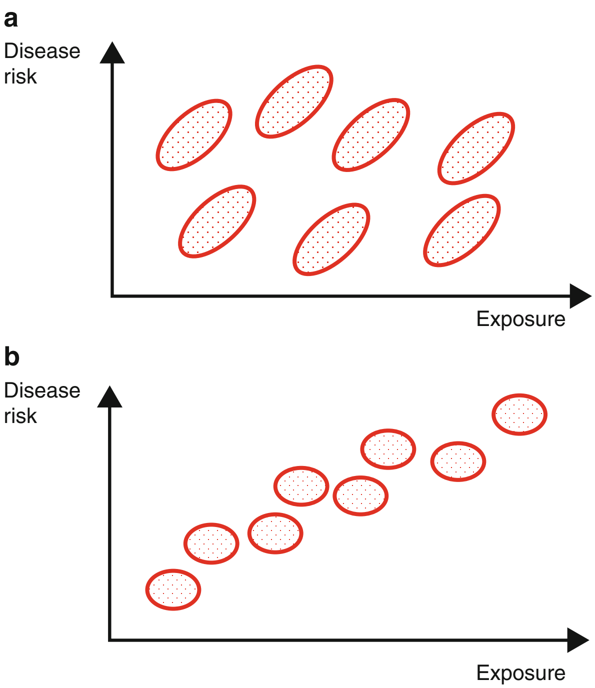

Fig. 5.4 Two situations illustrating the difference between ecological and individual associations between exposure and disease (From Walter 1991)

of exposure applies to all members of the group. This is rarely so. Often, it is obvious (e.g., exposure variable is a group mean, with its own variance). Else, it is intuitive (e.g., exposure variable is an environmental measure – e.g., solar UV, nitrate in drinking water), but individual behaviors result in varying exposure to it (wearing hats, long holidays or work periods elsewhere, using bottled water, etc.). As a result, there may be a difference between the relationship at the individual level (within groups) and group level (between groups). Ecological associations may be weaker, or stronger, than relevant associations at individual region. Figure 5.4 (from Walter 1991) illustrates two extreme scenarios. In A, there is a strong covariance between exposure and outcome within groups, but a very weak one between groups. An ecological analysis, based on a single aggregate measure of exposure and outcome for each group would show only a weak association. In B, the association within groups is weak but appears strong when examined between groups.

- *Ecological Bias*
  Due to the failure of the expected ecological effect estimates to reflect the biological effect at the individual level, two forms of bias are said to exist (Morgenstern 1982). Aggregation bias: data are aggregated, ignoring the information from the subgroups from which the individual observations came. Specification bias: a problem of using groups that in some way are related to the disease (irrespective of the exposure under study). It may result from extraneous risk factors being differentially distributed by group or from property of the

Table 5.4 An example of ecological (cross-level) bias

	Prevalence	Exposed			Non-exposed			Total		
Population	of exposure	n_E	N_E	R_E	$n_{\bar{E}}$	$N_{\bar{E}}$	$R_{\bar{E}}$	n_T	N_T	R_T
A	0.25	1,200	1×10^6	1.2	1,800	3×10^6	0.6	3,000	4×10^6	0.75
B	0.50	3,330	2×10^6	1.67	1,670	2×10^6	0.84	5,000	4×10^6	1.25
C	0.75	6,000	3×10^6	2.0	1,000	1×10^6	1.0	7,000	4×10^6	1.75
All	(0.50)	10,530	6×10^6	1.76	4,470	6×10^6	0.75	15,000	12×10^6	1.25

group itself (contextual effects). The sum of these two components provides "the ecological bias" (cross-level bias) which is present. Table 5.4 gives an example.

The relative risk of exposure in each of the three populations, A, B, and C, is 2.0 ($R_E/R_{\bar{E}}$ with R_E and $R_{\bar{E}}$ denoting the disease rates in the exposed and non-exposed subjects, respectively), that is, there is no difference in the effect of exposure within the different groups. Although the overall (crude) relative risk, summing the cases and populations at risk for the three groups, is 2.35 = 1.76/0.75, the relative risk, standardized for group, can be estimated by

$$\widehat{RR} = \frac{\sum n_E}{\sum (n_{\bar{E}} N_E)/N_{\bar{E}}},$$

where the summation is across groups, with n_E denoting the number of diseased subjects among the exposed and N_E denoting the total number of exposed subjects in the population (analogously for the non-exposed and the total population). In the example shown, therefore

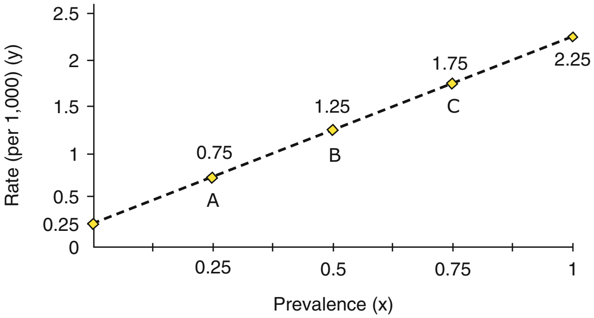
$$\widehat{RR} = \frac{1{,}200 + 3{,}330 + 6{,}000}{(1{,}800 * 1)/3 + (1{,}670 * 2)/2 + (1{,}000 * 3)/1} = 2.0.$$

The difference between the unadjusted and adjusted estimates (2.35 and 2.0) shows that there is confounding by other risk factors, which are different between the groups (as shown by different risks in the non-exposed) indicating a specification bias. Figure 5.5 shows the linear regression of the rate of disease (R_T) on the prevalence of exposure and the ecological estimate of relative risk (Sect. 5.4.2.3). The large difference between the estimates based on ecological and crude individual data (9.0 and 2.35) is the result of aggregation bias since the extraneous factor that increases the risk among the non-exposed is most prevalent in the most exposed population (C).

Confounding and Effect Modification in Ecological Studies

Confounding in epidemiological studies arises when two exposure variables are statistically associated (correlated), and at least one of them is also an independent risk factor for the disease under study, so that both will appear to be so if examined separately. In individual-based studies, with many subjects, it is feasible to separate their effects (by stratification or multivariate methods), because perfect correlation

Fig. 5.5 Ecological analysis (linear regression: $y = \alpha + \beta x$) of the hypothetical data summarized in Table 5.4: $\alpha = 0.25$, $\beta = y - \alpha / x = 2.0$, $RR = 1 + \beta / \alpha = 9.0$



between variables is very unlikely. When groups are studied, however, there may be perfect correlation between variables, particularly if the populations studied are few in number (e.g., the hi-lo two group studies beloved of laboratory workers) and large in size.

Furthermore, risk factors that are independent of exposure at the individual level may be correlated with it, and thus be confounders, when aggregated at the population level. Conversely, a confounding variable at the individual level may not be so at the ecological level; for example, although the risk of most cancers is quite different in males and females, sex, as an ecological variable, will not be associated with disease rates in geographical areas because the ratio of males to females is broadly similar in all.

Effect modification (or interaction) refers to variation in the magnitude of the effect of an exposure across the levels of a third (covariate). Effect modification can be present in an ecological association, even when not evident at the individual level. Greenland and Morgenstern (1989) give an example of a cofactor (e.g., nutritional deficiency) with different prevalence in the populations (regions) studied, which is not a risk factor in the absence of the study factor (smoking). Thus, the non-smoker rates would be the same in all regions (and region would not, therefore, be a confounder in an individual-based study of smoking and disease), but the effect of smoking would differ by region.

5.5 Descriptive Studies

5.5.1 Personal Characteristics

Routine sources of information on morbidity and mortality include information on the so-called "demographic" variables (age, sex, marital status, religion, race, education, occupation, etc.) of the cases, and the corresponding data on population-at-risk may likewise be available. This allows investigations of how characteristics of the individual relate to the risk of disease. Since they may often have striking effects on disease intensity, a number of these variables (particularly age) can be considered as among the foremost risk factors for many diseases. Exploration of the relationship between personal characteristics and disease has generated and confirmed many hypotheses and, importantly, elucidated particular mechanisms concerning other putative factors, by taking account of the strong confounding effects of routine variables that may otherwise have distorted the relationship between outcome and the exposure of interest.

5.5.1.1 Age

The increases with age in morbidity of, and mortality from, disease are more apparent than for any other variable. Excluding accidental and violent deaths, there is a 500-fold variation in the death rate from all causes between the ages of 20 and 80 (Peto and Doll 1997). For epithelial cancers, as well as for cardiovascular disease and chronic respiratory disease, there is more than a 1,000-fold difference. The age-specific patterns also differ between and within diseases; Fig. 5.6 compares the age-specific incidence of several types of cancer. The effects of age are most commonly ascribed to an individual's cumulative exposure to environmental insults (e.g., sociocultural or behavioral factors) over a life span or, in the case of, for example, breast cancer, to the effects of hormonal changes. While the process of aging is commonly put forward as a possible mechanism in its own right, for example, through declining immunological defenses, or an increasing number of mutations in certain somatic cells (Lilienfeld and Lilienfeld 1980), others suggest that while aging is clearly related to disease, there is no evidence that aging itself is a biological process that causes disease (Peto and Doll 1997).

The fundamental importance of age as a major confounder in almost all epidemiological studies is exemplified by age standardization or stratification to control for its effects (see Sect. 5.3.1.1).

Interesting forms of the distribution of disease risk by age have motivated a series of hypotheses as to the biological mechanisms underlying particular diseases. The bimodality of Hodgkin lymphoma (Fig. 5.6) suggested that it comprised at least two distinct forms of the cancer and the likelihood of differing etiologies. Early investigations seeking biological explanations for particular age-disease patterns led to hypotheses concerning the importance of early development to disease later in life. Recently, frailty models have been used to examine heterogeneity in incidence and obtain biologically relevant estimates of the proportion of susceptible individuals and the number of events required for cancers to develop (e.g., Moger et al. 2009). More recently, a life course approach to chronic and infectious disease has been conceptualized, which considers the long-term effects of factors during gestation, childhood, and adolescence on subsequent adult morbidity or mortality (Kuh and Ben-Shlomo 1997; cf. chapter ▸Life Course Epidemiology of this handbook).

The importance of period of birth (birth cohort) is clear when investigating changes in disease risk over time (see Sect. 5.5.3.3); it was through the study of age curves that the influence of generation effects on disease was first realized, however. In examining the age-specific mortality rates from tuberculosis in different calendar periods of time, Frost (1939) after Andvord (1930) showed that the peak in more recent cross-sectional age-mortality curves (in 1930) at later ages (50–60) compared to peaks in young children (0–4) previously (in 1880) and at the ages 20–40 (in 1910) was an illusion – an examination of the same age curves by cohort indicated subjects comprising the 1930 age curve passed through greater risks in previous

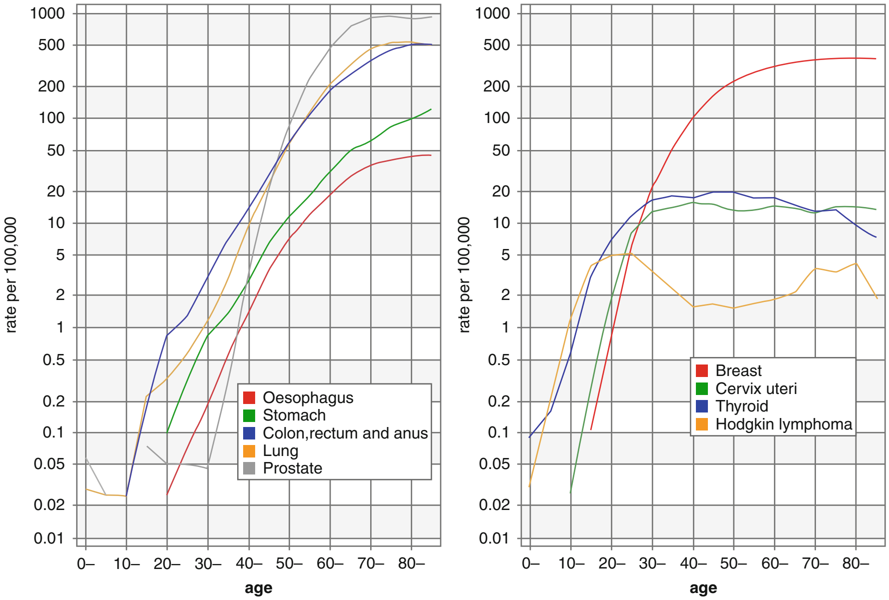


Fig. 5.6 Age-specific incidence rates. Canada, selected cancer sites, 1998–2002

decades – the class of individuals who were children in 1880 and who were aged 50–60 (if still alive) by 1930 (Fig. 5.7). In concluding, he noted that contemporary peaks of mortality in later life did not signify a postponement of maximum risk but rather were the residuals of higher rates in early life.

Korteweg (1951) similarly demonstrated that a cross-sectional view of age curves of lung cancer mortality led to an erroneous interpretation as the age curves were artificially pushed down by the increase in lung cancer in younger age groups – the consistent pattern of declining rates at relatively early ages (65 and over) for five consecutive periods between 1911 and 1945 was therefore not an observation that required a biological explanation. The mechanisms that promoted lung cancer, he observed, acted particularly (but not exclusively) in younger people.

Several well-known biases may distort the underlying age-disease relationship. The quality of mortality statistics in the very elderly is particularly affected by the precision and coding of the death certificate, as well as the decision as to the underlying cause of death. For incidence data, case ascertainment is less effective in the very old, in part due to inaccuracy in the abstraction and coding of diagnostic information and in part due to competing causes of death.

5.5.1.2 Sex

There are, for certain diseases, substantial differentials in the rates in men compared to women (sex ratio) that may represent fundamental differences in exposure to environmental risk factors and/or response to them. Mortality rates from several common causes of death, such as ischemic heart disease, malignant neoplasms,

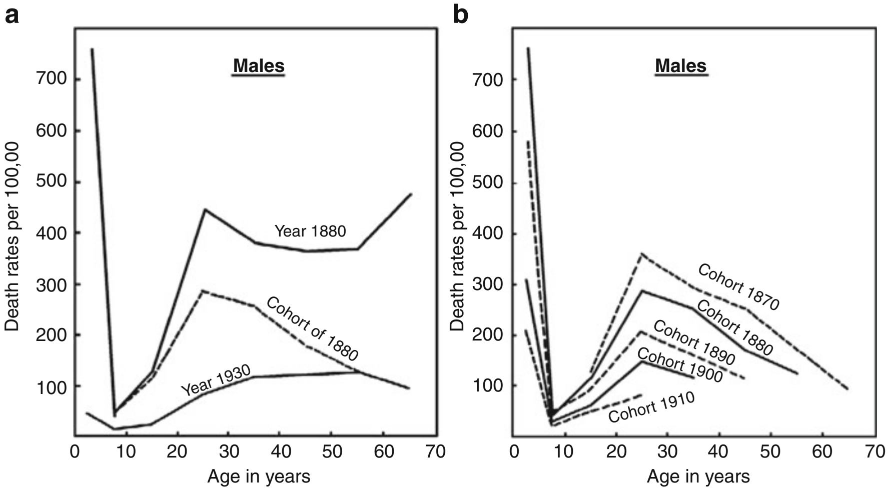

Fig. 5.7 Age-specific mortality rates from tuberculosis in Massachusetts, by period (**a**) and by birth cohort (**b**) (Frost 1939)

and HIV-AIDS (in Western countries), have sex ratios substantially greater than one. The disparity is perhaps not surprising given the contrasting social, cultural, and behavioral practices of men and women and the strong lifestyle component of such diseases. Other than environmental exposures, endogenous factors, such as the sex hormones, may contribute to differences in risk between the sexes, acting as promoters of disease pathogenesis or as protective factors, while our understanding of the putative impact of sex-specific genetic predisposing factors is in its infancy.

The marked differences between the sexes in the incidence of some common cancers are shown in Fig. 5.8; for many of these neoplasms, much of the variation can be explained by contrasting levels of exposure to well-established carcinogens in men relative to women. Hence, the high male:female (M:F ratio) for mesothelioma is largely a consequence of historical exposure to asbestos in men through certain occupations, while lung cancer largely replicates the past history of tobacco smoking in men relative to women. Based on site-specific M:F ratios of age-standardized rates in developed countries, the majority of the cancers of the head and neck, as well as of the bladder and esophagus, are also much more common in men reflecting the heavier alcohol consumption acting independently and multiplicatively with tobacco smoking.

For M:F ratios lower than one, the most outstanding example is for breast cancer for which there is a 500-fold difference in risk in women relative men, which might be attributable to the mammary gland mass, as a correlate of the number of cells susceptible to transformation, as well as hormonal milieu. Differences in gallbladder cancer are probably attributable to a higher prevalence of gallstones in women relative to men. A corresponding distribution of sex ratios is observed for cancer mortality, but additionally, differences in survival (through gender rather than biological differences, e.g., stage of presentation) modify the differentials.

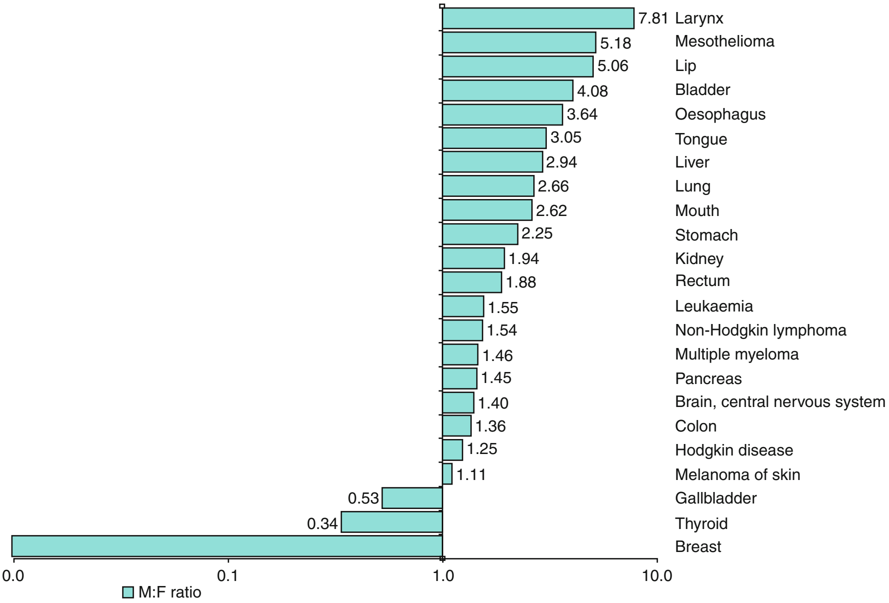

Fig. 5.8 M:F ratios of age-standardized rates for the common cancers in developed areas worldwide (Parkin et al. 2002)

5.5.1.3 Ethnic Group

Variations in the risk of disease and differences in the health experience of individuals from different ethnic groups have been the subject of many studies (Macbeth and Shetty 2001). Studies within multiethnic societies are more valuable than international comparisons, if the primary variable of interest is ethnicity or racial group, since at least some of the environmental differences present in international comparisons are reduced or eliminated. There are plenty of examples of such studies from multiethnic populations in all parts of the world.

Interpretation of ethnic differences in risk should first consider the possibility of data artifact. Even within a single country, it is possible that differential access to health-care and diagnostic services by ethnic group may influence reporting rates of disease, for example, access to and acceptance of screening programs has been shown to differ by ethnic group in several countries (Parker et al. 1998; Seow et al. 1997). Differences in access to treatment certainly can affect outcome, so that survival rates from cancer are well known to vary by race/ethnicity (Baquet and Ringen 1986); since mortality rates are determined by both incidence of disease and survival, this is a major consideration if mortality is being used, as it often is, to provide information on cancer risk.

Artifact aside, the principal question posed by observed interethnic differences in risk is how much is due to variation in exposure (to “carcinogens” or “risk factors”),

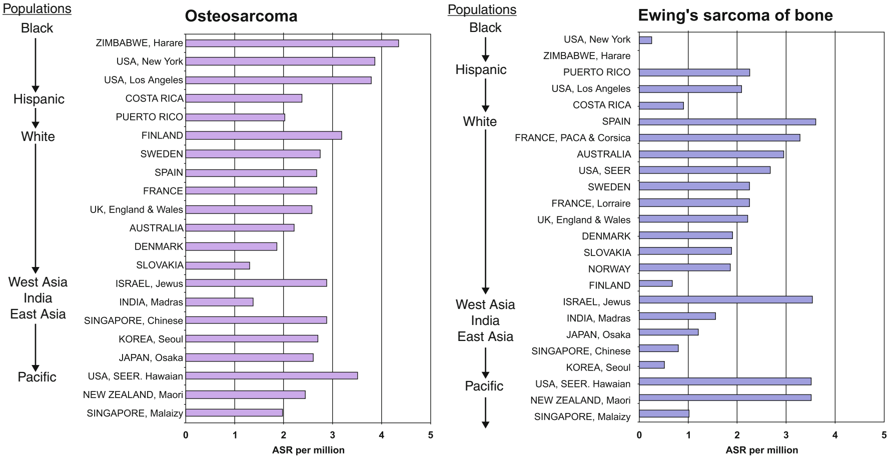

Fig. 5.9 Incidence of osteosarcoma and Ewing's sarcoma in childhood (Parkin et al. 1998)

and how much is the result of inherent differences in susceptibility to such exposures (and hence genetically determined).

From an epidemiological point of view, the variable "ethnicity" or "race" defines a constellation of genetic factors, which relate to susceptibility to a given disease. Of course, there is considerable variation *within* a given ethnic or racial group (however this is defined), but there are often sufficiently large differences between them to yield distinctive patterns of risk. If "ethnicity" is the variable of interest, the first consideration is to eliminate the effect of confounding variables, associated with the risk of disease and differentially distributed by ethnic group. The relevant exposure variable is quite likely to be exposures such as tobacco, alcohol, diet, and infection, but in descriptive studies, there will generally only be information on so-called demographic variables such as social class (or occupation, educational level), place of residence, and marital status that are proxies for these.

A striking illustration of the likely influence of genetic factors on risk of disease is provided by certain cancers of childhood. For bone tumors (Fig. 5.9), there are very marked differences in incidence between ethnic groups for which no plausible environmental "exposure" can be imagined. Any such exposure would have to be very carcinogenic (to act so early in life), very tissue specific, and be very unevenly distributed by ethnic group.

The most fruitful approach using routine data sources is through the study of migrants (see Sect. 5.5.4.2) that attempts to separate the "genetic" and "environmental" components of differences by studying disease risk in a given migrant population in comparison with that in the host population (similar environment, different genetics) and in the population living in place of origin (similar genetics, different environment).

5.5.1.4 Socioeconomic Status

Socioeconomic status is an extremely important but rather vague term for a whole host of factors that require individual consideration and action, such as income, occupation, living conditions, education, and access to services. For many diseases, such as cardiovascular disease (Rose and Marmot 1981) and cancer (Smith et al. 1991; Kogevinas et al. 1997), a clear gradient by social class is observed, with the highest disease rates or the poorest outcome often observed within the lowest socioeconomic grouping. The influence of social status has a marked effect on disease outcomes in adults and in both prenatal development and infant mortality.

While the magnitude of gradients of many disease outcomes tend, to vary additionally with time reflecting in part changing social and economic circumstances (Marmot 1999), the impact of general improvements in health often fail, to reach the most disadvantaged: Since the 1920s, for instance, improving infant survival rates over half a century in the UK was not observed among those considered least advantaged (with the consistently highest infant mortality rates) (Rosen 1993).

A recent advance has been the linking of "deprivation" scores, an index that combines a number of social variables from censuses according to area of residence, to data records from routine data sources (e.g., cancer registries) at the small area level (Carstairs 1995). In measuring socioeconomic status, a number of potential surrogates may provide a reproducible definition, such as affluence (income), living conditions, or occupation. From a perspective of routine systems based on populations, some of the most illustrative stem from the pioneering series of reports published by the Office for National Statistics, formerly the Registrar General for England and Wales. The Registrar General's social classes were derived from a classification of occupations according to status and level of responsibility (and for married women, on the basis of their husband's employment). Figure 5.10 demonstrates the uniform socioeconomic gradients of infant mortality by cause, with the most abrupt increases observed for accidents and respiratory disease.

There are interpretational difficulties with socioeconomic data from routine sources. Although selection bias should be minimal if the comparison of health events with survey data is made from the same population at the same time, measurement bias is of particular concern. In occupational studies, the respondent is asked for only one occupation, even though they may have had a history of different professions (see Sect. 5.5.1.6).

The consistent findings of poorer disease outcomes among the more disadvantaged social groups have political as well as public health implications. In addition to pinpointing the need for health promotion and disease prevention strategies targeted at low socioeconomic groups, health inequality also demonstrates a need for change at the societal level: improving health by improving incomes, basic housing, and working conditions. However, the practical importance of the variable as an independent risk factor in epidemiological studies is perhaps overstated. Health-deprivation gradients are now well established in most disease domains, and specific public health actions are difficult to formulate and implement given social

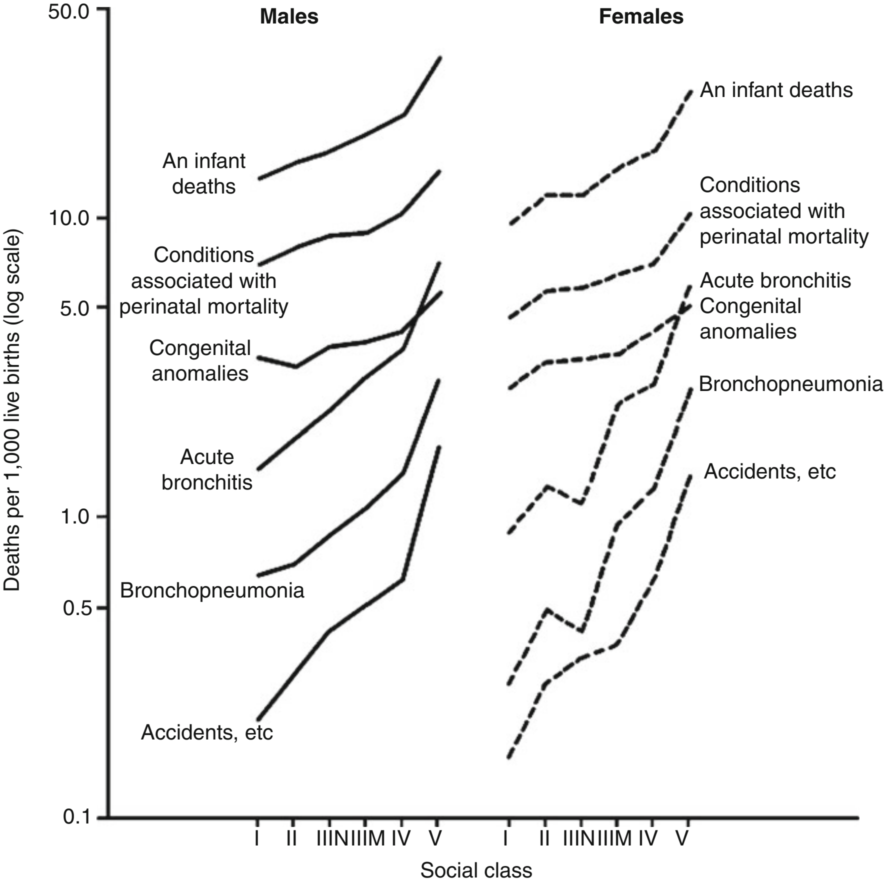

Fig. 5.10 Infant mortality by sex, occupational class, and cause of death (Occupational Mortality 1970–1972; Registrar General's Office for England and Wales 1978, p. 158)

class acts as a surrogate for a vast and complex array of social and environmental processes, congenital characteristics, and early life experiences.

5.5.1.5 Marital Status

A number of epidemiological studies have examined marital status in relation to disease risk. While it is apparent that there are major differences in disease rates according to this variable – married persons often have lower death rates than single persons – there are commonly difficulties inferring the true nature of the association. The main difficultly arises in determining whether being married per se offers health advantages or if there are certain characteristics of good health or long life that favor an individual's predisposition to marriage. The variable has, however, proved useful in determining certain surrogate populations – such as never-married males as proxies for homosexual men (Biggar et al. 1987). In this context, the variable was used to establish increases from the mid-1970s in AIDS-related cancers such as Kaposi's sarcoma in single men aged 20–49 years old (Biggar et al. 1987).

5.5.1.6 Occupation

Descriptive studies have made an important contribution to occupational epidemiology, through the analysis of routine record sources. In some countries, occupations are recorded on death certificates or in disease registers. Such routine record datasets can be used to calculate cancer risks in different occupations. If the comparisons are to involve rates (of mortality, or incidence), then suitable population-at-risk data must be available from the census or population register, with occupations classified in the same way; failing this, proportionate methods may be used (Sect. 5.4.1.2). Routine record studies are relatively inexpensive and often entail very large numbers of subjects. Occupation is specified in terms of job titles. A limiting factor of such analyses is the validity of the job title information collected. With an interviewer-administered questionnaire, quite valid job histories can be obtained, but the validity of occupations recorded on routine records such as death certificates or tumor registers is typically mediocre (Wigle et al. 1982; Steenland and Beaumont 1984; Armstrong et al. 1994). In addition, routine records typically contain only one of the subject's jobs, usually the most recent which may include "retired." In a large sample of Montreal workers, it was estimated that, on average, about 62% of working years were spent in the job of longest duration and about 50% in the last job (Siemiatycki 1996). Some of the defects of the limited information on occupation available in routine records can be reduced by linkage with more valid sources of occupational data. Examples are in Canada (Howe and Lindsay 1983) where a government-run labor force survey was linked to mortality records and especially in the Nordic countries where census data have been linked to the cancer registry (Lynge and Thygesen 1990; Andersen et al. 1999).

Despite these limitations, analyses using job titles are useful. Several associations with cancer have been discovered by means of analyses based on job titles. Table 5.5 shows results from the decennial occupational mortality analysis (Registrar General 1978) based on deaths occurring in England and Wales in 1970–1972, and cancer registrations in 1968–1969. Analyses such as these are most valid and valuable when the workers have a relatively homogeneous exposure profile – for example, miners, motor vehicle drivers, butchers, and cabinetmakers. However, job titles are limited as descriptors of occupational exposures (Siemiatycki et al. 1981). On the one hand, many job titles cover workers with very diverse exposure profiles, while on the other, multiple exposures are found to occur in many occupation categories. Several approaches have been used to better define actual exposures. One such is the job-exposure matrix (JEM). A JEM is simply an automatic set of indicators showing which exposures may occur in which occupations (Hoar et al. 1980; Siemiatycki 1996; chapter ▶Exposure Assessment of this handbook).

Table 5.5 Stomach cancer deaths and registrations by occupation unit and cancer: men aged 15–74 giving units with significantly raised proportionate mortality ratios *PMR*s and proportionate incidence ratios *PIR*s in 1968–1969 ($p < 0.01$) (Registrar General's Office for England and Wales 1978)

5.5.2 Place of Residence

Place of residence is an important variable in descriptive epidemiology. It is almost always available in routine sources of events of disease (registers, surveys, death certificates), and population-at-risk is very often available for small geographical units too. “Geographical pathology” – comparisons of disease rates or risk of individuals living in different areas – has been one of the longest established and productive types of descriptive study for more than a century (Hirsch 1883). National populations have often been the unit of study. The reason is that this dimension is the one for which statistics – especially mortality – are collected and published. Differences in disease between countries may indeed be striking. Sometimes, the reasons are obvious and correspond to the known distribution of causal agents – as for some infectious diseases. But for some diseases, the clear international variations in incidence or mortality have prompted research to better understand the reasons behind them.

Valid comparisons of data deriving from routine data sources in international studies require that there is fair comparability in diagnostic criteria and in recording and coding the events concerned. Variation in quality and completeness of death registration has been mentioned as a source of bias in epidemiological studies, and it is easy to find examples of uncritical use of such data (Carroll 1975). For diseases where there are differences in diagnostic criteria internationally, special studies of disease incidence/prevalence may be undertaken, using similar definitions and criteria in the different participating centers. Examples are international studies of cardiovascular disease and its determinants (the MONICA project, Tunstall-Pedoe et al. 1988) and of asthma (ISAAC study, Pearce et al. 1993).

National boundaries have not always been based on levels of exposure to environmental risk factors, nor of the genetic homogeneity of the populations within them. Thus, study of populations within, and sometimes across, national boundaries has been particularly informative. The geographical units of study can be as small as compatible with a sufficient number of events to generate stable disease rates within them and availability of information on the population-at-risk. Issues of comparability, that may be a source of bias in international comparisons, are usually less important, because recording procedures are in general more similar within countries than between them.

5.5.2.1 Mapping

“Spot maps,” which show the location of individual cases/deaths, have a long history, initially in the investigation of the epidemiology of infectious diseases, more recently as an adjunct to the investigation of clusters of disease (Sect. 5.5.4.1). For non-communicable diseases, the more familiar method is the chloropleth (thematic) map, which uses distinct shading or color to geographical units; usually these are administrative or statistical areas. The reasons for presenting data on risk by place of residence as a map rather than a table are not simply aesthetic. As well as conveying the actual value associated with a particular area, a map conveys a sense of the

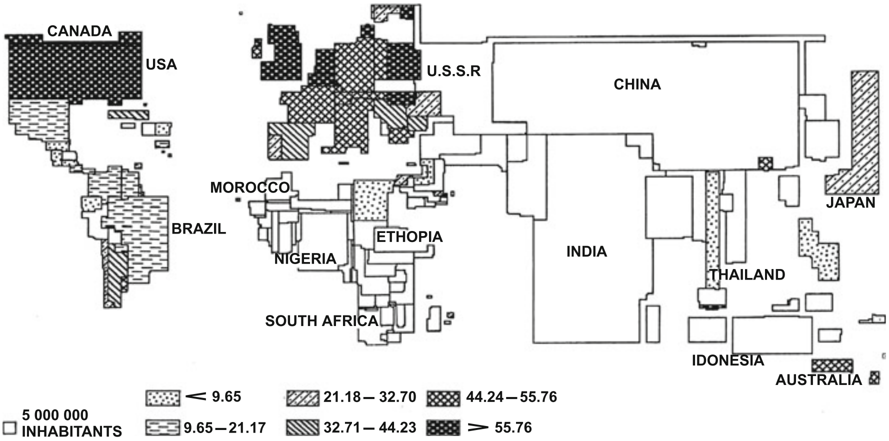

Fig. 5.11 Cartogram of mortality from cancers of the trachea, bronchus, and lung (1981–1984) (Howe 1977)

overall geographical pattern of the mapped variable and allows comparison between the patterns on different maps. This is especially valuable when used to suggest possible causative hypotheses. There are now a large number of disease atlases available, for individual countries (USA, Pickle et al. 1987; UK, Gardner et al. 1984; France, Salem et al. 1999; China, Editorial Committee 1979) or for regions where it is considered that issues of comparability between the participating countries can be overcome (Europe, WHO 1997; Baltic region, Pukkala et al. 2001).

There are a number of specific technical issues to be considered:

- *Choice of Map*

  As well as the various map projections, the *cartogram* has been used by some authors (see Fig. 5.11) (e.g., Verhasselt and Timmermans 1987; Howe 1977). This allocates to the units of study an area proportional to their population size. The idea is to draw attention to the relative numerical importance of the differences displayed, but the resulting maps generally appear somewhat bizarre.
- *Choice of Geographical Unit*

  As noted above, the size of the unit for study is a compromise between the need to provide as much geographical detail as possible (so as to show up any pockets of high or low risk) and achieving stable rates (small variance), so that any spatial patterns are not obscured by random variation.
- *Choice of Parameter*

  The functions plotted are usually rates or ratios. The basic problem is how to compromise between illustrating the actual value of the rate/ratio (generally age standardized in some way) in the different units, which may be influenced by random variation, and giving more weight to those areas with lower variance in the statistic that are unlikely to be due to chance. It is often the case that sparsely populated units cover large geographical areas, while densely populated cities are small. Mapping may well result in impressive high or low

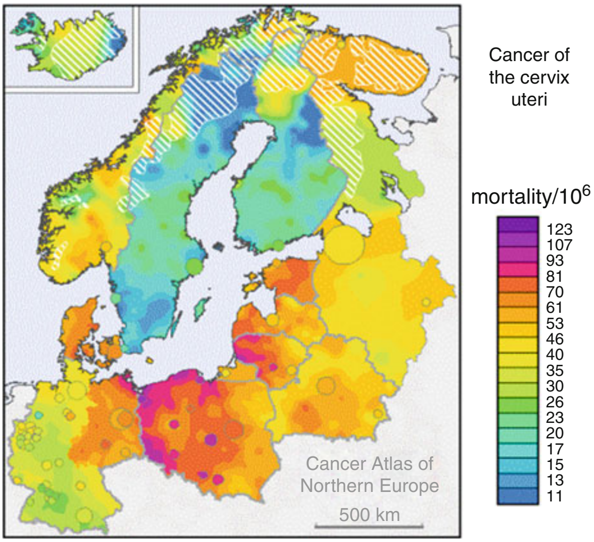

Fig. 5.12 Mortality rates from cancer of the cervix uteri in Northern Europe (Pukkala et al. 2001)

values for eye-catchingly big areas. Plotting the p-values as level of "statistical significance" is not the answer, as this simply highlights differences between the populous units, even when the magnitude of the difference (reflecting its biological significance) is small.

There have been various attempts to circumvent this fundamental problem. The US Atlas of Cancer Mortality used a scale that was a combination of the relative value (e.g., top 10th percentile) and its statistical significance. There is no logical solution to the problem of how to present such maps (is a relative risk of 2 with $p = 0.002$ more or less impressive than an $\hat{R}R$ of 4 and $p = 0.05$?). A different approach is to try to reduce the random variation of rates in small units by assuming that rates in adjacent units will tend to be similar, under the assumption that there is an underlying geographical pattern. Pukkala et al. (2001) color their maps by giving a value to each unit that is the weighted (by distance) average of the other units within 200 kilometers (Fig. 5.12). A more formal method is to plot empirical Bayes estimates of the rates, whereby the values for the units (areas) that are imprecise are improved by estimates from other appropriate areas (Clayton and Kaldor 1987).

- *Choice of Range*

  The number of classes into which to divide the range of values is a compromise between detail and clarity. Usually, five to ten classes are used. There are various choices for the class intervals to be used. The simplest is to use constant intervals (equal steps), in which the range of values is divided into a number of categories of equal size; this works well if the distribution of the data between the units is relatively even but otherwise may be dominated by extreme values, even leaving some classes with no entries at all. If the dataset displays an approximately

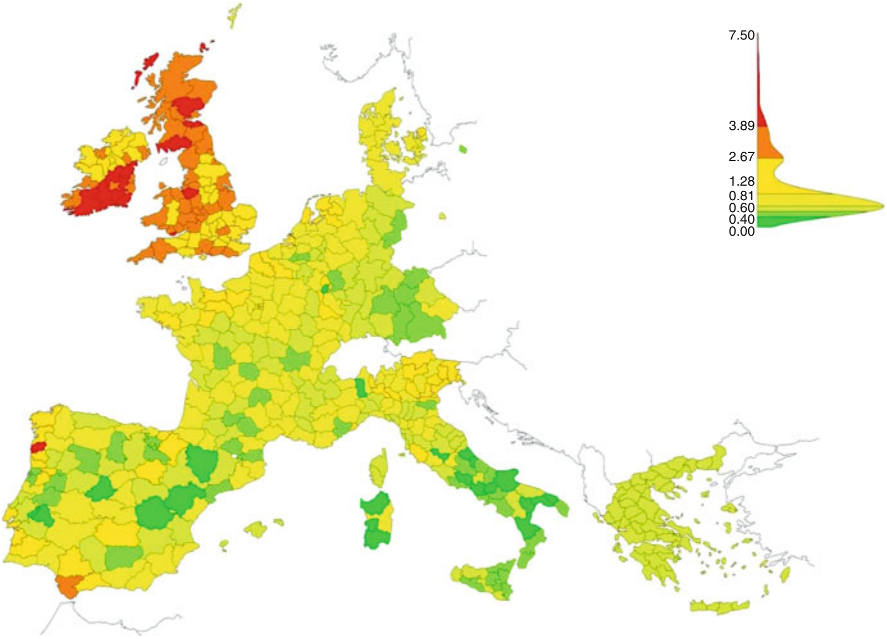

Fig. 5.13 Mortality from esophageal cancer in Europe 1971–1978 (females) (Smans et al. 1992)

normal frequency distribution, class intervals may be standard deviation values; it is useful if the idea of the map is to illustrate deviations from a mean value. Natural divisions of the scale may be used, based upon low points observed in the actual frequency distribution or on some prior knowledge or hypothesis of important dividing values. A relative scale, based on percentiles of the units being mapped, results in irregular variable intervals, but a predictable number of values in each class. The percentiles do not need to be even – in the Scottish Cancer Atlas, the percentiles were 5th, 15th, 35th, 65th, 85th, and 95th, which draw attention to areas of both high and low incidence (Kemp et al. 1985). The same scheme was used for the atlas of cancer mortality in Europe (Smans et al. 1992; Fig. 5.13). This approach means that there is no arbitrary selection of values to plot and that the coloring of all maps tends to be about the same. However, it will obscure outlying (very high or very low values).

- *Choice of Shading/Color*
  The change of shading or color should convey as closely as possible the progression of risk. Color maps are more visually pleasing and can convey more information than those in monochrome. The choice of colors to illustrate the gradations of the scale of the map is not arbitrary and ideally should follow a scale based on the sequence of the spectrum and degree of whiteness (chroma) (Smans and Estève 1992).

5.5.2.2 Urban-Rural Comparisons

There have been many studies in which individuals have been classified into urban or rural dwellers, on the basis of some characteristic of their place of residence, usually, its administrative designation or otherwise as a town/city, or on the basis of population density of the administrative areas (Nasca et al. 1980; Friis and Storm 1993; Barnett et al. 1996). Although distinct differences in the risk of various diseases may be observed, the reasons underlying them are generally obscure. Often, the interest may be in the effects of air pollution on health, given that most air pollution (due to traffic, domestic smoke, or industry) will be more intense in urban areas. However, urban-rural classifications of place of residence is an inefficient way to approach this topic, given the multiplicity of covariates involved.

5.5.2.3 Clustering

The topic is briefly introduced in Sect. 5.5.4, where combinations of person, place, and time are considered.

5.5.3 Time

Investigations of the occurrence of diseases over time are standard tools in epidemiological science and public health surveillance. In the context of investigative epidemiology, temporal studies may generate novel etiological hypotheses or provide confirmatory evidence of existing ones. As well as offering a unique possibility to quantify how risk in populations is changing over time, they offer clues as to the underlying determinants of the observation. Changes in the evolution of incidence rates with time usually imply (in the absence of artifacts) consideration of plausible mechanisms of, and changes in, environmental exposures (time lagged by an approximation of the induction period). Excepting large migrational effects, genetic factors only have a minor impact on time trends of disease (MacMahon and Pugh 1970).

Time trends are also of major importance in measuring the impact of disease control and in studying the effects of primary prevention interventions, screening programs, and the efficacy of treatment regimes. The evaluation of implemented programs (planned or unplanned) may take a “before and after” approach to assess the impact of the intervention on incidence or mortality at the population level. In determining the effectiveness of screening (organized or opportunistic), trends in incidence or mortality, dependent on the specific disease under study, targeted population before and after implementation or comparisons between screening and non-screened groups.

5.5.3.1 Time Trends of Routine Data

The strengths and weaknesses of incidence and mortality data in studying time trends is a subject of much debate. There are complexities in examining trends in either measure, and to avoid erroneous conclusions, it is usually necessary to consider the possibility that artifactual changes over time may have in some way distorted the observed trend.

If the mortality rate is used as a surrogate measure of the risk of developing the disease, a strong assumption of constancy over time in the fatality ratio is required. As survival for many diseases has been improving for several decades, it may be inappropriate to utilize mortality trends as proxies for risk other than for the most fatal diseases. Ideally, mortality rates are best utilized as measures of outcome, rather than occurrence in time trend studies.

Generally a description that utilizes several of these indicators serves to clarify their key properties and aid understanding of the underlying disease processes. There are also a number of temporal datasets on putative or known risk factors collected for particular studies based on, for example, repeated surveys or national surveys, that may be of some utility in elucidating observed trends. Correlation analyses that link such data with trends may clarify particular hypotheses but are limited by their coverage and quality, as well as various potential ecological biases (Morgenstern 1998, Sect. 3.4.2).

5.5.3.2 Describing Secular Trends

Time trend data should be analyzed according to the problem under investigation and the structural characteristics of the data. In the field of health monitoring, the goal might be to quantify the recent secular trend. An estimate of the magnitude and direction (the EAPC – estimated annual percentage change) of the trend over a limited period of time (the last 10 years, say) could be obtained using a simple log-linear model. The EAPC is a useful descriptive measure but should be interpreted with some caution. 95% confidence intervals for the slope should always be given and should help in assessing whether the fitted linear trend may have arisen through chance. If there are elements of curvature in the trend, the EAPC will give incorrect and imprecise estimates of the average unit change. In describing recent trend patterns, the particular choice of time points is often arbitrary, and, in the absence of highly stable rates over time, the EAPC may vary according to the period of time nominated. A preferable description might involve some modeling procedure that could identify sudden changes in the long-term trend and, on that basis, estimate the direction and magnitude of the slope for each epoch of time in which rates are relatively stable.

Methods that quantify trends in segments determined by abrupt linear changes in the trend have been devised by Chu et al. (1999) and by Kim et al. (2000), the latter technique having been implemented in a specially written (and freely available) statistical software package entitled "JoinPoint." The joinpoint regression model essentially searches the temporal data for a few continuous linear phases. The procedure is motivated by the problem of determining the number of joinpoints, that is, breaks in time where abrupt linear changes occur, and an estimate of the EAPC between joinpoints. The minimum and maximum number of joinpoints are user-specified in the software package. To determine up to two joinpoints, for example, a model indicating no change is compared against the model containing two joinpoints. If the null hypothesis of no joinpoints is rejected, then the procedure is applied to test the null hypothesis of one joinpoint against the alternative of two joinpoints. Otherwise, the test for the null hypothesis of no change is considered against the alternative of one joinpoint. Further adaptions of such models have been discussed in Clegg et al. (2009).

5.5.3.3 Age-Period-Cohort Analyses

The first use of the term "cohort" is attributed to Frost in a letter written to a colleague in 1935. The note was published posthumously alongside his landmark paper that discussed some insights that could be attained by visually examining age-specific death rates from tuberculosis according to cohorts, members of a community who share the same birth period, rather than simply in the usual cross-sectional way (Frost 1939). The present day usage of cohort obviously extends well beyond the closed or hypothetical sense of the term – *age-period-cohort analysis* is usually employed to describe temporal studies that include birth cohort analyses, to distinguish it from the generic usage of cohorts in prospective studies (Liddell 1988). In general, such an analysis allows one to examine the influence of each of the three time components and the importance of the particular properties they represent:

- *Birth cohort effects*, on the one hand, may relate to birth itself or may approximate factors related to birth only by exerting influences that are shared in the same group as they age together. An examination of rates according to birth cohort may thus give some insight into the nature and intensity of disease-correlated exposures that may vary across successive generations, and has played a vital role in corroborating evidence from other types of epidemiological study. Temporal patterns in environmental risk factors tend to affect particular generations of individuals in the same way as they age together, and are more likely to exert particular influence on earlier stages of disease development.
- *Period effects*, on the other hand, may act as surrogate measures of events that quickly change incidence or mortality with the same order of magnitude regardless of the age group under study. These effects may be the result of planned interventions that act at later stages of the disease process, for example, novel therapies that improve survival in all age groups. More frequently, they are due to artifactual changes over time, for example, changes in ICD revisions or improvements in diagnostic procedures.
- Age is without doubt a powerful determinant of cancer risk, since it parallels the cumulative exposure to carcinogens over time and the accumulation of the series of mutations necessary for the unregulated cell proliferation that leads to cancer.

A graphical representation of the age-specific rates by period and birth cohort is an essential element of the analysis. Rates versus age though common representations are not always helpful in elucidating the importance of each of the time components – without transformation of the y-axis, the rates can be too closely packed to clearly display the changes, while additionally for cohort trends, they are difficult to interpret, in view of the obvious fact that each rate is only observed for a maximum of a few age groups and at the extremes, only for one age band. More informative perhaps is the depiction of the age-specific rates with period and

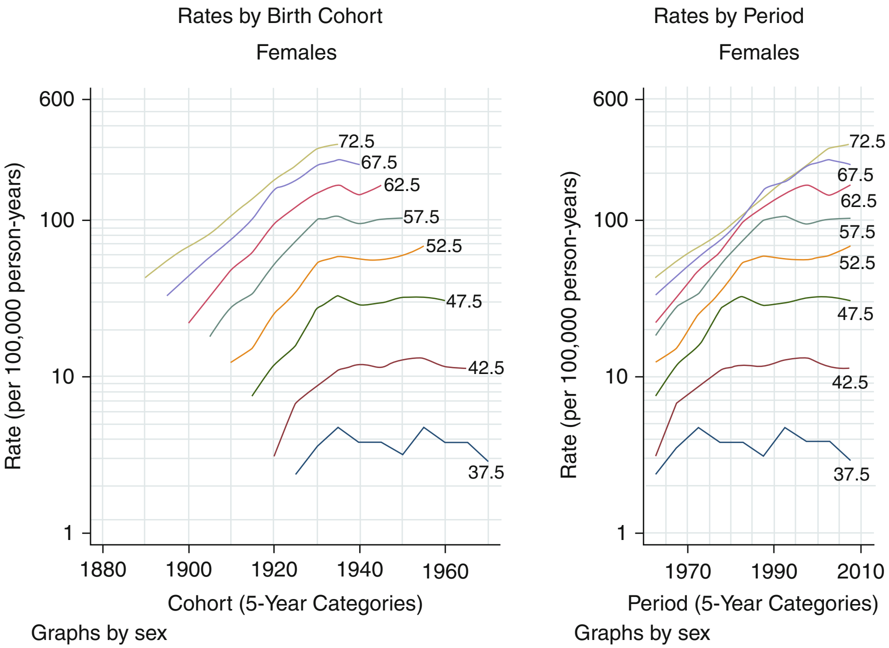

Fig. 5.14 Rates versus calendar period by age group (*left panel*) and rates versus birth cohort by age group, Denmark, lung cancer, females, 1960–2009. The midpoint of the 5-year age groups are indicated in the figures (ANCR (Association of the Nordic Cancer Registries) 2012)

cohort representing the x-coordinates of the two graphs, respectively (Fig. 5.14). Time effects of either origin are therefore apparent when the trends on a semi-log scale are changing in parallel (e.g., by the same relative magnitude) across all age groups in consecutive periods or cohorts.

The effects of the components are sometimes evident to the extent that further investigation may seem unnecessary, given the limited number of variables that require attention. The interpretation of the majority of temporal analyses is however usually more complicated. Rates may fluctuate over time according to the level of random error inherent in the data, dependent on the magnitude of the person-time and the rarity of the disease under investigation. In most situations, the random variation is particularly high in younger persons in recent cohorts. The attribution of changes in the trend to period or cohort effects on the basis of visual means is therefore often not straightforward nor satisfactory, and a comparison of the two-dimensional age-period versus age-cohort graphs can lead to arbitrary opinions as to which component more adequately describes the data. It is in these situations that our understanding of the evolution of cancer risk can be enhanced by the use of more formal statistical procedures. Models offer quantitative and comparable estimates of trend based on objective criteria for choosing the best description of the data, and statistical tests to decide whether the trends are real or random (Estève 1990).

The consequences of subjective judgments based exclusively on graphical descriptions are thus avoided. Statistical models of this nature do not provide definitive answers but offer some guidance as to the importance of each component.

5.5.3.4 The Age-Period-Cohort Model

The emerging importance of birth cohort analyses is in part due to the extensive theoretical and applied research into the age-period-cohort (APC) model in recent times and, importantly, knowledge of its inherent mathematical limitations (Holford 1983; Clayton and Schifflers 1987a, b). The accumulation of available data and advances in statistical theory, including development of the generalized linear model (Nelder and Wedderburn 1972) alongside an increasing availability of software dedicated to fitting such models, also contributes to the development.

As birth cohort is related to a linear function of calendar period and age, the full APC model cannot, given a default set of model constraints, identify all of the parameters of the three components, nor – on the introduction of a further constraint – provide a unique set of estimates. While the APC model is used extensively in applied temporal analyses of disease, the statistical methodologies used to circumvent this problem are numerous and diverse, an indicator of an enduring lack of consensus as to how best to provide satisfactory inferences.

In parallel with advances in statistical theory and computing power, theoretical and applied research on the APC model began to flourish in the late 1970s. During the next couple decades, a number of solutions were offered as how should one present the joint components (e.g., Glenn 1976; Moolgavkar et al. 1979; Day and Charnay 1982; Osmond and Gardner 1982; Holford 1983; Fienberg and Mason 1985; Kupper et al. 1985; Clayton and Schifflers 1987a, b; Tarone and Chu 1992, 1996). A number of reviews and critique of APC models have also been published (e.g., Holford 1998).

The Lexis diagram considers the location of incident cases on one plane, with three time coordinates used to classify events, the date of diagnosis, age at diagnosis, and the date of birth of the individual(s) affected. The third axis, denoted by the diagonal bands crossing the plane from top left to bottom right, represents the date of birth. The APC regression model involves additive contributions of the three time effects on the rate and is given by

$$E[\ln r_{ij}] = \mu + a_i + p_j + c_k$$

where $r_{ij} = Y_{ij} \big/ n_{ij}$ is the incidence (or mortality) rate with n_{ij} as the number of person-time in age group i and period j, assumed fixed and known. a_i is the fixed effect of age group i ($i = 1, 2, \ldots, I$), p_j the fixed effect of period j ($j = 1, 2, \ldots, J$), and c_k the fixed effect of birth cohort with $k = 1, 2, \ldots, K$ where $k = I - i + j$. The number of cancer cases, y_{ij}, is assumed to be distributed as a Poisson random variable with mean λ_{ij}. The model can be estimated readily using maximum likelihood techniques. The numbers of events are fitted via a generalized linear model assuming Poisson errors and a log-link function relating the mean to the linear component. The logarithm of the corresponding person-time is declared as an *offset*, an added constant set to unity for which estimation is not required. The goodness-of-fit is determined as usual by the deviance.

The Identifiability Problem Intrinsic to recognizing the inherent limitations of the APC model is the fact that knowledge of any two factors implies knowledge of the third, making one of the factors redundant. As mentioned above, the index of cohort is defined by the corresponding indexes of age and period, and hence, the three factors are exactly linearly dependent on each other. One further linear constraint must be imposed to ensure the parameter estimates are unique, but the crux of the problem is that this choice of constraint is completely arbitrary in the absence of compelling external information that one can bring to bear in making the selection.

Period and cohort can be considered as weak proxies for our own ignorance regarding the real determinants of time trends (Hobcraft 1985), and it is important that the APC model should be considered as an exploratory tool for investigating the underlying reasons for significant period and cohort effects, adjusted for age. Despite their limitations, such models can render informative results capable of augmenting interpretations based on purely visual approaches.

Classifying Solutions to the Identifiability Problem A number of methods have been proposed that introduce particular constraints on the above APC parameterization so that the identifiability problem appears to be at once resolved, thus yielding unique trend estimates. Such methods often make assumptions founded, necessarily, on mathematical rather than biological principles, that, if inconsistent with reality, induce a bias in all trends, leading to erroneous interpretation. Therefore, such solutions must be carefully scrutinized alongside our present knowledge of the etiology of the cancer under study. Among the methods proposed, a distinction can be drawn that classifies ways of dealing with the analysis and presentation of results from the APC model.

As Holford (1998) points out, a number of quantities can be derived that are estimable and may fulfill the investigative objectives of a temporal study. Such *estimable functions* avoid any imposition of mathematical statements. Rather they are specific reparameterizations that offer summaries of the trends that are identical for any particular set of APC parameters. These conservative but (statistically) correct strategies will be compared with methods that incorporate external data or provide a certain mathematical solution for the cancer outlined, in order to ascertain the level of insight obtained, and the similarities and differences between the methods.

Several authors, notably, Holford (1983) and Clayton and Schifflers (1987b), have noted that certain reparameterizations of the parameters are unique regardless of the constraints imposed, ensuring identifiability, without making any further biological, epidemiological, or mathematical assumptions. Holford (1983) suggested, given the large number of parameters included in the full APC model, for simplicity it is sensible to highlight the non-identifiability in terms of two parameters, one representing a linear function of the three (non-identifiable) slopes and the other, the identifiable curvature of each effect. Clayton and Schifflers (1987a) introduced the term drift or net drift in describing a model for which the two-factor models, age period and age cohort, fit the data equally well.

Drift or δ can be thought of as the average annual change in the rates over time, the passage of time that is common to both axes, calendar period *and* birth cohort, a quantity that cannot be disentangled between the time axes of calendar period and birth cohort. It has become an integral part of the APC modeling strategy, drift being utilized as an estimate of the rate of change of the regular trend, and a partitioner of first-order and curvature effects. The age-drift model implies the same linear change in the logarithm of the rates over time in each age group. Given the linear component over time is identifiable but cannot be allocated in any way to period or cohort, δ can be estimated by either specifying period or cohort as a continuous covariate, and the resulting EAPC estimated as $e^{\delta} - 1$, expressed in the unit of origin.

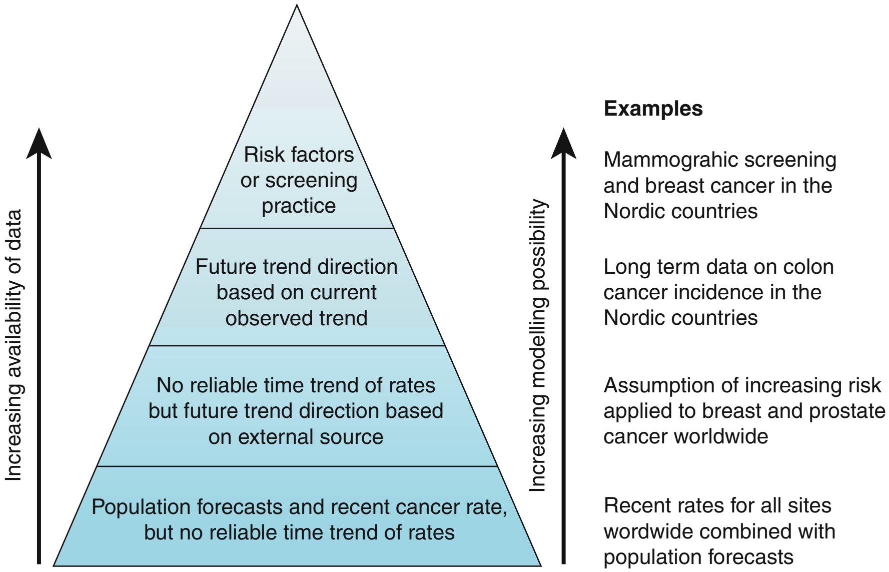
Perhaps the easiest way to avoid the issue is to ignore the possibility of a three-factor model. However, if such a preference is founded simply on the basis of adequacy of model fit, such an approach may be biased if one of the three effects follows a purely linear pattern (Kupper et al. 1985). In addition, the age-period and age-cohort models are not nested within each other and are therefore not directly comparable. Given its simplicity relative to methods dealing with the three-factor model, however, two-factor models are commonly applied, often when there are a priori beliefs in the nature of the temporal pattern.

5.5.3.5 Predictions of the Future Cancer Burden

A logical extension of the questions "how," "why," and "by how much" posed and potentially answered by the study of temporal analyses is the inquiry as to "what will happen in the future?" The utilization of past trends is a common means of providing such answers and dates back to Andvord (1930), who extrapolated trends in tuberculosis mortality in younger generations into later ages to ascertain the future mortality burden. The response of Frost (1939) – that the exercise was "both tempting and encouraging, but perhaps a little dangerous" – encapsulates the hazardous nature of trend-based disease predictions; we can be reasonably confident that trends observed in the past will not necessarily hold in future.

Still, prediction exercises are highly relevant for administrators requiring accurate information of future numbers of cases to aid health planning (given finite resources), while in public health, future increases or decreases in rates may provide advanced warning of the need for concerted actions or evidence of the enduring success of a specific intervention, planned or otherwise, respectively (Hakulinen 1996).

Predictions of future disease burden are important at the global, regional, and national level. An example of the provision of global predictions of cancer is provided in Fig. 5.15; as the availability of data increases and modeling becomes increasingly possible, predictions should become more accurate (Bray and Møller 2006). The slow decrease in fertility alongside increasing life expectancy projected over the next few decades is having major consequences on the burden of disability and chronic diseases in most populations. On a global scale, taking into account recent trends in different age groups (or birth cohorts) is difficult given the lack



Increasing availability of data
Risk factors or screening practice
Future trend direction based on current observed trend
No reliable time trend of rates but future trend direction based on external source
Population forecasts and recent cancer rate, but no reliable time trend of rates
Increasing modelling possibility
Examples
Mammograhic screening and breast cancer in the Nordic countries
Long term data on colon cancer incidence in the Nordic countries
Assumption of increasing risk applied to breast and prostate cancer worldwide
Recent rates for all sites wordwide combined with population forecasts

Fig. 5.15 Effect of availability of data and flexibility of analytical modeling on cancer prediction strategies (Reproduced from Bray and Møller 2006)

of detailed information on changes in the age-specific incidence in many world areas, and even where such data exist, they are often heterogeneous in different regions. Future scenarios are thus often confined to projecting the effects of probable demographic changes, assuming that future rates remain constant at the present level. As a result of population growth and improved longevity, for example, annual deaths from non-communicable diseases have been projected to rise to 52 million worldwide by 2030 (WHO 2011).

Alongside demographic growth and aging, the changing prevalence and distribution of risk factors (e.g., tobacco smoking, reproductive factors, diet, and unhealthy lifestyles) in different populations makes it important where possible to take into account recent time trends in disease rates so as to improve the accuracy of predictions. If long-term data of reasonable quality are available, APC models (see Sect. 5.5.3) can be used to directly estimate the future burden. Osmond (1985) was one of the first to advocate the projection of the age-, period-, and cohort-specific trends into future time periods to make future predictions of cancer, while Holford (1985) showed that the changes in rates over time, for example, between the projected rate and the rate within the study period (prediction base), were an estimable function, and therefore, predictions did not suffer from a lack of identifiability.

Clayton and Schifflers have however noted that the assumption that drift would remain constant in future periods is a strong assumption that “will rarely be justified in practice,” and several studies have attempted to address this issue by “damping” the projected trend. A Nordic study systematically predicted the number of cases up to 2020 of 20 types of cancer for each sex in the five countries (Møller et al. 2002) based on an APC model that allowed for an increasing reduction in the projection of drift with future time.

Another inherent difficulty is that log-linear models give rise to predictions that grow exponentially over time and, for some cancer types, unrealistically elevated predictions of the number of future events (Hakulinen and Dyba 1994). A power model has been proposed to reduce the growth in the predicted rates and found to improve predictions, as did methods that emphasized trends in the last decade (Møller et al. 2003).

Other methods are available. Berzuini and Clayton (1994) developed a Bayesian APC model to smooth the effects of age, period, and cohort, taking a second difference approach that prevented the rates in adjacent groups from differing too much from each other, as on a multiplicative scale such differences represent adjacent relative risks. Generalized additive models (GAMs) using two-dimensional smoothing splines for age and period have been shown to provide reasonable predictions of female lung cancer rates relative to Bayesian APC models (Clements et al. 2005). Simpler models containing only age and time components have been developed (Hakulinen and Dyba 1994; Dyba et al. 1997; Dyba and Hakulinen 2000) that are particularly useful for data spanning shorter time periods. To avoid the exponential growth over time, models non-linear in parameters but linear in time were applied to cancers with increasing trends (Dyba et al. 1997); these have been shown to perform well compared with other prediction methods (Møller et al. 2002). Log-linear models have also been applied to project new cases of type 1 diabetes in Europe to 2020 (Patterson et al. 2009).

Another approach, the fitting of regression models based on trends in indicators of social and economic development, has been used in projecting cause-specific mortality rates. The methods applied fall into two broad categories (Mathers and Loncar 2006). The most widely used are *aggregate* models which make use of data on historical trends in rates to make future predictions. *Structural* models on the other hand make use of observed correlations between disease rates and independent variables and are the result of projections of these independent variables. This approach has been most widely used in the *Global Burden of Disease* (GBD) exercises, where future mortality rates are predicted based on predictions of the likes of GDP, years of schooling, and prevalence of smoking (Mathers and Loncar 2006).

5.5.4 Combinations

5.5.4.1 Space-Time Clustering

Clustering results from the aggregation of cases (or deaths) in terms of disease group, time, and space, where the number of cases is substantially greater than we would expect when the natural history of the disease and chance fluctuations are taken into account. Investigation of observed clusters, or search for clustering of different diseases, is probably one of the most frequent types of study in descriptive epidemiology. There are, in general, two aims: to identify a possible etiological role for infectious agents in non-communicable diseases and to identify health hazards of sources of environmental contamination, the most popular suspects being sources of pollution (toxic waste dumps, industrial plants) or radiation (nuclear power, electromagnetic fields). Cancer and congenital malformations are the usual subjects of study. It is doubtful if the etiological insights gained are commensurate with the huge volume of research effort (Rothman 1990), although explanations for some clusters of disease have been forthcoming (mesothelioma and sources of asbestos (Baris et al. 1987; Driscoll et al. 1988), mercury and Minamata disease in Japan (Tsuchiya 1992), and dental caries and fluoride in water (Dean 1938)).

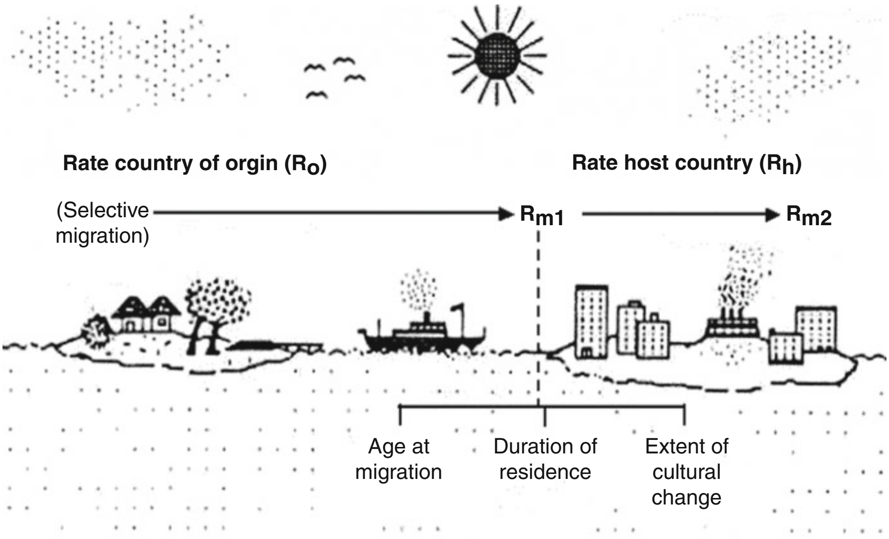
Studies of clustering are either a priori or ad hoc. A priori investigation is the search for evidence of clustering in space and/or time in datasets where none is known to exist beforehand but where the investigator may have some prior hypothesis about its existence. Post hoc clusters are observed groupings of events in neighborhoods, schools, occupational units, households, or families, that are considered by someone to be unusual. In both cases, the existence of a point source, responsible for the observed excess, may be suspected.

There are some important considerations in all cluster investigations. The boundaries or units of investigation need to be clearly defined, without reference to the actual observations. The definition should include the disease entity studied, including the diagnostic criteria of a case, the age and sex groups of subjects to be included, and the geographical and temporal boundaries within which the disease event will be counted. Ideally, these are based on biological criteria or on the a priori hypothesis that is being tested. The boundaries should not be defined by the nature of the observations themselves. Demonstrating a clustering effect means that the observed spatial/temporal patterns of disease are significantly different from the expected result, based on an appropriate reference area. Any diligent investigator should be able to achieve this, if sufficient sub-analyses are performed, on varying combinations of diseases, areas, and timescales. Less ideally, post hoc clusters are, by definition, combinations of place, time, and disease that accidentally appeared to be significantly unusual.

A large number of methodological approaches are available for examining datasets for evidence of clustering (see Smith 1982; Marshall 1991; Alexander and Cuzick 1992; Bithell 1992; Alexander and Boyle 1996). Guidelines have been prepared to aid epidemiologists working in public health departments to investigate local post hoc clusters brought to their attention (Centers for Disease Control 1990; Leukaemia Research Fund 1997).

5.5.4.2 Migrant Studies

Migrant studies provide a useful insight into the relative importance of environment and genetic makeup in disease etiology. Disease risk is compared between populations of similar genetic background living in different physical and social environments. Figure 5.16 illustrates the principles; comparison is usually between the rate of disease in migrants (R_{m1}) and the population from which they originated (R_{o}) or between the rates in migrants and those of the new host country in which



Rate country of orgin (R_o)
Rate host country (R_h)
(Selective migration)
R_{m1}
R_{m2}
Age at migration
Duration of residence
Extent of cultural change

Fig. 5.16 Principles of migrant studies (McMichael and Giles 1988)

they have settled (R_{m1} vs. R_h). The most informative migrant studies are those that permit study of the rate of change of risk following migration. This may be by partitioning migrant rates (R_{m1}) according to age at migration or duration of residence or by comparison of risk in first generation migrants (R_{m1}) and their offspring (R_{m2}).

Studies of disease risk in migrants may involve interview/examination of subjects, in which case information is available not only on the variables of place of origin/place of residence – the focus of migrant studies – but also on covariates. Descriptive studies rely upon data from routine sources (Sect. 5.1.2), and all environmental exposures are subsumed by the variables birthplace and place of residence. Although these may be highly reproducible and subject to little misclassification, in an etiological sense, they are themselves related to numerous more proximate unmeasured "exposures," not only in the external environment (air, soil, water) but also through sociocultural factors (diet, fertility, smoking, etc.), as well as genetic predispositions to them. Adjustment for confounding factors related to birthplace is generally limited, since the variables available are usually few (sex, age, place of residence, occupation, etc.). Nevertheless, as well as the simplicity and convenience that characterize descriptive studies in general, such studies are population based and often of large size (e.g., 120,000 subjects in one study of migrants to Israel; Steinitz et al. 1989). The prospective (cohort) design of most permits risk for several different diseases to be examined.

Migrant studies can only provide useful information when there is a difference in risk between the country of origin (specifically, the population from which the migrants came) and the host population. In the particular instance of the host population comprising the offspring of earlier migrants, there might well be less difference than were it genotypically quite different. Migrants from Spain and Italy might have considerable genetic similarity to the inhabitants of Argentina and Uruguay, for example, countries with populations largely of southern European descent.

Descriptive studies in which “exposure” is investigated in terms of birthplace and residence are not very useful for diseases for which there are obvious causes, with a high population attributable fraction. For example, tobacco smoking is responsible for such a large proportion of cases of lung cancer that risk in migrants will be almost entirely determined by past smoking habits, and the contributions of other environmental factors, for example air pollution, will be quite impossible to evaluate in the absence of detailed knowledge of exposure to tobacco smoke. Conversely, the changes of risk experienced by migrants for cancers of the breast, large bowel, pancreas, and prostate have been far more useful pointers to the relative importance of environmental factors in etiology and to the stage of carcinogenesis at which they may act.

The definition of migrant status is dependent upon the data sources used in a particular study. The most common classification is by place of birth, a relatively well-defined, unchanging attribute, likely to be comparable between the data sources being used (census, vital statistics, registration). Place of birth can also be used in the study of migrants within one country (internal migration). Citizenship or nationality is often recorded on death certificates; it is less useful than place of birth, since migrants will become naturalized to varying degrees, and there are more problems of definition (e.g., dual nationality, stateless persons). Other variables, particularly ethnic group (but also language or religion), have been widely used in comparative studies of populations of different genetic background living in similar environments (or vice versa), in a manner analogous to studies of risk by birthplace (Sect. 5.5.1.3). Studies that employ a combination of ethnic group and birthplace to distinguish first-generation migrants and their offspring are much more informative than either one alone.

The term “environment” embraces, of course, more than the physical surroundings of an individual; it also encompasses all elements of lifestyle that influence disease risk. Thus, while certain aspects of the physical environment (e.g., air and its pollutants, water and trace elements, irradiation-solar, and other forms) change abruptly on migration, other aspects of lifestyle which are related to sociocultural norms will be retained to a greater or lesser degree in the new place of residence. Examples are patterns of diet, childbearing, alcohol and tobacco consumption, sexual habits, and so on. Sociocultural factors also influence the degree of exposure to external environmental agents; thus, given that potential exposure to ultraviolet radiation from the sun is determined by geographical locality, the actual exposures will be modified by culturally defined behavior. As a result, although migrants to countries with sunny climates, such as Israel or Australia, clearly have the same potential for exposure to ultraviolet radiation as the local population, they may be culturally more or less inclined to avoid the sun than the locally born.

The study of disease risk in relation to duration of residence in the new country, or, alternatively, according to the age at the time of migration, is feasible when information is available on the date of migration of the individuals. Provided migrants settle permanently in the host country, age at diagnosis or death is the summation of age at arrival and duration of stay, and it is not possible to evaluate the effect of one of these variables independently of the other. As age is such a strong determinant of risk, and an essential component of any analysis, there is no variability left in duration of stay after controlling for age at arrival, or vice versa; these two variables are therefore inextricably linked. This problem constitutes an extension of the non-identifiability property of age-period-cohort models in the study of time trends (see Sect. 5.5.3.4). A pragmatic solution is to examine each variable in turn (age/duration of residence or age/age at arrival) to see which provides the most plausible pattern of change of risk. "Duration of residence" can be interpreted in terms of dose, that is, assuming that longer periods spent in the new location imply a greater change in cumulative exposure to the relevant etiological factors. It might equally be interpreted in terms of the stage of the disease process at which particular environmental exposures may act. Thus, a rapid change in risk following migration implies change in exposure to a relevant factor and a short period between exposure and disease. Alternatively, the pattern of change may suggest that prolonged exposure is needed before risk is altered or that the agent is only important with respect to exposures early in life. Analysis of risk by "age at migration" may show a clear distinction, in this case, between migrants arriving as children or as adults.

The importance of genetic susceptibility in determining risk is suggested by the persistence of characteristic rates between generations, since the offspring of migrants have been exposed to the environment of the host country for their entire lifespan. However, it is quite likely that they retain some aspects of their parents' lifestyle (as well as their genetic makeup). Some insight into the effect of this can be gained if the rates in the second generation (R_{m2}) can be partitioned according to birthplace of parents (neither, one, or both in the country of origin). These studies require that the data source used contains information on birthplace of parent(s), or ethnicity (if the migrants comprise a distinct ethnic group), or both.

Descriptive studies using routine sources for disease incidence, mortality, or prevalence will have no information on levels of exposure (diet, tobacco, fertility, etc.). However, other data sources may be able to provide population-level data on prevalence or intensity of exposures and permit ecological analyses of risk versus exposure according to birthplace (see Sect. 5.4.2.2). The opportunities for such studies are, unfortunately, limited. Although population surveys may be available, based on interviews (smoking, drinking, dietary habits, reproductive history) or physical examinations (height/weight, blood pressure, blood sugar, etc.), either place of birth is not recorded or, if it is, the samples are usually too small for meaningful results to emerge for any particular group of migrants, who usually comprise only a small fraction of the general population. Occasionally, there have been special ad hoc surveys of migrant populations – and sometimes data from control groups in case-control studies where ethnicity or place of birth has been a major variable of interest (e.g., in studies of diet and cancer in Hawaii (Kolonel et al. 1980; Hankin et al. 1983)). These may provide information on, for example, dietary habits in different migrant groups for comparison with those of the locally born population.

Biases in Migrant Studies

- *Use of Mortality Data*
  Mortality data are normally used as a proxy for incidence (risk of disease); a perfectly valid procedure providing the ratio between mortality and incidence is constant for the groups being compared. This may not be true for international comparisons, since there are known differences in survival between countries (Berrino et al. 2009; Sankaranarayanan et al. 2010). It is less clear whether there are differences in survival by birthplace within a country, although ethnic-specific differences are well documented in the USA (Miller et al. 1996).
- *Data Quality*
  Variation in the quality of data from different sources is particularly troublesome when mortality rates in one country (locally born and migrants) are compared with those from another (country of origin). International variation in completeness and accuracy of death certificate data has been discussed above (Sect. 5.2.4). It may introduce spurious differences in mortality rates. Thus, if the migrant population under study moves from a country with poor certification (of all causes or a specific cause of death) to one with more accurate recording, there will be an apparent increase in the observed rate. Better ascertainment of cause of death, especially for diseases that present diagnostic difficulties, may account for some of the examples of "overshoot" (rates in migrants higher than host country but country of origin rates lower), reported in several studies (Lilienfeld et al. 1972; McMichael et al. 1980).

  Incidence rates from cancer registries are probably more comparable between countries than mortality data. Nevertheless, incidence can be influenced by the detection of asymptomatic cancers during screening, surgery, or autopsy, and is thus related to the extent and nature of such practices. Systematic histological examination of material removed at transurethral prostectomy was responsible for the detection of many "incidental" (non-symptomatic) cancers of the prostate in the USA, and it has been suggested (Shimizu et al. 1991) that the incidence in Japan would have been three to four times higher in the same circumstances. This would explain the apparent rapid increase in the risk of prostate cancer in Japanese migrants to the USA.
- *Mismatching Numerator/Denominator*
  In descriptive studies, person-years at risk are estimated from census data (or from population registers), typically broken down by rather few variables including, in addition to birthplace, age, sex, and place of residence. It is essential that the definition of migrant status is the same in the census and case/death data, but even with the same definition, individuals may be classified in a different way in the two sources. Lilienfeld et al. (1972) present unpublished data on differences between country-of-birth statements on death certificates and census returns for the USA in 1960 – this varied from a 10.8% deficit on death certificates for UK birth to 16.7% excess for Ireland. A source of bias more difficult to detect results from migration that is related to the disease event itself – for example, when migrants return to their country of origin soon before death (so that mortality rates of migrants in the host country are underestimated).

A more practical difficulty in using population-at-risk data results from the fact that censuses are rather infrequent, and interpolations are needed to derive person-years at risk. This can be quite prone to error when several variables are involved, and active migration is still occurring during the study period.

- *Selection Bias*

  Migrant populations are a non-random (self-selected) sample of the population of their country of origin. Very often they come from quite limited geographical areas. For example, migrants to the United States of Italian origin come mainly from the south of that country (Geddes et al. 1993), and a large proportion of US Chinese originate from Guangdong province (King et al. 1985). Alternatively, the migrants may be special social or religious groups with quite distinctive disease patterns. For example, Jews comprised a large proportion of the migrants from Central Europe in the late 1930s and 1940s. Whenever possible, disease rates appropriate to the source population of the migrants should be used for comparisons, rather than the national country of origin rates.

  Migrants are often assumed to be healthier than the average population (the "healthy migrant effect"); this may be because the fact of seeking a new life overseas implies a population that is resourceful and energetic (or at least not chronically ill) or because the sick and disabled are excluded by the immigration authorities of the host country. Conversely, it has been suggested (Steinitz et al. 1989) that permission for Jews to migrate to Israel from countries of the Soviet block was more easily obtained for those in ill health, giving rise to an "unhealthy migrant effect." It is possible to check for the "healthy/unhealthy migrant effect" if risk according to duration of stay in the new country can be estimated. A significant change in rates from those in the host country in recent migrants should suggest this form of bias. Swerdlow (1991) found no sign of any such effect in Vietnamese refugees to England and Wales, and Steinitz et al. (1989) found that exclusion of cancer cases diagnosed within a year of arrival in Israel made no difference to relative risks for short stay (less than 10 years) migrants.

- *Confounding*

  Several demographic variables recorded in the sources of disease information (death certificates, disease registers, etc.) can be considered as confounders – influencing disease risk and associated with exposure (migrant status) – in a study aiming to investigate the effect of birthplace on disease risk. These include date of diagnosis/death, marital status, place of residence, and possibly ethnic group, occupation, and socioeconomic status (such as employment status, income, and educational level).

  Migrants are in the first place rarely distributed homogeneously in their new host country: they tend to settle in certain areas, generally in urban areas, and the establishment of a migrant "colony" in a place tends to attract later migrants to settle there. It may well be inappropriate therefore to compare disease rates in migrants with the entire population of the host country. Table 5.6 illustrates an example of confounding by place of residence. Polish migrants to Argentina live mainly in Buenos Aires (81.2%, compared with 48% of the local born), where mortality rates from colon and breast cancer are higher than elsewhere.

Table 5.6 Confounding by place of residence in a study of cancer mortality in Polish migrants to Argentina (95% confidence intervals in brackets)

Cancer mortality and place of residence	Buenos Aires	Elsewhere in Argentina
Relative risk of colon cancer (M)	1.9	1.0
Relative risk of breast cancer (F)	1.4	1.0
Place of residence and birthplace	Buenos Aires	Elsewhere in Argentina
Born in Poland	81.2%	18.8%
Born in Argentina	47.9%	52.1%
Cancer mortality and birthplace [*Relative risk in Poland-born* vs. *Argentina-born (1.0)*]	Crude	Adjusted for place of residence
Colon cancer (M)	1.34 (1.06–1.68)	1.16 (0.95–1.43)
Breast cancer (F)	0.90 (0.75–1.08)	0.82 (0.63–1.05)

Adjustment for place of residence reduces the relative risk of both cancers, and for colon cancer, the difference from the local born is no longer statistically significant.

Social class and occupation are also known to be strong determinants of disease risk, and it is often clear from census data that migrants are over-represented in specific occupational categories and are atypical of the general population in their socioeconomic profile. Meaningful comparisons should therefore take the social dimension into account.

Temporal trends in incidence or mortality of disease may also be different in the migrant population and in the host country. When data from a long time period are used, the relative risk between them may differ according to time period. This is particularly troublesome when the effect of duration of stay is being studied, since, in general, data from more recent time periods will contain more migrants with long periods of residence than those from earlier years: an adjustment for time period is thus necessary.

Examples of Migrant Studies

- *Single-comparison studies* are the least informative, showing differences in risk between migrants and the locally born but providing no information on the populations from which the migrants came. This may be the consequence of absence of appropriate sources of data (e.g., no accurate mortality statistics) or that rates of disease are unavailable for the appropriate population subgroups from which the migrants came.

  Figure 5.17 (Marmot et al. 1984) shows data on mortality from hypertensive disease (ICD-8 A82) and from coronary heart disease (A83) in men of different migrant groups in England and Wales. There is very large variation in the former (fivefold) and a rather poor correlation of death rates from these two causes between the populations. For most of the countries of origin of the migrants, there are no available data on mortality.

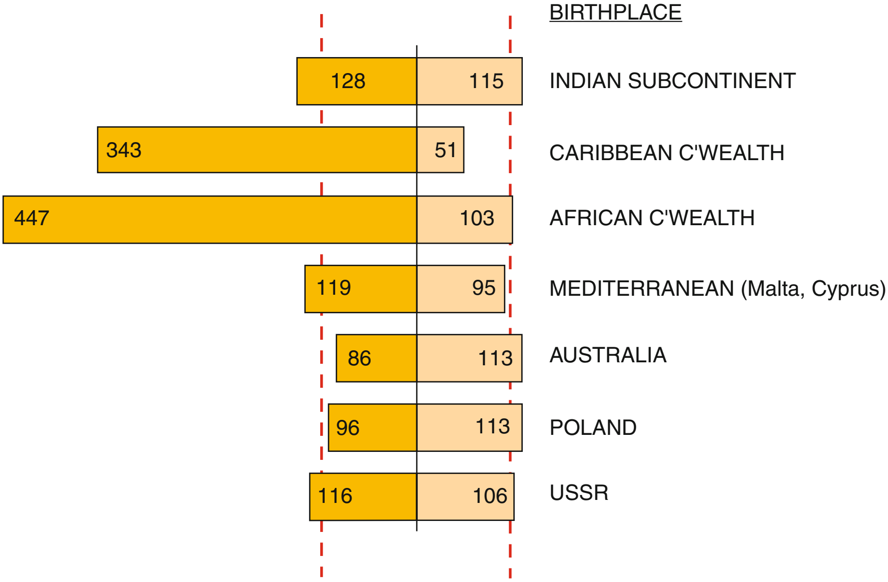


Fig. 5.17 Mortality in migrants to England and Wales, age 20+, 1970–1972 SMR (relative to England and Wales = 100) (Marmot et al. 1984)

- *Two-comparison studies* are the most common type of study reported. They aim to demonstrate the degree to which the risk of a given disease changes in the migrant population away from that in the country of origin and towards that of natives in the new host country. Examples are the several studies that examine mortality rates in populations of predominantly European origin moving to the United States (Haenszel 1961; Lilienfeld et al. 1972), Australia (Armstrong et al. 1983; McCredie 1998), England and Wales (Marmot et al. 1984; Grulich et al. 1992), and South America (Matos et al. 1991; De Stefani et al. 1990). The fact that the data for the two comparisons came from different sources must always be borne in mind, and bias in the first (country of origin) probably explains some of the findings in published studies.

  Figure 5.18 shows results from a study of migrant mortality in the United States (Lilienfeld et al. 1972), comparing age-specific rates in migrants with those in US born whites, and in the countries of origin of the migrants. One of the most impressive differences between migrants and country of origin is for Italians. It is probably in part the result of selection bias: Italian migrants originated mainly from southern Italy, where stomach cancer rates are much lower than in the north (or for the country as a whole) (Geddes et al. 1993).
- *Studies with a time dimension* are studies of the effect of duration of residence or age at migration. Relatively few published studies have been able to study cancer rates in first-generation migrants by duration of stay (or age at arrival) in

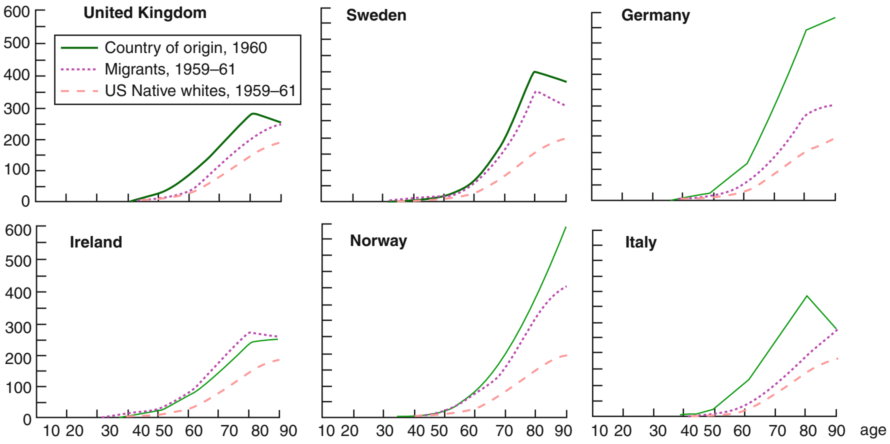

Fig. 5.18 Mortality from cancer of stomach (rate per 10^5) in migrants to United States (Lilienfeld et al. 1972)

the host country. The routine recording in Australian death certificates of date of migration has permitted several studies of mortality in relation to duration of residence in Australia; the findings in relation to gastrointestinal cancers (McMichael et al. 1980) and to malignant melanoma (Khlat et al. 1992) are of particular interest. Figure 5.19 (Khlat et al. 1992) shows the risk of death from melanoma of six migrant populations in relation to either duration of stay or age at arrival, using the Australia-born as the reference group. Since these two variables are completely interdependent (long durations of stay are associated with early ages at arrival), it is impossible to separate their effects. The figure gives the impression that arrival in childhood is associated with relatively high risks but that in age groups 15–24 years, and 25 years and above, risk remains significantly lower than that of the Australia-born. The irregular increase in risk with duration of stay, with a relatively sharp increase after 30 years for many of the groups, makes little biological sense and could well reflect the excess of childhood immigrants in the long stay category.

The Israel Cancer Registry records date of migration for all cases of cancer. This has allowed the risk of cancer to be examined for different populations of migrants in relation to their duration of residence in Israel (Steinitz et al. 1989; Parkin and Iscovich 1997). Figure 5.20 illustrates the risk of cervical cancer in migrants to Israel, relative to the local born, in relation to duration of stay. The data is derived from a long time period (1961–1981) during which there were marked temporal trends in the risk of cervical cancer and in particular a striking increase in incidence (2.5 times) in the Israel-born but little change or even slight declines in risk for the migrant groups. Because most migrations took place before the data collection period, duration of stay is strongly confounded by

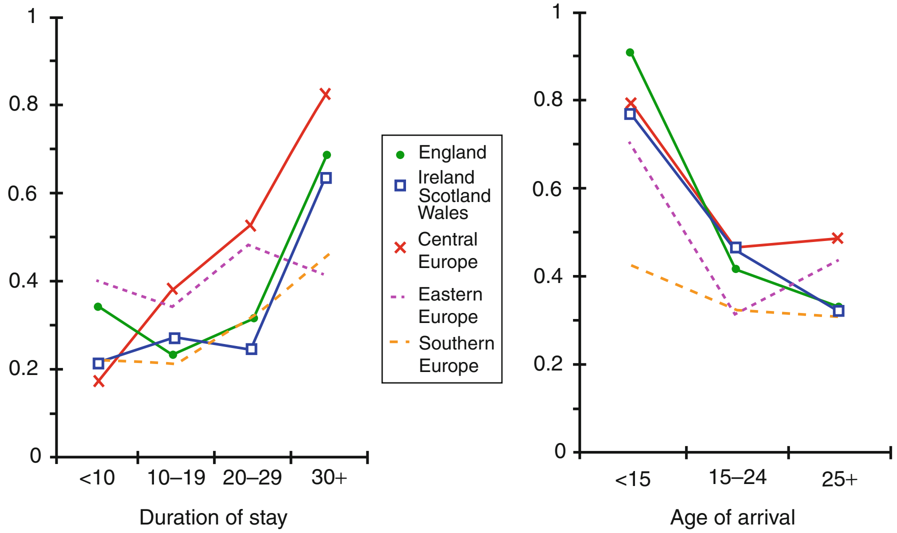

Fig. 5.19 Estimated relative risks of melanoma in male immigrants to Australia, by region of birth and according to duration of stay and age at arrival (both in years), compared with the Australian-born and adjusted for age, period, cohort, and state: Australia, 1964–1985 (Khlat et al. 1992)

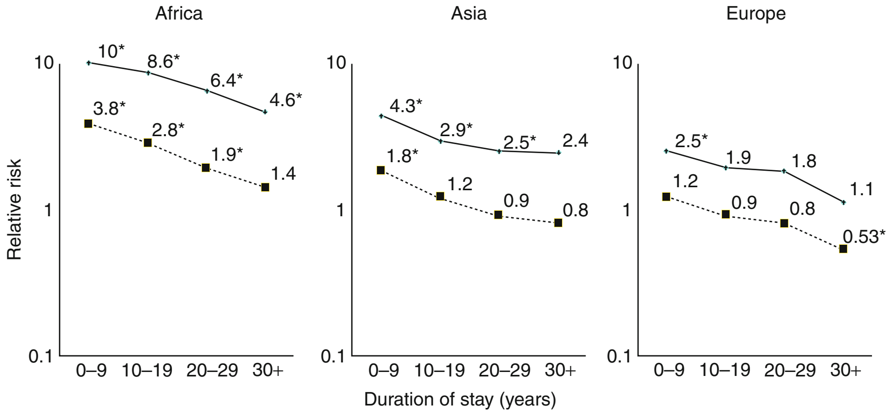

Fig. 5.20 Risk of cervix cancer in migrants (relative to local born) (Parkin et al. 1990)
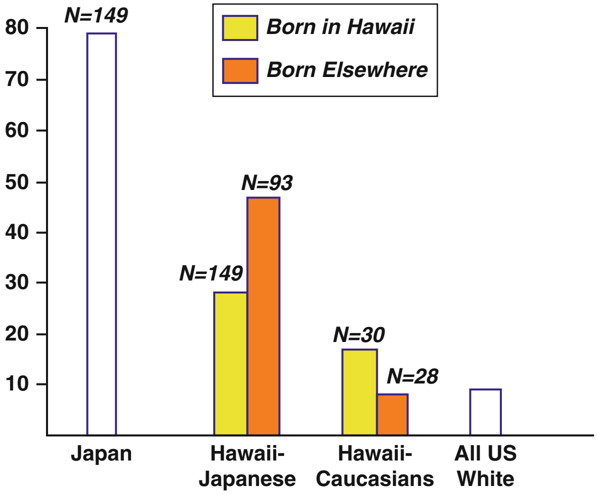
+—+ Adjusted for age at diagnosis
▪ - - - ▪ Adjusted for age and period of diagnosis

time period (short duration-of-stay cases come mainly from earlier periods, and vice versa), and adjustment for time period has a very striking effect on relative risks (Fig. 5.20). These observations may be explicable in terms of cumulative exposure to Pap smear testing following migration, since the high risk of cervical cancer in these populations is well known to clinicians.

Fig. 5.21 Age-adjusted stomach cancer incidence in Hawaii-Japanese and Caucasians by place of birth, 1973–1977 (Kolonel et al. 1981)



- *Studies of second and subsequent generations of migrants.* The best known studies are those of Japanese in the USA (Haenszel and Kurihara 1968; Locke and King 1980) and Hawaii (Kolonel et al. 1980; Hankin et al. 1983) and of Chinese in the USA (King et al. 1985), distinguishing the foreign-born (first-generation migrants) from the USA-born (their offspring).

  Figure 5.21 shows incidence rates of stomach cancer in two ethnic groups in Hawaii-Japanese and Caucasian (white) in relation to place of birth and provides rates for the populations of the countries of origin, Japan and USA. Incidence rates in Japanese migrants to Hawaii are lower than in Japan, and in Hawaii-born Japanese, they are lower still but still higher than in the white population. Conversely, in the white population of Hawaii, there is an increase in stomach cancer risk in the locally born compared to US whites (or migrants from the USA).

  A number of migrant studies examining cancer risk have already been conducted in Scandinavia. Myrup et al. (2008) linked a cohort of over two million males born after 1930 and living in Denmark 1968–2003, with information in the Danish Civil Registration System including immigration histories to investigate testicular cancer risk. First- and second-generation immigrants had relative risks of testicular cancer of 0.37 and 0.88, respectively, compared with men born in Denmark of parents born in Denmark. The rate in first-generation immigrants was not modified by age at immigration or duration of stay, reflecting rather their country of origin. Together these findings implicate that early-in-life exposures are a major determinant of later risk of this disease.

  Hemminki and Li used the nationwide Swedish Family-Cancer Database to examine cancer risks related to migration based on over 600,000 adult immigrants to Sweden. Comparing cancer rates between immigrants and the locally born in Sweden (Hemminki et al. 2002), all cancer rates were 5 and 8% lower among immigrant men and women, respectively. However, male immigrants had a 41% increased risk of lung cancer. Using the same database to examine second-generation migrants (Hemminki and Li 2002) based on descendants of an immigrant father or mother, all cancer rates were marginally lower among the offspring of migrants relative to the host population. Comparison of risk between the first- and the second-generation migrants suggests that the first 2 decades of life are influential in determining the pattern of cancer development in later life.

Birthplace of parents, which is sometimes recorded on death certificates or cancer registries, has been little used to study cancer risk in offspring of migrants. Balzi et al. (1995) used mortality data from Canada to study cancer risks in Italian migrants and Canadian-born individuals of Italian parentage. The latter group was separated into either those with two parents born in Italy or only one. Figure 5.22 shows results for the two most common cancers, stomach and lung. The risk of stomach cancer, which in migrants is two to three times that in the reference population (Canada-born of Canadian parents), is no longer significantly raised in their offspring, while trends in the opposite direction are seen for lung cancer. Parkin and Iscovich (1997), using data from the Israel Cancer Registry, presented odds ratios for migrants and the Israel-born population according to parents' birthplace. Individuals with parents from North Africa retained the increased risk of nasopharynx cancer seen in migrants from that area, while the risk of melanoma remained low in migrants from this area and their offspring.

- *Studies that include information on exposures* at population-level data for the migrants and the population of the host country, and sometimes for country of origin, are examples of ecological studies (Sect. 5.4.2.2).

  McMichael and colleagues (1980) related mortality rates from gastrointestinal cancers in European migrants to Australia with per capita food consumption data from a period 10 years earlier in Australia and the countries of origin; results from a national dietary survey were included later (McMichael and Giles 1988).

  For the Japanese population of Hawaii, the dietary intake of a range of nutrients can be estimated from the control subjects in case-control studies and from special surveys (Kolonel et al. 1980; Hankin et al. 1983), and the Japanese population (as well as Hawaii whites) can be separated into those born in Hawaii or elsewhere. The Japan-Hawaii heart study also provides a large amount of information on dietary patterns in Japan and Hawaii (Kagan et al. 1974). These data have been used to help in the interpretation of the changes in risk of stomach cancer in Japanese migrant populations (Fig. 5.21). Thus, second-generation Japanese eat less pickled vegetables and dried salted fish than Japanese migrants (born in Japan), whereas the whites who were born in Hawaii seem to eat these foods more frequently than whites born elsewhere. Both of these items have been associated with an increase in the risk of stomach cancer in case-control studies. The observations were similar for consumption of rice (and total carbohydrate intake), also suggested as etiologically important in some studies.

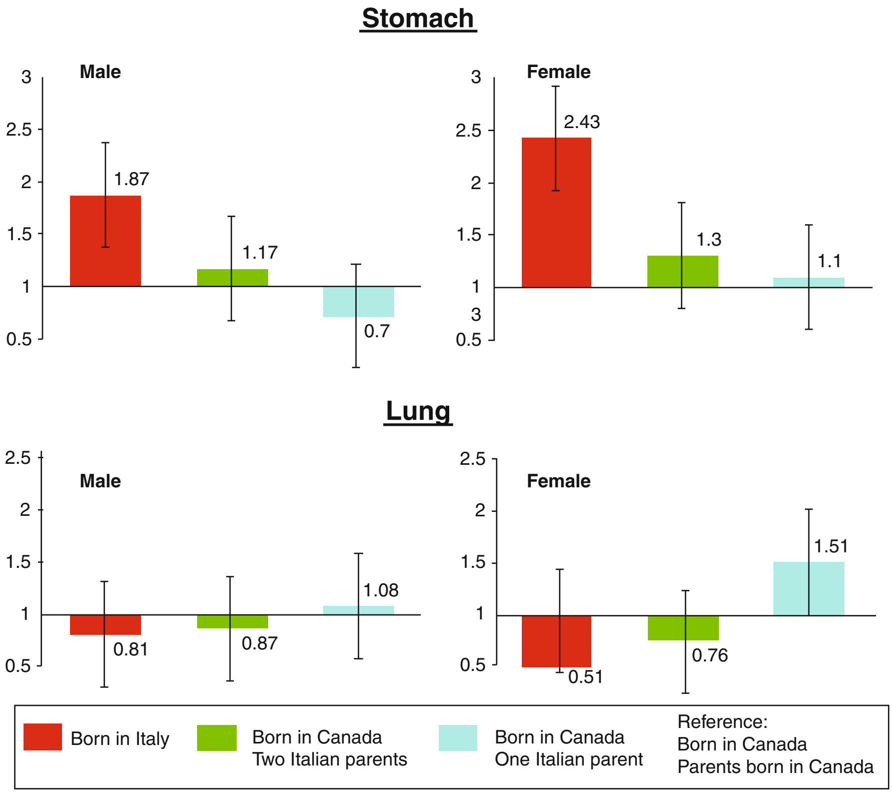


Fig. 5.22 Risks and 95% confidence intervals of stomach and lung cancer in Italian migrants and Canada-born individuals of Italian parentage (Reference population: Canada-born of Canadian parents, Balzi et al. 1995)

5.6 Conclusions

Studies of disease patterns using registers of vital events are often cited as the foundations of modern epidemiology – the work of Graunt on "Bills of Mortality" (Graunt 1662) foreshadowing the enormous contribution of Farr, as statistician to the Registrar General, in analyzing the material on cause of death, provided by the routine registration of vital events in England and Wales. Descriptive epidemiology is a continuation of this theme. The increasing availability of databases related to the health of individuals, or to their possible exposure to causes of disease, has enormously increased the scope for investigations providing clues to etiological associations. As we describe in this chapter, the information on individuals that is contained in personalized databases is rarely closely related to pathogenetic mechanisms, so that observed associations will generally be suggestive only of causative pathways, and a stimulus to more focused investigations. Thus, differences in the risk of disease according to locality (place of residence, or of birth, or both) may be quite suggestive of an underlying cause (e.g., in contaminants of water, background radiation, soil mineral deficiencies), but the hypotheses will require testing, if possible, by studies that involve collection of information from individual subjects, on variables that are related to the hypothesized more proximal causes.

This chapter provides some background on the tools available in descriptive epidemiology: The sources of routine data on health status, and the basics of measurement and comparison. It illustrates how these can be applied in the study designs familiar to epidemiologists, and provides a series of examples, illustrating the principles of descriptive studies.

In an era of genomics, proteomics, metabolomics, etc., the study of disease risk according to demographic characteristics of individuals, or their place of birth, or residence, and the evolution of risk over time may seem mundane, with little relevance to unraveling the secrets of life. However, the relative simplicity of descriptive studies, in which large populations can be investigated, at relatively little expense, means that they will continue to be widely used. The ecological study, for all its defects, is probably the most popular study design in epidemiology (and much beloved of other disciplines too, e.g., in economics). Even within the framework of etiological research, some of the most basic observations remain a challenge to biological explanation (e.g., the striking sex ratios for some cancers).

Descriptive epidemiology has, of course, a wide application beyond the realm of the academic epidemiologist focused on investigating the causation of disease. Epidemiology, is, after all, concerned with "the application of this study [of the distribution and determinants of health-related states or events in specified populations] to control of health problems" (Sect. 5.1.1). Planning and evaluation of health care requires a knowledge of the magnitude of different problems – their distribution in subgroups within the community, their past and likely future evolution, and their amenability to different interventions – and monitoring of the effectiveness of interventions, be they in prevention, early diagnosis, or therapy. Epidemiology is the keystone of public health, and attention to the well-being of the health of the populace requires a sound knowledge of the principles of descriptive epidemiology, rather than a detailed knowledge of the proteomics of gene interactions. It remains the basic toolkit of the community-orientated health specialist.

6.1 Introduction

This chapter summarizes the basic features of cohort studies, a type of observational epidemiology study that some have also called longitudinal, or prospective, though these terms also apply to other epidemiological designs. A cohort study evaluates both the risk and the rate of disease or disease-related outcomes in a population that is characterized in terms of relevant risk factors or exposures, placed under observation, and followed for some time until disease develops or not. In contrast to its classical counterpart, the case-control study (cf. chapter ▸Case-Control Studies of this handbook), cohort studies can relate multiple diseases to the exposure or exposures identified. On the other hand, cohort studies are frequently restricted to a limited number of exposures and potential confounders that can be included in the study, especially if historical data are used.

The chapter is organized as follows: First, a brief historical perspective on cohort studies is given, showing the importance of this study design by giving examples. Second, conceptual features of cohort studies are presented, where the two basic types of cohort studies, concurrent and non-concurrent historical cohort studies, are summarized, and the basic concepts of data analysis in cohort studies are described. These concepts include the description of outcome events in the cohort, the comparison with external data, and the analysis of effects of exposure. The chapter then deals with key concerns of cohort studies, including selection of the study population and on the important question of how to determine exposure and outcome events in the framework of a cohort study. Ethical issues, mainly raised through the potential future use of specimens, are also discussed. Examples are given on many issues. Although some of these may seem simplistic, they are presented in this way to ensure that general principles are clearly depicted.

6.2 A Brief Historical Perspective on Cohort Studies

Cohort studies have been used for over a century to study determinants of disease. Since the early days of epidemiology, they have been used as a powerful tool to study a broad range of exposures such as infections, nutritional factors, occupational factors, and lifestyle factors, as the following examples illustrate.

The classical study on the London cholera epidemic of 1849 conducted by John Snow is an example of a cohort study on infectious diseases (Snow 1855; Sutherland 2002). Reports from the Registrar General had drawn attention to the possibility that differences in water supply were associated with differences in cholera rates across sections of London. Two different water companies (the Lambeth and the Southwark and Vauxhall) supplied households within various regions of London, and frequently these two water companies supplied adjacent households. The companies differed in one important feature, the location of the water intake. The Lambeth had moved their water intake upstream from the sewage discharge point in 1849, whereas the Southwark and Vauxhall continued to obtain water downstream of the sewage discharge point. Dr. Snow classified households according to their exposure to the two water sources and showed a substantial difference in cholera mortality, 37 versus 315 cholera deaths per 10,000 households served by the Lambeth and Southwark and Vauxhall companies, respectively.

Cohort studies continue to be an important tool in the investigation of infectious diseases. For example, McCray (1986) used a cohort design to quantify the risk of developing the acquired immunodeficiency disorder (AIDS) among healthcare workers exposed to blood and body fluids of AIDS patients.

Joseph Goldberger employed a variety of epidemiological approaches, including cohort methods, to study pellagra, a systemic disease endemic in the southeast of the United States in the late nineteenth and early twentieth century (Terris 1964). In one investigation, Goldberger examined the dietary exposures of households in relation to the occurrence of pellagra and demonstrated that a cornmeal subsistence diet was associated with pellagra. Subsequent trials showed that pellagra could not be transmitted from person to person, as might be expected for an infectious disease, but could be prevented by the “pellagra-preventive factor,” later determined to be niacin. More recently, Oomen et al. (2001) studied the association of trans-fatty acids, a hydrogenation product of oils containing polyunsaturated fatty acids, and heart disease among men in the Netherlands. They found a relative risk of 1.28 of heart disease for an increase of 2% of energy from trans-fatty acid intake at baseline.

Occupational epidemiology is another classical field of application of cohort studies. Typically, workers exposed to a putative harmful substance are compared to other workers in the industry or to the general population. Occupational cohorts were used to study, for example, the association between exposure to dyes and urinary bladder cancer (Case et al. 1954), exposure to mustard gas and respiratory cancer (Wada et al. 1968), and exposure to benzene and leukemia (Rinsky et al. 1987). The health effects for workers exposed to asbestos have been the subject of many studies (e.g., Liddell et al. 1997; Selikoff et al. 1965) and continue to be examined. Ulvestad and colleagues (2004) conducted a cohort study of members of the Norwegian Trade Union of Insulation Workers hired between 1930 and 1975 and followed through 2002, demonstrating relative increases in risk of mesothelioma and lung cancer when compared with the experience of the general population.

Lifestyle exposures have also attracted the attention of epidemiologists, including physical activity, tobacco and alcohol use, diet, and nutrition. Morris and colleagues (1953a, b) demonstrated that British bus drivers had approximately twice the risk of heart disease in comparison to the more active conductors (who went up and down the stairs to collect tickets). This result was confirmed in a comparison of postmen with telephonists and clerks (Morris et al. 1953a, b). In 1951, Doll and Hill (1954) initiated a cohort study of British physicians by collecting data on tobacco use via questionnaire. By collecting death certificate data, they were able to demonstrate a tenfold increased risk of lung cancer death for smokers compared to non-smokers (Doll and Peto 1976). Doll et al. (1994a) also reported on the association of alcohol consumption with mortality among British doctors demonstrating a u-shaped relationship, with greater mortality among abstainers and heavy drinkers and the lowest mortality among moderate drinkers, defined as

1–2 drinks per day on average. Concerns were raised that the increased risk described in abstainers may be falsely elevated by the experience of former drinkers who may have quit drinking due to health decline. This concern was addressed by Eigenbrodt et al. (2001) using cohort methodology within the Atherosclerosis Risk in Communities (ARIC) study. Eigenbrodt et al. measured perceived health status and alcohol consumption behavior longitudinally and were able to identify changes in health status that preceded changes in drinking behavior. They demonstrated that perceived health decline predicted cessation of drinking, thereby providing evidence that the risk among abstainers may have been inflated in studies that failed to distinguish between lifelong abstainers and former drinkers.

Despite disadvantages regarding cost and complexity, cohort studies remain of substantial public health importance as indicated by several of the previously cited examples and by such evidence as was recently provided by the National Institutes of Health (NIH). The NIH is considering the establishment of a 500,000-person cohort study to examine genetic and environmental influences on common diseases in the United States (National Institutes of Health 2004). Similar large cohort studies have been or are being initiated in Canada, Germany, and the UK. The large sample sizes under consideration for these studies will enable the examination of gene-gene and gene-environment interaction in the general population and in subgroups of interest. Therefore, a sound understanding of cohort methodology is of substantial importance to the modern epidemiologist.

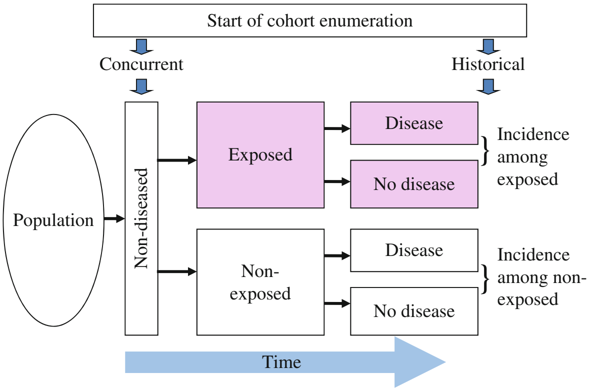
6.3 Conceptual Foundations

6.3.1 Types of Cohort Studies: Concurrent and Non-Concurrent Approaches

The central feature of a cohort study is the collection of exposure data in a defined population and the subsequent surveillance of possible outcome events regarding health, morbidity, and mortality. For this purpose, healthy members of a defined population (the cohort) are classified according to their exposure status (e.g., exposed vs. unexposed) and followed over a long period with respect to their health status. Then, the question can be answered if incidence of outcome events is associated with former presence or absence of exposure, which would indicate a possible causal relationship.

Within this framework, cohort studies can be classified in two major categories depending on the timing of follow-up period relative to the time of study conduct. In *concurrent or prospective cohort studies* (a simplified scheme is given in Fig. 6.1), a defined population is assembled and possibly screened to eliminate persons with disease where the resulting non-diseased population is the so-called population at risk. Then, information on exposure, possible confounders, and other important factors is gathered. The cohort members are subsequently followed into the future recording outcome events of interest. In *non-concurrent* or *historical cohort studies* (Fig. 6.1), a population is assembled from available historical data records, for

Fig. 6.1 Design of a cohort study



example, from company files. Exclusion of persons with preexisting disease defines the population at risk; assessment of exposure and other factors is based on the available data from the past. Cohort members are monitored for outcome events through existing documents and data systems (e.g., vital statistics files or disease registries) from some point in the past to the present. As in concurrent studies, outcome rates may be compared across exposure categories within the cohort, or, if all members of the cohort are assumed to be exposed, outcome rates may be compared between the cohort and the general population, assumed to be the unexposed reference population. A combined approach is also possible, with the cohort assembled and followed initially through historical documents or other data sources such as data from registries and subsequently followed using concurrent methods. Kleinbaum et al. (1982) introduced this as ambispective study design. The distinction between these two major categories of cohort studies has important implications regarding data collection.

In concurrent studies, the methods for cohort assembly and data collection can more easily be controlled, whereas in non-concurrent studies, the investigators must rely on data recorded in historical records, almost always for reasons other than medical research. This notable disadvantage of the non-concurrent approach is compensated by the ability to study exposures, such as occupational exposures, that meet one or more of the following key conditions: (1) the exposure can be attributed to selected employed populations based on individual records of job descriptions or other employment data, (2) the exposure is relatively rare in the general population outside the occupations of interest, (3) the induction period is long, and (4) the health concern is substantial; thus, an early answer can be obtained to questions of risk, an important advantage from a public health perspective. In practice, the design and analysis of cohort studies require advanced methods in order to account for exposures that are not fixed, not dichotomous, and not time invariant. Individuals may move from being exposed to being unexposed and vice versa over time. Advanced models also need to account for dynamic cohorts where subjects enter or leave a population at risk at various points in time during the observation period.

Because many diseases tend to be multifactorial in causation, a crucial point in the validity of cohort studies is the inclusion of data on possible confounders at baseline. This is a problem in historical cohort studies that will be discussed in the section on determining exposures below.

Two modern extensions of cohort studies that try to integrate the advantages of cohort and case-control studies are designed to have nearly all the power of classic cohort studies but utilize relatively economically detailed exposure information from questionnaires or biomarkers or other biological measurements determined from the collection of biological specimens at the time the study is initiated. These analytical designs, that is, nested case-control studies and case-cohort studies, are discussed in detail in chapter ▸Modern Epidemiological Study Designs of this handbook and will not be further considered here.

6.3.2 Description of Outcome Events in the Cohort

Cohort studies allow direct comparisons of exposed and unexposed subgroups and can provide measures of effects for various outcome events, such as different endpoints (morbidity, mortality, pre-morbidity) and/or different diseases. Nevertheless, analysis of cohort data requires reasonable care especially in the steps of data preprocessing for description and analysis. The often necessary change of perspective from persons at risk to person-time at risk needs special attention to ensure that unbiased results can be obtained. This subsection will refer mainly to disease incidence; however, other measures can, in principle, be treated in the same manner.

The results from a cohort study can be presented as shown in Table 6.1.

The easiest way to describe outcome events in a cohort is by counting the number of persons experiencing the event of interest and relating this number to the number of persons at risk in the cohort. Disease incidence, for example, can be described by the cumulative incidence or risk, which is calculated by dividing the number of incident cases by the number of persons at risk at baseline:

$$\widehat{\text{Risk}} = \text{number of incident cases}/\text{number of persons at risk}, \tag{6.1}$$

that can be calculated as

$$\widehat{\text{Risk}} = (a + c)/N \tag{6.2}$$

Table 6.1 2 × 2 table summarizing the results of a cohort study

		Second observe		
		Disease contracted	No disease	Total
First select	Exposed	a	b	$a + b = n_E$
	Non-exposed	c	d	$c + d = n_{\bar{E}}$
Total		$a + c$	$b + d$	$a + b + c + d = N$

and, accordingly for the exposed and unexposed study populations, as

$$\widehat{\text{Risk}}_E = a/(a+b) = a/n_E$$

$$\widehat{\text{Risk}}_{\bar{E}} = c/(c+d) = c/n_{\bar{E}}.$$

The cumulative incidence or risk is unit free and represents an individual risk of developing the disease. It is a proportion, not a rate, and it does not account for possible different periods of disease-free follow-up time of cohort members and assumes a fixed cohort. Thus, it is necessary always to specify the time period for incidence ascertainment for any cumulative incidence to avoid the fallacy of comparing cumulative incidence from different studies with different follow-up periods.

In cohort studies on acute diseases with short induction periods and a short time of follow-up, like outbreaks, the risk of disease can be estimated directly using the cumulative incidence, given a fixed cohort with fixed period of follow-up and a low fraction of dropouts. In cohort studies on chronic diseases with their long follow-up periods, however, the use of the cumulative incidence is not appropriate because usually disease-free follow-up periods differ among cohort members. In this case, occurrence of outcome events is preferably described by rates that represent the number of outcome events divided by the cumulated duration of event-free follow-up periods of all cohort members at risk. For further analysis, all rates presented in the following can be used to determine rate ratios and rate differences as described in chapter ▶Rates, Risks, Measures of Association and Impact of this handbook. Disease incidence can be expressed as incidence rate (I):

$$\hat{I} = \text{number of incident cases/cumulative person-time at risk,} \tag{6.3}$$

where each cohort member is contributing the time from entry into the study to either development of disease or end of follow-up to the denominator of the incidence rate, thus accounting for different times at risk of the cohort members to develop the disease. The incidence rate is sometimes called incidence density or hazard rate and should not be confused with cumulative incidence. Assuming equal person-time of follow-up of t, with t_E and $t_{\bar{E}}$ follow-up of exposed (E) and unexposed ($\bar{E}$) populations, (6.3) results in

$$\hat{I} = (a+c)/(N * t), \tag{6.4}$$

where $N * t$ denotes the total person-time at risk. Calculating the incidence rates separately for the exposed and unexposed study populations gives

$$\hat{I}_E = a/[(a+b) * t_E] = a/(n_E * t_E),$$

$$\hat{I}_{\bar{E}} = c/[(c+d) * t_{\bar{E}}] = c/(n_{\bar{E}} * t_{\bar{E}}).$$

Measures of risk and incidence of disease may provide important information regarding the public health burden of the outcome or disease of interest. Since incidence rates often vary considerably, for example, by age, sex, calendar year, and race, the calculation of specific incidence rates instead of crude incidence rates may be desirable. For this purpose, different strata (for one group variable) or cells (for two or more group variables) have to be defined over the group variables' range.

The individual contributions of the cohort members to numerator and denominator of the incidence rate have to be assigned to the respective stratum or cell. Usually, each cohort member will contribute to more than one stratum or cell as he/she moves through the cohort during follow-up. Age- and calendar-specific incidence rates can be approximated well enough on the base of calendar year data if more precise information on months and days is not available (see Breslow and Day 1987).

A simple example demonstrates the principle steps for the calculation of specific incidence rates for the age groups 30–39 years, 40–49 years, and 50–59 years. Table 6.2 shows the data of a fictitious cohort, for which we will calculate age-specific incidence rates. Since exact dates in terms of months and days are not available in our example, age and follow-up time will be approximated by full and half years. The contribution of the year at entry into the study and the year of diagnosis is approximated as half a year (see Fig. 6.2).

The cohort consists of 10 persons who were followed for 9–20 years resulting in a total of 155 person-years of follow-up, deaths, and dropouts accounted for the lacking 45 person-years. Three cases of the disease of interest occurred in the cohort during follow-up, resulting in a crude incidence rate of $3/135 = 0.022$ cases/person-year. The difference between the total of 155 observed person-years and the 135 person-years in the denominator of the incidence rate results from 20 years of cumulated follow-up time after diagnosis in the three cases. A useful general way in which to think of cohort data is to separate person-time at risk and person-time under observation.

Table 6.2 Data from a fictitious cohort

No.	Age at entry	Years of follow-up	Age at end of follow-up	Age at diagnosis	Person-years at risk
1	34	15	49		15
2	39	20	59	54	15
3	31	12	43		12
4	36	17	53	41	5
5	38	9	47		9
6	38	16	54	51	13
7	41	11	52		11
8	32	20	52		20
9	39	18	57		18
10	42	17	59		17
Total		155			135

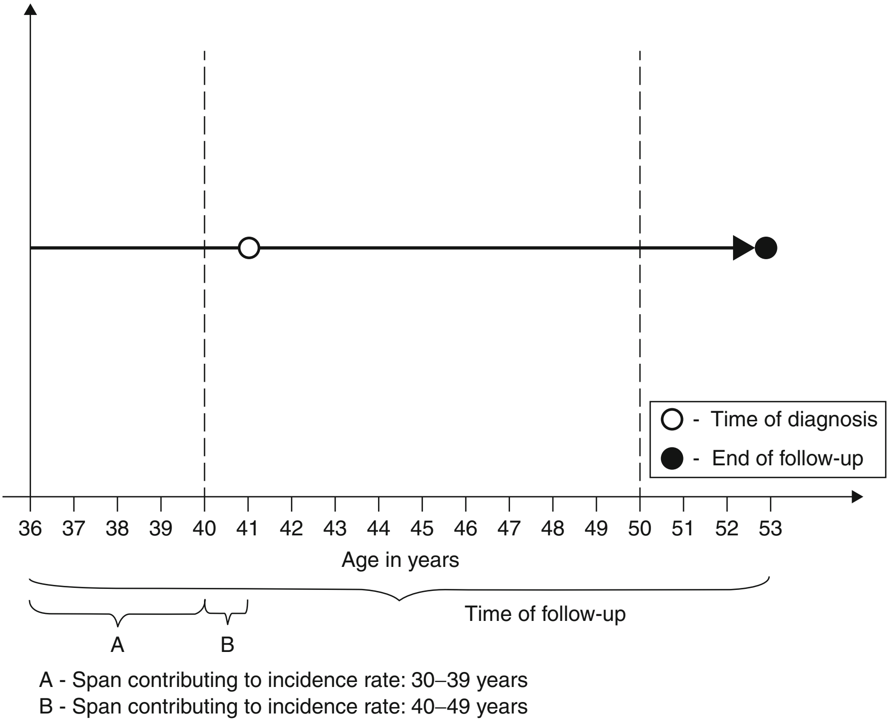


Fig. 6.2 Follow-up time of cohort member no. 4 of the fictitious cohort with respect to age

A subject is "at risk" at a given moment if the event of interest can happen. Thus, if a subject gets thyroid surgery, she/he is no longer at risk of getting a thyroid cancer. If on the other hand the event of interest were a pregnancy, a woman would not be "at risk" of becoming pregnant if she already is pregnant or during spells of abstinence. In this case, however, the woman is "at risk" again from the moment she desires another child. In the example above, a subject is no longer considered "at risk" after diagnosis of the disease. Of course, no subject is "at risk" from the moment of his/her death. Being at risk depends only on the endpoint studied.

On the contrary, being under observation (i.e., being followed up) depends on the precise definition of the cohort and the method of follow-up adopted in the study. A subject is under observation at a time t, if, were the event of interest to occur at this moment, it would be recorded. Thus, for example, if the cohort definition were "all subjects employed in a given factory with at least 1 year of employment," the follow-up would start only at the moment the subject satisfies this criterion. In this case, all the person-time in the first year must be ignored as if the event of interest occurred in this year; it would not satisfy the inclusion category. Similarly, a subject would be dropped from the follow-up at a time t if no information as to his/her disease status could be retrieved from time t on (e.g., the subject moves abroad), and the

Table 6.3 Age-specific incidence rates for fictitious cohort data

Age group	Incident cases	Disease-free follow-up time (years)	Age-specific incidence rate
30–39	0	$5.5 + 0.5 + 8.5 + 3.5 + 1.5 + 1.5 + 0 + 7.5 + 0.5 + 0 = 29$	$0/29 = 0$
40–49	1	$9.5 + 10 + 3.5 + \mathbf{1.5} + 7.5 + 10 + 8.5 + 10 + 10 + 7.5 = 78$	$1/78 = 0.013$
50–59	2	$0 + \mathbf{4.5} + 0 + \mathbf{0} + 0 + \mathbf{1.5} + 2.5 + 2.5 + 7.5 + 9.5 = 28$	$2/28 = 0.071$

subject is then considered “lost to follow-up” or “censored.” A subject contributes person-time to the study at any moment t if and only if at this moment he/she is “at risk” and “under observation.”

Coming back to the example, each incident case is assigned to the age group he/she belonged to until diagnosis. In the same manner, the disease-free time of follow-up of each cohort member is allocated to the three age groups yielding the age-specific incidence rates presented in Table 6.3.

Incidence rates are commonly rescaled, for example, to cases per 100,000 person-years underlining their reference to populations rather than to individuals. The crude incidence rate of 0.022 cases/person-year of the fictitious cohort, for example, would then be expressed as 2,222/100,000 person-years.

In Fig. 6.2, the follow-up time of cohort member no. 4 is depicted schematically with respect to age. The first three and a half years, denoted with A, of the 5 years of disease-free follow-up time (41 years at time of diagnosis – 36 years at entry into the study) are contributing to the denominator of the incidence rate of the first age group (30–39 years), and the next one and a half year, denoted with B, contribute to the numerator of the incidence rate of the second age group (40–49 years).

To quantify the frequency of exposure in the population under study, the prevalence of exposure may be considered:

$$\hat{P}_E \quad = (a + b)/N = n_E/N. \tag{6.5}$$

Note that this assumes that the exposures do not change in individuals over time. The various quantities presented here can be used to derive measures of association accordingly (see Sect. 6.3.4).

6.3.3 External Comparisons

One important form of validation of cohort studies is the ability to make comparisons with external data, preferably from the general population. Irrespective of the existence of internal comparison groups, external comparisons always give valuable insights by putting the cohort data in a broader context. For external comparisons, either age-, sex-, and calendar year-specific incidence or mortality rates or cumulative measures can be used. Standardized incidence rates can be calculated from specific incidence rates by weighting them with the age, sex, and calendar year distribution of the external comparison data (direct standardization). However, cumulative measures have to be interpreted cautiously since they can mask underlying differences in specific disease patterns, such as an unusually high incidence rate among younger persons in the cohort. With d_i denoting the number of cases in the age group i, n_i denoting the disease-free person-years accumulated in the age group i, and w_i denoting the proportion of persons in the age group i in the standard population, the directly age-standardized incidence rate $\hat{I}_W$ is calculated as

$$\hat{I}_W = \sum_{i=1}^{I} w_i d_i / n_i . \tag{6.6}$$

Indirectly standardized measures requiring morbidity or mortality rates of the standard population are the standardized morbidity or incidence ratio (*SIR*) and the standardized mortality ratio (*SMR*). Since morbidity data are not routinely available in most countries, the standardized mortality ratio is used much more frequently. The *SMR* compares the observed numbers of deaths in the cohort with the expected numbers, given the age structure of the cohort and the age-specific mortality rates λ_i of a reference population. With d_i denoting the number of deaths in the age group and n_i denoting the person-years accumulated in the age group, the *SMR* is estimated as

$$\widehat{SMR} = \sum_{i=1}^{I} d_i \Big/ \sum_{i=1}^{I} n_i \lambda_i , \tag{6.7}$$

where $\sum\limits_{i=1}^{I} d_i$ represents the total number of observed deaths in the cohort under investigation and $\sum\limits_{i=1}^{I} n_i \lambda_i$ the expected number of deaths that are obtained by applying age-specific incidence rates of the reference population to the cohort under investigation. An *SMR* above 1 indicates a larger mortality in the cohort, and an *SMR* below 1 a smaller mortality in the cohort compared to that of the reference population. Statistical testing of a single *SMR* can be done with a simple χ^2–test (observed vs. expected) with one degree of freedom. Assuming that the number of observed cases $D = \sum\limits_{i=1}^{I} d_i$ follows a Poisson distribution with expectation $\gamma = E(D)$, confidence limits for the *SMR* ($\widehat{SMR}_L$, $\widehat{SMR}_U$) can be obtained by finding confidence limits $\hat{\gamma}_L$, $\hat{\gamma}_U$ for the number of observed cases:

$$\widehat{SMR}_L = \hat{\gamma}_L / \sum_{i=1}^{I} n_i \lambda_i \text{ and } \widehat{SMR}_U = \hat{\gamma}_U / \sum_{i=1}^{I} n_i \lambda_i . \tag{6.8}$$

The confidence limits for γ can be determined as

$$\hat{\gamma}_L = (1/2)\chi^2_{2D,\alpha/2} \text{ and } \hat{\gamma}_U = (1/2)\chi^2_{2(D+1),1-\alpha/2}, \tag{6.9}$$

where $\chi^2_{2D,\alpha/2}$ denotes the $100(\alpha/2)$th percentile of the χ^2-distribution with $2D$ degrees of freedom and $\chi^2_{2(D+1),1-\alpha/2}$ denotes the $100(1-\alpha/2)$th percentile of the χ^2-distribution with $2(D+1)$ degrees of freedom (Sahai and Khurshid 1996).

If the age-specific rates of the reference population are just estimations of the true rates, as is often the case with morbidity data, calculation of confidence intervals for *SMR* can be performed by the method described in Silcocks (1994). A method for estimating *SMR* where information on vital status is complete but information on cause of death is partly missing, as may be the case in historical cohort studies, can be found in Rittgen and Becker (2000).

Comparison of rates by direct standardization has poor statistical properties, especially due to large variances of age-specific rates in small cohorts. Therefore, indirect standardization is usually preferred (see also chapter ►Rates, Risks, Measures of Association and Impact of this handbook).

6.3.4 Internal Versus External Comparisons

In the previous section, the event rate (morbidity or mortality) of a cohort is compared to the rates of an external population. This is done by comparing the observed number of deaths in the cohort with the expected numbers, given the age structure of the cohort and the age-specific mortality rates λ_i of a reference population. The ratio of observed to expected (the *SMR*) is then interpreted as a rate ratio between the cohort and the general population taken as the reference.

If the cohort is set up for investigating a specific risk factor, as would be the case in an occupational cohort, one can be tempted to interpret the *SMR* as a risk ratio due to the risk factor under investigation. However, this interpretation would only be valid if the cohort were comparable to the general population for all factors except for the risk factor under investigation. This is obviously only rarely the case. The general population consists of all subjects including the very ill and very poor, which would rarely be included in the same proportion in a cohort. Thus, the mortality in the general population is usually higher than in any (unexposed) cohort. In occupational cohorts, this phenomenon has been termed the "*Healthy Worker Effect*" (see, e.g., Li and Sung 1999; Goldberg and Luce 2001). Other factors, like regional differences, owing to social, behavioral, nutritional, and environmental factors, might cause the mortality of a regionally based cohort to be different from a nationwide general population.

In summary, the *SMR* is a potentially biased estimate of the effect of any risk factor. This bias can be reduced by choosing a reference population which is as similar as possible (except for the risk factor of interest) to the cohort under investigation or by comparing the cohort to another reference cohort. In the latter case, however, the computation of the confidence interval of the *SMR* is no longer valid as it assumes that, because of the large number of subjects in the reference population, the disease rates and hence the expected numbers are observed without any sampling error. Then the only statistically valid methods are those presented in the following section, although the confidence intervals of the risk ratio become wider. The choice between an external comparison and an internal comparison is thus the choice between accepting a (often small) bias and accepting a larger variance, which implies a lower power. Such a choice can only be made in the context of each study, and, if possible, both approaches should be tried. Finally, methods have been proposed including external reference rates to stabilize internal comparisons (e.g., Breslow and Day 1987, p. 151) that might be used as a reasonable compromise.

6.3.5 Summary Effects of Exposure

The main goal of cohort studies is to compare morbidity and/or mortality in exposed and non-exposed subjects or between different exposure groups of the cohort and to investigate dose-effect relationships between exposure and disease. If the exposure is constant and can be determined at entry into the cohort, internal comparisons can be performed by calculating specific incidence rates for each exposure category separately as if each group were a separate cohort. Cumulative rates can be used, again provided the subgroups do not differ in important determinants of disease, for example, age.

In the simple case of a single dichotomous exposure, several measures of association of exposure with disease can be estimated from results provided by a cohort study (see Table 6.1). In the following, the most important ones will be briefly introduced. A detailed discussion of their properties and examples for their calculation can be found in chapter ▸Rates, Risks, Measures of Association and Impact.

Perhaps the most popular measure of association is the risk ratio (*RR*), also known as relative risk that compares the experience of exposed and unexposed populations. With the notation given in Table 6.1 and the risks for the exposed and unexposed subjects calculated according to (6.2), it can be estimated as

$$\widehat{RR} = \widehat{\text{Risk}}_E / \widehat{\text{Risk}}_{\bar{E}} = [a/(a+b)]/[c/(c+d)] = (a/n_E)/(c/n_{\bar{E}}). \qquad (6.10)$$

The incidence ratio (*IR*) compares the incidence rates in the exposed and unexposed study populations. According to (6.4), its estimator is given as

$$\widehat{IR} = \hat{I}_E/\hat{I}_{\bar{E}} = \{a/[(a+b)*t_E]\}/\{c/[(c+d)*t_{\bar{E}}]\} = [a/(n_E * t_E)]/[c/n_{\bar{E}} * t_{\bar{E}})]. \qquad (6.11)$$

The *RR* and *IR* provide estimates of the relative strength of the association between the exposure of interest and the outcome or disease of interest.

The absolute difference in risk (*AR*) between the exposed and unexposed groups provides an estimate of the impact of the exposure on the risk of disease in absolute terms. This measure is not to be confused with the absolute risk, which is the absolute probability that a disease-free individual will develop a given disease over a specific time interval (Benichou 1998). Using the above formulas for the risks among exposed and unexposed, it can be obtained from a cohort study as

$$\widehat{AR} = \widehat{\text{Risk}}_E - \widehat{\text{Risk}}_{\bar{E}} = [a/(a+b)] - [c/(c+d)] = a/n_E - c/n_{\bar{E}}. \quad (6.12)$$

Based on the concept of attributable risk, several other measures can be derived, though care must be used in their computation and interpretation (Greenland and Robins 1988, and see chapter ▸Rates, Risks, Measures of Association and Impact of this handbook). The attributable fraction (AF) can be interpreted as the proportion of risk due to exposure in exposed individuals. It may be useful for quantifying the degree to which risk can be reduced at the individual level if the exposure (and its effects) can be eliminated. It may, therefore, be a sensible measure for counseling individuals:

$$\begin{aligned}\widehat{AF} &= \widehat{AR}/\widehat{\text{Risk}}_E = \{[a/(a+b)] - [c/(c+d)]\}/[a/(a+b)]\\ &= (a/n_E - c/n_{\bar{E}})/(a/n_E).\end{aligned} \quad (6.13)$$

The population attributable risk (PAR) reflects the absolute level of risk of the outcome in the population due to the exposure. It can be used to estimate the public health impact, in absolute terms, of elimination of the exposure, at least with respect to the outcome of interest. Based on the attributable risk and the prevalence of exposure (see Eq. 6.5), it is given as

$$\begin{aligned}\widehat{PAR} &= \widehat{AR}/\hat{P}_E = \{[a/(a+b)] - [c/(c+d)]\}/[(a+b)/N]\\ &= (a/n_E - c/n_{\bar{E}})/(n_E/N).\end{aligned} \quad (6.14)$$

The last measure to be mentioned here may be used to estimate the proportion of all events of interest that could be prevented in the overall population if the exposure (and its effects) can be eliminated. The population attributable fraction (PAF) is defined as the proportion of all events of interest that occur in the population due to the exposure:

$$\widehat{PAF} = \widehat{PAR}/\widehat{\text{Risk}} = (a/n_E - c/n_{\bar{E}})/\{(n_E/N)[(a+c)/N]\}. \quad (6.15)$$

6.3.6 Internal Modeling of the Effects of Exposure

The situation is more complicated if cohort members continuously add exposure over follow-up time. Simple categorization on the basis of cumulative exposure would lead to biased results. Person-years accumulated shortly after entry into the study of cohort members with high cumulative exposure would wrongly be allocated to a high exposure category, although the cumulative exposure at that time point was still low for these cohort members, resulting in underestimation of high exposures and overestimation of low exposures. Therefore, the disease-free

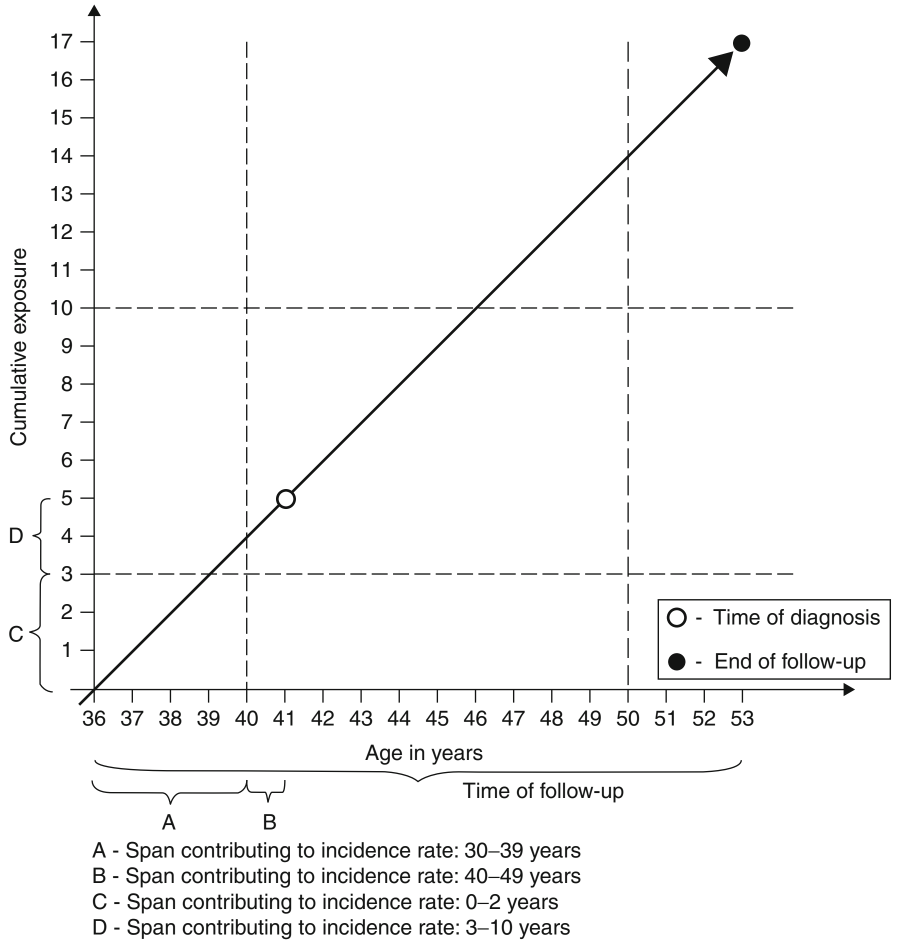

Fig. 6.3 Follow-up time of cohort member no. 4 of the fictitious cohort with respect to age and cumulative exposure

person-time of each subject has to be subdivided and assigned to the respective age- and sex-specific exposure category the cohort member belongs to as he or she moves through the cohort, meaning that most cohort members contribute to different age-exposure categories. In the same manner, the incident cases have to be assigned to the categories where they occurred.

In Fig. 6.3, the follow-up time of cohort member no. 4 is again depicted schematically, this time with respect to age and cumulative exposure assuming that the exposure starts at the beginning of the follow-up and that it is constant over time. For age- and exposure-specific incidence rates, the disease-free-follow up time is assigned to the groups according to the squares in the figure that are defined by the categorization of the group variables, resulting in a contribution of cohort member no. 4 of two and a half years to the denominator of the incidence

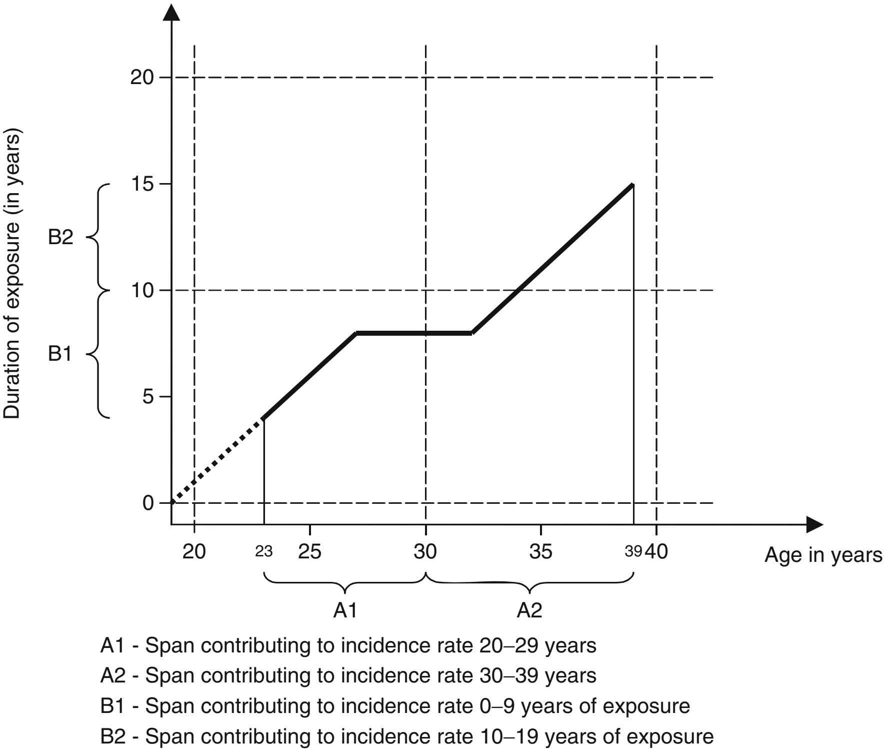

Fig. 6.4 Person-time classification with varying duration of exposure

rate of category A × C (30–39 years of age and <3 units of cumulative exposure), 1 year to the denominator of the incidence rate of category A × D (30–39 years of age and 3 – <10 units of cumulative exposure), and one and a half year to the denominator of the incidence rate of category B × D (40–49 years of age and 3 – <10 units of cumulative exposure). The case itself contributes to the numerator of the incidence rate of category B × D, since this is the category in which he/she was diagnosed.

This procedure can be extended in several ways. The exposure may have started before beginning of follow-up or may start later. It can vary over time, and it can even vary from individual to individual or can be lagged to account for induction time. Several measures of exposure (e.g., time since first exposure and/or confounders) can be considered simultaneously, and possible confounders can be included in the analyses as additional variables. Figures 6.4–6.6 illustrate some of these features. For simplicity, no half years are considered in these examples.

In Fig. 6.4, a subject is followed up from age 23 but has been exposed from age 19 on; he/she is exposed until age 27 followed by an unexposed 5-year period. He/she is again exposed until age 39 at which time his/her person-time

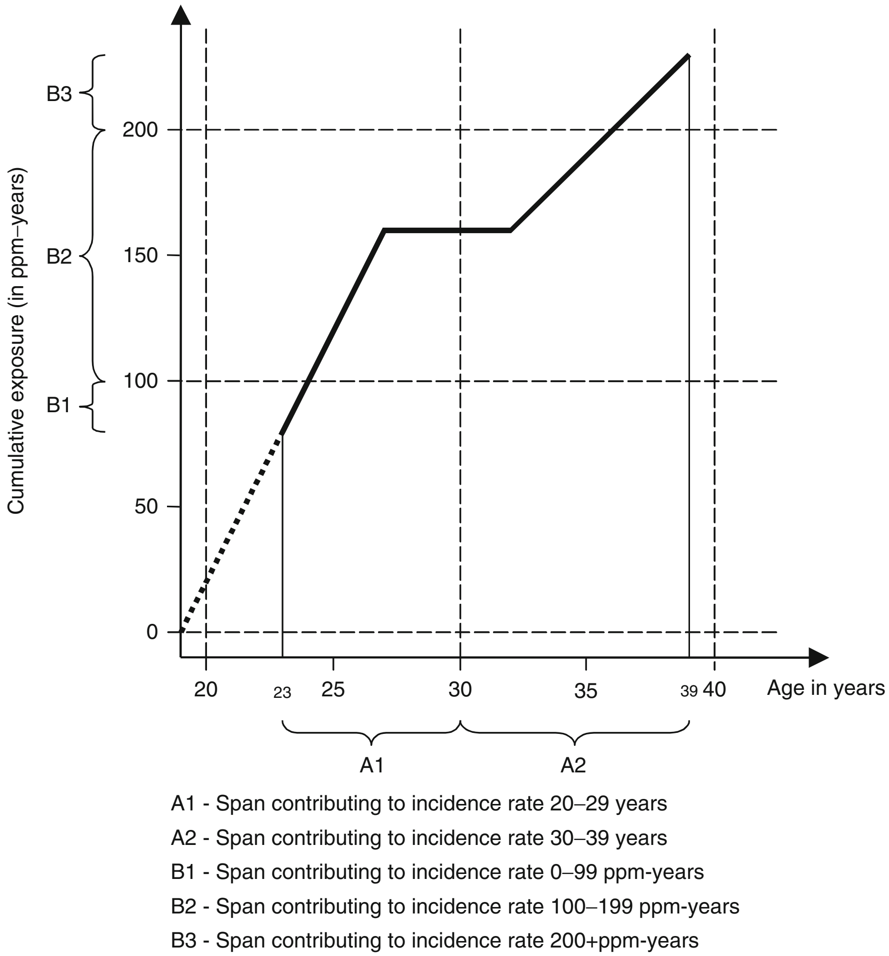

Fig. 6.5 Person-time classification with varying cumulative exposure

at risk ceases either because of disease diagnosis or because of end of follow-up. This subject would contribute 7 years (from age 23 to age 30) to the A1 × B1 group (20–29 years of age, 0–10 years exposure), 4 years (from age 30 to 34) to the A2 × B1 (30–39 years of age, 0–10 years of exposure), and 5 years (from age 34 to 39) to A2 × B2 (30–39 years of age, 10–19 years of exposure).

Figure 6.5 presents the same subject assuming that the first exposure spell was twice as intensive (e.g., 20 ppm of a given chemical) than the second exposure (10 ppm). The units of cumulative exposure on the y-axis are now ppm-years. The subject would contribute 1 year to group A1 × B1 (his cumulative exposure is then 100 ppm-years), then 6 years to group A1 × B2 (at age 30, his cumulative exposure

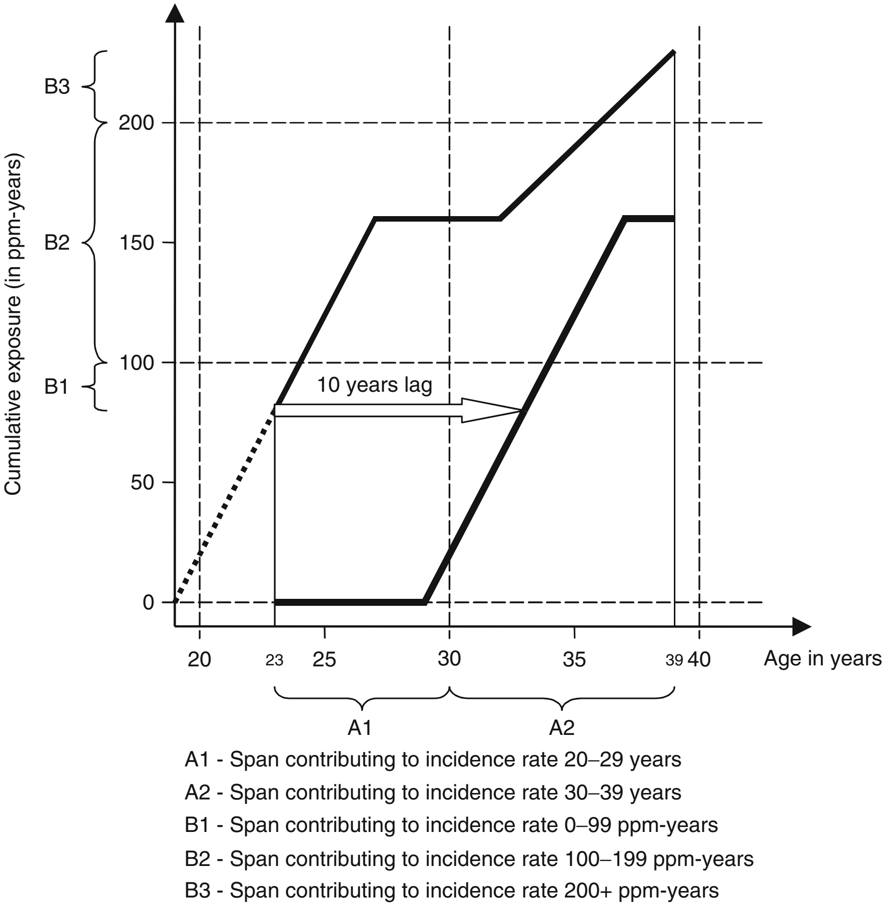

Fig. 6.6 Person-time classification with varying lagged cumulative exposure

is 160 ppm-years), then 6 years (from age 30 to age 36 at which he reaches 200 ppm-years) in group A2 × B2 and finally 3 years in group A2 × B3.

Figure 6.6 considers the same subject again, but this time, the exposure is lagged by 10 years, say, to account for disease induction time. The first period would then be a non-exposed period. The rationale is that, were the disease to occur in these first 10 years, it would not be attributable to exposure. Applying the same rationale as before, the subject would stay 6 years in 0 × A1, then the subject would contribute 1 year in group B1 × A1, 4 years in group B1 × A2, and finally 5 years in group B2 × A2; the lagged cumulative exposure at end of follow up (i.e., at age 39) is 160 ppm-years.

Another exposure can occur during the follow-up, for example, the preceding subject starts smoking at age 25. In this case, a further splitting of the time periods would be done separating periods in which the subject was a non-smoker and periods in which he/she smoked.

This splitting of person-time into age and exposure groups must be done for each subject of the cohort and gets more complex with a growing number of group variables. Specialized software packages exist (e.g., Coleman et al. 1986) to perform these computations, but they are usually limited in the complexity they can handle. Interestingly, these restrictions do not apply to some more general packages as Stata (version 7 or later – StataCorp 2001) or Epicure (Preston et al. 1993) in which the statistical modeling procedures of such data are included. The end result of the calculations carried out in these packages can then be presented as a data table with each line corresponding to a separate combination of age and exposure classes (other classifications like calendar periods might also be included) and containing the following variables: the value of each age and exposure group, the number of person-years n_i accumulated in this category over the entire cohort, and the number d_i of events of interest falling in this category.

In cohort studies, the standard model for analyzing such data is the Poisson model which is a statistical model of the disease rates. Basically, the Poisson model assumes that the number of events d_i in each category i (combination of age category j and the kth combination of exposure variables) follows a Poisson distribution with parameter $n_i \lambda_i$. The standard (multiplicative) model would then assume that

$$\ln(\lambda_i) = \alpha_j + \beta_k, \tag{6.16}$$

where λ_i are the unknown true disease rates, the α_j are nuisance parameters specifying the effects of age and (possibly) other stratification variables such as calendar periods, and β_k the parameters that describe the effects of primary interest. As usual, in regression models, $\beta_0 = 0$ would be a baseline category. $\exp(\beta_k)$ is then an estimate, adjusted on the nuisance parameters, of the relative risk of the kth exposure category versus the baseline category assuming absence of interaction between exposure. The full modeling strategy of the Poisson regression is beyond the scope of this chapter but is not different from any regression modeling (see chapters ▶Regression Methods for Epidemiological Analysis and ▶Survival Analysis of this handbook). A comprehensive account of Poisson modeling is given by Breslow and Day (1987, Chap. 4).

An alternative way of analyzing event history data (another denomination of cohort data focused on events) is by using Cox's proportional hazards regression model. This model acknowledges that the categorization of continuous data always implies a loss of information and therefore generally a loss in statistical power. Moreover, there is no need to explicitly estimate the effects of nuisance parameters if it can be avoided.

The first step in proportional hazard modeling is the choice of one of the time variables considered. This basic time variable can either be age, as was implicit at the beginning of this chapter, or in some settings, the calendar time or even the time since the beginning of follow-up. Once this time variable has been fixed, its effects can be estimated non-parametrically.

The key idea of Cox's regression is that no information is lost when considering only the time points t_i at which an event of interest occurs. At each such time point, a "risk set" is established including all members of the cohort contributing person-time (at risk and under observation) at this time point. If one wants to use a Cox model, the first step is thus to identify all risk sets. Then, one must obtain the value at each time t_i of all variables to be included in the model for all members of the corresponding risk set. The statistical analysis is then similar (in fact, the same software can be used) to a conditional logistic regression analysis, in which the matching variable is the indicator of the risk set. As in the logistic regression, the exposure at time t_i of the case, that is, the subject experiencing the event at time t_i, and the exposure at time t_i of the other members of the risk set are compared. Again, the full modeling strategy of the Cox's proportional hazards regression model and its various extensions are beyond the scope of this chapter (see chapters ▸Regression Methods for Epidemiological Analysis and ▸Survival Analysis of this handbook). A comprehensive though somewhat dated account of this model is given by Breslow and Day (1987, Chap. 5). As for Poisson models, both Stata and Epicure provide easy to use software, but once the risk sets and the corresponding exposure variables have been computed for each risk set, any logistic regression package (e.g., Proc PHREG in SAS) can be used.

6.4 Key Concerns in Cohort Studies

6.4.1 Selection of the Study Population

If external comparisons are to be made, usually, vital statistics data of the general population or data derived from national disease registries are used as a reference for the calculation of expected cases. However, they can only be regarded as valid for deriving an expectation of mortality and disease rates if the cohort under investigation is a representative sample of the general population. Indeed, many cohorts are convenience samples, derived from a group that happens to be accessible. Representative cohorts can, for example, be derived from national censuses, utilizing the data collected for the specific census. Obtaining access to census data is generally not easy, however, since most censuses guarantee confidentiality to participants. Exceptions to that rule are, for example, a Swedish occupational census-based sample and a 10% sample of the Canadian labor force, derived from data collected on Canadians having a social insurance number required for all who are employed in an active occupation (Howe and Lindsay 1983). These types of population samples are very valuable because subsets among them chosen for specific analysis can be regarded as comparable to the general population apart from the characteristics that caused them to enter, or be selected for, that subset.

Occupational cohorts (cf. chapter ▸Environmental Epidemiology of this handbook) are usually identified by company files or sometimes by workers' union files. Access to these cohorts is usually granted if the company or union is interested in determining whether a suspected increase in disease rates has occurred or there is concern that exposure to a potential hazard bears an increased risk of disease. For example, many carcinogens have been confirmed to be hazardous to humans, often after evidence first derived from animal studies, by investigations of specific cohorts (Tomatis et al. 1990). This mechanism is still being used, as exhibited by a tri-utility study of electrical and magnetic field exposures (Theriault et al. 1994) and a study of Motorola employees on the potential risks of exposure to radiofrequency fields (Morgan et al. 2000). It is very helpful if employment records indicate exposure to specific agents. This is the case when routine measurements are taken for safety reasons, as for most workers exposed to radiation. In their absence, estimation of exposures may be required, as discussed further below.

So-called multipurpose cohorts identified for study, however, have to be recruited by some mechanism that provides the opportunity for potential subjects to volunteer. For example, much has been learnt from an ongoing study of American nurses, who were given the opportunity to volunteer for the study by completing a questionnaire of dietary and other lifestyle factors (Willett et al. 1992). Similar studies were initiated in Canada by providing self-administered questionnaires to women already participating in a mammography screening trial (Howe et al. 1991) and in Sweden by approaching women who participated in a routine mammography screening program (Wolk et al. 1998). In Europe, a large multicenter cohort study was initiated in 10 countries using different approaches (Riboli and Kaaks 1997). Some used population registers as the basis for mailing invitations to participate. The response proportions were good in most countries, but still tended to include more health conscious and more highly educated people than the general population as is often the case in volunteer studies (cf. chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook).

Another recent feature of cohort studies has been the attempt to bring many together and analyze them almost as a multicenter study to enable the investigators to identify risks which none of them individually were capable of demonstrating. The Pooling Project is a case in point, originally funded to evaluate further uncertain associations between diet and breast cancer; it has proven a very useful source of additional knowledge because of the ability of cohort studies to identify multiple endpoints (Smith-Warner et al. 2006). Thus, it has already been extended to lung cancer (Smith-Warner et al. 2003), with findings similar to the EPIC study (Miller et al. 2004), and other diseases have followed (e.g., Cho et al. 2004; Koushik et al. 2006).

When a truly representative cohort cannot be obtained, because the mechanism used involves the opportunity to volunteer and to refuse to participate, comparisons with the general population in terms of mortality and disease rates may not be valid. Thus, the cohort study may lack external validity. However, provided that the recruitment mechanism is unbiased with regard to the exposure of interest, and the data obtained on exposure enables the investigators to stratify their population into exposed and unexposed subgroups, the estimation of the association between the exposure and the outcome will be valid (internal validity).

Tables 6.4 and 6.5 demonstrate the effects of different participation patterns (selection) on estimates that can be obtained from cohort studies. In the presence

of a fair sample, all of the measures of disease occurrence and association will be unbiased (Table 6.4). In the presence of overrepresentation of exposed persons (Table 6.5), the prevalence of the exposure will be overestimated and the risk of the outcome will be over- or underestimated depending on whether the exposure is positively or negatively associated with disease. Nevertheless, the estimates of the relative risk and the attributable risk will be unbiased. Since the estimate of the prevalence of exposure is biased, estimates of the public health impact will be biased. Other participation patterns that can theoretically introduce selection bias including overrepresentation of diseased individuals and participation rates that differ by both exposure and disease status are unlikely to affect cohort studies due to the customary exclusion of persons with the outcome of interest at baseline. This assurance is only relative, relying on the degree to which persons with prevalent disease can be excluded from the cohort. In general, selection bias can be minimized by avoiding the use of volunteers (or using volunteers exclusively) and by minimizing non-participation. The potential for selection bias can be assessed by evaluating non-participants for study characteristics, if possible.

6.4.2 Exposure and Confounders in Cohort Studies

As already indicated, some cohorts will have exposure data readily available, especially those derived from occupational groups where exposure was routinely collected for safety monitoring purposes. It is the strength of such cohorts that they offer the possibility to report the exposure before the disease occurs. However, for population-based cohorts, the investigators will have to collect data specifically for the study or refine existing data.

Because most cohorts will be very large, the collection of exposure data is not a simple task. If exposure data is to be collected by questionnaires, the scale of the effort required will generally mean that neither personal nor telephone interviews are feasible, as would normally be planned for case-control studies. This means that the exposure data will generally be collected by mailed self-administered questionnaires, often linked to the recruitment mechanism of the cohort, with response to the questionnaire qualifying the individual for inclusion in the study. Inevitably, the amount of data that can be collected by self-administered questionnaire is limited. The degree of detail for a given variable that can be obtained by such instruments is also restricted (cf. chapter ▸Exposure Assessment of this handbook), so that in addition to the problems of the ability of the respondent to recall accurately the exposure he/she has experienced, the data will be potentially subjected to major misclassification.

The extent of misclassification in cohort studies has only recently been appreciated, probably explaining the fact that the results of many cohort studies, especially when diet was the exposure of interest, have been negative (Day and Ferrari 2002). Thus, although many of the questionnaires used in cohort studies have been subject of validation studies, and correlation with other assessment methods seemed reasonable, these validation studies have served to reassure the investigators but probably have not protected them from reporting negative or very weak results. Even for smoking, the information obtained in cohort studies cannot be regarded as precise as investigators would have wished.

Misclassification of exposure can be differential or non-differential with respect to the outcome of interest, that is, the degree of misclassification of the exposure can

Table 6.6 Non-differential misclassification of exposure

	True Cohort (no error)			Observed Cohort (error)		
Cigarettes	MI	No MI	Total	MI	No MI	Total
Yes	60	300	360	54	270	324

Total	90	630	720	90	630	720
Rate Ratio	2.00			1.83		

differ, or not, by outcome status. In cohort studies, non-differential misclassification is the more typical form of misclassification due to the customary exclusion of persons with prevalent disease at baseline. It is unlikely that the measurement of exposure at baseline will be influenced by the development of an outcome sometime in the future. Differential misclassification is potentially a much greater problem in case-control and cross-sectional studies. Non-differential misclassification always introduces a bias toward a null finding (a finding of no association) if the exposure status is dichotomized, whereas differential misclassification can introduce a less predictable bias. Table 6.6 shows the impact of a 10% non-differential error rate in classifying smokers, in a cohort study in which occurrence of myocardial infarction (MI) was the observed endpoint. In this example, 90% of exposed individuals were correctly classified regarding exposure and 100% of unexposed individuals were correctly classified. Assuming a true relative risk of 2.0, the observed relative risk would be 1.8. With greater degrees of misclassification, the bias toward the null would increase. This bias can be minimized through the use of standardized and validated procedures for exposure assessment. It should be noted, however, that the bias due to non-differential misclassification can be toward or away from the null if the exposure has more than two categories.

Another issue that affects cohort studies differently than case-control studies is the effect of change in exposure with time. In case-control studies, detailed exposure biographies that include changes in exposure patterns, for example, change in intensity of smoking, or cessation of smoking, or even measures taken to affect dietary change, can be retrieved using just one survey, with the problem of uncertainty, and possibly differential error, in recall. The concurrent cohort study with its prospective data collecting does offer the possibility of assessing changes in exposure while they happen. To assess changes in exposure patterns, a mechanism has, however, to be set up specifically, for example, by readministering the questionnaire on a regular basis. This could be done as part of the follow-up mechanism adopted, though some loss to follow-up will be inevitable. An alternative to incorporating this new information into the analysis is shown in the Nurses Health Study (Willett et al. 1992). The follow-up period with regard to the time from the first exposure information to the second was used as a separate cohort from the follow-up period subsequent to the second exposure information. This is justifiable as blocks of person-time in different periods are statistically independent, regardless of the extent they are derived from the same people (Rothman and Greenland 1998). However, usually cohorts are analyzed with regard to the exposure determined at baseline, and although that may seem distant from the period when many endpoints are determined, for those with a long induction period from exposure to outcome, as for many cancers, this has not always been regarded as a major disadvantage.

Exposure assessment by questionnaires always depends on subjects' accuracy of recall and their willingness to participate, and many efforts have been made to introduce more objective measures of exposure determination. For radiation exposure, cohorts with occupations that require wearing film badges provide cumulative and, in some instances, peak measurements of exposure. For uranium and other hard rock miners, measures of the radiation exposure in mines were often made for safety reasons to limit the length of exposure of those at risk, and these measurements can be assigned to the job history of the individual.

However, in many instances, exposure has to be estimated simply from the type of occupation at a certain time since no further information is available and misclassification of exposure assessment cannot be avoided. In occupational studies, attempts have been made to refine exposure assessment by developing a job exposure matrix (cf. chapters ▶Exposure Assessment and ▶Occupational Epidemiology of this handbook). Often, using data from hygiene assessments performed in the past, a matrix can be constructed with the different job tasks in the rows and columns indicating the probability and/or intensity of exposure within that job to the agents (chemical or physical) of interest. The approach was, for example, used in a study of electrical and magnetic field exposures in electric utility workers in Canada and France (Theriault et al. 1994). Extension of the work upon a sample of workers wearing portable electric and magnetic field exposure meters and using historical data of electrical usage in the province enabled the investigators to identify strong associations of leukemia and non-Hodgkin's lymphoma risk with high electric field exposure (Miller et al. 1996; Villeneuve et al. 1998).

Another source of exposure data collected in cohort studies is gained from biological material of the cohort members. Historically, rather simple parameters were under study, like blood pressure or cholesterol levels, derived from blood samples that were collected in the framework of large cohort and intervention studies on cardiovascular disease. Now, there is increasing interest in the study of disease etiology by biomarkers of exposure and/or of genetic factors, as, for example, in the European Prospective Investigation of Diet and Cancer (EPIC) (Riboli and Kaaks 1997).

The findings of cohort studies regarding the effects of exposure can be strengthened if it is possible to evaluate a dose-response relationship. This requires the assessment of intensity of exposure that can be quantified as peak, average, or cumulative exposure. Sometimes duration of exposure is used as a surrogate for cumulative exposure. However, using duration in this way is problematic if the exposure is associated with an early, perhaps toxic, effect. Then it could be anticipated that these workers would tend to change their employment and could not cumulate long durations of exposure. If such workers represented a particularly susceptible subgroup, perhaps for genetic reasons, it is possible that in this subgroup, a relatively brief exposure results in the same incidence of disease than in subgroups with a longer duration of exposure that are less susceptible. The absence of a dose-response relationship without appropriate statistical control for the genetic background might then be incorrectly interpreted as indicator that the exposure is not causal for the disease (Blair and Stewart 1992).

The treatment of potential confounding factors is the major challenge of the analysis of cohort studies. This is in part because the basic data set may not contain information on all relevant confounders, particularly not in historical cohort studies but also because the data available on confounders may not be assessed with sufficient precision to take account of their effect. An example is the possible confounding effect of cigarette smoking with fruit and vegetable consumption and lung cancer. Although two large cohort studies (one multicenter and one the result of a pooled analysis) which fully adjusted for the effects of cigarette smoking in the opinion of the investigators were available (Miller et al. 2004; Smith-Warner et al. 2003), a working group of the International Agency for Research on Cancer (IARC) was not convinced that there was not residual confounding of fruit consumption by smoking with lung cancer and therefore judged the evidence to be limited rather than sufficient (IARC 2003).

6.4.3 Determining Outcome Events

A limiting factor for cohort studies is that most diseases are relatively rare, with rates determined in the population per 100,000 persons. Therefore, to accrue sufficient cases of the disease, the size of the cohort has to be large and/or the follow-up time has to be long. Another factor affecting the length of follow-up relates to the long induction period from the beginning of many exposures to the occurrence of disease. For many cancers, for example, the induction period exceeds 10, often 20, years. One example for the importance of a long enough follow-up period is the British Doctors' Study that showed much higher lung cancer risks of cigarette smoking after 40 years of follow-up than in the 10- and 20-year reports of this study (Doll et al. 1994b). The reason for this was a dominant effect of duration of smoking compared to intensity of exposure on the risk of lung cancer (see also Flanders et al. 2003). It seems probable that this is not the only example of this phenomenon – it may particularly affect exposures with a long induction period from initiation of exposure to effect. The possibility of such an effect should encourage investigators to maintain the follow-up of well-documented cohorts for as long as proves feasible, and granting agencies will agree to provide the necessary funds. If grants are limited, it may be useful to store the necessary data and extend the follow-up after a certain time lapse. It is unusual for cohort studies to start from the first exposure and the possible initiation of disease, covering the whole spectrum of exposure in a subject's lifetime. Attempts have to be made to determine or to estimate past exposure, with all the error and potential misclassification of such inquiries. Nevertheless, a major advantage of cohort studies over case-control studies is that exposure is determined prior to the diagnosis of disease, thus avoiding a major bias of concern in case-control studies, that is, the information (recall) bias.

As already indicated, the follow-up of cohorts enables multiple endpoints to be determined, for example, different types of cardiovascular disease and/or different cancer sites. In determining endpoints in cohort studies, it is essential that ascertainment bias is avoided. Ascertainment bias relates to the possibility that the surveillance of cohort members, by virtue of the fact that they are in a study, may result in greater efforts to make a diagnosis than would occur in the general population. Special surveillance mechanisms in a cohort study are valid if internal comparisons of exposed versus unexposed within the cohort are planned but would invalidate external comparisons with general population data. Orencia et al. (1995) provided an example of this bias in a non-concurrent cohort study examining the association of mitral valve prolapse (MVP) with stroke. Using the database of the Mayo Clinic, they assembled a cohort of persons with MVP, followed them for the occurrence of stroke, and compared the rate of stroke with the rate in the general population of Olmsted County, Minnesota. The overall standardized mortality ratio was 2.1, indicating a risk of stroke twice of that of the general population. However, Orencia et al. noted that MVP can be diagnosed by auscultation or as a serendipitous finding during an echocardiogram conducted for other medical reasons (e.g., following myocardial infarction, chronic heart failure, atrial fibrillation) often associated with risk of stroke. When the cohort was further subdivided according to method of diagnosis, the auscultatory group demonstrated no increase in risk. The increased risk was confined to the group identified serendipitously during a cardiac evaluation motivated by other medical concerns associated with risk of stroke.

In some cohort studies, annual or less frequent contact by mail, generally with the cohort member directly or sometimes with his or her designated physician, will identify the probable occurrence of a study endpoint or death from a cause unrelated to the disease of interest. However, these processes are costly and also pose the risk of losing an increasing proportion of cohort members with time. Further, if the participant has died, family members may not always be willing to collaborate in providing the required information. Hence, in many studies, other mechanisms are used for follow-up and indeed may have to be used also for subjects lost if the basic mechanism of follow-up is by mail. Losses to follow-up lead to a loss of power due to the resultant loss of sample size and can introduce bias in a manner similar to the selection processes described previously. Losses that do not differ by either exposure or disease status result in a picture similar to that shown in Table 6.4, that is, no bias but a loss of power. Losses that differ by exposure (but not outcome) status introduce the same bias as that described in Table 6.5. More problematic are losses that differ by outcome status (Table 6.7) and those that differ by both exposure and outcome status (Table 6.8). In these situations, estimates of the relative risk may be biased in unpredictable directions.

Apart from special surveillance mechanisms, including screening for the disease of interest, there are many sources of routinely collected data for endpoints in cohort studies. These include medical records of physicians, health maintenance organizations and hospitals, vital statistics systems, and disease registries. The process to

determine whether a particular record relates to a cohort member involves some form of record linkage, determining whether the identifying data in the study file of a cohort member corresponds with the identifying data on the medical or other record of endpoint information. In the past, much of this linkage used to be done manually. Increasingly some form of computerized record linkage is performed.

Although such linkages are easier if both sets of records contain the same (national) identifying number, computerized record linkage can still be extremely efficient and less costly than individual-based follow-up. If record linkage is planned to determine endpoints in a cohort study, great care should be taken at the time of recruitment to collect sufficient identifying information for record linkage purposes; this includes full name, full date of birth, place of birth, mother's maiden name, social security number, other identifying number (if available), and current address. Further, the name and address of friends or relatives of the cohort member should also be collected, to facilitate tracing an individual if other means of tracing them have failed or if record linkage to another data source has resulted in an uncertain linkage.

In many countries, in addition to disease registries, such as cancer registries, there are other data sources that have been developed to facilitate record linkage for cohort studies and large-scale trials. These include the National Health Service Central Register in the UK, the Canadian National Mortality Database, the National Death Index in the USA, and similar national registers in the Scandinavian countries. Relatively new in this context are the population-wide databases of genetic data, like the biobank already established in Estonia (Estonian Genome Center 2011). Record linkage using these national databases overcomes many of the issues regarding confidentiality of data, as confidentiality procedures are readily available for such systems. In Canada, what is returned to the investigator is generally anonymous (i.e., stripped of personal identifiers), unless the subjects have signed a prior consent form that specifically permitted record linkage. This was the case, for example, in a cohort study that was linked to a large multicenter trial of breast screening (Howe et al. 1991).

6.5 Ethical Issues

It is now generally accepted that studies on humans should be carried out with informed consent. This principle, originally developed in relation to controlled clinical trials, has generally now been extended to observational epidemiology studies, including cohort studies.

In the past, if a cohort was recruited that involved the subject's participation in providing data, their agreement to supply the data (e.g., respond to a questionnaire) was generally regarded as implied consent. However, now, in addition to providing information on questionnaires, for many cohorts, biological specimens (e.g., blood, buccal cells) are requested, and then it becomes mandatory that the respondent provides consent for the future use of such specimens for research purposes. However, at the time the specimens are provided, it is impossible to know the precise use the investigators may wish to apply to this material. An example relates to the fact that the majority of participants in the sub-cohorts of the European Prospective Investigation of Diet and Cancer (EPIC; Riboli and Kaaks 1997) provided blood specimens in the early 1990s; a few without signing a consent form, the majority did so. However, now that genetic studies are commonplace on such specimens, it has become apparent that some of the consent forms did not specifically mention genetic analyses as potential research usages. This has led to difficulties in obtaining approval for such sub-studies from human experimentation committees, some of which wanted new consent forms to be signed, specific to the genetically associated sub-study planned. Obtaining new consent, however, will become increasingly difficult as time goes on, and a number of subjects with the endpoint of interest may have died. In the United States, potential restrictions upon studies such as these have caused difficulties. In Europe, especially Scandinavia, there has been a more relaxed view of the ethical acceptability of studies on stored specimens, many such collections having been originally made without a formal informed consent process, but for which studies conducted, often involving record linkage to national registries, have been deemed to be ethically acceptable as full preservation of confidentiality can readily be achieved.

The issue as to whether respondents whose stored specimens have been tested should be informed of the results of such tests is also controversial. The European view tends to be that as the testing is being conducted as part of research, it may be impossible to interpret the results of tests for individuals, until this particular research track reaches agreed conclusions. Thus, it is not necessary, indeed possibly unethical, to inform the respondent of the results. Some consent forms specifically state this as a policy. In the United States, however, the opposite viewpoint tends to hold, it being regarded as ethically inappropriate for investigators to take a decision on whether or not a subject receives information on themselves. The difficulty with a universal application of such a principle is that for some, the test results may come too late for any possibility of benefit, but, especially in the case of genetic-related information, this may not preclude the test result having implications for the relatives of the subject, and such knowledge is not always a blessing. However, all would agree that if a test reveals information of potential benefit to a subject, they should be informed.

The question of consent for historical cohort studies in general does not arise, though again there may be issues on informing surviving subjects of the findings of the research. In general, as the research is unlikely to harm the individuals and providing confidentiality is maintained, human experimentation committees will approve such studies.

One further ethical issue has already been mentioned in Sect. 6.4.3, and that relates to the use of record linkage in obtaining outcome data. In general, providing full confidentiality is maintained, and this should not cause difficulties in obtaining approval from human experimentation committees. For further discussions of ethical aspects, we refer to (chapter ▸Ethical Aspects of Epidemiological Research of this handbook).

6.6 Conclusions

Cohort studies are a critical method for evaluating causality in epidemiology and may also be used in evaluating screening (see chapter ▸Screening of this handbook). There are, however, several needs if they are to be valid. You need skilled investigators familiar with the peculiarities of the planning and the conduct of cohort studies, a sensible source for cohort recruitment, evaluable hypotheses to consider, a validated questionnaire for use at enrolment, unbiased mechanisms to administer the questionnaire as well as for follow-up, quality-controlled procedures to collect biological material if relevant for the question under research, facilities for data entry, and of course the expertise as well as the facilities for analysis and interpretation.

Cohort studies are often rated at a higher level than case-control studies, largely because the latter are susceptible to recall bias. However, both are usually regarded as "level II" evidence (level I are randomized controlled trials), and there are potential deficiencies in cohort studies that may be less intrusive than in case-control studies, especially a greater propensity for measurement error. Both, however, continue to have an important role in disease epidemiology.

7.1 Introduction

7.1.1 A Brief History

The case-control study examines the association between disease and potential risk factors by taking separate samples of diseased cases and of controls at risk of developing disease. Information may be collected for both cases and controls on genetic, social, behavioral, environmental, or other determinants of disease risk. The basic study design has a long history, extending back at least to Guy's 1843 comparison of the occupations of men with pulmonary consumption to the occupations of men having other diseases (Lilienfeld and Lilienfeld 1979). Beginning in the 1920s, it was used to link cancer to environmental and hormonal exposures. Broders (1920) discovered an association between pipe smoking and lip cancer; Lane-Claypon (1926), who selected matched hospital controls, investigated the relationship between reproductive experience and female breast cancer; and Lombard and Doering (1928) related pipe smoking to oral cancer. The publication in 1950 of three reports on the association between cigarette smoking and lung cancer generated enormous interest in case-control methodology as well as bitter criticism (Levin et al. 1950; Wynder and Graham 1950; Doll and Hill 1950). The landmark study of Doll and Hill (1950, 1952), in particular, inspired future generations of epidemiologists to use this methodology. It remains to this day a model for the design and conduct of case-control studies, with excellent suggestions on how to reduce or eliminate selection, interview, and recall bias.

From the mid-1950s to the mid-1970s the number of case-control studies published in selected medical journals increased four- to sevenfold (Cole 1979). Aird et al. (1953) discovered the association between gastric cancer and the ABO blood groups. The impact of hormonal factors on cancers of female organs was brought to light, starting with confirmation of the association between late first pregnancy and breast cancer (MacMahon et al. 1970). Herbst et al. (1971) investigated an unusual outbreak of vaginal adenocarcinoma in young women, finding that mothers of seven of eight cases had exposed their daughters *in utero* to the fertility drug diethylstilbestrol (DES). None of 32 control mothers had a history of estrogen use during pregnancy. Treatment of menopausal women with exogenous estrogens similarly increased the risk of endometrial cancer (Ziel and Finkle 1975; Smith et al. 1975). Powerful joint effects of alcohol and tobacco consumption on esophageal cancer were demonstrated (Tuyns et al. 1977), as was the strong association between liver cancer and Hepatitis B carrier status (Prince et al. 1975). These successes encouraged more investigators to adopt the case-control study as the method of choice for the study of rare chronic diseases, particularly cancer. A survey by Correa et al. (1994) identified 223 population-based case-control studies published in the world literature in 1992. Subsequent discoveries obtained using case-control methodology have included the role of salted fish in the etiology of nasopharyngeal carcinoma in Chinese populations (Armstrong et al. 1983; Yu et al. 1986), the hazards of prone sleeping position for sudden infant death syndrome (SIDS) (Fleming et al. 1990), and the relationship between use of intrauterine devices (IUDs) and tubal infertility (Daling et al. 1985).

This plethora of case-control studies, stimulated by their relatively low cost and short duration, also had its drawbacks. Not all investigators were as careful as Doll and Hill in following a protocol for selection of cases and controls, in conducting the study to mitigate against bias, and in thoughtfully analyzing the collected data. Nor did they have the good fortune to study associations as strong as that between lung cancer and cigarette smoking. The increasing availability of high-speed computers made it possible to collect more and more data and to look for all manner of associations with putative risk factors. Investigators eager for research funding were sometimes too quick to publish their findings and draw media attention to them. The inevitable result was an increasingly negative reaction on the part of the public, and from segments of the scientific community, to the false alarms and contradictory results (Taubes 1995). One goal of this chapter, and of others in this handbook, is to describe basic scientific principles whose application should help to improve public confidence in published findings of epidemiological studies.

7.1.2 Early Methodological Developments

> The sophisticated use and understanding of case-control studies is the most outstanding methodological development of modern epidemiology.
>
> (Rothman 1986, p. 62)

The initial interpretation of the case-control study was the comparison of exposure histories for a group of diseased cases with those for non-diseased controls. Typical analyses involved two group comparisons of exposure distributions using chi-squared and t-tests. The critics argued that such comparisons provided no information about the quantities of true epidemiological interest, namely, the disease rates. Cornfield (1951) corrected this misconception by demonstrating that the exposure odds ratio for cases vs. controls was equal to the disease odds ratio for exposed vs. non-exposed. With $D = 1$ indicating disease, $D = 0$ disease-free, and $X = 1/0$ likewise denoting exposed or non-exposed, he showed using Bayes theorem that

$$\frac{\Pr(D = 1|X = 1)\Pr(D = 0|X = 0)}{\Pr(D = 0|X = 1)\Pr(D = 1|X = 0)} = \frac{\Pr(X = 1|D = 1)\Pr(X = 0|D = 0)}{\Pr(X = 0|D = 1)\Pr(X = 1|D = 0)} \tag{7.1}$$

and noted that the disease odds ratio approximated the *relative risk* $\Pr(D = 1|X = 1)/\Pr(D = 1|X = 0)$ provided the disease was rare. He also pointed out that, if the overall disease risk was known from other data sources, this could be combined with the relative risk to estimate *absolute* disease risks for exposed and non-exposed, respectively.

Disease risk as considered by Cornfield (1951) was *prevalence*, the probability that a member of the population was ill at a given point in time. For studies of disease etiology, however, it is preferable to work with disease *incidence*, the probability of developing disease during the study period among subjects who are free of disease initially. Otherwise, one confuses the effect of exposure on causation of disease with its effect on the case fatality rate (Neyman 1955). Controls for a study of the cumulative risk of developing disease during a given period would be persons who were free of disease during the entire period. Although it laid the foundation for what was to follow, this conceptualization of the case-control study in terms of cumulative disease risk was awkward for two reasons. First, as the study interval lengthened the risk of disease increased for both exposed and non-exposed. The relative risk for a common disease could approach one. Even if it did not, it was undesirable to have the basic effect measure so dependent on study duration, which varies between studies. Second, for a study of long duration, ensuring that the controls were disease-free throughout the study period could be problematic in practice. The modern conception of a case-control study involves sampling of controls who are disease-free at random times during the study period (Sect. 7.2.1). Exposure odds ratios are used to estimate ratios of incidence *rates* rather than ratios of risks. No rare disease assumption is needed in this case.

Mantel and Haenszel (1959) clarified the status of the case-control (or retrospective) study in comparison with the cohort (forward or prospective) study in one of the most highly cited papers in the scientific literature (Breslow 1996). They stated emphatically:

> A primary goal is to reach the same conclusions in a retrospective study as would have been obtained from a forward study, if one had been done.
>
> (Mantel and Haenszel 1959, p. 722)

This insight underlies the modern conception of the case-control study as involving *sampling*, on the basis of outcome, from an ongoing real or imagined cohort study that has been designed to provide the best possible answer to the basic question. Mantel and Haenszel introduced a new test and a simple, highly efficient estimator for the relative risk after stratification on control factors. Their methods required the epidemiologist to carefully examine the tabular data and thus to identify strata where there was a lack of information or where there were discrepancies between summary and stratum specific relative risks. They remain valuable today as an adjunct to more elaborate model fitting.

By the end of the 1950s, the case-control study was firmly established as the method of choice for the chronic disease epidemiologist, certainly when the budget was limited. The role of statisticians in bringing the study design to this place of scientific respectability was widely acknowledged (Cole 1979; Armenian and Lilienfeld 1994). Further methodological advances were made during the next two decades, particularly in statistical modeling of case-control data. The development of the proportional hazards regression model for life table data (Sheehe 1962; Cox 1972) provided a sound mathematical basis for methods long used by epidemiologists and led to refinements and extensions of those methods (Breslow et al. 1983). The nested case-control study, originally conceived as a method to reduce the computational burden of fitting Cox's model to data from large cohorts (Liddell et al. 1977), was recognized as an efficient epidemiological design for the collection of expensive explanatory data (Langholz and Goldstein 1996). It now serves as a paradigm for all case-control studies. Many of the methodological developments were described in texts by Breslow and Day (1980) and Schlesselman (1982) that led to further appreciation and use of the case-control study.

7.1.3 Chapter Outline

The remainder of this chapter discusses the modern conceptualization of the case-control study, largely from a statistical perspective. Matching of controls to cases at the design stage is viewed as a technique to be used in carefully limited contexts to increase the statistical efficiency of a highly stratified analysis. The implications of these theoretical developments for the practical selection of cases and controls are explored. Major pitfalls include the unique susceptibility of the case-control study to selection bias and, especially when exposures are assessed by interview, to measurement error. The design of any particular study usually involves trade-offs between potential biases arising from these sources. Following established principles of sound statistical science, including the use of an appropriate protocol for subject selection and exposure assessment, can help reduce the variability in study results that has contributed to the low esteem accorded risk factor epidemiology in some scientific circles (Breslow 2003).

7.2 Conceptual Foundations

7.2.1 Sampling from a Real or Fictitious Cohort

The Mantel and Haenszel (1959) goal, of reaching the same conclusions from a case-control study as from a cohort study if one had been done, provides the key to understanding of case-control methodology. Rather than start the planning process by thinking about how to conduct a case-control study, it often is helpful to first plan the ideal cohort study that would be conducted to investigate the same hypothesis if unlimited resources were available. Planning would include cohort identification, definition of the times of entry into and exit from the cohort, ascertainment of the disease endpoint, measurement of the exposure histories, consideration of potential confounders, and methods of statistical analysis. The corresponding case-control study would then be viewed as the random sampling of subjects from this idealized cohort to achieve, so far as possible, the stated goal.

Cohort Definition In concept, the underlying cohort for a case-control study consists of all subjects who, had they experienced the disease endpoint at a specific time, would have been ascertained as a case at that time. When case-control sampling is carried out in the context of an actual cohort study, to select individuals for genotyping or other expensive measurements, for example, the cohort is completely enumerated by and known to the investigator. More typically, however,

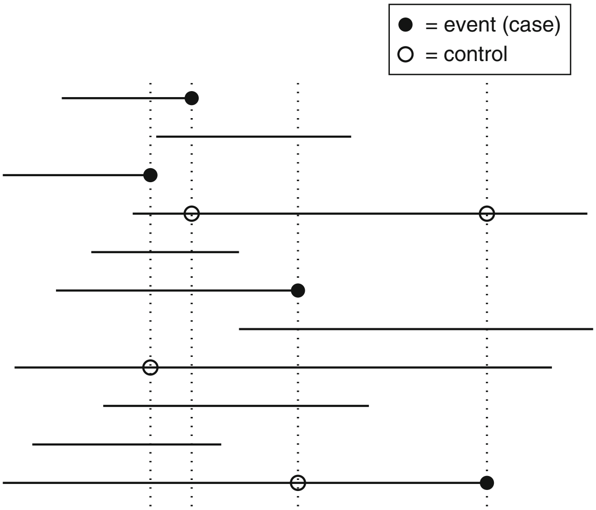

Fig. 7.1 Schematic of a (nested) case-control study

the underlying cohort is not fully identified and is effectively defined by the method of case ascertainment. When cases are ascertained from a particular hospital, for example, one considers the cohort to consist of all subjects who, had they developed the disease in question, would have been diagnosed in that hospital.

Figure 7.1 illustrates the basic idea of case-control sampling. Each of the 11 horizontal lines represents time on study for a member of the cohort. Subjects enter follow-up at the left-hand endpoint and exit at the right. They are considered to be *at risk* of becoming a case throughout this period. It is even possible, though not shown here, that a subject could enter the cohort, leave for a while and then return. Four of the 11 subjects are cases. Their follow-up ends at diagnosis since they are no longer at risk of becoming an incident case thereafter. The vertical dotted lines, plotted at each of the times that a case occurs, intersect the trajectories of those who are at risk at that time, that is, the trajectories of subjects in the corresponding *risk set*.

Nested Case-Control Sampling When the cohort study is a real one, so that times of entry and exit are known for all members, the investigator may completely enumerate each risk set. A nested case-control study is then possible in which controls are selected by finite population random sampling, without replacement, from non-cases in the risk set. The usual assumption is that the sampling of controls from each risk set is completely independent of sampling from all other risk sets. Two consequences are that a subject sampled as a control at one point in time may later become a case and that the same subject may be sampled more than once as a control. Figure 7.1, which depicts the situation where exactly one control is sampled from each risk set, illustrates each of these possibilities.

Robins et al. (1986) describe other sampling schemes, and corresponding methods of analysis, for nested case-control studies.

Density Sampling These ideas also may be applied, at least in principle, to the more typical situation in which the cohort is not completely enumerated. An essential assumption, which in fact well approximates the design of many studies, is that the cohort is sampled throughout the study period. More specifically, controls are selected at any given time at a rate proportional to the disease incidence rate at that time (Sheehe 1962). Miettinen (1976) termed this *incidence density sampling*. A second assumption is that each subject at risk at a given time has the same probability of being sampled as a control. This implies that, from the standpoint of an individual, the likelihood of being included in the study as a control increases with increasing *time on study*. If the disease incidence rate is constant, someone who is a member of the cohort for twice as long as someone else has twice the chance of being selected as a control. In the statistical literature, this is known as *length biased* sampling. One important consequence, under the assumption of constant disease incidence, is that the number of controls sampled is proportional to the *total time at risk*.

7.2.2 Incidence Rate Ratios are Estimable from Odds Ratios

We consider here the simplest situation in which the disease incidence rate is constant and there are two groups of subjects, exposed and non-exposed, that are homogeneous apart from exposure. Confounding is therefore not an issue. Denote by A the total number of incident cases ascertained from the cohort during the study period (t_0, t_1) and suppose that A_0 are determined to be non-exposed whereas $A_1 = A - A_0$ are exposed. Similarly, denote by $T = T_0 + T_1$ the total person-time on study, decomposed into its non-exposed (T_0) and exposed (T_1) components. While the numbers of cases A_0 and A_1 are known to the investigator, T_0 and T_1 may not be unless the underlying cohort is a real one. Instead, the case-control study provides information on how many of the total $M = M_0 + M_1$ of controls are non-exposed (M_0) and how many are exposed (M_1). Denoting by M_1/M_0 the observed odds of exposure for controls and likewise by A_1/A_0 the observed odds of exposure for cases, the corresponding exposure odds ratio is $(A_1M_0)/(A_0M_1)$.

Let $\pi\tau$ denote the probability that a subject who contributes τ person-years of follow-up is sampled as a control. With $T = \sum_{i=1}^{N} \tau_i$ denoting the sum of the times on study for N cohort members, that is, the total time at risk, the expected number of controls is $E(M) = \pi T$. In practice, π is often selected by the investigator to yield a fixed number of controls, at least as a target value. Its actual value remains unknown unless information is available about T. Nonetheless, provided π is constant for all subjects, both exposed and non-exposed, $E(M_0) = \pi T_0$ and $E(M_1) = \pi T_1$. Hence, the control ratio M_0/M_1 estimates the corresponding ratio T_0/T_1 of person-time. Since the exposure specific incidence rates are estimated by $\hat{\lambda}_0 = A_0/T_0$ and $\hat{\lambda}_1 = A_1/T_1$, it follows (see Rothman and Greenland 1998, Chap. 10) that the rate ratio may be estimated by the exposure odds ratio:

$$\frac{\hat{\lambda}_1}{\hat{\lambda}_0} = \frac{A_1 T_0}{A_0 T_1} \approx \frac{A_1 M_0}{A_0 M_1} \ . \tag{7.2}$$

See Sect. 7.3.1 for a numerical example.

7.2.3 Time-Dependent Rates and Exposures

Section 7.2.2 assumes that the parameter of interest is the ratio of instantaneous incidence rates, each assumed constant in time, for exposed and non-exposed subjects. A more general conceptualization takes the interest parameter to be the ratio $\psi \equiv \lambda_1(t)/\lambda_0(t)$ of instantaneous rates where the ratio, but not necessarily the underlying rates, is assumed constant in t. Let $N(t)$ denote the total number of subjects at risk at time t in the underlying cohort, of which a proportion $p_1(t)$ are exposed and $p_0(t)$ are non-exposed. These proportions could vary with time either because the exposure status for individual subjects changes or because the exposure composition of the cohort changes through entries and exits. Note that the expected number of exposed cases is given by $\int N(t)p_1(t)\lambda_1(t)\mathrm{d}t$ and similarly for the non-exposed cases. The expected number of controls sampled in the interval $(t, t + \mathrm{d}t)$ is therefore $M(t)\mathrm{d}t$ where $M(t) = N(t)[p_0(t)\lambda_0(t) + p_1(t)\lambda_1(t)]$. It follows that the unadjusted exposure odds ratio under density sampling estimates:

$$\begin{aligned}\psi^* &= \frac{\int N(t)p_1(t)\lambda_1(t)\mathrm{d}t \int M(t)p_0(t)\mathrm{d}t}{\int N(t)p_0(t)\lambda_0(t)\mathrm{d}t \int M(t)p_1(t)\mathrm{d}t} \\ &= \psi \frac{\int N(t)p_1(t)\lambda_0(t)\mathrm{d}t \int M(t)p_0(t)\mathrm{d}t}{\int N(t)p_0(t)\lambda_0(t)\mathrm{d}t \int M(t)p_1(t)\mathrm{d}t}\end{aligned} \tag{7.3}$$

(Greenland and Thomas 1982). Thus, the exposure odds ratio estimates the incidence rate ratio, that is, $\psi^* = \psi$, provided either that the exposure proportions are constant in t or else that $\psi = 1$. Otherwise, time t acts as a *confounder* of the exposure–disease association. In this case, a time-matched analysis using standard methods for matched case-control studies (Breslow and Day 1980, Chap. 7) is needed to estimate ψ unbiasedly. The marginal (unmatched) odds ratio usually provides a slightly *conservative* estimate of this parameter.

7.2.4 Cumulative Risk Ratios and Case-Cohort Sampling

While it is generally agreed that case-control studies of chronic disease are best designed using density sampling to estimate the incidence rate ratio, alternative sampling designs may be superior for other purposes. Vaccine efficacy is usually defined as the proportional reduction, over the study period, in the number of cases among subjects who are vaccinated compared to those who are not. Equivalently, it is 1 minus the ratio of cumulative disease risks for vaccinated vs. non-vaccinated. Suppose the effect of vaccination is to render completely immune a proportion P_{I} of subjects, while the remainder of those vaccinated have the same disease incidence rates $\lambda_0(t)$ as do non-vaccinated persons (Smith et al. 1984). For simplicity, assume that all subjects, both vaccinated and non-vaccinated, are followed from a common starting time t_0 and that there is no loss to follow-up. The cumulative risk of disease by time t_1 for those not vaccinated is $P(t_0, t_1) = 1 - \exp[-\int_{t_0}^{t_1} \lambda_0(t)\mathrm{d}t]$, and the vaccine efficacy is thus

$$1 - \frac{\text{risk for vaccinated}}{\text{risk for non-vaccinated}} = 1 - \frac{P_{\mathrm{I}} \times 0 + (1 - P_{\mathrm{I}}) \times P(t_0, t_1)}{P(t_0, t_1)} = P_{\mathrm{I}}\,. \quad (7.4)$$

Here, the cumulative risk ratio, not the incidence rate ratio, is independent of study duration $t_1 - t_0$ (Rodrigues and Kirkwood 1990). Suppose now a *subcohort* of M subjects is drawn at random from the combined cohort of vaccinated and non-vaccinated subjects such that each individual has the *same* probability π of inclusion in it, *regardless* of duration of follow-up. If M_0 and M_1 denote the numbers of non-vaccinated and vaccinated in the subcohort, while A_0 and A_1 denote the numbers of disease cases diagnosed by time t_1, then vaccine efficacy is simply estimated as

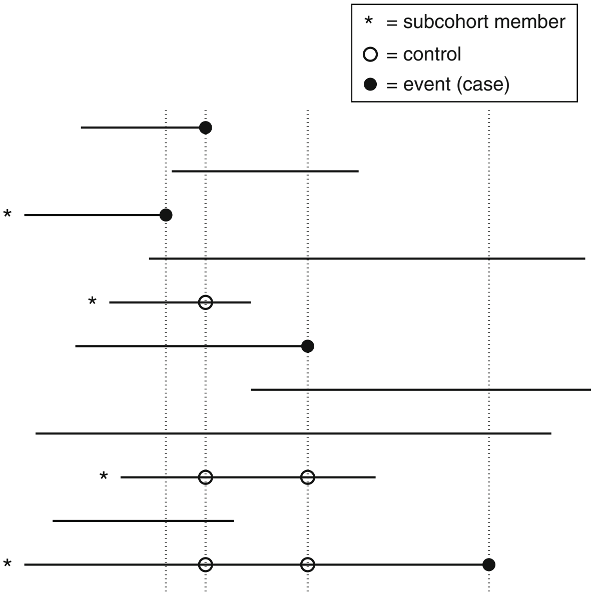
$$\widehat{P}_{\mathrm{I}} = 1 - \frac{A_1/M_1}{A_0/M_0}\,. \quad (7.5)$$

More generally, the case-cohort design (Kupper et al. 1975; Miettinen 1982; Prentice 1986) involves random sampling of a subcohort at study entry, without regard to time on study. Figure 7.2 contrasts this design with nested case-control sampling (Fig. 7.1). Incidence rate ratios may be estimated for dynamic (open) cohorts, with staggered entry and loss to follow-up as pictured, just as they are with nested case-control sampling (Prentice 1986; Lin and Ying 1993; Barlow 1994). Subcohort members under observation at the time of disease occurrence serve as the controls for each case in a time-matched analysis. Since the subcohort is a simple random sample from the full cohort, it is suitable for estimation of population genotype or exposure frequencies, whereas the controls from a nested study are not. Furthermore, the same subcohort may be used to provide controls for two or more different types of disease cases. Because of this flexibility, the case-cohort design is increasingly used for sampling from defined cohorts.

7.2.5 Estimation of Absolute Risks

The key feature of case-control sampling in the context of an actual cohort study, where the underlying cohort is completely enumerated and entry and exit times are known for all cohort members, is that the sampling probabilities for cases and

Fig. 7.2 Schematic of a case-cohort study



controls are known or can be estimated from the available data. The case-control study provides supplementary information on explanatory variables for a randomly selected group of cohort members. Analysis of the combined cohort and case-control data may be approached using standard methods for incomplete data (Little and Rubin 2002). The Horvitz and Thompson (1952) survey sampling approach is often easiest to implement. Here, the contribution to estimators or estimating equations from each subject with complete data, that is, each subject included in the case-control sample, is weighted by (an estimate of) the inverse probability of having been included. Any analysis that could have been carried out were explanatory data available for the entire cohort can also be carried out using the combined data from the cohort and the case-control sample. This principle applies to estimation of absolute as well as relative risks.

A demonstration that absolute risks can be estimated from case-control data that are supplemented with information regarding the underlying population was provided by Doll and Hill (1952). They restricted the analysis to cases and controls drawn from the Greater London area, for which the numbers of persons and the numbers of deaths due to lung cancer were known from government records for each category of age and sex. Table 7.1 shows numbers of male cases n_{1j} and controls n_{0j} aged 45–64 years at the jth of 6 levels of average cigarette consumption during the preceding 10 years ($j = 1, \ldots, 6$). Assuming that the smoking habits of the controls were representative of the habits of the general population in each age-sex category, and likewise that the habits of the cases were reasonably similar to those of persons who died of lung cancer, they were able to estimate the numbers of persons N_j and of deaths D_j at each of the 6 smoking levels. Specifically, knowing

Table 7.1 Numbers of lung cancer cases and controls in Greater London among males aged 45–64 years, by average amount smoked in preceding 10 years, with estimated death rates of lung cancer per 1,000 persons per year (Reconstructed from data of Doll and Hill (1952, p. 1278))

	Ave. daily number of cigarettes						
	0	1-4	5-14	15-24	25-49	50+	Total
Controls (n_{0j})	38	87	397	279	119	12	$n_{0+} = 932$
Cases (n_{1j})	2	19	197	171	129	21	$n_{1+} = 539$
Rates ($\hat{\lambda}_j$)	0.14	0.59	1.35	1.67	2.95	4.76[a]	1.57

[a] Doll and Hill give 4.74 for this entry

that the total male population of Greater London aged 45–64 was $N_+ = 937000$, they estimated the subpopulation (in thousands) at the jth smoking level as $\widehat{N}_j = (n_{0j}/932) \times 937$. Similarly, knowing that $D_+ = 1,474$ deaths from lung cancer occurred annually in this population, they estimated the numbers of deaths at that level by $\widehat{D}_j = (n_{1j}/539) \times 1{,}474$. Thus, the absolute rates per 1,000 persons per year at smoking level j were estimated as

$$\hat{\lambda}_j = \frac{\widehat{D}_j}{\widehat{N}_j} = \frac{n_{1j} \cdot n_{0+} \cdot D_+}{n_{0j} \cdot n_{1+} \cdot N_+} .$$

See Table 7.1 and Doll and Hill (1952), Table XII. Neutra and Drolette (1978) formally justified this commonly used procedure while Greenland (1987) provided an extension for matched case-control studies.

Langholz and Borgan (1997) developed more specialized methodology for estimation of absolute risks from nested case-control studies under the Cox (1972) model. The absolute risk of disease over the time period (t_0, t_1) for a subject with explanatory variables x who is disease-free at its start is

$$P(t_0, t_1; x) = \int_{t_0}^{t_1} S(t_0, t; x)\lambda(t; x)\mathrm{d}t \ , \tag{7.6}$$

where $S(t_0, t; x)$ denotes the probability that the subject remains on study and free of disease from t_0 to t and $\lambda(t; x)$ is the disease incidence rate. Increments in the baseline cumulative incidence rate function at each time of disease diagnosis, needed to estimate both S and λ, are obtained from the usual formula for the cohort study applied to *reduced* risk sets consisting of the case and sampled control(s). The denominator term, representing the sum of relative risks for all subjects in the risk set, is weighted by n/m where n denotes the size of the risk set and m the number of subjects, including the case, sampled from it. Benichou and Gail (1995) studied similar methodology for unmatched case-control sampling from an actual cohort when all explanatory variables are discrete. Econometricians also have developed methods for incorporation of external information on background rates into the analyses of data collected in "choice-based" sampling designs, the social science analog of case-control studies (Hsieh et al. 1985).

7.3 Matching and Stratification

> While the logical absurdity of attempting to measure an effect for a factor controlled by matching must be obvious, it is surprising how often investigators must be restrained from attempting this.
>
> (Mantel and Haenszel 1959, p. 729)

Investigators planning case-control studies used to consider matching of individual controls to cases as a means of making the two groups as comparable as possible, thereby increasing the perceived validity of study results. It is now recognized that such matching, or stratified sampling of controls to make them more like the cases – known as frequency matching, has a much more limited and specific role. This is to improve the efficiency of rate ratio estimators (exposure odds ratios) that are statistically *adjusted* to account for possible confounding effects. Inappropriate matching may have the unintended effect of compromising design efficiency or even of rendering the results completely uninterpretable. Furthermore, since the sampling design must always be considered, matching usually complicates the statistical analysis.

7.3.1 Consequences of Matching

The goal of matching in case-control studies is to balance the numbers of cases and controls within strata that will be used for statistical adjustment purposes. If the factor(s) used for stratification are associated with exposure, the matched control sample will generally have an exposure distribution more like that of the cases than would an unmatched control sample.

Some interesting and important consequences of matching are illustrated by the fictitious data shown in Table 7.2, which is adapted from Table 10.5 of Rothman and Greenland (1998). In the underlying cohort, the disease rates for exposed and non-exposed are identical for males and females. Consequently, there is no effect modification nor confounding by sex, and the crude (marginal) rate ratio equals the sex-specific ratios. The frequency matching of controls to cases by sex, however, has *induced* apparent confounding in the case-control data. The sex-specific rate ratios are correctly estimated by the sex-specific odds ratios, in accordance with Eq. 7.2, but they are substantially under-estimated by the crude exposure odds ratio. An analysis that accounts for the matching is essential to correctly estimate the interest parameter.

Table 7.2 Distribution of cases and person-years of observation in a fictitious cohort study and expected distribution of cases and frequency matched controls (Adapted from Table 10.5 of Rothman and Greenland (1998))

A. Results for underlying cohort study				
	Males		Females	
	Exposed	Non-exposed	Exposed	Non-exposed
Diseased	450	10	50	90
Person-years	90,000	10000	10000	90,000
Rate ($\times 10^3$)	5.0	1.0	5.0	1.0
Rate ratio	$\psi_{\mathrm{E}} = 5$		$\psi_{\mathrm{E}} = 5$	
	Crude rate ratio = $\frac{(450+50)/100{,}000}{(10+90)/100{,}000} = 5$			
B. Expected results for the case-control study				
	Males		Females	
	Exposed	Non-exposed	Exposed	Non-exposed
Cases	450	10	50	90
Controls	414	46	14	126
Odds ratio	$\widehat{\psi}_{\mathrm{E}} = 5.0$		$\widehat{\psi}_{\mathrm{E}} = 5.0$	
	Expected crude odds ratio $\approx \widehat{\psi}_{\mathrm{E}} = \frac{(450+50)\times(46+126)}{(10+90)\times(414+14)} = 2$			

7.3.2 Efficiency of Matching

The advantages of a frequency-matched sample become evident when one considers extreme situations. In the study of esophageal cancer of Tuyns et al. (1977), for example, 775 controls were sampled at random from electoral rolls for comparison with the 200 cases. Not surprisingly, the lowest age stratum contained only a single case and 115 controls. Since they contributed very little to the age-stratified odds ratio, the time spent interviewing the 115 youngest controls was largely wasted. When the potential for imbalance is less extreme, however, the advantages of matching are not so clear. Some insight is provided by considering the ratio of asymptotic variances of crude and adjusted (stratified) odds ratio estimators for frequency-matched and random samples in the simplest of situations, that involving a binary exposure factor, a binary confounding factor, and a rare disease. Assuming equal numbers of cases and controls, and that the exposure rate ratio ψ_{E} is the same at both levels of the confounder, the variances are determined by five quantities: ψ_{E}; p_{E}, the population proportion exposed; p_{C}, the proportion positive for the confounder; ψ_{C}, the rate ratio for the confounder; and ψ_{CE}, the odds ratio associating confounder and exposure in the population. Table 7.3, adapted from Breslow (1982), shows ratios of variances and biases for different odds ratio estimators when $p_{\mathrm{C}} = 0.5$ and $p_{\mathrm{E}} = 0.3$. Similar results were given by Thomas and Greenland (1983) and by Smith and Day (1984).

A stratified analysis is not needed to control confounding when $\psi_{\mathrm{CE}} = 1$ or $\psi_{\mathrm{C}} = 1$. For as shown in rows 1–5, 9, and 13 of Table 7.3, the bias B_{R} of the pooled estimator using a randomly selected control sample is then zero. Columns labeled

Table 7.3 Variance ratios and biases, in percent, for estimators of ψ_E in case-control studies with matched and random samples (Adapted from Breslow (1982), Table 2)

		$\psi_E = 1$				$\psi_E = 2$				$\psi_E = 5$				$\psi_E = 10$			
ψ_{CE}	ψ_C	$\frac{V_M}{V_R}$	$\frac{V_M}{V_{R^*}}$	B_R	B_M	$\frac{V_M}{V_R}$	$\frac{V_M}{V_{R^*}}$	B_R	B_M	$\frac{V_M}{V_R}$	$\frac{V_M}{V_{R^*}}$	B_R	B_M	$\frac{V_M}{V_R}$	$\frac{V_M}{V_{R^*}}$	B_R	B_M
1	1	100	100	0	0	100	100	0	0	100	100	0	0	100	100	0	0

	10	74	97	106	0	76	98	106	−4	82	101	106	−8	90	105	106	−9

ψ_{CE} odds ratio associating exposure and confounder
ψ_E rate ratio for exposure ψ_C rate ratio for confounder
B_R bias of pooled estimate of ψ_E, random sample, as, percent of ψ_E
B_M bias of pooled estimate of ψ_E, matched sample, as percent of ψ_E
V_M variance of the stratified estimate in the matched sample
V_R variance of the stratified estimate in the random sample
V_{R^*} variance of the pooled estimate in the random sample

$V_{\mathrm{M}}/V_{\mathrm{R}}^{*}$ show the increase in variance, that is, the loss in efficiency, if a matched control sample and stratified analysis were used instead. There is no efficiency loss through matching when $\psi_{\mathrm{CE}} = 1$ but increasing loss for estimation of large rate ratios when the correlation between confounder and exposure is high. Since the "confounder" is not a risk factor for disease ($\psi_{\mathrm{C}} = 1$), it need not be controlled in the analysis. By needlessly matching on it, the exposure distributions for cases and controls have been made more alike, thus reducing the efficiency of estimation of the exposure effect. The negative biases associated with the crude analysis of the matched data reflect the same phenomenon as the example in Table 7.2. This is a case of *overmatching*.

Stratification *is* needed to control confounding when both $\psi_{\mathrm{CE}} > 1$ and $\psi_{\mathrm{C}} > 1$. Then, as shown in rows 6–8, 10–12 and 14–16 of the table, the bias B_{R} using the unadjusted design and analysis is non-zero and becomes increasingly serious as the effect of the confounder and its correlation with the exposure increase. The efficiency of the matched design to the standard design, using in both cases the correct (stratified) analysis, may be read from columns labeled $V_{\mathrm{M}}/V_{\mathrm{R}}$. Values *under* 100% indicate greater efficiency, meaning a smaller variance, for the matched design. When the potential confounder increases disease risk but exposure does not, matching is always more efficient and its efficiency increases with the degree of confounding. Even in the most extreme situation ($\psi_{\mathrm{CE}} = \psi_{\mathrm{C}} = 10$), however, no more than 26% of efficiency is lost by failure to match. A conclusion is that confounder and disease must be strongly associated for matching to produce major gains. Matching may actually *lose* efficiency when ψ_{CE} and ψ_{E} are both large.

7.3.3 Overmatching

Overmatching refers to matching on a factor that is not a confounder of the disease–exposure association. There are three possibilities.

Factor Related Only to Exposure This is the situation just considered in Tables 7.2 and 7.3 (rows 5, 9, 13). Matching is not needed to control confounding and leads to a loss of efficiency.

Factor Related Only to Disease This has been called "the case of futility" because the matching is effectively at random with respect to exposure (Miettinen 1970). Frequency matching has no effect on efficiency, as the variance ratios $V_{\mathrm{M}}/V_{\mathrm{R}*} = 100$ when $\psi_{\mathrm{CE}} = 1$ suggest. Were one to "incorrectly" fail to account for the matching in the analysis, however, there would be efficiency loss relative to the frequency matched analysis; note the percentages below 100 in the column labeled $V_{\mathrm{M}}/V_{\mathrm{R}}$. Individual pair matching in such circumstances could cause a loss of efficiency because of the need to account for this in the analysis and the consequent reduction in degrees of freedom for estimation of the main effect. With binary exposure measurements, for example, only the discordant case-control pairs would contribute to estimation of the exposure odds ratio, and these would become fewer and fewer as the association between the matching factor and disease increased.

“Confounder” an Intermediate in the Causal Pathway The most serious type of overmatching occurs when one matches on a factor that is both affected by exposure and a cause of disease. If the effect of antihypertensive medication on the risk of myocardial infarction was being investigated, for example, yet cases and controls were matched on blood pressure measurements taken after treatment commenced, the data would be completely useless for estimation of treatment effect. Ignoring the matching in the analysis would only compound the error by driving the odds ratio even closer toward unity.

7.3.4 When to Match

In view of the drawbacks of overmatching, and the often modest efficiency gains even when statistical adjustment is indicated, one may well ask whether matching is ever justified. The administrative costs of locating matched controls, and the loss of cases from analysis if none can be found, further argue for careful consideration of matched designs. Individual case-control matching is most appealing when needed to control the effects of a confounder that is not easily measured. The paradigm is use of an identical co-twin to control for genotype (Jablon et al. 1967). Otherwise, stratification of the control sample on gender and broad categories of age to achieve rough comparability with the case distribution, provided that this can be accomplished without great cost, is likely all that is advisable. Greater attention to stratification of the control sample may be needed when the primary goal is to evaluate statistical *interaction*, or effect modification, between exposure and a covariate (Smith and Day 1984).

7.4 Selection of Subjects

The two preceding sections outline the basic ideas of sampling of subjects for a case-control study from a theoretical statistical perspective. While the theory is an important guide to practice, implementation is usually imperfect and requires some compromise to minimize the various types of bias to which case-control studies are particularly susceptible (Sect. 7.5). In this section, we consider some of the choices available to the investigator for putting the theory into action.

7.4.1 Selection of Cases

7.4.1.1 Disease Definition

Careful definition of the disease endpoint to conform to the goals of the study is critical to success. Specific cancers are reasonably well defined by primary site and histologic type. Studies of diabetes, rheumatoid arthritis, or psychiatric conditions should follow standard criteria for diagnosis established by professional societies. In the typical study of disease etiology, the investigator may choose to enhance efficiency by including only those cases of disease most likely a priori to have been caused by the particular exposure. Thus, instead of "uterine cancer," studies of hormonal risk factors would best be restricted to adenocarcinoma of the endometrium whereas those investigating sexual practices or viral etiology would focus on squamous cell cancer of the cervix. Of course, in the early stages of an investigation, demonstration that the exposure effect is *specific* to a particular disease subtype can be an important part of the evidence that the association is causal (Hill 1965; Weiss 2002). For case-control studies of the public health impact of exposure, furthermore, a broader definition of disease may be desirable.

As mentioned in Sect. 7.1.2, studies of disease etiology are best restricted to incident cases. This may not always be possible, however. Congenital anomalies are generally ascertained as those that are prevalent at birth, and consideration of possible exposure effects on fetal loss forms an important part of the interpretation. Cohort studies may be preferable for estimating the true effects of exposure on reproductive outcomes (Weinberg and Wilcox 1998).

7.4.1.2 Sources of Cases

Population Registries Population-based disease registries, particularly of cancer and birth defects, are often considered the ideal source of cases. This is because the population at risk, whose identification is needed for control selection, is well defined by geographical or administrative boundaries. Practical limitations on their use include the speed with which cases can be identified and interviewed, to avoid selection bias from exclusion of those who may have died, and the feasibility of random sampling of controls.

Health Maintenance Organizations Large health maintenance organizations (HMOs) are advantageous as a source of cases for several reasons. The source population is enumerated and demographic data, as well as some exposure and covariate data, may already be available for everyone. This permits judicious selection of cases and controls using nested case-control, case-cohort or stratified two-phase sampling designs (Sect. 7.6). Relatively objective and inexpensive exposure assessments may be possible using routine medical or pharmacy records, some of which may already exist in electronic form. Similarly, cases are usually easily ascertained from reports of diagnoses within the organization. Of course, some assurance is needed that members of the HMO are unlikely to go elsewhere for diagnosis and treatment.

Hospitals and Clinics Historically, many case-control studies have been conducted using either a single or a small group of hospitals or clinics. This facilitates timely access to cases and increases the likelihood of their cooperation, thus limiting selection bias. On the other hand, definition of the source population from which the cases arose may be problematic, not to mention the practicality of obtaining random samples of controls from it.

7.4.1.3 Exclusion Criteria

In principle, any exclusion criteria may be used for cases so long as they are equally applied to the controls, and vice-versa, since they serve simply to restrict the source population. Thus, subjects may be excluded who reside in areas difficult to reach or who are not native speakers of the language of interview. Practical applications of this rule can be more subtle, however. Wacholder (1995) argues, for example, that exclusion of cancer cases who lacked a histologic diagnosis could inadvertently tend to exclude those from smaller, rural hospitals who were more likely to have exposures related to agriculture.

Exposure Opportunity Case-control studies are most informative when there is a substantial degree of exposure variability, so that the exposure is neither rare nor ubiquitous (Chase and Klauber 1965). Subjects known a priori to have no opportunity for exposure could be excluded on grounds of efficiency if the exposure was rare, since they would contribute little additional information. Thus, for example, women who were past reproductive age when oral contraceptives became popular should be excluded from a study of OC use and breast cancer (Wacholder et al. 1992a). On the other hand, since they provide valid information on the non-exposed, there is no logical basis for insisting that subjects without the opportunity for exposure should be routinely excluded from cohort and case-control studies (Schlesselman and Stadel 1987; Poole 1987).

7.4.2 Selection of Controls

7.4.2.1 Principles of Control Selection

Wacholder et al. (1992a) described three basic principles of control selection. The first two correspond roughly to considerations already developed regarding conceptual foundations and the use of matching. The third stems from the desire to minimize the effects of measurement error to which case-control studies are particularly susceptible.

The "Study-Base" Principle This is the principle that controls be randomly selected from disease-free members of the underlying cohort, also known as the source population (Kelsey et al. 1996) or study base (Miettinen 1985), at the times that cases are being ascertained (Sect. 7.2). When controls are in fact selected later, it sometimes mandates the random selection of a reference date for each control so that the distributions of the case diagnosis dates and control reference dates are comparable. Only exposures occurring prior to the reference/diagnosis date would be taken into account. This principle also implies that whatever exclusion criteria have been applied to the cases must also be applied equally to the controls.

The Deconfounding Principle This principle underlies the stratified sampling of controls to render possible, or improve the efficiency of, an adjusted analysis designed to control confounding (Sect. 7.3).

The Comparable Accuracy Principle This principle, controversial even in the authors' view, suggests that controls be selected so that the errors of measurement of their exposures and covariates are comparable to the measurement errors of the cases. The suggestion that dead controls be selected for dead cases, for example, is sometimes made on the basis of the comparable accuracy principle (Gordis 1982). Unfortunately, there is no guarantee that adherence to the principle will eliminate or even reduce bias (Greenland and Robins 1985). Unless the measurement error can be completely controlled, for example, by obtaining error-free measurements for a *validation* subsample of cases and controls and appropriately incorporating these data in the analysis, it can seriously compromise study validity even if case and control data are equally error prone (Sect. 7.5.3).

7.4.2.2 Sources of Controls

The appropriate source population for sampling of controls is determined by the study-base principal. When cases arise from an enumerated source population such as an HMO, controls may be sampled from this cohort using a nested case-control or case-cohort design (Figs. 7.1 and 7.2). One principal advantage of conducting epidemiological studies in the Nordic countries is their maintenance of national disease and population registers which may be exploited for case and control selection, respectively (see chapter ▸Use of Health Registers of this handbook). Standard survey sampling methods are often used to select controls for "population-based" studies in countries that do not maintain population registers. The most difficult and controversial problems of control selection arise with hospital-based studies.

Survey Sampling Methods for scientific sampling of populations have been developed by census bureaus and other government agencies throughout the world. The particular method most advantageous for any given epidemiological study will likely depend on the local administrative infrastructure. Survey sampling often proceeds in stages, where one first samples a large administrative unit, then a smaller one, and finally arrives at an individual household or subject. Such multi-stage "cluster" sampling introduces modest correlations in the responses of individuals sampled from the same primary sampling unit, more marked ones for individuals sampled from the same lower level cluster. Although often ignored by epidemiologists, usually at the cost of some underestimation of the variability in estimated relative risks, these correlations should be accounted for in a rigorous statistical analysis (Graubard et al. 1989). Fortunately, simple methods to accommodate cluster sampling are now routinely incorporated in the standard statistical packages.

Random Digit Dialing In view of the high costs of census bureau techniques in the United States, methods of survey sampling through the telephone exchanges have been developed (Waksberg 1978; Harlow and Davis 1988). Random digit dialing (RDD) has become increasingly popular for control selection in populations that have high rates of telephone access. Some implementations start with the telephone exchange of each case for sampling of controls that are thereby matched on somewhat ill-defined neighborhood factors (Robison and Daigle 1984). RDD methods may be costly for ascertainment of controls from minority populations, requiring dozens of calls to locate a suitable household (Wacholder et al. 1992b). They are particularly susceptible to bias because of higher selection probabilities for households that have more than one phone line or more than one eligible control and because of high rates of non-response (Sect. 7.5.1). The latter problem is likely to become increasingly serious in view of the persistent use of answering machines to screen out unwanted calls. The popularity of cell phones, moreover, eventually may make it infeasible to use RDD to draw a random control sample from a source population defined by geographical or administrative boundaries.

Neighborhood and Friend Controls Matched controls may also be selected from neighbors or friends of each case. For the former method, a census is taken of all households in the immediate geographical area of the case, and these are approached in a random order until a suitable control is found. Care must be taken to ensure that the control was resident at the same time the case was diagnosed. Even with these precautions, neighborhood sampling may yield biased controls for hospital-based studies since it will not be guaranteed that the control would have been ascertained as a case if ill, thus violating the study-base principle (Wacholder et al. 1992b). Neighborhood controls are also susceptible to overmatching due to their similarity to the cases on factors associated with exposure that are not risk factors for disease (Sect. 7.3.3). These same difficulties confront the use of friend controls, whereby a random selection is taken from among a census of friends provided by each case. There may be further selection on factors related to popularity since the friend selected as control may well not have listed the case as a friend had the friend become ill (Robins and Pike 1990). The primary advantage of friend controls would be a low level of non-response.

Hospital-Based Controls Many studies that ascertain cases through hospitals also select controls from these same hospitals, which is of obvious logistical convenience. Such controls are likely to have the same high response levels as the cases. The fact that they may be interviewed in a hospital setting, as the cases are, is an advantage from the perspective of the comparable accuracy principle (Mantel and Haenszel 1959). The major difficulties stem from the fact that the hypothetical study base, the *catchment* of persons who would report to the particular hospital if they developed the disease under study, may be different from the catchment population for other diseases. Furthermore, many of the disease categories from which controls could be selected may themselves be associated with the exposure. A large part of the planning of hospital-based case-control studies is devoted to the choice of disease categories thought to be independent of exposure and to have a similar catchment. The hope is that controls with such diseases will effectively constitute a random sample, vis-à-vis exposure, from the study base. Since the independence of exposure and disease diagnosis is rarely known with great certainty, a standard recommendation is to select controls having a variety of diagnoses so that the failure of any one of them to meet the criterion does not compromise the study (Wacholder et al. 1992b; Rothman and Greenland 1998, p. 101). If it is found later that a certain diagnosis is associated with exposure, those controls can be excluded.

7.4.3 How Many Controls per Case? How Many Control Groups?

Case-Control Ratios For a fixed number of study subjects, statistical power for testing the null hypothesis is optimized by having equal numbers of cases and controls. When the disease is extremely rare or acquisition of cases particularly expensive, however, it may be important and cost-effective to increase the numbers of controls. In order to have the same statistical power (to reject the null hypothesis of no exposure effect against local alternatives) as a design with equal numbers of cases and controls, a design with M controls per case would need only $(M + 1)/2M$ as many cases. When $M = 2$, for example, this would imply the use of three-fourth as many cases, but twice as many controls, to achieve the same power as a design with equal numbers. For a fixed number of cases, the relative efficiency of a design with M controls per case relative to one that uses an unlimited number of controls is therefore only $M/(M + 1)$. Since 80% of maximum efficiency can thus be obtained with $M = 4$, it is often inadvisable to seek a higher ratio. Exceptions occur when sampling and data collection for controls is substantially cheaper than for cases or if accurate estimation of large rate ratios, rather than a test of the null hypothesis, is the primary statistical objective (Breslow 1982; Breslow et al. 1983).

Multiple Control Groups Early case-control investigations, including the classic study of Doll and Hill (1952), often utilized two or more control groups. Indeed, multiple control groups were recommended by Dorn (1959) to improve the case-control study so that it would "provide a more valid basis for generalization." As explained by Hill (1971, pp 47–48), "If a whole series of control groups, for example, of patients with different diseases, gives much the same answer and only the one affected group differs, the evidence is clearly much stronger than if the affected group differs from merely one other group." Similar informal arguments have been put forward in favor of multiple control groups as a means of addressing the possible biases that may be associated with the use of any one of them (Ibrahim and Spitzer 1979). Working from a more formal perspective, Rosenbaum (1987) concluded that a second or third control group was useful *only* if supplemental information was available on whether such use addressed a specific bias. If controls sampled from separate sources have different exposure histories, even after statistical adjustment for potential confounders, this indeed suggests that similar adjustment of the case-control comparison may be inadequate to control confounding. However, failure to detect a difference among control groups may give a false sense of security unless they were deliberately selected to differ with respect to unmeasured potential confounders. Implementation of this last criterion would clearly require some guess as to what those unmeasured confounders might be.

Recent reviews of case-control methods have tended to shy away from the use of multiple control groups (Rothman and Greenland 1998, p. 106; Wacholder et al. 1992b). They argue that there is usually a single "best" control group and that since the discovery of an adjusted exposure difference with other control groups will force these to be discarded, the effort involved will have been wasted. However, there may not be a "best" control group, or its identification may be controversial. Discovery of a difference between control groups should generally encourage the investigator to seriously suspect that confounding may have compromised study results.

7.5 Pitfalls

Case-control studies are susceptible to the same biases and problems of interpretation that afflict all observational epidemiological studies. These include confounding, selection or sampling bias, measurement error, and missing data. Selection bias can be considered an extreme version of bias due to missing data where the entire observational record is missing for subjects who are in the source population but fail to be included in the study. Each of these topics is considered in detail in other chapters of this handbook. Many methods described there for dealing with such issues apply to case-control studies as well as to cohort studies. Attention is confined here to a few of the potential problems to which case-control studies are particularly susceptible.

7.5.1 Selection Bias

As elaborated at length in Sect. 7.2.1, the cases and controls in a case-control study are best viewed as resulting from outcome-dependent sampling from an underlying, often idealized cohort study. The goal is to estimate the degree of association of disease risk with exposure that would have been found had complete records been available for the entire cohort. The sampling of controls and sometimes even of cases may be stratified, for example, by sex and broad categories of age, but otherwise is supposed to be random within the subpopulations of diseased and non-diseased subjects. Selection bias arises when the sampling is in fact not random. It poses a major threat to the validity of case-control studies.

The effect of sampling bias is easy to demonstrate quantitatively for an exposure variable with two levels. For simplicity, we consider the effect on the odds ratio associating exposure with the cumulative risk of disease during a defined study period. The first 2 × 2 subtable displayed in Table 7.4 contains the population

Table 7.4 Effect of selection bias on odds ratio measures of association

	Population frequencies		Sampling fractions		Expected sample frequencies	
	Case	Control	Case	Control	Case	Control
Exposed	P_{11}	P_{10}	f_{11}	f_{10}	$f_{11} \times P_{11}$	$f_{10} \times P_{10}$
Non-exposed	P_{01}	P_{00}	f_{01}	f_{00}	$f_{01} \times P_{01}$	$f_{00} \times P_{00}$
Odds ratios	$\psi = \frac{P_{11} \times P_{00}}{P_{10} \times P_{01}}$		$\psi_{\mathrm{f}} = \frac{f_{11} \times f_{00}}{f_{10} \times f_{01}}$		$\psi^* = \psi_{\mathrm{f}} \times \psi$	

frequencies of subjects who are exposed and become diseased during the study period (P_{11}), who are not exposed and become diseased (P_{01}) and likewise the frequencies of being exposed or non-exposed and remaining disease-free (P_{10} and P_{00}, respectively). The target parameter of interest is the odds ratio ψ based on these population frequencies. As shown in the next two subtables, the odds ratio ψ^* expected from the case-control sample equals the product of the true odds ratio, ψ, times the cross products ratio of the sampling frequencies, denoted ψ_{f}. Hence $\psi = \psi^*$, that is, there is no bias, provided that $\psi_{\mathrm{f}} = 1$. This will occur when the sampling fractions for cases and controls are all the same, depend *only* on the disease outcome, that is, $f_{10} = f_{00}$ and $f_{11} = f_{01}$, or depend only on exposure, that is, $f_{01} = f_{00}$ and $f_{11} = f_{10}$. Often, the sampling fractions for cases are both near 1 whereas those for the controls are much smaller. The fact that this does not matter, provided that the sampling fractions for exposed cases and non-exposed cases are the same and similarly for controls, is another way of understanding why case-control studies provide estimates of the relative risk (disease odds ratio). Bias does occur when the sampling fractions depend *jointly* on exposure and disease, usually because exposed controls are more or less likely to be sampled than non-exposed controls. In a study that ascertained all the cases but sampled exposed persons as controls with twice the frequency as non-exposed persons, the estimated relative risk (odds ratio) would be twice the correct value. This is known as Berkson bias (Berkson 1946).

Some of the factors that contribute to selection bias are as follows:

Patient Dies Before Interview When cases are ascertained through a population based disease registry, a significant interval of time may elapse between initial diagnosis and notification to the registry. Some patients whose disease course is rapidly fatal may therefore not be interviewed in person, but are either excluded from the study or represented by a proxy interview subject to increased measurement error. This selection factor may affect both cases *and* controls in hospital based studies. It constitutes a major problem in reproductive epidemiology (see chapter ►Reproductive Epidemiology of this handbook).

Physician Refuses Consent Committees charged with protection of human research subjects may require that permission for participation be given by the patient's physician. This could affect control participation in hospital-based studies or case participation in general.

Subject Refuses Participation The most common reason for selection bias in case-control studies is refusal of the subject to participate, either actively by refusing to sign a consent form or passively by failure to return a questionnaire or turn up at the appointed hour for a laboratory examination. Cases with disease are often highly motivated to participate, whereas controls selected from the population are not. Unfortunately, control participation rates often depend on some correlate of exposure. Refusal rates for telephone surveys, for example, are higher for people who are older, have fewer social relationships, are less well educated, and have lower income (O'Neil 1979).

Subjects Ascertained Through Their Household Selection bias can occur when controls are ascertained by first contacting households to determine whether a control lives there who is suitable for matching to the case, and only a single control is selected from each household. In studies of childhood disease, where controls are matched on age within 2 years of the case, a child with a sibling in the same age range is less likely to be selected than one who has no such siblings (Greenberg 1990).

Random Digit Dialing Some other problems of selection bias are associated with the use of RDD for control ascertainment besides the fact that this method identifies households rather than individuals. Households without telephones stand no chance of selection, for example, whereas those with multiple telephones will be over-represented. The absence of a telephone may particularly affect minority populations.

7.5.2 Adjustments for Selection Bias in Study Design and Analysis

The most important consideration regarding selection bias is to avoid it so far as possible. At the design phase of the study, the exclusion criteria for both cases and controls may be chosen to maximize the probability of their ascertainment and participation. If RDD is used for control selection, this means taking the obvious step of excluding cases from households that lack telephones. Demographic, geographical, and linguistic factors may enter into the exclusion criteria for the same reason.

If selection bias cannot be avoided, as much data as possible should be gathered on *potential* case and control subjects to allow *prediction* of which of them go on to participate and which refuse. When sampling from the general population, it may be possible to use a recent survey of the same population for this purpose, provided of course that the survey itself had nearly complete response. If cases and controls are drawn from an enumerated population such as an HMO, data may already exist in medical or other records that can be used for this purpose.

At the time of analysis, one may attempt to adjust for selection bias in the same way that one adjusts for missing data. This is to use sampling weights for each participating subject, that is, those with "complete data," equal to the inverse predicted probability that the subject would have been selected given the data collected for this purpose at the design stage. This is only useful, of course, if there is substantial variability in the predicted probabilities. Alternatively, or additionally, one may statistically adjust the analysis for factors that are thought to be associated with selection but for which data are only available for participating subjects. Such adjustment would consist of stratification of the analysis on factor levels, or inclusion of the factor in a regression model for disease given exposure, just as one adjusts for confounders (Breslow and Day 1980, Sect. 3.8). However, if there is a substantial degree of non-response, it is quite unlikely that any adjustment will mitigate the serious biases that can result. There is simply no way to deal with it if selection fractions within factor levels used for adjustment purposes depend jointly on disease and exposure.

7.5.3 Measurement Error

A second major limitation of case-control studies is their susceptibility to measurement error. Cases and controls are often ascertained long after the relevant exposures have occurred. In spite of Dorn's (1959) admonition to use *objective* measures of exposure, most case-control studies of environmental risk factors continue today to measure exposure by interview or questionnaire. The potential for misclassification of exposure levels in such research is enormous. First, subjects may have only a vague memory of past exposures. Second, those who are diseased at the time of interview may recall these past events in a different way than those who are healthy controls. This may be in part because the early stages of their disease led to changes in behavior that made recollection of past practices more difficult. Interviewers may solicit and record answers differently if they have knowledge of the diagnosis or of the patient's status as case or control.

Austin et al. (1994) reviewed published reports of nine case-control studies of diet and cancer in which an attempt had been made to assess the accuracy of recall of dietary histories separately for cases and controls. According to their authors, three studies provided "weak" and four "moderate" evidence for recall bias. However, these results themselves were likely subject to measurement error and may have been understated in consequence.

Measurement error, whether or not it is differential between cases and controls, can compromise conclusions by seriously biasing the relative risk estimates from case-control studies that use dietary self-reports or similarly error-prone measurements. Prentice (1996) developed a mathematical model for measurement error that allowed for correlation of the error with the true exposure level and for systematic underreporting of exposure for persons with high exposure levels. He fitted the model to replicate measures of dietary fat intake, some taken using a 4-day food record and others using a food-frequency questionnaire for control subjects enrolled in the Women's Health Trial (Henderson et al. 1990). Employing results from international geographical correlation studies to generate the "true model," in which subjects at the 90th percentile of the distribution of dietary fat intake had three or four times the risk of disease as those at the tenth percentile, he showed that measurement error could plausibly reduce the relative risks to 1.1. The obvious conclusion from these calculations was that "dietary self-report instruments may be inadequate for analytical epidemiological studies of dietary fat and disease risk because of measurement error biases" (Prentice 1996).

A substantial and concerted effort has been made by statisticians to develop methods of data analysis that correct for the bias in relative risk estimates caused by measurement error (see chapter ▸Measurement Error of this handbook and the text by Carroll et al. 1995). Some require the availability of "gold standard," that is, error-free, measurements on a fairly large number of subjects in the validation subsample. Others assume that statistically independent true replicate measurements are available. Unfortunately, data collected in case-control studies rarely meet these stringent requirements, at least not in their entirety. It therefore behooves us to recall Bradford Hill's (1953, p. 995) sage advice:

> One must go and seek more facts, paying less attention to techniques of handling the data and far more to the development and perfection of the methods of obtaining them.

7.6 Conclusions

The case-control study played a major, successful role during the second half of the twentieth century in identifying risk factors for chronic disease. It has also proven helpful for evaluation of the efficacy of vaccination (Comstock 1994) and screening (Weiss 1994) programs. The twenty-first century will witness its continued use as a cost-effective study design, with increasing application in genetic epidemiology (Khoury and Beaty 1994) and particularly in the study of gene-environment interactions (Andrieu and Goldstein 1998). Statisticians and epidemiologists will continue to develop more efficient study designs and methods of data analysis that take full advantage of all available data. When a case-control study is conducted in an HMO, for example, some data will likely be available on either the exposure or the control variables for all subjects in the underlying cohort. *Two-phase* sampling designs, whereby *biased* samples of cases and controls are selected using the data available for all subjects, then offer the potential for much greater efficiency than the standard case-control design (White 1982; Breslow and Cain 1988; Langholz and Borgan 1995; Breslow and Chatterjee 1999). Chapter ▸Modern Epidemiological Study Designs of this handbook discusses these and other evolving study designs and analyses.

The advantages of case-control methodology in terms of speed and cost may have also contributed, ironically, to a diminished stature for epidemiology and biostatistics in the eyes both of the scientific community and of the general public (Breslow 2003). Part of the problem is an inherent aversion to the "black box" approach of risk factor epidemiology that associates cause and effect without the need for any understanding of pathogenetic mechanisms. Epidemiological findings are most convincing when supported by relevant laboratory research. Another part of the problem is the saturation of the news media with conflicting reports based on case-control and other studies that are too small, poorly designed, improperly analyzed, or overly interpreted. Taubes (1995) began his controversial and influential article on the limitations of epidemiology with the observation: "The news about health risks comes thick and fast these days, and it seems almost constitutionally contradictory." The epidemiologists he interviewed for this article cited the ability of confounding, selection bias and measurement error to overwhelm smaller exposure effects. One even suggested that no single study, no matter how well conducted, should be viewed as "persuasive" unless the lower limit of the 95% confidence interval for the rate ratio exceeded 3 or 4. Very few published studies, even when reported by the press as "suggestive" of an association, meet this stringent criterion.

Medical science and public health would be well served by fewer, larger case-control studies designed to test specific hypotheses that are carefully articulated in advance. Studies that can barely "detect" a relative risk of 2 may not provide convincing evidence of a dose-response gradient and are unlikely to enable one to determine whether an elevated relative risk in a particular disease subgroup, even one specified in advance, is evidence for the *specificity* of association that can be useful in causal interpretation (Weiss 2002). (There are of course exceptions, as when a unique exposure contributes to an outbreak of an extremely rare disease. Recall the DES-adenocarcinoma of the vagina story mentioned in the Introduction.) Investigators are also well advised to develop a strict protocol for selection of cases and controls and for collection and *analysis* of the data. Doll and Hill (1952) utilized such a protocol. They also had the advantage of working during the punch card era that discouraged "data dredging" and the inclusion of all but the most important variables in the analysis. A reasonable strategy might be to perform a maximum of three carefully planned analyses of the association between the primary exposure and disease: one without adjustment, one adjusted for a short list of confounders known a priori to be associated with disease, and the third adjusted for a specified list of known and suspected confounders. In case of conflict, the major interpretation would be based on the second analysis though the results of all three would be reported. Flexibility would be needed in application, of course, especially to accommodate changes in the study protocol after the study had commenced. Finally, investigators would be well advised to exercise greater caution in advertising their findings to the press before confirmation was forthcoming from other sources. By following basic principles of good statistical and scientific practice, the case-control study can gain credibility within the research community and enhance its standing as a basis for public health action.

8.1 Introduction

A fundamental challenge pervasive to all experimental and non-experimental (observational) research is valid inference of causal effects. Although actions (through undefined mechanisms, but conventionally denoted by treatment, exposure, etc.) and reactions (e.g., disease, remission, cure) must occur by definition in individuals, the realm of epidemiology principally lies in the study of individuals in the aggregate, such as patients enrolled in clinical trials, participants at risk in cohorts, and populations. Until recently, innovations in epidemiological study design methods developed in the last half-century have hence largely fallen into the domain of the two major observational study designs used: cohort and case-control studies (cf. chapters. ►Cohort Studies and ►Case-Control Studies of this handbook).

The justification for these two designs has seemingly rested on their ability to approximate – albeit non-experimentally – the widely accepted paradigm of applied biomedical research: the randomized trial. But the potentially exquisite control that study investigators can often exercise to approach comparability of groups, and hence (in the absence of other biases) validity, cannot in general be commensurately achieved in non-experimental research. To compensate, some epidemiologists have invoked conventions such as the "study base" concept, which have intuitive appeal and some practical value in study design, but ultimately do little to contribute to an understanding of the theoretical underpinnings of observational studies. Whether one accepts randomized trials as models for epidemiological designs to emulate, or envisions study bases as natural referents, however, is immaterial, because these concepts neither add to the transparency of causal inference nor do they lend themselves to further advances in modern observational study design. Clearly and by necessity, a different paradigm is required.

The premise underlying such a paradigm is that individuals potentially live in a simultaneous duality of exposure and non-exposure, with a corresponding duality of observable and hypothetical outcomes. That individuals living under one exposure condition should, in theory, be compared with themselves under other counterfactual (i.e., counter to fact) conditions leads in turn to the premise of "case-only" studies. This chapter is thus predominantly concerned with those studies that juxtapose a case series (i.e., individuals that have experienced a singular health event) with a hypothetical comparison group. The legitimacy of such an approach, which implicitly precludes the need for studying an observable comparison (e.g., control) group, derives from the "potential outcomes" formulation of establishing causal inferences (Little and Rubin 2000). We proceed to show its utility in recent, and most probably future, developments in modern epidemiological study design.

Nevertheless, not all settings are conducive to comparing cases against hypothetical distributions. When these circumstances arise, such as when exposure effects are not intermittent and transient or when induction times are not transitory (enhancing the likelihood of carryover effects), traditional case-control studies and their more modern variants take on a greater relevance. This chapter will therefore also address two of these designs: case-cohort and cohort-centric case-control studies (better known as "nested case-control studies"). They share in common a conceptual understanding of case-control studies that is somewhat at odds with the more traditional view of these designs, namely, a de facto comparison of cases to non-cases. The latter viewpoint fails to account for the artificial nature of this dichotomy: non-cases can become cases, even during the course of a study. The issue is resolved by recognizing that incidence case-control studies are effectively cost- and size-efficient modifications of cohort studies, in which cases are not simply compared with non-cases, but instead with a sample from a cohort of individuals at risk, some of whom might become cases. So in reality, all case-control studies are cohort-centric, that is, "nested" within a cohort (though the constituents of cohorts are not always obvious and may defy enumeration, as in hospital-based case-control studies). Viewed in this unifying light, the case-control studies discussed in this chapter assume a rational connection (albeit with sometimes different validity assumptions) not only to cohort studies but in turn to case-only, experimental, and potential outcomes research as well.

8.2 Case-Cohort Studies

To illustrate the relationship between case-control studies with differing control selection strategies, consider a study period (t_0, t_1) within which cases occur and are recruited. The traditional view of case-control studies has been that of sampling controls from the population at risk at the termination of the study period (t_1). Although direct estimation of exposure-specific incidence proportions is not possible without ancillary information, employment of such cumulative incidence sampling of controls allows the use of the exposure odds ratio for estimation of the incidence proportion ratio (IPR) in a fixed population under the rare disease assumption (Cornfield 1951, chapter ▶Case-Control Studies of this handbook). An alternative control sampling approach frequently employed in nested case-control studies, *incidence density sampling*, allows odds ratio estimation of the constant incidence rate ratio without invocation of the rare disease assumption (Miettinen 1976). Interestingly, when the parameter of interest is the incidence proportion ratio, the matched odds ratio under density sampling even generally outperforms the exposure odds ratio under cumulative incidence sampling as a better estimator (Greenland and Thomas 1982).

Several authors (Kupper et al. 1975; Miettinen 1982; Prentice 1986) envision yet another type of case-control study in which controls are sampled exclusively from the cohort at risk at t_0, that is, prior to the onset of case occurrence in (t_0, t_1) and without regard to their future outcome status. This design, hereafter referred to as a case-cohort study (but also known as a case-base study for binary outcomes), is notable not so much for its dissimilarity with other case-control design variants, but rather for what it has in common. The key feature distinguishing an incidence density sampled (nested) case-control study from a case-cohort study is whether controls are matched to cases on time to outcome of the case (Wacholder and Boivin 1987). Thus, a case-cohort study can be likened to an *unmatched* nested case-control study, with controls randomly sampled from the population at risk at t_0 (hence excluding prevalent cases) without regard to failure times (a condition of being sampled is that all individuals are at risk at t_0). Still, a nested case-control study requires control sampling from the entire cohort at risk throughout (t_0, t_1), while the case-cohort study does not because controls are selected prior to any occurrence of incident cases. Exposure information, therefore, need only be obtained on those individuals sampled as controls at t_0 and any subsequent cases that may or may not be controls. This makes the study design particularly advantageous relative to a cohort study when collecting and processing of exposure information, such as laboratory samples, becomes expensive and time-consuming, and can hence be reserved for only the study subjects, with only a modest reduction in efficiency. Indeed, if the study is prospective, such processing can occur in advance of any cases. Another advantage of the case-cohort study is the ability to employ the same subset of the cohort as a control group for studies of multiple outcomes. In contrast, a nested case-control study requires different matched risk sets for each outcome studied.

When an outcome is rare (i.e., most observations are censored), follow-up of a full cohort, whether closed or dynamic, can be expensive and inefficient. In contrast, by sampling only a subset of the cohort, the case-cohort study affords advantages found in both cohort and case-control studies while offering considerable efficiency relative to both. Table 8.1 shows how a hypothetical case-cohort study from a cohort of N individuals is implemented when estimating the incidence proportion ratio is desired. In this example, an individual in the cohort has probability p of being randomly sampled (with sampling independent of exposure) when cohort membership is fixed at t_0. Thus, the *sub-cohort* is comprised of pN individuals on whom exposure information is ascertained (assuming no loss to follow-up). Note, however, that this principle can be extended to a dynamic cohort, allowing entrance at different times. Over the study period (t_0, t_1), a total of A exposed cases + B non-exposed cases occur, only some of whom $(pA + pB)$ are members of the sub-cohorts. The efficiency of the study is attributable to the economy of not evaluating

Table 8.1 Expected distribution of cases and controls in a case-cohort study with sampling fraction p, with sampling independent of exposure

	Exposed		Non-exposed		
	Sampled sub-cohort	Non-sampled remainder of cohort	Sampled sub-cohort	Non-sampled remainder of cohort	Total
Cases	$pA = A_1$	$(1-p)A = A_0$	$pB = B_1$	$(1-p)B = B_0$	M_+
Censored individuals	$p(N_1 - A) = C$	$(1-p)(N_1 - A)$	$p(N_0 - B) = D$	$(1-p)(N_0 - B)$	$N - M_+$
Individuals at risk at t_0	pN_1	$(1-p)N_1$	pN_0	$(1-p)N_0$	N

A number of exposed cases in cohort, B number of non-exposed cases in cohort, N_1 number of exposed individuals in cohort, N_0 number of non-exposed individuals in cohort, M_+ total number of cases in cohort censored individuals outside the sub-cohort (e.g., $(1-p)(N_1+N_0-A-B)$). It is noteworthy that cases from the entire cohort, not only those that are members of the sub-cohort, are utilized as cases in the study. Although it is advantageous to obtain a census of the cases, particularly when the outcome is rare, cases can potentially be sampled as well. A sub-cohort experiencing censoring over the study period can also be repopulated from the underlying cohort.

When the cohort is fixed, direct estimation of the crude *IPR* is possible without the rare disease assumption. Intuitively, with complete case ascertainment, one would expect the case-cohort odds ratio $(A/B)/(pN_1/pN_0)$ to estimate the *IPR*. However, Sato (1992a) develops a maximum likelihood estimator (MLE) that is asymptotically more efficient:

$$\widehat{IPR}_{\text{MLE}} = \frac{A\left[\frac{BM_1}{M_+} + D\right]}{B\left[\frac{AM_1}{M_+} + C\right]}, \tag{8.1}$$

where $A_1 = pA, A_0 = (1-p)A, B_1 = pB, B_0 = (1-p)B, C = p(N_1 - A)$, $D = p(N_0 - B)$, $M_1 = A_1 + B_1$, and $M_+ = A + B$ (see Table 8.1). It is important to note that this equation does not in general algebraically simplify further because, by design, control exposure information is obtained only on the members of the sub-cohorts N_1' and N_0', where $N_1' = pN_1$ and $N_0' = pN_0$, and not on the entire cohort N. The key difference between the two IPR estimators lies in how the number of sampled cases is employed. For the case-cohort odds ratio, the actual exposure-specific number of sampled cases (A_1 and B_1) is used in the calculation of the size of the cohort sample (i.e., $N_1' = A_1 + C$, and $N_0' = B_1 + D$). In contrast, the MLE estimates the exposure-specific number of cases as substitutes for A_1 and B_1 by multiplying the total number of cases in the exposed or non-exposed sub-cohorts (A or B) by the unconditional (on exposure) overall sampling fraction of cases (M_1/M_+, i.e., the proportion of all cases in the cohort originally chosen (i.e., prior to becoming cases) for inclusion in the combined exposed and non-exposed sampled sub-cohorts). Note that when the exposure-specific sampling fractions are equal to the overall sampling fraction, the two *IPR* estimators will be equal.

To illustrate these points, consider the data from a case-cohort study by Miettinen (1982) and cited by Sato (1992a). The study included ten individuals sampled in the exposed sub-cohort (N_1'), five of which became cases (A_1), and an additional five exposed cases occurred that were not in the sub-cohort (A_0). It also included 90 individuals sampled in the non-exposed cohort (N_0'), 15 of which became cases (B_1); an additional 35 non-exposed cases occurred (B_0). The intuitive estimator of the *IPR* for these data is 1.8, while the MLE is 2.2. In this example, the overall case sampling fraction, M_1/M_+, is $20/60 = 0.33$, and the exposed and non-exposed case sampling fractions are $5/10 = 0.5$ and $15/50 = 0.3$, respectively. However, if the exposure-specific sampling fractions of cases are identical, i.e., if the 35 non-exposed cases not in the sampled sub-cohort are changed to 15 non-exposed cases, then the exposure-specific case sampling fractions (0.5) are equal to the overall sampling fraction of cases, and both *IPR* estimates will equal 3.0.

When the outcome is not rare, random sampling of cases may be utilized. Sato (1992a) provides further details about incorporating such sampling into the analysis. When the outcome is rare, then few if any cases would be expected in the cohort sample ($M_1 << M_+$), and (8.1) reduces to the case-control odds ratio (AD/BC).

A large sample variance estimate of ln ($\widehat{IPR}_{\text{MLE}}$) (Sato 1992a) is given by

$$\widehat{\text{var}}[\ln(\widehat{IPR}_{\text{MLE}})] = \frac{1}{A} + \frac{1}{B} + \left[1 - 2\left(\frac{M_1}{M_+}\right)\left(\frac{1}{\frac{AM_1}{M_+} + C} + \frac{1}{\frac{BM_1}{M_+} + D}\right)\right] \qquad (8.2)$$

$$- \frac{N'^2 AB(A_0 + B_0)(A_1 + B_1)}{(A+B)^3\left(\frac{AM_1}{M_+} + C\right)^2\left(\frac{BM_1}{M_+} + D\right)^2},$$

where $N' = N_1' + N_0'$.

A $(1-\alpha)\%$ confidence interval for the crude *IPR* can be obtained from

$$\widehat{IPR}_{\text{MLE}} \exp\left\{\pm Z_1 - \alpha/2(\widehat{\text{var}}[\ln(\widehat{IPR}_{\text{MLE}})])^{\frac{1}{2}}\right\} \qquad (8.3)$$

where $z_{1-\alpha/2}$ denotes the $(1-\alpha/2)$-quantile of the standard normal distribution.

Calculation of the *IPR* estimator and its large sample distribution can be extended to stratified analyses using a Mantel–Haenszel estimator (Sato 1992b). With k strata, the estimator is given by

$$\widehat{IPR}_{\text{MH}} = \frac{\sum\limits_k \frac{N_{0k}' A_k}{T_k}}{\sum\limits_k \frac{N_{1k}' B_k}{T_k}}, \qquad (8.4)$$

where T_k is the total number of distinct individuals in stratum k ($A_k + B_k + C_k + D_k$).

The variance estimator of ln ($\widehat{IPR}_{\text{MLE}}$) that applies to both large strata and when data are sparse is

$$\widehat{\text{var}}[\ln(\widehat{IPR}_{\text{MH}})] = \frac{\sum\limits_k \frac{[(B_{0k}+D_k)A_k N_{1k}' + (A_{0k}+C_k)B_k N_{0k}' + A_{0k}D_k + B_{0k}C_k]}{(T_k)^2}}{\sum\limits_k \frac{N_{1k}' B_k}{T_k} \sum\limits_k \frac{N_{0k}' A_k}{T_k}}. \qquad (8.5)$$

As before, confidence limits can be obtained by applying the following formula:

$$\widehat{IPR}_{\text{MH}} \exp\left\{\pm z_{1-\alpha/2}\left(\widehat{\text{var}}\left[\ln(\widehat{IPR}_{\text{MH}})\right]\right)^{\frac{1}{2}}\right\}. \qquad (8.6)$$

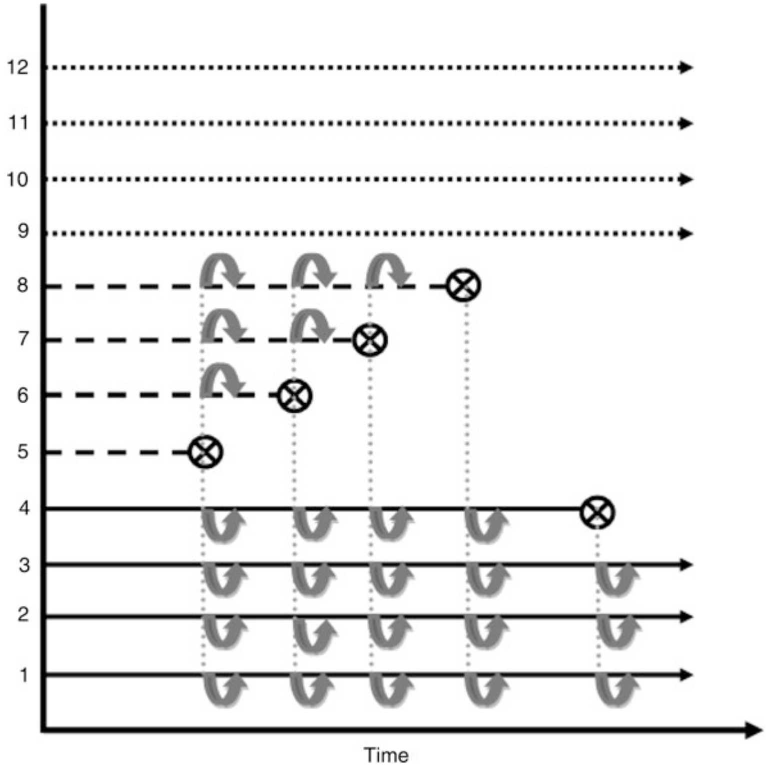

Fig. 8.1 Control sampling in case-cohort studies. Subjects 1–4 are selected for inclusion in the sub-cohort; subjects 5–8 are cases in the cohort (but not the sub-cohort); subjects 9–12 are members of the cohort who were not sampled for inclusion in the sub-cohort and did not become cases. *Circle* with X inside represents an incident case; *counterclockwise arrows* represent members of the sub-cohort used for the risk set at time of case occurrence; *clockwise arrows* represent non-members of the sub-cohort who were included in the study as cases and so were secondarily used as members of risk sets at times of earlier cases occurring

Additional details on crude and stratified incidence proportion ratio estimation can be found in Sato (1994).

When the parameter of interest is the incidence rate ratio, the analysis becomes more complex, and as noted earlier entrance into the cohort, and hence sub-cohort, can be dynamic. If all members of the cohort were followed and their exposure and outcome status (i.e., failure times) measured, a Cox proportional hazards regression model could easily be employed. Instead, a modification of this model is required for case-cohort data. Unlike a cohort study, at every time of case (regardless of sub-cohort membership) occurrence in the observation period, a risk set is created from the case and the uncensored members of the sub-cohort at that time (Fig. 8.1). For additional discussion about analytical issues in case-cohort studies, see Barlow et al. (1999) and Zhang et al. (2011).

Further developments in the methodology of dynamic case-cohort studies are addressing sampling approaches to make them even more efficient in weighing costs associated with exposure ascertainment and sampling cohort members and statistical precision. Breslow et al. (2009a) underscore the obvious point that conventional approaches to case-cohort studies fail to utilize available information that exists on cohort members not sampled. Sampling cases and non-cases within covariate strata, and then applying adjustments for stratum-specific weights, although not new (e.g., Walker 1982; White 1982) represents one area of development, as does incorporation of information from the non-sampled members of the cohort into analysis models. These approaches build upon the paradigm that case-cohort studies are de facto two-stage stratified sampling designs: the "first" stage recognizes the cohort as a representative sample of an unspecified target population, while the "second" stage involves sampling of cases and non-cases, either unconditionally or conditionally (stratified) on covariates, into the sub-cohort (Breslow et al. 2009a). Sampling weights for each individual are inversely related to their sampling probabilities in their strata, necessitating a weighted analysis that allows the stratum-specific contribution to equal what it would have been if all cohort members of the stratum had been analyzed. This weighting principle is illustrated using data from the Atherosclerosis Risk in Communities (ARIC) study (1989) reproduced in Breslow et al. (2009a), where sampling was stratified on age, sex, and ethnicity (Table 8.2). If additional confounding variables not utilized for stratified sampling are identified, the strata can be further subdivided using post-stratification.

Other methods of improving precision in the second sampling stage include calibration to adjust weights (Deville and Särndal 1992; Breslow et al. 2009a, b) and estimation to instead derive weights as inverse probabilities of sample selection from logistic regression (Robins et al. 1994). These improved weights enhance precision by utilizing covariate information available on the entire cohort. Additional information in implementing improving precision of regression coefficients can be found in Lin and Ying (1993) and Kulich and Lin (2004).

Although these methods have not yet been widely incorporated into commercial software, there are readily accessible options for implementing them. One based on the R language can be found at http://faculty.washington.edu/norm/IEA08.html

Table 8.2 Composition of cases and non-cases in the The Atherosclerosis Risk in Communities (1989) study population, stratified by ethnicity, sex, and age

	Non-coronary heart disease patients (non-cases)								Coronary heart disease patients (cases)
	Black				White				
	Female		Male		Female		Male

(Software IEA) (accessed on November 28, 2011), which utilizes the R-based "survey" package of Lumley (2008) at http://faculty.washington.edu/tlumley/survey/ (survey analysis in R) (accessed on November 28, 2011). A second based on R is the NestedCohort software of Mark and Katki (2006), available for download at http://dceg.cancer.gov/tools/analysis/nested-cohort (NCI Analysis Tools – NestedCohort) (accessed on November 28, 2011), with an accompanying tutorial at http://cran.r-project.org/web/packages/NestedCohort/vignettes/NestedCohort.pdf (accessed on November 28, 2011).

The choice between which type of case-control study to undertake – case-cohort or nested case-control – ultimately rests less on study-specific efficiency considerations than on what primary effect measure is required and whether the study is investigating one or multiple health outcomes. These issues are discussed in detail in Langholz and Thomas (1990) and Wacholder (1991).

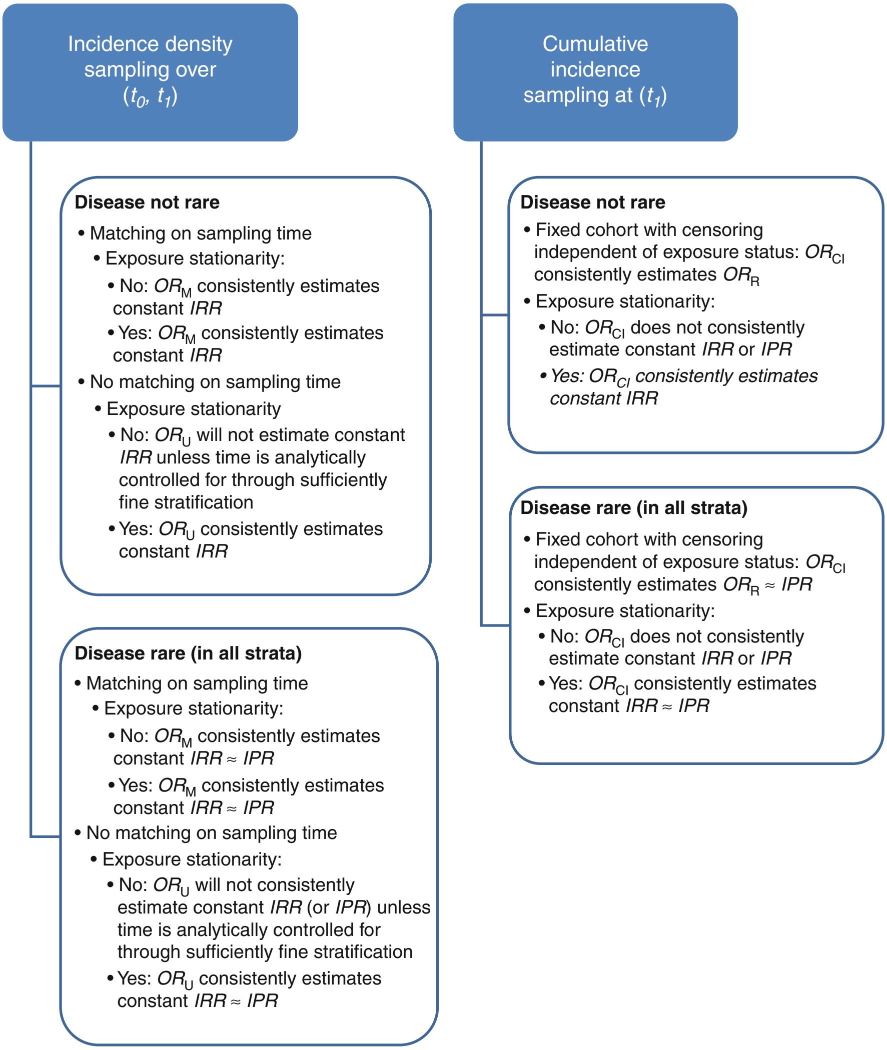
8.3 Cohort Logic for Nested Case-Control Studies

Early incarnations of case-control studies owed their conceptual and inferential standing to Jerome Cornfield, who in 1951 demonstrates both that the exposure odds ratio could be estimated from a contrast of cases to controls (non-cases) and that under certain incidence assumptions (i.e., a low incidence proportion in a defined time interval in all groups of individuals with varying levels of exposure – and, by extension, within strata of controlled variables – hence the nominal "rare disease assumption"), it would closely approximate the incidence proportion ratio (or, as Cornfield calls it, the relative risk) in a fixed population. This conception of the case-control study, however, lacks a coherent linkage to the longitudinal structure of a cohort study and to the vision of a source population at risk from which cases arose. For a period of time in their formative years, case-control studies instead were sometimes fallaciously envisioned as directionally the opposite of cohort studies, leading to what later colloquially became the "trohoc fallacy."

The correspondence between longitudinal study designs became better understood and more widely accepted in the 1970s with the publication of the article *Estimability and estimation in case-referent studies* (Miettinen 1976). Here, Miettinen demonstrates that under certain designs involving control sampling from the population at risk, the exposure odds ratio is a consistent estimator of the incidence rate (density) ratio. Pointedly, unlike in the case-control design envisioned by Cornfield, no assumption of disease rarity is obligatory for estimation of the incidence rate ratio, a recognition that portended an even deeper understanding of control selection strategies to come.

Without yet defining specific examples, consider a population at risk followed over time; it is irrelevant whether this is retrospectively, ambispectively, or prospectively accomplished. The population may be closed or open; it may be completely enumerated or have its membership left uncharacterized; its distribution of exposure(s), baseline disease incidence, and relative effect of exposure (e.g., the incidence rate ratio) may be constant or time dependent. Regardless of which combination of these characteristics a population at risk possesses, the goal of the case-control study remains the same: an unbiased estimate of an epidemiological measure of impact (e.g., a synoptic incidence rate or risk ratio). This requires the exposure odds in the controls to equal (apart from random error incurred through sampling) the ratio of exposed relative to non-exposed time at risk in the population. Selection of controls to achieve this correspondence is accomplished through *incidence density* sampling (sometimes referred to as *density* or *risk set sampling*), where controls are sampled either directly from the population at risk or within strata of the population under observation, thereby providing a highly efficient way of studying a cohort without needing to obtain potentially expensive exposure information (e.g., abstracting medical records, genotyping, laboratory testing) on all members. The principle of sampling risk sets from this population provides a natural correspondence with failure-time cohort studies, which has spawned the name *nested* case-control studies. In practice, the word *nested* is used to distinguish case-control studies whose underlying cohorts are well defined from those whose members are not identified or ill-suited to enumeration. Controls, by virtue of their population membership, are at risk of becoming cases; conversely, individuals not at risk are ineligible to be controls because they are statutorily precluded from becoming cases in the study. Again, this underscores the subtle but important distinction between considering controls as individuals at risk as opposed to being strictly non-cases. Furthermore, controls remain members of the population at risk until the study period (i.e., the period of case acquisition) ends, and they are censored, until they exit the population or until they become diseased and become eligible to enter the study as cases. So long as they remain members, they are also eligible to be sampled in later risk sets as controls and are repeatedly counted. Just as cases in a cohort study no longer contribute time at risk to a cohort study, they are similarly no longer eligible to be selected as controls in a case-control study.

Figure 8.2, constructed primarily using Cornfield (1951), Greenland and Thomas (1982), and Greenland et al. (1986), summarizes the relationship between the exposure odds ratio from a case-control study under incidence density sampling and its corresponding measure of effect under the different scenarios discussed above (assuming that the effect of exposure can be synoptically represented in the absence of meaningful modification by other factors). Many scenarios depend upon the assumption that the distribution of exposure during the period of case accrual is invariant (exposure stationarity), although this assumption becomes less plausible if exposure is related to disease incidence and the disease is not rare in the source population, thus differentially depleting the exposed sub-cohorts. The latter authors also demonstrate that when the goal of a study investigator is to represent the effect of exposure through comparative risks, the exposure odds ratio derived under incidence density sampling of controls is a superior estimator of the incidence proportion ratio than the exposure odds ratio derived under cumulative incidence sampling (when controls are only taken at the end of the period of case acquisition and are hence ineligible to become cases).



Incidence density sampling over (t_0, t_1)
Disease not rare
• Matching on sampling time
• Exposure stationarity:
• No: OR_M consistently estimates constant IRR
• Yes: OR_M consistently estimates constant IRR
• No matching on sampling time
• Exposure stationarity
• No: OR_U will not estimate constant IRR unless time is analytically controlled for through sufficiently fine stratification
• Yes: OR_U consistently estimates constant IRR
Disease rare (in all strata)
• Matching on sampling time
• Exposure stationarity:
• No: OR_M consistently estimates constant IRR ≈ IPR
• Yes: OR_M consistently estimates constant IRR ≈ IPR
• No matching on sampling time
• Exposure stationarity:
• No: OR_U will not consistently estimate constant IRR (or IPR) unless time is analytically controlled for through sufficiently fine stratification
• Yes: OR_U consistently estimates constant IRR ≈ IPR
Cumulative incidence sampling at (t_1)
Disease not rare
• Fixed cohort with censoring independent of exposure status: OR_{CI} consistently estimates OR_R
• Exposure stationarity:
• No: OR_{CI} does not consistently estimate constant IRR or IPR
• Yes: OR_{CI} consistently estimates constant IRR
Disease rare (in all strata)
• Fixed cohort with censoring independent of exposure status: OR_{CI} consistently estimates OR_R ≈ IPR
• Exposure stationarity:
• No: OR_{CI} does not consistently estimate constant IRR or IPR
• Yes: OR_{CI} consistently estimates constant IRR ≈ IPR

Fig. 8.2 Interpretation of odds ratios from case-control studies under two different control sampling schemes over the period of case accrual (t_0, t_1). *IPR* incidence proportion ratio, *IRR* incidence rate ratio, *OR* odds ratio, OR_{CU} odds ratio under cumulative incidence sampling, OR_M matched odds ratio under incidence density sampling, OR_R risk (incidence) odds ratio, OR_U unmatched odds ratio under incidence density sampling (Adapted from Cornfield (1951), Greenland and Thomas (1982) and Greenland et al. (1986))

Early recommendations for the ratio of controls to cases when exposure is constant relied on a simple formula under the null hypothesis (odds ratio = 1) for estimating the asymptotic relative efficiency of an unmatched case-control study relative to a cohort study, $r/(r+1)$, where r = the number of controls per case

(Breslow et al. 1983) in the crude situation where no confounders were analytically controlled. When $r = 0$, the study is trivially non-informative with respect to estimation of the odds ratio; when r becomes large, the case-control study efficiency approaches 1 and essentially approximates a cohort study. The relative improvement in efficiency and study power diminishes as r becomes larger, leading some to claim that there is little to be gained by having more than four controls per case in either a matched or unmatched design. Later study in control number sampling efficiency demonstrated the lack of universality of this formula (as demonstrated in Fig. 7.1 of Breslow and Day 1987) and the improved relative efficiency even with more than four controls per case for some combinations of odds ratio and prevalence of exposure in the source population. These authors showed that study efficiency conditional on the number of controls was also a function of the magnitude of the odds ratio and the prevalence of exposure in the source population, as well as whether or not matching was employed. In some instances, fewer than four controls per case would be satisfactory, while in others more than four would be indicated.

When exposure is not stationary (i.e., constant over time), as in administration of medicine, its effects can be both intermittent and transient. While it is typical to assess case and control exposure at the time of or immediately prior to the outcome (e.g., disease diagnosis or event), exposure in controls can more broadly be envisioned as a time-dependent variable divided into successive and distinct time windows. Such control individuals, representing the person-time at risk in the source population, would alternatively each have contributed exposed and non-exposed person-time in a cohort study.

Suissa et al. (2010) propose that sampling more than one of the control time windows (called control "person-moments") to improve study power when obtaining exposure information for multiple windows is more pragmatic than identifying more control individuals. The phrase "multitime case-control design" is thus coined to denote obtaining exposure information on all such time windows for which exposure information exists. Utilizing Suissa et al.'s notation, let k = the number of time windows, $k = 1, 2, \ldots, t$, with $k = 1$ representing the window closest in time to and t representing the window furthest in time from case occurrence. Let n = the number of cases and y_i, i = $1, 2, \ldots, n$ represent their binary exposure (0 = non-exposed, 1 = exposed), and m = the number of controls with x_{jk} representing their binary exposure (0 = non-exposed, 1 = exposed), with $j = 1, 2, \ldots, m$ and $k = 1, 2, \ldots, t$. Thus, while a conventional case-control study would restrict use to n cases and m control time windows, there are no theoretical impediments to utilizing all n cases together with exposure measurements from mt control windows. The unadjusted synoptic exposure odds ratio under this design, $\widehat{OR}_{MT}$, is calculated as

$$\widehat{OR}_{MT} = \frac{a/c}{\sum_j B_j / \sum_j D_j}, \tag{8.7}$$

where $a = \sum_i y_i, c = \sum_i (1 - y_i), B_j = \sum_k x_{jk}$, and $D_j = \sum_k (1 - x_{jk})$.

Because exposures in successive time windows for each individual are unlikely to be independent, the variance of $\widehat{OR}_{MT}$ must be corrected as follows:

$$\widehat{\text{var}}\left(\ln(\widehat{OR}_{MT})\right) = \frac{1}{a} + \frac{1}{c} + V, \tag{8.8}$$

where $V = \Sigma((B_j/t) - R)^2/(R^2(1-R)^2 m(m-1))$ and $R = \Sigma B_j/mt$.

The above estimate assumes that the odds ratio is invariant across duration of exposure, which allows exchangeability (and potentially random sampling) of control exposure time windows (Suissa et al. 2010). If exposure did not vary over time, then the dependency between control person-moments would lead to complete concordance (i.e., the intraclass correlation = 1), and there would be no efficiency gain by sampling more person-moments; instead, more controls would be needed. If, in contrast, exposure was free to vary between person-moments, as in time-dependent exposures of transient duration, then it may be advantageous to sample multiple within-subject control intervals instead of acquiring more controls. For example, Suissa et al. note that with complete independence between person-moments, the improvement in precision by having five versus two person-moments is roughly equivalent to having four versus one control individuals. Furthermore, this approach is suited to acute exposures of limited duration, but not for those whose effects are cumulative (where each control subject would only have a single exposure time window). It also holds promise for extension to regression models that correct for the within-control correlation over time and can adjust for other covariates.

As with case-cohort studies, two-stage sampling for incidence density sampled case-control studies has been proposed to improve study efficiency (Breslow and Chatterjee 1999). To demonstrate its justification, these authors utilize data from the National Wilms' Tumor Study Group (D'Angio et al. 1989) shown in Table 8.3. The table contains 4,088 embryonal kidney cancer patients who either did (cases) or did not (controls) relapse, cross-classified by initial (institutional) tumor histological finding of prognostically favorable or unfavorable. The authors sought to validate the initial histology due to concerns about misclassification but wanted to do so without reassessing every tumor. A probability sample of the entire patient cohort would yield an unacceptably low number of cases while capturing an unnecessarily high number of controls. An alternative approach would be to do

Table 8.3 Data from National Wilms' Tumor Study Group, reproduced from Breslow and Chatterjee (1999)

	Entire cohort		Case-control study		Weighted case-control study	
Histology	Cases	Controls	Cases	Controls	Cases	Controls
Favorable	415	3,262	415	536	415	316
Unfavorable	156	255	156	35	156	255
Total	571	3,517	571	571	571	571
Odds ratio	4.8		5.8		0.47	

a nested case-control study, with all cases and a sample of controls to achieve a 1:1 ratio. This approach is scarcely satisfactory, however, due to the relatively small number of controls ($n = 35$) whose tumor histology was unfavorable. By performing weighted sampling that constrained the number of controls to remain the same ($n = 571$) while including all controls with unfavorable histology, the authors were better able to achieve a "balance" between the favorable ($n = 316$) and unfavorable ($n = 255$) sub-cohorts.

The odds ratio in the weighted case-control study is clearly biased, reflecting that the weighted sampling violated one of the central tenets of control selection: that the probability of control selection through sampling is statistically independent of exposure distribution. Of course, matching is an obvious counterexample, but the selection bias is easily remediated through appropriate analytical methods. As with case-cohort studies, weighting reflects the probability of being sampled in stage two conditional on stratum defined by one or more covariates and that an individual was sampled in stage one. Upon analysis, Breslow and Chatterjee (1999) find very close concordance between the regression coefficients and standard errors from the entire cohort and the weighted case-control study while only needing to validate histology on 571 of 3,517 (16%) of controls.

Special survey software must be applied to remediate the bias. Many software packages (open source and commercial) provide options for survey analysis. These include Lumley's "survey" package at http://faculty.washington.edu/tlumley/survey/ (survey analysis in R) (accessed on November 28, 2011). A recent review by Witt (2009) examines software commercially available to provide sample weight adjustments.

Another approach to two-stage sampling of controls in risk sets for improving efficiency is proposed by Langholz and Borgan (1995) who recognize that when exposure is rare in the cohort, randomly sampling controls would be unlikely to yield precise measures and that matching cases and controls on one or more confounders can lead to matched sets concordant on exposure that do not contribute to exposure effect estimation and preclude confounder effect estimation (although not exposure effect measure modification by the stratification variable). They develop a control sampling method called *counter-matching* to improve discordancy by maximizing exposure variability within risk sets. While the conventional notion of individual matching in a case-control study is to make controls as alike as possible to the cases on the matching factors, the opposite holds in counter-matching. Although the sampling mechanism is counterintuitive because control selection is not independent of exposure, case-control studies can be made substantially more efficient under certain conditions with proper analysis that controls for the deliberately weighted sampling (Langholz and Clayton 1994).

Consider a nested case-control study in which the goal is to estimate the effect of an exposure with two or more levels on the incidence of a binary outcome (e.g., disease status). If exposure is difficult to obtain or expensive to measure (stage two information), it would be wasteful of human and/or financial resources, if not outright infeasible, to obtain exposure information from an entire cohort when only a fraction of it will ultimately be selected as controls. However, there may exist a readily available surrogate for exposure (stage one information) from the entire cohort whose measurement may provide a useful although imperfect substitute, for example, utilizing readily obtainable duration of mining employment as a surrogate for cumulative silica dust exposure (Steenland and Deddens 1997) or assessing whether an individual received any vaccines in a defined time period as a substitute for knowing if a specific vaccine brand or lot (the exposure) suspected of causing an adverse event was administered. Alternatively, there may be complete ascertainment of exposure on all members of the cohort, but detailed information on confounders essential for study validity may be only cost-effective to obtain once controls have been selected for risk sets. For example, radon exposure histories from the Beaverlodge Uranium Miners Cohort of over 10,000 miners were obtained to assess its association with lung cancer mortality, while detailed smoking histories were selectively obtained from next of kin on only 46 cases and 95 controls who died between 1950 and 1980 (L'Abbé et al. 1991).

The procedure for performing counter-matching can be understood by first considering a nested pair-matched (1:1 design) case-control study and a dichotomous exposure. Each case in a surrogate exposure stratum is matched to a single control in a surrogate non-exposure stratum (i.e., the *opposite* stratum of the case), and a case in a surrogate non-exposure stratum is matched to a single control in a surrogate exposure stratum. By extension, more than one control per risk set can be accommodated for multiple strata (Langholz and Clayton 1994; Langholz 2005). In the matched case of one case per risk set (individual matching), suppose the counter-matching factor, known on all risk set members, has r strata, $r = 1, 2, \ldots, R$, with the case falling into only one stratum. The cohort is comprised of N individuals divided into the R strata, with n_r individuals in each stratum from which m_r individuals are sampled without replacement. The variability in exposure (or its surrogate) is realized by taking m_r controls from each stratum *except* the one containing the case; for that stratum $m_r - 1$ controls are sampled (Table 8.4). In an unmatched study (i.e., multiple cases (d_r) occupying R strata), the number of controls per counter-matched stratum will be determined by the number of cases, that is, $m_r - d_r$.

Table 8.4 Illustration of counter-matching using one case matched to m_r controls (Langholz 2005)

	Sampling stratum					
	1	2	3	…	R	Total
Cases	0	0	1		0	1
Controls	m_1	m_2	$m_3 - 1$		m_R	$\Sigma_r m_r - 1$
Total sampled in risk set	m_1	m_2	m_3		m_R	$\Sigma_r m_r$
Total eligible in cohort for risk set	n_1	n_2	n_3		n_R	$\Sigma_r n_r$
Weight	n_1/m_1	n_2/m_2	n_3/m_3		n_R/m_R	

To obtain unbiased estimators, counter-matched nested case-control studies must correct for selection bias induced by the sampling design. This is accomplished by utilizing the log weights (i.e., ln (n_j/m_j)) as an offset in a conditional logistic regression analysis. Unlike conventional case-control matching, where main effects of matching factors are not estimable, counter-matching allows direct estimation of the effects of the stratification factor, as well as its interaction with other model variables.

When counter-matching on an exposure or its surrogate, a nested case-control study can be more efficient than one in which matched controls are randomly sampled from a risk set. However, it is important that the counter-matching variable is correlated with the variables of interest for the analysis, be they precise exposure measures or confounders. Thus, counter-matching on a rare exposure can make a study much more efficient if the goal is to estimate an exposure effect. To see this, in the special case of a dichotomous (+ = present, − = absent) exposure (E) and counter-matching covariate (C), consider the sensitivity (Se) and specificity (Sp) of the covariate (P($C+|E+$) and P($C-|E-$), respectively) for predicting true exposure. When exposure and disease are independent, the asymptotic relative efficiency of a 1:1 counter-matched versus a 1:1 randomly sampled nested case-control study is given by (Langholz 2005):

$$2[SeSp + (1 - Se)(1 - Sp)]. \tag{8.9}$$

Thus, the efficiency gained from counter-matching arises when both Se and Sp are either greater or less than 0.5. Additional asymptotic relative efficiencies for 1:1 and 1:3 matching under exposure prevalences of 5% and 50% when the sample-based incidence rate ratio = 2 are provided in Table 1 of Langholz and Borgan (1995) when counter-matching on a surrogate of exposure. In general, relative efficiency rises as sensitivity and specificity both rise, but specificity is more influential than sensitivity, particularly as the effect of exposure increases; relative efficiency is also higher for rare rather than common exposures. When counter-matching on true exposure and controlling for a confounder, counter-matching results in substantial gains in efficiency for various combinations of exposure effects and confounder-exposure associations, particularly when exposure is rare and the effect of exposure increases (Table 2 of Langholz and Borgan 1995; Table 3 of Langholz and Clayton 1994). As a practical matter, Steenland and Deddens (1997) find in their silicosis study that counter-matching with three controls had an equivalent efficiency of randomly sampling ten controls.

In contrast, the advantages of counter-matching on exposure (or its surrogate) fail to extend to counter-matching on a confounder. Langholz and Clayton (1994) demonstrate in their Table 4 such deleterious consequences: when both the confounder and exposure are rare, the efficiency of the counter-matched study is often profoundly less efficient than a nested case-control study unless the association between the confounder and exposure is very strong (i.e., when the confounder becomes a de facto surrogate of or proxy for the exposure).

8.4 Case-Crossover Studies

8.4.1 Introduction

Under circumstances that could be described as both ideal and impossible, it would become a trivial matter to evaluate causation within an individual, thus obviating the need for observational studies at all. This ideal, which is assumed in Table 8.5, reflects the counterfactual capacity to evaluate not only the health or disease experience of a cohort of exposed individuals (column 1) but what the experience of this cohort would have been had it been possible to evaluate these same individuals during the same time frame as when they were actually exposed, with exposure hypothetically being removed or its effect completely blocked (column 2).

Such a comparison between these same individuals under two identical conditions (save for the fact of exposure) could then lead not only to an individual-by-individual assessment of the causal or preventive effect of exposure but also the average causal effect of exposure in the exposed *cohort (A/A*)*. The value of the non-exposed cohort (column 3) for comparison with the exposed cohort (column 1), and hence effect estimation, lies in the validity of its exchangeability property, that is, $B/N_0 = A^*/N_1$.

Given the pragmatic limitations which epidemiologists operate under – pointedly, the inability to have study participants and investigators reexperience events in time, rendering column 2 unobservable – it becomes a challenge, if not an imperative, to design studies to come as close as possible to the ideal. In experimental research, the crossover study, in which individuals crossover between periods of different exposures (possibly including non-exposure, as in a control, placebo, or sham treatment), affords the opportunity to observe different treatments within the same individual, albeit at different (and potentially confounding) time periods. The allure of this experimental approach, underlying the ability to control for individual-level confounders, is offset by the assumption that neither period nor carryover effects occur. Thus, this design is optimally suited to exposures with both a rapid onset of action as well as a brief effect period.

Table 8.5 Hypothetical incidence data from exposed (as well as counterfactually non-exposed) and non-exposed cohorts

		Exposed*	
Diseased	A	A^*	B
Non-diseased	C Exposed	C^*	D Non-exposed
Total person-time at risk	N_1	N_1	N_0
Incidence proportion	A/N_1	A^*/N_1	B/N_0

Note that * indicates the same exposed group when counterfactually non-exposed. Therefore, A+C is constrained to equal A*+C*

The case-crossover design (Maclure 1991) is the observational study analog of the crossover study. A key distinguishing characteristic of the former is that study participants – not investigators – non-experimentally determine their own exposure. A very important feature of case-crossover studies, like crossover studies, is that they are apposite to episodic exposures with short induction and transient effect periods for uncommon events. Thus, it is possible to envision, following an exposure that modifies risk in individuals, a brief induction period during which risk does not change, followed by a period subdivided into intervals characterized by varying degrees of altered risk, and ultimately a return to baseline risk. The time interval of elevated or decreased risk following exposure is known as the effect period. In practice, the effect period may not be known, but may be inferred from ancillary information (e.g., pharmacokinetic properties of a drug or environmental agent, duration of effect of endogenous catecholamine release following physical exertion, period of heightened immune activity following vaccination, half-life of a chemical, incubation times of a pathogen following infection, etc.). Sensitivity analyses postulating different combinations of induction time and duration of exposure effects can provide insights into periods of maximum influence. As noted by Maclure (1991), postulating effect periods that are either too brief or too long leads to non-differential misclassification of exposure, resulting in effect measures that are biased toward the null. In the absence of other biases, the optimal choice of an effect period is that which minimizes non-differential misclassification and hence maximizes the effect measure.

8.4.2 Case-Control Logic for Case-Crossover Studies

The simplest conception of a case-crossover study envisions, for every subject, a contrast of the duality of states: a comparison of their exposure immediately prior to their event time (the event period) to their exposure at an *antecedent* (i.e., non-event) time. This bears closely analogy to a pair-matched case-control study in which a case's exposure is compared to a control's exposure, but with subtle differences. All individuals in a case-crossover study are, by definition, "cases" because they experienced the event, so the exposure at the time of the event substitutes for the case's exposure in a case-control study, and the exposure at the antecedent time – when the individual is still at risk of the event – substitutes for the control or referent in a case-control study. To avoid confusion and reinforce the case-only design model, non-event comparison times are heretofore referred to as *referent* times. Taking referent times exclusively from the time window prior to the event has the advantage of ensuring that the event itself does not affect the exposure measurements (i.e., as in "reverse causation"), but there are also disadvantages that will be discussed below.

Although the case-crossover construct is conducive to controlling within-individual time-independent confounding, the choice of referent times preceding the event period must judiciously be made when time-dependent variation in exposure is plausible (i.e., when the assumption of a constant distribution or stationarity of exposure across referent times is unlikely to be met). Just as matched case-control studies can achieve greater efficiency when the number of controls per case increases, potentially increasing the number of discordant case-control sets for analysis, more than one referent time can be selected for every event time. The injudicious use of referent times in the absence of exposure stationary can lead to a case-crossover form of selection bias analogous to that of a case-control study (Greenland 1996). This can especially be manifest when referent times are taken long before the event time, even in the absence of time (e.g., seasonal or weekly) trends.

Mittleman et al. (1995) examine different approaches to modeling case-crossover data from the control period, and the relative sampling efficiencies and restrictiveness of the assumptions inherent in each approach. Four of the modeling approaches involved different methods of studying the control period in the 25 one-hour periods immediately preceding myocardial infarction, with exposure being heavy exertion. The first approach the authors evaluate is called the "Pair-Matched Interval Approach," in which the one-hour hazard period immediately prior to the onset of myocardial infarction is contrasted with the one-hour control period from the same time of day 24 h earlier within the same subject. These data control for confounding by time of day, without the need to specify the baseline hazards in each of the day's 24 one-hour periods. The analysis can be made more statistically efficient by increasing the number of control intervals sampled. However, this method is not well suited to evaluating other exposures that occur at regular and predictable intervals during a 24-h period. For example, if an individual reliably self-administers a medication with potential cardiovascular effects to be taken at 08:00 and 20:00 h each day, then by comparing exposure on the day of disease occurrence to the same time 24 h earlier, this approach will ensure perfect concordance between hazard and control periods, resulting in bias toward the null. A second strategy, the "Nonparametric Multiple Intervals Approach," involves explicitly modeling exposure information on each of the 24 one-hour categorical intervals in the day prior to the myocardial infarction. This model, besides controlling for confounding by time of day, assumes a homogeneous exposure effect on each of the 24 hour-specific times (i.e., time is not an effect measure modifier). Although this categorical model, with indicator variables representing the one-hour intervals, makes no assumption about the functional relationship between the time of day and myocardial infarction incidence, a third model, the "Parametric Multiple Intervals Approach" does exactly that. Instead of indicator variables, the authors employ sine and cosine functions, based on consistency with prior (external) information on temporal patterns of myocardial infarction occurrence. Under the assumption that the model is correctly specified, it provides a synoptic estimate of the effect of exposure while controlling for confounding by time of day.

Maclure (1991) illustrates another referent selection strategy using case-control logic by assuming that some exposures (e.g., behavioral) occur in individuals with predictable frequency (note that many such exposures would be highly susceptible to modification following the event). In this "Usual Frequency Approach" a time window prior to the event is subdivided into time within or outside exposure effect

Table 8.6 Representation of case-crossover data for a single individual developing an outcome event either within or outside an exposure effect period

	Time		
	Within effect period	Outside effect period	Total
Case occurrence	a_i	b_i	
Person-time	N_{1i}	N_{0i}	T_i

periods. Assuming the absence of a time trend in exposure within the window, the referent person-time exposure odds can be contrasted with the exposure odds at the event time for effect estimation. Data from an individual i in a "Usual Frequency Approach" case-crossover study can be envisioned in Table 8.6. When the distribution of exposure is stationary over the case and control period and the outcome event is uncommon, the Mantel–Haenszel incidence rate ratio ($\widehat{IRR}_{\text{MH}}$) is approximately asymptotically unbiased (Vines and Farrington 2001). Each case occupies a unique stratum. $\widehat{IRR}_{\text{MH}}$, corresponding to the average proportionate change in the rate of the outcome resulting from exposure, can be calculated from the following formula (note: $N_{1i} + N_{0i} = T_i$):

$$\widehat{IRR}_{\text{MH}} = \frac{\sum_i a_i N_{0i} / T_i}{\sum_i b_i N_{1i} / Ti} \tag{8.10}$$

The variance of $\ln(\widehat{IRR}_{\text{MH}})$ (Greenland and Robins 1985) can be estimated by

$$\widehat{\text{var}}[\ln(\widehat{IRR}_{\text{MH}})] = \frac{\sum_i (a_i + b_i) N_{1i} N_{0i} / T_i^2}{\left(\sum_i a_i N_{0i} / T_i\right) \left(\sum_i b_i N_{1i} / T_i\right)}. \tag{8.11}$$

To illustrate, consider the hypothetical data in Table 8.7 (adapted from Table 4 of Maclure 1991). The column of referent exposure odds is equivalent to Maclure's expected concurrence odds and refers to the ratio of the expected amount of time an individual spends in the effect period, based on the usual frequency of exposure, to the expected amount of time an individual spends outside the effect period (N_{1i}:N_{0i} from Table 8.6) over the duration of retrospective follow-up for cerebrovascular accidents. In this example, the period of retrospective follow-up was 6 months, or equivalently 4,383 h. For example, for participant 1, the usual frequency of aerobic exercise was three times per week. If the effect period is assumed to be 2 h beginning immediately after the cessation of exercise, then the expected number of hours spent in the 6-month effect (exposure) period = 2 h/day × 3 days/week × 26 weeks = 156 h (N_{1i} in Table 8.6), leaving $4,383 - 156 = 4,227$ h non-exposed (N_{0i} in Table 8.6). Because participant 1s cerebrovascular accident occurred within

Table 8.7 Data from a hypothetical case-crossover study evaluating the relationship between aerobic exercise and the onset of cerebrovascular accident. The effect period is 2 h. The period of retrospective follow-up is 6 months or equivalently 4,383 h

			Exposure odds	
Individual (i)	Usual frequency of exposure	Last exposure before cerebrovascular accident	Event time (a_i:b_i)	Referent (N_{1i}:N_{0i})
1	3/week	30 min	1:0	156:4,227
2	1/week	1 day	0:1	52:4,331
3	1/month	21 days	0:1	12:4,371
4	0/month	1 year	0:1	0:4,383
5	5/week	45 min	1:0	260:4,123
6	0/month	2 years	0:1	0:4,383
7	2/month	15 h	0:1	24:4,359
8	4/week	3 h	0:1	208:4,175
9	1/week	6 h	0:1	52:4,331
10	0/month	4 years	0:1	0:4,383

the 2-h effect period, the observed exposure odds for this individual – the ratio of the a$_i$ and b$_i$ cells in Table 8.6 is 1:0. Using (8.10) and (8.11), the Mantel–Haenszel incidence rate ratio for cerebrovascular accidents within 2 h of aerobic activity in this sample of individuals and its corresponding 95% confidence interval are 24.0 and 3.1–188.1, respectively.

The preceding example derived the usual frequency of exposure by utilizing a census of the information from the 6 months prior to the event onset. In practice, retrospective follow-up time may be briefer or longer, depending on the stability of the exposure distribution. The analysis presupposed that no within-individual confounding occurred over time and that the effect of aerobic exercise did not depend on time of day.

In all the above models, it was possible to estimate a single summary effect of exposure under the assumption of no effect modification of the exposure-outcome association by time of day. Mittleman et al. (1995) show that while the number of control periods sampled has little effect on the incidence rate ratio estimate, as the periods sampled increase, the relative efficiency (marked by a narrowing of the respective confidence intervals) concomitantly increases as well, regardless of what underlying model assumptions are invoked. The "Usual Frequency Approach" leads to the smallest variance of the estimated logarithm of the incidence rate ratio, and hence narrowest confidence interval, but at the cost of assuming no within-individual confounding unless further information is available on the complex conditional relationships among all determinants of risk. Although the modeling approach by these authors may not be appropriate in all circumstances, they do underscore the point that case-crossover studies, like their case-control counterparts, can be conducted using different control period sampling schemes and employing different exposure and confounder/effect modifier assumptions.

8.4.3 The Exchangeability Assumption

Already noted is the potential for bias arising from time trends in exposure when referent periods are constrained to occur prior to the period (Greenland 1996). A more subtle source of bias arises when exposures measured from different referent periods within individuals are not independent (Vines and Farrington 2001). Recall that in a case-control study's matched set comprised of one case and two or more controls, there is no natural ordering of controls, so their respective exposures are *exchangeable* in the sense that switching exposures among the controls would have no impact on odds ratio estimation. In contrast, multiple referent periods and the event period are constrained to be ordered in case-crossover studies because they are deliberately selected to occur at fixed times prior to the event (i.e., using the case-control logic cited above). The assumption of exchangeability therefore need no longer be valid because of the potential for exposures within individuals to be correlated, and hence non-independent, between different time intervals. A necessary condition for the valid use of the Mantel–Haenszel estimator is that pairwise exchangeability exists between the event period and each referent period; that is, the probability of exposure at the event time and non-exposure at each referent time is equal to the probability of non-exposure at the event time and exposure at each referent time. Pairwise exchangeability is a less restrictive assumption than global exchangeability, which requires exposure independence between all time periods within matched sets in a case-crossover study. Such lack of global exchangeability in a case-crossover study can lead to biased odds ratio estimates when utilizing conventional multivariate approaches for matched data, such as conditional logistic regression, because the latter's likelihood is in general not equivalent to the case-crossover likelihood. This bias has been called *overlap bias* and can be substantial in the presence of strong temporal variability in event incidence and exposures. To quote Vines and Farrington (2001):

> It can be shown that for a dichotomous exposure, pairwise exchangeability is equivalent to requiring that the marginal probability of being exposed is the same in the case period and the control period. Thus if the exposure distribution is stationary over time, the Mantel-Haenszel estimator for the odds ratio is approximately asymptotically unbiased. When there are two or more control periods per case, global exchangeability (sufficient for the use of conditional logistic maximum likelihood estimator) is a stronger condition than pairwise exchangeability. In particular, stationarity of the exposure distribution over time is no longer sufficient. Over and above stationarity, it implies that the dependence in exposure between any two periods is identical. In matched case-control studies, exposures within each matched set can usually be assumed exchangeable, the numbering of controls being arbitrary. However this is not the case for case-crossover studies for which the time ordering of case and control periods is a fundamental aspect of the design. In most cases one might expect the exposure dependence between two periods to decline with the time interval between them. In practice, it is only safe to analyze case-crossover studies with M [referent times] >1 when the exposures across time periods are independent for each individual.

To appreciate this, consider the following example from Vines and Farrington (2001) examining the effect of a binary exposure (0 = non-exposed, 1 = exposed)

Table 8.8 Hypothetical case-crossover study from a cohort of 16,000 individuals illustrating how non-independence of exposure across time periods leads to biased odds ratio estimates from conditional logistic regression (Adapted from Vines and Farrington (2001))

Exposure pattern			Non-independence		Independence	
$t = 0$	$t = -1$	$t = -2$	Probability	Expected number[a]	Probability	Expected number
0	0	0	0	0	0.125	2
0	0	1	0	0	0.125	2
0	1	0	0	0	0.125	2
0	1	1	0.5	8	0.125	2
1	0	0	0.5	32	0.125	8
1	0	1	0	0	0.125	8
1	1	0	0	0	0.125	8
1	1	1	0	0	0.125	8

[a] Expected number = (population at risk) × (incidence proportion|case exposure at $t=0$) × (probability of exposure pattern)

on case occurrence in a case-crossover study of 16,000 individuals with two referent periods ($t=-2$ and $t=-1$) and the event period ($t=0$); in each period, the unconditional probability of exposure equals 0.5. The incidence proportion among the non-exposed is 0.001, and the incidence proportion among the exposed is 0.004, so the incidence odds ratio should approximately equal 4.0. Table 8.8 shows each combination of exposure in each of the three time periods and their respective probabilities under two distinct scenarios: non-independence and independence. Under non-independence, only two exposure patterns are possible, and exposure in both the referent times is dependent on (and opposite that of) exposure at $t=0$. A Mantel–Haenszel analysis of the data under non-independence yields the correct odds ratio of 4.0, while a conditional logistic regression analysis leads to a biased odds ratio of 6.6. In contrast, under independence all exposure patterns are equally likely to occur, so knowing exposure at $t=0$ provides no information on the distribution of exposures at $t=-1$ and $t=-2$. Both the Mantel–Haenszel and conditional logistic regression analyses yield an unbiased odds ratio of 4.0.

Non-independence might arise, for example, in a study of anti-inflammatory drug use in individuals allowed to self-medicate: during periods of elevated pain, people would be more likely to take the medication, while during periods of relief, they would be less likely. Because self-medication in one time interval is likely to provide some insight into self-medication in adjacent time intervals, the exposure information cannot be considered independent. When there is no true relationship between exposure and the outcome of interest, so long as exposure is stationary over time, the conditional logistic regression model should not erroneously suggest such a causal effect of exposure, although time of day, if explicitly modeled, could still demonstrate an effect on disease incidence. In contrast, the greater the true effect of exposure, the greater is the model's potential for bias, which can be either toward or away from the null.

8.4.4 Cohort Logic for Case-Crossover Studies

When time trends of exposure are present, the case-control logic of fixing the event time and comparing it to antecedent referent times leads to bias and must be discarded in favor of a counter-approach allowing the ordered referent time periods to be fixed, with the event time as random. This not only bears resemblance to the cohort paradigm and the self-controlled case-series method but also implies that referent times can be sampled both before and after the event time (i.e., ambidirectionally). Further innovations in case-crossover studies have exploited this design in studies of environmental exposures with transient effects exhibiting time trends. This is also consonant with the underlying structure for the case-crossover design as a proportional hazards model for a rare outcome for individual i with a constant baseline hazard who experiences the event at time t as

$$\lambda_i(t, x_{it}) = \lambda_i \exp(x_{it}\beta), \tag{8.12}$$

where x_{it} represents variables that are time dependent (Navidi 1998).

Two early examples by Navidi (1998) demonstrate the fallibility of unidirectional designs in the absence of exposure stationarity. The data in Table 8.9 show the experience of two cohorts over two successive time periods. The time trend in this example is obvious: one-third of people are non-exposed in Period 1, while two-thirds of people are non-exposed in Period 2. In both periods, the risk among the non-exposed is 0.001, the risk among the exposed is 0.002, and the risk ratio is 2. If a conventional unidirectional case-crossover study was performed with these data, where referent times anteceded fixed event times, it would only be possible to compare event times from Period 2 to referent times in Period 1. The single non-exposed case from sub-cohort 1 during Period 2 was exposed during Period 1, and the four exposed cases from sub-cohort 2 during Period 2 were non-exposed during Period 1. The ratio of these discordant event/referent pairs equals 4/1 = 4, which overestimates the true effect twofold. The bias arises because there were 2,000 individuals initially non-exposed in Period 1 that become exposed in Period 2, compared to only 1,000 individuals exposed in Period 1 who became non-exposed in Period 2. However, if the case-crossover study was instead bidirectional, then

Table 8.9 Hypothetical cohort study illustrating incidence of an outcome caused by exposure that varies over two time periods. The effects of exposure in each time period are independent (Adapted from Navidi (1998))

	Period 1				Period 2			
	Sub-cohort 1		Sub-cohort 2		Sub-cohort 1		Sub-cohort 2	
	Exposed	Non-exposed	Exposed	Non-exposed	Exposed	Non-exposed	Exposed	Non-exposed
Cases	2	0	0	2	0	1	4	0
Non-cases	1,000	0	0	2,000	0	999	1,996	0
Total	1,002	0	0	2,002	0	1,000	2,000	0

Table 8.10 Hypothetical cohort study illustrating incidence of an outcome caused by exposure in two time periods with differing baseline incidence. The effects of exposure in each time period are independent (Adapted from Navidi (1998))

	Period 1				Period 2			
	Sub-cohort 1		Sub-cohort 2		Sub-cohort 1		Sub-cohort 2	
	Exposed	Non-exposed	Exposed	Non-exposed	Exposed	Non-exposed	Exposed	Non-exposed
Cases	16	0	0	2	0	8	4	0
Non-cases	2,000	0	0	2,000	0	1,992	1,996	0
Total	2,016	0	0	2,002	0	2,000	2,000	0

the two exposed cases from sub-cohort 1 would have non-exposed referent times and the two non-exposed cases from sub-cohort 2 would have had exposed referent times. The matched pairs (Mantel–Haenszel) odds ratio would then become $(4+2)/(1+2) = 2$.

Table 8.10 shows an alternative example of how time trends in baseline risk, even in the absence of time trends in exposure, can lead to bias under a unidirectional referent sampling design. While there is no longer an association between the distribution of exposure among periods, as there was in Table 8.9, the risk in the non-exposed sub-cohort in Period 1 is 0.001, compared to the risk in the non-exposed sub-cohort in Period 2 of 0.004. With four exposed cases in Period 2 that were non-exposed in Period 1, and eight non-exposed cases in Period 2 that were exposed in Period 1, the ratio of these discordant event/referent pairs equals $4/8 = 0.5$. If a bidirectional design was instead employed, the 16 exposed cases that became non-exposed in Period 2 and the two non-exposed cases that became exposed in Period 2 would also be included, leading to a matched pairs odds ratio of $(4 + 16)/(8 + 2) = 2$, which equals the ratio of the exposed to non-exposed incidence in both sub-cohorts 1 and 2 ($0.008/0.004$ and $0.004/0.002$, respectively).

Although sampling referent times following the event is only strictly valid if an individual remains at risk following the event, and their exposures are unaffected by the event (i.e., exogenous, which is a reasonable assumption for environmental exposures), this bias is relatively minor compared to that incurred by only unidirectional sampling (Lumley and Levy 2000; Janes et al. 2005a) with rare events.

A greater understanding through likelihood specification of the assumptions inherent in cohort-centric sampling for case-crossover studies has been accompanied by a proliferation of newer designs. Navidi (1998) proposes what has come to be known as the full stratum bidirectional (FSBI) case-crossover design, although it is closely related to the self-controlled case-series design of Farrington (1995). This design utilizes the entire ordered time period of exposures as fixed, with the event time as random, leading referent times to be both before and after the event time. The underlying incidence rate is assumed to be constant over this period, which would not be correct in the face of seasonal or other period effects;

confounding by such temporal variation would need to be analytically controlled using either conditional logistic or Poisson regression.

Bateson and Schwartz (1999) propose taking referent times at identical intervals both before and after the event time to control for temporal confounding (e.g., by day of week). This has been referred to as the symmetric bidirectional (SBI) design. This approach fixes by design the referent times relative to the event time, sharing the case-control logic of unidirectional designs with the cohort logic of taking referent times before and after event times. Although taking referent times in close temporal proximity to the event time controls for long-term trends, this design requires exchangeability, without which conditional logistic regression estimates will be biased.

Lumley and Levy (2000) develop a referent sampling approach that requires the fixed ordered time period to be stratified by measures of time, such as month, week, or year, to control for these temporal effects, called the time-stratified (TS) design. The FSBI design can be considered a special case of the TS design with a single stratum encompassing all eligible referent times. Nevertheless, residual confounding from temporal effects may persist, leading to biased estimates (Whitaker et al. 2007). Analysis of this design can be achieved with either conditional logistic or Poisson regression, with time controlled with step functions using indicator variables. This model has been extended by Farrington and Whitaker (2006a) to allow for residual seasonal effects and called the time-season-stratified (TSS) design.

A modification of the SBI design is proposed by Navidi and Weinhandl (2002), called the semi-symmetric bidirectional (SSBI) design. Instead of two referent times symmetrically placed around the centered event time, only one referent time is randomly selected. This design assumes that temporal effects are constant, so referent times should be temporally in close proximity to the event time. Janes et al. (2005a) note that conditional logistic regression yields biased estimates unless an offset is incorporated into the model for days at the beginning and end of the exposure period.

This design is in turn modified by Janes et al. (2005a) to deal with event times at the respective ends of the exposure periods, where selecting only one referent time is possible. If a referent time was selected outside the exposure period, then the case would be eliminated from the study. This has been called the adjusted semi-symmetric bidirectional (ASSBI) design. Whitaker et al. (2007) note that this minor adjustment is a technical violation of the cohort logic of the case-crossover design because events at the two extreme times are excluded and that conditional logistic regression will yield valid estimates only so long as pairwise exchangeability is met.

In a review of the literature of 19 air pollution case-crossover studies between 1991 and 2004, Janes et al. (2005b) find that 63% utilized the SBI referent selection design, followed by 26% using the TS design. Nevertheless, these and other case-crossover designs all rely on assumptions that may be tenuous in practice. This leads Whitaker et al. (2007) to admonish epidemiologists against their use: "… we find little to recommend the continued use of the case-crossover approach in the analysis of environmental time series data: these methods are either biased or are special cases of more versatile methods. Time series regression is simple to use, does not suffer from overlap bias, and allows for flexible modeling of seasonality and time trends: this ought to be the method of choice."

8.5 Case-Time-Control Studies

One of the assumptions – and limitations – of the case-crossover design is that of stationarity (stability) of the distribution of study exposure over time. Such an assumption takes on a reasonable legitimacy for a transient exposure assessed over a relatively short referent time interval. However, as the period of prior exposure assessment lengthens, time trends in exposure from changing external factors may become emergent and evident, precluding the measurement of "usual frequency" of exposure. Period effects lead in turn to confounding.

Suissa (1995) recognizes time trends as a threat to validity in case-crossover studies, which leads him to propose a modification of a case-crossover study, which he calls a "case-time-control" study. The premise behind this design is that information about time trends in exposure can be obtained from individuals conventionally sampled as controls in a classical case-control study. This information can in turn be used to adjust the effect estimate from a case-crossover study, yielding less biased results by removing the confounding introduced by period effects.

To illustrate this bias practically, Suissa uses as a central example in pharmacoepidemiology (cf. chapter ▸Pharmacoepidemiology of this handbook) the problem of assessing drug effects in the face of confounding by indication. That is, prescription drug use is not only more likely among patients with more serious manifestations of an illness but as disease severity progresses over time, the therapeutic indication for such drug use is also likely to commensurately change as well. Because severity is typically both an independent predictor of a health outcome and an indication for treatment, nor is it an expected sequelae of therapeutic drug use, it fulfills the necessary criteria for confounding. Were severity an easily measurable host characteristic, it would be trivial to control for its confounding effects. However, severity within and between patients falls on a continuum that usually defies even imprecise measurement, such that even attempts to control for it would lead inevitably to meaningful residual confounding. Thus, neither conventional (i.e., case-control) nor case-only (e.g., case-crossover) studies would be capable of distinguishing drug (exposure) effects from temporal (confounding) changes in exposure.

Suissa's solution to this problem is to envision the odds of exposure (recognizing that sampling is based on outcome) in an individual as an exponential function of the following elements (retaining his notation):

$$\mathrm{odds}(E_{ijkl} = 1) = \exp(\mu + s_{il} + \pi_j + \vartheta_k), \tag{8.13}$$

where E represents a binary exposure, i represents the outcome group status (case or control), j represents a current or referent time period, k represents the outcome event in a particular period, and l represents the individual in group i; $\exp(\mu)$ is the overall exposure odds, $\exp(s_{il})$ is the participant-specific odds ratio, $\exp(\pi_j)$ is the period odds, and $\exp(\theta_k)$ is the odds corresponding to the outcome event. This function can be expressed separately for cases and controls and for the current and referent time periods. As will be seen shortly, this model is notable for its lack of interactions among the different elements. It can be shown that the effect measure of interest, $\exp(\theta_k)$, is not distinguishable from the nuisance period effect, $\exp(\pi_j)$, in the cases alone, but that the addition of a control series renders the former estimable.

This model, in which each individual's current and referent period constitute a matched pair, can be envisioned within the framework of conditional logistic regression. Again, utilizing Suissa's notation, let T denote the outcome variable which is the respective time period (1 = current, 0 = referent) for each participant's component of the matched pair, E the exposure, and G the outcome group status (case or control). The odds that the outcome T equals 1 is given by

$$\text{odds}(T = 1) = \exp(\beta_0 + \beta_1 E + \beta_2 (E \times G)). \tag{8.14}$$

The odds ratio corresponding to the effect of time period is $\exp(\beta_1)$, while the odds ratio corresponding to the effect of drug therapy on the outcome after removal of the period effect is $\exp(\beta_2)$.

The case-time-control study is not without its detractions. As Greenland (1996) points out, in addition to the usual assumptions of a case-crossover study (e.g., absence of carryover effects), the analysis can be confounded by the presence of unmeasured – and hence uncontrollable – confounders. Strictly speaking, for a case-time-control analysis to yield a valid point estimate of exposure, it must be assumed that there exist no interactions among any of the elements in (8.13). That is, the exposure-outcome association is unaffected by time period ($\pi_j \theta_k = 0$), the exposure-outcome association is unaffected by unmeasured confounders ($s_{il} \theta_k = 0$), and the exposure-time period association is unaffected by unmeasured confounders ($s_{il} \pi_j = 0$) (Suissa 1998). While the first assumption, that the effect measure remains stable, may be reasonable, particularly over shorter rather than longer time periods, the latter two assumptions are more problematic. The presence of unmeasured confounders is invariably a concern, though hardly unique to case-time-control studies. Those unmeasured variables may act on either the exposure effect as effect modifiers or on the time period effect as confounders.

The utility of this method, then, rests on the veracity of unverifiable assumptions of no-confounding by indicators of disease severity. A more recent modification of this approach, called the "case-case-time-control" design (Wang et al. 2011) relies solely on future cases as the source of controls. Greenland (1996) points out the problem of selecting between competing study designs to cope with the problem of confounding by indication when it is unclear which design would yield a less biased result. Without a recommendation that uniformly applies to all study settings, it may ultimately be advisable when possible to employ a sensitivity analysis of two or more designs within the same cohort in order to see how their different properties and assumptions can affect conclusions.

8.6 Self-Controlled Case-Series Methods

Considerable interest in the last decade has focused on the putative relationship between vaccines and adverse outcomes (both acute and chronic) that are too rare to be detected in limited-size safety trials. If such outcomes are sequelae to vaccines, they are unlikely to be recognized until substantial utilization and experience in populations have been realized. Conventional non-experimental studies suffer from methodological inadequacies: depending on the rarity of the event, cohort studies would likely be prohibitively large, requiring populations difficult to enumerate, and hospital-based case-control studies would be compromised by an unclear choice of a source population and valid control series, and the issue of transient duration of vaccine effect. The relative rarity of cases would likely also compromise the investigator's ability to control for the myriad of factors known to be related to choice and timing of vaccination.

One design option to address this challenge of studying time-variant exposures with transient effects is proposed by Farrington (1995). The study population is comprised of a case series of individuals belonging to an underlying source population who experience one or more instances of the outcome of interest during a defined observation period and who have retrospectively obtained vaccination (exposure) histories. Although it only includes cases, its design allows the self-control of within-individual time-invariant confounders (e.g., genetic propensity and environmental factors) and coupled with outcome rarity allows the estimation of consistent effect measures of relative incidence. The design differs from the case-crossover model, which assumes stationarity of the exposure distribution, and allows the assessment of age and time effects, as well as multiple events (Whitaker et al. 2006). In addition, when exposure is not rare, this design is nearly as efficient as a study of the entire underlying cohort (Farrington 2004).

A number of key assumptions are inherent in this model (Whitaker et al. 2009). While exposure is time dependent, in the case of recurrent events, it is assumed that one event does not affect the probability of subsequent exposure, although the authors have proposed modifications if there is either one or multiple exposures by excluding all cases whose exposures were not prior to the event. A second assumption is that the duration of the observation period must be independent of the occurrence of one or more events.

The model (in the notation of Whitaker et al. 2009) can be represented by the following:

$$\lambda_{ijk} = \exp(\varphi_i + \alpha_j + \beta_k), \tag{8.15}$$

where λ_{ijk} is the incidence rate of the ith individual in the jth age stratum and kth risk period, φ_i is the effect of individual i, α_j is the effect of age group j, and β_k is the effect of exposure in risk period k. n_{ijk} is the number of events occurring within a risk period of length e_{ijk}, which are assumed to arise in a non-homogeneous, age-dependent Poisson process, that is, $n_{ijk} \sim$ Poisson $(\lambda_{ijk}e_{ijk})$. Non-homogeneity reflects that incidence changes within the observation period due to periods of intermittent altered and attenuated risk from exposure, and agedependent reflects that incidence is allowed to vary across age strata while homogeneous within age strata. Exp(β_k) is the incidence rate ratio comparing the incidence in the kth risk period relative to the control period (i.e., $k = 0$). Medical knowledge informs the definition of the risk periods coming before or after exposure k, where $k = 1, 2, \ldots$, K, during which cases are at presumptive lower or higher risk of an event. Any other times within the observation period before, after, or between the risk periods constitute the control periods, indexed by $k = 0$. Cases will thus contribute time within some (but not necessarily all) combinations of age and risk periods. Fixed covariates can be included in the model if there is suspicion that they may modify the effect of exposure on event incidence by including interaction terms.

The approach is flexible enough to accommodate multiple risk periods, as when multivalent vaccines are evaluated in which the respective components have different periods of increased risk. It can straightforwardly accommodate multiple events, and if the events cluster together in time, but the clusters themselves are longitudinally independent, then it is possible to use the first event in each cluster of events while still using multiple clusters.

Care must be exercised in the construct of a case series to assess effects of transient exposures, whether they are vaccines or other pharmacological agents. The probability of case selection should be statistically independent of exposure status; this should be achieved if a census of cases conditional on eligibility criteria is taken or if exposure information is retrieved only after sampled cases are enrolled. Ages and observation period studied should be selected to achieve periods of time both in and out of risk periods. The choice of risk period is non-trivial and must be based on prior medical knowledge and biological plausibility. A single risk period can also be subdivided into non-overlapping intervals to detect when, within the period, exposure effects are most pronounced. Although the model was designed to model age interval effects, other time-dependent categorical variables can be substituted or added (e.g., season).

Figure 8.3 conceptually demonstrates how vaccines administered to children in two age groups experiencing immune-mediated hemolytic anemia could be evaluated. Each child's 2-year period of observation ($j = 1, 2$) is subdivided into four risk periods: baseline ($k = 0$) and three successive 2-week intervals ($k = 1, 2, 3$) in which vaccines could potentially trigger the immune system to begin hemolysis. Vaccines were administered on the first day of the first risk period ($k = 1$) under the premise that an acute hypersensitivity reaction could lead to an immediate hemolytic crisis. If this is not medically plausible in the context of other problems, then a lag period of no risk ($k = 0$) can be inserted between the day of vaccination and the first day of the first risk period. Table 8.11 translates these patients' experiences into the data model appropriate for analysis (e.g., using conditional Poisson regression). Although receiving a vaccination in the observation period guarantees that patients will contribute time to all levels of k (unless patients receive vaccines within 6 weeks of the end of the observation period), not all combinations of age and risk categories need have intervals populated with time (e.g., patient three).

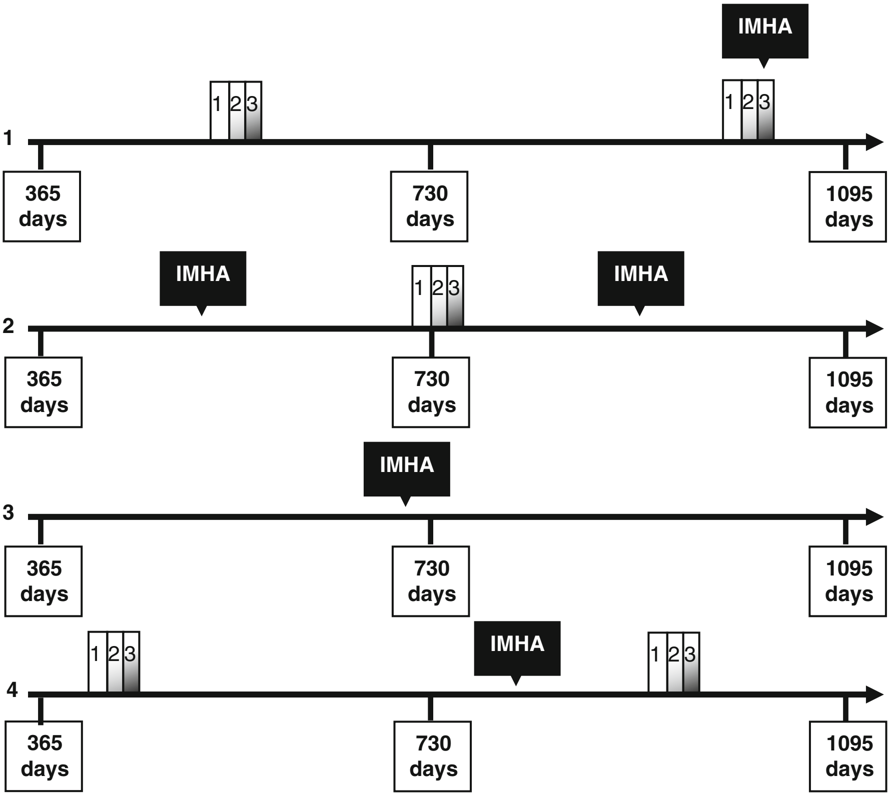


Fig. 8.3 Four hypothetical cases of immune-mediated hemolytic anemia (IMHA) under observation from 1 to 3 years of age. *Black box* arrows indicate time of onset of IMHA. Vaccine effects were postulated to occur in three successive risk periods of 14 days duration (*vertical boxes* numbered 1, 2, and 3). Vaccination was given on the first day of the first risk period (k = 1), so no lag period of no risk was assumed

The self-controlled case-series methods continue to evolve. Farrington and Whitaker (2006b) modify the approach to modeling baseline ($k = 0$) incidence by using a semi-parametric approach. When the assumption that the event does not affect the probability of subsequent exposure (e.g., a person dies from the event), then adaptations can be made to estimate hypothetical time at risk. The method has also been adapted for use in prospective post-marketing pharmacosurveillance for periods of short risk as well as long and indefinite risk periods. These methods are discussed further in Whitaker et al. (2009).

Sample size formulas for self-controlled case series have been developed by Musonda et al. (2006). A useful website has been created to update users on the methodology of self-controlled case series, as well as to provide instruction and guidance to creating datasets partitioned by age, risk period, and potentially other covariates, and to performing regression analyses using commercial software packages: http://statistics.open.ac.uk/sccs (accessed on November 28, 2011).

Table 8.11 Data layout for four patients (ages 1–3 years) in Fig. 8.3 with one or more episodes of immune-mediated hemolytic anemia. Vaccine effects were postulated to occur in three successive intervals of 14 days duration. Interval lengths of 0 days (e.g., where no periods of vaccine risk occurred in an age group) are not shown

Patient	Age group	Period of vaccine risk (K)	Number of events (n_{ijk})	Interval length (e_{ijk})

8.7 Case-Specular Studies

Earlier discussions surrounding the study of exposures with intermittent effects and whose durations are transient have promoted a counterfactual paradigm as superior in conception and function to a study base paradigm in motivating the selection of a comparison series for cases experiencing a health outcome. This builds upon a conceptual framework that envisions the measurement of a unit-level effect as a causal contrast between an individual's outcome under one condition and what that individual's outcome would have potentially been under the absence of that condition. This contrast has been extended to population level effects as well: the contrast between the incidence of an outcome in an assemblage of individuals sharing some exposure and what the incidence of the outcome potentially would have been had the exposure been absent or its effect annulled.

With little effort, these principles can be extended to population studies in which sampling is based on outcome, rather than exposure. In an actual case-control study, antecedent exposure histories are compared with those from a control series drawn from a source population at risk. This can be juxtaposed with a "potential exposures" vision: controls should ideally reflect the potential distribution of exposure in the case series had any causal link been abolished prior to the outcome initiation.

In the context of the case-crossover study, this concept has a natural correspondence: comparing cases' proximate (relative to the incident outcome event) exposure history to the same cases' potential proximate exposure history in the absence of causation. Confounding by factors that are inherent time-invariant properties of the individual (e.g., genetic predisposition) becomes irrelevant because each individual's actual exposure, together with her/his counterfactual exposure, is analyzed as if from a matched pair in a unique stratum.

By adapting such reasoning to other settings, novel study design approaches become both possible and practical. One example is the residential case-specular method of studying the hypothesized causal relationship between wire codes (used as an indirect estimate of historical exposure to electromagnetic fields) and childhood cancers (Zaffanella et al. 1998). Wertheimer and Leeper (1979) initially promote the use of power line wire code categories, which are functions of wire thickness and distance from power lines to residences (Table 8.9). The use of wire codes as an imperfect surrogate for field measurements has a practical implication: household members need not participate for exposure measurements to be taken, which eliminates selection bias if voluntary enrollment is associated with wire code and allows for larger study population sizes (Ebi et al. 1999).

Unfortunately, use of wire codes has an important drawback: spatial proximity of power lines to residences is not only a proxy for exposure to electromagnetic fields but also can serve as a proxy for other characteristics, either unknown, unmeasured, or unmeasurable characteristics of neighborhoods, such as socioeconomic status, traffic congestion and air pollution, and environmental contamination. These may marginally or jointly have effects on health issues such as childhood leukemia. Therefore, any residential study of the electromagnetic field hypothesis would necessitate distinguishing two distinct, but not necessarily competing, effects: that of the electromagnetic fields and those other effects that are intrinsic characteristics of the neighborhood.

The case-specular design was conceived to mitigate the problem of distinguishing electromagnetic field effects, if any, from others that defied analytical control. The premise is that case residences with quantifiable wire code exposures could be contrasted with the potential wire code exposures of purely hypothetical (counterfactual) residences. In this design inception, the counterfactual residence is specular: an imaginary or virtual residence created by symmetrically (sagitally) reflecting a case residence across the center of its street, creating a matched case-specular pair (Fig. 8.4). Matched analyses of case-specular data with wire code exposures, with matching on residential street, should then distinguish potential

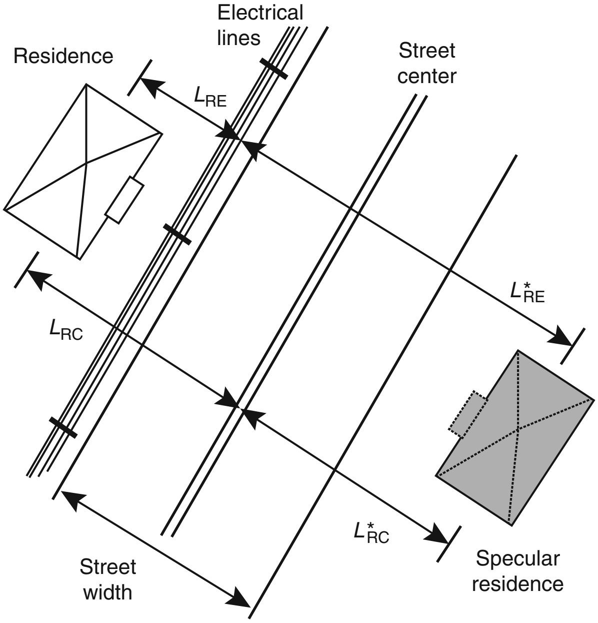

Fig. 8.4 Example of construction of a specular residence on a street with case residence on the same street side as electrical lines. Note that the distance from the residence to the center of the street, L_{RC}, is equal to the distance from the center of the street to the specular residence, L^*_{RC}. Also, L_{RE} = distance from the case residence to the electrical lines, while L^*_{RE} = distance from the specular residence to the electrical lines

effects of electromagnetic frequencies from the neighborhood "effect." Alternative speculars have also been proposed, including reflected images of power lines and translational or rotational movement of houses or power grids (Allard 1998).

Following the approach of Zaffanella et al. (1998), the distance from a case residence to the center of the street (L_{RC}) is used to create a specular control residence with an identical, albeit hypothetical, distance (L^*_{RC}). Two measurements are then taken to assist with determining exposure: the distance from the case residence to the electrical lines (L_{RE}) and what the distance from the specular control residence would be, had it existed, to the electrical lines (L^*_{RE}). The wire code category of the case residence (Table 8.12) can then be contrasted with the counterfactual wire code of the specular residence. The matching of this pair of residences is so spatially fine that, apart from potential discordance in wire code, it is plausible to assume that most if not all other environmental or social determinants of outcome are concordant within the matched pairs. If the wire code acts only as a surrogate for such neighborhood risk factors, then no residual association should exist between the higher current wire codes postulated to be related to cancer risk and case residence. The statistical analysis for this design is typical of those

Table 8.12 Wire code ordinal categories as described by Wertheimer and Leeper (1979) and Ebi et al. (1999)

Category[a]	Line class[b]	Distance to residence
UG	Not applicable	All distribution lines within 46 m (150 feet) are located underground
VLCC	6	End-pole situations
OLCC	5	Within 46 m (150 feet)
	4	Within 46 m (150 feet)
	1–3	From the OHCC upper distance to 46 m (150 feet)
OHCC	3	Within 15 m (50 feet)
	2	Between 7.5 and 19.5 m (25–64 feet)
	1	Between 15 and 39.5 m (50–129 feet)
VHCC	2	Within 7.5 m (25 feet)
	1	Within 15 m (50 feet)

[a] *VHCC* very high current configurations, *OHCC* ordinary high current configurations, *OLCC* ordinary low current configurations, *VLCC* very low current configuration, *UG* underground wiring

[b] Class 1 = transmission lines, three-phase primary distribution lines with thick wires or with multiple circuits; Class 2 = three-phase primary distribution lines with thin wires; Class 3 = long first span secondary distribution lines; Class 4 = second span secondary distribution lines; Class 5 = short first span secondary distribution lines; Class 6 = end-pole situations

for matched pair data (e.g., conditional logistic regression), with the polytomous exposures corresponding to the wire code categories.

Zaffanella et al. (1998) note, in contrast, that if the electromagnetic field hypothesis is correct, a preponderance of case households should occur on the same side of a street as power lines and that case residences should have, on average, higher wire codes than specular residences. Several assumptions are necessary for these predictions, if empirically found in a study, to have causal interpretation. The first, called "symmetry of the residence-specular probability matrix," implies probabilistic independence between placement of power lines and placement of residences on the sides of a street. The second assumption is an implicit "randomization" of residences on both sides of a street with respect to unmeasured, unmeasurable, or unknown confounders (analogous to the customary no-confounding assumption underlying causal interpretation of all non-experimental studies). The third assumption is no systematic misclassification of wire codes by residence type (case or specular), a problem that cannot be mitigated by blinding if only case residences are studied in situ. Differential misclassification may be a particular problem due to subjectivity in assigning wire codes to specular residences.

The case-specular method shares an advantage of neighbor-matched case-control studies: the control of confounding attributable to intrinsic properties of the neighborhood. It also enjoys an economical advantage of not requiring environmental measurements from a control group. It has the disadvantages of requiring the specification of speculars in unrealistic situations, high frequencies of concordant residence-specular pairs (particularly when power lines are located behind homes and uniform wire classes are used), and the inability to verify the assumption of symmetry of the residence-specular probability matrix without a validation control series. For further issues and caveats related to the analysis of case-specular and other forms of case-only (case-distribution) studies, and the incorporation of controls into the study (i.e., case-control-specular), see Greenland (1999).

8.8 Conclusions

The designs addressed in this chapter, all of relatively recent incarnation compared to their progenitor observational counterparts, should be appreciated less for their differences and more for their common lineage. These more recent designs are the evolutionary culmination of a long-held view that causal inference in populations is not fundamentally a comparison of individuals to each other, but is instead a collective comparison of single individuals to themselves. This view is rendered practical via the use of empirically derived or hypothetical exposure distributions, such as in case-crossover and case-specular studies, respectively, thus supplanting the need for an external comparison group. It seems inevitable that future advances in design, analysis, and efficiency will build upon this conceptualization. As epidemiologists employ these new designs and contrast them with older ones, the designs will undoubtedly undergo even greater scrutiny with respect to their assumptions and limitations. Such circumspection will particularly be necessary when conflicts in findings resulting from use of the different designs arise. These conflicts, however, should be regarded as the natural consequence of a progressive series of improvements in epidemiological methods that will inevitably lead to more valid assessment of potential causal relations.

Acknowledgements I would like to gratefully acknowledge the invaluable advice of the anonymous reviewer of the first edition of this chapter, who suggested numerous additional references and topics deserving greater attention, in turn helping to greatly improve its second edition.

9.1 Introduction

Most causes of premature death are avoidable. This is true not only of infectious diseases, but also a large proportion of cardiovascular diseases and cancer (Doll and Peto 1981). A major goal of public health is to find the causes of disease in a population and then intervene to remove them.

As discussed by Doll (2002), an agent may be considered to be a cause of a disease if increased exposure to the agent is followed by an increased risk of the disease and decreased exposure by a decreased risk. This is an empirical definition which may be tested without reference to a specific mechanism. It is particularly useful for chronic diseases, such as cancer, which may take decades to develop and in which the disease process may involve a variety of preclinical changes before the disease manifests itself. Intervention to remove a cause of disease may then range from behavioral changes, such as tobacco control (IARC 2007), to minimizing consequences of accumulated damages by, for example, regression of precancerous lesions using antioxidant vitamins (Stewart et al. 1996).

Descriptive and observational epidemiological studies have provided considerable evidence for causal relationships and have, in some instances, provided the final answer (Doll 2002). However, observational studies are not always sufficient to motivate large-scale public health interventions as they have some important limitations. Firstly, when relative risks of the order 2 or less are observed, it is difficult to rule out bias and confounding as possible explanations for the association. A second limitation of observational studies is that they rely on "experiments of nature" – unplanned variation in exposure within and between populations – and cannot therefore evaluate the effect of interventions that attempt to block the disease process in a way that is not found in nature. Two examples are a cholesterol-lowering drug (Heart Protection Study Collaborative Group 2002b) or a prophylactic vaccine against human papilloma virus (HPV) (Koutsky et al. 2002). Both of these interventions are motivated by a large body of observational evidence as well as understanding of the mechanism of disease. However, the magnitude of the benefit from intervention cannot be evaluated from observational data. The third limitation of observational studies is that it is very difficult to balance the benefits of intervention against possible risks. Finally, observational data do not always provide evidence that exposure to an agent preceded incidence, which is a requirement for establishing causality. All of these limitations can be overcome by a properly conducted intervention trial. An intervention trial is an experiment to evaluate the efficacy of an intervention so that its more widespread use can be justified.

Intervention trials ideally take the form of a randomized controlled trial (RCT) in which the intervention is compared with a control and the allocation to treatment or control is randomized. The control may be a placebo or an alternative intervention. RCTs are often used for *therapeutic trials* in which different treatments for a given disease are compared in a clinical setting. This application of RCTs is beyond the scope of this chapter, which is concerned with trials on healthy or apparently healthy individuals with the aim of preventing future morbidity or mortality. We refer to such trials as *preventive trials*.

Since RCTs offer a unique opportunity to eliminate the problems that beset observational studies, the results of such trials are generally considered to be a "gold standard," and are often taken to outweigh previous observational evidence in the case of discordant results. However, the advantages of RCTs are easily lost through poor conduct or analysis. Hence, RCTs are held to much higher standards of conduct and reporting (see Sect. 9.1.1).

9.1.1 Guidelines for Reporting of Clinical Trials: The CONSORT Statement

The CONSORT (Consolidated Standards of Reporting Trials) statement is a set of guidelines for reporting of RCTs (http://www.consort-statement.org). These guidelines take the form of a checklist of 22 items (see Table 9.1) which should be included in a report of a randomized trial and a model flow chart to show the flow of participants through the trial (see Fig. 9.1).

The guidelines were created by an international group of clinical trialists, statisticians, epidemiologists, and biomedical journals in an effort to improve the quality of reporting of RCTs, which several reviews had shown to be inadequate. Without adequate reporting, it is not possible for a reader to judge the quality of a trial and so trust its conclusions.

The original CONSORT statement was published in 1996 (Begg et al. 1996). It was revised in 2001 and is available in a short form (Moher et al. 2001) and a long form with explanation and elaboration (Altman et al. 2001). The guidelines have been adopted by a growing number of biomedical journals and editorial committees.

9.2 Therapeutic Versus Preventive Trials

The methodological considerations for therapeutic and preventive trials are very similar. In particular, in the last two decades, therapeutic trials have grown in size. Some therapeutic trials have been able to randomize many thousands of individuals in studies of breast cancer (Early Breast Cancer Trialists' Collaborative Group 1998), heart disease (ISIS-2 (Second International Study of Infarct Survival) Collaborative Group 1988), and stroke (CAST (Chinese Acute Stroke Trial) Collaborative Group 1997). In this chapter, we will rely heavily upon the experience gained in the performance of therapeutic trials. (For details on prevention in general, please refer to chapter ►Screening of this handbook.)

Although there is no clear dividing line between therapeutic and preventive trials, a crucial factor distinguishing the two kinds of trial is the "exposure window." In a therapeutic trial, the timing of an intervention is determined by a disease indication. In a prevention trial, the intervention may take place at any point along a disease process that may last several decades. The appropriate timing of the intervention is not always evident. Often, the decision on when to intervene is

Table 9.1 Checklist of items to include when reporting a randomized trial (Source: http://www.consort-statement.org)

Paper section and topic	Item	Description
TITLE AND ABSTRACT	1	*How participants were allocated to interventions* (e.g., "random allocation," "randomized," or "randomly assigned")
INTRODUCTION		
Background	2	*Scientific background and explanation of rationale*
METHODS		
Participants	3	*Eligibility criteria for participants and the settings and locations where the data were collected*
Interventions	4	*Precise details of the interventions intended for each group and how and when they were actually administered*
Objectives	5	*Specific objectives and hypotheses*
Outcomes	6	*Clearly defined primary and secondary outcome measures* and, when applicable, any *methods used to enhance the quality of measurements* (e.g., multiple observations, training of assessors)
Sample size	7	*How sample size was determined* and, when applicable, *explanation of any interim analyses and stopping rules*
Randomization – sequence generation	8	*Method used to generate the random allocation sequence*, including *details of any restriction* (e.g., blocking, stratification)
Randomization – allocation concealment	9	*Method used to implement the random allocation sequence* (e.g., numbered containers or central telephone), clarifying whether the sequence was concealed until interventions were assigned
Randomization – implementation	10	*Who generated the allocation sequence, who enrolled participants, and who assigned participants to their groups*
Binding (masking)	11	*Whether or not participants, those administering the interventions, and those assessing the outcomes were blinded to group assignment.* When relevant, *how the success of blinding was evaluated*
Statistical methods	12	*Statistical methods used to compare groups for primary outcome(s); methods for additional analyses*, such as subgroup analyses and adjusted analyses
RESULTS		
Participant flow	13	*Flow of participants through each stage* (a diagram is strongly recommended). Specifically, for each group report the numbers of participants randomly assigned, receiving intended treatment, completing the study protocol, and analyzed for the primary outcome. *Describe protocol deviations from study as planned, together with reasons*

(continued)

Table 9.1 (Continued)

Paper section and topic	Item	Description
Recruitment	14	*Dates defining the periods of recruitment and follow-up*
Baseline data	15	*Baseline demographic and clinical characteristics of each group*
Numbers analyzed	16	*Number of participants (denominator) in each group included in each analysis and whether the analysis was by "intention-to-treat."* State the results in absolute numbers when feasible (e.g., 10/20, not 50%)
Outcomes and estimation	17	*For each primary and secondary outcome, a summary of results for each group, and the estimated effect size and its precision* (e.g., 95% confidence interval)
Ancillary analyses	18	*Address multiplicity by reporting any other analyses performed*, including subgroup analyses and adjusted analyses, indicating those prespecified and those exploratory
Adverse events	19	*All important adverse events or side effects in each intervention group*
DISCUSSION		
Interpretation	20	*Interpretation of the results*, taking into account study hypotheses, sources of potential bias or imprecision, and the dangers associated with multiplicity of analyses and outcomes
Generalizability	21	*Generalizability (external validity) of the trial findings*
Overall evidence	22	*General interpretation of the results in the context of current evidence*

determined by the practical requirement to have a sufficient number of cases of disease in the control group by the end of the trial. This limits interventions to individuals who are at high risk, either because they have long-term exposure to known risk factors or because they have advanced preclinical disease. Examples of such trials are the prevention of recurrence of colorectal adenomas (Bonithon-Kopp et al. 2000; Jacobs et al. 2002) and prevention of lung cancer in middle-aged heavy smokers or workers exposed to asbestos (Omenn et al. 1996a; ATBC (Alpha-Tocopherol Beta Carotene) Cancer Prevention Study Group 1994). The paradox of such late interventions, however, is that they may miss the "exposure window" within which the intervention may possibly have a protective effect.

9.2.1 Surrogate Endpoints

It is difficult to conduct intervention trials using disease endpoints, such as cancer, that are rare or have a long latency. Such studies may require very large numbers,

or long follow-up time, or both in order to yield a sufficient number of cases to judge the efficacy of the intervention. One possible strategy to overcome this problem is to use a surrogate endpoint – a short term marker of the disease process – as a substitute for a hard endpoint such as disease incidence or death. For example, a prophylactic vaccine against human papilloma virus given during adolescence is intended to prevent occurrence of cervical cancer in middle age, but its efficacy was evaluated using precancerous endpoints (cervical intraepithelial neoplasia grade 2, grade 3, and adenocarcinoma in situ) (Future II Study Group 2007). It should be noted that cervical cancer is preventable, in the absence of a vaccine, by screening. Hence, it would not be ethical to use cervical cancer as an endpoint.

The promise of surrogate endpoints is that they may make intervention trials smaller, faster, or cheaper. Despite the attractiveness of this promise, the use of surrogate endpoints is fraught with difficulty. Schatzkin and colleagues have,

Table 9.2 Phases of intervention trials

Phase	Aims	Comment
I	Route of administration and dosage: maximally tolerated dose by using a dose escalation scheme	Often on volunteers
II	Evidence of "activity" of our intervention by means of "promising" outcome measures	Better randomized than not
III	Efficacy of an intervention by means of randomized comparisons and a "definite" endpoint	
IV	Effectiveness of proven interventions in wide-scale use, sometimes through post-marketing surveillance	Better randomized than not

in a series of articles, reviewed the problems of using surrogate endpoints in cancer research (Schatzkin et al. 1990, 1996; Schatzkin and Gail 2002). They suggest that there are currently only two clear candidates for surrogate endpoints in cancer research: prevention of HPV infection for subsequent cervical cancer and prevention of colorectal adenomas for subsequent colorectal cancer. Apart from these two examples, they suggest that surrogate endpoints may have more use in phase II trials than phase III trials (for a definition of phase II and phase III trials, see Table 9.2).

The problem of validation of surrogate endpoints is an area of active statistical research. In a seminal paper, Prentice (1989) suggested the following definition of a valid surrogate: it must yield a valid test of the null hypothesis of no association between treatment and the true response. In operational terms, this means that the incidence rate of the true disease must be independent of the treatment history given the current value of the surrogate endpoint. Prentice's criterion is too restrictive to be satisfied in practice as it requires the effect of the treatment on the disease outcome to be mediated entirely through the surrogate endpoints. Some attempts have been made to broaden the definition of a surrogate endpoint by quantifying the proportion of treatment effect explained by a surrogate (Freedman et al. 1992), but this extension has not been widely accepted. A summary of current research is given by the report of an NIH (US National Institutes of Health) workshop on surrogate endpoints (De Gruttola et al. 2001).

9.2.2 From Observation to Intervention

Whereas the choice of intervention in a prevention trial is often suggested by observational studies, the intervention may be a radical simplification of those observations. This is especially true in nutritional epidemiology (see chapter ▶Nutritional Epidemiology of this handbook) in which chemoprevention (e.g., administration of specific vitamins) has often been used as a substitute for dietary modification. This simplification involves an extra level of extrapolation – above issues of timing, dose, and duration – which makes the results of such studies particularly hard to interpret when they contradict observational studies.

Intervention studies can sometimes produce results suggesting that a treatment is harmful, increasing the risk of disease instead of decreasing it. The most notorious example is the use of beta-carotene supplements to prevent lung cancer (see Example 9.1).

Example 9.1. Beta-Carotene and lung cancer: An unexpected harmful effect of treatment

One of the most consistent findings in nutritional epidemiology is the protective effect of fresh fruit and vegetable consumption on cancer risk (World Cancer Research Fund – American Institute for Cancer Research 1997). Peto et al. (1981) put forward the hypothesis that beta-carotene was the active agent responsible for this protective effect, and subsequently a number of cancer chemoprevention trials were conducted using supplementation with beta-carotene as an intervention. The ATBC (The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study Group 1994) and CARET (Omenn et al. 1996b) trials were two large chemoprevention trials using beta-carotene in men at high risk of lung cancer, i.e., long-term heavy smokers (ATBC/CARET) or asbestos-exposed workers (CARET). The ATBC trial showed a higher incidence of lung cancer among participants receiving beta-carotene compared with those who did not with a relative risk of 1.6 (95% confidence interval CI: 1.02–1.33). Subsequently, the intervention with beta-carotene in the CARET study was stopped 21 months early, after a median of 3.7 years of follow-up because of clear evidence of no benefit and substantial evidence of possible harm. The actively treated group had a relative risk of lung cancer of 1.28 (95% CI: 1.04–1.57) compared with the group receiving placebo. The results of the Physicians' Health Study (PHS) were published at the same time (Hennekens et al. 1996) and showed no effect of beta-carotene on lung cancer risk, with 82 cases of lung cancer in the beta-carotene group and 88 in the placebo group. However, the PHS had low power to detect small changes in lung cancer risk due to the small number of cases.

The trials of beta-carotene relied on a number of extrapolations from observational data. The first extrapolation was that beta-carotene was the active agent in the protective effect observed for fresh fruits and vegetables. Although direct associations with plasma levels of beta-carotene have also been observed, it may be that beta-carotene is acting as a marker for fresh fruit and vegetable consumption and is not the active agent. The second extrapolation concerns the dose level. The dose of beta-carotene given and the median serum beta-carotene concentration achieved in these studies exceeded by many times the level that could be achieved by normal dietary intake (IARC 1998), and it is possible that beta-carotene becomes harmful at such high doses, while remaining protective at doses associated with a healthy diet. Last, but not least, it was assumed that high-risk, middle-aged, individuals, who probably harbored premalignant lesions in the lung, would benefit from the same active substances that were believed to be beneficial in the prevention of early stages of carcinogenesis.

When planning an intervention study, it may be a useful exercise to consider the possible interpretations of adverse effects of treatment. This thought experiment may reveal weaknesses in the motivation for, or design of, the intervention study.

9.3 The Origin of Randomized Trials

The technique of randomization was originally developed in agricultural experiments in the 1920s when individual plots of land were randomized. Trials in humans strictly controlled by random allocation date back to the mid-1940s. Many of the earliest trials were carried out in Britain by the Medical Research Council (Hill 1962). The first trial in which treatment was randomly allocated to individuals, although not the first to be reported (Doll 1998), was a prevention trial designed to test the efficacy of immunization against whooping cough (Medical Research Council Whooping-Cough Immunization Committee 1951). Parents of children aged 6–18 months were asked to volunteer to have their children entered into the trial. They were given a pamphlet describing the study, which included the information that half the inoculations would not be against whooping cough but would be "anti-catarrhal." No child was entered until a parental consent form had been signed.

The spread of randomization, until it became an essential requirement for the licensing of new drugs, was initially slow and not without opposition. Many clinicians considered randomization to be less worthy than the use of criteria to distinguish between individuals who will and will not respond to the intervention. There is currently no competing methodology for randomized controlled trials, although there are attempts to adapt the design and analysis to special contexts and difficulties such as outcomes that are extended in time and trials with informative dropout (Lavori and Kelsey 2002).

9.4 Planning of Trials

Trials are traditionally classified into four phases (Table 9.2). In this chapter, we will be dealing only with issues related to phase III and phase IV randomized trials. For design issues of phase I and phase II trials, readers are referred elsewhere (Simon 2001).

The organization of a trial requires careful advance planning. This is particularly true for multicentric trials, which have become increasingly common. The aims and methods of the trial should be described in detail in a protocol document. This will contain the scientific background of the problem under study. In topics where a substantial amount of work has already been done, a systematic review (meta-analysis, see chapter ▸Meta-Analysis in Epidemiology in this handbook) of the outcomes of published randomized trials on the same type of intervention is highly preferable to a narrative review. A meta-analysis will, in fact, greatly help to evaluate the consistency of the methods and results of previous work, any avoidable pitfalls in study design, and the most likely effectiveness of the intervention under study. The latter information allows the sample size for the trial to be calculated (see chapter ▸Sample Size Determination in Epidemiological Studies of this handbook). The protocol should also include clear statements about (1) preventive measures to be used (both intervention and control); (2) types of individuals or groups to be admitted (participants); (3) assessment of response (endpoints); (4) entry criteria and treatment allocation; (5) exclusions, withdrawals, and protocol departures; (6) size and duration of the trial; (7) strategy for the statistical analysis; and (8) ethical aspects.

When the protocol has been written, information about the trial design should be deposited into a clinical trials registry before the onset of patient enrollment. The World Health Organization sets standards for clinical trial registries through the International Clinical Trials Registry Platform (http://www.who.int/ictrp). It stipulates a list of 20 items that must be given for a trial to be considered fully registered.

The International Committee of Medical Journal Editors has stipulated a policy requiring preregistration as a requirement for publication of a trial's findings (DeAngelis et al. 2004). This policy is designed to prevent selective reporting of trial outcomes. However, a recent systematic review shows that preregistration of trials still poorly adhered to Mathieu et al. (2009).

9.5 Definition of the Intervention

The effectiveness of interventions to be compared in randomized primary prevention trials are usually known in broad terms from the outset. Many questions of primary prevention have first been evaluated in trials of treatments or secondary prevention. For example, the Physicians' Health Study (Steering Committee of the Physicians' Health Study Research Group 1989) demonstrated that a daily low-dose (325 mg) aspirin reduced the risk of first myocardial infarction by 44%. But when the trial was begun, there was already substantial statistical evidence for the preventive efficacy of aspirin from secondary prevention trials of those who had already experienced a cardiovascular event (ISIS-2 (Second International Study of Infarct Survival) Collaborative Group 1988). Similarly, the suggestion to use tamoxifen or the new selective estrogen receptor modulators (e.g., raloxifene) in the primary prevention of breast cancer came from the observation that tamoxifen reduced the incidence of contralateral breast cancer when used as an adjuvant therapy in women with breast cancer (Early Breast Cancer Trialists' Collaborative Group 1998). Such previous experiences in "diseased" people have generally established a "safety profile" and enabled exclusion or estimation of side effects that occur once in thousands (if not necessarily in ten thousands) of recipients of a certain type of treatment. Other times, when the intervention consists in behavioral changes, prior evidence for the benefits of certain lifestyle modifications (e.g., smoking cessation, dietary changes, adoption of safe sex behavior) has come from a consistent body of knowledge on risk factors accumulated in a large variety of contexts (e.g., ecological studies, studies of observational epidemiology or, as it is the case for some infectious agents, clear knowledge on the routes of transmission of the infections).

Based on this background knowledge, two major questions need to be addressed in order to identify unambiguously the type of intervention study. The first question concerns what is being compared with what. The basic design for primary prevention trials is a two-arm comparison. As discussed by Green (2002), however, this simple structure can encompass a variety of different comparisons, as shown in Table 9.3.

Table 9.3 Possible types of comparison in intervention trials

Intervention vs	No intervention
	Placebo
	Another intervention
	Same intervention at a different dose (or duration)
	Same intervention, but later (only for participants who experience a certain event)

The feasibility and necessity to include a placebo arm depend on the nature of the intervention and of the outcome measure. When two drugs are being compared, it is generally easy to create a placebo, provided that the route of administration is an oral one. In therapeutic trials, the use of a non-active compound has caused ethical concerns. A comparison of new treatment with old treatment is often more appropriate. As noted by Temple and Ellenberg (2000), however, placebo controls are ethical if there are no permanent adverse consequence of delaying or omitting available treatment and if the participants are fully informed about their alternatives. These favorable conditions typically apply to preventive trials. For intra-muscular treatments (e.g., vaccines), the use of one or more "dummy injections" is hard to justify. It has, however, been advocated in special circumstances. In a randomized trial of a prophylactic vaccine against HPV type 16, a sexually transmitted virus which is now considered a necessary cause of cervical cancer, three injections of the aluminum adjuvant used in the active vaccine were deemed justifiable in order to avoid possible imbalances in the sexual behavior of the young female participants and to evaluate side effects attributable to the active agent (i.e., virus-like particles) (Koutsky et al. 2002). Indeed, the percentage of women who discontinued the study owing to an adverse effect of treatment (0.4%) was the same in the vaccine arm and the placebo arm (Koutsky et al. 2002).

One way to avoid the use of placebo is to compare different doses or durations of a specific intervention. This is typically feasible when some type of drug or dietary supplement, whose minimal effective dose is unclear, is under evaluation. More frequently, however, in prevention trials, it is the intensity of the intervention that can be modulated. In behavioral intervention trials, it is often very useful to compare a labor-intensive and expensive package for smoking cessation or dietary changes with some simple and inexpensive message at a community or individual level (e.g., pamphlets, simple recommendations from a general practitioner, etc.).

Finally, the timing of the intervention can be randomized into an early versus delayed intervention trial. This approach is very often indicated in therapeutic trials (e.g., chemo- or radiotherapy at primary cancer diagnosis vs the same therapy at cancer recurrence), but it has some appeal in certain prevention trials as well. An example is provided by cervical cancer screening, which is currently based on use of the Papanicolaou (Pap) smear to detect abnormal cells that may indicate precancerous lesions on the cervix. The majority of such lesions regress without intervention, but a few may progress to cervical cancer over the course of several years. HPV testing is now considered a more sensitive test than Pap smear in the detection of precancerous lesions (Cuzick et al. 2000). Its use is already approved in the triage of cytological abnormalities. Thus, an appropriate design for testing the efficacy of HPV testing in cervical cancer screening would be to use Pap smear in both arms and compare the concurrent use of HPV testing and Pap smear in one arm with delayed HPV testing in the other arm among women with abnormal Pap smear findings.

9.6 Factorial Design

The factorial design represents an efficient alternative to two-arm comparisons. The simplest design is the balanced 2×2 factorial but factorial designs can be generalized to more than two dimensions (Table 9.4). In a factorial design, two or more interventions are simultaneously tested in the same population. Allocation of interventions is carried out in such a way that there is no association between different interventions in the study population, and therefore no confounding, under the assumption that there is no interaction between interventions. As noted by Armitage and Berry (1987), this design contravenes a good principle of experimentation, namely, that only one factor should be changed at a time. The principal advantage of the factorial design is its ability to answer two or more questions in a single trial.

Table 9.4 Illustration of the factorial design with 8,000 participants and three possible treatments. As the number of treatments simultaneously under test increases, the number of participants receiving each combination of treatment diminishes, but the number receiving any given treatment (e.g., treatment A) is always 4,000

	Number of	Treatment		
Arm	participants	A	B	C
Two arm trial of treatment A				
1	4,000	Yes		
2	4,000	No		
2 × 2 trial of treatments A and B				
1	2,000	Yes	Yes	
2	2,000	Yes	No	
3	2,000	No	Yes	
4	2,000	No	No	
2 × 2 × 2 trial of treatments A, B and C				
1	1,000	Yes	Yes	Yes
2	1,000	Yes	Yes	No
3	1,000	Yes	No	Yes
4	1,000	Yes	No	No
5	1,000	No	Yes	Yes
6	1,000	No	Yes	No
7	1,000	No	No	Yes
8	1,000	No	No	No

In a recent trial of 20,536 UK adults with occlusive arterial disease or diabetes (Heart Protection Study Collaborative Group 2002a, b), participants were randomly allocated in a factorial design to receive 40 mg of simvastatin (a cholesterol-lowering agent) or placebo, and antioxidant vitamin supplementation or placebo. These two interventions seemed to be, at the time the study was started, equally promising. It would have been possible to evaluate the two interventions separately in two independent trials, but this would have required twice the sample size, or over 40,000 participants. A highly significant 18% proportional reduction in the coronary death rate was found among participants who had received simvastatin. This beneficial effect was reflected also in an overall mortality reduction compared to the placebo group. Conversely, antioxidant vitamins did not produce any significant reduction in the 5-year mortality from, or incidence of, any type of vascular disease, cancer, or other major outcome. An asset of the factorial design is also the opportunity to evaluate interactions, i.e., whether two interventions in combination differ, with respect to efficacy or side effects, from either intervention alone. In the HPSCG trial, for instance, the efficacy of simvastatin was not modified by antioxidant vitamins.

The factorial design, on account of the corresponding gain in cost efficiency, is especially valuable in prevention trials that are, on average, much larger than therapeutic trials. A factorial design is often excluded out of fear of complicating trial operations. In fact, the randomization process can be easily adapted to allocate participants to different combinations of interventions. As mentioned by Buring (2002), it is, however, essential that none of the interventions under evaluation (1) complicates eligibility criteria by, for instance, important contraindications for certain interventions or (2) causes any side effect that could lead to poor compliance or loss to follow-up.

9.7 Definition of Participants

Eligibility criteria in intervention studies must aim at three things: (1) optimizing the potential benefit to the participants while minimizing the risk of adverse effects, (2) enrolling participants who are likely to adhere to the intervention and follow-up requirements, and most importantly (3) including a sufficiently large number of participants to produce unambiguous results even if the benefit of the intervention is small. In many types of trials, but especially in preventive trials, broad eligibility criteria are desirable because they can simplify enrolling procedures and avoid the need for complicated and expensive tests at study entry (see Box 9.1). They also increase the generalizability of the results.

A “run-in” period can be implemented to allow potential participants who have difficulties adhering to the protocol to withdraw prior to randomization. As discussed by Buring (2002), the format of the run-in period depends on the nature of the trial. In trials of pill-taking regimens, as in the HPSCG (Heart Protection Study Collaborative Group 2002a, b) factorial trial of simvastatin and antioxidant vitamins, the run-in period involved a few-week period of placebo to allow review of blood exams, followed by a few weeks of active treatment to allow a pre-randomization assessment of LDL (low-density lipoprotein)-lowering responsiveness of each individual and to exclude major adverse effects. In studies of behavioral interventions, the run-in period may consist of attendance at visits

Box 9.1. Large, simple randomized trials

Many lives could be saved by moderate reductions in the common causes of death.

In a series of articles, Peto and colleagues (Collins et al. 1987; Peto et al. 1995; Peto and Baigent 1998; Yusuf et al. 1984) have promoted the idea of large, simple randomized trials to investigate the benefits of widely practicable treatments for common conditions. The essence of their argument is that only large, randomized trials can answer questions about moderate health benefits in a way that is free of bias and the play of chance. Moderate reductions in mortality may correspond to a large number of deaths prevented if the condition is common and the treatment is widely available. For example, 100,000 deaths per year could be prevented or substantially delayed in developed countries by routine use of antiplatelet therapy in all patients with clinical evidence of occlusive vascular disease. This reduction corresponds to a 10% reduction in all vascular deaths in the age range 35–69 (Antiplatelet Trialists' Collaboration 1994).

Examples of the large randomized trials promoted by Peto and colleagues include the ISIS (International Study of Infarct Survival) trials (ISIS-1 (First International Study of Infarct Survival) Collaborative Group 1986; ISIS-2 (Second International Study of Infarct Survival) Collaborative Group 1988; ISIS-3 (Third International Study of Infarct Survival) Collaborative Group 1992; ISIS-4 (Fourth International Study of Infarct Survival) Collaborative Group 1995) in which tens of thousands of participants were randomized. The need to randomize such large numbers of subjects imposes some design constraints on the trial. In particular, the entry criteria, treatment, and data requirements must all be greatly simplified. In order to simplify the entry criteria into large trials, Peto et al. (1995) have proposed an "uncertainty principle," which states that the sole eligibility criterion for entry is that both patient and doctor should be substantially uncertain about the appropriateness for this particular patient of each of the trial treatments (a more complete statement is given by Peto and Baigent (1998)). Broad eligibility criteria can simplify enrolling procedures and avoid the need for complicated and expensive tests at study entry.

The principle of conducting large, simple randomized trials is not appropriate for the development of novel drugs. In this context, an extensive regulatory framework has developed, which is summarized by the guidelines of the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (http://www.ich.org).

or laboratory procedures, including completion of forms similar to those that would be used in the actual trial. Restricting a prevention trial to proven good compliers may result in a pool of participants that differs from the general population with respect to outcomes. This problem may be perceived as a loss of external validity or generalizability of trial findings. As noted, however, by Hennekens and Buring (1998), the primary requirement of a generalizable study is internal validity, which may in fact be increased by the exclusion of poor compliers.

A more practical way to improve the generalizability of the results of a trial is to broaden eligibility criteria as much as possible, thus allowing the benefits of trial participation to be available more widely across populations. In the HPSCG study, for instance, substantial benefit was demonstrated not only in those already known to have had coronary disease, but also in those without diagnosed coronary disease who had cerebrovascular disease, peripheral arterial disease, or diabetes, irrespective of the blood lipid concentrations when treatment was initiated. Widespread implementation of these findings on the basis of some clinical diagnoses would therefore be relatively straightforward, without the need for extensive screening in the general population. Finally, broad eligibility criteria can also allow to enroll a larger number of participants and, in some instances, some cautious subgroup analysis.

An eligibility criterion which, however, allows substantial efficiency gain, and which must therefore be seriously considered, is high risk for the disease meant to be prevented. Age, sex, or family or personal history might be considered to identify such individuals. Since the power of the study is proportional to the number of endpoints, not simply to the number of participants enrolled, an intervention study which includes high-risk individuals will be small and of shorter duration (and, as a consequence, cheaper and likelier to be accomplished) than a study which includes lower risk participants. The demonstration of a benefit among those with high-risk characteristics will have to be applied, however, with great caution to a more heterogeneous population.

9.8 Enrollment

Enrollment of thousands participants in prevention trials is a major challenge and deserves to be monitored carefully. Since prevention trials do not require diseased people, they rarely use hospitals as sources of participants. Outpatient clinics are, however, used in some secondary prevention studies.

A preliminary question in community-based enrollment is whether trial participants can be volunteers, provided they meet the eligibility criteria and can be recruited in the required number or whether it is necessary to extend an invitation to join the study to all eligible persons in a predefined area. If the former applies, local media, pamphlet distribution, and direct contacts with special associations can be used in order to invite as many participants as required. In the previously mentioned trial of a vaccine against HPV 16, for instance, young women were recruited in the United States through advertisements on college campuses and in the surrounding communities (Koutsky et al. 2002). In order to diminish the probability of enrolling women who were infected with HPV16, only women who reported that they had no more than five male sex partners during their lifetime were eligible for participation. Obviously, when participants are volunteers recruited from a population or subpopulation that has not been enumerated, it will be impossible to evaluate accurately the fraction of the persons who eventually opted for participating in the trial, let alone any difference between participants and non-participants. This approach is, however, the only possibility when participants are defined according to lifestyle characteristics (e.g., current smoking habit, overweight, sleeping disorders, sexual habits, etc.) that cannot be derived from administrative records.

In other instances, however, it may be important to have access to the entire list of the population of a predefined area and to make an effort to achieve, as much as possible, high participation or, at least, to estimate the participation fraction. This is necessary when the results of the trial must be generalizable to the whole of the host population and in particular when the trial must include certain subgroups. In developed countries, complete and fairly well updated population lists exist, such as censuses, electoral rolls, and general practitioners' lists. In the latter case, a direct involvement of general practitioners in the recruitment of their own patients is known to improve the yield of participants (Knatterud 2002).

In most developing countries, especially in the many areas where substantial migrations from rural to urban areas are ongoing, reliable population lists are seldom available, and a door-to-door enumeration of the target population of the trials is generally a prerequisite of the recruitment exercise. The complete enumeration of the target population is especially important in the evaluation of interventions such as immunization programs or screening programs, where a good coverage is essential for the efficacy of the intervention. The participation fraction (i.e., the acceptance of the intervention) becomes part of the evaluation of the intervention under study.

9.9 Randomization

An eligible participant should be admitted formally to the trial, by entry of his or her name into a register and the allocation of a unique identification number. The random allocation of the intervention should be determined after entry or a run-in period. The fundamental reason for random allocation is to maximize the likelihood that participants with similar characteristics will be allocated in similar proportions to the different interventions being investigated. The decision to enter a participant must be made irreversibly regardless of which trial arm the participant will be allocated. This precludes systematic allocation systems and discourages easily guessable coding systems, such as one in which an active intervention is coded as A and the placebo as B, which may lead to unblinding of the study. The bias inherent in non-randomized studies may be more severe in therapeutic trials (where diseased patients can differ substantially according to prognostic factors, at least in the clinician's opinion) but is not negligible in preventive trials as well.

A common allocation technique, discussed by Knatterud (2002), is to generate a separate randomization schedule for each of the trial sites and, within each site, to have some blocking so that, after a fixed number of participants enrolled, there will be equal numbers assigned to each trial arm. It is advisable to make smaller blocks at the beginning, when the enrollment capacity of trial sites is unknown. Ideally, there should be a central office where the randomization is carried out and which enforces good record keeping and adherence to the protocol. A telephone call to the randomization office can include some verification of the patients eligibility before randomization. With current technology, it is possible to implement an automated menu-driven telephone system that is available 24 h a day, 7 days a week (Heart Protection Study Collaborative Group 2002b). Elaborate "stratification" schemes in which a separate randomization block is made for participants with different characteristics are not encouraged in large trials (Peto et al. 1976). Proper statistical methods (see chapter ▸Regression Methods for Epidemiological Analysis of this handbook) can make due allowance, when comparing interventions, for what was initially known about each participant.

9.10 Cluster Randomization

Interventions in communities or other groups have frequently been investigated without using randomization. Longitudinal studies of the health consequences of water fluoridation (Horowitz 1996) and initial cardiovascular disease prevention studies such as the North Karelia Project (Puska et al. 1976) provided early evidence that community-level health interventions could benefit large groups of individuals. However, non-randomized community intervention trials may be confounded by secular trends. For example, in the two studies cited above, the incidence of dental caries and cardiovascular disease may have diminished due to widespread use of fluoridated toothpaste and improvements in the treatment of hypertension, respectively.

The use of randomization is, therefore, just as important for community trials as for individual-level studies, but it is not appropriate to randomize individuals when the intervention is defined at the group level. Instead, groups of individuals or "clusters" are randomized. A cluster may be defined geographically (e.g., cities, countries, villages) or otherwise (e.g., workplaces, schools, clinical practices) (Atienza and King 2002). Cluster randomization can also avoid the potential for contamination between interventions, which may occur in individually randomized trials if the intervention involves education or behavior modification. Furthermore, cluster randomization by village improves the chances of long duration follow-up in developing countries where personal identifiers, such as name and date of birth, are unreliable (Gambia Hepatitis Study Group 1987), but strong community links exist.

The main consequence of randomizing clusters is that the outcomes for trial participants in the same cluster are no longer independent. This lack of independence has implications for both analysis and design. The analysis of the study must take into account the presence of the clusters (for a detailed discussion of cluster randomized trials, see also chapter ▸Cluster Randomized Trials of this handbook).

Various techniques for doing so are reviewed by Donner (1998). If the clustering effect is ignored, as in 70% of cluster trials reviewed by Divine et al. (1992), p-values will be too small and exaggerate the statistical significance of the results. Likewise, confidence intervals will be too narrow. Even if a correct statistical analysis is used, the power of a cluster randomized trial is reduced compared to an individually randomized trial. When the outcome of the trial is the mean of a continuous variable (e.g., serum cholesterol level), the increase in sample size needed to maintain the same power as an individually randomized study is given by the formula $1 + (m - 1)r$, where m is the number of participants per cluster and r is the intracluster correlation coefficient (Kerry and Bland 1998), which measures the proportion of variation of the outcome in the study population that is due to differences between clusters. Typical values of r are very close to zero, but when the number of participants per cluster (m) is large, there may be a serious loss of efficiency compared with an individually randomized study.

A large number of clusters also increases the possibility that the randomization will produce balanced intervention groups compared to trials where a small number of clusters has been randomly allocated. "Restricted randomization" after matching or stratifying communities according to selected factors has been attempted. In the Community Intervention Trial for Smoking Cessation (COMMIT Research Group 1991), for instance, investigators examined 11 pairs of communities that were matched on sociodemographic factors. Matching is only justified for variables that are strongly related to the outcome of interest (Klar and Donner 1997). The same principle applies to sampling of controls in observational studies (see chapter ▸Case-Control Studies of this handbook).

Notwithstanding unsolved issues, cluster design can greatly contribute to the evaluation of preventive strategies and methodological advances should be pursued.

9.11 Outcomes

In the design of prevention trials, a distinction is generally made between primary and secondary outcomes (Anderson and Prentice 1999). The primary outcome is typically the clinical disease to be prevented or controlled that provides the central justification for the trial and determines the study size. Secondary outcomes are disease events that also motivated the trial, but that by themselves would be unlikely to justify a full-scale intervention.

The outcome measurements could be influenced by a knowledge of which intervention was used, thus producing serious bias. In a single-blinded trial, the identity of the allocated treatment is concealed from the participants. A double-blinded trial is one in which the doctor, or other technical expert, who assesses response also is unaware of the intervention identities. As discussed by Green (2002), it may not be desirable to extend blinding to the independent data and safety monitoring board (DSMB). The DSMB, as often stated in the participant's consent form, is the watcher of accumulating data and needs, therefore, to be aware of the allocation.

Unlike therapeutic trials, large prevention trials cannot rely on outcomes that require frequent clinical visits for specialized tests or potential adverse reactions. Indeed, the safety of any intervention has to be documented before the planning of any large preventive trial. Furthermore, even if participants in preventive trials are selected on the basis of elevated risk for the diseases that are targeted for the prevention, primary outcome events may constitute a small minority of the disease events experienced by study participants during the course of the trial and perhaps even a small minority of disease events that may in some way be affected by intervention activities. Hence, there is an obligation to define sets of outcomes to be fully ascertained, including often overall mortality, that provide an opportunity to assess the overall risks and benefits in the target population.

The International Breast Cancer Intervention Study (IBIS-I), for instance, was a double-blind placebo-controlled randomized trial of tamoxifen, 20 mg/day for 5 years, in 7,152 women at increased risk of breast cancer (IBIS Investigators 2002). The primary outcome measure was the frequency of breast cancer, but outcomes other than breast cancer were found to be very important, too. A 32% reduction (95% CI: 8–50%) in the primary outcome was found. It was accompanied, however, by a 2.5-fold increase (95% CI: 1.5–4.4) in thromboembolic events. Eventually, a significant excess of deaths from all causes was observed in the tamoxifen group (25 vs 11, $p = 0.028$). The conclusions of IBIS-I were that the overall risk to benefit ratio for the use of tamoxifen in prevention was still unclear and continued follow-up of the trial was essential.

Although sample size determination is dealt with elsewhere in this volume (chapter ▸Sample Size Determination in Epidemiological Studies), the dangers of inadequate statistical power on intervention studies cannot be overemphasized. More than therapeutic trials, preventive trials cannot be easily replicated, for economical and logistic reasons, and collaborative reanalyses can seldom remedy at the lack of a definitive answer from a specific trial. As discussed by Buring (2002), every effort should be made during the planning phase of the trial to choose an adequate sample size and length of follow-up. Secular declines in disease rates within the general population and the failure to achieve a sufficient sample size or to accrue sufficient endpoints are frequent in prevention trials. Extending the duration of the trial is often a good option to achieve a more definitive result for a relatively small increase in total cost.

9.12 Follow-Up, Exclusions, and Withdrawal

Various aspects of the statistical analysis of follow-up data from intervention trials are dealt with elsewhere in this volume (chapters ▸Analysis of Continuous Covariates and Dose-Effect Analysis, ▸Regression Methods for Epidemiological Analysis, ▸Survival Analysis and ▸Missing Data).

The series of articles by Peto et al. (1976, 1977) gives a clear and comprehensive overview of the analysis of long-term follow-up in randomized controlled trials. Survival analysis is the standard method of analyzing time-to-event data because it makes use of the full information (i.e., not just which events occurred, but also when they occurred) and can take into account right censoring, which occurs when the study ends or when participants are lost to follow-up. Interval censoring can also occur when the events under study are only known to have occurred in some interval in time, generally between two follow-up visits. For example, if the event is not death but some measurement that requires a clinical examination (e.g., the appearance or the disappearance of HPV infection, which is asymptomatic and requires a specimen of exfoliated cervical cells for detection), the exact time of the event is unknown, except that it occurred between two visits. Appropriate statistical methods can take this uncertainty into account.

Censoring resulting from losses and dropouts is problematic if the censoring is "informative" (i.e., related to outcome), a situation that is difficult to rule out. As noted by Peto et al. (1977), "rigorous entry criteria are not necessary for a randomized trial, but rigorous follow-up is. Even patients who do not get the proper intervention must not be withdrawn from the analysis." Often referred to as analysis by intention to treat, this approach is the only one that provides a valid answer to a real question. It tests the "policy" (or intention) to be evaluated at the time of randomization. Every possible effort must therefore be made, at the level of trial design and implementation, to identify and, as much as possible, avoid any causes of non-adherence. This may entail a run-in period and a simplified follow-up protocol.

A special problem, different from the one of losses at follow-up, is represented by participants who may be discovered to contravene the eligibility criteria after randomization. In a double-blind trial of a prophylactic vaccine against HPV 16, 2,392 young women were randomized (Koutsky et al. 2002). Since the tested vaccine was not supposed to work among women who were already infected with HPV 16, 36% of the randomized trial participants were subsequently excluded, mainly because HPV tests revealed that they were already infected at enrollment. In principle, no bias should have been introduced since the results of HPV tests became available only after the randomization. An alternative would have been to postpone the randomization, but this was considered impractical. The trial by Koutsky et al. (2002), however, was the first test of a vaccine against HPV. It was not meant to test a "policy" of vaccination in the general population, but the efficacy of a new vaccine under optimal conditions (i.e., among women unexposed to HPV). A larger, population-based trial of HPV vaccine would be necessary to evaluate the effectiveness of HPV vaccine as a tool for cervical cancer control (Plummer and Franceschi 2002). Analysis of such a trial by intention to treat would give the programmatic efficacy of the vaccine program, which is distinct from the efficacy of the vaccine itself.

Finally, a special challenge is represented by the follow-up of community-based health interventions. As discussed by Atienza and King (2002) and Koepsell et al. (1992), it is typically not possible to assess all individuals of interest in the selected communities. Two main approaches to obtaining these longitudinal individual-level data are (1) to follow-up groups of individuals over time and (2) to assess different cross-sections in each time period. Several large-scale community-based interventions (e.g., COMMIT) have utilized both approaches, cognizant of different strengths and weaknesses (Koepsell et al. 1992).

9.13 Conclusions

The randomized controlled trial is one of the most powerful tools available in epidemiology. When properly conducted and reported, it allows the evaluation of a disease risk factor that is free from bias and may also, with an appropriate design, give a quantitative estimate of the public health benefit that may be expected from an intervention.

Even well-conducted randomized controlled trials have problems of interpretation. These problems center on the generalizability of the findings and concern not only the selection of the study participants, but also the timing, dose, and duration of the intervention and the length of time over which a beneficial effect was observed. If there are no such problems, the results of randomized controlled trials may be taken to provide a definitive answer and, in particular, overrule the results from observational studies when these disagree. In general, however, the results of intervention trials must be considered as part of the spectrum of available evidence that includes observational studies in humans and experimental data that provide mechanistic evidence.

10.1 Introduction

10.1.1 Basics

A cluster randomized trial is one in which groups of subjects are randomized rather than individuals. They are sometimes known as group randomized trials. This chapter will describe the design and analysis of such trials. Examples of cluster trials in health are given in Box 10.1.

Cluster trials are used widely in the evaluation of interventions in health services research. They can be divided into two types. The first type is exemplified by the first three rows in Box 10.1: community randomized trials where the clusters are complete communities (some authors call these "large field trials"). These are generally characterized by a relatively small number of clusters each enrolling a large number of subjects. The aim of the trial by Grosskurth et al. (1995) cited in Hayes and Moulton (2009) was to reduce the prevalence of HIV infection by treating other sexually transmitted diseases. It involved six intervention communities and six matched control communities. In each, a random sample of 1,000 adults was selected in each community and followed up for 2 years to measure the incidence of HIV infection. The trial COMMIT (Gail et al. 1992) was to test an intervention aimed at communities to encourage citizens to stop smoking. It had 11 matched pair clusters. The sex-education trial by Wight et al. (2002) randomized 25 schools, 13 into intervention and 12 control, and interviewed all 13- to 14-year-olds at the schools and the same children after 2 years.

The second type of cluster trial is closer in design to an individually randomized trial. It typically uses more clusters and relatively smaller cluster sizes. Examples of "small cluster size" trials are given in the second half of Box 10.1. As an example of the second type, consider in more detail the DESMOND trial described by Davies et al. (2008) (DESMOND – Diabetes Education and Self Management Ongoing and Newly Diagnosed), which involved 105 general practices in the intervention and 102 in the control. The purpose of the trial was to investigate whether an intensive education package can be used to reduce glycosylated haemoglobin (HbA1c%) in patients who have type II diabetes. In the UK diabetes is usually treated in primary

Box 10.1. Examples of cluster trials

Unit	Intervention	Example
Rural communities	Treatment of coexisting disease	Grosskurth et al. (1995)
Communities	Education	Gail et al. (1992)
Schools	Education packages	Wight et al. (2002)
Groups	Diabetes education	Davies et al. (2008)
Doctors	Patient-centered care	Kinmonth et al. (1998)
Patients	Teeth fillings	Soncini et al. (2007)

care, and it was deemed impossible to randomize people in the same practice to different treatments. Thus practices were chosen (at random) as either “intervention” practices or “control” practices. DESMOND is usually taught as a course to groups of eight people at the same time, so the course was the cluster in this case. Kinmonth et al. (1998) randomized general practitioners into those who would receive training in “patient-centered care” and those who did not. A total of 21 practitioners were trained and 20 acted as controls. It would be difficult or impossible for a doctor to change from “patient-centered care” to “paternalistic” care with successive patients. The outcome was measured by HbA1c% in their diabetic patients. Soncini et al. (2007) looked at the survival of amalgam versus composite fillings in teeth and randomized 267 children into each group. It was deemed simpler to ensure each child either had amalgam or composite fillings and so survival times of the fillings will be clustered by mouth.

The main reason for using a cluster trial is fear of contamination. This occurs when subjects in the control group are exposed to the intervention. Thus people living in the same community could not fail to notice a mass education program delivered on the television or local newspaper. In the DESMOND trial, patients may wonder why people with the same doctor were getting different treatment and demand the same for themselves. Doctors trained in a new technique will find it difficult to revert to an old technique at the toss of a coin and so may not deliver the standard treatment as they used to do before being trained to deliver the new treatment. Another reason is that it may be more effective or cheaper to deliver an intervention to a group. For example, patients in the same education program will interact with each other and may learn more than if learning on their own. This was particularly true with DESMOND, where patients learned from each other as well as the trainer. A third reason for adopting a cluster design is administrative convenience or necessity; it is often easier to deliver an intervention to a group of people when it may involve an expensive piece of equipment or training health professionals or it may be impossible to randomize individuals. Again, this was true of DESMOND, where it was much cheaper to deliver the intervention in groups. Sometimes it appears easier to get ethical consent when all of a group are getting the intervention.

The most important point, with regard to the analysis, is that observations are not independent. Observations within a particular cluster are correlated, and although this correlation may be weak, it can have a major effect on the analysis as we shall see.

It is worth defining a few terms. The *intraclass correlation (ICC)* is the ratio of the between cluster variance to the total variance of an outcome variable and is often denoted by ρ. Different designs can lead to different formulas for estimating ρ. A simple method is described in the next section. The *design effect (DE)* is the ratio of the variance of an outcome measure when clustering is accounted for to the variance of the outcome measure when clustering is not accounted for. It is often referred to as the *variance inflation factor (VIF)* since it measures the amount that one should increase a variance estimate obtained by ignoring clustering to allow for the clustering effect. For clusters of equal size m, it can be shown that

$DE = 1 + (m - 1)\rho$. This is also called the *sample size inflation factor (SSIF)* in chapter ▶Generalized Estimating Equations of this handbook, since the same factor that inflates the variance will also inflate the required sample size. Extensions of this formula to the case of variable cluster sizes are given in Sect. 10.2.2.3.

10.1.2 Looking at Data

Figure 10.1 shows the HbA1c% in diabetic patients after 1 year from randomization by practice and by intervention/control from the DESMOND trial (Davies et al. 2008).

We are interested in the difference in the mean HbA1c% for intervention and control. However, one can see that there is a good deal of variation within practices but that some practices have in general high values and some practices have low values. This illustrates the key point: that we cannot think of the outcomes for individuals as being independent, we need to allow for the fact that two people in the same practice are more similar than two people selected at random from different practices. The intraclass correlation ρ is a measure of how much subjects within a cluster are correlated. It is the ratio of the between cluster component of variance σ_B^2 to the total variance $\sigma_B^2 + \sigma_W^2$ where σ_W^2 is the variance within clusters. We can estimate these using a simple analysis of variance. This is shown in Table 10.1 as the

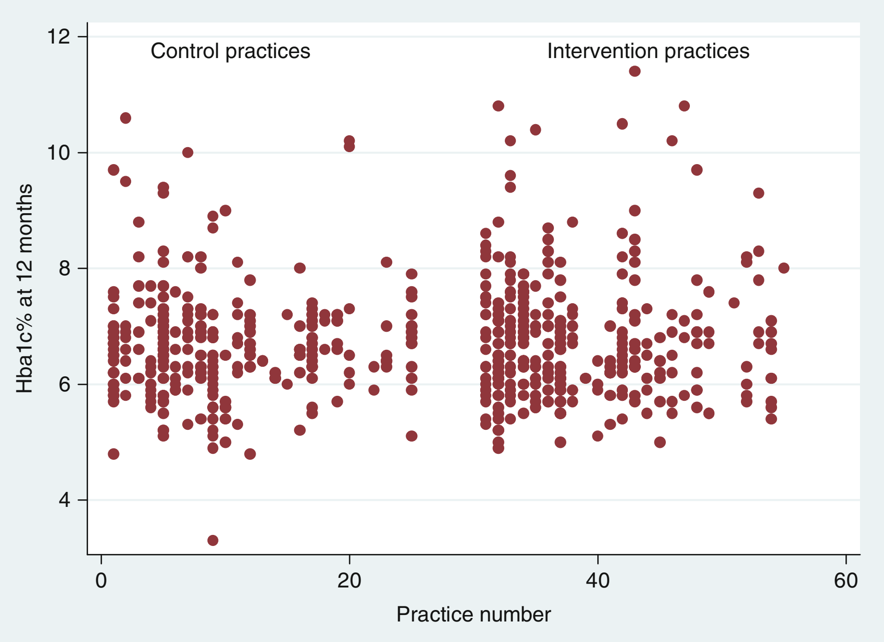

Fig. 10.1 HbA1c (%) at 1 year by control/intervention from DESMOND (Davies et al. 2008)

Table 10.1 Output showing ANOVA to estimate the ICC for data from DESMOND using Stata v11

```

output from the Stata command "loneway" (Statacorp 2009). We have 636 subjects in 47 practices. Here, σ_W^2, the *within practice mean square* (*MS*), is 0.9158. For a fixed cluster size, m, we can estimate the between cluster component of variance from the fact that the *between practice* $MS = \sigma_B^2 + m\sigma_W^2 = 1.6817$. Since here m is about 13.5, we find that $\sigma_B^2 = 0.0567$ and so ρ is $0.0567/(0.0567 + 0.9158) = 0.0583$. The program gives $\rho = 0.0591$, which is slightly different since it takes into account variable cluster size. It is important to appreciate that this procedure gives reasonable values for ρ even for binary outcomes, since it is a moment estimator and does not require distributional assumptions.

10.1.3 Overview of Chapter

Section 10.2 is concerned with the design of cluster randomized trials and how to estimate the number of patients and the number of clusters required. Section 10.3 discusses the analysis and presentation of such trials. Section 10.4 discusses other considerations for cluster trials and software for their analysis. Section 10.5 concludes the chapter and suggests further reading.

10.2 Design of Cluster Randomized Trials

10.2.1 Cohort Versus Cross-Sectional Designs

Many community intervention trials are longitudinal in nature, allowing a choice between a cohort design and a cross-sectional design. For a cohort design, clusters are randomly assigned to intervention groups, with or without stratification. Cohorts sampled from each cluster are then measured over two or more time points, with at least the first measurement occurring before randomization. They are useful in looking at how the intervention changes the health or behavior of individual subjects. The baseline and follow-up subjects are the same people. People who drop out will often be different from those that stay and so the follow-up group may not be typical of the whole population from which the cohort was chosen. Thus it is important to report drop-out rates and do sensitivity analyses to consider whether the nature of the drop-outs may affect the conclusions.

In contrast a cross-sectional design involves randomizing large groups of subjects, such as towns. A random sample is taken before and a random sample taken after the intervention with similar samples taken in the control population. Thus the subjects before and after the intervention are not necessarily the same. On the one hand, a cross-sectional study should be a representative sample of the population, since it is based on a random sample. On the other hand, some of the sample may have recently arrived in the population and so not received the intervention. This will reduce the size of the contrast between the intervention clusters and the control clusters. Cross-sectional designs are useful when the main focus is on change in behavior or health in a community. It can be helpful in some situations to ask those after the intervention whether they were aware of it. For example, in an evaluation of a government advertising campaign, we asked subjects after the campaign if in fact they had seen it (Mills et al. 1986). Only 31% of the sample were, in fact, aware of the campaign, which may partly explain its lack of effectiveness.

Because responses within the same subject often have a strong positive correlation, one can use the baseline measurement as a covariate and usually this will reduce the standard error of the treatment effect. Thus in theory a cohort design may be more efficient than a cross-sectional one. However, Feldman and McKinlay (1994) presented a unified statistical model that embraces both designs as special cases, thus allowing an assessment of how the values of different design parameters affect their relative precision. A principal conclusion from their investigation was that cohort designs have unique disadvantages that may outweigh any advantage in theoretical efficiency. The first of these is related to possible instability in cohorts of large size, with the resulting likelihood of subject loss to follow-up. Although this disadvantage can be compensated for by oversampling at baseline, this might well negate the original reasons for adopting a cohort design. Differential loss to follow-up by intervention group also creates the risk of bias. The second disadvantage is related to the issue of representativeness of the target population, which is invariably hampered by the aging of the cohort over time. Assuming that changes related to the aging process are independent of the intervention assignment, this effect will not invalidate the principal comparison of interest. However, it does imply that a difference observed in a cohort trial with respect to a given outcome variable cannot be directly compared to the corresponding difference between observed cross-sectional samples. Thus if the primary questions of interest focus on change at the community level rather than at the level of the individual, cohort samples are the less natural choice. This point was discussed by Ukoumunne and Thompson (2001) and by Nixon and Thompson (2003), who described and compared several approaches that might be taken to the analysis of repeated cross-sectional samples.

10.2.2 Power and Sample Size

10.2.2.1 Number of Clusters and Number of Subjects per Cluster

In cluster randomized trials, there are two sample size choices to be made: the number of clusters and the number of subjects per cluster. The usual situation is where the cluster size is fixed, and to increase the power we need to increase the number of clusters.

Suppose we needed n' subjects in an individually randomized trial to detect an effect size δ with two-sided significance α and power $1-\beta$ (e.g., using the tables in Machin et al. 2008). Then to allow for clustering where we have equal clusters of size m, we should increase the sample size (using *VIF/SSIF*) to n where n is given by

$$n = n'(1 + (m-1)\rho) \tag{10.1}$$

to achieve the same power and significance level (Hsieh 1988). The number of clusters is determined by $k = n/m$.

An alternative situation is where the number of clusters is fixed, and one wishes to determine the number of subjects per cluster. Since the design effect requires knowledge of the number of subjects per cluster, m, one has to guess m first, to find n and then recalculate m from $m = n/k$ and then reiterate. A simpler solution is to use the fact that (Campbell 2000)

$$m = \frac{m'(1-\rho)}{1-m'\rho}, \tag{10.2}$$

where $m' = n'/k$ is the number of subjects per cluster required before adjusting for clustering. Suppose that for a given effect size, significance level, and power, we require m' subjects per cluster in an individually randomized trial. If ρ is greater than $1/m'$, then m becomes negative, which is impossible and so one can never achieve the required power simply by increasing the number of subjects per cluster, and one will have to increase the number of clusters. Even if ρ is only slightly less than $1/m'$, the numbers per cluster become very large. Thus a useful rule of thumb for continuous outcomes is that the power does not increase appreciably once the number of subjects per cluster exceeds $1/\rho$. For example, if it is believed that the *ICC* is about 0.05, then it is not worth enrolling more than about 20 subjects per cluster for a continuous outcome. However, if the *ICC* of a continuous outcome is near 0.001, which is often typical of community intervention trials, then a sample of 1,000 subjects per cluster may be worthwhile, particularly if recruiting new clusters is difficult. Of course, with binary outcomes, when the incidence is low, large numbers of patients per cluster are required unless the effect of the intervention is very large.

Flynn et al. (2002) addressed the issue of whether it is worth recruiting an extra cluster, or to recruit more individuals to existing clusters. They showed how the use of contour graphs of power by number of clusters per treatment arm and cluster size can be usefully exploited. For example, consider a hypothetical trial in which

18 clusters have already been recruited in each of two treatment arms and in which at least 30 individuals can be recruited from each cluster. Suppose the *ICC* is 0.05 and the target standardized difference is 0.25. We then currently expect about 75% power. To achieve at least 80% power, we can show there are two options: (1) recruiting 20 extra individuals in each existing cluster; (2) recruiting two extra clusters in each arm. The question may then be which of these options is the least costly, and this would be the option to choose.

Although values of ρ in cluster randomized trials tend to be small (typically around 0.05 for primary care trials (Campbell 2000)) and in community randomized trials even smaller (usually less than 0.01 and often near 0.001, Donner and Klar 2000), the resulting inflation of the sample size may be very substantial when combined with clusters of large size. For example, in the trial of HIV reduction (Grosskurth et al. 1995), communities were on average 1,000 adults and so even an *ICC* as low as 0.0001 would have the effect of doubling the required sample size. Results from earlier studies in a specific setting of design effects likely to arise in cluster randomized trials implemented are also helpful to investigators. Gulliford et al. (2005) gave examples of variance components for some common outcomes which can be helpful for future planning.

The sample size formulas we give here assume that data for sample size estimation are obtained from a single sample of clusters from the population of interest, that is, that the intervention itself is not associated with the cluster size. The problem here is that variable cluster sizes will affect the power, and this will be discussed in Sect. 10.2.2.3. Examples where this is not true have been given by Campbell (2000). A particular example is Kinmonth et al. (1998) where the intervention was to train doctors in treating newly diagnosed diabetics, and these same doctors were the ones who diagnosed the diabetes and recruited the patients. They found the intervention clusters were larger than the control because the doctors who had received the intervention seemed more likely to find people with diabetes. This is known as recruitment bias and is a particular problem with cluster trial.

In summary, ignoring clustering effects in the design stage of a trial can lead to an elevated type 2 error, while ignoring it at the analysis stage inevitably leads to an elevated type 1 error. In other words, if an investigator ignores clustering when planning a study, the study is likely to be too small and so underpowered. If the investigator ignores clustering in the analysis, then the standard error of the estimate is likely to be underestimated, and so the observed p-value will be too low, and results declared significant at a given level, when in fact the null hypothesis should not have been rejected at that level.

10.2.2.2 Allowing for Imprecision in the *ICC*

Much of the sample size literature deals with the difficulty of obtaining accurate estimates of between community variation, and hence of ρ, that are needed for sample size planning.

In practice estimates of ρ for a given outcome variable are usually derived from previously reported studies using similar randomization units. However these estimates are frequently based on studies which themselves are of small size, and thus their inherent inaccuracy may lend the investigators a false sense of confidence.

Turner et al. (2004) have shown how to incorporate uncertainty in the *ICC* in a Bayesian framework to obtain an "average" power (cf. chapter ▸Bayesian Methods in Epidemiology of this handbook). They discussed the use of prior distributions for the ICC and showed how the uncertainty about this parameter can be expressed in the form of a parametric distribution which naturally leads to a distribution of projected power for any particular design. This Bayesian approach toward the determination of sample size could then be followed by a statistical analysis within the traditional frequentist framework. If the total sample size were fixed, and $n = m \times k$, it is better to increase the number of clusters k and have smaller cluster sizes. Increasing the number of clusters also considerably reduces the lower limit of the posterior distribution of power. In other words, uncertainty in the *ICC* will produce uncertainty in the actual power of a study, but a design based on a greater number of clusters has less chance of having a very low power. In general, one should try and recruit as many clusters as possible.

An alternative approach to dealing with uncertainty in observed values of ρ is described by Feng and Grizzle (1992), who proposed the use of a method similar in principle to the bootstrap procedure. For a simple discussion of the bootstrap in this context, see Carpenter and Bithell (2002). Their approach requires the simulation of results of studies of the same size to that which yielded the observed estimate. One then can substitute the values of ρ obtained from each simulation into the appropriate sample size formula to generate a distribution of projected powers, followed by the selection of a point on this distribution, for example, the 90th percentile, that reflects the degree of conservativeness desired.

10.2.2.3 Allowing for Varying Cluster Sizes

Variation in cluster size is another source of imprecision, and Kerry and Bland (2001) following Donner et al. (1981) suggested using

$$DE = 1 + (m_a - 1)\rho, \text{ where } m_a = \sum m_i^2 / \sum m_i. \tag{10.3}$$

The problem of using this formula is that the individual cluster sizes must be known prior to conducting the trial.

Eldridge et al. (2006) modified (10.3) to give

$$DE = 1 + ((cv^2 \frac{(k-1)}{k} + 1)\bar{m} - 1)\rho, \tag{10.4}$$

where $\bar{m}$ is the mean cluster size, s_m is the standard deviation ($s.d.$) of the cluster size given by $s_m = \sqrt{\sum (m_i - \bar{m})^2 / (k-1)}$, and the coefficient of variation $cv = s_m / \bar{m}$. They suggested that formula (10.4) is more practical than (10.3) since the value of cv may often be known in advance. Eldridge et al. (2006) also provided some examples of the coefficient of variation for sample sizes typically seen in cluster randomized trials. Data from similar trials would be the first source of values for cv. Alternatively one could ask what is likely to be the maximum and minimum size cluster and estimate s_m as the range is divided by 4 (although strictly speaking this would require the data to be normally distributed).

Eldridge et al. (2006) showed empirically that as the average cluster size increases, the coefficient of variation tends toward 0.65. Primary care trials in the UK tend to have values of cv between 0.42 and 0.75. In the trial of Davies et al. (2008), the mean cluster size was about 14, and the $s.d.$ of cluster size was 12, suggesting a cv of about 0.86 which is somewhat more variable than many. The range of cluster sizes was 1 to 48, so the rule of thumb of estimating s_m as $(48 - 1)/4 = 11.75$ is quite accurate. We give an example of a sample size calculation in the next section.

10.2.2.4 Example of Effect of Variable Cluster Size

Suppose an investigator stated that the expected number of patients per cluster was 10 and the estimated intra-cluster correlation coefficient was 0.05. A preliminary sample size calculation showed that the estimated sample size required for a given power, significance level, and effect size without taking account of clustering was 200 patients and so 20 clusters. Then the estimated sample size required taking account of clustering but ignoring variation in cluster size is

$$n = (1 + (\overline{m} - 1)\rho)x\,200 = 1.45 \times 200 = 290 \text{ patients } = 29 \text{ clusters.}$$

We can argue that a conservative estimate of the expected minimum size of a cluster is 1 patient (no cluster can have less than 1) and the expected maximum is 30 (since we would stop recruiting above this level). The cv is then estimated $(29/4)/10 = 0.725$. From Eq. 10.4, the design effect

$$DE = 1+((1+cv^2\times 28/29)\overline{m}-1)\rho = 1+((1+0.725^2\times 0.966)10-1)0.05 = 1.70.$$

Thus we would need $1.70 \times 200 = 340$ patients $= 34$ clusters, an increase of 5 clusters to allow for cluster size variable.

10.2.2.5 Sample Size Re-Estimation

When we do not know the value of the variance components required to ascertain a sample size, one suggestion is to conduct a pilot study to provide these estimates (Friede and Kieser 2006). We can then obtain an estimate of how many more patients we will need to recruit and use the patients from the pilot in the final analysis (an internal pilot). This procedure has been extended to cluster randomized trials by Lake et al. (2002). With this approach, we conduct a pilot cluster trial, and at an interim point in the study, several nuisance parameters, including ρ, the mean cluster size and measures of cluster size, variation, are estimated, followed by re-estimation of the final required trial size. Although this procedure is most suited to trials that randomize a relatively large number of clusters, such as families or households, over an extended period of time, Lake et al. (2002) pointed out that it could also be applied to at least some community intervention trials provided the participating clusters are recruited prospectively. However, Turner et al. (2004) showed that imprecision in the estimate of ρ is not accounted for in this application and suggested their Bayesian method could easily be extended to do so. More experience on the application of internal pilot studies to such trials is clearly needed.

10.2.2.6 Adjusting for Covariates

Sometimes the reason for a positive *ICC* is that subjects within a cluster have similar covariates. Several authors have shown that adjusting for covariates either at the community or individual level can improve the power of a trial by reducing the magnitude of the between cluster variation (Campbell 2000; Feng et al. 1999). Additional gains in power may be realized by modeling individual level covariates (e.g., age) and also cluster level covariates (e.g., mean cluster age) as described by Klar and Darlington (2004). Moerbeek (2006) suggested that often a cheaper strategy than recruiting another cluster would be to measure additional covariates related to the outcome in order to reduce the variance. This, of course, requires the cost of measuring the covariate to be relatively small and the correlation of the covariate and the outcome to be reasonably high.

10.2.3 Matched Pair Trials

10.2.3.1 Design of Matched Pair Studies

Because cluster trials involve randomizing relatively low numbers of groups, we cannot rely on randomization to ensure balance between treatment arms in important prognostic variables. A common technique to try and ensure balance is to match clusters into pairs and then randomly allocate one member of each pair to the intervention and one to the control.

Matched pair studies are not frequently seen in clinical trials randomizing individual subjects to different intervention groups. However, they have proven to be the design of choice for many investigators embarking on a community intervention trial largely because of the perceived ability of this design to create intervention groups that are comparable at baseline with respect to important prognostic factors, including, for example, community size and geographical area. The relatively small number of communities that can be enrolled in such studies further enhances the attractiveness of pair matching as a method of reducing the probability of substantively important imbalances that may detract from the credibility of the reported results.

Freedman et al. (1990) investigated the gain in efficiency obtained from matching in a community intervention trial. This was done in the context of the COMMIT trial (Gail et al. 1992). Eleven pairs of communities were matched on the basis of several factors expected to be related to the smoking quit rates, such as community size, geographical proximity, and demographic profile. Within each matched pair, one community was allocated at random to the intervention group, with the other acting as the control. It is also interesting to note that this trial was one of the first large-scale community intervention studies to use formal power considerations at the planning stage and, perhaps not coincidentally, to be substantially larger in size than its predecessors.

The gain in efficiency (measured by the sample size required for a given power and effect size) due to matching may be quantified by the factor $G = 1/(1 - \rho_{\mathrm{m}})$, where ρ_m is the correlation between members of a pair with respect to the outcome variable. This latter quantity is simply the Pearson correlation between outcomes for the intervention and control. Thus if the correlation was 0, there would be no gain in efficiency, whereas a value of 0.5 would reduce the required sample size by 50% if matching were employed. Freedman et al. (1990) showed that matching can lead to considerable gains in statistical precision when it is based on an effective surrogate for outcome. However, since G is simply the ratio of population variances ignoring or accounting for pair-matching, it does not take into account the difference in degrees of freedom for estimating these variances, a factor which is particularly relevant in trials enrolling a small number of communities. For example, in the COMMIT study, there were 11 matched pairs. The degrees of freedom associated with the error from the paired differences in event rates would be only ten, as compared to the 20 degrees of freedom available for an unmatched analysis. This issue was subsequently addressed in detail by Martin et al. (1993), who concluded that for studies having no more than 20 pairs, matching should be used for the purpose of increasing power only if the investigators are confident that ρ_m exceeds 0.20. By considering the practical difficulties that often arise in securing "good" matches, they also concluded more generally that "matching may be overused as a design tool" in community intervention trials.

These considerations suggest that a tempting strategy in practice may be to perform an unmatched analysis of data arising from a matched pair design, particularly when matching is adopted mainly for the purpose of avoiding a "bad" randomization. The effectiveness of such a strategy was investigated by Diehr et al. (1995), who concluded on the basis of an extensive simulation study that breaking the matches can actually result in an increase in power when the number of pairs is less than ten. Thus the loss in precision identified by Martin et al. (1993) in the presence of weak matching correlations can be at least partially regained.

A secondary objective of many community intervention trials is to investigate the effect of individual level risk factors on one or more outcome variables. Focusing on the case of a continuous outcome variable, Donner et al. (2007) showed that the practice of performing an unmatched analysis on data arising from a pair-matched design can lead to bias in the estimated regression coefficient and a corresponding test of significance which is overly liberal. However, for large-scale community intervention trials, which typically recruit a relatively small number of large clusters, such an analysis will generally be both valid and efficient.

10.2.3.2 Limitations of Matched Pairs Designs

Klar and Donner (1997) explored some further limitations of the matched pair design that are more general in nature. These limitations arise largely from the total confounding of the intervention effect with the natural variation that exists between two members of a matched pair. One consequence of such confounding is that it precludes the use of standard methods for estimating the underlying *ICC*, which in turn reduces analytical flexibility. For example, a secondary objective of many studies is to estimate the effect of selected individual level risk factors on one or more outcome variables using regression modeling. However, the calculation of appropriate standard errors for the regression coefficients obtained from such a model requires a valid estimator of ρ. Thus, although it is possible to perform adjustments for the effect of such risk factors, the task of testing for their independent relationship with outcome is more difficult (Donner et al. 2007). It is difficult to directly model the joint effects of cluster level and individual level risk factors, and the matched pair design frequently does not bring large gains in precision. Klar and Donner (1997) recommended that greater attention should be paid to the possibility of adopting a stratified design, in which two or more clusters are randomized to each intervention group within strata. This design may be particularly attractive when investigators find it challenging to create matched pairs that correspond to unique estimates of risk for each pair. Most importantly, the cluster level replication inherent in this less rigid allocation scheme removes many of the analytical limitations associated with pair-matching, while increasing the degrees of freedom available for estimating error.

Perhaps the most commonly adopted matching factors in large-scale community randomized trials have been cluster size and geographical area (e.g., urban vs. rural). Matching by cluster size is attractive not only because it protects against large imbalances in the number of subjects per intervention group, an efficiency consideration, but also because cluster size may be associated with other important but unaccounted for baseline variables, such as socioeconomic status and access to health-care resources (Lewsey 2004). Matching by categorized levels of baseline versions of the trial outcome rate would also seem attractive. However, results reported by Feng et al. (1999) suggest that if the primary interest is in change from baseline, such matching is not likely to add benefits in power beyond that yielded by an analysis of change scores. This is because including the baseline in the model analysis is as effective as matching for baseline.

10.2.4 Problems with Identifying and Recruiting Patients to Cluster Trials

In the trial conducted by Kinmonth et al. (1998), the subjects were newly diagnosed people with type II diabetes. The doctors who recruited them were the same doctors who were given training in patient-centered care. After the trial, it was discovered that there were more patients diagnosed in the intervention arm than in the control possibly because the doctors were unblind to treatment. However, concealment of allocation is usually regarded as crucial for individually randomized trials, and one of the advantages of randomization is that it ensures that it is impossible to predict which treatment the next potential recruit will get (see also chapter ▶Clinical Epidemiology and Evidence-Based Health Care of this handbook). This advantage is lost for cluster trials where randomization of clusters is usually accomplished at the start of the trial and so concealment is more difficult. In most cases, it is impossible to conceal the identity of the treatment from the patients when they receive it but it is useful to conceal what treatment patients will get until after they are recruited to the trial. In a new trial, currently in the planning stage, an insulin pump is being tested in patients with type II diabetes. The patients are educated in the use of the pump in groups of size six. The patients are recruited to the trial and asked to give consent to either treatment. When six have been recruited, they are randomized to either the pump therapy or control. In this way the recruiters are ignorant of the treatment the patients will receive. Eldridge et al. (2010) also discussed various options for trying to ensure concealment. These include recruiting clusters and patients before randomization, masking recruiters, or using a standardized recruitment procedure across clusters to try and ensure the procedure was not affected by subsequent treatment.

10.3 Analysis of Cluster Randomized Trials

10.3.1 Cluster Specific Versus Marginal Models

Assume that the clusters are sampled from a larger population and the effect of any particular cluster i is to add a random effect Z_i to the outcome Y. We assume the Z_is have the same distribution for all i. We add a covariate X for the treatment effect, where $X = 1$ for the intervention and $X = 0$ for the control. Suppose the effect of an intervention is to add an amount β_1. We assume that the actual cluster effect is a separate and independent effect to that of the treatment effect. A *cluster specific (CS)* model measures the effect on Y of changing X, while Z is held constant. This is a common model for longitudinal data, where it is possible to imagine, say in a cross-over trial, a treatment value changing over time. A suitable model might be

$$E(Y_i|Z_i) = \beta_0 + \beta_1 X + Z_i, \tag{10.5}$$

where $E(Y_i|Z_i)$ is the expected value of the outcome conditional on Z_i. We further assume that $E(Z_i) = 0$ and $\mathrm{var}(Z_i) = \sigma_Z^2$ and the Z_is are independent of the fixed effect X for all i. The distribution of Z_i is generally assumed to be normal, but for binary data, a gamma distribution can be used. In a Bayesian context, other distributions such as a t-distribution can be also used (see Sect. 10.3.4).

Equation 10.5 can be generalized to any outcome variable Y_i (continuous or binary), with expected value μ_i and a generalized link of the form

$$g(\mu_i) = \beta_0 + \beta_1 X + Z_i, \tag{10.6}$$

where the function g is assumed strictly monotone and differentiable.

However, in a cluster randomized trial, everyone in a cluster receives the same treatment, and although a *CS* model can be fitted, the result can be interpreted only theoretically. There is an analogy here with the "counterfactual" argument for causality in epidemiology (see also chapter ▸Basic Concepts of this handbook), where we interpret casual effects as being the difference in outcome from either exposure to a hazard or non-exposure in the same person, even though in practice this is not observed.

An alternative method is to fit a model which looks at the average effect of X over the range of Z. This is the so-called *population averaged (PA)* or *marginal* model. Consider a model where we fit only X and ignore Z_i, so that

$$g(\mu_i) = \beta_0^* + \beta_1^* X. \tag{10.7}$$

Model (10.7) is a *PA* model, that is, we estimate the effect of X on Y as averaged over all the clusters i.

Neuhaus and Jewell (1993) contrasted the approach between cluster specific models and population averaged models by observing that Model (10.7) is simply Model (10.6) with the variable Z omitted. If we assume that the coefficients for X in the two models are related by $\beta_1^* \approx B\beta$, where B is the bias factor, then they show that for a linear model and a log-linear model $B = 1$, and so the interpretation of cluster specific and marginal models is the same. However for a logistic link, $\mu =$ logit $(P(Y = 1|X, Z))$, they showed that $B \approx 1 - \rho$ where ρ is the correlation of the Ys within clusters assuming $\beta_1 = 0$. Since $0 < \rho < 1$, so $0 < B < 1$, and so the general effect of using a population averaged model is to attenuate the regression coefficient toward zero. One can also see that for a logistic link, the greater the variability of the random variable Z_i, and so the greater the intracluster correlation, the greater the attenuation. However, as discussed earlier, the value of ρ in community randomized trials is usually less than 0.01, and this suggests that the bias in assuming a marginal model should not be great.

Since $B = 1$ for a log link, this would suggest that in prospective studies such as clinical trials, it would be advantageous to use a log-linear model which estimates the relative risk rather than a logistic model which yields odds ratios (Campbell 2008). However, experience has shown that in general logistic models are easier to fit and have fewer convergence problems. These can arise with a log-linear model when the fitted values for the risk become greater than 1 or less than 0. This is more likely to happen when the number of events is relatively high.

10.3.2 Standard Methods of Analysis

10.3.2.1 Inflating the Standard Error

For a linear model, we assume the observed outcome y_{ij} is the outcome of the random variable Y_{ij} for the jth subject ($j = 1, \ldots, m_i$) in the ith cluster ($i = 1, \ldots, k$), and it differs from the expected value by a random error. We write

$$Y_{ij} = \beta_0 + \beta_1 X_i + Z_i + \varepsilon_{ij} \tag{10.8}$$

and we assume $E(\varepsilon_{ij}) = E(Z_i) = 0$, ε_{ij} and Z_i are independent, var$(\varepsilon_{ij}) = \sigma^2$, and var$(Z_i) = \sigma_Z^2$. In a trial with no other covariates, X_i is an intervention indicator variable (0, 1) which depends only on whether the cluster i is in the intervention group or not. An *exchangeable* correlation structure is assumed, which effectively means that one can exchange subjects j and j' within a cluster without changing the covariance. This breaks down if subjects are measured more than once (e.g., at baseline and at follow-up) since the correlation of the same subject measured twice will not be the same as the correlation of two different subjects within a cluster. It also means that the *ICC* must be assumed to be the same within each arm of the trial, an assumption which is guaranteed in a randomized trial under the null hypothesis of no intervention effect, but may not be true under the alternative hypothesis that the intervention affects the outcome.

Let $\bar{d}$ be the estimate of the difference in means between the intervention and control group and suppose there are $k/2$ clusters in each group (k assumed even). Then we can show that

$$\operatorname{var}(\bar{d}) = \frac{4\sigma^2}{mk} + \frac{4\sigma_Z^2}{k}. \tag{10.9}$$

The first term in (10.9) is simply the variance that would have been obtained if the data were not clustered. Equation 10.9 can be rewritten as

$$\operatorname{var}(\bar{d}) = 4(\sigma_Z^2 + \sigma^2)VIF/mk,$$

and we can estimate $\sigma_Z^2 + \sigma^2$ by the pooled variance of the outcome variable over groups. Thus a technique originating in sample survey is to simply multiply the variance obtained from ignoring the clustering by the variance inflation factor *VIF*. The design effect given in Sect. 10.1 may be estimated by replacing the *ICC* with its sample estimate (Donner and Klar 2000). A simple test of whether a parameter is zero, known as a modified Wald test, is to divide an estimate of the parameter by its modified standard error which is then compared to the quantile of a standard normal distribution. The authors give a number of methods for continuous and binary outcomes which modify the standard error associated with either the t-test or the chi-squared test respectively. It is important to note that the estimate of the treatment effect is unchanged, only the standard error is inflated. An alternative method is to use the so-called "sandwich," "robust" or Huber-White estimator (Huber and Ronchetti 2009) which has a long history in econometrics for estimators with continuous data and with heterogeneous variances. The advantage of the robust standard error is that one does not need to estimate the *ICC* separately before conducting the analysis.

10.3.2.2 Summary Measures

A simple method, which is applicable to both binary and continuous data, is the method of summary measures, as popularized by Matthews et al. (1990). For continuous data, one uses the mean of each cluster, and for binary data, one would use the proportion of events (or a transformation such as the logit). This works best when the clusters are all approximately the same size. It gives equal weight to each cluster, irrespective of size, and is a cluster specific method. It has a great deal to recommend since it simply uses the summary statistics for each cluster and is easy to apply without specialist software. However, one cannot adjust for individual level covariates directly using this approach.

10.3.2.3 Generalized Estimating Equations

The generalized estimating equations (GEE) method, developed by Liang and Zeger (1986) in the context of longitudinal studies, has proved to be very popular for the analysis of data arising from cluster randomized trials. It fits the *PA* model and uses an iteratively reweighting algorithm to estimate the parameters and a robust method (the "sandwich" estimator) for the standard error. It is described in more detail in chapter ▶Generalized Estimating Equations of this handbook. Use of the GEE yields a "shrinkage" estimator which is a compromise between no weighting and weighting by the sample size. It deals with the correlation within clusters by assuming a "working" correlation and then adjusting it according to the data. In cluster trials the choice is between an independent error structure and an exchangeable error structure. An independent error structure is plausible if in fact the intracluster correlation coefficient of the outcome variable is close to zero. An exchangeable error structure means that one can exchange subjects within a cluster and not change the correlation matrix. An exchangeable correlation structure effectively weights each mean by $m_i/(m_i\sigma_z^2 + \sigma^2)$. This weights the means by the sample size m_i when $\sigma_Z^2 = 0$ and gives equal weight when $\sigma^2 = 0$ or when the cluster sizes are all the same. In practice, estimates of the variance components, s_Z^2 and s^2, are used and so s^2 will always be greater than zero which implies the weight will vary unless the outcome were constant.

The use of robust standard errors means that even if a model has an incorrect variance-covariance structure, valid inferences can still be made. For example, one could have a model with an independent error structure and use robust standard errors. This is the same as using the variance inflated method described in Sect. 10.3.2.

GEE is used widely for hypothesis testing and confidence interval construction because it can control for the influence of potential confounders on outcome without the need to specify an underlying distribution for the sample observations. The robust variance estimation relies on between cluster information to assure the validity of the resulting inferences. It is therefore important to be wary of this approach to community intervention trials where the amount of such information tends to be relatively small.

Feng et al. (1996) recommended for continuous data that GEE should not be applied to trials having 20 or fewer clusters. It has been found that using a t-distribution (with a Satterthwaite type correction for the degrees of freedom to allow for unequal variances) and a technique known as the jackknife (Efron and Tibshirani 1998) improves the estimate of the standard error (Mancl and DeRouen 2001). Pan and Wall (2002) proposed replacing the GEE Wald test by approximate t- or F-tests. Although the proposed procedures showed type 1 errors closer to nominal than the usual Wald test, they were shown to be strictly applicable only in clusters of small size. It is therefore clear that more research is needed on the development of adjusted GEE procedures that can be applied to clusters of the size that typically arise in community intervention trials.

10.3.2.4 Random Effect Models

The alternative method of analyzing data from cluster trials is to use a cluster specific model (10.5 and 10.8). We now have to assume distributions for the two error terms. For continuous data the subject level error is assumed normal and for binary data it is assumed binomial. For continuous data the cluster level error is usually assumed normal, and also for binary data, although sometimes a gamma distribution is used. Although this model does not directly reflect the design of a cluster trial since treatment is contrasted to control within the same cluster, as stated earlier it does provide a valid estimate of the treatment effect. These models are also known as "mixed" models (since they contain a mixture of random and fixed effects) or "hierarchical" models since one can think of a hierarchy of clusters and then subjects nested within clusters.

The probability density of an observation from Eq. 10.8 conditional on Z_i is normal with mean $\beta_1 X_i$. Thus $P(y_{ij}|Z_i) = f(y_{ij}|Z_i,\beta,\sigma^2)$ where $f(\cdot)$ is the normal density function. Within a cluster and conditional on Z_i, we assume the observations are independent and so, given observations $y_{i1}, y_{i2}, \ldots, y_{im_i}$

$$P(y_{i1}, y_{i2}, \ldots, y_{im_i}|Z_i) = \prod_{j=1}^{m_i} f(y_{ij}|Z_i,\beta,\sigma^2).$$

This depends on the random variable Z_i, and to find the expected value, we integrate over possible values of Z_i to get

$$P(y_{i1}, y_{i2}, \ldots, y_{im_i}) = \int_{-\infty}^{+\infty} f(Z_i,\sigma_Z^2) \prod_{j=1}^{m_i} f(y_{ij}|Z_i,\beta,\sigma^2)dZ_i.$$

The full likelihood is the product of the above integrals over k clusters

$$L(\beta,\sigma_Z^2,\sigma^2) = \prod_{i=1}^{k} \int_{-\infty}^{+\infty} f(Z_i,\sigma_Z^2) \prod_{j=1}^{m_i} f(y_{ij}|Z_i,\beta,\sigma^2)dZ_i. \tag{10.10}$$

As discussed in Sect. 10.3.1, binary models using different link functions can estimate different population parameters and so deserve special consideration.

Let Y_{ij} (0 or 1) be the jth observation ($j = 1,\ldots,m_i$) in the ith cluster ($i = 1, 2, \ldots, k$). The cluster specific logistic model, following Eq. 10.6, is

$$\text{logit}\,(\pi_{ij}) = \beta_0 + \beta_1 X_i + Z_i, \tag{10.11}$$

where Z_i is the effect of being in cluster i and where $\pi_{ij} = E(Y_{ij}|X_i, Z_i)$. This model can be extended to include individual specific covariates X_{ij}. The random variable Z_i is assumed to be independent of X_i and may be usually assumed to be normally distributed with mean 0 and variance σ_Z^2 although sometimes a gamma distribution fits the data better. Given the Z_i, the Y_{ij}s are assumed independently distributed with binomial parameter π_{ij}.

The full likelihood L is given by

$$L(\beta, \sigma_z^2) = \prod_{i=1}^{k} \int \prod_{j=1}^{m_i} \pi_{ij}(\beta, Z_i)^{y_{ij}} \{1 - \pi_{ij}(\beta, Z_i)\}^{1-y_{ij}} f(Z_i, \sigma_Z^2) dZ_i. \quad (10.12)$$

Equation 10.10 can be solved directly to maximize the likelihood with respect to the parameters β, σ_Z^2, and σ^2 but not so Eq. 10.12. An early method for binary outcomes and which avoided the integration is a penalized quasi-likelihood approach, using a Laplace method for approximating the integral (Breslow and Clayton 1993). However, this has been replaced by methods which conduct the integration directly using Gaussian quadrature or other numerical methods to obtain estimates of the regression coefficients. Other methods, using iteratively generalized least squares (IGLS), are commonly used for hierarchical models (Goldstein 2002) and are implemented in the package MlWin.

10.3.3 Examples

10.3.3.1 The Analysis of Continuous Data

Table 10.2 gives the results from the DESMOND study (Davies et al. 2008) of the analysis of the outcome HbA1c%, which is treated as a continuous variable. The first row is the result of using a simple t-test on the means of the clusters. This ignores the size of each cluster. The second row uses a robust correction factor for the standard error. The estimate 0.0792 is what one would get from an analysis ignoring clustering, but the standard error is inflated using a "sandwich" estimator (cf. chapter ▸Generalized Estimating Equations of this handbook). The third row uses an exchangeable error structure and shows the effect of "shrinking" the smaller clusters toward the center. The random effects model using maximum likelihood gives nearly the same outcome as the GEE with exchangeable errors, a common finding. One can see that the GEE (independent errors) gives a smaller p-value than the other methods possibly because the independence assumption is implausible.

It is sensible to plot the residuals from the random effect to check for approximate normality. Figure 10.2 shows a plot known as a QQ plot, which plots the residuals against the value that would have been expected from a normal distribution with

Table 10.2 Results of analysis of continuous outcome HbA1c% from DESMOND

	Treatment effect	Std. Err.	z	$P > z$
t-test using means	0.0615	0.1321	0.47	0.64
GEE (independent errors)	0.0792	0.1118	0.71	0.48
GEE (exchangeable errors)	0.0531	0.1098	0.48	0.63
Random effects (max.lik.)	0.0518	0.1100	0.47	0.64

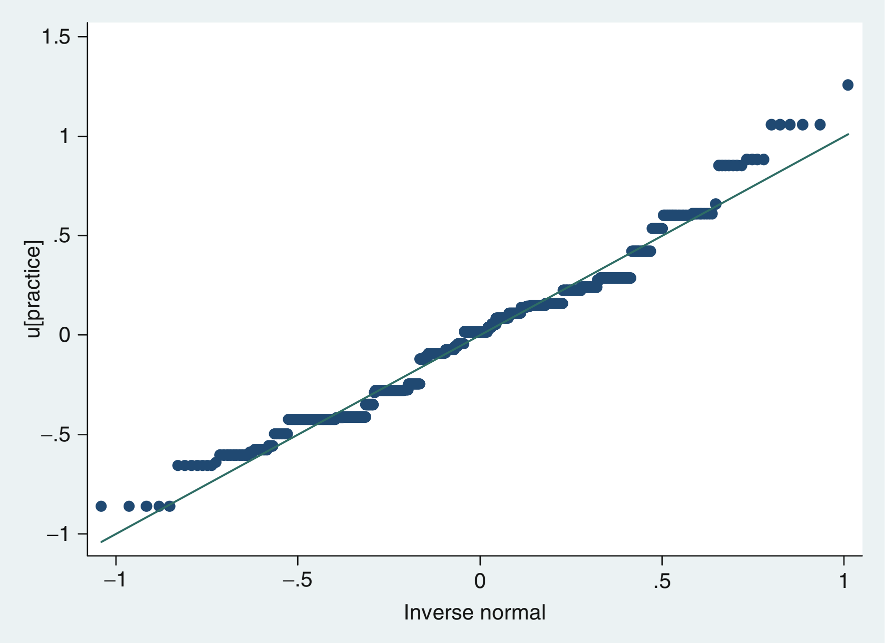

Fig. 10.2 A QQplot of the cluster level residuals from a random effect model from the DESMOND study

the same mean and standard deviation. If the residuals are normally distributed, one would expect this plot to be a straight line. The model fitting procedure means that the residuals are closer to a normal distribution than if we had not estimated the parameters from the data, but the plot is useful for gross departures from expected. The figure suggests that the residuals are plausibly normal. If the plot had been grossly away from normal, one would look for outliers, include potential covariates, and try transformations of the outcome to search for a better fitting model.

10.3.3.2 The Analysis of Binary Data

Table 10.3 shows the outcomes of three analyses from the DESMOND study (Davies et al. 2008) where the outcome is a binary indicator variable (HbA1c% > 7.5%). One can see that the GEE (population averaged) model with exchangeable errors gives a smaller odds ratio (*OR*) than that for independent errors. As with the continuous data analysis of Sect. 10.3.3.1, this is because smaller clusters are shrunk closer to the overall mean in a model with exchangeable errors and it is more likely that small clusters will have larger effects, the effect of which is diminished with exchangeable errors. The *OR* estimated using a random effects model is similar to that for the GEE population averaged model with exchangeable errors since the *ICC* is relatively small (0.061 in this case), but the GEE estimate is very slightly smaller as might be expected. Further discussion of these points has been given by Ukoumunne et al. (2007, 2008).

Table 10.3 Results of analysis of binary outcome for DESMOND using a logistic link

	Odds ratio for treatment	Std. Err.	z	P > z
GEE (independent errors)	1.8318	0.4689	2.36	0.018
GEE (exchangeable errors)	1.8056	0.4568	2.34	0.20
Random effects (adap. quad.)	1.8190	0.5012	2.17	0.30

Tests for the assumptions concerning the residuals with binary data are more difficult to achieve than for continuous data. They are most easily accomplished using Bayesian methods described in the next section. In view of the close agreement between the GEE (exchangeable) and random effects models, we will not pursue this further.

10.3.4 Bayesian Methods

An alternative method to solve Eqs. 10.10 and 10.12 is to use simulation via Markov Chain Monte Carlo (MCMC) algorithms. These are usually associated with a Bayesian analysis, but choice of suitable non-informative priors will yield results similar to the conventional likelihood methods. Spiegelhalter (2001) described methods for the Bayesian analysis of cluster randomized trials with a continuous response. This was extended to a binary outcome by Turner et al. (2001). They used Eq. 10.11 and looked at different prior distributions for σ_Z^2. Since σ_Z^2 is closely related to the *ICC*, they argued that often it is more appropriate to use a prior distribution on the *ICC*, and information for prior distributions for the *ICC* is now becoming available (Gulliford et al. 2005). Turner et al. (2001) experimented with different prior distributions and showed that the estimate of the treatment effect is not entirely robust to the distributional assumptions of the model and suggested caution in using the conventional normality assumption. They showed that the variance components tend to be underestimated when using the non-Bayesian approach. Thompson et al. (2004) and Clark and Bachmann (2009) used Bayesian methods to analyze binary outcomes. They looked at two aspects. Firstly, they looked at rate ratios and rate differences. The latter are particularly important for economic analyses. They showed that use of Bayesian methods facilitated looking at differences in rates. Secondly they looked at the effect of different prior distributions on the outcome. Both sets of authors found that the choice of a prior distribution could have a significant effect on the treatment estimate.

10.3.5 Modeling in Matched Pair Designs

Thompson et al. (1997) replaced standard modeling approaches by techniques borrowed from meta-analysis. Thus an intervention/control pair replaces an individual clinical trial of a meta-analysis. This is essentially equivalent to relying on between-stratum information to estimate ρ under the assumption of no intervention by stratum interaction. An attractive feature of this is that the forest plot can show which pairs appear to be outliers. However, this approach requires a large number of strata (pairs) to ensure its validity and is therefore not applicable to many community intervention studies. The meta-analysis method as applied to the matched pairs design was extended to binary data by Alexander and Emerson (2005) using a Bayesian approach.

The strict lack of applicability of the t-test to binary outcomes in a matched pair design has led some investigators to alternatively recommend non-parametric approaches, such as Fisher's one sample randomization (permutation) test. Simulations performed by Gail et al. (1996) showed that inferences for matched pair binary data using permutation procedures will have significance levels near nominal under conditions likely to arise in community intervention trials. Essentially the same conclusions were reached by Brookmeyer and Chen (1998) for person-time data arising from matched pair trials. It is useful to note, however, that the one sample permutation test requires a minimum of six pairs to yield a two-sided p-value of less than 0.05, reflecting its relatively weak power. Donner and Donald (1987) showed that a weighted paired t-test based on a logistic transformation of the crude event rates tends to be more powerful than both the permutation test and the standard paired t-test in trials having a small number of strata.

10.3.6 Advice on Methods of Analysis

A method of analysis we have not discussed here is the so-called "fixed" effect method. This involves fitting dummy variables for each of the clusters. This would be relevant if we were particularly interested in the results for particular clusters. However, in general, the clusters are just a source of variation; if the trial were run again, different clusters would be used. Thus treating clusters as fixed incorrectly removes a source of variability, and so the standard errors from this approach will be incorrect.

Heo and Leon (2005) compared different methods of analysis using Eq. 10.12: (1) full likelihood, (2) penalized quasi-likelihood, (3) generalized estimating equations and (4) fixed effects logistic regression. The third method is a marginal method which, following the discussion in Sect. 10.3.1, estimates a different population parameter than the regression coefficient in Eq. 10.10. However, it does not require one to assume a normal distribution for the Z_i. The last method does not take the ICC into account and is an invalid method in general for cluster randomized trials. However, if $\sigma_Z^2 = 0$, it may be expected to yield valid tests and efficient estimates.

Heo and Leon (2005) found the full likelihood method and the penalized likelihood methods to be similar and no worse than the fixed effects method even when the within-cluster correlations are zero. As expected, the GEE method gave biased estimates of β_1, the cluster specific parameter for the treatment effect from Eq. 10.6. They did not investigate the effects of estimating β_1^*, the population averaged parameter from Eq. 10.7. Preisser et al. (2003) showed how to apply a *PA* model to a pretest posttest cross-sectional design, where the assumption of an exchangeable correlation matrix breaks down. They stated that the GEE approach is asymptotically equivalent to the summary measure approach and quoted Mancl and DeRouen (2001) to the effect that using bias-corrected variances can yield valid test sizes even with unequal cluster sizes and with as few as ten clusters.

Ukoumunne et al. (2008) carried out a number of simulations contrasting a cluster level t-test with GEE methods, when the outcome is either the difference in proportions, the risk ratio, or the odds ratio. They found that GEE had little bias in any scale, when the number of clusters per arm was at least ten. In contrast the cluster level t-test only performed reasonably for the difference in proportions.

There are other methods for the analysis of cluster trials such as the use of the bootstrap (Carpenter and Bithell 2002) and methods which fit models in stages. Feng et al. (1996) conducted a comparison of maximum likelihood assuming a normal mixed model, GEE, a bootstrap, and a "4-stage method." The bootstrap used by the authors draws a random sample of size k from the original k clusters. Then one can use ordinary least squares to estimate the βs and repeat a large number of times. The four-stage method is non-iterative, where the first step is to estimate the βs by ordinary least squares and obtain the residuals $e_i = Y_i - X_i\hat{\beta}$. Then the e_is are regressed against the Z_is, leading to estimates of σ^2 and σ_Z^2. One can then use these estimates in a weighted least squares regression of Y_i versus X_i. For small numbers of clusters (<10 per arm) and for nearly balanced data, the bootstrap has been shown to do well, especially if one does not wish to assume normality. For larger numbers of clusters, the maximum likelihood method performed better than GEE.

In practice there is a choice of four main types of analysis: use of summary statistics, generalized estimating equations (GEE), random effects models, and Bayesian random effects models. These are summarized in Fig. 10.3.

As stated earlier, within the GEE method, there is a choice of independent error structure or exchangeable error structure. Within the random effects method, there are a number of ways of fitting models which usually give similar results. For community intervention trials with few large clusters, there is much to recommend a summary measure approach: easy to implement and to understand. If the design includes matched pairs of clusters, then if the number of pairs is less than 10, an analysis ignoring matching is likely to be worthwhile. For "small cluster size" trials with more than 20 clusters per intervention group, the GEE methods using an exchangeable correlation structure are simple and robust. With fewer clusters, one could adopt a random effects model or use a cluster level method. As with any statistical analysis, with few data there is a compromise to be made between the number of assumptions about the data and the power to test hypotheses. With random effects models, it is important to test the assumptions regarding the distribution of the random effects. As stated earlier, this is most easily done using a Bayesian approach, but this requires a degree of expertise and is less commonly done.

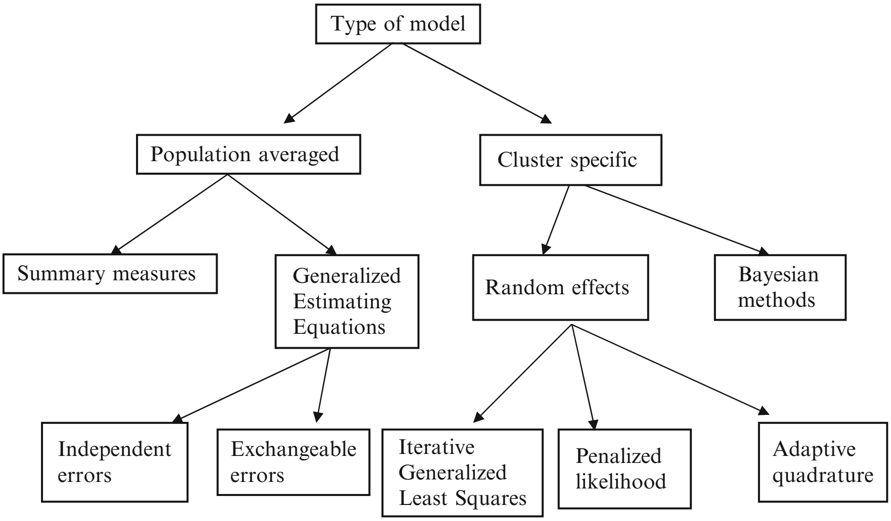

Fig. 10.3 Choices of model and fitting methods

10.4 Other Considerations

10.4.1 CONSORT Statement for Presenting Results from Cluster Randomized Trials

Cluster randomized trials are often poorly reported (Eldridge et al. 2004). The original CONSORT statement was an attempt to improve reporting of individually randomized trials. This statement was subsequently adapted for cluster randomized trials and revised by Campbell et al. (2004). The most important distinctions from the original CONSORT statement are (1) to give a rationale for adopting a cluster design, (2) to describe how the effects of clustering were incorporated into the sample size calculations, (3) to describe how the effects of clustering were incorporated into the analysis, and (4) to describe the flow of both clusters and participants through the trial, from assignment to analysis. Thus, in a primary care trial, for example, one would like to know how any primary care groups were approached, how many agreed to participate, how many were randomized, and how many dropped out during the trial, as well as the characteristics of the patients in the study. The most up-to-date statement is available at www.consort-statement.org.

10.4.2 Clustering by Therapist

Investigators may need to contend with clustering of subjects' responses even for trials using individual randomization. For example, patients may be randomized as they enter a trial by whether or not they will receive a new intervention (say acupuncture). However, there may be a limited number of acupuncturists and so a single acupuncturist may treat a number of patients. The outcomes will thus be affected not only by whether the patient received acupuncture but by which acupuncturist treats them. The model is

$$Y_{ijk} = \beta_0 + \beta_1 X_i + \gamma Z_k + \varepsilon_{ij_,}$$

where the subscript k indicates the effect of different acupuncturists and $Z_k = 0$ for the control group. However, it is important to note that the subjects in the control group are not naturally clustered. Issues in the analysis of these trials have been covered by Roberts and Roberts (2002). Lee and Thompson (2005) discussed a Bayesian approach to the analysis of such trials and pointed out how taking account clustering in the analysis can affect the results.

10.4.3 Compliance and Recruitment

We now discuss some potential sources of bias that are peculiar to cluster randomization trials. As we discussed in Sect. 10.2.2.1, if the subjects in a trial are newly diagnosed patients and the intervention is some new approach to treating a disease, then it is possible that practitioners in the intervention arm, being newly educated about this disease, may be more likely to diagnose the disease (Campbell 2000). This may lead to serious problems of selection bias if patients in the intervention arm have less serious disease than patients in the control arm. Trials should be analyzed by what is known as the "intention to treat" (ITT) principle. This means that patients randomized to a particular treatment will be analyzed as if they received that treatment, irrespective of their actual treatment. This is a so-called "pragmatic" approach which attempts to reflect what will happen in practice, when patients will not necessarily comply with treatment. An ITT approach is appropriate when compliance varies over clusters but varying compliance has major implications for any attempt at casual modeling. Loeys et al. (2001) demonstrated how to use standard GEE and random effects models to allow for variable compliance among clusters.

From experience, factors that improve compliance include building a "team spirit" within a cluster, regularly communicating to the patients about the trial, and providing the control group access to the intervention after the trial. For example, in the Hampshire Depression Trial (Thompson et al. 2000), general practitioners (GPs) in the intervention were trained to recognize depression in their patients. GPs in the control group were offered training when the trial was over, and this increased their willingness to stay in the trial.

10.4.4 Software

The selection of the general packages which can fit these models discussed in this chapter is given in Table 10.4. Stata (Statacorp 2009) has simple commands

Table 10.4 Web addresses for software packages

Name	URL
MLwiN	http://www.bristol.ac.uk/cmm/software/mlwin/
R	http://www.r-project.org/
SAS	http://www.sas.com/technologies/analytics/statistics/
Stata	http://www.stata.com/
WinBUGS	http://www.mrc-bsu.cam.ac.uk/bugs/

for applying a cluster robust standard error and for checking the distribution of the residuals. These can also be accomplished in R, but it is not as easy to use. MLwiN enables more than two-level clustering (e.g., by pupil by class by school) or therapist by patient by time within patient. It also can fit models using Markov Chain Monte Carlo methods which enable a Bayesian approach. WinBUGS can be used to analyze trials using Bayesian methodology with prior distributions for the parameters. SAS is particularly flexible for mixed models.

10.5 Conclusions

10.5.1 Review

Cluster randomized trials are an order of magnitude more complicated than ordinary randomized controlled trials. If the risk of contamination is low, then an investigator would be well advised to consider whether an individually randomized trial might be more efficient. However, the last 10 years have seen a flourishing of research into cluster randomized trials and they are now better understood and can be analyzed relatively easily using common software. There is still a need for information about likely values of the intracluster correlation coefficient for common outcomes and clusters so that trials can be planned with more precision. Trial design is still comparatively simple, and research is needed on issues such as group sequential trials where interim analysis can inform the future design of the trial.

10.5.2 Further Reading

The standard text books on cluster (or group) randomized trials are those by Murray (1998); Donner and Klar (2000) and Eldridge and Kerry (2012). A recent book by Hayes and Moulton (2009) emphasizes the use of cluster trials in infectious diseases, particularly in developing countries. There have been a number of reviews of cluster randomized trials. Klar and Donner (2001) and Donner and Klar (2004), following on from their book (Donner and Klar 2000), reviewed developments up until that time and suggested areas of further research. Murray et al. (2004) reviewed methods in public health. Methodological developments for cluster randomized trials have also been reviewed more recently by Campbell et al. (2007).

11.1 Introduction

This chapter describes theories and methods underlying successful *comprehensive community-based health promotion* and provides five examples. These studies represent well the field of *experimental* epidemiology, involving the total populations of communities, and often done following insights derived from *observational* epidemiology or from *randomized clinical trials* in smaller populations. Three of these were designed to reduce risk factors for cardiovascular disease (CVD) and relied heavily on locally available channels of mass communication in addition to community organizing and other education methods, relatively low-cost approaches with the potential to reach and change lifestyle behaviors of entire populations, in contrast to traditional individual or group counseling. One example, studying alcohol-involved trauma, used only community organizing to promote adherence to existing laws, rather than public education for behavior change. A second example, designed to decrease consumption of dietary trans fats, used primarily new laws and regulations. By community organizing, we mean the process of enlisting community leaders in support of project goals, and also in insuring their continued support. The Stanford Prevention Research Center (SPRC), beginning in 1972, pioneered development of the intervention methods of comprehensive community-based CVD prevention and other methods of health promotion and chronic disease prevention. SPRC was connected to four of the five examples, either as initiator (for two studies) or collaborator (for two studies). This review also describes the theoretical background, methods of intervention, the past history of such studies, the cultural basis for barriers to change, and lessons learned for the future. Although the examples given are derived from studies in high-income countries, the underlying theories and the intervention principles fully apply to countries at all development levels (Institute of Medicine (IOM) 2010).

A community-based program is defined as one organized locally and promoted through the community's institutions and communication channels. The traditional definition of a "community" is used in this review (a residential area with legally defined geographical boundaries, where a *local* governmental system regulates many aspects of schools, businesses, transportation, law enforcement, and recreational activities). A community is ordinarily last in a nation's regulatory chain, where education must ultimately occur, although for rural areas (in the United States) the county becomes the governing agent for education.

This chapter will address the following issues:

1. The advantages are presented for community-wide interventions rather than for more limited locales, such as clinics, hospitals, worksites, or schools.
2. The theories underlying successful community-based projects are described, including:
   a. Community organizing theory and its relationship to community self-development and diffusion of innovation theories

   b. The health communication-behavior change theory and its relationship to social cognitive theory, social marketing, and to other determinants of successful use of mass media for health promotion

3. The methods needed for success are presented, including:
   a. Message design through formative research
   b. Process analysis for comprehension of causes for change
   c. The role of community activism, advocacy, laws, and regulations

4. The history of four recent decades of comprehensive community-based health promotion for cardiovascular disease prevention is described.
5. The cultural basis for barriers to success is outlined.
6. Lastly, a *Master Plan* for achieving success in this type of health promotion is presented.

11.2 Advantages of a Total Community Approach

Health promotion in schools, worksites, and clinics has a long history of individual success, but synergistic interactive effects can occur when they are imbedded in a *total community* campaign that adds inherently cost-effective mass media and environmental change (Schooler et al. 1997). Evidence for synergism was given by Rogers (1983), who found that diffusion of innovations within a community accelerates when adoption of the innovation reaches about 20% of the population – thus only comprehensive total community education programs have the capacity to achieve such effects. Lifestyles, such as tobacco use, dietary habits, and exercise patterns, so strongly influenced by custom and by the media in developed countries, cannot be countered through simple means. Community-wide approaches fit the public health model because the usual medical model can neither prevent most chronic disease nor reach the entire population in need. By the "medical model," we mean the aspects of a nation's health care system, focused on the individual, that rely primarily on clinic outpatient and hospital services provided by physicians. The total community model provides influence through *locally produced* electronic and print mass media and through worksites, recreation sites, libraries, schools, medical, hospital, and pharmacy settings, and social gatherings of many sorts. It offers opportunities for health-promoting regulations, such as providing opportunities for physical activity for all, school fitness classes, healthful school lunches, "point of purchase" nutrition information in local food markets, alcohol sales limits, and preventing tobacco product marketing to children.

Studies at the SPRC have shown that only *multiple and persistent* influences produce meaningful changes in the dietary, exercise, or tobacco-use behavior of adults, adolescents, and children. For adolescents, always resistant to health behavior change, the following influenced success: parent and teachers whose personal habits allow them to be supportive role models; amount and quality of school-based education on tobacco, fitness, and nutrition; peer influence; and amount, duration, and quality of community-wide health education. Also, certain personal characteristics were influential – for example, the presence before the education's onset of *self-efficacy* toward one's behavior-change abilities (Fortmann et al. 1995).

11.3 Underlying Theories

Community-based health education carried out by SPRC and by some analogous projects has been guided by two major theories (community organizing and health communication-behavior change), with success dependent upon a judicious blending of the two (Flora et al. 1989; Farquhar et al. 1991).

11.3.1 Community Organizing Theory

Community organizing theory describes methods of identifying the health problem (and resources needed or available), mobilizing the community's opinion leaders and organizations, gaining populace support, forming coalitions, launching and maintaining education programs, achieving regulatory changes, and *empowering communities* to reach and maintain their goals. Community organizing for health requires continued attention similar to the accepted role of political leaders – to assess periodically the needs of both governmental and non-governmental organizations, and, in the case of health promotion, to aid in planning and coordinating health promotion campaigns. Community organizing as defined here has analogies to "community self-development" as described by Green and Kreuter (1991), and it also relies on elements of diffusion theory (Rogers 1983) – which has shown how innovations are adopted through natural social networks, aided by a community's opinion leaders. Rogers' account of "failure of water-boiling in a Peruvian village" provided an excellent example of the need to identify and work with a community's opinion leaders as a prerequisite for the success of a health innovation initiated solely by self-appointed "experts" who are not seen as trustworthy by the community's residents.

11.3.2 The Health Communication-Behavior Change Theory

The health communication-behavior change theory provides the basis for designing, sequencing. and distributing messages for the total population and its subgroups based on their health needs, cultural attributes, social networks, media habits, attitudes, motivation, knowledge, and self-management skills. It describes theories underlying educational *content*, such as social cognitive theory (Bandura 1986), which is primarily based on an individual's capacity for self-directed change. Bandura's research confirms that "learning by doing" is more effective than "learning from observing" (modeling a behavior), and both are more effective than an "information-only" approach that changes knowledge alone. These principles are contained in his *social cognitive theory*, which posits that guided practice in a new behavior can lead to increased self-efficacy and to greater behavior change (Bandura 1986). Thus, "knowledge-only" campaigns have been found less effective than those that apply Bandura's recommendations.

The health communication-behavior change theory also incorporates methods of reaching the total population using principles described as "social marketing," (Kotler 1975; Lefebvre and Flora 1988). These marketing principles described first by Kotler as "product, price, and promotion" lead to insuring the relevance of the "product" (health messages) and to the low material and psychological cost of attending to the health message. Additionally, successful social marketing occurs only when the health messages are promoted and distributed efficiently to a large proportion of the populace.

Another behavior change method included within the communication-behavior change theory is the method of teaching counterarguing skills, as described by Roberts and Maccoby (1973). This method, also called "inoculation," can be presented either through the media or face-to-face and teaches the learner how to best argue against a deleterious message, such as an advertisement promoting cigarette use. This "inoculation" method was found to be very effective in prevention of adolescent substance abuse, notably for prevention of initiation of tobacco use when used in a manner that can be incorporated into comprehensive community-based health promotion (Robinson et al. 1987).

Lastly, Cartwright's (1949) pioneering work on mass persuasion principles is also quite germane to the health communication-behavior change theory. He described the need to change not only a person's knowledge and motivation, but that changes in "action structure" were also needed. These principles, when combined with Bandura's methods for self-management skills training and with certain elements of Rogers' diffusion theory, lead to a logical sequence of steps recommended for both the delivery and behavioral objectives, as derived from the health communication-behavior change theory (Table 11.1).

Table 11.1 The health communication-behavior change components (Adapted from Farquhar et al. 1991)

Communication inputs	Communication functions (for the sender)	Behavior objectives (for the receiver)
Face-to-face messages	Determine receiver's needs	Become aware
Mediated messages	Gain attention (set the agenda)	Increase knowledge
Community events	Provide information	Increase motivation and interest
Environmental cues	Provide incentives	Take action, assess outcomes
	Provide training	Maintain action, practice self-management skills
	Provide cues to action, including environmental change	Become an opinion leader (exert peer group influence)

11.4 Methods

11.4.1 Initial Steps

Problem Identification The initiating agency, group, or person can emanate either from within or outside of the community. The first task is to identify the problem. Local (community) interventions should ideally coexist with and interact with national programs and must be linked to scientific support from the national or international level, which has indicated that both CVD prevention (WHO 1986) and alcohol sales control (Holder and Wallack 1986) are problems requiring *local* action. Other than the initial steps of problem identification and formation of a coalition, most of the methods to be described are relevant only to the three CVD prevention examples described in this chapter. However, any chronic disease that requires widespread education designed to change "lifestyle" behaviors (such as exercise, diet, and cigarette use) will require analogous methods.

Coalition Formation Key political and opinion leaders as well as relevant organizations must form a coalition. This coalition must create a resource inventory, obtain populace support, and plan the intervention. Relevant organizations, particularly in developed countries, are listed below under Sect. 11.4.3 and include the following: the County Medical Society, or its equivalent, municipal hospital community affairs departments, city parks and recreation departments and voluntary health agencies (i.e., the local branches of national heart, lung, cancer and diabetes organizations). Any organization that will act as a conduit (or "channel") for the distribution of mediated instruction or classes must also be represented (i.e., television and radio stations, local newspapers, schools, churches, libraries, pharmacies, clinics, and physician and dentist offices). As the coalition grows in size, a "steering committee," preferably restricted to six members, needs to be formed to carry out more detailed planning, including formation of expert groups in education and evaluation and "task forces" assigned to particular topics (Flora et al. 1989; Farquhar et al. 1991).

11.4.2 Planning

Formative Evaluation As the term "formative" indicates, these activities form (create) the education effort and can be divided into categories of audience needs analysis, message design, pretesting of education programs, and evaluation of education programs. The needs analysis, message design, and pretesting phases are part of the social marketing aspect of health communication-behavior change theory. Also, the evaluation of education programs, although properly labeled as "formative," is also often termed "process" evaluation since it determines the contributions to success of different components of each education program (Farquhar et al. 1991). Process analysis is also done at the completion of the total program as part of "summative evaluation," although the distinction between formative and summative is sometimes quite arbitrary, depending on the intent of the evaluator (Farquhar et al. 1991).

11.4.3 Implementation

Need for a Comprehensive Approach Interventions must go beyond attempting to change knowledge, the usual goal of an educational system, by providing training in behavior-change *skills.* They must also go well beyond the individual, enlisting multiple community organizations in campaigns for change and seeking changes in the social environment and in regulations that promote access to the facilities and resources needed for healthful practices. Multiple communication channels (such as radio, television, newspapers, mass-distributed print products, schools, and the Internet) are needed to reach different subgroups, recognizing differing media usages, knowledge, and desire for change. A comprehensive intervention should involve schools, worksites, senior citizens' centers, voluntary health agencies (such as the local branches of any national organization that deals with cardiovascular disease, diabetes, and cancer), churches, and facilities for sport, recreation, and health. These organizations and others can serve as education conduits, with the community's electronic and print mass media organizations assisting in message design, content, and delivery. The Internet provides a new channel, whose community education role is now becoming better defined (Baker et al. 2003). Interactive computer learning, now becoming common in classrooms, can be designed for large groups – an emerging variant of mass media. Newer communication technologies, such as handheld computers, provide new points of entry for health promotion (King et al. 2008).

Comprehensiveness requires variety. For example, in tobacco control programs of SPRC's community campaigns, local medical clinics, dental offices, pharmacies, and libraries distributed a low-cost skills training "Quit Kit"; a local smoking cessation class was shown on television; many newspaper articles and columns appeared; local businesses supported costs of a smoking cessation contest; and all newspapers and electronic media "cross-advertised" activities designed for mass audiences (Altman et al. 1987). Formative evaluation must be continued throughout the entire implementation period of any planned intervention campaign. Success requires a well-designed mix and sequence of programs delivered through varied channels. This integration, with goals set in advance and goal changes based on early results, is analogous to a commercial marketing campaign, hence the term "social marketing." The distinction from commercial marketing is that social marketing uses marketing methods for social betterment without a commercial or profit-making intent. As described above, social marketing is the explanatory term for the needs analysis, message design, and pretesting phases of formative evaluation. These phases require message tailoring to fit any subgroup's needs and preferences, respecting cultural differences, learning styles, and preferred learning sites (Slater and Flora 1991). A message sequence should increase awareness, then, increase knowledge, and last, increase motivation and provide training in the skills needed for adoption and maintenance of a new behavior (Bandura 1986). Electronic media can carry out the first two parts of this sequence and stimulate use of the more information-dense print media of newspapers and booklets, which are inherently more effective in *skills training* than are electronic media (Flora et al. 1997).

Message Characteristics Messages must be clear, focused, and salient. Salience requires broad reaching media, arousing interest and awareness – topics must break through passive indifference engendered by the information overload of many societies and become "on the public agenda." Given the large advertising budgets of today's commercial mass media, health agencies' messages must be of sufficient production quality to compete for the public's attention. The competition for the public's attention is great indeed since the average adult in the United States in the past decade was exposed annually to 35,000 television advertisements, equaling 292 h of exposure (Fortmann et al. 1995). Formative evaluation must continue during a campaign and alter message content in accordance to the state of readiness of the population. Thus, early in a campaign, messages should increase knowledge and awareness, followed by those that increase motivation and provide skills training – with resultant behavior change (Schooler et al. 1997).

11.4.4 The Amount of Intervention Needed

The amount of intervention (the "dose" of intervention) needed depends on many factors: lesser amounts are needed in smaller communities, at earlier stages in a country's adoption of a "health innovation," and when the advocated behavior change is reasonably simple (such as mammography, hypertension screening, and immunization campaigns). Clearly, more complex changes are needed in individuals and in society's norms to alter eating or exercise patterns or to control tobacco use. Complexity in respect to nutrition arises from many sources, including long-standing cultural beliefs and practices; entrenched methods in agriculture, food production, and retailing; advertising of "unhealthful" foods; and the advent of widespread fast-food chains that are dominated by commercial interests unresponsive to local demands and needs. Few projects have measured intervention dose, except in very general terms that do not allow accurate estimates of the amount of exposure. One excellent method records the total number and duration of messages distributed over a defined time period, albeit with a defect due to lack of message quality measures (Farquhar et al. 1990). This method's use increased evaluation costs (which comprised almost two-thirds of total expenses) in the Stanford Five-City Project (FCP – see below). This expense may explain why others have not used it nearly to the same degree of completeness. However, it is clear that public health education would be served if more campaigns were analyzed this thoroughly. The following describes this method's use in the Stanford Five-City Project (see Sect. 11.5.3). The number of adults aged 18–74 were known in the communities receiving the education programs, and they were used for the analysis. The number and duration of messages from TV/radio, newspaper, other print messages, and face-to-face messages (largely classes) were enumerated each year for 5 years. The number of messages from newspaper, other print and face-to-face encounters were obtained from the education group's records. The TV broadcast hours were obtained from the Neilsen (A.C. Neilsen Co, Chicago IL) monitoring system, which records the proportion of households viewing a particular TV station for all hours for each major community area in the United States. Radio hours were obtained from the local radio station survey data. Calculations are then made for the number of messages for each education channel and their duration for the average adult in the community (Flora et al. 1989; Farquhar et al. 1990).

11.4.5 Evaluation

Comprehensive community-based campaigns aiming for widespread behavior change in the community's population need the following types of evaluation: (1) formative evaluation to plan and test messages (as described in Sect. 11.4.2), (2) process evaluation to study the effects of each individual educational activity, and (3) summative evaluation to determine the effects of the campaign at different levels (the individual, in organizations, and in community's social or physical environment). Formative evaluation determines the likelihood that a message, class, or group activity will reach the intended audience, and requires measures of audience segmentation, trials of effects of message design, evaluation of form and content of mediated message delivery, and other features of social marketing (see Sect. 11.4.3) (Lefebvre and Flora 1988; Slater and Flora 1991; Cirksena and Flora 1995; Williams and Flora 1995). Process evaluation examines the success or failure of a program component and also allows insight into why it succeeded (or failed). Process analysis requires a dissection of relative effectiveness of multiple channels, differentiating their reach, specificity, and impact (Schooler et al. 1998). Process analysis allows insight into "how" and "why" a change campaign worked, or failed – finding the reasons explaining outcomes measured by summative evaluation (Flora 1991). As mentioned in Sect. 11.4.2, process analysis may be classified under either "formative" or "summative," depending on timing and purpose (Flora et al. 1989; Farquhar et al. 1991). Summative evaluation methods are generally more rigorous than either formative or process evaluation methods and, in the case of chronic disease prevention interventions, often will entail measures of physiological states (such as blood pressure), as well as attitudes, knowledge, or behavior (such as cigarette use) (Farquhar et al. 1977, 1990). The unit of analysis is commonly the individual, although both the Stanford Three Community Study (Williams et al. 1981) and the Five-City Project (Farquhar et al. 1990) also analyzed risk factor change by the more conservative method, using longitudinal regression analyses with the community as the unit of analysis (recognizing time-by-town variance). This is an example of multilevel analysis, or as a nested model, with the survey data on smoking rates, blood pressure and other variables representing the individual level, and the mean levels of these variables for the entire population representing the community level. When, as was the case in both the TCS and FCP, the two levels have congruent outcomes, causal inference is strengthened (Farquhar et al. 1977, 1990). More complex multilevel analyses are needed for projects with more complex designs. For example, a multi-school project designed to decrease student's tobacco use was analyzed at three levels (individual, classroom, and school) by a random regression model which was shown to be better able to discern variance missed by ordinary regression techniques (Hedeker et al. 1994). In future intervention studies, especially when community sub-units such as schools or worksites are being studied, multilevel methods should be used with greater frequency, and thus allow greater insight into both causality and process of change (Hedeker et al. 1994).

11.4.6 Additional Methods Needed

Successful community-based health promotion requires effective leaders, community activists with the courage and charisma to advocate health innovations. Advocacy campaigns derived from international, national, state, or provincial sources can provide a local activist leader with the popular support to fight entrenched bureaucrats who defend the status quo. Tobacco control in Australia and the United States provides examples. National and state advocacy groups with access to mass media created a strong mass movement for change, allowing advocates to enlist popular support for local tobacco control measures. In both California and Australia's State of Victoria, this popular support led to statewide increases in tobacco taxes, with some retained for education against tobacco, a measure that had been resisted by state legislators who had long been influenced by tobacco lobbyists – an example of community activism moving up the "ladder" of bureaucracy to a higher political level (Victorian Health Promotion Foundation 1994; Pierce et al. 1994; The Catalonia Declaration 1996).

Changes in policies, laws, and regulations (PLR) are needed for success, especially for long-term success. Local PLR can affect alcohol and tobacco sales and create environments that improve nutrition and enhance physical activity. However, national, state, or provincial actions can magnify local PLR and education efforts on topics such as tobacco taxation, automobile seat-belt laws, food and drug safety, school nutrition, school physical activity policies, and (in the United States) laws on firearms. As described above, widespread popular attitude changes in numerous communities can also affect the political process at the state, province, or federal level. Tobacco control is a case in point, with major decreases in tobacco use in many countries in the past four decades (NHS Information Service 2007; Fiore and Jaen 2008). These successes, and their accompanying political ferment, were largely responsible for the passage of the WHO Framework Convention on Tobacco Control in 2003, with ratification by more than 100 countries by 2007 (Koh et al. 2007).

11.5 History of Comprehensive Community Health Promotion

The history of the past four decades described in this chapter is devoted largely to eight formal research projects designed to affect cardiovascular disease (CVD) risk factors, and one designed to limit alcohol use in a community. All but one involved entire populations of at least one *education* community, compared to at least one *control* community. One of those was restricted to a before/after analysis in a single large community (New York City). Five projects are described in greater detail to provide examples of the methods and results. Dissemination worldwide into practical applications of community organizing and mass communication technologies, derived in part from these research projects, occurred throughout these four decades, with a relatively small number using research methods analogous to those described here.

11.5.1 The First Two Examples: The First Decade

The first and second example, the Stanford Three Community Study (TCS), in three small agricultural marketing towns in California (total population 45,000), and the North Karelia Study (NKS), in two adjoining predominately rural Finnish counties (North Karelia population about 180,000), each began in 1972.

TCS, the first Stanford project, was carried out from 1972 to 1975 in both English and Spanish, comparing effects of mass media alone in one community and mass media plus ten-session risk reduction classes for some high-risk adults in a second, with a third as a control (Farquhar et al. 1977; Schooler et al. 1997). Groups exposed to varied education amounts showed a dose-response change in smoking, blood pressure, and blood cholesterol, with a proportionately larger effect in the Spanish-speaking residents than in the Anglo majority. This minority population outcome required intervention resources in Spanish to be proportionately larger than those provided in English to the Anglo majority. A composite CVD risk reduction of about 23% and 30% occurred in the mass media-only and mass media-plus classroom conditions, respectively. The risk score (a probability) was derived from each adult's "before-after" risk levels (age, gender, systolic blood pressure, blood total cholesterol level, cigarette use, and relative weight). These risk parameters were entered into a multiple logistic regression model to predict the 12-year future probability of a coronary heart disease event (myocardial infarction, sudden death, or angina pectoris). The scoring system was based on coronary events experienced by adults in the long-term prospective Framingham Heart Study (Truett et al. 1967). Thus, a relatively modest amount of mass media (about 30 television and radio "spots," weekly newspaper columns on heart health, and four separate mass mailings of booklets) was sufficient to change the population's body weight, cholesterol and blood pressure levels, and smoking prevalence. The education followed the principles outlined in Sect. 11.3 for the community organizing and health communication-behavior change theories. As an example of community organizing, close cooperative relationships were created with two influential opinion leaders (a local Anglo physician and the Hispanic program director of the local Spanish language radio station). As an example of the social marketing aspect of the health communication-behavior change theory, message design for the smoking cessation print materials were different in the English and Spanish languages, as dictated by formative evaluation. Both the eight session classes held for a high-risk subset of the population and the print products mailed to households incorporated some of Bandura's self-management principles, such as building awareness, making a clear commitment (i.e., a written "contract"), and adopting gradual, stepwise changes in behavior designed to increase confidence in one's ability to achieve the desired behavior change (Bandura 1986).

NKS evaluated two matched, rural Finnish counties that contained many villages with farming and lumbering as the main occupations. North Karelia (about 180,000 population) received an education campaign that began in 1972, continuing to the present and expanded to the entire country. After 10 years, CVD risk factor changes comparable to the TCS occurred, and significant net reductions in CVD events occurred (Puska et al. 1985; Schooler et al. 1997). This study was marked by extensive community organizing, resulting in strong partnerships with residents and their organizations. The NKS influence on its country's policies was unparalleled among the CVD projects, providing its most important lesson – that a well done project led by respected scientists can move an entire country. As examples, Finland's food and agricultural industries made large changes: Fertilizers were supplemented with selenium (a substance low in Finland's soil that is needed for health), milk pricing was changed (based on protein instead of fat content), programs were created to replace dairy farms with berry farms, a new canola industry replaced jobs lost in dairying, and increased production of low-saturated fat foods occurred (Puska et al. 1985; Puska 1995; The Catalonia Declaration 1996). In 1972, population-wide nutrition change and smoking cessation interventions were an innovation internationally, which may partly explain the success of these two pioneering programs (TCS and NKS).

11.5.2 Early International Diffusion, 1977–1983

Studies similar to the TCS were done in Italy (The Martignacco Project, 1977–1983, one treatment, mass media and screening, one control – CHD risk fell in men only); Australia (The North Coast Project, 1978–1980, similar to TCS, one mass media, one mass media plus classes – effects on smoking, greater in the mass media "plus" community); Switzerland (two treatment, two control pairs, German and French speaking, mass media, classes, environment changes – effects on smoking, blood pressure, and obesity); and South Africa (similar to TCS, one mass media, one mass media plus classes plus community events – decreased CHD risk, blood pressure, smoking; both treatments were equivalent). All four studies, reviewed in Schooler et al. (1997), reported significant risk factor changes, adding evidence for the effectiveness of the TCS model, namely, that a predominately community-wide mass media campaign is effective, but that supplemental face-to-face instruction usually adds some extra effects (Farquhar et al. 1991). It is noteworthy that all of these studies were done in rather small communities (population sizes of about 12,000–15,000 residents); thus, these effects may be more difficult to achieve in larger and more complex communities.

11.5.3 The Second and Third Decades: Projects Begun in the 1980s and 1990s

The third example is the Stanford Five-City Project (FCP) (USA). Its intervention phase from 1980 to 1986 extended TCS methods to larger populations (total population of about 360,000) with multifactor CVD prevention directed at two northern California cities. There were three control cities (Farquhar et al. 1990). It differed from TCS in the larger size of the communities, in greater use of community organizing, and in greater collaboration with the communities' health, media, and education organizations in planning and implementing programs. It was similar in generous use of mass media, both print and electronic. The *proportion* of messages received by the average adult over 5 years of education was as follows: television and radio 67%, newspaper 28%, other print (such as booklets and "tip" sheets) 4%, and face-to-face 1%. Duration of exposure over 5 years was as follows: television and radio 35%, newspaper 18%, other print 41%, and face-to-face 5%. It was unique in measuring total dose of education (about 5 h/year and about 100 episodes of exposure/year to all forms of media and classroom education) (Flora et al. 1989; Farquhar et al. 1990). This means that an "average adult" who has followed the whole program on mass media and in classrooms would have experienced 100 single exposure episodes (including TV, radio, newspaper or other print, workshop training, or community sponsored exercise sessions) which add up to 5 h duration in total in each year.

FCP's initial year of television messages (defined as "high reach/low involvement") stimulated the public's use of print media, which supplied more effective training than from television in the skills needed for smoking cessation, healthful food purchasing or preparation, learning appropriate exercise habits or ways to lose or control body weight (Flora et al. 1997). However, television can be quite effective in skills training. For example, the FCP presented an 8 week "live" TV broadcast of a local smoking cessation class, which contained considerable modeling of the smoking cessation skills being learned by the class attendees (such as behavioral problem solving, self monitoring, tapering, goal setting, deep muscle relaxation, and group social support) (Altman et al. 1987). The composite antismoking campaign of a "quit smoking" contest, the television and face-to-face classes, and a widely distributed print "Quit Kit" were analyzed separately (Altman et al. 1987). Results were comparable to the TCS (about a 15% fall in Framingham composite risk of CVD) (Truett et al. 1967), with a major impact on blood pressure (4–5%) and smoking (13%) (Farquhar et al. 1990). Health bureaucracies, usually timid, should gain courage from the FCP's "David and Goliath" demonstration that only 3 h/year of high quality television health education can counteract the public's exposure to about 100 h/year of television advertising devoted to unhealthy nutrition. The exposure of the US population is estimated as 292 h of TV advertisement based on the Neilsen monitoring system (cf. Sect. 11.4.4). Michael Jacobson of the Center for Science in the Public Interest estimated that about one-third of these are for "unhealthy" nutrition (personal communication). Almost all TV nutrition advertising is "unhealthy" since the food industry is so inclined. For example, after the nutritionists and preventive medicine scientists succeeded in the 1970s, through education, in decreasing egg and butter intake, the counterattack began to bring the US population back to their previous unhealthy consumption. Although all preceding CVD studies showed effects in small towns and/or rural districts, FCP showed benefit in *cities* (with populations as high as 100,000). Also, these effects occurred despite the advent (at least in the state of California) in the 1980s of dual working families and increasing public use of fast food, factors that made achieving nutrition-behavior change more difficult.

FCP's modest resources and greater effects, as compared to similar projects, support the benefits of the mass media presentation components of the health communication-behavior change theory, including its adaptation of the skills training aspects of Bandura's social cognitive theory. Perhaps the most practical lesson to policymakers is that adult quitters saved over three times more money from their cessation of cigarette purchases (2,860 quitters @ $274/quitter/year) than the cost of the entire population-wide campaign ($4/adult/year) – savings retained by the individuals of the community, not counting savings in long-term health costs and short-term decreases in absenteeism from the individual's employment. Also, the relatively low cost of the intervention is highlighted by the fact that the total yearly cost of cigarettes to the 22,000 smokers (over $6 million) was 23 times greater than the yearly campaign costs (about $260,000/year). Lastly, the communities expanded the health promotion activities of the county's Department of Health and adopted FCP's technologies, later applying them to seat-belt promotion, changes in saturated fat use by restaurants and violence and adolescent pregnancy prevention.

Other successful CVD projects, both large and small, occurred in these decades in the United States, Sweden, Denmark, Canada, Germany, the Czech Republic, and China. Also, World Health Organization-sponsored projects began in about 23 other countries (Schooler et al. 1997) and have expanded beyond that since 1997. In all instances, they borrowed heavily from the experiences of the three exemplars and in many instances received training from either the Stanford or the North Karelia groups. In some of these projects, changes seen were less than was the case in the Stanford and North Karelia projects. Although it is difficult to know the reasons for a relative lack of success (e.g., the magnitude of the interventions was incompletely described), in some instances, the cause appeared to be related to inadequate use of the inherently cost-effective mass media.

11.5.4 Community Projects in Other Health Topics

Interventions on alcohol, mammography, tobacco control, immunization, motor vehicle injuries, and HIV/AIDS are prominent examples of other community-based projects done in developed countries, but with fewer well-controlled studies than in CVD. Also, many community studies of CVD have been done in developing countries, where effective recruiting methods and effective mass media use (often using radio messages) have been reported. A review of these is beyond the scope of this chapter, but may be found in the extensive review of measures to improve cardiovascular health in developing countries (IOM 2010). One well-controlled US study, Preventing Alcohol Trauma (PAT),[1] is the fourth example. This 5-year study of three US communities showed a 10% decrease in alcohol-related traffic injuries and a 50% decrease in adolescent alcohol use (Holder et al. 1997). The traffic injuries were analyzed for 3 years prior to the study and were compared to police and hospital records for the 5-year study duration. The alcohol use data were compiled from various records, prior to and during the study. These records included (1) arrest records of adolescents under the age of 18 for drinking while driving and (2) sales records from retail liquor stores and bars or taverns, using underage adolescents as attempted purchasers (to test the system). Coalition building and organizational behavior change among the police, alcohol sales outlets, and alcohol servers (such as bar tenders and restaurant personnel) were the main interventions. The public responded to a fear, instilled through publicity, of the penalties of greater enforcement of existing laws on underage alcohol purchases or drinking and driving. Therefore, in contrast to the three CVD exemplars, PAT showed that *major* public education is not needed for large public behavior changes. PAT estimated a cost saving of about $3 for every dollar invested, a number close to that found in many worksite health promotion studies, where the “return on investment” was $3–$6 for each dollar invested, measured in 2–5 years of the program (Aldana 2001). The cost savings came from decreased medical costs secondary to the reduced rate of alcohol-related automobile injuries. PAT found their communities had the required infrastructure for the campaigns, requiring only training provided by one indigenous community coordinator, a part-time clerk, an imaginative plan, and the will to proceed. A fifth example, from a very recent study, showed remarkable success from institution of a new health code regulation banning artificial trans fat from New York City restaurants (Angell et al. 2009). This study showed that educational persuasion of restaurants failed, but with public support, the regulatory approach succeeded in reducing the proportion of restaurants using trans fats from 50% in 2005 and 2006 to 1.6% in 2008. This project may be seen as a success predicated upon antecedent generation of public support, coupled with a legally enforceable regulation, analogous to the tobacco control successes cited in Sect. 11.4.6 above. The NYC study is an example of a single community (NYC) with a set of five serial surveys before, during, and after the intervention, without a comparison control community. Although causal inference is threatened by such a design, this risk was outweighed by both the repeated measurements and the finding of an extraordinarily large effect from the regulatory intervention (Angell et al. 2009).

TCS, the first, and PAT and NYC trans fat, the fourth and fifth examples, are opposites: TCS had a maximum of mass media education and a minimum of organizing, whereas PAT had the opposite. NYC had the benefit of antecedent nationwide education over the dangers of heart disease from trans fat, with excellent success from organizing an enforceable regulation. Thus, any of these three

[1] The Stanford Prevention Research Center collaborated with the investigators of this study.

models work, but to change complex behaviors, community educators must use sophisticated behavior-change methods, such as those of the health communication-behavior change theory described above. If fear of arrest or a fine for breaking existing laws and regulations suffice to change personal drinking-and-driving habits or restaurant practices, then the education process is simpler.

11.6 Past Experience Leads to a "Master Plan"

A five-step approach emerges from these studies, with many lessons derived from the Stanford FCP done in the early 1980s:

(a) Define the problem. Does the community need a health promotion campaign? A decision can be made from national or local survey data.

(b) Organize the community, creating a campaign that includes behavior change education, continued organizing, training of community organizations, empowerment of the public and the community's organizations, and future maintenance of programs developed during an initial phase of about 2 years.

(c) Implement an intervention, delivering 3–5 h of education exposure directed toward the total adult population per year for 2 years, using in year one, about 70% television/radio to arouse interest and provide knowledge, about 15% from more specific and instructive print media (emphasizing newspapers, if available) and 15% from community events and programs (such as health fairs, contests, and classes). In the second year, decrease TV/radio to about 40% and increase print to 35% and community events and programs to 25%.

(d) Evaluate the intervention, using the process and summative methods described above. Insure that adequate tracking of exposure to the intervention (the independent variable) is done, with calculations of both the amount and type of intervention. Preferably use a repeated survey cohort design in order to obtain a clear measure of the intervention's effect on behavior and risk. If resources allow, add a repeated independent sample design for a better measure of the total community impact on the community, recognizing the dilution of effect from in-migration. As an example, 33% of the FCP's final independent samples were relatively new residents. The independent sample design, with its greater variance and inclusion of migrants, can therefore miss the important question of whether the intervention is working.

(e) Institutionalize programs. The community becomes a demonstration project, with its "empowered" organizations functioning as health promotion resource centers for a wider region.

(f) Use the new community resources and its residents' potential power to advocate for local, regional, and national governmental regulations and laws that will increase local intervention effects and extend them beyond the community.

Any individual or organization that wishes to engage in community-based health education should gain courage from the words of the now deceased anthropologist, Margaret Mead, as quoted in the closing passage of the The Catalonia Declaration

(1996, p. 75), “Never doubt the capacity of a few dedicated individuals to change the world, in fact, it is the only way it ever has.”

11.7 The Cultural Basis for Barriers to Success

A *healthy city* has been defined by the absence of crime, crowding, and poverty and by the presence of educated residents and enlightened (and trained) organizations. Together these lead to a community empowered to solve its social problems (i.e., to increase its social capital) (Travers 1997; Smith 2007).

Considering barriers, MacIntyre (2000) found Glasgow’s environmental factors to be major barriers to healthful exercise behavior. Certain macroeconomic factors inherent in *globalization*, such as capital flight and increased wealth and income gaps, have been described as barriers to planned change (Cahill 1983; Bezruchka 2000). All such barriers threaten *community stability*, inhibiting greatly the success of health promotion attempts. However, wise compensatory resource allocation can overcome many barriers, as was shown in the Hispanic minority of the TCS. Therefore, the challenge for the future is: Responsibility for success in community-based health interventions lies with the interventionist, not with the community’s residents! Secondly, it is clear that successful community-based health promotion requires attention to the cultural, environmental and social determinants of health that underlie the modern epidemics of chronic disease. Colditz (2001) reminds us of Rudolph LK Virchow’s words, to paraphrase, that: “The history of epidemics is therefore the history of disturbances of human culture.” Certainly the increasing worldwide prevalence of obesity, the spread of tobacco use, and the urban barriers to physical activity fit Virchow’s definition of “disturbances of human culture.” As Colditz points out, many scientific endeavors put false hope in the search for new risk factors, rather than in applying the now well-established means and economic benefits of reducing the culturally determined risk factors for chronic disease. For example, Aldana (2001) cites evidence for cost savings from three to six times the cost of health promotion for lifestyle change in large worksites. Despite this and other extensive evidence for the benefits of primary prevention (The Victoria Declaration on Heart Health 1992; The Catalonia Declaration 1996; IOM 2010), many countries, including the USA, spend less than 5% of total health care expenditures on prevention activities of all kinds (including immunizations, mammography, and health promotion) (Marwick 1994; World Health Report 1997). Although the reasons for the *unreasonable* diversion of a nation’s resources from disease prevention to disease treatment are many, it certainly includes pressure exerted by the pharmaceutical and medical device industries. Also, the tobacco industry is still a prosperous growth industry worldwide, especially in middle- and low-income countries (The Osaka Declaration 2001; Sebrie and Glantz 2006; IOM 2010). Therefore, from a political economy perspective, success in chronic disease prevention requires vigorous governmental policy changes (i.e., on taxation, advertising, promotion of tobacco use to minors, etc.), in addition to more economic resources (The Osaka Declaration 2001; Koh et al. 2007; IOM 2010).

11.8 Conclusions

Four decades of the "total community" health promotion approach in developed countries strongly support the feasibility, at relatively low cost, of achieving transfer of public education technologies to a community's infrastructure (public health, media, schools, etc.), resulting in significant changes in health habits of populations. Although most studies derive from small communities, recent successes in Tianjin (China), a city of 400,000 (two exemplars examined populations of >100,000), suggest that the model also works in large populations (Schooler et al. 1997). Theory matters: When the population gains self-efficacy through education, the result – *community efficacy* – enhances capacity to change institutional policy and practice, thus maintaining community change. Organizing and educating communities requires *advocacy*, *activism*, *coalition building*, and *leadership*; success is enhanced by *regulatory change*. Synergism occurs when the needed laws and regulations come from state, provincial or national governments. Such dual approaches are needed for any major success in preventing chronic disease, which is particularly important for developing countries (IOM 2010).

Science cannot serve society if its evidence for educational benefit is ignored. This is not a new concept. As written over 2,000 years ago in the Chinese *Book of Lessons,* "If a virtuous and learned scholar aims to influence the people as a whole, one must first educate the people."

12.1 Introduction

Currently, almost two billion persons worldwide, that is 30% of the world population, have access to the Internet (Internet World Stats). These numbers are accurate as of June 30, 2010, and will soon be outdated: access has grown by 445% from 2000. The proportion of users varies by country, being 77% in North America and 58% in Europe, with notable peaks in the Nordic countries, where Denmark and Finland are above 85% and Norway and Sweden are above 90%. Figure 12.1 provides a global view on the proportion of users and growth in use in the last 10 years.

The proportion of users is not homogenously distributed in the population. In 2007, for example, according to Eurostat data, in all EU countries, with no exceptions, the proportion of Internet users was higher among men than women and among people aged 16–24 than older persons (United Nations Economic Commission for Europe (UNECE) 2011). It is reasonable, however, to expect that sooner or later almost everybody in the world will have access to the Internet, with no marked country, age, or sex differences. This is a very attractive prospect for epidemiologists and human researchers in general, who already recognized the possibility of using the Internet to conduct field studies in the early 1990s.

It is perhaps surprising that the Internet has been initially used mainly to conduct surveys rather than longitudinal studies or interventions, although the latter are less vulnerable to selection bias. The first medical surveys, such as those of patients with inflammatory bowel diseases (Hilsden et al. 1999; Soetikno et al. 1997) or diabetes (Baehring et al. 1997), have been published at the end of the 1990s. These

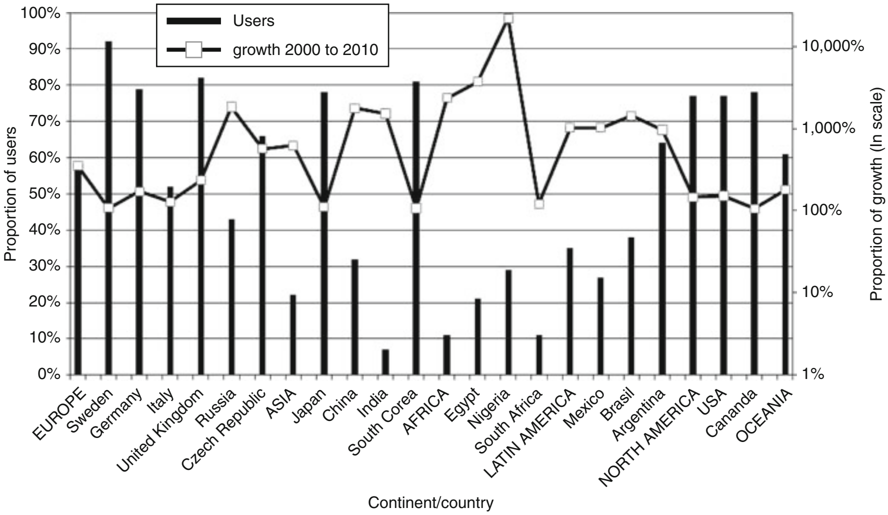

Fig. 12.1 Proportion of Internet users on June 30, 2010, and growth from 2000 to 2010 in selected countries (Internet World Stats 2011)

studies were pioneered by surveys carried out by psychologists and sociologists (Berrens et al. 2003; Buchanan and Smith 1999; Kraut et al. 2004; Skitka and Sargis 2006). In 1997, Kushi and colleagues reported the launch of a pilot study for an Internet-based cohort on diet and breast cancer (Kushi et al. 1997), and a small number of web-based birth cohort studies have been conducted in the last 10 years (Hercberg et al. 2010; Mikkelsen et al. 2009; Richiardi et al. 2007; Treadwell et al. 1999; Turner et al. 2009). However, most of the Internet-based medical studies are currently intervention trials. The Internet was first suggested as a tool to manage all aspects of the trial, including randomization and data acquisition (Kelly and Oldham 1997; Pepine et al. 1998), but, in the last 10 years, it has often been used for the purpose of recruiting study participants (McAlindon et al. 2003; Wang and Etter 2004).

The idea of using the Internet in empirical research in general and epidemiological research in particular often receives skeptical reactions. Typical concerns include problems related to lack of exposure heterogeneity in the study participants, phantom participations, duplicate records by the same participant, low data quality, and confidentiality issues (Gosling et al. 2004; Skitka and Sargis 2006; van Gelder et al. 2010). In fact, most of these problems have limited implications or can be solved technically. For example, the lack of heterogeneity does not apply to most of the exposures, as in many countries more than half of the population has access to the Internet. Similarly, various methods have been developed to identify duplicate entries, to enhance data quality, and to ensure data security and confidentiality, including the use of encrypted connections, registration through individual username and password, the use of screening questions to detect duplicates, and checks for implausible answers (Baer et al. 2002; Bowen et al. 2008; Dillman and Smyth 2007; Gosling et al. 2004; van Gelder et al. 2010).

As for any study based on volunteers, the main critical issue related to Internet-based research is, however, the representativeness of participants for the study population and the likelihood of selection bias. This is currently largely debated. At an international conference held in 2008, for example, one of the authors heard the editor of an epidemiological journal saying that because of concerns about self-selection, he was a priori against publishing results of Internet-based surveys. Issues of selection and selection bias will be extensively discussed in this chapter both in an ad-hoc section and within the context of the discussion about the use of the Internet in each type of study design.

In contrast to its limitations, the use of the Internet in epidemiological research offers several advantages, including decreased costs, simplified logistics, rapidity, flexibility, the possibility to tailor the questionnaire to the participants' characteristics, and instantaneous checks to identify inconsistencies as well as to reduce errors resulting from data entry (Baer et al. 2002; Dillman and Smyth 2007; van Gelder et al. 2010). Moreover, online studies have fewer constraints than traditional studies, both from a geographical and a temporal point of view: they can reach distant or "hidden" populations as well as they can recruit continuously for several years. Some other advantages are specific to the different study designs and will be discussed further in the corresponding sections of this chapter. However, a common feature of Internet-based studies, often overlooked, is the active involvement and empowerment of the study subjects (Rhodes et al. 2003). They can give feedback over the whole duration of the project and receive (and comment on) information about the study results. For example, it is not uncommon that, within the framework of an Internet-based study, researchers keep constant contact with the study participants using social networks.

In several studies, the Internet has been used to submit online questionnaires to a prespecified population, including members of a "traditional" cohort (Ekman et al. 2006; Russell et al. 2010), members of Internet panels (Silver et al. 2002; West et al. 2006), or members of a mailing list (Ruddy et al. 2010). In all these studies, the Internet was not used to directly recruit participants, whereas it was used as a tool to deliver a questionnaire to a preselected population. We will not discuss advantages and limitations of online questionnaires and technicalities on how to prepare them in this chapter (about these issues, see, for example, references Baer et al. 2002; Dillman et al. 2009; Ekman et al. 2007; Kongsved et al. 2007; Russell et al. 2010; Schleyer and Forrest 2000; van Gelder et al. 2010). Rather, we will focus on the Internet as a method to recruit study participants and its influence on study design and validity. Typically, Internet-based studies use online questionnaires, but this is not a necessary feature. Indeed, researchers may have a direct contact with participants via the Internet, for example, to complete a telephone interview or to obtain biological samples (Etter et al. 2005; Richiardi et al. 2007).

In this chapter, we will address general methodological issues about Internet-based studies and discuss examples of the use of the Internet in the context of different types of epidemiological designs, from surveys to randomized studies. Debates about the use of the Internet in epidemiological research may be affected by preconceived opinions either in favor or against it. Being involved in Internet-based research, we cannot be objective, but we will aim at discussing the different issues impartially.

12.2 Selection and Selection Bias in Internet-Based Studies

Participants in an Internet-based study are doubtless a selected population, regardless of the epidemiological design chosen to carry out the study. This is due to two main reasons: (1) the source population is restricted to Internet users (either all Internet users or users of specific websites), and (2) participation of subjects should be voluntary. What does instead depend on the study design is the mechanism through which bias may be induced by the sample selection process. We will illustrate these mechanisms in different study designs also using directed acyclic graphs (DAG) (see chapter ▶Directed Acyclic Graphs of this handbook) indicating E as the exposure of interest, R as a risk factor (or a set of risk factors) for the outcome of interest D, U_i as other unknown/unmeasured variables, and S as the indicator of selection into the sample. In all figures, a square around S will indicate conditioning on study participation.

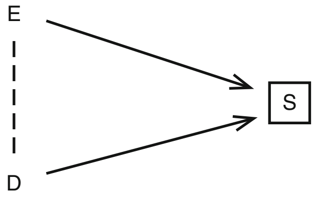

Fig. 12.2 Diagram of a study where selection of the study subjects (*S*) depends on both the exposure (*E*) and the outcome (*D*) of interest. The *dashed line* represents an association induced by conditioning on *S* (represented by a square around *S*)

In surveys aiming at estimating the prevalence of a disease, there is selection bias if the disease status or any determinant of the disease is associated with the selection probability. This is very likely to happen in Internet-based studies. If determinants of selection are known, it is possible to apply weights and obtain a valid estimate of the prevalence. However, in most situations, it is very difficult to obtain a good picture of the determinants involved in the selection in a study based on volunteers recruited through the Internet.

In studies aiming at estimating associations, in general there is selection bias if the probability of selection depends on both the exposure (E) and the outcome (D) of interest (Hernán et al. 2004). This is illustrated in Fig. 12.2. For example, in an Internet-based cross-sectional study on asthma, the probability of volunteering to take part into the study could be associated with having asthma (D) as well as with living in a heavily polluted area (E). Under these circumstances, because of the conditioning on selection, an Internet-based study would most likely find an association between air pollution and asthma even in the case of a lack of a true causal association between these two variables. This type of selection bias can be large.

12.2.1 Longitudinal Studies

In longitudinal studies where the outcome of interest occurs after being selected into the study sample, the mechanism that we have just described does not apply but selection bias may still occur (Glymour 2006; Hernán et al. 2004). In particular, if the likelihood of participation in the study depends on both exposure (E) and a disease risk factor (R) for the outcome of interest (D), and these are independent of each other in the general population, the selection process induces an association between E and R; R becomes a confounder of the E-D association and thus, if we cannot adjust for it in the analyses, the estimate of the association is biased (Fig. 12.3). We (Pizzi et al. 2011) and others (Greenland 2003) showed that the potential bias induced by this mechanism is usually moderate. For example, assuming no effect of the exposure on the incidence of the disease (true rate ratio = 1.0), the estimated exposure to disease rate ratio is 0.95 even if (1) the odds ratio of selection associated with the exposure is 2.0, (2) the odds ratio of selection

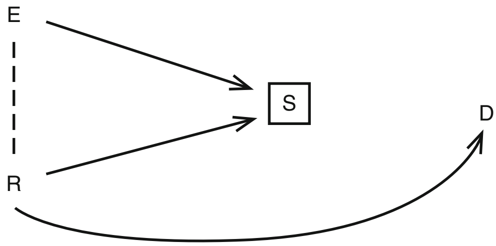

Fig. 12.3 Diagram of a cohort study based on a selected sample. In the population, the exposure of interest (*E*) is independent of the risk factor (*R*) and is not associated with the outcome of interest (*D*). Both *E* and *R* affect the likelihood of being selected as member of the study (*S*). In the selected sample (i.e., conditioning on *S* – represented by a square around *S*), *E* and *R* become associated (indicated by a *dashed line*)

associated with the risk factor is 4.0, and (3) the risk factor increases the risk of the disease by fourfold (Pizzi et al. 2011). The ideal situation is a randomized study in which, thanks to randomization which occurs after selection of study subjects, the exposure is not associated with selection in the study. Under this situation, assuming compliance to the treatment assigned, there is no possibility for selection bias even when some risk factors (R) are strong determinants of the selection.

It should be noted that, when the exposure and the disease risk factor are associated in the general population, the selection mechanism will alter the confounding effect of the risk factor, either increasing or decreasing it, according to the strength and direction of the association between E and R (in the general population) and also of the associations between E and R with S.

Let us now focus on the specific case of an Internet-based *cohort study* and the effect of restriction on Internet users, by discussing some hypothetical examples.

1. In the first example, the exposure of interest (E) and the risk factor (R) are independent in the general population and both are associated, either directly (Fig. 12.4a) or indirectly (Fig. 12.4b), with the likelihood of being an Internet user and thus of being selected into the sample.
   In Fig. 12.4a, for example, socioeconomic status (E) as well as year of birth (R), which are assumed to be independent in the general population, could affect the probability of being an Internet user. In Fig. 12.4b, socioeconomic status (U_1) could be a cause of being an Internet user and of being a smoker (E), while year of birth (U_2) could affect both the likelihood of being an Internet user and height (R). In these scenarios, the restriction on Internet users induces a spurious association between E and R, and, therefore, year of birth becomes associated with socioeconomic status (Fig. 12.4a) and smoking becomes associated with height (Fig. 12.4b).

2. In a second example, the exposure of interest (E) and the disease risk factor (R) are already associated in the general population as they share a common cause (U_3). This scenario is illustrated in Fig. 12.5.

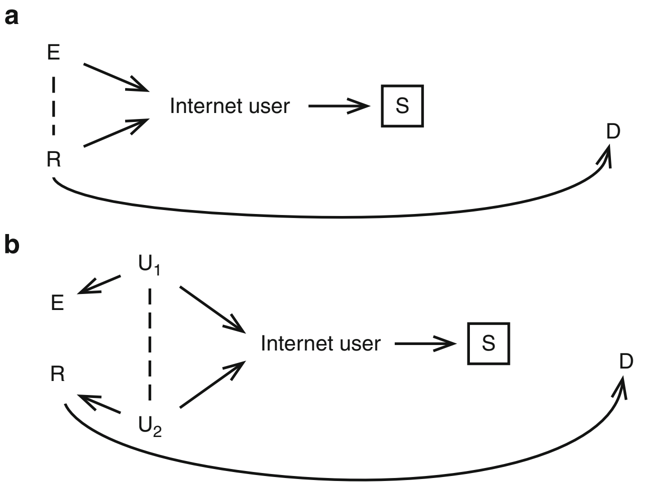

Fig. 12.4 Diagram of an Internet-based cohort study. (**a**) In the population, the exposure (*E*) and the disease risk factor (*R*) are independent, and *E* is not associated with the outcome of interest (*D*). Both *E* and *R* affect the likelihood of being an Internet user and thus of being selected as member of the study (*S*). In the selected sample (i.e., conditioning on *S* – represented by a square around *S*), *E* and *R* become associated (indicated by a *dashed line*). (**b**) Here, *E* and *R* affect the likelihood of being an Internet user as proxy of other factors (U_1 and U_2)

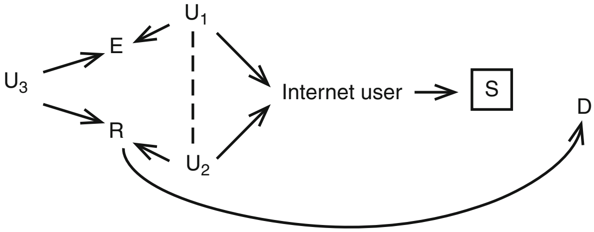

Fig. 12.5 Diagram of an Internet-based cohort study. In the population, the exposure (*E*) and the disease risk factor (*R*) are associated as they share a common cause U_3, and both *E* and *R* are associated with the likelihood of being an Internet user. In the selected sample (i.e., conditioning on *S* – represented by a square around *S*), U_1 and U_2 become associated (indicated by a *dashed line*) thus altering the original association between *E* and *R*

This is in fact an extension of the scenario depicted in Fig. 12.4b, where an additional factor (U_3), for example, place of birth, could affect both smoking (E) and height (R). Under this scenario, it is hard to predict whether the restriction of the source population to Internet users would increase or decrease the bias, as this depends on the strength and direction of the E-R association existing in the general population and on the strength and direction of the spurious E-R association induced by the sample selection process (as a consequence of the association induced between U_1 and U_2).

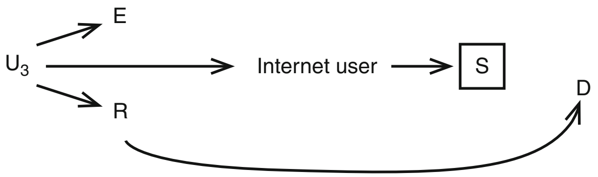

Fig. 12.6 Diagram of an Internet-based cohort study. In the population, the exposure (*E*) and the disease risk factor (*R*) are associated as they share a common cause U_3, which also affects the likelihood of being an Internet user. In the sample, the condition on *S* (represented by a square around *S*) implies a partial condition on $U_{3,}$ thus attenuating the association between *E* and *R*

3. A further example of interest is when E and R are associated in the general population because they share a common cause which, in turn, is a determinant of being an Internet user. This is shown in Fig. 12.6 that summarizes the case of a study in which socioeconomic status (U_3) is a cause of being an Internet user as well as of being a smoker (E) and taking regular exercise (R).

Under this scenario, restricting the study to Internet users implies a partial conditioning on U_3 and therefore a likely attenuation of the E-R association among the study participants compared with the general population. This means that the restriction would diminish the confounding effect of R and thus the corresponding bias induced in the exposure-outcome association.

In these examples, we only considered the restriction to Internet users as a potential source of selection. Similar considerations can be made for the second source of selection that is volunteering. Our examples demonstrate, however, that the effect of selection on the exposure-disease association in longitudinal studies is difficult to predict and can induce or attenuate confounding bias present in the general population (Pizzi et al. 2012). However, even when it induces bias, its magnitude is expected to be small as discussed above.

If the aim of the study is to estimate the incidence of the disease, bias is more likely to occur. The disease status itself cannot affect the likelihood of selection (as it may occur in surveys) but any disease risk factor (R in Figs. 12.3–12.6) that is associated with being an Internet user or volunteering would bias the estimate of the incidence.

12.2.2 Case-Control Studies

Case-control studies can be restricted to a specific population and still reveal valid associations (apart from some of the considerations just mentioned for cohort studies). Thus, the restriction to cases who are Internet users (or, e.g., who seek information about their disease on the Internet) is not expected to introduce a large bias by itself. The concern is, however, on the effect of this restriction on the control selection, as control subjects should be representative of the source population from which the cases originated. When cases and controls arise from two different source

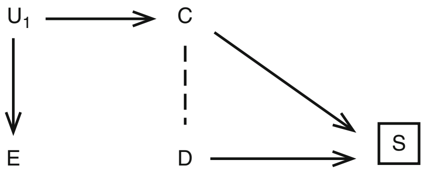

Fig. 12.7 Diagram of a case-control study in which cases have the disease of interest (*D*) and controls have a control disease (*C*). Both *C* and *D* affect the probability of selection in the study (*S*), and *C* is also associated with the exposure of interest (*E*), as they share a common cause U_1. In the selected sample (i.e., conditioning on S - represented by a square around S), C and D become associated (indicated by a dashed line) thus altering the original association between E and D

populations, there are clearly factors with different distributions across the two groups, which, when associated with the exposure of interest, lead to cases and controls being no longer comparable.

Even when the principle of the same source population is met, selection bias may occur if the exposure is associated, either directly or through other factors, with the probability of selection, that is, the sample fraction of controls (and cases when applicable) is not constant across exposure levels. In this situation, the causal structure becomes similar to that depicted in Fig. 12.2 or Fig. 12.7, both implying selection bias. Figure 12.7, for example, could depict a scenario in which cases with a disease of interest (D) are compared with controls originating from the same source population but having another disease (C). If the disease (C) is associated with the exposure of interest (E) (in this scenario through the common cause U_1), then there is selection bias (Hernán et al. 2004).

Since participants in an Internet-based case-control study are self-selected, it is not unlikely that some of the determinants of the exposure or the exposure itself are associated with volunteering and thus with selection. It should be noted, however, that the causal structures summarized in Figs. 12.2 and 12.7 do not always introduce bias. Indeed, there is no bias if the ratio of the selection probabilities of exposed and unexposed cases is the same as the ratio of the corresponding selection probabilities in exposed and unexposed controls. Under this special scenario, E and D are still determinants of the selection but the association remains to be valid.

12.3 Internet-Based Recruitment

The use of the Internet allows recruitment of study participants from large populations with a decrease in cost and time. Internet recruitment is similar to “traditional” studies in that it requires the specification of the source population. For example, the source population of an Internet-based study aiming at surveying cancer patients residing in Italy is defined by those Internet users who reside in Italy and have cancer. However, in Internet-based studies, there is no available list for random sampling from the source population and participants are self-selected volunteers. Thus, apart from defining the source population by means of eligibility criteria,

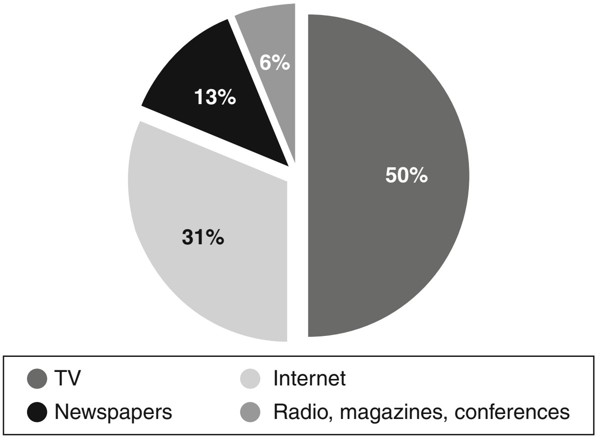

Fig. 12.8 Distribution on how participants to the Influweb study got to know about the existence of the study (based on about 2,000 respondents), Influweb, Italy, 2008–2009 (Influenzanet 2011)

researchers have little possibility to influence the selection of study participants. Internet-based recruitment typically goes through two processes: (1) people in the source population need to become aware of the existence of the study, and (2) they need to agree to participate.

The study has to be advertised in order to efficiently reach all members of the source population. The advertisement of a study of individuals with a specific disease or exposure would have to involve websites targeting that disease/exposure, while a study targeting the general population would be more efficiently advertised by means of a publicity campaign involving television, radio, and newspaper coverage and word of mouth. The Internet-based Nutrinet-Santé study, for example, which aims at recruiting a large cohort of individuals from the French general population, advertises the existence of the study through a multimedia campaign, different websites, and professional health channels (Hercberg et al. 2010). On the basis of our experience in the Italian Influweb study (an Internet-based monitoring project for influenza surveillance in Italy), when the target is the general population, television seems to be the most effective means of communication, especially if the advertisement takes place in Scientific Communication programs, while articles on the front page of online newspapers seem to be very efficient in terms of visits to the website but not in terms of new volunteers (Fig. 12.8) (Paolotti et al. 2010).

The Danish Pregnancy Planning Study, an Internet-based cohort study of women of reproductive age, was advertised through a pop-up advertisement in a national health-related website as well as with press releases to reach the media (Mikkelsen et al. 2009). An Internet-based study of determinants of gout attacks was advertised using a Google advertisement linked to the search term “gout” (Zhang et al. 2007). Over a period of 11 months, the advertisement was displayed 866,703 times, 6.6% of which led to a visit of the study website.

An often overlooked issue is that an integrated approach to advertise an Internet-based study aiming at recruiting for a long period implies intense and continuous efforts. Conversely, if the study is only advertised via selected websites, the recruitment process is less demanding, although the recruitment rate will be lower. Thus, to reach large sample sizes, an integrated approach is generally necessary. Furthermore, the methods used to advertise the existence of the study will impact on the characteristics of the study participants and the probability of selection bias. If a mother-child cohort, for example, is advertised only during antenatal courses, there will be an oversampling of nulliparous women who are more likely to attend these courses. An integrated approach could reduce this source of selection and spread the information about the study to the whole source population. A recent study compared three methods of advertisement for a survey of young adult smokers, namely, (1) advertisement on a single general website (Craiglist 2011), (2) an Internet campaign to target social networks and lifestyle-based websites, and (3) an invitation sent to members of an Internet panel (Ramo et al. 2010). The Internet campaign yielded the largest number of participants, but it was less cost-effective (about US$43 per completed survey) and was the method associated with the largest proportion of incomplete surveys. Roughly spoken, the three samples differed in terms of age, sex, ethnicity, education attained, nicotine dependence, and recent use of marijuana and cigars. Fewer or no differences were found in other variables, including alcohol use and smoking prevalence.

Once the members of the source population are aware of the study, they should access the study website and volunteer to participate. This is obviously a key issue. During the pandemic season, from October 2009 to March 2010, the Influweb website (Influenzanet 2011), for example, was visited 90,000 times and roughly 3,000 persons participated. The success of volunteering depends on several elements: the study website should not only induce participation but the study topic should also be of interest among the source population. For example, influenza during the H1N1 pandemic was a topic prone to gain the interest of the public and to reach the media. In other words, Internet-based recruitment is more efficient when the study is about a topic of general interest (Paolotti et al. 2010; Tilston et al. 2010), or targets a strongly motivated population, such as smokers trying to quit smoking (Civljak et al. 2010) or pregnant women (Richiardi et al. 2007). Even when an integrated approach for advertisement is used and the population is motivated to participate in the study, the participation proportion is not going to be high compared to traditional studies. For example, we used several means to advertise the existence of the NINFEA (Nascita ed INFanzia: gli Eetti dell'Ambiente) study (NINFEA 2011), a birth cohort study, to the population of the city of Turin, Italy. We have recently estimated that about 3–4% of the total number of pregnant women present in the population (excluding those born outside Italy) participated in the study (Pizzi et al. 2012). Considering that about 60% of the pregnant women have access to the Internet, and thus belong to the source population, this proportion translates into a participation proportion of 5–7%.

Some Internet-based surveys collect anonymous data but many Internet-based studies require registration and collect demographic information. This is an obvious requirement for follow-up studies in which subjects should be identified and be recontacted, but it is also used in surveys, for example, to limit the problem of duplicate or phantom participations. Researchers undertaking a Web-based study should therefore check that their platform is compliant with privacy regulations in the country where the study is ongoing. Upon registration, users have to be informed what these requirements are and, as in any epidemiological study collecting non-anonymous data through questionnaires, they should sign an informed consent form. In many studies, an online informed consent is used to decrease costs and organizational efforts and to enhance participation (the alternative being a mailed hard copy of the informed consent to be signed by participants). For example, in the NINFEA study, women provide online consent when they register and complete the study questionnaires, while they provide an additional written consent if they also donate a saliva sample.

The use of the Internet to collect non-anonymous data may raise concerns about safety and confidentiality issues. Researchers typically use technical solutions, such as encryption, firewalls, HTTPS (hypertext transfer protocol secure) protocol etc., which provide the same level of safety as traditional epidemiological studies, as, for example, mail surveys (Baer et al. 2002; Kraut et al. 2004). It is possible that potential participants are reluctant to participate in an Internet-based questionnaire fearing that their data could be accessed by people from outside the study. To address this issue, within the NINFEA study, we interviewed a small number ($n = 37$) of women who were both aware of the study and had access to the Internet but did not participate in the study (Richiardi et al. 2007). No woman reported that she did not participate for fear of revealing personal information, while the most common reason of non-participation was lack of interest in the study.

12.4 Study Designs

The Internet has been used in the context of most of the classical epidemiological studies, including cross-sectional (see chapter ▸Descriptive Studies of this handbook), cohort studies (see chapter ▸Cohort Studies of this handbook), interventions (see chapter ▸Intervention Trials of this handbook), and case-control studies (see chapter ▸Case-Control Studies of this handbook). Basic characteristics of these study types are discussed in detail in the chapters listed above.

12.4.1 Cross-Sectional Studies

Cross-sectional studies or surveys are typically carried out to measure prevalence and are particularly vulnerable to selection bias. If participants have a different prevalence of the disease of interest compared to non-participants, and it is not possible to apply weights to counterbalance this difference, results of the study will be difficult to interpret. This drawback makes the use of the Internet in surveys very problematic.

Although characteristics of Internet users can be investigated and may sometimes be known for certain populations, determinants of self-selection in a specific study are almost unknown. It is possible to obtain a rough estimate of the number of individuals who visit the study website to estimate a sort of response proportion (number of participants out of the number of visitors). However, this proportion is relatively useless as the number of visitors differs from the number of subjects who became aware of the study. Furthermore, the response proportion would give little information on the amount of bias in the estimate of the disease prevalence, as the key issue is whether volunteering is associated or not with the probability of having the characteristic of interest.

Having this strong limitation in mind, Internet-based surveys can still be useful for a number of reasons, including to conduct qualitative studies in which population representativeness is less relevant, to rapidly obtain information to generate hypotheses or develop a study protocol, to reach hidden populations, and to identify patients with rare diseases.

Simmons and colleagues carried out an Internet-based cross-sectional study between 2001 and 2002 to obtain information on possible precipitating factors of multiple sclerosis (MS) (Simmons et al. 2004). The aim was to generate hypotheses and select potential precipitating factors to be investigated in a cohort study of MS patients. An anonymous questionnaire in English was posted on the MS Australia and the MS International Federation websites for a period of about 10 months. About 2,500 self-selected patients from 60 countries in total, mainly from the USA, Australia, and the UK, completed the questionnaire. They reported factors that in their opinion were improving their condition or worsening their MS symptoms.

Behavioral research or studies on HIV and sexually transmitted diseases among men who have sex with men (MSM) are most often conducted on convenience samples, as MSM is a hard-to-reach population (a so-called “hidden” population). Therefore, Internet-based surveys using anonymous questionnaires are becoming increasingly common in this field (Elford et al. 2009; Evans et al. 2007; Hirshfield et al. 2004; Rosser et al. 2009). A study conducted in London in 2002 and 2003 recruited about 4,000 participants from HIV-positive patients attending outpatient clinics (12%), men seeking an HIV test (10%), men using gyms in central London (35%), and Internet users, the latter either via chat rooms or the websites of gaydar (2011) and gay.com (2011) (43%). The samples had different socioeconomic and behavioral characteristics, and most likely none of them was representative of the whole MSM population.

A number of studies aimed at comparing characteristics of participants in an Internet-based cross-sectional study with study participants based on a representative sample of the population (Andersson et al. 2002; Etter and Perneger 2001; Evans et al. 2007; Klovning et al. 2009; Marcus et al. 2009; Miller et al. 2010; Ross et al. 2005). Unsurprisingly, participants recruited via the Internet had different characteristics and disease prevalence, most often in an unpredictable direction and magnitude. This reinforces the concept that cross-sectional studies can only be conducted over the Internet if their aim does not require a population representative sample.

12.4.2 Cohort Studies

In 1997, an editorial on the use of the Internet in epidemiology suggested the possibility of conducting a cohort study of Internet users, defining this study population as an epidemiologists' dream coming true (Rothman et al. 1997). Authors were briefly listing some of the most evident advantages, such as fast enrollment of a large sample, prolonged contact with cohort members, inexpensive and efficient follow-up, as well as some possible problems, underlying the risk of marauder and phantom users, and issues of information validity. According to a response letter to this editorial, Kushi and colleagues were already piloting at that time the feasibility of an Internet-based cohort study (Kushi et al. 1997).

Indeed, the use of the Internet to recruit a cohort is very attractive as, in longitudinal studies, a representative sample is not a necessary requirement to get valid associational estimates. The epidemiological dream, however, has infrequently materialized in the last decade (Hercberg et al. 2010; Mikkelsen et al. 2009; Richiardi et al. 2007; Treadwell et al. 1999; Turner et al. 2009).

In 2005, we started the NINFEA study, which is an Internet-based mother-child cohort carried out in Italy (NINFEA 2011). A parallel study was started 2 years later in New Zealand (The Early Life Factors Study of Childhood Diseases). We will therefore use the NINFEA cohort as an example to illustrate advantages and limitations of using the Internet to conduct a cohort study.

NINFEA is a multipurpose cohort aiming at investigating the effects of certain exposures during prenatal and early postnatal life on infant, child, and adult health (Richiardi et al. 2007). It enrolls pregnant women in order to follow-up their children for at least 18 years. Members of the cohort are children born to women who are Internet users, become aware of the study, and volunteer to participate. At any time during the pregnancy, they can register through the project website (www.progettoninfea.it) and complete the first questionnaire that lasts about 30 min. They are asked to complete two other 30-min long questionnaires at 6 and 18 months after delivery. Long-term follow-up involves linkage with available population registries and periodical very short online questionnaires focusing on specific outcomes (e.g., cognitive development, respiratory diseases).

We advertise the existence of the study using both "active" and "passive" methods. Active methods involve the collaboration of health personnel to distribute leaflets and/or to introduce the study to pregnant women when they reach hospitals or family clinics for reasons related to the pregnancy. Therefore, this approach is inherently limited to selected geographical areas and targets a (roughly) prespecified catchment population. Currently, the NINFEA study is actively advertised in the city of Turin (900,000 inhabitants), in the Tuscany Region (4,000,000 inhabitants) and, with a lower intensity, in the Piedmont Region (4,000,000 inhabitants including those living in Turin). One of the potential advantages of active recruitment that we have not yet explored is the involvement of specific populations characterized by high levels of specific exposure or diseases of interest. Let us suppose, for example, that in a community living around a large industrial area there are concerns on the possible reproductive effects of industrial emissions. It would be hard to quickly set up a "traditional" mother-child cohort in this population, especially if there are no research infrastructures already available in the area. It would, however, be possible to actively advertise the existence of the Internet-based cohort in that population in order to recruit a sufficient number of pregnant women. The online questionnaires could be modified accordingly to incorporate questions about the exposure of interest in the area.

Passive recruitment includes methods that do not involve the health personnel, including the Internet and the media. So far we have not launched a media campaign to advertise the NINFEA study, while we use the Internet in various ways: links to our study website posted on the hospitals' websites and on websites dedicated to pregnant women, participation in discussion forums related to pregnancy, and a NINFEA page in Facebook. This type of passive recruitment is not entirely automatic, as forums change constantly as well as they become more or less popular among Internet users. This implies constant monitoring of the accesses and the need to routinely post reminder messages. Furthermore, there should be bilateral interaction with the users of the forum to keep the discussion lively and attract new participants.

Doubtless, participants in the NINFEA cohort are strongly selected. When compared with the general population, we found that NINFEA participants have a higher socioeconomic status, a lower parity, are less frequently non-Italian citizens, and smoke less but have a higher alcohol consumption during pregnancy (Pizzi et al. 2012; Richiardi et al. 2007).

As mentioned above, participating women should complete 30-min follow-up questionnaires at 6 and 18 months after delivery and shorter questionnaires thereafter. The use of the Internet makes the follow-up rather efficient. In the NINFEA study, we collect information via e-mail, landline telephone, cell phone, and postal address at the time of the registration. When it is time to complete a follow-up questionnaire, we e-mail the women asking to access the website and complete the questionnaire. Non-responders are additionally contacted first by e-mail and then by telephone and regular mail. Currently, about 60–65% of the women reply after e-mail contacts, while remaining women have to be contacted using traditional approaches. Overall, the final response to the second and third questionnaires is about 85–90%.

During the first 5 years of the study, we have learned some valuable lessons regarding the follow-up. First, it is fundamental that contact information is obtained through mandatory questions at the time of the registration. This allows a much higher follow-up completeness at the cost of a small baseline dropout of participants who are not willing to reveal this type of information. Indeed, in cohort studies, baseline selection is a much smaller problem than incomplete follow-up, and the initial contact strategy should aim at assembling a cohort whose members guarantee high long-term participation. Second, although many authors have concerns about phantom participants in Internet-based studies, in the NINFEA cohort, this was a minor problem. Some people registered to the website to further understand about the questionnaires, but if public information about the project is clear enough, we believe that phantom participants and registration from non-eligible individuals are not important issues. For example, in our cohort, participation should occur before delivery. Indeed, so far, nobody participated after delivery, but we have been contacted by women asking if it is possible to participate after the baby was born. This suggests that the information on the website was clear enough to prevent registration after delivery. The possibility of duplicate registrations of the same participant is a more relevant issue. Although it is not difficult to identify them at the time of the statistical analyses, using key variables based on the available demographic information, duplicate registrations can make the follow-up procedures more complex. Let us take the example of a pregnant woman who registers twice with two different dates for the last menstruation (because of typos or because the pregnancy was redated between the two registrations): what date should be considered for the follow-up? When should the woman be recontacted? Most likely this person will be contacted twice. It is possible to introduce checks in order to limit the number of duplicate registrations and facilitate the follow-up procedures but, in our experience, it is not possible to avoid them completely. A third issue is change of e-mail address. Pregnant women and families with small children quite frequently change job and/or home. It is therefore important to keep frequent contact with the participants to give them updates about the study as well as to check contact information. If the e-mail address has changed, it is possible to contact the woman by telephone or letter and ask her to update her information. Indeed "traditional" cohort studies are affected by the same problem, and having the participants' e-mail address and a population restricted to Internet users only helps in obtaining a high follow-up participation proportion.

A potential limitation of the Internet-based recruitment is that there is no direct contact with the participants and thus, exposure information is self-reported and it is more difficult to obtain biological samples. In the NINFEA cohort, we collect samples of saliva from the mothers and the children using self-collection kits sent by regular mail. About 60% of the members of the cohort, so far, agreed to donate a sample. Successful collection of biological samples has also been achieved in other Internet-based studies, such as collection of saliva samples from subjects enrolled through a smoking cessation website (Etter et al. 2009). In an ongoing nationwide French cohort study aiming at recruiting half a million individuals (Nutri-Santeé cohort), participants can donate a blood sample by visiting local sample collection centers (Hercberg et al. 2010).

Currently the NINFEA study recruits and follows up about 25 subjects per week, employing overall (including IT experts and research assistants) less than three persons-years per year. Its Internet-based design offers two main advantages, namely, efficiency and flexibility, which are obtained at the cost of population representativeness. Flexibility is an often overlooked characteristic. The cohort will be able to recruit for an indefinite period, and its population coverage has changed and will change over time. Other Italian regions will be able to start active recruitment in the future, and it will be possible to adapt the questionnaire to other populations. Indeed, a parallel study has been launched in 2007 in New Zealand (The Early Life Factors Study of Childhood Diseases 2011), and other countries may join in the future. Furthermore, compared to traditional studies, it is easier to add, delete, or modify questions to all participants or selected subgroups, both to improve the questionnaire and to assess exposures previously uncovered. For example, during the H1N1 pandemic in the winter of 2010, we added some specific questions about vaccinations that were not planned in 2005. Based on our experience and other Internet-based cohort studies, we believe that this methodology will be increasingly used in the next years, especially when the target of the cohorts will concern highly motivated people (e.g., pregnant women), or populations difficult to reach or difficult to follow-up (e.g., short-term migrants) or when researchers will aim at fast recruitment of large samples.

12.4.3 Case-Control Studies

In case-control studies, cases and controls should be selected from the same source population, independently of their exposure status. As discussed before in this chapter, this is difficult to achieve using Internet-based recruitment. Thus, it is not surprising that we could not find any example of a study in which both cases and controls were selected using the Internet. A recent study describes the selection of a control sample to be used for genetic analyses: about 4,500 subjects were selected in the USA both among a group of Internet panelists and using ad-hoc Internet recruitment (Sanders et al. 2010). However, study cases were traditionally selected, and the study focused on genetic variants, which are unlikely to be strongly associated with self-selection in the study.

Case and control selection could be very problematic using the Internet but not impossible. We can imagine different approaches, which are described using a hypothetical example of a case-control study on celiac disease in Italy.

In a first approach, cases could be selected via a link posted on a specific website, for example, the website of the Italian Celiac Association. All potential cases visiting the website would be informed about the study, and a small proportion of them would volunteer to participate. The advertising efforts would have to last until a sufficient number of patients is enrolled in the study. The source population for this study would include all subjects that, if diagnosed with celiac disease, would search information on the Internet. Then controls could be recruited by posting information about the study in a number of disease-specific websites, say the websites of the Italian Associations for asthma, chronic bowel disease, and type 1 diabetes. Obviously, these diseases would have to be unrelated with the exposure of interest. Again, control participants would be self-selected volunteers, and the participation proportion would be expected to be very low. The association estimates obtained from an Internet-based case-control study of this type would be valid had the determinants of self-selection been similar among cases and controls or had these determinants been unrelated with the exposure status. Unfortunately, these conditions are both rather strong and difficult to check in the data.

A second approach for an Internet-based case-control study would begin with the definition of the source population. For the hypothetical Internet-based study on celiac disease determinants in Italy, a broad definition of the source population would include all Italian Internet users. Recruitment of case patients would then involve the website of the Italian Celiac Association, any other website of potential interest for celiac disease patients, as well as media campaigns. Case participants would again be strongly selected. Controls would have to be selected from the same source population, namely, from Internet users. Recruitment would thus involve media campaigns and links posted in various websites, not necessarily of interest for celiac patients.

A stricter definition of the source population could improve this study design. For example, the source population could include users of a specific website, say the website of a national newspaper. Everybody accessing the website would be invited to participate in a study, and case patients would include volunteers with celiac disease while control subjects would include all the other volunteers. It could be possible also to adopt a two-stage approach in which, in the first stage, a generic health Internet-based survey is offered to persons accessing the website and, at the second stage, cases with celiac disease and a sample of controls without celiac disease are further interviewed.

Irrespectively of whether a broader or a stricter definition for the source population is used, case and controls would again be strongly selected, and the critical issue would be whether the determinants of the selection are associated with the exposure of interest and if they differ between cases and controls.

This brief description of hypothetical Internet-based case-control studies emphasizes their vulnerability to selection bias. Careful methodological work and empirical testing is still needed before an Internet-based case-control study can actually be conducted. Apart from selection bias, however, Internet-based case-control studies would have other important limitations. Firstly, recruitment of incident cases through the Internet seems even more problematic and most likely an Internet-based case-control study would involve prevalent cases, with the well-known corresponding limitations. Secondly, even if a study manages to involve cases and controls from the same source population without selection bias, the use of the Internet introduces selection among cases. It is hard to predict if case participants would have a more or less serious disease, but the selection would most likely introduce problems of generalizability. Furthermore, it would be difficult to distinguish between factors causing the disease and factors affecting its severity or the patients' overall health status.

A case-crossover design (see chapter ▶Modern Epidemiological Study Designs of this handbook) which does not involve the selection of control subjects could be a more sensible option for an Internet-based study. An Internet-based case-crossover study on gout (Online Gout Study 2011) has indeed been launched in 2003 (Zhang et al. 2007). The existence of this study was advertised using Google links. Gout patients were invited to register and asked to complete a control-period questionnaire every 3 months investigating risk factors for gout attack in the preceding 2 days. Moreover, they were asked to complete an "attack questionnaire" if they were experiencing a gout attack. Participants were also provided a hard copy of the attack questionnaire in case they could not access the Internet during the gout attack, but in fact this option has been rarely used during the study.

As any other case-crossover study, this study aimed at evaluating trigger factors and acute effects (Hunter et al. 2006; Zhang et al. 2006). Exposure information was collected prospectively, because patients were recruited before having the actual gout attack, thus limiting the possibility of selection bias. It is also possible to imagine a different design, in which patients participate when they have an event, say a gout attack, and complete the exposure information for the control period/s retrospectively. Under this scenario, there is possibility of selection bias if their likelihood of accessing the study website and participating in the study depends on some of the trigger factors under investigation. For example, a patient could experience a gout attack after having used a diuretic. He or she might suspect that the diuretic was the cause of the gout attack and use the Internet to check for this hypothesis. Then, he or she accesses the study website, in which there might also be some general information about the disease, and decide to participate. Obviously, this would induce selection bias.

12.4.4 Intervention Studies

For a number of reasons, Internet recruitment fits very well with intervention studies, namely, (1) randomization is likely to cancel bias due to self-selection, (2) the randomization can be easily managed centrally through the website, also stratifying for a number of variables and patients' characteristics, and (3) pragmatic and explanatory trials become very similar in design and conduct. Indeed, Internet recruitment is the most correct setting in which to test tailored interventions offered via the Internet to unselected patients/populations. These types of interventions are becoming more and more frequent. We have carried out an admittedly cursory PubMed search restricted to clinical trials using "Internet-based" and "intervention" as the keywords. It revealed a clear trend in increasing number of papers with time (Fig. 12.9).

Internet-based trials in medicine have been conducted starting from the end of the 1990s and/or beginning of 2000s. In 2000, for example, McAlidon and colleagues started online recruitment for a feasibility study of an Internet-based clinical trial of glucosamine vs. placebo in patients with osteoarthritis of the knee (McAlindon et al. 2003). The main outcome was knee pain, assessed using a validated online self-completion questionnaire 12 weeks after intervention. Volunteers completed an eligibility screening questionnaire, and, if applicable, they were asked to send a signed hard copy of the informed consent and copies of medical records. Upon confirmation of the osteoarthritis of the knee, they were randomized into the treatment or placebo group. To those subjects included in the treatment group, the pills were mailed every second week. Although this study involved Internet-based recruitment, the intervention to be tested was not an online intervention (as it involved mailed pills) and relied on having access to the actual medical records to confirm the diagnosis and obtain detailed information on the disease. These aspects may decrease the possible methodological advantages of using the Internet.

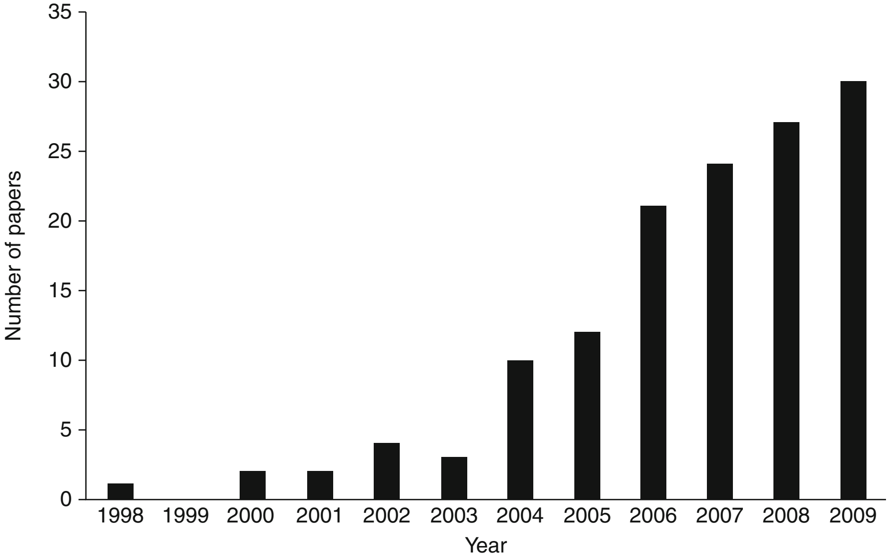

Fig. 12.9 Number of papers identified in PubMed using "Internet-based" and "intervention" as the keywords and restricting the search to clinical trials (search carried out in November 2010)

Studies testing online primary care interventions for health risk behaviors are more common, including those on diet and nutrition, physical activity, smoking habit, and alcohol consumption (Civljak et al. 2010; Portnoy et al. 2008; Vandelanotte et al. 2007; Webb et al. 2010). A recent Cochrane review on Internet-based interventions for smoking cessation identified 20 studies published until June 2010 (Civljak et al. 2010). Most of these studies used an Internet-based recruitment and all of them were published after 2004. Some of the trials compared an Internet intervention with either no intervention at all or an offline intervention; others compared different types of Internet interventions. In general, the study designs were very heterogeneous, and many studies had a relatively high proportion of dropouts. Authors concluded that the evidence of long-term benefits for programs delivered only by the Internet (as compared with offline interventions) is very limited, while there is some evidence that tailored (i.e., interventions specifically designed to meet the characteristics of a target individual or group) Internet interventions are more effective than non-tailored Internet interventions.

Rabius and colleagues advertised an intervention trial targeting smokers who wanted to quit smoking on the website of the American Cancer Society (Rabius et al. 2008). Potential participants were asked to complete a baseline questionnaire and provide informed consent. If eligible, they were randomized to receive access to one of five tailored interactive websites providing interventions for smoking cessation or a more static page set up at the American Cancer Society website serving as control treatment. The main outcome (successful abstinence for the last 30 days) was assessed 13 months after randomization, first e-mailing a survey questionnaire and then contacting by phone those who did not answer. Out of almost 6,500 individuals enrolled in the study, only 38% answered the follow-up questionnaire. Analyses were first conducted among the respondents only and then reconducted assuming that non-respondents did not quit smoking: in no case there was a significant difference in smoking cessation across the intervention arms. The high dropout rate between follow-ups, however, limited the study power.

Low completeness of follow-up was also observed in a trial set up on the Stop-tabac.ch website (Stop-tabac.ch 2011) to compare an original and a modified version of an online tailored program for smoking cessation (Etter 2005). The main outcome (smoking abstinence in the last 7 days) was assessed via e-mail 11 weeks after randomization, using up to three reminders. Almost 12,000 subjects were randomized in the study, with a response proportion at the follow-up questionnaire of 35%. In the analyses, non-respondents were assumed to still smoke. The original version of the program was found to be more effective, with 1 additional quitter every 26 participants.

Although many Internet-based randomized intervention studies have a high proportion of loss to follow-up, we do not think that this is a characteristic inherent to the study design. It is possible to increase participation by obtaining more detailed contact information at baseline (telephone number, cell phone number, address, second e-mail) and by recruiting a more committed and motivated population, for example, by having 1–2 follow-up questionnaires before randomization. Furthermore, in a pragmatic setting, a certain proportion of loss to follow-up should be expected.

Randomized trials recruiting participants through the Internet are feasible and, thanks to randomization, do not suffer from selection bias more than if a traditional approach of recruitment is used. Generalizability problems, namely, the restriction to self-selected Internet users, are minor when the intervention involves online programs. There are, however, some limitations. Firstly, it is difficult to have direct contact with participants and to include medical exams in the protocol, thus limiting the use of this study design in clinical settings. Secondly, in many studies, attrition to follow-up questionnaires was low and thus there is a need of methodological improvements to limit dropouts and increase motivation of the participants. Thirdly, Internet-based recruitment may lose its efficiency when the aim of the trial is to test an offline intervention.

12.4.5 Surveillance

The main aim of surveillance is to monitor trends in the rate of disease occurrence, both to gain insight in the current situation of an established disease and to detect outbreaks of emerging diseases.

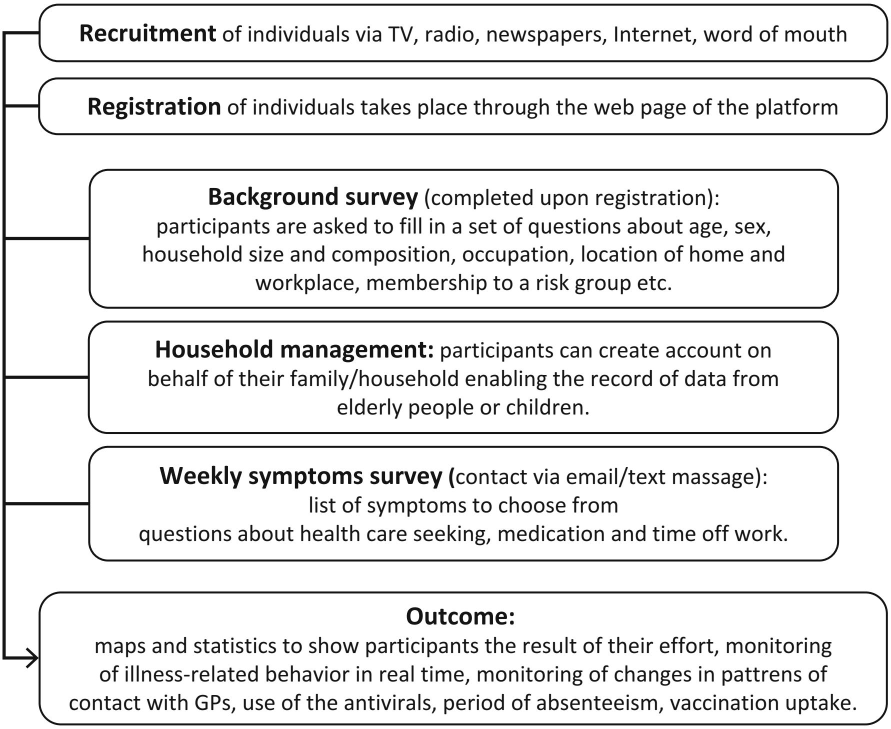
In this paragraph, we will not go into detail in describing the aspects of surveillance, already illustrated in (see chapter ▶Emergency and Disaster Health Surveillance of this handbook). Instead, we will concentrate on surveillance conducted by means of the Internet as a way to collect data from sources not easily accessible by traditional surveillance.

The widespread diffusion of computers and of the Internet has provided a tool capable of the earliest possible detection of epidemics, giving allowance to a timely and maximally effective public health response worldwide. Surveillance data, as well as behavioral data, social contacts, and risk perception can be collected by exploiting new information and communication technology (ICT) techniques and methodologies to better understand the spread of infectious diseases (e.g., by collecting information on behavioral data to understand human immunodeficiency virus transmission) and obtain real-time data, which are crucial to rapidly identify public health emergencies, understand global trends, feed realistic data-driven models to assess the impact on the population, and optimize the allocation of resources.

Existing traditional disease surveillance systems have limitations. For example, in the case of influenza-like illness (ILI), monitoring methods rely on sentinel networks of physicians, laboratory scientists, public health professionals, and epidemiologists. Although they may mirror influenza activity, they cannot be implemented as real-time surveillance tools: either they only record proxy measures of influenza, or they contain unavoidable time delays between incidence and reporting. Traditional schemes require individuals to access health services and rely on the propensity of individuals to consult. Age-stratified rates of physician consultation may vary widely with different healthcare and health insurance systems. For non-severe diseases especially, only a minor (and unknown) fraction of all infected individuals sees a doctor, and frequently after a considerable delay, when a complication has occurred or in case a doctor's certificate is required. A web-based platform can be used to detect cases from those individuals who are less prone to consult a doctor when sick but agree to fill in a brief web survey about their symptoms. Moreover, traditional monitoring schemes typically lack uniform standards for clinical definitions that vary considerably between countries and even between reporters (EISN – European Influenza Surveillance Network). By using web surveys, standard platforms can be used across different countries to collect uniform data without major economic efforts.

In the following, we will focus on the case of influenza-like illnesses (ILI) for which Internet-based technologies have been successfully used. These Internet surveillance systems for ILI have been implemented in Belgium and the Netherlands in 2003 (under the name "Der Grote Griepmeting" – the Great Influenza Survey), in Portugal in 2005 ("Gripenet"), in Italy in 2007 ("Influweb"), in the UK in 2009 ("Flusurvey"), and in Sweden in 2010 ("Influensakoll") with the aim of measuring influenza activity and collecting important public health information in real time (e.g., during the 2009 H1N1 pandemic, the web platform detected the peak activity of the influenza more than 1 week in advance with respect to the general practitioners (GPs)). Platforms are now grouped under the umbrella of Influenzanet, forming a network of platforms to measure ILI in the community at a European level.

For each platform, registration of participants takes place through the web page (see flowchart in Fig. 12.10). Upon registration, following provision with a password-protected account, participants are asked to complete a baseline



Recruitment of individuals via TV, radio, newspapers, Internet, word of mouth
Registration of individuals takes place through the web page of the platform
Background survey (completed upon registration): participants are asked to fill in a set of questions about age, sex, household size and composition, occupation, location of home and workplace, membership to a risk group etc.
Household management: participants can create account on behalf of their family/household enabling the record of data from elderly people or children.
Weekly symptoms survey (contact via email/text massage): list of symptoms to choose from questions about health care seeking, medication and time off work.
Outcome: maps and statistics to show participants the result of their effort, monitoring of illness-related behavior in real time, monitoring of changes in pattrens of contact with GPs, use of the antivirals, period of absenteeism, vaccination uptake.

Fig. 12.10 Diagram of recruitment and follow-up in the Influweb study

questionnaire with questions about age, sex, household size and composition, occupation, location of home and workplace, membership of a risk group, etc. Participants are also able to create accounts on behalf of their family/household enabling the entry of data from elderly people or children. Each week, participants are asked to complete a symptoms questionnaire as to whether or not they had symptoms in the previous week. To maintain participants' interest and remind them to complete the questionnaire, a newsletter containing influenza facts and news is sent each week. The platforms, called Internet monitoring systems (IMS), are updated on a daily basis during the whole influenza season with items including the estimated incidence and the spatial distribution of cases.

Results from the Belgian, Dutch, and Portuguese surveys have been analyzed under the name "Great Influenza Survey (GIS)" (Friesema et al. 2009). The estimated seasonal influenza incidence curves given by these systems were highly correlated with those obtained through the traditional surveillance method. These analyses also offer the encouraging indication that the Internet-based approaches can detect increased influenza activity more rapidly than surveillance-based reports by general practitioners (Marquet et al. 2006). Moreover, it is possible to estimate delays between the onset and the consultation dates and to detect changes in contact patterns and general behavior (Friesema et al. 2009).

During the 2009 H1N1 pandemic, IMSs have proved to be valuable tools in gaining an insight into the evolution of the pandemic in real time. In particular, the web-based system was launched in the UK during the first pandemic wave and went on collecting data until the end of the pandemic. Participants answering the symptoms questionnaires during the pandemic were asked more accurate follow-up questions about healthcare-seeking behavior, the delay of consultation with respect to the onset of symptoms; if they took time off work and for how long; if they took antiviral medication; if they were willing to be vaccinated against H1N1; etc. (Tilston et al. 2010).

Since participants would select their symptoms from a prespecified list, it was also possible to test different definitions of ILI, and to compare the resulting incidence with the one estimated by the Health Protection Agency (HPA). During the pandemic, to get a clearer picture of the epidemic evolution, the HPA asked for random testing of patients accessing different healthcare settings, which allowed evaluation of the true number of cases and thus adjustment of the estimates, by means of a method that was expensive and induced further delays in the data stream. The IMS to monitor ILI in the community was a direct and timely alternative, providing an incidence curve with a timing of the peak being close to the adjusted HPA case estimates. In making comparisons between web-based system estimates and HPA case numbers, results suggest that trends can be captured by the IMS even more reliably than standard GP-based systems, even though it remains unclear how accurate they are for estimating the absolute level of incidence (Tilston et al. 2010).

The UK web-based surveillance platform that ran continuously from July 2009 to March 2010 (i.e., during both the first (summer) and the second (autumn) pandemic wave in England in 2009) has also detected changes in healthcare-seeking behavior between the two waves (Brooks-Pollock et al. 2011). These behavioral modifications, due to changing scientific information, media coverage, and public anxiety, affected official case estimates. The web-based platform was able to detect a decrease from 43% to 32% in the percentage of individuals with ILI symptoms who sought medical attention from start to the end of the epidemic. Adjusting official numbers accordingly, it was possible to estimate that there were 1.1 million symptomatic cases in England, over 40% more cases than previously estimated, and that the autumn epidemic wave was 45% bigger than previously thought.

A further aspect for which surveillance is crucial is the development of accurate prediction models. When an outbreak occurs, usually short- and long-term predictions are based on observed data (provided by GP consultations or death/hospitalization records) combined with mathematical models updated as more data arise. For example, Baguelin et al. (2010) carried out a real-time assessment of the effectiveness and cost-effectiveness of alternative influenza A/H1N1v vaccination strategies. To generate plausible autumn scenarios under different vaccination options, they fitted a transmission dynamic model using the estimated number of cases determined by means of a web-based surveillance platform, calls to the UK National Pandemic Flu Service, and GP calls and consultations. In this specific case, data collected by means of the web platform were used to estimate the proportion of ILI cases calling the GP during the influenza A/H1N1v in the UK.

One of the important limitations that remain related to Internet-based surveillance is the lack of medical or laboratory confirmation of diagnosis. Data collected by means of a web platform will never be able to replace the virological analysis or clinical diagnosis carried out by GP surveillance.

In direct contact with the patient, the GP can exclude other diseases than ILI, and the virological analysis can give further information about the subtype of influenza virus. A possibility to overcome the latter limitation could be to send self-sampling kits to a selected subset of the Internet-based system participants. An attempt in this direction has already been made (Cooper et al. 2008), and this possibility should be explored further. Another possible limitation of Internet-based surveillance is that participants are not representative of the general population. This issue has been addressed by reweighting the sample according to the age and sex distribution in the general population (Tilston et al. 2010), although it is never possible to exclude that participation in an Internet-based system is positively or negatively associated with the risk of ILI.

In conclusion, Internet-based surveillance has the potential to capture a wider range of ILI cases than traditional surveillance, as well to track changes in healthcare attendance patterns in real time. Even though Internet-based surveillance has limitations and cannot replace traditional GP-based surveillance, it can provide an important support to enable the collection of valuable additional information, both in ordinary surveillance and during public health crises when the sentinel GPs surveillance and public health systems are under stress. While ILI has been used in the early deployment of the system, in subsequent years, these IMSs will consider other diseases and infections.

12.5 Web 2.0

Very recently, the Internet has started offering new possibilities for epidemiological research based on the so-called Web 2.0, which refers to the active generation of contents by the Internet users through various means including online communities, web searches, social networks, etc. (Lee 2010). For example, these new communication and information habits over the Internet may be used to quantify outbreaks of specific diseases (Eysenbach 2002, 2009). A well-known example is the use of Google searches to obtain real-time estimates of influenza-like illnesses (ILI) in the United States (Ginsberg et al. 2009): Ginsberg and colleagues developed a method to identify automatically ILI-related web search queries and use them to estimate ILI weakly percentages; these estimates had a correlation above 0.90 with data obtained from the US Surveillance Network of the CDC (Centre for Disease Control and Prevention).

The potential sources of information available in the Web 2.0 are growing fast. As examples, data on disease outbreaks can be obtained from chat rooms, blogs, press release, or Facebook (Brownstein et al. 2009, 2010; Eysenbach 2009), while exposure data, say on air pollution, can be obtained continuously from sensors worn by self-selected volunteers, and automatically transferred in real-time for model analyses (Mobile Environmental Sensing System Across Grid Environments, Message 2008; Mobile Air Quality Monitoring Network, Institute for Software Integrated Systems 2011). There are, however, obvious limitations in using these sources of data, including issues of generalizability, bias, and exposure and outcome measurement. Currently, areas of epidemiological research which may actually benefit from the use of Web 2.0 remain to be explored and identified.

12.6 Conclusions

Fifteen years ago, the Internet was advocated as a promising tool for epidemiological research (Rothman et al. 1997). Since then, some Internet-based studies have been conducted, including a number of surveys and intervention trials along with few cohort studies. Nevertheless, the use of the Internet in epidemiological research is still very limited. Van Gelder and colleagues have recently reviewed analytical epidemiological papers published in 2008–2009 in four top general medical journals (the British Medical Journal, the Journal of the American Medical Association, The Lancet, and the New England Journal of Medicine) and in three top epidemiological journals (American Journal of Epidemiology, Epidemiology, and International Journal of Epidemiology), finding that only about 1% of the scrutinized 2,094 studies used Internet-based questionnaires (van Gelder et al. 2010). Since online questionnaires can be also used in studies which do not recruit online, the actual number of Internet-based studies is smaller. For this chapter, we have scrutinized papers published between September 21, 2009, and September 20, 2010, in 11 leading epidemiological journals (Environmental Health Perspective, American Journal of Epidemiology, Epidemiology, International Journal of Epidemiology, American Journal of Public Health, American Journal of Preventive Medicine, European Journal of Epidemiology, Preventive Medicine, Journal of Epidemiology and Community Health, Journal of Clinical Epidemiology, Annals of Epidemiology). We have identified only two papers, both methodological, concerning an Internet-based cohort (Huybrechts et al. 2010) and an Internet-based survey (Klovning et al. 2009).

These data demonstrate that the use of the Internet has not yet routinely entered the epidemiological practice. Moreover, most publications of Internet-based studies deal with feasibility or proof-of-concept studies.

Evidence on the validity and reliability of web-based questionnaires has started accumulating (Apovian et al. 2010; Brigham et al. 2009; Donker et al. 2009; Miller et al. 2002; Rankin et al. 2008; Touvier et al. 2010, 2011; West et al. 2006), and some studies have successfully used mixed methods involving both web-based and mailed questionnaires for the follow-up of traditionally recruited cohorts (Ekman et al. 2006; Russell et al. 2010). However, methodological research on the use of the Internet to recruit unspecified populations in the context of the various types of study designs is still in its infancy. In detail, we need to better understand when an Internet-based survey can be carried out and if it is possible to tackle some of its inherent problems of selection bias; we need to further investigate the impact of baseline selection in Internet-based cohort studies, as well as evaluate the determinants of completeness of follow-up; we should refine our ability to advertise the existence of Internet-based studies to the relevant source population; we should develop methods to improve attrition in Internet-based randomized studies; we should understand if it is possible to conduct Internet-based case-control studies; and we should understand when surveillance can (or should) be carried out via the Internet.

In our opinion the short-, medium-term agenda for Internet-based research applied to epidemiology should prioritize innovative field work and methodological studies on the acquired data. In other words, the debate on whether Internet-based research is valid or not should overcome a-priori formed opinions and become more evidence-based where this chapter has indicated that randomized trials, cohort studies, and surveillance may be successfully carried out using the Internet.

13.1 Introduction

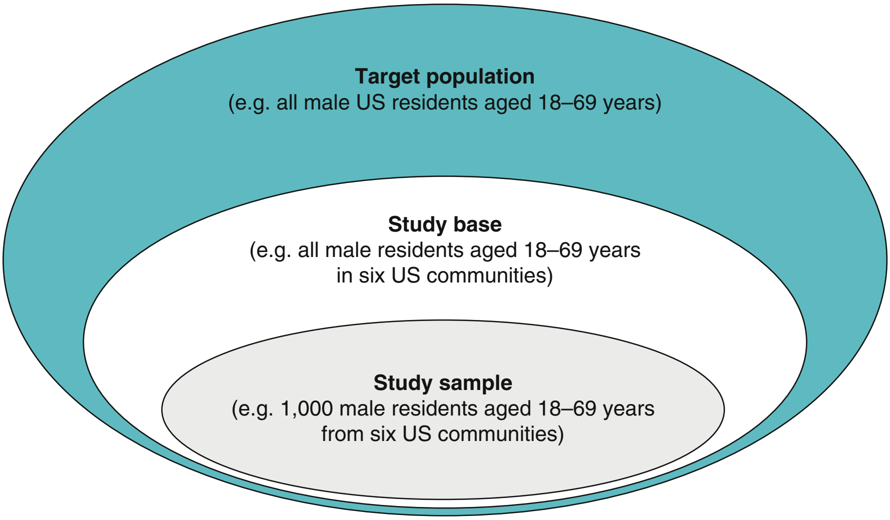
This chapter deals with basic principles and practical issues in designing and planning epidemiological studies. Although most of the practical issues are consequences of the theoretical principles of epidemiology as presented in this handbook as well as standard textbooks (Breslow and Day 1981, 1987; Gordis 2009; Rothman and Greenland 1998; Rothman et al. 2008; Miettinen 1985) and in different chapters (▸Basic Concepts, ▸Cohort Studies, ▸Case-Control Studies, ▸Confounding and Interaction, ▸Sample Size Determination in Epidemiological Studies, ▸Measurement Error, and ▸Missing Data) of this handbook, the emphasis here is on how to proceed practically when planning a study.

This chapter is based on our experience in conducting epidemiological studies and on a series of references in which many of the concerns in the practical planning of studies have been described at length. Among the key sources we used are the books by Hernberg (1992), White et al. (2008), Olsen et al. (2010), and Kreienbrock et al. (2012). The series of papers by Wacholder et al. (1992a, b, c) have also inspired much of our writing. It will start with a section on early planning in which the general setting of any study is described as well as the key planning document, that is, the study protocol. The second section is devoted to the choice and implementation of an actual design where we focus on cohort and case-control studies. The next section focuses on data collection and biological samples, both, with respect to the exposure and the disease outcome. The final section is devoted to practical issues and gives a list of topics arising in all studies that may not always get the appropriate attention while planning an epidemiological study.

13.2 Scientific Framework

13.2.1 Study Questions and Hypotheses

The first step in the planning of an epidemiological study is the definition of the problem, that is, the statement of the hypotheses and the justification of their relevance. Researchers must ensure that they have a clear view of the problem at the general level. At this conceptual level, a problem takes the form: "does X cause Y?" or "how much will a certain amount of exposure to X affect Y?" (Hernberg 1992, Chap. 4). To answer such questions, we first have to define the target population, say all male residents of the USA aged 18 to 69 years (see Fig. 13.1). For pragmatic reasons this population has to be narrowed down to the so-called study base, for example, all male residents of six selected US communities aged 18 to 69 years. A random sample drawn from this study base may serve as the study sample or study population. It should be stressed that in etiological as well as in descriptive studies, researchers are interested in the relationship between factors and disease which are valid beyond the study population, that is, which are informative for the study base and for the target population which is represented by the study base. Ultimately,



Target population
(e.g. all male US residents aged 18–69 years)
Study base
(e.g. all male residents aged 18–69 years
in six US communities)
Study sample
(e.g. 1,000 male residents aged 18–69 years
from six US communities)

Fig. 13.1 Hierarchy of target population, study base, and study sample

they are interested in the particular morbidity experience of the target population as far as it can be extrapolated to other populations.

The general interest of the investigator first has to be translated into precisely formulated, written objectives. A limited number of study objectives should be defined. These objectives may be of two kinds.

First, the study may be focused on specific questions with a predefined hypothesis. For instance, "does exposure to extremely low-frequency (ELF) electromagnetic fields cause childhood leukemia?" Here the hypothesis should be formulated as a series of operational questions. One can specify the ELF fields in a variety of ways both qualitative (yes/no or low/medium/high) and quantitative (e.g., present intensity, mean intensity over the last years, or cumulative exposure). Other predefined operational hypotheses may include subgroup analyses based on the disease subtype. These operational hypotheses will have to be decided by confirmatory tests. Additional findings beyond these primary hypotheses can then be clearly sorted out.

Second, the study may be designed to generate new hypotheses that will be investigated by exploratory analyses such as the following "what occupations are associated with an increased risk of laryngeal cancer?" Even in this case a predefined list of exploratory questions is useful. In the present example, this would consist in a list of occupations considered. Again an unsuspected excess in an occupation not considered a priori as entailing an excess risk should be reported as such.

13.2.2 Scientific Background

It is of crucial importance to undertake a thorough literature search and to know the literature in detail before planning any new project. Occasionally, the literature review may show that the study question has already been answered and that further data collection would be wasted.

Typically, the formulation of the study question (cf. Sect. 13.2.1) and the review of the scientific background are interacting steps in the initial phase of a new study that lead to the development of a study protocol (see Sect. 13.2.3). The scientific background has to support the research question and must justify its relevance in the light of the state of the art. This relates to both the subject matter to be investigated and the methodological approaches and instruments to be used.

Evaluating epidemiological evidence from the literature is often challenging even for experienced researchers. Because a single positive finding may be a chance finding, a complete literature search, including negative results, should be conducted. One should consider systematic errors (biases) and confounders that may have led to a particular result in previous studies. Several independent studies using the same design and the same procedure of data collection may have similar results due to common biases or confounding. It is therefore important that the sources of spurious results are identified and controlled in subsequent investigations. It would be ineffective to simply replicate previous studies, without consideration of new research questions raised by previous studies that could not be addressed because the information was not collected. A large body of literature on how to perform a systematic literature synthesis is available; see chapter ▶Meta-Analysis in Epidemiology of this handbook and references therein.

The literature review should, however, not be restricted to epidemiological studies, but has to encompass a range of topics from biological mechanisms or biomarkers related to the hypothesis under study to techniques of exposure measurement and other methodological aspects relevant to answer the study question(s).

13.2.3 The Study Protocol

An epidemiological study is generally a complex undertaking of long duration, requiring substantial personnel and financial resources. The success of a study depends on a careful preparation. It is self-evident that such an undertaking cannot be done without a written study protocol. The study protocol gives the scientific reasoning behind a study, specifies the research question, and describes the methods to be applied including those for statistical data analysis.

After describing the scientific rationale, the study background, and the specific objectives, the study protocol should define the study design including the precise study base and an estimate of the corresponding statistical power to achieve the objectives. Finally it should summarize the main tasks, their sequence, and the means to achieve the corresponding deliverables. This entails, for instance, procedures for identifying the outcome parameter, measuring of exposure and confounders, data management, and all steps taken for quality assurance. Further practical details of the fieldwork and the study logistics should be worked out separately in a manual of operations. The study protocol should also address the strategy for statistical analysis, quality control and training, time schedule, ethical considerations and principles of data protection, the general project organization, publication rules, and the financial breakdown.

According to Miettinen (1985), a study protocol serves five purposes, namely to

- crystallize the project to the researchers themselves
- give referees the possibility to review the project (especially for funding)
- inform and educate all those taking part in the project
- ensure the main researchers do not forget any details of the plan in the course of the study
- document the procedures of the project for the future.

It should be noted that Miettinen obviously did not differentiate between study protocol and manual of operations as to the authors' view the last three purposes are more appropriately addressed by a complementary manual of operations (see Sect. 13.7.4).

In summary, a protocol must be so detailed that an independent researcher could carry out the study based on it. An outline of the issues to be covered in the study protocol is given in Box 13.1. Most of them will be discussed in what follows. For further details we refer to chapter ▶Quality Control and Good Epidemiological Practice of this handbook.

Box 13.1. Overview of a study plan and corresponding key problems to be addressed in the planning phase

1. *Research questions and working hypotheses*
   - Relevance/previous knowledge
   - Choice of an appropriate target population
   - Precise definition of endpoint
   - Precise definition of independent variables and confounders
   - Choice of statistical measures (proportions, means, risks)
   - Translation into a hypothesis that can be tested statistically
   - Confirmatory testing of hypothesis/exploratory analyses

2. *Study design*
   - Optimal design (theoretical)
   - Practical limitations/feasibility
   - Justification of chosen design

3. *Target population, study base, and study sample*
   - Data source
   - Sampling procedure
   - Representativeness of study base for target population

4. *Size of study and its justification*
   - Size of acceptable type II error to be considered (power!)
   - Sample size determination

- Definition of subgroups (e.g., sex, age, ethnic group, study center)
- Power calculations based on fixed sample size

5. *Selection and recruitment of study subjects*
   - Measures to avoid selection bias (survival bias, referral bias)
   - Definition of appropriate reference groups
   - Matching, if applicable
   - Access to subjects
   - Means to maximize response
   - Means to facilitate equal participation of population subgroups

6. *Outcomes, risk factors, potential confounders, and effect modifiers*
   - Operationalization and quantification of variables
   - Temporal reference
   - Choice of assessment method (e.g., questionnaire or examination)
   - Derived variables/composite scores

7. *Measurement and data collection*
   - Measures to avoid information bias (recall bias, measurement bias)
   - Type of instruments (self-completion, face-to-face, telephone)
   - Design and content of instruments (structure, layout, comprehensibility, length, sensitive issues)
   - Media (paper-pencil, computer, online)
   - Use of existing (secondary) data (e.g., hospital records)
   - Measurements and examinations
   - Coding of free text (occupation, disease, medication)
   - Biomaterials: collection, processing, shipment, and storage

8. *Data entry and data storage*
   - Database system
   - Ergonomic layout and functionality of data entry screen
   - Validation of data entry
   - Validation of coding
   - Plausibility checks (concurrent to data collection)
   - Data corrections and documentation of data cleaning (always retain raw data!)
   - Merging of data
   - Data safety (back-ups)

9. *Quality assurance*
   - Standard operation procedures (SOPs) for data collection, measurement, interview (interviewer and operation manual)
   - Training and supervision of staff
   - Monitoring of data collection
   - Assessment of response incl. minimal information on non-responders

- Audio recording of interviews
- Tasks of internal/external quality control board
- Validation studies
- Comparison with reference data external to the study
- Description of changes of original study plan
- Project diary

10. *Strategy for analysis including statistical models*
    - Strategy to analyze a priori hypotheses
    - Strategy of exploratory data analysis (if applicable)
    - Procedures for secondary analysis
    - Control of confounders
11. *Data protection and ethical consideration*
    - Informed consent
    - Anonymization/pseudonymization of individual data
    - Sensitive issues (e.g., handling of genetic data, invasive procedures, long-term storage of data or biomaterials)
    - Handling of incidental findings and feedback to study participants
12. *Timeline and responsibilities*
    - Chronological sequence
    - Project governance (e.g., steering committee in multicenter studies)
    - Scientific councils
    - Publication rules

13.3 Design

The study design governs all procedures for selecting and recruiting individuals in the study sample. It also governs strategies to avoid bias and methods for data analysis. The design depends on both the study objectives and on practical issues such as costs or availability of data. Most epidemiological studies, with the exception of clinical trials and intervention studies, are purely observational, in that the investigator cannot assign the exposure to the study subjects as in experimental settings. The definition of a study design includes a definition of both the study base and the study type. The main types of observational studies are the cohort study and the case-control study (sometimes called case-referent study). Although they have a common basis, as every case-control study has to be considered as being rooted in a cohort (see chapter ►Case-Control Studies of this handbook), the practical implications of conducting a cohort or a case-control study are quite different. A number of other designs have been used or proposed and are mostly variations of these basic types (see chapter ►Modern Epidemiological Study Designs of this handbook).

13.3.1 Study Base

Once the general objective of the study has been defined and before the study type can be decided, the investigator should identify the actual setting, or study base, which is most suitable to study the particular research question. The study base should represent not only the target population but also the morbidity experience of this population during a certain period of time (Hernberg 1992, Chap. 4). This means that both the distribution of exposures and the morbidity and mortality experience of the study base have to be comparable to the target population.

For example, if the target population consists of workers within a particular industry where a potentially hazardous chemical was used, the study base may be the 10-year follow-up of workers employed for at least 1 year in a particular plant of this industry where the chemical in question has been used during the observation period (hypothesis testing). Another example would be the general population in a country with a number of environmental and lifestyle-related exposures (target population). Here the study base could be defined as the residents of a geographical area – where these exposures are all present – in this country at a certain point in time. The association of one or more health outcomes with a wide range of exposures can then be assessed in exploratory analyses (hypothesis generating).

Ideally, a study base should allow for a scientific generalization of study results (e.g., the association between exposure and disease). This can be achieved if exposure conditions as well as potential confounders and effect modifiers can be measured within the study base. Otherwise, the particular morbidity experience of the study sample would be mostly descriptive and would apply only to the population under study.

13.3.2 Cohort Studies

The design and analysis of cohort studies is described in detail in chapter ▸Cohort Studies of this handbook. In cohort studies the study sample to be included is either the whole study base or a sample of it based on certain criteria like existing exposure information.

The complete assessment of the occurrence of the morbidity outcomes or other endpoints, for example, biological markers, during the follow-up is one of the challenges of such prospective studies. While certain endpoints can be obtained from a *passive follow-up* by record linkage with routine records of mortality or incidence using registries or administrative data (cf. chapter ▸Use of Health Registers of this handbook), others need an *active follow-up* by which the health status or the biological marker of every subject in the cohort is determined at several points in time during the observation period. In this case, the study design is also called longitudinal study or panel study (see, for instance, Wild et al. 2008a).

In principle, the assessment of the exposure is not influenced by disease status as it is recorded before the disease arises. Conceptually, all cohort studies are prospective in the sense that one measures the exposure before the disease occurrence. In practice this approach is often modified when the outcome of interest is a disease with a long induction period like cancer, so that a purely prospective observation of the morbidity would imply either a study duration of several decades or very large numbers of participants. One way to shorten this duration is to set up the cohort historically, that is, from a past point in time onward and to mimic the prospective follow-up of the cohort until present. This design is called *a historical cohort* design in contrast to the *prospective cohort* design.

When subjects are *lost to follow-up* their morbidity, outcomes and/or other time-dependent factors are not observed from that point in time onward. When such a dropout occurs, its influence can only be controlled for in the analysis if it can be assumed that the dropout is only determined by recorded factors. This means that we have to know for each missing subject why she/he is missing and in particular that the dropout does not depend on the unmeasured health outcome. In technical terms this is the "missing at random" (MAR) assumption (cf. chapter ▶Missing Data of this handbook). This assumption cannot, however, be assessed from the study data as – per definition of dropout – we cannot know his/her morbidity or other outcome. An example of this would be a study in which the outcome of interest is smoking cessation comparing different cessation strategies. If the study participants fail to show up at later interviews aimed at investigating whether the subjects are still abstinent, this may be because they have relapsed and are ashamed of this fact or because smoking is no longer a problem as they have been abstinent for a long period of time. The effect of study dropouts can then only be assessed through sensitivity studies by which one would simulate reasonable data for the missing outcome, that is, the change of behavior. In this smoking cessation example, one could, for instance, assume that all dropouts relapsed or a 90%, 70%, etc. proportion of the dropouts. Minimizing the number of study dropouts is one of the main challenges to avoid selection bias in cohort studies.

13.3.2.1 Historical Cohorts

The historical cohort design mimics a prospective follow-up of a historically defined study base. This entails that at any point in the past, it must be possible to check whether a subject satisfies the cohort-inclusion criteria as defined in the protocol. Furthermore if a subject from this cohort developed the outcome of interest, one must be sure to observe it and to determine at which point in time this event occurred. In historical cohorts, the operational definition of follow-up is the following: if, during the observation period, the event of interest occurs at a given point in time for a given subject, it must have been recorded on a routine basis, and this record must be traceable with certainty. If this cannot be assured from a certain point in time onward, the subject must be considered as lost to follow-up since then.

The historical cohort design has been the design of choice for industry-based epidemiology of chronic diseases, especially cancer (cf. chapter ▶Occupational Epidemiology of this handbook), and we shall discuss the relevant issues in this context.

Cohort Recruitment The first step in planning is to determine whether information exists by which one can be assured that the population satisfying the theoretical cohort definition can be enumerated without bias. Completeness with respect to the cohort definition is of paramount importance. For instance, if the cohort definition is "all subjects having worked on a given industrial site since 1970," a document dated from 1970 listing all those subjects must be available as well as yearly lists of all subsequently hired and dismissed subjects. Computerized files can rarely be trusted as they were usually created for administrative purposes and are often at least partially overwritten or may exclude some categories of employees. Individual files as a single source of data are insufficient. Negligence, lack of space for archives, or floods and fire may have led to the selective deletion of files. It cannot be assumed that these lacking data are independent from either exposure or health outcome. Wage lists can be considered as reliable data source as all processes related to financial transfers are usually recorded with great care. In order to reliably identify a historical cohort, at least two data sources which can be considered as independent should be available. One example would be lists from the pension scheme and salary records of the personnel department. An alternative would be a union membership list and historical documents in which yearly counts of employed subjects are given.

Case Ascertainment and Loss to Follow-Up In historical cohorts the main concern is to assure that any event of interest that occurred during the follow-up period is detected. As an active follow-up is retrospectively impossible, the tracing of subjects must rely on linkage of the cohort data with routine records or on the collection of death certificates for deceased cohort members. These routine records are usually restricted to a defined geographical area. The traditional approach of a historical cohort study is a mortality study where the cause of death is abstracted from death certificates. This approach is quite convenient in some countries that have a national death index like the USA or the Netherlands and more laborious in others where local files have to be abstracted and coded. A mortality study, however, may give misleading results if the validity for a given cause of death is low and may even not be suitable to investigate diseases with a good survival. In the latter case, linkage with disease registries or hospital records is a better approach.

Disease or mortality registries are regional in most countries (with the notable exception of the Scandinavian countries and some others like France and the USA) and sometimes linked to the place of birth or residence. When either information is incomplete or missing for some subjects or if some subjects moved out of the covered geographical area, they are lost to follow-up, that is, from that moment on an event of interest is no longer traceable with certainty. In the statistical analysis, the subject should therefore no longer contribute any person-time (cf. chapter ►Cohort Studies of this handbook).

It is important to set up procedures by which one can determine whether and when a subject is lost to follow-up, for instance, by trying to trace address and vital status of study subjects through records of residents or pension schemes. Setting up such procedures can be difficult or even impossible for specific groups. For example, historical cohorts may include foreign-born subjects who may have returned to their country of origin after enumeration. If a subgroup is identified, for which such loss to follow-up is likely but no individual tracing can be set up, the only solution might be to drop all members of this subgroup from the study at the time of last contact. Thus, in a historical occupational cohort study, one may need to consider as lost to follow-up all foreign-born employees from the date of last employment onward.

As an informed consent cannot be obtained from study subjects, recording of individual diseases or medical causes of death may be restricted by data protection laws. Specific procedures are therefore required, often involving third parties, by which the epidemiologists can link disease or death records with study data on an individual level (e.g., Wild et al. 1995a).

13.3.2.2 Prospective Cohorts

The major advantage of cohorts where individual-level data are collected prospectively is that the dynamics of the etiological process can be observed more accurately because time-dependent data such as exposures, biological markers, and confounders of interest can be measured repeatedly in temporal order with disease outcomes. On the contrary, in historical cohorts the exposure is assessed retrospectively based on historical exposure data which are not collected for the purpose of the study. Such data are limited with regard to their validity and are often not directly linked to a given individual as, for example, environmental or occupational measurements. The resulting imprecision may lead to a misclassification bias not unlike that potentially occurring in case-control studies that may mask an existing association between exposure and outcome.

Another advantage of prospectively collected data lies in the possibility to perform intermediate analyses and to include additional markers and novel instruments in subsequent follow-ups. This is typically the case in so-called multi-purpose cohorts, where multiple exposures entailing lifestyle, environmental, psychological, and sociodemographic factors are assessed together with physiological measurements and where biological materials like blood, urine, saliva, genetic material, and feces are collected and stored in biobanks for later analyses. Examples for this type of cohorts are the UK Biobank (2007; Biobank UK 2012), the Nurses' Health Study (2011), and the National Cohort (2012) in Germany.

Although there is the general belief that prospectively conducted cohorts are not suitable to study long-latency chronic diseases, that is, in general diseases with long induction periods, several very large studies like the American Cancer Prevention Studies (Garfinkel 1985), the Nurses' Health Study, or the European Prospective Investigation into Cancer and Nutrition (EPIC) study (IARC 2012) are designed to investigate endpoints like cancer and cardiovascular diseases. However, other prospective cohorts with shorter follow-up periods are primarily targeted at subclinical disorders assessed by questionnaires and functional or biological measurements. So-called birth cohorts that start with the collection of data and biological material during pregnancy and around delivery entail a particular innovation potential. They allow to study the long-term effect of intrauterine factors and possibly formative influences during infancy as well as the sequence of events leading to chronic disorders later in life (cf. chapter ▸Life Course Epidemiology of this handbook).

An inherent limitation of prospective studies is the long-term commitment needed by both the research institutions and the funding agencies. Moreover, the prospective recruitment and follow-up of populations require repeated contacts with each study subject of the cohort and are very cost-intensive. The informed consent to be given by study participants must include the permission to analyze the collected data longitudinally but also to store the contact data over an extended period of time to enable further follow-ups. It should also foresee the permission to store biological material in biobanks and to use the stored samples for analyses that cannot be defined precisely at the time of data collection because otherwise new knowledge and technological advances available only several years after their collection could not be utilized to the best scientific benefit of these materials.

The burden put on study participants may impair the willingness to participate. Thus, the participation proportion is often rather low, especially if participation entails repeated contacts or an extensive examination protocol. For instance, participation varied between 22% and 38% in the German centers of the EPIC study (Boeing et al. 1999). Limited information (Goldberg et al. 2001) tends to show that participants are generally in better health than non-participants. Thus prospective cohorts are not fully representative of their target populations. Fortunately, representativeness is not a key issue in such studies as long as the loss to follow-up is limited. In prospective cohorts, loss to follow-up occurs either due to actual loss of contact or more often due to the refusal of continued participation. An unpublished survey by Moulin (personal communication) of all large ongoing prospective cohorts in France suggested that loss to follow-up can only be reduced by regular contacts, regular information about the study results to the participants, and, if possible, presence in the media. Researchers should incorporate elements that involve a benefit to study participants themselves, for example, by providing useful feedback about a subject's health status or by providing individualized advice for health promotion. When planning prospective studies, enough resources should therefore be allocated not only to the recruitment of the subjects (i.e., mailing of questionnaires and reminders) but also to the communication, both with the media and with the study participants. Also, new media like the Internet and mobile devices may become important avenues through which participants can be motivated and cohorts can be maintained (see chapter ▸Internet-Based Epidemiology of the handbook).

13.3.3 Case-Control Studies

In a case-control study, subjects who have contracted a given disease are gathered from the study base and are contrasted to a sample of control subjects drawn from the same base. Exposure histories are then collected from cases and controls. The basic principle of a case-control design (also called a case-referent approach as in Miettinen (1985)) is closely related to that of a cohort study (see also chapter ▸Case-Control Studies of this handbook) as it can be considered as an instantaneous condensation of a cohort. It resembles the morbidity experience of a cohort – represented by the cases – without the need to observe the full person-time at risk. Instead of comparing the disease incidence between exposure groups, it compares the exposure between controls representing the population at risk and cases, that is, the exposure history that was accumulated by both groups over the person-time at risk is assessed retrospectively.

According to the most frequent definitions, a case-control study conducted within a dynamic population may be *population-based* or *hospital-based* depending on the selection procedure of cases and controls. When the study base is a previously enumerated cohort, the case-control study is often called *nested within the cohort*. Each of these types has different practical implications which we will detail below. In most cases it is recommended to include only patients who were newly diagnosed, in particular when the case fatality rate is high, in order to avoid selection effects.

13.3.3.1 Population-Based Case-Control Study

In a population-based case-control study, the cases are all patients newly diagnosed with the disease during the study period in a defined population, for example, those who live within a country or a geographical region. The controls are sampled from this same population. In this design, the study base, that is, the population living in this country or region during the study period, is precisely defined a priori before the start of the study.

Case Recruitment

A researcher may choose a population-based case-control design if all new cases of the disease (or at least a representative sample of all cases) can be identified in the study base. As it is essential to ensure completeness of case finding, a disease registry may be helpful for identifying the cases. The existence of a disease registry may also guide the decision for a given study region. However, the value of a registry may be limited if there is a substantial time lag between diagnosis and registration, particularly if the disease is rapidly fatal and collection of data from the respondent is necessary. Thus, an efficient procedure for case identification and recruitment has to be set up by the research team. For example, a case-finding network may be organized including all hospitals, clinics, and pathology departments in the study region to identify and interview the cases. This should also be extended to nearby areas if some of the diseased persons in the source population defined by residence in a given geographical region may be diagnosed and hospitalized outside that region. It is also strongly recommended to perform an active search of the patients, by organizing periodic retrieval of hospital records, rather than to rely on a passive notification of the cases by the medical staff of the clinics or the hospitals.

Selection of Controls The controls should be selected at random from the same source population giving rise to the cases. Ideally, the probability of selecting a particular control subject should be proportional to the amount of time that he/she contributes to the study period or to person-time at risk (Rothman et al. 2008, p. 116). For example, if a subject moved out of the source population at half the study period, he/she should have only half the probability of being selected as a control than a subject who stayed in the source population during the entire study period. To be eligible, a control subject should belong to the study base at the date of diagnosis of the index case. Controls who recently moved into the source population and are chosen to match cases diagnosed several years earlier should be excluded since they do not belong to the study base. Excluding controls who have recently moved into the population reduces the problem, but does not solve it, since people who have moved out of the base will still be missed.

An incidence density sampling of the study base can avoid these problems. Density sampling can be achieved, for example, by selecting the controls at a steady rate throughout the study period proportional to the number of cases. In practice, the protocol may define several points in time, for example, once a month or once a year, where controls will be selected from the population present in the study base at that time. In a design where the cases and the controls are matched individually, it is also possible to use sampling sets of possible controls, one per case, composed of all persons present in the source population and at risk of contracting the disease at the time of the case's diagnosis. The desired number of matched controls is then drawn at random from each of these risk sets.

Selection of Population Controls Based on a Listing of Individuals

To be feasible, these procedures of selection of controls necessitate not only a fully enumerated study base but also regular updates of this population, to take emigration and immigration during the study period into account. In Scandinavian countries, study investigators may rely on central population registers to select controls using a simple random sampling at regular intervals during the study period (see also chapter ▸Use of Health Registers of this handbook). More often, however, a complete population register, including the identification of individual members by name and address as well as stratification variables such as sex and date of birth, will not be available, and other methods of selection of controls must be chosen.

In the absence of a population register, the researcher may use other *lists of individuals*, such as lists of municipality residents, electoral lists, and listings of health insurance members. As long as such lists cover 100% of all residents in the study region, they are as useful as population registers. In other cases, using these lists for selection of controls may, however, introduce bias if the probability for an individual in the study base to be listed is related to the exposure of interest. Telephone books would not be suitable for a study on cancer in relation to an occupational chemical, for example, if phone numbers of highly educated and less exposed individuals are less frequently published in the directory than phone numbers of subjects of other socioeconomic categories. Persons not registered in electoral rolls may also differ from those listed and may not include immigrant workers. Municipal lists may not be updated regularly. Besides completeness of the list, the possibility of tracing individuals based on the information provided (name, address, phone number, etc.) must also be considered. One may cross-check whether the cases are also listed on the roster from which the controls are drawn. The analysis should then exclude the cases not listed, such as those who are not citizens when using electoral rolls.

Selection of Population Controls Without a Listing of Individuals

Other sampling schemes may be used for selecting controls when no list of residents is available. Multistage random samplings starting with sampling of dwellings or based on random digit dialing procedures are commonly used. The controls then have to be selected within each household.

Neighborhood Controls This method implies a two-stage sampling, with a random sampling of households followed by the selection of an eligible individual within the selected residence. Households sampling may be conducted from a roster of residences, obtained, for example, from census data. When a roster of households is not available, controls may still be selected from residences in the case's neighborhood. Starting from the case's residence, the interviewer may follow a predefined procedure for selecting a household, by means of a map, aerial pictures, or by a systematic walk algorithm starting at the index household (Wacholder et al. 1992b). This sampling method implies that the controls are individually matched to cases on place of residence. To avoid bias, the interviewer should not be given the flexibility to choose which house to select, rather a simple and unambiguous algorithm for selecting households should be developed to remove the possibility of interviewers avoiding certain areas. A potential problem of neighborhood controls is overmatching on the exposure due to similarities between cases and controls living in the same neighborhood.

Random Digit Dialing Random digit dialing can be used to select population controls when no population roster exists and when almost every household has a landline telephone. Random digit dialing generates telephone numbers, and it does not rely on a telephone book where new or unpublished phone numbers are not listed. Several variants of the standard method exist (Waksberg 1978). Briefly, a phone number is created using the first numbers, including area code, of working telephone numbers provided by the telephone company, which are then completed with random numbers. The number is dialed a predetermined number of times. The first contact with a household member is used for screening and to obtain a census of the household. Based on the responses and a predetermined sampling scheme, eligible subjects are selected to be controls. These individuals can be interviewed by telephone directly, or they can be contacted afterward for an in-person or a telephone interview.

Random digit dialing is not appropriate if the coverage of landline telephones is low, which is an increasing phenomenon since mobile phones conquered the market. Other problems associated with random digit dialing include residences that can be reached by more than one phone number or if more than one person in the household is eligible to be a control, since it may lead to different selection probabilities of the controls. It should also be realized that random digit dialing is an expensive and time-consuming procedure, particularly when targeting subgroups of the population, since a large number of phone calls may be necessary before the desired number of eligible controls are recruited. Non-response and refusal is an additional problem, and it may not be possible to have an exact estimate of the participation proportion. It is recommended that the distribution of the final sample is compared according to key variables such as age, sex, or socioeconomic status to an expected distribution obtained, for example, from the last census.

The random digit dialing has been used successfully in a large number of studies, but the widespread and sometimes exclusive use of mobile phones or Internet-based phone numbers causes further problems as these numbers are not defined regionally in many countries.

13.3.3.2 Hospital-Based Case-Control Study

In hospital-based case-control studies, the cases are patients admitted to a given hospital or clinic who were diagnosed and hospitalized with the disease during the study period. The controls have to be selected from the population from which the cases arose, that is, the group of individuals who would be treated in this hospital if they had developed the disease. Because the study base is not easily identified as the catchment areas of hospitals are not precisely delineated, a random sample of controls can hardly be selected directly from this population. Instead, it is usually more practical to select controls among patients admitted for other diseases to the same hospital, representing a non-random subset of the study base. An appropriate group of control patients should have the same referral pattern to that hospital as the cases, so that the controls have the same probability as the cases to be admitted to this hospital if they had the disease under study.

The possibility of selecting hospital controls rests on the assumption that they are representative of the exposure distribution in the study base. This assumption is reasonable if the hospital admission of controls is not associated with exposure. In a study on smoking and lung cancer, for example, patients admitted for smoking-related diseases like bladder cancer or myocardial infarction have a higher probability of being smokers than it is the case in the study base. Their inclusion as controls would therefore lead to an underestimation of the strength of the association between smoking and lung cancer. The appropriate choice of hospital controls becomes difficult, if the knowledge about the diseases that are caused by the exposure(s) of interest is limited. Two different strategies have been proposed to deal with this problem. According to the first strategy, a single disease that – according to current knowledge – is unrelated to the exposure(s) of interest is selected. In cancer studies often colon cancer has been selected for controls because it is not or only weakly associated with many agent exposures that have been studied (Lynge et al. 2005). The advantage of this approach lies in the fact that cases and controls suffer from a disease of comparable severity which may reduce a possible recall bias. Also, because the disease eligible for controls is well-defined, subsequent evidence of a specific – previously unknown – association with an exposure of interest may be taken into account by a correction factor or for the quantitative assessment of the selection bias in a re-analysis of the case-control study.

The second strategy tries to minimize the risk of biased risk estimates due to a – yet unknown – relationship between the exposure(s) of interest and the disease eligible for controls by dilution. Here all diseases that are unrelated to the exposure(s) are eligible as controls, but none of them should dominate the control group. For example, in the European case-control study of head and neck cancers, none of the diseases in the control group were allowed to exceed a proportion of 30% (Lagiou et al. 2009).

13.3.3.3 Case-Control Study Nested Within a Cohort

When the study base consists of an enumerated cohort with recorded entry and exit times, a case-control study may be initiated by drawing cases and controls from this cohort as the source population. This is called a "case-control study nested within a cohort" which requires an existing cohort from which the controls can be selected. In a matched design, for example, a set of possible controls can be constituted with all non-diseased individuals in the cohort at the time of each case's diagnosis, the so-called risk set. One or several controls may then be drawn at random from each set (see chapter ▸Modern Epidemiological Study Designs of this handbook).

An advantage of this design consists in the efficient and cost-saving use of biological samples that were collected within the framework of the cohort study because the expensive laboratory analyses can be restricted to those who contracted the disease and a sample of cohort members serving as controls. Another reason for embedding a case-control study into an existing cohort is the possibility to enrich the data, for example, by performing an in-depth exposure assessment or by retrospectively collecting confounder information that is unavailable for the whole cohort. This was done in the case of a historical cohort study of workers exposed to bitumen fumes which showed inconsistent results with regard to lung cancer mortality. As some positive associations might have been due to confounding by smoking while some inconsistent exposure-effect relationships might have been due to misclassification of exposure histories, a nested case-control study was performed including an individual exposure assessment and the collection of smoking histories for each subject (Olsson et al. 2010).

13.3.4 The Study Base Principle: Selection, Exclusion, and Resulting Bias

The study base principle, the first of three principles Wacholder et al. (1992a) developed for the selection of controls in case-control studies that also applies to the design of cohort studies, simply states that "cases and controls should be representative of the same base experience" (see also chapter ▸Case-Control Studies of this handbook). *Representativeness* for the target population is not a conditio sine qua non in studies of the association between an exposure and a disease. Thus, for the aim of scientific inference of the relation between an exposure and disease, any exclusion or inclusion criteria are valid as long as they apply equally to cases and controls. However, if an exposure-disease association is observed in a highly selected group, the external validity of this association is deemed to be questionable.

Wacholder et al. (1992a) identified the following reasons for which exclusion criteria can be applied:

- Inconvenience: Subjects of a given subgroup might be hard to reach. Failure to exclude a priori such a group may lead to a very poor response proportion and an a posteriori exclusion, with the corresponding waste of resources.

- Anticipated low or inaccurate responses, for example, of subjects who do not speak the language of the interview sufficiently. Failure to exclude a priori such a group may yield non-interpretable data.
- Lack of variability of the exposure: If one intends to set up a cohort investigating the dose-response effect of a potential occupational carcinogen like cobalt salts, inclusion of a large number of workers from industries who do not use these chemicals makes little sense although including a small group of unexposed may still be justified for stabilizing the baseline category.
- Subjects at increased risk of disease due to other causes: In a prospective study investigating environmental effects on asthma, subjects at high asthma risk due to their occupational exposure (e.g., bakers) should be excluded because cases are likely to be attributable to the occupational exposure and therefore may not contribute to the understanding of other risk factors.
- Combination of the above: In a historical occupational cohort study based on a factory, short-term employees may be difficult to track, their exposure is likely to be determined much more by previous or subsequent work, their cumulative exposure within the company is bound to be low, and they may be at increased risk for many diseases as they constitute a group of socially unstable workers who are likely to have other risk factors. It is thus standard in such settings to exclude short-term workers. This has, however, the consequence that any given subject of the study base contributes person-time only from the date on when she/he has reached the minimum employment duration.

As said above, the comparison of a highly selected study sample with the target population may be misleading. The so-called *Healthy Worker Effect*, by which is meant that a series of extraneous factors lower the observed mortality among employed workers in an occupational cohort, is an example of such a selection bias. A simple comparison of the mortality of a cohort with population mortality rates as expressed, for instance, through the standardized mortality ratio is thus of limited validity. Of course, as discussed above, internal comparisons of exposure groups are still valid but may lack the necessary power for useful scientific inference except in very large cohorts.

Another consequence of very restrictive eligibility criteria in a cohort or case-control study is the reduced variability of exposures. This may reduce the ability of a study to detect an existing exposure-effect relationship if the spread between low and high exposure is small. It may also limit the ability to detect any effect modification: If the effect of smoking were to amplify the effect of an environmental exposure, restricting the study base to non-smokers may lead to a spurious absence of effects.

In some instances, representativeness is an important requirement. If the study aims to assess attributable or absolute risks in the target population, the study must be either exhaustive or representative. Otherwise, external information must be retrieved with respect to the fractions of the strata in the study sample relative to the target population.

13.3.5 Choosing Between Epidemiological Designs

Many other etiological designs like case-cohort designs, case-only designs, two-phase sampling, counter-matched designs, and multilevel designs to cite just a few have been proposed in the epidemiological literature (Wacholder et al. 1992c; chapter ▶Modern Epidemiological Study Designs of this handbook). These designs usually combine elements of the case-control and the cohort design either by stating additional hypotheses (case-only design) or by making use of additional data like in two-phase designs (see, e.g., Breslow and Chatterjee 1999; Pohlabeln et al. 2002).

Another design is the so-called ecological design, in which the units of investigation are groups of people rather than individual subjects. The groups may be classes in a school, factories, cities, or administrative areas within a country. The only requirement is that a measure of the exposure and disease distributions is available for each group. Because the data in ecological studies are measurements averaged over individuals, the degree of association does not reflect the association between exposure and disease among individuals (so-called ecological bias, see Greenland and Robins (1994)). Thus, while ecological studies can be useful for detecting associations of exposure distributions with disease occurrence, that is, for hypothesis generation, such a design should not be used for etiological investigations and quantification of exposure-disease relationships.

Another possible design consists in selecting a cross-section of the study base with no time dimension (cross-sectional study). Here both exposure and disease status are collected simultaneously at one point in time. It is therefore not the incidence but rather the prevalence of the disease that is investigated, so that it is usually impossible to assess whether the exposure actually preceded its presumed effect on health. Moreover, cross-sectional studies are particularly prone to selection bias as diseased subjects may have left the study base or may be less willing to participate. A longitudinal observation of exposure and disease in a study that is the paradigm of both the cohort and the case-control design is better suited for answering etiological questions than a prevalence study. Possible exceptions are diseases with short induction periods or exposures that cannot change such as genetic characteristics or other invariable personal characteristics (see Rothman and Greenland 1998, p. 75). If, however, a prospective cohort design is not feasible for financial reasons or simply because it is impossible to follow up a large enough group of subjects, the cross-sectional design can, despite its above-mentioned limitations, provide important information especially if targeted on non-fatal health outcomes (see Wild et al. 1995b) or if a number of different exposures and health outcomes are to be investigated simultaneously. Moreover, a cross-sectional study may serve as the starting point for a subsequent follow-up of (non-diseased) study participants which will then evolve into a multipurpose cohort. An example for this is the US National Health and Nutrition Examination Survey (NHANES) which formed the basis for the NHANES I Epidemiologic Follow-up Study (NHEFS) (Centers for Disease Control and Prevention 2010).

Table 13.1 Strengths and limitations of different observational study designs

	Study design		
Investigation of . . .	Cross-sectional	Case-control	Cohort
Rare diseases	–	+++++	–
Rare causes	–	–	+++++
Multiple endpoints	++	–	+++++
Multiple exposures including confounders	+++	++++	(+++)[a]
Temporal sequence of exposure and disease	–	(+)[b]	+++++
Direct measurement of incidence	–	(+)[c]	+++++
Long induction periods	+	++++	(+++)[d]

Suitability of study design: +++++ highly suitable, ++++ very suitable, +++ suitable, ++ moderately suitable, + limited suitability, – not suitable

[a] If prospective (multipurpose cohorts)

[b] If nested in a cohort

[c] If population-based, combined with an incidence study

[d] If historical

The main study types to assess etiological relationships remain the cohort and the case-control designs. Choosing one or the other design depends on a number of issues among which the incidence rate of the disease of interest and the prevalence of the exposure of interest are prominent. Table 13.1 summarizes strengths and weaknesses of the major study types.

On the one hand, if the disease is rare (for instance, a rare cancer as testicular or brain cancer), a cohort approach would necessitate huge numbers of participants and a long follow-up to identify enough cases to make useful inferences. A case-control study is the more efficient approach for rare diseases. Another situation where the case-control design is the preferred approach is if the aim is to generate hypotheses concerning various exposures in relation to a given disease. Determining possible occupational origins of laryngeal cancer is such an example.

On the other hand, if the exposure is rare and restricted to specific subpopulations or if one is interested in all possible disease outcomes of a given exposure, a cohort study, either historical or prospective, is the most efficient choice. Examples of the former are the studies of the carcinogenic effects of hard-metal dusts among manufacturers of hard-metal tools (Moulin et al. 1998a) or of bitumen fumes in asphalt and road-paving workers (Boffetta et al. 2003). An example of the latter is the study of the health consequences of hormonal replacement therapy in postmenopausal women (Nurses' Health Study 2011).

Another aspect that can influence the choice of a design is the induction period of the disease (although it may depend on the exposure). For long induction periods, a prospective cohort study is clearly not the design of choice as this would imply waiting a long time for a sufficient number of events to occur. This problem can be circumvented by the historical cohort design. Most historical cohorts are focused on cancer, a long-induction disease per se. The choice between a case-control and a historical cohort study is then dependent on whether (or not) a historical cohort can provide an answer to the research question.

Other issues which might influence the choice of a given design include the precise scientific aim of the study. Direct estimation of the incidence of disease would require enrolment of the target population that ideally needs a cohort design or at least a population-based case-control approach. If one is, however, interested in the precise temporal sequence, as, for instance, in the study of the evolution of CD4+ cell numbers in HIV-infected patients (Kaslow et al. 1987), cohort studies are virtually the only available design which may, however, be supplemented by a nested case-control study.

The final choice, once a theoretically optimal design has been determined, depends on the actual feasibility of a given study type as well as on the practical terms of access to the data as well as the time and costs involved.

13.3.6 Statistical Power and Sample Size

As mentioned in the first section, any study protocol should include a calculation of the sample size to detect a predefined effect of the exposure for a given statistical power and a predefined probability of the type I error (significance level). Alternatively, if the available sample size is limited, a power calculation should inform about the effect size that can be detected. When computing the statistical power or sample size, the need for building subgroups, based on either exposure levels or confounder strata, should be taken into account.

If several exposures which differ in their prevalence and/or in their expected effect size are to be investigated, then a table displaying the necessary sample size for different combinations of effect sizes and exposure prevalences can be very helpful to find a reasonable compromise between power and sample size. An example is given in Table 13.2 for a case-control study. For example, if you want to detect an odds ratio of 2.0 at a significance level of 5% with a power of 80%, you would need to include at least 449 case-control pairs in a 1:1 matched study, if the prevalence of the exposure in question is 5% in the study base. A similar approach can be used for a cohort study where a given exposure is to be investigated with regard to outcomes with different incidence rates.

If the study addresses more than one hypothesis, the power calculation should be done for the main hypothesis. If, however, several hypotheses have to be evaluated simultaneously based on a statistical test, that is, in case of a so-called multiple

Table 13.2 Number of case-control pairs required to provide an 80% power to detect a given relative risk at the 5% significance level

Odds ratio	Proportion of population exposed			
	1%	5%	10%	20%
1.5	6,672	1,415	763	448
2.0	2,087	449	246	150
2.5	1,114	243	135	84
3.0	732	161	91	58

testing problem, appropriate methods have to be applied to account for multiplicity. The simplest but also most conservative approach is the Bonferroni correction where each statistical test out of, say, k tests is not performed at significance level α, but at a significance level of size α/k to control the family-wise error rate. In case that thousands of hypotheses have to be tested as, for example, in genome-wide association studies, this approach is of course no longer feasible, and more sophisticated methods have to be applied (see chapter ▸Statistical Methods in Genetic Epidemiology of this handbook).

In practice the choice of the sample size (or to be exact the size of the study sample) is a compromise between what one would ideally be able to detect and practical limitations. A common limitation can be an insufficient number of study subjects, either because the incidence of a disease is low as in the case of rare cancers or because the exposure is rare. An example of this would be if we were to study the interaction between a rare genetic variant (prevalence <0.01) and a rare environmental exposure. If the latter has a prevalence of 5%, less than 5/10,000 of controls would show both features so that the minimum sample size to investigate such an interaction would be in the tens of thousands.

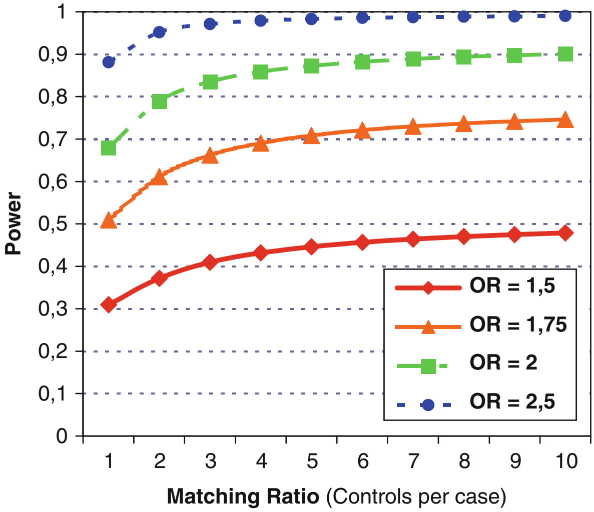
In general, a statistical power of 80% is considered a reasonable power to achieve objectives of an observational study investigating etiological associations, and any power below this arbitrary figure may be considered too low. In case that one needs to reduce the risk of failing to detect a certain effect that is truly present – as it might be the case in clinical trials – one needs to increase the statistical power which of course inflates the necessary sample size. If methods of prior assessment, either formal or intuitive, suggest that the study will be too small to be informative, there are several options:

One can reduce the level of ambition. For instance, instead of choosing a statistical power to detect an odds ratio of 1.3, the detection limit can be raised to 1.5. The drawback of this strategy is of course that if no effect of the exposure is observed, risks below the level for which the study is powered cannot be excluded. Thus, if the main interest lies in exposures with presumably low effect sizes, then such a strategy is not feasible.

If the number of cases is the limiting factor in a case-control study, the study power can be increased by selecting several controls per case. Up to four controls per case lead to a reasonable gain of statistical power, while further increases of the case to control ratio have only a marginal effect (Fig. 13.2). One may also extend the recruitment period to enhance the number of incident cases. This usually entails that the results will become available later. An analogous strategy would be the extension of the observation period (follow-up period) in a cohort study to increase the person-time at risk and thus the number of events.

Another strategy consists in the combination of several smaller studies in one multicenter study. When organizing multicenter studies, one should be reasonably sure that the gain in sample size is not offset by between-center differences in exposure circumstances and assessment or differences in case ascertainment. Another issue in this case is that the harmonization of centers has its costs too. An advantage, however, may be the broader range of exposure levels which may lead

Fig. 13.2 Statistical power of a case-control study for various matching ratios of m controls per case to detect different odds ratios (OR) for a number of 100 cases with $\alpha = 0.05$



to a better chance to detect an exposure-effect relationship. If there is no feasible compromise, one has to abandon the project. It can be considered unethical to undertake a study which would not add to the general knowledge but costs money and resources which could better benefit other research. Finally one can increase the statistical power by making use of external information through the aforementioned innovative design (see, e.g., Wild et al. 2008b).

Statistical power is, however, not the only criterion by which to judge the appropriateness of a study. In addition to the power of a study, the relevance of the research question and the expected knowledge gain have to be justified in light of the presumed qualitative and quantitative dimensions of the effect. Also the burden and implications for study participants have to be balanced against ethical concerns and the expected scientific merit.

13.4 Measures of Disease Outcome and Exposure

13.4.1 Measurement and Classification of Exposure

13.4.1.1 Choice of the Exposure Measure

Epidemiological studies are designed to assess the impact of an exposure or of a preventive measure on the development of a disease. The sources of error and the ways in which exposure and disease are assessed are quite different, and thus the mechanisms by which errors arise are different as well.

The range of exposures of interest in epidemiology is broad (Savitz 2003). Exposures include exogenous agents such as drugs, diet, and chemical or physical hazards present in the environment; genetic attributes that affect ability to metabolize specific compounds; stable characteristics such as height or eye color;

physiological attributes such as blood pressure; life habits such as physical exercise or tobacco smoking; mental states such as depression; and social environment. This wide range of exposures corresponds to many different methods for measuring exposure (White et al. 2008; chapter ▶Exposure Assessment of this handbook).

The measurement method depends on the exposure under study, the required precision and accuracy, the availability of existing records, the ability of a subject to recall an exposure, cost of a given method, etc. The study protocol should describe the operational approach chosen for exposure ascertainment and its rationale. The accuracy of an operational approach is best described in relation to the method of ideal measurement, that is, the gold standard (if it exists) which is usually not feasible in epidemiological field studies.

The ultimate goal of exposure assessment is to quantify the exposure that directly contributes to the etiological process under investigation. Ideally, an exposure assessment should focus on the biologically effective exposure. Most often, however, this goal cannot be reached by an operational exposure indicator. One reason is that the biological mechanism by which exposure might cause disease is often unknown. For example, in studies on the potential cancer risks associated with exposure to extremely low-frequency (ELF) magnetic fields, it was not clear whether the most relevant exposure indicator with respect to etiology should be an average exposure over the entire life or over the most recent period before cancer diagnosis or if it should be a measure of peak exposures over a certain threshold or during particular time windows. This problem could be partially overcome if a temporal exposure profile can be assessed, to calculate different exposure indices, where each of them is then analyzed with regard to its association with a disease. Another reason is that it is often impossible to obtain the data that reflect the biologically effective exposure. For example, the persistent organochlorine pesticide dichlorodiphenyltrichloroethane (DDT) and its metabolite dichlorodiphenyldichloroethylene (DDE) were suspected to be causally related to breast cancer risk (Wolff et al. 1993). If we assume that the biologically effective exposure is the level of DDT/DDE present in breast tissue in the time window 5 to 15 years before cancer diagnosis, it is obvious that this exposure cannot be measured directly in a case-control study.

Instead, different exposure metrics could be used to study the relationship between DDT/DDE exposure and breast cancer (Savitz 2003), including environmental levels measured in the area of residence at the time of diagnosis (taking into account the residential history of the subject), present-day blood levels, or blood levels measured in the etiologically relevant period using serum specimens drawn in the past and kept in a biobank. Clearly, these exposure measures are not equivalent as they correlate differently with the biologically effective exposure. Using environmental exposures as a surrogate exposure indicator is probably ineffective, since the observed breast cancer risk may be biased toward the null due to non-differential misclassification and thus fall below what can be detected. However, if blood levels of metabolites are strongly correlated with breast tissue concentrations even after several years, an association with breast cancer may still be observable. Therefore, although blood levels are not the ideal measure, certain metabolites measured in blood may serve as an indicator of past exposure if the half-life of the agent is sufficiently long (Flesch-Janys et al. 1998). The choice of an informative indicator of exposure requires knowledge about chemical and biological processes and adequate models describing the relationship between the indicator and the exposure of interest.

All laboratory data are subject to error due to imprecise measurement. However, the conceptual error by which the measure obtained relates to the exposure of interest is often of much greater importance. In a study on the effects of microbiological contamination, measurement of viable colonies may be only of marginal interest if these bacteria are not the pathogenic ones. Bacterial endotoxin has been shown to be the more relevant exposure with respect to lung diseases (Rylander 2002).

Another challenge in exposure assessment is that often different types of exposure coexist and their individual effect cannot be separated from the effect of accompanying exposures. The level of exposure categorization must reflect scientific hypotheses. For instance, a nutritional epidemiology study investigating the role of coffee in miscarriages could consider two relevant categorizations. The role of caffeine itself would be investigated by grouping all of its sources including tea and caffeine-containing medications, whereas the role of constituents of the coffee other than caffeine would be investigated by grouping caffeinated and decaffeinated coffee.

13.4.1.2 Temporal Aspects

Some exposures are constant over time, such as genetic constitution, but all exogenous exposures such as diet and chemical pollutants vary substantially over time. In addition to the identification of a biologically relevant exposure, it is necessary to identify an etiologically relevant time window during which the exposure may be related to disease occurrence so that the data collection concentrates on etiologically relevant time windows.

It has been long recognized that many diseases such as cancer appear a long time after they have been induced. The time between the beginning of the exposure and the clinical manifestation (detection) of a disease is often called the *latency* period, although in a strict sense, latency period refers to the period between disease initiation and detection. It serves as a surrogate for the biological *induction* period in epidemiological studies, that is, the time between the beginning of the exposure and the initiation of the disease process. Often, the onset of exposure does not necessarily result in immediate induction, as for example, in the case of cancer. Epidemiological studies should allow for the fact that diseases with long induction periods that were contracted immediately after the exposure may not be attributable to this exposure. In the statistical analysis of such data, the usual practice is to shift the exposure by a given *time lag* which is typically about half the usual induction period, that is, exposure during recent years is ignored.

The consequences for planning are that whenever the presumed induction period is long, the investigator must include a sufficient number of subjects for whom the exposure reaches back far enough. Whenever the expected effects of exposure are of a short-term nature as, for instance, a reversible genotoxic effect as assessed by a comet assay, it is important to precisely assess the relevant short-term exposure.

The temporal pattern of the exposure is of interest in itself. If peak exposure is the metric that is most strongly associated with disease risk, then its effects are likely to be much more important when the exposure is highly variable over time than in circumstances in which the exposure is virtually constant. For such presupposed effects, the exposure metric of primary interest may be the number of peak exposures. If we, however, assume that the exposure acts through a cumulative damage, the total cumulative exposure is the adequate metric to express its effects. If the effect of an exposure on a disease is reversible, the cumulative exposure may be insufficient, and time since cessation of exposure needs to be considered in addition.

13.4.1.3 Sources of Exposure Data

Various sources of exposure data and their characteristics are described in White et al. (2008). The following section summarizes some key issues covered in this book (see also chapter ▸Exposure Assessment of this handbook).

Questionnaires A prominent and often the only way to assess an individual exposure is by questionnaire. The main types of instruments are self-administered questionnaires or personal interviews, administered by either telephone or face-to-face. Traditionally, self-administered questionnaire was a synonym for a simply structured paper-pencil instrument. These are more and more replaced by web- or computer-based questionnaires.

Interviews and computer-/web-based questionnaires allow avoiding errors and missing values. In particular, complex skip patterns can be used where specific questions are only presented after some trigger information has been provided by the respondent. This has been used in occupational exposure questionnaires in which job histories are obtained and specific questionnaires are only used for a limited number of jobs and/or tasks (Ahrens et al. 1993; Ahrens 1999). However, the interviewer may increase error if he/she influences the subject's responses by his/her appearance, manner, method of administration, etc. Intensive training of field staff, strict adherence to the wording of each question, and provision of fixed probing questions for the interviewer support standardization of the interview. By training interviewers in neutral interviewing techniques and by standardization of questionnaire wording and administration, the likelihood that the interviewer's personal attitudes will affect the responses is much reduced.

The use of paper and pencil for personal interviews has mostly been replaced by computer-assisted telephone interviews (CATI) or computer-assisted personal interviews (CAPI). By this technology, replies are entered electronically on the spot, and in-built plausibility checks provide instant control of possible errors. However, since validation of data entry is not possible, typing errors are not fully controllable. As the use of computers and the access to the Internet have become more and more common, their use for self-administered questionnaires (and tests) will increase in the future. They will also allow an easy and intuitive use by respondents, particularly if clearly arranged and combined with touch screen monitors. They may also help to increase the willingness of study subjects to participate if they are offered to complete the questionnaire at home or at work via the Internet. However, the validity and reliability of such instruments need to be assessed (see chapter ▸Internet-Based Epidemiology).

The main advantage of a self-administered questionnaire is its relatively low cost. Armstrong et al. (1994, p. 44) concluded that “there appears to be little difference between these methods (subjective recall of exposure collected through face-to-face, telephone or self-administered questionnaires) with respect to the validity of the data obtained. (. . .) Face-to-face interviews are the dominant approach and are clearly best for the collection of large amounts of complex data. However, where subjects are widely dispersed and the questionnaire can be kept comparatively brief, telephone interviews can be favored. Self-administered questionnaires should be considered for low budget studies for which small amounts of reasonably simple data are required.”

In setting up a questionnaire, many sometimes contradictory issues arise. While obviously more details can theoretically be assessed if it is longer, long questionnaires take more time and (especially among diseased subjects) may become burdensome and lead to fatigue effects. A questionnaire has to be well arranged and should be comprehensible for less educated people. Questions like “Have you been exposed to bischloromethylether?” should be avoided. Sensitive issues (religion, sexual habits, alcohol consumption, etc.) should be avoided if they are not central to the study and should be given careful consideration if necessary in order to avoid withdrawal of the respondent. Embarrassment of subjects and biased replies can be reduced by using self-completion instruments, by explaining why such a question is asked, and by placing the question toward the end of the questionnaire (see also chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook).

A questionnaire should always be tested before use. The use of validated instruments is of course desirable. A large number of publications exist on validating existing questionnaires (see, for instance, Rouch et al. (2003) or Bogers et al. (2004)). It is probably a good strategy to choose, whenever possible, an already existing questionnaire that has been validated in settings and target groups comparable to its intended use. If one decides, nevertheless, to adapt a questionnaire for a given study, a pretest should be carried out to investigate its properties, notably feasibility, clarity, and reproducibility, so that necessary adaptations can be made before applying it to a broader group. If a completely new instrument has to be designed, a validation study should be taken into consideration to investigate its properties as, for example, validity and responsiveness to change, that is, its ability to reflect changes in behavior or subjective symptoms (Bogers et al. 2004).

Diaries Diaries refer to detailed prospective records of exposure by the subject. As such they can be used neither in case-control studies nor in historical cohort studies. This method has been used in many contexts among which their use in nutritional epidemiology for measuring dietary intake is prominent (cf. Andersen et al. 2004; chapter ▸Nutritional Epidemiology of this handbook). Ongoing monitoring of symptoms of a disease is another application of diaries (cf. Goebel et al. 2002).

Armstrong et al. (1994, p. 219) concluded, “The use of diaries may be highly accurate method of measuring present common behaviors. The limitations of diaries, in comparison with interview methods, are the greater burden on subjects, which may lead to poorer response rate and the greater cost for subject training and for coding the data. The accuracy of diary information can be enhanced by use of multiple diary days spread over a sufficient time period, and by careful training of subjects and coders.”

Records of Exposures Historical records may be a valuable and sometimes the single source of early exposure data. Usually such data are recorded for administrative purposes or to account financial claims as in the case of health insurance data. Two types of records can be useful for exposure assessment. A first type of records contains information on the individual study subjects, for instance, prescriptions, diagnoses, and treatments contained in medical records but also social or occupational data contained in population registries. A second type of records provides exposure data only for groups of people. Examples are environmental exposures assessed by ambient air monitoring or noise measurements or descriptions of histories of industrial processes in occupational epidemiology. The main drawback of such group level data is the inherent inaccuracy in ascribing exposures to individual subjects and the difficulty to assess the validity of the historical data. The primary advantage of records is that they provide prospectively recorded information that is not influenced by health outcomes. Exposure assessment based on historical records is robust against information or recall bias. For example, use of pharmacy records in a case-control study of prescription drug use could replace a questionable recall.

Biological Measurements and Biobanking The collection of blood, urine, saliva, feces, or tumor tissue is common practice in epidemiological studies to assess medical endpoints, biological effects as early endpoints or predictors of later disease, genetic polymorphisms, or markers of exposure. In principle, measurements made directly in the human body might be considered the ideal approach to assess exposure for etiological studies because they do not depend on a subject’s ability to recall a previous exposure to a specific agent and because they are not biased by subjective judgment of a respondent.

In practice, however, a number of problems exist. A first problem is to identify the correct metabolite and the appropriate point in time that is relevant for the presumed biologically effective dose. At the same time it should always be strived for the least invasive method to obtain the marker of interest. Particularly in population-based studies, more invasive methods may reduce the willingness to participate, that is, if a drop of capillary blood is sufficient, then the researcher may abstain from a blood draw by venipuncture.

A second problem is the often large within-person variability which can be of the same size or even larger than between-person variation. This has been observed repeatedly in industrial exposures (see Kromhout et al. 1994), but it is often also true for biological measurements. Liu et al. (1978) reported a ratio of within-person to between-person variances as high as 3.20 for 24-hour urinary sodium, a marker of sodium intake.

The fast development of analytical techniques for biological materials may, however, give rise to many useful indicators. The epidemiologist should be aware of the developments in this area. Methods of which the validity has been assessed should always be preferred, and the manual of operations (see Sect. 13.7.4) should include Good Laboratory Practices (WHO (World Health Organization) 2008). In planning sample logistics and laboratory work, it may be important to keep track of the internal quality control procedures, and provision should be taken that factors influencing sample quality are recorded. The collection of biological samples requires specific provisions and precisely defined procedures to ensure that each processing step is highly standardized, that temperature limits are kept, and that adherence to temporal limits in the processing, shipment, and storage ensures maximum quality of the analytes (Peplies et al. 2011). Especially in multicenter studies, all samples should be analyzed centrally by a certified laboratory to foster standardization and quality assurance. A laboratory information management system (LIMS) may help to document the timing and circumstances of each step of collection, management, transport, and storage for each sample including, for example, temperature logs. An LIMS is a useful tool to trace each aliquot and to document their number, type, volume, and physical location.

Especially in prospective studies, the long-term storage of biological samples is of increasing relevance. On the one hand, the scientific-technological progress allows the identification of new markers and a valid biochemical analysis of continuously shrinking sample volumes. On the other hand, prospective studies allow the targeted analysis of subgroups, for example, in the context of nested case-control studies and thus an efficient and cost-saving approach with maximum gain of knowledge. Such an asservation in a biobank requires the informed consent by study participants.

Measurement of Behavior In recent years, novel technological advances have made it possible to complement the assessment of health-related behavior by the use of monitors. This is particularly useful when the intensity and duration of highly variable behaviors like physical activity have to be measured where even short bouts of activity may be relevant if summed up. For example, accelerometers which are worn for a couple of days are such a device that records any acceleration of the body. The readout of these devices allows to calculate the energy expenditure due to physical activity as well as the pattern and distribution of activities. However, measurements on the subject over a limited time span may be insufficient to cover all of the intra-individual variation of physical activity, and seasonal variations are difficult to assess. Also, modern accelerometers are still limited in that they do not allow the discrimination between different types of activities. Such measurements may therefore require the use of complementary diaries and questionnaires. For further details, refer to chapter ▶Physical Activity Epidemiology of this handbook.

Measurements in the Environment Measurements of physical, chemical, or biological exposures in the environment are best achieved by personal sampling over extended periods of time. Relying on samples collected over relatively short periods of time without clear sampling design may induce substantial error in the exposure assessment. While sensitivity of measurements can be very high, the measurement error caused by the analytical method is often only a small part of the total variance of exposure which is usually dominated by the day-to-day variability in exposure. Planning exposure measurements for an epidemiological study should therefore rely on factors likely to influence the exposure (Sauleau et al. 2003). The methods for exposure measurement have to be included in the manual of operations. Reliable past exposure measurements rarely exist in sufficient numbers. Moreover, their representativeness for the average exposure situation of the study group is doubtful as they were usually obtained for purposes other than an epidemiological study, typically environment control, compliance with TLVs (threshold limit values), or on demand in case of complaints. In such cases an attempt may be needed to assess individual exposure by use of conversion tables such as job-exposures matrices combined with data derived from records, questionnaires, or expert assessment. Moulin et al. (1998a) showed an example where existing past measurements were highly variable and scarcely related to the exposure assessed by experts. Only using the latter, they were able to demonstrate a dose-dependent carcinogenic effect of hard-metal dusts. Nevertheless, even though occupational exposure data are usually not available for each individual study subject, they have been used successfully to model historical exposure levels for specific job tasks and to assign these to individual workers in industry-based cohort studies (e.g., Burstyn et al. 2003) as well as in population-based case-control studies (e.g., Peters et al. 2013).

In other cases, when environmental exposures are monitored continuously as, for example, is the case for close meshed noise registers in the vicinity of airports, the exposure of residents can be assessed with high accuracy, allowing detailed assessment of dose-effect relationships (cf., e.g., the review by Stansfeld and Crombie (2011)).

To assess the impact of the built environment on the behavior of residents such as their physical activity or their food choice, questionnaires can be used to assess the subjective perception of urban forms. In contrast, Geographic Information Systems (GIS) provide geodata on aspects of the built environment to objectively assess urban forms such as street connectivity, land use, or destinations like parks with measures for distance, density, or diversity. Based on appropriate measures of urban forms, indices can be developed to reflect the impact of the built environment as, for example, a moveability index to capture the influence of the built environment on children's physical activity (Buck et al. 2011). Future research will link such environments to actual behaviors by using GPS (global positioning system) monitors.

Finally the use one intends to make of the exposure measurements in the analysis of the data has to be stated in the protocol. This is required in order to assess whether a certain number of measurements with a given precision and a presumed variability of exposure will be sufficient to achieve statistically valid results with respect to the association of exposure and outcome.

13.4.2 Measurement and Classification of Health Outcomes

The main distinction to be made concerning measurement and classification of health outcomes is between diseases for which a clear diagnosis can be made at a precisely defined point in time and health outcomes which are defined by a measurement by either questionnaire or a functional or laboratory test.

In the case of a well-defined disease for which the time of occurrence can be traced individually, both historical cohorts and case-control designs can be used. Still the precise definition of the disease is one of the challenges of a clear design. The main issue is whether to group or to separate disease subtypes. Different subtypes of a same disease may have different risk factors even within a cancer site. The recent rise in adenocarcinoma of the lung has, for instance, been related to the increased use of “light” cigarettes. However, a too narrow definition of a disease may lead to smaller number of cases. This is even more an issue when the diagnosis is obtained from registry data or death certificates as is usually the case in historical cohorts. The precision of such data may be limited, and grouping of diseases thought to have similar etiologies may be a reasonable strategy.

An intermediate case would be a well-defined disease like COPD (chronic obstructive pulmonary disease) for which no systematic recording of patients is available. Here case-control studies face the challenge of estimating the time of onset of the disease in order to ignore all exposures, prior to the occurrence of the disease. Prospective cohorts can circumvent this problem, but if the incidence rate is small, they may not be feasible.

Determination of the point in time when to measure the health outcome is crucial. If one is interested in acute effects of an exposure, for example, the immediate effect of the chlorine in a swimming pool on genotoxicity using the comet assay, the health effect must be measured immediately after the exposure. If one is interested in chronic effects of an exposure, for example, of organic solvents on chronic neurotoxicity, care must be taken to measure the health outcome after a period of washout as, for instance, after the weekend in the case of a study on chronic neurotoxic effects of solvents, as the acute effects of the exposure may be mixed up with its chronic effects. Such considerations may have serious implications on the planning, cost, or even feasibility of such studies.

Often the health outcome of interest is better expressed on a continuous scale rather than classified as diseased/non-diseased like osteoporosis (bone mineral density), chronic obstructive pulmonary disease (FEV1), hyperlipidemia (serum lipid concentration), obesity (body mass index), or hypertension (blood pressure). Then a clear-cut incidence date can hardly be assessed, and the prospective cohort design is best suited to ensure that the exposure precedes the disease.

Similar to what is discussed in the context of exposure assessment, information on health outcomes may be obtained from disease registries as for example, cancer registries that are available in most countries or from claims data where in particular clinical discharge diagnoses can be considered as valid. Use of these individual-level data requires “bullet-proof” procedures for record linkage. Alternatively, information on health outcomes may be obtained from study subjects themselves. However, the ability to recall specific diagnoses is often limited, and underreporting is common, as, for example, in the case of diabetes or hypertension.

13.4.3 Information Bias

A major bias related to data collection is the information bias that occurs if the exposure assessment is different for cases and controls or the health outcome is measured differently for exposed and non-exposed subjects. The first situation arises mainly in case-control studies when cases are worried about the origin of their disease (e.g., smoking or asbestos exposure among lung cancer cases) or deny their disease (an observation made in cancer patients) and therefore recall past exposure differently than controls. It is possible to minimize this type of bias by standardized questionnaires and, if possible, by a data collection blinded with respect to the case-control status. The latter approach, although an option in hospital-based case-control studies, is, however, virtually impossible in population-based case-control studies. The same type of information bias is possible with historical cohorts if information is obtained a posteriori from proxies.

An information bias can also be due to the unavoidable measurement error in retrospective exposure assessment. The comparable accuracy principle (Wacholder et al. 1992a) states that the degree of accuracy in measuring the exposure of interest for the cases should be equivalent to the degree of accuracy for the controls unless the effect of the inaccuracy can be controlled in the analysis, as, for instance, by using appropriate validation data. Although adherence to this principle does not eliminate the corresponding misclassification, its rationale is to avoid that a positive finding is induced simply by differences in the accuracy of information about cases and controls (see also chapter ▶Case-Control Studies of this handbook).

13.5 Confounding

The *deconfounding principle*, another principle given in Wacholder et al. (1992a), states that confounding should not be allowed to distort the estimation of an effect. Confounders are by definition factors that are determinants of the disease and that are related to the exposure of interest (see also chapter ▶Confounding and Interaction of this handbook). Setting up a list of confounders is therefore a primary task in the exploration of the scientific knowledge related to the research question of the planned study. This identification of confounders should not be based on statistical associations alone. It must also include knowledge of potential causal pathways. For instance, if one were to study the effect of nutrition on coronary heart diseases (CHD), a factor that might be considered a potential confounder is obesity as it is related to both nutrition and CHD. But one might consider that obesity is on the causal pathway between nutrition and CHD in which case controlling for obesity would bias the estimation of the effect of nutrition (*overadjustment*). Careful thought should therefore be given to each factor that has to be included as a confounder. An operational result of this first step would be a list of three groups of confounders:

(i) Established confounders that are known to determine disease and to be related to the exposure of interest but which are not on the causal pathways. Sex and age are virtually always included in this group. Such confounders are to be included even if they do not show a statistically significant association with the disease in the study sample.

(ii) Probable confounders that are established risk factors and for which there are reasons to believe that they might be related to the exposure.

(iii) Possible confounders including other risk factors of the disease that might be or not related to the exposure of interest. If a given risk factor is a strong determinant of the disease (e.g., smoking for lung cancer), it might confound the association of a potential risk factor although the confounder is only weakly associated with the exposure of interest in the study sample.

At the design stage, controlling for confounders can be done either by restricting the study sample to certain values of the confounder (e.g., a lung cancer case-control study among non-smokers) or by matching. The latter ranges from broad frequency matching on age and sex to the individual matching on factors thought to be related to non-measurable factors (e.g., neighborhood matching). Matching aims at equalizing the variation of the confounder between cases and controls. This should, however, not reduce the differences and the variation of the exposure of interest between both groups. Nevertheless, if the matching variable could also serve as a proxy for the exposure of interest, it may happen that the effect of the exposure is decreased or even eliminated by matching.

This so-called overmatching is one of the main pitfalls in controlling for confounders at the design stage. It must also be stressed at this point that controlling for confounders in the design may well be counterproductive as it is irreversible and may forbid to explore interesting post hoc hypotheses (see also Sect. 13.3 on matching in chapter ▸Case-Control Studies of this handbook). A last strategy is to collect the relevant data on confounders in order to be able to control for them later in the analysis. Details of how to deal with confounding using any of these methods can only be decided within the context of a given study.

13.6 Statistical Analysis

Enough time and human resources should be planned from the start of a study for the statistical analysis. Many large-scale studies we know of are underreported because of lack of resources for the statistical analysis. It is impossible to detail all statistical analyses already in the planning stage. Nevertheless, the main research questions should be formulated in the protocol, and these questions should be operationalized

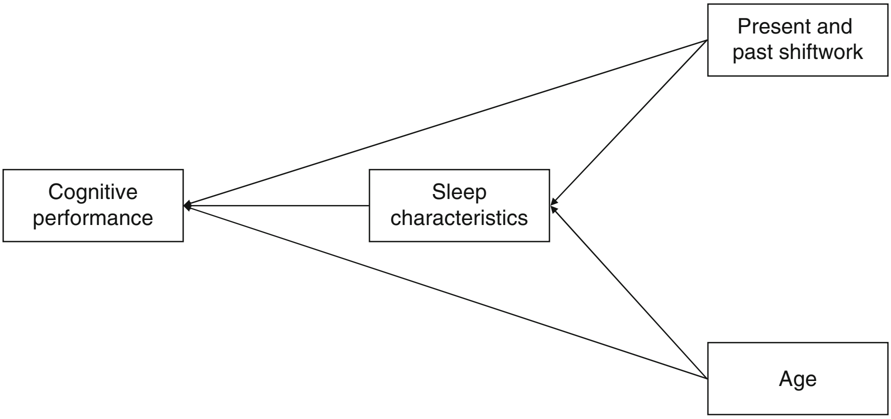


Fig. 13.3 Causal hypotheses of effects of shiftwork and age on cognitive performance

already at this stage, that is, translated in a statistical hypothesis to be tested. In addition, a statistical analysis plan should be developed at least for analyzing the main research question. General principles as well as special applications of statistical analyses of epidemiological studies are described in Part III (Statistical Methods in Epidemiology) of this handbook.

It is helpful at this stage to draw hypothetical causal graphs describing a priori models to be applied to the data of the study (see Greenland et al. 1999; Hernán and Robins 2006; Pearl 1995, 2000; chapter ▶Directed Acyclic Graphs of this handbook). Figure 13.3 shows a very simple graph formulating a series of hypotheses on the effect of shiftwork and age on cognitive performance which may be mediated by sleep problems. Such a conceptual framework helps to develop a strategy for statistical analyses based on a priori hypotheses and to identify potential confounders.

Additional ad hoc analyses which are more or less data driven may follow. The minimum statistical contents to be defined at the planning stage are the endpoint variable(s), the exposure variables, and the confounder variables to be adjusted for. The statistical measures (proportions, odds ratios, means, standard deviations, etc.) and models (mostly regression models) to be calculated should also be fixed in advance. Moreover, sensitivity analyses should be foreseen to check the robustness of the results against deviations from model assumptions. Finally, the subgroups for which stratified analyses will be done should be identified.

The fact that the a priori hypotheses are operationalized means that, for instance, the main endpoint(s) is clearly defined by certain values of the outcome variable(s). This is relatively straightforward in case-control studies for which the endpoint is the case status whatever its definition. For cohort studies investigating the mortality or incidence of diseases, the list of diseases possibly related to the exposure of interest should be well defined. For prospective cohorts or cross-sectional studies, the endpoint of interest may be less straightforward and can possibly require data transformation, for example, a score of depression obtained from a mental health questionnaire.

The variables characterizing the exposure should also be precisely specified. These can include (possibly lagged) cumulative, peak, or mean exposure metrics. Although for power computations this exposure may have to be considered as a yes/no variable, the main message cannot be that simple. Established confounders have to be included in the final model in any case. However, although the robustness of an association should be tested against all measured confounders, the list of presumed confounders to be included in the main model cannot be finalized at the planning stage.

13.7 Practical Issues

13.7.1 Fund Raising and Budgeting

Usually, large-scale epidemiological studies require external funds which can be acquired from industry or from public sources like foundations, research organizations, or governmental research funding. Often, the latter are offered through thematic calls where competing proposals are submitted and then evaluated by an ad hoc board of scientific experts as is the case in the periodic Framework Programmes of the European Commission. Sometimes the structure according to which such project proposals are to be set up is given by the funding agency. In general, the points to be addressed overlap to a large degree with what is required for the study protocol (see Box 13.1) where a detailed cost plan has to be added and the major cost items have to be justified. Technically, the expenses have to be broken down as regular salaries (paid by the parent organization), salaries for temporary staff, durable equipment, travel expenses, consumables (mailing, telecommunication, office material, laboratory), fees, consultants, subcontracts, overhead costs, and, if applicable, VAT.

It is also important to adjust the disbursement of the budget to fit the respective stages of the project. If funding comes from several different sources, the tentative share of each one must be specified. Experience has shown that the situation is easier to handle if only one funding agency is involved, but very large projects may require more than one source of funding (Hernberg 1992, p. 189f).

Once a grant application is successful, regardless of whether the sponsor is private or public, a contract should be set up between the researcher and the sponsor that:

(a) Ensures independence of the research project by prohibiting interference of the sponsor with the study conduct, analysis, and interpretation
(b) Guarantees full publication rights to the researcher, that is, that the results will be submitted for publication regardless of outcome and without a veto of the sponsor
(c) Defines the deliverables, the timeline, as well as the budget and its installment plan
(d) Regulates the intellectual property rights

Regarding the latter, the IEA (International Epidemiological Association) states in its guidelines for proper conduct of epidemiological research (Good Epidemiological Practice (GEP), IEA 2007) that “All results of a study, whether government or industry-sponsored, should be the intellectual property of the investigators, not the sponsor. Requests to withhold findings, to change or tone down the content of a report to produce a misleading or delayed publication should be categorically refused.”

13.7.2 Data Management

Data management is a crucial step especially with multicenter studies (see Long (2009) for a recent account on these issues, chapter ▸Data Management in Epidemiology of this handbook).

A first task in planning the data management is to identify the different data tables which are to be set up and to plan their structure and their linkage. Usually, data protection requires that all direct identifiers like name and address or social security number have to be kept separately from data tables (pseudonymization) or even that direct identifiers have to be deleted immediately after data collection (anonymization). In both cases a numerical subject identifier is assigned to each study subject and added to the corresponding data records which in itself does not allow the re-identification of the individual.

For linkage with external data, be it an administrative file or a file containing causes of death or diseases, as it is often necessary in (historical) cohort studies, a data table must be set up containing only the minimal information for linkage. Usually this entails the pseudonymized number used in the analysis dataset and the information by which linkage is facilitated, for example, name and address or a unique personal identifier like the social security number. The table used for linkage is provided to the institution holding the external data. External records matching with the direct identifiers can then be sent back without the direct identifiers and merged with the study data by the numerical subject identifier.

The data management of prospective cohorts and other population-based studies is especially challenging as there are several dimensions in the data. It is nearly unavoidable in such studies to keep a separate file for the management of all contacts. In this file all letters sent and received, all telephone contacts, all datasets, or information received should be documented for every study subject. Such a (complex) recruitment system allows to quickly identify non-responders, to control adherence to the recruitment protocol and to follow up the study subjects. If a subject has moved, for instance, such a system can support tracing and recording of new addresses. It may also ensure that no repeated letters are sent to deceased subjects. It is important to know at each moment if a given subject is due for another contact and whether she/he has reacted to the last mailing or phone call. This also implies that a recruitment system is able to trigger mailing of the correct letter according to the subject's status (questionnaire to be sent, questionnaire received, lost to follow-up, pending questionnaire, tracing of new address initiated, etc.). The contact data received must always be kept separately from the study data.

It is also important to clearly identify and label the variables containing the same information collected at different points in time when planning a longitudinal study. If these variables have the same names, they are at risk to be overwritten. Careful a priori structuring of the database makes life much easier when creating a dataset for statistical analysis. Owing to the extended time scale of such studies, the documentation is particularly important as it is not guaranteed that the same data managers will handle the data throughout the study.

Other issues to be planned carefully are data entry and coding. Three main options exist for data entry. A first option is to input data directly when interviewing the study participants. This is the rule with telephone interviews, and it is widely used with laptops in face-to-face interviews. An important aspect with direct input is the layout of the screen; the interviewer must follow the questions she/he has to ask without being disturbed by computer problems. Issues like skip patterns, the ability to easily correct already entered data, toggling between keyboard and mouse, and online detection of invalid codes or inconsistencies between different data items are to be programmed carefully and to be tested under real conditions. A widely used computer program is the freeware Epi Info available from the division of public health surveillance and informatics of the Centers of Disease Control, Atlanta (Centers for Disease Control and Prevention 2011). However, it has some limitations making it unsuitable for complex large-scale studies. A large range of commercial software exists, each with its own advantages (see chapter ▶Data Management in Epidemiology of this handbook). A second option is to obtain data through paper questionnaires and to enter the data later. In this situation a double entry is to be recommended whenever possible, especially if the questionnaires were self-administered. The data should be entered as they are, but the data problems (errors, inconsistencies) should be documented in a log-file to be cleared as soon as possible. Another option is to obtain machine-readable questionnaires which are scanned electronically. Such an approach has been implemented in actual large-scale studies, notably in the French part of the EPIC study (e.g., Clavel-Chapelon et al. 2002). Future developments will make the use of electronic self-completion instruments more accessible, in particular in combination with user-friendly touch screens and online access allowing real-time data transfer to a secure central data server (see chapter ▶Internet-Based Epidemiology). Such online tools can be easily accessed from anywhere as they only require Internet access and a usual web browser (Lumsden 2005; Reynolds et al. 2007).

Data coding, that is, transforming free text information (examples are places of residence, jobs, tasks, or food items), in a closed list of items is also an aspect to be planned and tested. It relies often on specialized knowledge. The closed list of items and coding rules must be set up before starting the data collection. Details on the construction of instruments are given in chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook.

The management of stationary exposure data deserves a specific discussion since they pertain to exposure groups rather than individuals, that is, they characterize specific circumstances (cf. chapter ▶Exposure Assessment of this handbook). These circumstances include, for example, measurements of air pollution in certain areas, households, or occupational tasks. These data must entail a link to the subject data. It is therefore important to include the same items (i.e., labels of the exposure group) in the exposure measurement database as in the subjects' database. A further complication arises when some of these exposure measurements are on individuals (e.g., personal sampling at the workplace or stationary measurements in households), including subjects from the epidemiological database. These measurements characterize both the exposure group and the specific individual. Both links must then be clearly identified from the start.

Finally, all steps of data management should be recorded in a logbook. This can be part of the overall project diary (see below).

13.7.3 Quality Assurance

Industrial standards for quality assurance and quality management are set down in the ISO 9000 series of standards (International Organization for Standardization 2012). Their application to epidemiological studies is not straightforward given that these standards (see Moulin et al. 1998b) are geared toward customer satisfaction and that the customers of epidemiology are not easily defined. The main ideas behind these standards are however useful.

The main principles as they apply to epidemiology are the following (see also chapter ▶Quality Control and Good Epidemiological Practice of this handbook). Write up in detail what you intend to do and document what you did. Try to be proactive in thinking of what can go wrong and plan accordingly. Set up means by which you can detect any problem as early as possible and by which you can correct your procedures accordingly. Specify and document all changes of procedures implemented after the start of the study.

We already insisted on the necessity of a detailed study protocol. A study protocol may be complemented by a manual of operations which includes all standard operating procedures (see below) describing the actual work to do (cookbook). One main point in being proactive is to specify all procedures for data collection in as much detail as possible. Details with respect to material conditions, for example, hardware, software, office, and storage room, need to be considered in advance. Training of the data collection staff is a key to good quality data. This training should encompass all survey instruments in the setting in which the actual data collection will be conducted. It is also important to acknowledge that there will be non-responders and to collect minimal information on non-participants from the beginning to assess the type and degree of a potential selection bias. In order to monitor errors as they arise and to enable immediate corrective action, data should be entered concurrently to their collection, and data checks and validation should be done as early as possible. In large-scale studies, the internal quality management may be supported by an independent external quality control (for an example, see Filipiak-Pittroff and Wölke 2007).

13.7.4 Study Conduct: Manual of Operations

As mentioned in the section on the study protocol, the collection of material and data as well as the methods and procedures must be described in detail. This can be done in a separate document: the manual of operations (cf. chapter ▸Quality Control and Good Epidemiological Practice of this handbook). The manual of operations compiles all standard operating procedures. It may therefore be considered as the technical operationalization of the study protocol which serves as the "cookbook" for the study personnel and ensures standardization of all measurement procedures. By this it becomes a central part of the quality management of a study. An exemplary table of contents of a manual of operations is given in Box 13.2.

Box 13.2. Table of contents of an exemplary manual of operations taken from the IDEFICS study (Ahrens et al. 2011)

1 General
1.1 Background and research question
1.2 Description of study base and study region
1.3 Inclusion and exclusion criteria for study subjects
1.4 Sampling design including instructions for drawing the sample
1.5 Public relations and corporate design
2 Fieldwork
2.1 Contact procedures and approaching study subjects
2.2 Informed consent
2.3 Treatment of participants and non-participants
2.4 Electronic control and documentation of contacts
2.5 Assignment of ID-numbers (pseudonymization)
2.6 Procedures for data protection
3 Data collection
3.1 Overview of data collection modules
3.2 Organization of data collection
4 Interviews and questionnaires
4.1 Structure and contents of questionnaires
4.2 Instructions for use of questionnaires/conduct of interviews

4.3 Editing of completed questionnaires
4.3.1 General instructions
4.3.2 Specific instructions
(a) parental questionnaire, (b) dietary assessment, (c) medical history, (d) teachers questionnaire, (e) setting questionnaires (schools and kindergartens)

5 Physical examinations
5.1 General rules and procedures
5.1.1 Functional checks of measurement devices
5.1.2 Completion of documentation sheets
5.1.3 Instructions for clothing of children during examinations
5.1.4 Hygiene
5.2 Anthropometric measurements
(a) body weight and bio-impedance, (b) body height, (c) waist and hip circumference, (d) skinfold thickness, (e) . . .

5.3 Blood pressure and heart rate
5.4 Actimetry (accelerometer)
5.4.1 Preparation of measurement devices
5.4.2 Measurement protocol and implementation of measurement devices
5.4.3 Readout and taking readings
5.4.4 . . .
6 Biological samples
6.1 General procedure for collection, processing, storage and transport
6.2 Specific instructions
6.2.1 Blood samples
6.2.2 Urinary samples
6.2.3 Salivary samples
6.2.4 . . .
7 Handling of devices
7.1 Scale with bioelectrical impedance measurement
7.2 Stadiometer
7.3 Skinfold calliper
7.4 Blood pressure measurement
7.5 Accelerometer
7.6 . . .
8 Quality management
8.1 Training of study personnel
8.2 Pretest of questionnaires and measurement procedures
8.3 Re-interviews and repeated measurements
8.4 Monitoring of data collection and site visits
8.5 External quality control
9 Ethical principles and data protection

10 Annex
10.1 Questionnaires and documentation sheets
10.2 Letter templates
10.3 Information material and consent declaration
10.4 Important contacts
10.5 Checklist supporting adherence to standard operating procedures (SOPs)
10.6 Checklist for regular functional checks of measurement devices
10.7 Reporting form for daily inspection of the equipment of the examination site
10.8 List of all devices and consumables
10.9 Instructions for parents

It describes in detail the recruitment of study subjects and how they are selected for the study. The eligibility criteria must be defined in cohort studies in terms of minimum exposure, calendar time of exposure, whether or not other exposures are allowed, and so forth. If a case-control design is adopted, all eligibility criteria except the diagnosis for both cases and controls must be comparable to ensure that both groups are drawn from the same study base. For example, what histological type of cancer will be included and how will the diagnosis be confirmed? What is the data source for identification of study subjects? Who will collect the data? What is the sequence of approaches to contact a study subject (letter, phone call, home visit), and what are the criteria to classify a subject as a non-responder?

The measurement methods and procedures need to be described as well. How will the interviewers be trained? Will there be a panel of pathologists for reviewing the diagnosis based on the histological slides? How are the questionnaires to be applied to study subjects? What are the exact steps and procedures in the measurement of blood pressure (posture of the study subject, resting time before taking the first measurement, number of measurements, time interval between subsequent recordings, choice of the correct cuff size, advice given to the respondent, etc.)? What is the definition of fasting, for example, what is the minimum time interval between the last meal and the blood draw of the subject? In the case of biological samples, the manual needs to describe exactly all procedures and the timing of collection, processing, shipment, and storage of samples to avoid biased measurements due to decay of metabolites. It may also include a description of the analytical laboratory procedures.

Moreover, the manual of operations should summarize the ethical principles of the study, the information to be given to study participants, and the procedures to ensure confidentiality during data collection and data management. It should entail all information that is relevant for the daily routine of the study personnel during fieldwork and data management.

13.7.5 Timeline and Workflow

The time schedule concerns the sequence and interrelationship of different operational tasks and resources. It is good practice to outline the tasks and subtasks at the design stage and to plan their time flow which can be visualized in a Gantt chart (after the method developed by Charles Gantt in 1917; for a simple fictitious example, see Fig. 13.4). A PERT (Program Evaluation and Review Technique) chart (for a fictitious example, see Fig. 13.5) gives a quick overview of the relationships between main tasks and helps to identify the critical paths. This will help to define milestones that need to be attained in time in order to successfully reach the aims of the project. It should be noted that milestones are not to be mixed up with deliverables. The latter define the end result of a given activity or task, while the former define a more complex stage that has to be reached in the overall roll-out of a project in order to enter the subsequent phase. Responsibilities have to be assigned for each task, and the necessary resources required for each have to be allocated. Once it has been decided how many subjects will be included and what methods of examination will be used, the time needed can be estimated rather accurately. At the planning stage, one should make sure that statistical and computer support will be available when needed. One should realize that the first data analysis may reveal unforeseen inconsistencies or other problems in the data that then trigger subsequent analyses not foreseen at the beginning.

Writing a manuscript takes time. Unexpected practical matters almost always disrupt the original time schedule. Enough time must be reserved for all these considerations. Hernberg (1992) recommended to foresee an allowance of half a year or more for unexpected complications.

The timeline and the corresponding resources are best planned using project management tools like Gantt and PERT charts (see Figs. 13.4 and 13.5). Basically these tools decompose a project in elementary tasks with certain duration, order, and interrelationship. Figure 13.5 presents the different tasks with arrows indicating which tasks must be terminated before the next one can start (e.g., the data collection

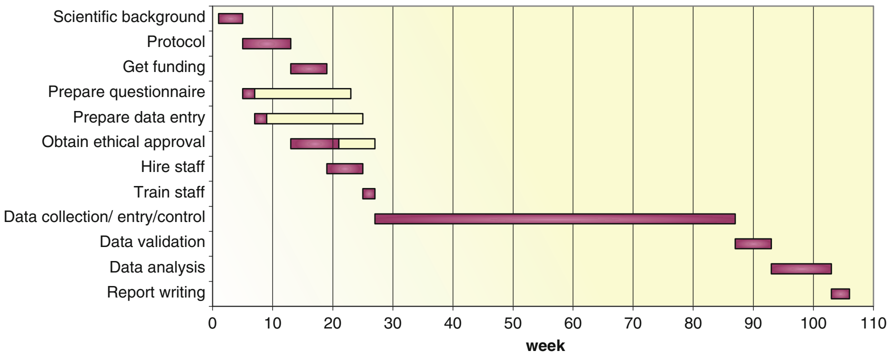

Fig. 13.4 Gantt chart for planning a study

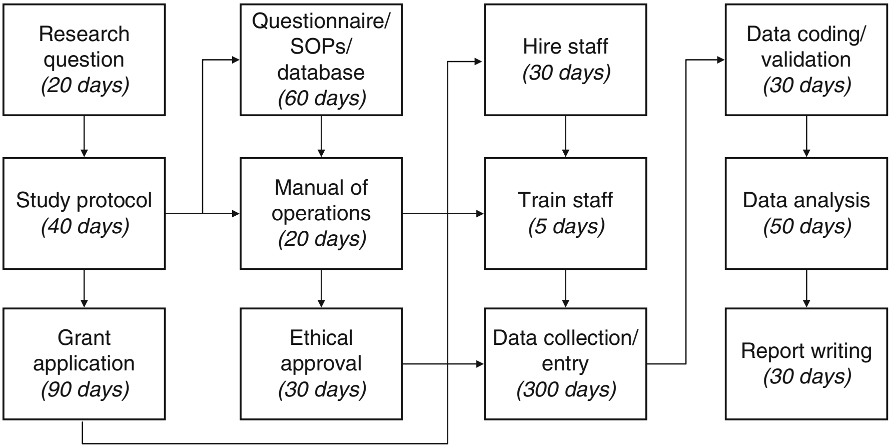

Research question (20 days)
Questionnaire/ SOPs/ database (60 days)
Hire staff (30 days)
Data coding/ validation (30 days)
Study protocol (40 days)
Manual of operations (20 days)
Train staff (5 days)
Data analysis (50 days)
Grant application (90 days)
Ethical approval (30 days)
Data collection/ entry (300 days)
Report writing (30 days)

Fig. 13.5 Simple fictitious example of a PERT chart for planning a study

can only start when the study has been approved by the ethics committee and when the staff has been trained). From this information, critical tasks (dark bars in Fig. 13.4) are identified, which – if delayed – will delay the whole study. Non-critical tasks such as preparation of data entry that may depend on completion of other tasks as, for instance, preparation of questionnaire can be delayed without endangering the successful attainment of milestones. However, non-critical tasks must be completed by the start of other activities (here, data entry). This is indicated by the light bars in Fig. 13.4. For examples of project planning tools and an introduction to project management in general, refer, for instance, to Schwalbe (2012). A number of sharewares easily available through the Internet provide the software to draw these charts and diagrams.

13.7.6 Project Diary

A project diary should trace the major activities performed during the course of the project. This includes the changes of the protocol, the data collection, and the data processing. A diary keeps track not only of the scientific realization of the operational plan of the project but also of its administrative and economic aspects.

Changes of the original work plan may be dictated either by external circumstances possibly by scientific reasons, for example, if new evidence arises after the start of the study concerning a potentially important confounder.

Documentation of data collection should monitor not only its advancement but all potentially important events that might distort measurement values. It should thus be documented if personnel involved in collection or management of data is replaced, if some measurement instrument is replaced or if and why, at some stage, the data collection is impaired. Temperature loggers facilitate documentation of involuntary thawing of frozen biosamples. Dates and results of instrument calibration should be recorded. When quality control measures result in corrective action (see chapter ▶Quality Control and Good Epidemiological Practice), this should also be recorded.

Electronic data handling, for example, names of raw data files, computer transfers, plausibility checks, data corrections, merging of files, recoding, and finally all statistical data processing, should all be documented including analyses which proved to be dead ends (cf. chapter ▶Data Management in Epidemiology of this handbook).

The project diary and the protocol, operation manual, and the raw data are the central pieces of evidence with which errors can be traced and the study can be replicated or be reanalyzed, if needed.

13.7.7 Ethical Aspects

The ethical aspects are diverse and have been well covered in chapter ▶Ethical Aspects of Epidemiological Research of this handbook. General ethical principles for all biomedical research have been laid down in the Helsinki declaration of the World Medical Organization (1996). The four central principles can be summarized as follows:

1. Doing good (beneficence)
2. Not harming (non-maleficence)
3. Respecting persons (autonomy)
4. Distributing goods and evils fairly (justice).

The following aspects are more specific to epidemiological research: The first ethical requirement is the respect of the data protection laws that are specific to each country. This may even require deletion or at least separation of parts of the data, usually the personal identifiers, at a certain point in time. The second is the requirement that all study participants are informed of the objectives of the study, which medical examinations will be done and what is their purpose and associated health risks. The written informed consent of the participants is obligatory. Confidentiality must always be adhered to, and no individual results can be revealed to third parties unless explicitly permitted by the respondent. If in the course of a prospective study it becomes evident that individual exposure levels exceed safety limits, the researcher must take the initiative to try to remove the subject from the hazardous exposure.

The results of individual investigations should be made available to study participants upon request as well as a summary of the overall results of the study. However, incidental findings pose a special problem. A medical examination might detect a hidden disease, for example, an X-ray or an MRI might detect a tumor. Participants have the right to know such findings, but they may also dissent to get informed when giving their informed consent. If the result of an examination is of therapeutic or preventive relevance, the study participant may be referred to a physician. Otherwise, pathological findings that are not amenable to treatment or prevention may be excluded from feedback.

Biological markers have become a major issue of concern with regard to the right to know or not to know mentioned above. Here, in planning a study, three types of markers should be distinguished. The first group is formed by biological characteristics with yet unknown relevance for the risk or prognosis of a disease that are under research and for which no reference values exist. This is the case for numerous genetic markers with unknown biological function. In this case knowledge of this value does not entail a direct benefit for study participants. The second group of markers is those that might have a direct therapeutic implication as in the case of blood lipids or certain chemical noxae. In this case it may be an ethical obligation to inform the affected study participant in due time about elevated or pathological values to avert any damage. The third group includes markers that are predictive of future disease but without any direct implications for therapy or prevention as in the case of some genetic disorders. In this case, the right to know or not to know is of particular importance. In such cases it should be carefully evaluated, whether the assessment of such markers is really necessary to reach the study aim. If this is the case, it may be an option to inform study participants that such information will not be disclosed. It is recommended to consult the responsible institutional review board/ethics committee how to proceed.

A final aspect is that the results of the study should always be made available to the community. Failing to publish the results means that the examinees have been abused and the funding has been wasted. In doing so, the interpretation of the results must be objective including a discussion of all relevant literature and all possible validity problems as well as alternative explanations of the findings. Further details and specific recommendations relevant for epidemiological studies were formulated by the Council for International Organizations of Medical Sciences in collaboration with the WHO (CIOMS 2009).

13.7.8 Scientific Collaborations and Multicenter Studies

An epidemiological study usually requires collaborations of the principal investigator with scientists from several fields which of course include epidemiology and usually a specialized medical field and statistics but may also include, depending on the study, genetics, molecular biology, microbiology, chemistry, industrial hygiene, psychology, and sociology. Another type of collaboration occurs if a multicenter study is set up in which several epidemiologists combine resources. Advantages and possible pitfalls have already been mentioned, and the standardization of the data collection is then a major issue. The data analysis may be centralized or decentralized. For instance, in multicenter studies organized by the International Agency for Research on Cancer (IARC), the national centers may publish their local data, but they may also take the lead for a pre-defined specific analysis of a particular topic of the pooled dataset. Usually, publications based on the pooled full dataset have priority over local analyses.

In any type of collaboration, the respective responsibility and role of each collaborator or collaborating center as well as the resources allocated to each partner should be settled before the study starts. These are the key components of the project governance. Provisions should be made for possibly divergent interests between study partners by laying down all important rights and obligations of each partner in a contract. This must include the regulation of intellectual property rights as well as access rights to data and results. Responsibilities for deliverables and corresponding deadlines should become part of such a contract, for example, by appending the study protocol. Establishment of a democratic governance structure has proven to be useful in large-scale multicenter studies, for example, by establishing a general assembly of all principal investigators. A steering committee consisting of the leaders of major work packages may support the risk management by initiating actions needed to follow the study plan and by adapting the plan if necessary. It may also take care that all partners collaborate on an equal basis (taking their contribution to the project into account) and get their share of the scientific output including publications.

13.7.9 Communication

Epidemiological research is of interest not only to epidemiologists but also to decision makers, funding agencies, and also the general public. The results should be published in a form and language that they are understandable to the different target groups. This often requires two or more levels of reporting, one scientific and one popular, possibly supported by a press release. It is worthwhile to plan responsibilities for each aspect in advance and how the information will be disseminated. Those taking part in a study have the right to know not only their personal results – especially when medical examinations are involved – but also, at least in general terms, the outcome of the whole study. The correct timing of the sequence of information delivery is important. First, those examined should be informed of their own results unless a subject declared that he/she does not want to be informed; then summary results should be given to funding agencies and only afterward to the news media. Ideally, a peer-reviewed scientific article should have appeared or at least have been accepted for publication before informing the news media. However, the scientific publishing procedure is often slow that it sometimes may be unethical to withhold urgent results from the public that long.

According to the precautionary principle, epidemiologists are responsible to communicate a justified suspicion regarding potential health hazards even if the evidence of the associated risk is still limited. In doing so, an epidemiologist has to balance out the information on potential risks and their implications and the communication of limitations and uncertainties of the study findings. This has been pointed out by Sandman (1991) in his guidelines on communication responsibilities of epidemiologists regarding health risks: “I do argue that poor communication comprises even the best epidemiology, and that epidemiologists therefore have communication responsibilities that cannot be ignored.”

A large project usually gives rise to several scientific publications, and it may be useful to outline their topics in advance. At the planning stage, it is advisable to agree within the team on who will be responsible, that is, the first author, and of what and how authorship will be facilitated. It is usually not possible to decide the order of names at this stage because each team member's input to the intellectual process can be judged only after the corresponding activity has been successfully completed. Publication rules may become part of the contract between researchers involved in a study as, for example, in the IDEFICS study (2011). Central guidelines as to who should be considered author of a publication are included in the Vancouver guidelines (International Committee of Medical Journal Editors (ICMJE) (2010)). These include the obligation to declare any potential conflicts of interest to avert doubts about the independence of the research.

13.8 Conclusions

Careful planning is a key in the successful completion of an epidemiological study. This planning should be based on up-to-date scientific knowledge and awareness of all possible pitfalls inherent in epidemiological studies. It should cover all aspects from study base definition, precise design used, statistical power, control of confounding, precise data collection, and exposure measurement methods to quality control, statistical methods, collaborations, dissemination of study results, and ethical issues. All these issues should be laid down in a scientific study protocol, and a manual of operations from which the quality of the study can be assessed. Multicenter studies require regulations to ensure respectful and fair collaboration between all partners. Finally, researchers have to admit their responsibility to communicate their findings not only to the scientific community but also to the public.

14.1 Introduction

The use of data is fundamental in epidemiology. Epidemiological research on causation uses data in a search for the true nature of the relationship between exposure and disease. Increasingly, research with biomarkers of susceptibility, exposure, and response seeks to characterize mechanisms of disease causation. Research on the consequences of interventions seeks an unbiased assessment of the effects of independently varying factors on the outcome measure(s).

One of the most rewarding moments for a researcher is obtaining the preliminary results from his or her study. However, the question "do I believe what I see?" should immediately come to mind. The answer to this question is determined in large part from the more mundane but critical question of how good is the quality of the data, rather than from the elegance of the scientific design and methods. Errors that occur during study population selection or in the measurement of study exposures, outcomes, or covariates can lead to a biased estimate of the effect of exposure on risk for the disease of interest. Misclassification of exposure or disease that occurs randomly between all study participants decreases the power of the study to detect an association where it exists. Data collection that is differentially biased may have more severe consequences and can lead to an incorrect assessment of the relationship between exposure and disease.

The inherently important issue of study quality is becoming of even greater consequence as the findings of epidemiological studies gain in impact and the field of epidemiology gains wider acceptance as an essential element of biomedical research (Hiatt 2010; Samet 2000; Samet and Lee 2001). Results of epidemiological studies are routinely reported in the media, receiving widespread attention because the findings have evident relevance to the populace. Epidemiological evidence is also used to inform regulatory and legislative policy making (Goldman 2001). The decision to set airborne standards for particulate matter in the United States, for example, was largely fueled by evidence from epidemiological studies (Bachmann 2007; Greenbaum et al. 2001). Epidemiology often figures prominently in litigation, where the study methodology can become a point of debate (Bryant and Reinert 2001; Goldman 2001; Michaels 2008). Given the significance of epidemiological evidence for decision making, the results of epidemiological studies often face close scrutiny and questions may be raised about every aspect ranging across data quality, study methods, study conduct, data analysis, and interpretation of findings.

Even if external questioning and auditing are not anticipated, the researcher nonetheless faces the responsibility of assuring the quality of the study and preventing the widespread dissemination of misleading or incorrect information. For example, findings from several cohort studies on air pollution and mortality figured prominently in a 1997 decision by the US Environmental Protection Agency (EPA) to promulgate a new standard for airborne particulate matter (Bachmann 2007). The great weight given to the data by the EPA led to a call for access so that others could check and analyze the data. An extensive reanalysis of the data was carried out, including validation of elements of the original data as well as replication and extension of the original analyses by an independent group (Krewski et al. 2000; Samet et al. 1997). The controversy surrounding the use of data from the air pollution cohort studies eventually led to a Congressionally mandated requirement for sharing data with policy implications that have been collected with support by federal funds (Data Quality Act 2000, Public Law 106–554, Sect. 515a).

Many hypotheses of current interest in epidemiological studies call for the incorporation of data from multiple centers and involve collection of data from large populations according to centrally standardized protocols. Data sharing has also become more common, and approaches to doing so for larger grants in the United States have been mandated by the National Institutes of Health (Samet 2009). In order to enhance statistical power, data from individual studies are often pooled, or summary results are combined using meta-analysis. The establishment of networks or cohort consortia also allows for enhanced statistical power to address increasingly complex research questions, particularly in the general area of molecular and genetic epidemiological studies. These approaches to data utilization place a further demand for meticulous study documentation so that data from a study are readily usable by persons other than the original investigators.

General methods have long been available for assuring the quality of data. The idea of creating a high quality end product using process improvement initially emerged in the context of industrial business models. Early efforts at delivering quality products to customers were based on inspecting products at the end of a factory line and eliminating those products that did not meet standards ("quality control"). The idea of improving all procedures that affect the quality of the manufactured products ("quality assurance") represented a fundamental shift in paradigm for industrial manufacture. Incorporating quality considerations into the process rather than the product has since gained widespread acceptance in the business and engineering communities (International Organization for Standardization 2003).

Although there is a vast literature on quality control in general, the issue has not received much formal attention in the epidemiological setting. Within epidemiology, much of the writing on data quality and good epidemiological practice is focused on the conduct of clinical trials and pharmacoepidemiology (Canner et al. 1983; Cooper 1986; Dischinger and DuChene 1986; DuChene et al. 1986; Etminan et al. 2006; Gassman et al. 1995; Hilner et al. 1992; Knatterud et al. 1998; Meinert and Tonascia 1986; Neaton et al. 1990; Vantongelen et al. 1989). While clinical and laboratory guidelines can easily be modified to make them more applicable to observational studies, few sources specifically address quality issues for the most common epidemiological study designs. In an early attempt to bridge this gap, the Epidemiology Task Group of the Chemical Manufacturers Association (CMA) compiled a set of guidelines for good epidemiology practice for occupational and environmental epidemiological research (Cook 1991; The Chemical Manufacturers Association's Epidemiology Task Force 1991). An overview of data quality issues for epidemiological studies is also provided by Szklo and Nieto (2000) and by Whitney and colleagues (1998). Methods to improve data quality in medical registries are reviewed by Arts et al. (2002).

This chapter provides a general overview of data quality and guidelines for good practice in epidemiological research. The fundamental premise is that quality considerations should be integrated into every phase of the study from initial hypothesis formulation to the final publication of findings and archiving of data. Obtaining data completely free from error clearly would be prohibitively expensive and often impossible. The goal is therefore not error-free data, but rather planning and implementing cost-effective procedures that guarantee the validity of the primary results to an acceptable degree. The epidemiological researcher needs to be able to gauge the extent of any errors and assess the consequences for interpretation of data analyses. The idea of "quality control" versus "quality assurance" is carried over from the industrial management literature into the epidemiological literature, with a distinction made between activities that take place prior to data collection (quality assurance) and activities that occur during and after data collection to correct data errors (quality control).

The ubiquitous nature of quality issues, both in terms of where these issues can arise and how they affect study results, can be captured by an extended metaphor. In an article describing the causation of bias, Maclure and Schneeweiss present the idea of an "Episcope" through which an epidemiologist views a putative association between a causal agent and morbidity. Just as a user of a large telescope would be skeptical about whether and how image degradation exists, an epidemiologist should think about how and why an observed association between exposure and disease might be biased (Maclure and Schneeweiss 2001). A similar idea can be applied to data quality. As published study results are viewed through a "datascope," a discerning epidemiologist should be wary of how the final image (the published results) may have been distorted by quality considerations during the design, conduct, and dissemination of the study. Working backward, the observer might ask a string of questions, such as "Were the observed results more likely to be published because they were positive findings? Based on the analysis, were published inferences appropriate? Were the methods of analysis suitable? Were data keyed in correctly? Has the data been collected appropriately? Was an appropriate population defined?" Each of these questions points to one or more study quality issues. Using the metaphor of the datascope, we will highlight the main issues regarding study design and conduct, and present ways in which to improve epidemiological practice and data quality.

14.2 The Datascope

Imagine, for a moment, that published study results can be viewed only through a large telescope. As you peer into the lens, the initial picture is barely discernible. On your right is a panel with focusing controls. The first dial allows you to adjust out any distortion caused by publication bias. When you optimize this dial, the image becomes slightly clearer. The next control allows you to tune out faulty inferences. Again, you turn this knob to make the image somewhat clearer.

The process continues until the results are finally sharply focused. Although we do not literally look through a telescope every time we view the results of a study, we are in fact looking at an association that may well be "out of focus," depending on how well the study was designed, conducted, and interpreted. Errors in the measurement of the exposure, outcome, or other covariates can be thought of as unfocused datascope controls that contribute to degradation of the final image.

Let us consider, in some more detail, the datascope controls that manipulate sources of measurement error. The farthest dials from the observer are located in the planning phase of a study and influence purely "quality assurance" activities. For a more in-depth discussion of the planning stage, see chapter ▶Design and Planning of Epidemiological Studies of this handbook. Errors occurring at the study planning stage are summarized below.

- *Errors in Study Conception*
  If the study rationale and design are not carefully formulated, the rest of the study could be rendered completely irrelevant. Errors in study conception include inadequate literature review, consideration of an inappropriate study design, and failure to plan the validation of exposure or outcome variables.
- *Errors in the Selection, Design, or Procedures for Use of Instrument Measuring Exposure*
  The instrument selected for study exposure measurement might not cover all sources of the active agent. Conversely, the measurement instrument might include sources of exposures that are not biologically relevant or measure exposure for a time period that is etiologically unimportant. In survey instruments, the phrasing of questions or instructions could lead to misunderstanding or bias (cf. chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook for a discussion of bias). Insufficient detail in the protocol for instrument use or inadequate consideration of a standardized method for dealing with unusual situations can lead to collection of poor quality data.
- *Inadequate Training of Study Personnel*
  Even if study procedures are very well defined, inadequate and non-standardized training of data collection staff in the application of these procedures can introduce errors in the data (cf. chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook)

The next set of controls is activated during the conduct of a study and includes activities that generally fall under the categories of quality assurance as well as quality control. For instance, validation studies of instruments and equipment ensure that collected data will be accurate (quality assurance) but can also be used to correct errors in data (quality control). Sources of exposure measurement error that can occur during data collection are described in detail elsewhere (White et al. 2008) and summarized below.

- *Improper Execution of the Study Protocol*
  Errors related to study protocol execution include the misinterpretation of, or deviation from, standard operating procedures by study technicians. Mistakes in interpretation of the study protocol often arise from poor clarity of the manual of

operations or inadequate training of study personnel. For example, if the standard operating procedure states that a fasting blood glucose level should be measured but does not specify the time required to have elapsed after the last meal, the interpretation of "fasting" may differ from technician to technician. Errors in data can also result from improper handling of biological specimens or the failure of subjects to read or understand instructions in self-administered questionnaires. For some biological assays, meticulous handling of a blood specimen may be needed.

- *Errors Related to Study Participants and Intra-individual Variability*
  Subjects may have poor recall of past exposures or allow recent exposure to influence their memory of past exposure. Individuals also tend to overreport socially desirable behaviors, such as exercise, and underreport socially undesirable habits such as smoking. Additionally, short-term variability in the biological characteristics of a subject can lead to unrepresentative measurements of exposure or outcome. For example, differences in the levels within or across individuals of an exposure biomarker measured at a specified time after exposure are likely to be due partially to individual differences in metabolizing the agent of interest.
- *Changes in the Accuracy of Measurements over Time*
  Failing to standardize and recalibrate laboratory equipment is likely to introduce data drift as calendar time progresses. In long-term studies, the instrument used for measurement may change over time, and the agent of interest in biological specimens may be subject to degradation. Also, as the study personnel gets more experienced through the course of the study, changes in the handling of procedures and instruments may occur.
- *Mistakes in Data Processing*
  Data that are recorded inaccurately, illegibly, or incompletely are very difficult to correct after the fact. Transcription of the data to electronic files introduces more chances for error, both within a study site and between field sites and the data coordinating center. At the coordinating center, programming or procedural errors may corrupt the database or modify data inappropriately. Errors can also be introduced by undocumented changes or modifications to a local or central database.

The final panel of controls on the datascope, closest to the observer, consists of purely "quality control" dials, which influence study quality after the data have been collected. Examples of these errors are presented below.

- *Inappropriate Data Analysis*
  If data analysis is not preceded by familiarization with the nature of the data, the chosen analyses may not be appropriate. Specifying the wrong model for analysis, for instance, can lead to completely erroneous results and inference.
- *Poor Reporting of Data*
  Omitting the results of important data analyses or presenting unnecessary information can obfuscate the study results. Lengthy, verbose explanations and poorly labeled graphs and figures add to the confusion. Inappropriate inference given the study results can also be misleading.

In order to achieve the highest quality data possible, each of the sources of error described in the planning, design, conduct, and conclusion of a study should be minimized. Conceptually, this can be thought of as turning the appropriate datascope dial to obtain the best image possible.

A review of the different sources of error that can occur during study planning, designing, and conducting informs the datascope user as to where he or she can affect final data quality. The ultimate goal is to optimize the datascope dials in order to minimize error and achieve the clearest possible picture of the study results. In the rest of this chapter, we present aspects of quality control and good epidemiological practice that can reduce data error. The chapter will follow the same organization as the datascope control panels, beginning with the planning phase of a study, moving onto quality considerations during study conduct, and finally describing activities that occur after data collection. Where applicable, the working of the datascope will be illustrated using the example of measuring blood pressure in a hypothetical study whose main research question is whether elevated blood pressure leads to increased risk of coronary disease.

14.3 Quality Considerations in the Planning Phase

14.3.1 Protocol

The development of a comprehensive study protocol is essential to good epidemiological practice. The *study protocol* is a narrative document that describes the general design and procedures used in the study. It can be distinguished from the study *manual of operations* (Sect. 14.3.3) by its generality and absence of specific details for day-to-day study conduct. The study protocol assists the staff in understanding the context in which their specific activities occur. A well-designed study protocol can, and should, guide all aspects of the study. In general, a protocol would include the following sections: a short descriptive title, a description of performance sites and personnel, a description of background and significance, results of preliminary studies, study design and methods, a time line for completion of major tasks, ethical considerations, and references. Quality assurance and quality control should be addressed in each relevant section of the protocol and also summarized in a separate section. Although restrictions or recommendations provided in the guidelines for research grants applications for the US National Institutes of Health may not be applicable to grants funded through other mechanisms, these guidelines nevertheless provide useful suggestions for creating study protocols (US Department of Health and Human Services 2009). Recommendations for protocol write-up are also included in the Guidelines for Good Epidemiology Practices for Occupational and Environmental Epidemiological Research (The Chemical Manufacturers Association's Epidemiology Task Force 1991). The typical sections of a study protocol are summarized in Table 14.1 (see also chapter ▶Design and Planning of Epidemiological Studies of this handbook).

Table 14.1 Guidelines for preparation of a study protocol (Adapted from the guidelines for good epidemiology practices, epidemiology task group (The Chemical Manufacturers Association's Epidemiology Task Force 1991))

Section	Guidelines for good epidemiological practice
Title	Descriptive and to the point
Names, titles, degrees, addresses and affiliations of the study director, principal investigator, and all coinvestigators	Possible conflict of interest should be identified and resolved
Name(s) and address(es) of the sponsor(s)	Possible conflict of interest should be identified and resolved
Proposal abstract	Informative and succinct
Proposed study tasks and milestones	Timetable should be realistic and identify possible sources of delay
Statement of research objectives, rationale, and specific aims	Clearly state the purpose of the investigation, describe whether the study will be hypothesis generating or hypothesis testing, and whether the study will confirm previous findings or result in new findings
Critical review of the relevant literature	Include animal, clinical, and epidemiological studies Do not restrict search to electronic databases (e.g., PubMed, TOXLINE), older articles might be missed Describe the occurrence of exposure and outcome variables Identify potential confounders and effect modifiers Identify gaps in current knowledge
Description of the research methods	Describe the overall research design and why it was chosen. Consider alternative designs Define exposure and outcome variables, and identify data sources for these and other variables of interest. Check whether the measure of exposure represents the biologically active agent and etiologically important time period Calculate the projected study size and statistical power (if appropriate) Describe procedures for collecting data Provide a detailed description of the methods of analysis Define how exposure and outcome variables will be categorized for analysis State how confounders and effect modifiers will be treated in the analysis Outline the major strengths and limitations of the study design Provide criteria for interpreting the study results, including ways of assessing statistical, clinical, and biological significance
Description of plans for protecting human subjects	Describe risks and benefits of participating in the study If appropriate, provide plans for obtaining informed consent Describe procedures for maintaining confidentiality of subjects and data

Description of quality assurance and control	Describe for all phases of the study
Resources required to conduct the study	Detail the expected time, personnel, and equipment required for the study
Bibliographic references	Include all relevant references
Addenda, as appropriate	Examples of useful addenda include copies of collaborative agreements, institutional approvals, informed consent forms, and questionnaires
Dated protocol review and approval sign-off sheet	Document dated amendments to the protocol

Improving the datascope image by choosing appropriate measures of hypertension

In the planning phase of the study, investigators should make provision for collection of appropriate measures of hypertension. While clinicians favor the diagnosis and treatment of hypertension in terms of diastolic blood pressure elevation, data from the Framingham Study in Massachusetts indicate that systolic blood pressure is a better predictor of disease outcome (Kannel 2000). Additionally, ambulatory blood pressure can be measured with an automated device so that multiple measurements can be made across the course of typical activities. Studies show that such recordings provide information predictive of disease risk beyond that obtained with measurements made at a single assessment (Clement et al. 2003).

14.3.2 Documentation of Operations and Procedures

The consistency and validity of study data are greatly enhanced by the establishment and application of *standard operating procedures* for routine data collection tasks (a *standard operating procedure* is defined here as a standardized method or process for conducting a routine research procedure). If standard procedures have been well described, variability is likely to be much lower across study sites, interviewers, or technicians. Uncorrected variability introduced by interviewers or technicians can decrease study power (Blomgren et al. 2006; Edwards et al. 1994, 1998).

Standard procedures should be clearly described for all study procedures, including (but not limited to) raw data collection, coding of death certificates, assessment of error rates, and management of archived data. Each standard operating procedure should state the purpose of the procedure, provide a detailed description of the procedure including forms and equipment to be used, and either designate the person responsible for the procedure, or explain what training will be needed

(The Chemical Manufacturers Association's Epidemiology Task Force 1991). The US Toxic Substances Control Act (TSCA) standard for Good Laboratory Practices provides detailed quality control and quality assurance guidelines for the collection of laboratory samples (US Environmental Protection Agency (EPA) 1989). Once the various study operating procedures are established, they should be integrated and summarized in the form of a study *manual of operations*. The *manual of operations* is a document or collection of documents that completely describes the procedures used in a study center. Developing a *study handbook*, which contains a series of tables, charts, figures, and specification pages that outline the main design and operating features of a study (largely without the use of a written narrative), is a useful first step in the development of the manual of operations and can also act as a quick reference for study personnel. The study protocol, handbook, and manual of operations should be reviewed for clarity and completeness.

Since the initial version of the manual of operations is almost certain to contain some errors, pretesting of the manual prior to finalization is essential. All aspects of the study protocol should be tested on a population similar to the one that will be studied, including the administration of surveys, sending of samples to laboratories, and the generation of and response to quality control reports. Refinements to the protocol that are identified from the pilot study can be incorporated into the final study manual of operations.

Improving the datascope image using standard operating procedures

Inter- and intra-technician variation in blood pressure readings viewed under the datascope can be reduced by clear and detailed descriptions of the method of measurement. Application of a standard operating procedure can also reduce variability in blood pressure measurement within a subject. Specifying details such as how the study participant should be seated, which arm the cuff should be applied to, and how long the study participant should remain quiet before the reading is taken can reduce the influence on the study measurement of factors that affect an individual's blood pressure.

14.3.3 Personnel: Training and Certification

Integral to study conduct is the availability of personnel with the necessary education, experience, and training to perform assigned functions. The planning stage of the study is the appropriate time to consider what personnel will be required, what kind of training will be necessary, and how often training should occur. Job descriptions should be written for each individual who will be supervising or engaging in study conduct. For jobs that require training, procedures for initial and retraining of personnel should be established. Retraining may be necessary if substantial time has elapsed since the initial training, if a technician is found to be introducing a systematic error into the data, or if the study protocol changes. For each of the study personnel, a summary of relevant training and experience, including study certification and recertification, should be maintained and kept up to date.

Consistency in the training of personnel across sites improves comparability of data collection across different study sites. This training can be centralized or site specific. Often, a combination of both approaches is used (see Sect. 14.4.1 for more detail). Study personnel should be required to follow standard operating procedures. If training will be difficult or time-consuming, it is prudent to train at least two individuals for each task in case one of the trained technicians leaves the study. Certification standards should be set and might include completion of a specified number of tests for key procedures, including some under observation.

Aside from the obvious benefit of consistency in data collection, training study personnel also increases the interviewers' or technicians' perceived value of the data that are being collected. This may influence the amount of care taken in following the protocol. Some studies use computer instruction, DVDs, or teleconferencing to reduce the costs associated with training. While the use of computer or DVD training is convenient, these methods lack some of the benefits of face-to-face training, such as the opportunity for staff members to share ideas and the opportunity for scientific presentations that remind personnel of the importance of their work (Whitney et al. 1998).

Improving the datascope image by training and certification

Some of the variation in blood pressure measurements viewed under the datascope could be due to a technician-measured blood pressure in a different way each time he or she takes a measurement or if different technicians have different ways of reading the same measurement. One way to minimize these sources of error and improve the datascope image is to train and certify study technicians. In the MRFIT (Multiple Risk Factor Intervention Trial), technicians were trained in taking blood pressure measurements using training tapes and a double stethoscope (Dischinger and DuChene 1986). The training tapes consisted of two recordings of the Korotkoff sounds for 12 subjects. The first tape of Korotkoff sounds was used for training and the second for testing. A video-training film that presented 12 blood pressure readings, with sufficient time to determine and record systolic and diastolic blood pressure after each reading, was also used. Finally, supervisors and trainees took simultaneous measurements of three subjects using a double stethoscope. The differences in the readings of the trainer and technician had to fall below a certain criterion for the trainee to pass. Technicians were certified after completing the training tapes, passing a written test on procedures for taking blood pressure measurement, and passing the double stethoscope test. Recertification was required at regular intervals or if examination of collected data indicated that a technician had a bias with respect to other technicians in a clinic.

14.3.4 Data Collection Forms and Instruments

Exposure and outcome measures for epidemiological studies can be collected in a variety of ways. Methods of data collection include mailed self-administered questionnaires, interviewer-administered questionnaires, measures of blood or other tissues, physical measures, medical tests, use of medical or exposure records, or sampling for environmental contaminants (White et al. 1998, 2008). Most studies use more than one method of data collection.

The use of data that have been collected already ("secondary data") has the key advantage that the data already exist. Studies using secondary data are thus likely to be more cost and time-efficient than studies with primary data collection. Sources of secondary data, such as population-based registries, often allow for a much larger sample size and are more representative of the general population (Hearst and Hulley 1988). A substantial disadvantage of using existing data, however, is that the collected data may not adequately address the particular research question of interest. An additional drawback is that the method of collection and the quality of the secondary data are not under the researcher's control. For this reason, researchers using secondary data should carefully review data documentation and evaluate the quality and validity of these data to the extent possible (Bray and Parkin 2009; Clive et al. 1995; Gissler et al. 1995; Goldberg et al. 1980; Horbar and Leahy 1995; Maudsley and Williams 1999; Sorensen et al. 1996; Wyatt 1995). For details on the use of secondary data, see chapter ▶Use of Health Registers of this handbook.

Most epidemiological studies collect some or all of their data using phone, mail, or self/interviewer-administered questionnaires. Data from such questionnaires, however, can be subject to various sources of bias. For instance, study participants filling out a self-administered questionnaire might report socially acceptable rather than strictly accurate results. Moreover, ways of responding to the survey may differ between participants in the study, depending on factors such as the age, gender, or racial/ethnic group of the participant. Conversely, participants may respond differently to interviewers of different age, gender or ethnic background. For further details, see chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook. Multicenter studies encounter the additional problem of differences in data collection between study centers. In long-term studies, these biases can change over time. Smoking, for example, is generally less socially acceptable today than it was 20 years ago in the United States and consequently more likely to be underreported (Ling and Glantz 2002; O'Connor et al. 2006; US Department of

Health and Human Services 2004). The acceptability of smoking also varies by ethnic groups, which may in part explain the fact that African-American high school seniors are far less likely to smoke than are white seniors (Wallace et al. 2002). Measurement error that occurs because of the use of a survey instrument can be minimized by careful design and pretesting of the survey and the application of standardized interviewing techniques.

The main objective of survey design is to allow the efficient collection of data that are valid, reliable, and complete. Standardizing forms within a study is important for internal validity. Consistency of forms across studies allows more meaningful comparison with other studies and also makes the study results more generalizable. Both internal and external form standardization can be achieved by the use of preexisting validated study instruments. Examples of validated questionnaire instruments include the American Thoracic Society questionnaire to assess respiratory symptoms (Comstock et al. 1979), the Willett food frequency questionnaire (Willett et al. 1985), the Piper Fatigue Scale (Piper et al. 1989, 1998) to assess fatigue in cancer patients, the Wechsler Preschool and Primary Scale of Intelligence (Wechsler 1989), and the International Physical Activity Questionnaire (Craig et al. 2003). If a validated instrument is not readily available, several sources in the literature provide guidelines for questionnaire design to maximize clarity and ease of administration. These include recommendations for physical format, as well as instructions on how to word the text of instructions and questions (Dillman 1978; Holford and Stack 1995; Knatterud et al. 1998; Meinert and Tonascia 1986; Wright and Haybittle 1979a, b, c). Studies that enroll participants of different ethnic groups may need to accommodate different languages by using interpreters or by having translated versions of the questionnaire. However, a question might change subtly upon translation, and data generated from different languages may not be entirely comparable. For this reason, independent back-translation of questions to the original language is strongly recommended. An example of the need for back-translation is provided by data from a health survey which showed lower data reliability of data for Hispanics interviewed in Spanish than for Hispanics interviewed in English when no back-translation was done. An independent back-translation aimed at creating a linguistically equivalent version to the Spanish version indicated several instances in which the two versions were idiomatically different and appeared to have affected the seriousness with which the interview situation was perceived, in turn leading to response discrepancies (Berkanovic 1980).

Pretesting of the survey instrument on a population similar to the study population allows the detection of flaws in the survey design and instrument before full-scale data collection begins. Separate analysis of pretest data by language version, for example, might identify problems in translation. In the Hypertension Prevention Trial, which was designed to test the effectiveness of changes in dietary intake of calories, sodium, and potassium, a test cohort of 78 participants was enrolled and used for the testing of forms and procedures. Data that were generated from the test cohort were used to identify problems in survey design and collection and were not analyzed with results from the main study (Prud'homme et al. 1989).

Accuracy and consistency are also important for laboratory or clinical equipment. The study should be planned so that all study personnel and sites begin by using identical equipment. In anticipation of measurement drift over time, procedures to maintain and recalibrate equipment should be established. In the Sleep Heart Health Study (Quan et al. 1997), overnight sleep data were collected from subjects using a portable monitor. Sites were notified to have the monitor evaluated and procedures assessed when less than 85% of results scored by the monitor were of "good" or better quality (Whitney et al. 1998). Standard and random zero sphygmomanometers for blood pressure measurement in the MRFIT study (Kjelsberg et al. 1997) were maintained and calibrated according to a regular schedule and subject to standard checks at least every other month in the case of the standard sphygmomanometer and every week in the case of the random zero instrument (Dischinger and DuChene 1986).

As more advanced technology becomes available to measure an exposure or outcome, there may be justification to update study equipment. For example, mobile phones and other personal digital assistants (PDAs) are increasingly being used for data collection (Aanensen et al. 2009; Kwok 2009). In such cases, data should initially be collected using both the old and new equipment to establish the comparability of the two instruments since a change may introduce subtle differences that are only apparent as substantial data are collected using the new approach.

14.3.5 Planning to Achieve a High Response Rate

In order to curtail the possibility of bias and increase the generalizability of study results, it is important to achieve the highest response rate possible (Gordis 2000; Wacholder et al. 1992). A systematic review of 372 trials found that factors which more than doubled the odds of response to surveys were the inclusion of a monetary incentive with the questionnaire, the designing of surveys to be of more interest to participants and the use of registered mail (Edwards et al. 2007). Other factors which have been reported to increase response rate are shorter questionnaire length (Dillman 1978; Eaker et al. 1998; Hoffman et al. 1998; Kalantar and Talley 1999; Kellerman and Herold 2001; Little and Davis 1984; Martinson et al. 2000; Spry et al. 1989), personalizing questionnaires (Maheux et al. 1989), using colored ink (Edwards et al. 2007), contacting participants before sending questionnaires, providing stamped return envelopes (Choi et al. 1990), and using written or telephone reminders (Asch et al. 1997). Questionnaires originating from universities are more likely to be returned than questionnaires from other sources, whereas surveys eliciting information of a sensitive nature are less likely to be returned.

While the use of a monetary incentive is probably the factor that has been shown most consistently to increase response rates (Gibson et al. 1999; Gilbart and Kreiger 1998; Hoffman et al. 1998; Kellerman and Herold 2001; Martinson et al. 2000; Parkes et al. 2000; Perneger et al. 1993), increasing the amount of the incentive results in diminishing returns of questionnaires after a certain point (Halpern et al. 2002; James and Bolstein 1992; Spry et al. 1989). In the

United States, the $2.00 bill has been a cost-effective monetary incentive in the past (Asch et al. 1998; Doody et al. 2003; Shaw et al. 2001). Making a prepayment of the incentive appears to be more cost-effective than promising payment on completion of the questionnaire (Schweitzer and Asch 1995). Including the monetary incentive in the first mailing rather than in subsequent mailings has resulted in higher response rates (John and Savitz 1994). Non-monetary incentives, while reported to increase response rates over having no incentive, do not appear as effective as monetary incentives (Kellerman and Herold 2001; Martinson et al. 2000).

Contact rates generally tend to be lower for individuals who are young, male, black, of lower socioeconomic status, or employed full-time (Collins et al. 2000; Cottler et al. 1987; Moorman et al. 1999). In the context of a case-control study, response rates are often lower for controls (Moorman et al. 1999). Even within control groups, different types of controls have different response rates. For example, in the United States, controls chosen from Health Management Organizations have been shown to have a higher response rate than controls drawn from lists of licensed drivers (Slattery et al. 1995).

Long-term cohort studies, in addition to having to address response rates to study questionnaires, also face the issue of loss to follow-up. The loss of cohort members to follow-up is conceptually similar to response rate, in that loss to follow-up can constitute an important source of selection bias and also limit external validity. Participants may be lost to follow-up either because they drop out of the study of their own volition or because the study investigators lose track of them. As with other types of epidemiological studies, loss to follow-up can lead to reduced study power and may result in biased estimates of risk. Strategies for minimizing loss to follow-up include pre-enrollment screening of participants for willingness to participate in a long-term study, collecting names of personal contacts and proxies for participants, maintaining regular contact with study participants, using incentives for remaining participants, and maintaining tracking systems to follow participants (Hunt and White 1998; White et al. 2008). One must keep in mind, however, that populations comprised of volunteers are usually different from the population as a whole. In general, measures of relative risk are less affected by the lack of external generalizability than measures of absolute or attributable risk.

14.3.6 Validity and Reliability

The absence of bias in data measurement is called *validity* or accuracy. The precision, or reproducibility, of collected data is known as *reliability*. See Fig. 14.1 for an illustration of the distinction between validity and reliability.

14.3.6.1 Validity Studies

The capacity of a measure to capture the true value of the exposure, outcome, confounder, or modifier of interest in the study population is known as its validity.

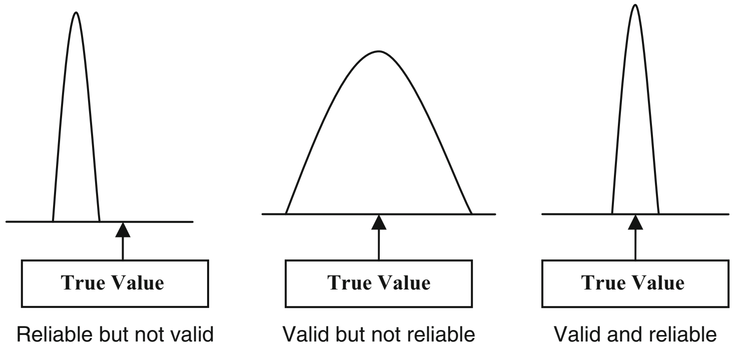

Fig. 14.1 Graphs of hypothetical test results illustrating the distinction between validity and reliability

While it is desirable to obtain the most accurate measurements possible of exposure or outcome, such measurements usually come at the price of increased cost, invasiveness, or time involvement. When faced with these constraints, epidemiologists often choose to collect less accurate measures of exposure.

The accuracy of the study's main method of exposure measurement can be assessed using validation studies which compare the study exposure measure to a more accurate measure of exposure ("gold standard"), either in a subsample of study participants or in a different population. For instance, evidence of validity can be provided by comparing study estimates of an environmental exposure to industrial hygiene measurements or biomarkers of exposure (Cherrie and Schneider 1998; Cherrie et al. 1987; Dosemeci et al. 1997; Hawkins and Evans 1989; Kipen et al. 1989; Kromhout et al. 1987; Tielemans et al. 1999). The comparison of reported nutrient intake on a questionnaire with a biochemical indicator provides another example of this approach (Ascherio et al. 1992; Johnstone et al. 1981; Post and Kromhout 1991; Sacks et al. 1986; Willett et al. 1983).

The establishment of a serum pool can facilitate validation of biological sample processing in the study. Study measurements can be compared with results from a "gold standard" external laboratory. If study measurements deviate randomly from the gold standard, the study result would be attenuated toward the null hypothesis. However, if deviations from the gold standard are found to vary according to the presence and level of important variables such as follow-up time or the exposure or outcome of interest, the study results may be biased.

Data from validation studies can, additionally, be used to account for uncertainty in the data analysis. Measurement error correction models can be developed that use validation study data to adjust the full data for measurement error (Holford and Stack 1995; Rosner et al. 1992; Spiegelman et al. 1997; Stram et al. 1999; Thompson 1990). In the Framingham Study (Dawber et al. 1951), for example, a small validation study was conducted to estimate the relationship between the surrogate measurement (food frequency) and the "true" measurement (diet record). Based on information from the main study relating the surrogate to disease outcome and information from the validation study relating true and surrogate exposure, corrected point estimates of risk were calculated (Rosner et al. 1992). For a general discussion of statistical methods to account for measurement errors see chapter ►Measurement Error of this handbook.

While validation studies may help to form a clearer picture of the true relationship between exposure and outcome, such studies are not without their own limitations. For one, the gold standard used for comparison may itself be subject to error, thus the term "alloyed" gold standard (Wacholder et al. 1993). While calibration methods for such alloyed gold standards have been described, these complex models cannot be applied in all situations (Kaaks et al. 2002; Spiegelman et al. 1997). A second limitation of validity studies is that participants in these studies are not always representative of all participants. Subjects who volunteer to take part in a validity study are likely to be more compliant than non-volunteers would have been. Additionally, feasibility constraints often limit validity studies to small sample sizes, which can lead to statistical imprecision.

14.3.6.2 Reliability Studies

Data variation can arise within study participants (*biological variability*) or due to variation in exposure assessment or physiological measurements introduced by study technicians. Blood pressure within an individual, for example, experiences short-term changes due to factors such as activity and mood. Different blood pressure measurements taken on the same individual are thus likely to vary for physiological reasons regardless of how accurately these measurements are made. Study technicians can add an extra component of variation to the measurements, either because a given technician reads a measurement in slightly different ways each time (*intra-observer variation*) or because different technicians read a measurement in different ways (*inter-observer variation*). Variability can also be introduced as samples degrade over time.

As illustrated in the paragraph above, variability in data can arise due to true change, measurement error, or random biological variation. The component of variability that the researcher is most interested in is the true change in study exposure that might influence the outcome under consideration. The separation of desired variability in the data (true change) from undesirable variability due to measurement error or random (biological) variation can be partially assessed by incorporating into the main study a series of substudies that are designed to assess the reliability of the study data.

Reliability studies can be used to assess various components of variability, such as the comparability of measurements taken by the same technician at a given visit, different technicians at a given visit, the same/different technician at different points of time, or the same/different technician using different instruments. Interobserver and intraobserver variability can be assessed using a set of calibration samples that are read several times by each technician and processed by multiple technicians. Biological variability can be assessed by having a single technician perform repeat studies on a subset of participants, although some amount of variability assessed in this way would be due to technician variability (Whitney et al. 1998). For durable data, such as X-ray films or dietary recall records, variation over time can be assessed by comparing evaluation of the same samples at different times in the study. In instances where samples are limited or perishable (e.g., blood or urine), a preselected set of "quality control" specimens should be set aside at the beginning of the study so that small amounts of these specimens can be periodically submitted for processing. Caution should be taken through careful planning at study onset to avoid specimen degradation from freeze thaw cycles. Technicians handling quality control samples should be unaware that the samples are different from other study samples being processed, in order to prevent differential handling.

Reliability studies which collect replicate measurements at the same point of time are useful in the identification of possible data errors, as well as in the calculation of more accurate measures of exposure. Averaging repeated measures has been recommended as an effective method of decreasing the measurement error associated with a single measurement (Canner et al. 1991; Holford and Stack 1995; White et al. 1998, 2008).

When validity is reported, the number of samples that are deemed unacceptable for analysis should be stated since this may indicate a bias in the remaining samples. The examination of whether reliability estimates differ according to relevant characteristics such as exposure, confounding factors, or outcome allows some assessment of whether differential misclassification is occurring in the data.

Improving the datascope image by obtaining a more valid exposure measure

Using the average of three blood pressure measurements taken on a study visit would result in a clearer picture of the individual's blood pressure than would a single blood pressure measurement.

14.3.6.3 Measures of Agreement

Quantifying the agreement between two different methods of measurement requires the use of some measure of agreement. The choice of statistic depends on the type of variables being compared and the purpose of the comparison (Table 14.2). Different measures of agreement and advantages and disadvantages of each measure have been reviewed by Szklo and Nieto (2000).

The basic measures of validity for binary categorical variables are sensitivity and specificity, for which the study value of the exposure or outcome is compared to the "true" value, measured by a more accurate method (Example 14.1). The *sensitivity* of a test is the ability to correctly identify those individuals who have the disease or exposure characteristic of interest. The test *specificity* is the ability to correctly

Table 14.2 Common measures of agreement, interpreted in the context of two separate technicians reading the same data

Statistic	Range	Type of data	Interpretation
Sensitivity and specificity	0–100%	Categorical	Sensitivity: ability to correctly identify individuals who have the disease or exposure characteristic of interest Specificity: the ability to correctly identify individuals who do not have the disease or exposure characteristic of interest
Overall percent agreement	0–100%	Paired categorical variables	The proportion of all readings that are categorized in the same way by two different observers Higher value means better agreement
Percent positive agreement	0–100%	Paired categorical variables	The proportion of all non-negative readings that are categorized in the same way by two different observers
Kappa statistic, κ	−1 to 1 (rarely below 0)	Paired categorical variables	The extent of agreement between two readers beyond that due to chance alone Higher value of kappa means better agreement
Weighted kappa	−1 to 1 (rarely below 0)	Paired categorical variables	The extent of agreement between two readers beyond that due to chance alone, allowing for consideration of partial agreement
Pearson's correlation, r	−1 to 1	Continuous ordinal variables	The degree to which a set of paired observations in a scatter diagram approaches the situation in which every point falls exactly on a straight line −1 is perfect negative correlation, 1 is perfect positive correlation
Spearman's correlation, r_s	−1 to 1	Non-parametric ordinal variables	The degree to which ranking of measurements is consistent between two readers
Intraclass correlation coefficient, *ICC*	−1 to 1 (rarely below 0)	Continuous variables	The proportion of the total measurement variability due to variation among individuals Analogous to the kappa statistic, but for continuous variables Higher *ICC* means better agreement
Linear regression, β, c		Continuous variables	Yields a measure of the intercept c and slope β of the regression function
Coefficient of variability, *CV*	0–100%	Continuous variables	The standard deviation expressed as a percentage of the mean value of two sets of paired observations Lower *CV* means better agreement
Average error	0–100%	Continuous variables	The ratio of the mean absolute difference of pairs of measurements to the overall mean value of the measurements Lower average error means better agreement
I_{APSD}	0 to ∞	Continuous variables	The percentage increase in among participant standard deviation due to intra-observer measurement error

identify those individuals who do not have the disease or exposure characteristic of interest. A limitation of the use of sensitivity and specificity is that very few diagnostic tests are inherently dichotomous. Most diagnostic tests are based on the characterization of individuals based on one or more underlying traits, such as blood pressure or serum glucose level. Values for the sensitivity and specificity would vary according to the cut-off level used to separate “diseased” (or exposed) from “undiseased” (or unexposed) individuals. In addition, if measurement error occurs, individuals with true levels of the underlying trait close to the test point are more likely to be misclassified. Since the distribution of underlying traits also determines disease prevalence, sensitivity and specificity can vary from population to population (Brenner and Gefeller 1997).

Example 14.1. Calculation of sensitivity and specificity

		Gold Standard Results		
		Positive	Negative	Total
Study Results	Positive	*a*	*B*	*a* + *b*
	Negative	*c*	*D*	*c* + *d*
		a + *c*	*b* + *d*	

Sensitivity = $a / (a + c)$
Specificity = $d / (b + d)$

Agreement for categorical variables (e.g., X-ray readings by radiologists) is generally reported using variations of the percent agreement and kappa statistics. While overall percent agreement is intuitive and easy to calculate (Example 14.2), it can make agreement look artificially high since there is likely to be considerable agreement between two observers reading negative, or normal, results. An alternative approach is to disregard subjects labeled as negative by both readers to calculate the percent positive agreement (Cicchetti and Feinstein 1990).

Example 14.2. Calculation of percent agreement

		Technician 2	
		Positive	Negative
Technician 1	Positive	*a*	*B*
	Negative	*c*	*D*

Percent agreement = $(a + d)/(a + b + c + d)$ x 100
Percent positive agreement = $a/(a + d + c)$ x 100

Neither overall nor percent positive agreement takes into account the fact that some amount of agreement between two observers will be due to chance alone.

The extent of agreement between two readers beyond that due to chance alone can be estimated by the kappa statistic (Example 14.3) (Agresti 1990; Fleiss 1981; Landis and Koch 1977). In comparisons of more than two categories, a weighted kappa approach allows consideration of the fact that disagreement between some categories may be more serious than disagreement between other categories (Cohen 1968). Like the sensitivity and specificity, variations of the kappa statistic are limited by the fact that most underlying traits are not dichotomous, and different cut-off levels can affect the value of kappa (Maclure and Willett 1987). Interpretation of the kappa statistic should also take into account the fact that kappa can be affected by the prevalence of the condition: for a fixed sensitivity and specificity, kappa tends toward 0 as the prevalence of the condition approaches either zero or one (Thompson and Walter 1988). Additionally, high values of kappa can be obtained if the marginal totals of the contingency table are not balanced (Feinstein and Cicchetti 1990; Maclure and Willett 1987; Thompson and Walter 1988).

Example 14.3. Calculation of kappa for a binary measurement variable

		Technician 2		
		Positive	Negative	**Totals by Technician 1**
Technician 1	Positive	45	5	50 (61.0%)
	Negative	2	30	32 (39.0%)
Totals by Technician 2		47 (57.3%)	35 (42.7%)	82 (100%)

$$\text{Kappa} = \frac{\text{(Proportion Observed Agreement – Proportion Expected Agreement due to Chance)}}{\text{(1.0 – Proportion Expected Agreement due to Chance)}}$$

Proportion Observed Agreement, $P_o = (45+30)/(45+5+2+30) = 0.91$

$$\text{Proportion Expected Agreement due to chance, } P_e = \frac{(50 \times 47)/82 + (32 \times 35)/82}{82} = 0.52$$

$$\text{Kappa} = \frac{P_o - P_e}{(1.0\ - P_e)} = \frac{(0.91 - 0.52)}{(1.0 - 0.52)} = 0.81$$

Common measures of agreement used to assess reliability for continuous measurements (such as blood pressure readings) are the *correlation coefficient*, the *intra-class coefficient,* the *average error*, and the *coefficient of variation* (cf. chapter ▶Analysis of Continuous Covariates and Dose-Effect Analysis of this handbook). *Linear regression* techniques can also be used to check for systematic differences (cf. chapter ▶Regression Methods for Epidemiological Analysis of this handbook).

Although the *Pearson's correlation coefficient*, *r*, is one of the most frequently used measures of agreement in the medical literature, its use is often not appropriate (Altman and Bland 1983; Szklo and Nieto 2000). For one, the correlation coefficient is equally high when both observers read the exact same value and when a systematic difference (bias) exists between observers but the readings vary simultaneously. The value of *r* is also very sensitive to extreme values and the range of values, with a broader distribution of values yielding a higher r. While the Spearman correlation coefficient r_s may be more appropriate to assess the comparability of the rankings of readings and would moreover be less sensitive to outliers, it does not address the main problem of the inability to detect systemic differences between observers.

The *intra-class coefficient* (*ICC*), or the reliability coefficient, estimates the proportion of the total measurement variability due to the variation between individuals (Fleiss 1981). The *ICC* is analogous to the kappa statistic used for categorical variables, and the value can be interpreted in a similar manner. The *ICC* is a true measure of agreement in that it combines information on both the correlation and the systemic differences between readings (Deyo et al. 1991). As with the correlation coefficient, however, the *ICC* is affected by the range of values in the study population.

Other commonly used measures of variability are the *average error* and the *coefficient of variation (CV)*. The average error is the ratio of the mean absolute difference of pairs of measurements to the overall mean value of the measurements. The coefficient of variation is the standard deviation expressed as a percentage of the mean value of sets of replicate observations. In a reliability assessment, the *CV* would be calculated for each pair of observations and then averaged over all pairs of original and replicate measures. A limitation of the *CV* and average error is that both measures may reflect the magnitude of the mean value more than the magnitude of the measurement error (Canner et al. 1983). An alternative measure that has been suggested for assessing variability is the increase in the among-participant standard deviation, the I_{APSD} (Canner et al. 1991). This measure can directly determine the impact of measurement error on the overall among-participant variability for a variable of interest.

Linear regression techniques can estimate systematic differences between readers which are reflected in the slope and intercept of the regression model. One drawback of using regression to assess reliability, however, is that measurement error occurs in both the dependent and independent variables, violating the assumption of an error-free independent variable required for regression (Altman and Bland 1983). However, only under unusual circumstances would measurement error lead to confusing or uninformative results.

14.3.7 Planning Data Management

The management of data in a large epidemiological study can be a formidable task. The sheer volume of data for a sizeable study with extended follow-up can become quite overwhelming, as illustrated by the following example. If 100 data elements are to be collected for each participant in a cohort study with 100,000 participants, the data collected at the end of each data collection cycle are comprised of 10^6 distinct data elements. Let us say that in order to update exposure and outcome information, data are to be collected yearly for each participant for 10 years. This increases the amount of data being collected by an order of magnitude, to 10^7distinct pieces of data. Superimposing on this volume of data the errors that can occur during data recording, transcription, and transfer of data to an electronic medium, it is easy to see how data quality can be compromised without careful planning of how data are to be managed. The potential magnitude of the task of data correction is also clear.

The first step in planning a data management system is to define what data will be collected and how often it will be collected, keeping in mind that as the volume of data increases, ensuring data accuracy becomes more difficult. In order to further minimize the amount of unnecessary data collected, the chosen data variables should be prioritized, and a "tolerance" of error established for each data field. For example, it might be decided that all values of crucial data variables (e.g., disease outcome) should be checked against written questionnaires, but auditing a random sample of questionnaires is sufficient for other fields.

The next key step in data management planning is to define essential identifying information for the study data. *Identifiers*, generally known as *key*, *header*, or *ID* fields, are fields that allow each form to be uniquely identified and correctly related to other forms (Hosking and Rochon 1982; Hosking et al. 1995). Study identifiers are usually located in a standard header section of the form. Entry of an incorrect number into one of these fields can cause the entire data record to be processed incorrectly.

Most studies require at least four types of identifiers: study identifiers, participant identifiers, form-type identifiers, and timepoint identifiers. Depending on the study, other identifiers (e.g., family identifiers) might also be necessary. *Study identifiers* designate the sponsor, study, protocol, or substudy. *Participant identifiers* uniquely identify the study participant. In general, a study-created participant identifier is preferable to a natural identifier such as participant name or social security number, especially in a climate increasingly concerned with participant confidentiality. It is useful to encode information about participant characteristics (such as a field site code) into the participant identifier since this allows later classification of participants by their identifiers alone. *Form identifiers* identify a particular questionnaire and often take the format of a two- or three-character abbreviation. Form identifiers in longitudinal studies should be planned so that multiple versions of each form can be accommodated. Adding a −1 at the end of the form identifier, for example, allows for future versions to end with the suffix −2 or higher. *Item identifiers* form the last group of identifiers and are assigned to each question on a form. While item identifiers bearing a one-to-one relationship to database fields might be useful for data analysis, this can become confusing if the study forms or database are revised. Data management systems that track the relationship between each database field and a corresponding item number in each form version provide a useful alternative.

Once data identifiers have been selected, general data management considerations that need to be addressed including identifying how data will be entered (electronically vs. manually); who will do the data entry; what software will be used; what types of edits will occur during data entry; how queries will be generated, communicated, and resolved; how suspicious values will be treated; and how corrections will be implemented and documented. The remainder of this section will be devoted to these considerations.

Table 14.3 Overview of the traditional data management process (Adapted from DuChene et al. (1986))

Steps in data processing	
Data collection and mailing	Complete forms at clinic/in field Visually review form while participant is in clinic (visual editing) Mail original copy to coordinating center, keep copy at clinic Create standard packing list for mailing
Receipt and conversion to electronic format	Receive forms at coordinating center Acknowledge receipt of forms from clinic using postcard or electronic mail Log receipt of forms into computer (including form number, ID code, date completed, date received, and unique log number) Key the form. Verify keying
Forms processing, posting, and backup	Process form through an edit program that checks type and range of each field, as well as internal consistency of form Generate computer edit report Check edit report and initiate appropriate error correction procedures Back up edited forms Post forms to master file. Back up master file File form
Clearance and archiving	Run further checks on data to ensure that posted data are consistent with other data on file Review edit reports that result from checks and initiate appropriate error correction procedures Document master file contents and prepare file for archiving

14.3.7.1 Design of a Data Management System

In a multicenter study, data are typically collected at various field centers and then sent to a coordinating center for processing, storage, and analysis. Table 14.3 provides an overview of the steps involved in data management. Newer approaches to data management (e.g., Web-based systems) are increasingly being used (Aanensen et al. 2009; Kwok 2009), but these approaches rely heavily on specialized automated systems for data collection, entry, and auditing. Since logistical barriers of cost, lack of expertise, and low computer literacy may render these systems impractical for some investigators, this chapter focuses on a more traditional approach to data management. Many of the underlying principles remain relevant to the newer data management approaches, which are addressed at the end of the section.

14.3.7.2 Data Recording and Visual Editing

The measurement and recording of data from study participants usually occurs at the field center, and initial data checks are generally conducted by field staff personnel. Field center interviewers or technicians should check data for consistency as it is being collected, while the study participant is available to clarify any immediate discrepancies, errors, or out-of-range characteristics.

For technical measurements, an independent review of samples by two or more readers should be performed on all or a subset of samples. This allows later assessment of validity and enables investigators to track down sources of error. On completion of the data form, field center staff should perform a routine review of forms to establish that the questionnaire is complete, that skip patterns have been followed, and that the data values appear reasonable. If routine review of the form does not identify any unusual data, the form can be processed further. Including an indication of who reviewed the form will facilitate later examination of the editing process.

14.3.7.3 Data Entry

Almost universally, epidemiological data are entered into electronic databases for storage and analysis. The processing, storage, and analysis of study data usually occurs at the data coordinating center. Errors that can occur during the processing and storage of data include keying errors, inaccurate data transcription, and programming errors (Arts et al. 2002). In the Hypertension Prevention Trial, key error was found to be the major source of data entry error, with 5.2/1,000 errors out of an overall error rate of 6.9 errors per 1,000 data items being key errors (Prud'homme et al. 1989).

Most automated data entry systems allow a variety of mechanisms for checking data. As data entry is initiated, form identifiers are checked for validity and consistency. *Range checks* during data entry can be used to electronically limit the data type or the range of possible values at entry. For example, date fields can be programmed to accept only valid dates, or table look-up systems can restrict the values of categorical data with a limited number of possible values. For continuous data, many studies use normal population ranges of a variable to flag outliers. While programmed range checks are a useful tool, retaining some flexibility to correct errors at the time of data entry is important since too many restrictions on modifying data at entry can lead to a higher error rate (Crombie and Irving 1986).

Data accuracy can also be improved by the use of *double data entry*. The independent keying of data twice, however, does not prevent all types of error. Examples of errors that would not be reduced by the double entry of data include errors in transcription or misinterpretation of data in the same way by two data entry operators.

If the data are to be manually entered, personnel should be masked regarding exposure or outcome status (depending on the study design) to prevent the possibility of observer bias. Additionally, the electronic database should have a provision to indicate who entered the data to allow for later review of data entry performance.

The use of electronic technology for data entry as an alternative to manual data entry is gaining in popularity. Software is available for scanning forms directly into an electronic database using optical character recognition (OCR). The accuracy of scanning software is quite variable, however, and a process to check scanned data should be in place. In general, OCR is better suited to numeric or check-box responses than to hand-printed characters. Another method of electronic data entry is computer-assisted data collection (CADC), whereby interviewers directly enter participant responses into a computer file. This technology completely circumvents the need for transferring data from paper to an electronic medium, thus eliminating errors associated with this process. A CADC system can automatically enforce skip rules, require completion of required fields, and flag suspicious values for correction while the study subject is still present. Since errors in CADC data cannot be compared later with a paper form, however, these systems need to include as many ways of checking data accuracy at entry as possible. One way to allow for examination of inconsistent values is to tape record interviews while data collection is occurring.

In a pilot study of CADC, five study staff members with no prior experience using a CADC system were trained and asked to administer both CADC and paper-based interviewers to 16 study participants. All five staff members preferred the CADC system, indicating faster and more accurate data entry and less likelihood of erroneously skipping an item. Ten of the 16 pilot study participants had no preference between paper and CADC and six preferred CADC. Although the median time for data collection at the reception, examination and interview stations was slightly longer for CADC than for paper interviews, the CADC data are already partially edited and in machine-readable format, whereas data from the paper forms still had to be edited and keyed. The percentage of suspicious data values was similar for each method, but 21 of the 25 suspicious data values were identified and corrected at the time of collection using CADC, compared to 1 out of 23 suspicious values corrected with the paper system (Christiansen et al. 1990).

Other recent methods of data collection for epidemiological studies include the use of electronic mail ("e-mail") (Kiesler and Sproull 1986; McMahon et al. 2003; Paolo et al. 2000), personal digital assistants (PDAs) or mobile phones (Aanensen et al. 2009; Kwok 2009), or other Internet-based surveys (Baer et al. 2002; Blackmore et al. 2003; Rhodes et al. 2003; Silver et al. 2002; Turpin et al. 2003). E-mail questionnaires have been reported to have a faster rate of return and more thorough completion of returned questionnaires, but response rates have generally been lower than for mail questionnaires.

The basic process for Internet-based, or Web-based, data collection is the translation of the study questionnaire into an Internet language (HTML or hypertext markup language) and posting of the questionnaire onto the World Wide Web. Respondents then complete the survey using a point and click interface. The survey is generally visually and functionally similar to traditional surveys.

Web-based data collection provides several advantages over paper form data collection. For one, researchers can access populations that previously might have been unreachable due to geographical or cultural boundaries. Use of the web may also speed up the time of data collection since no testing site or appointment scheduling is necessary, and the need for data entry by study personnel is eliminated. Web-based systems can also minimize the variation due to differences in survey administration, interviewer interpretation, and entry of data. Since complicated branch and skip patterns can be programmed into the survey, the amount of interviewer or respondent attention necessary is reduced. Costs can drop dramatically with the use of web-based data collection, as there is no need for printing, mailing, and data collection personnel. Web-based surveys also provide a greater degree of anonymity for the collection of sensitive personal information (Baer et al. 2002).

It is important to realize, however, that depending on the situation, some advantages of web-based systems can become disadvantages. In some populations or countries, for example, the cost of printing, mailing, and administering a paper questionnaire might be considerably less than the cost of setting up a web-based system and providing training and access to study participants. Other disadvantages of web-based data collection include the possibility of selection bias when choosing a study population and security problems during data transmission. The issue of computer users being unrepresentative of the general population can be overcome to some extent by providing Internet access to a randomly sampled study population (Silver et al. 2002). Literacy or language barriers, however, may still prove to be an issue.

Incorporating strict security measures in an electronic data entry system is crucial to maintaining data confidentiality and can require considerable time and monetary resources. In some instances, it might be possible to provide a quick solution to this problem by linking the survey security to an existing high-security system, such as a university network.

While the use of web-based systems is a promising avenue of data collection for studies, such systems require considerable expertise for adequate setup. Often, initial versions of web-based questionnaires present frustrating technical problems to users and may require several iterations before a working system is in place. Web-based systems may be inappropriate for populations that are not computer literate. Additionally, data entry errors by users can still occur. Ethical concerns which arise in the study still need to be addressed and may be more difficult in the context of web-based data collection. For example, the investigators still bear responsibility for verifying informed consent or for providing local targeted support in case the respondent needs a referral as a result of the research. For these reasons, the pretesting of data instruments, postentry error-checking, and other forms of data quality control described in this chapter are as crucial for more technologically advanced data collection as they are for more traditional forms of data collection.

14.3.7.4 Data Audits

Once data have been entered, they must be submitted to further accuracy checks. One method of assessing data accuracy is to perform a series of consistency checks, such as ensuring that the date of birth and age of a participant are in agreement. Reviewing samples that fall outside some number of standard deviations of the mean is a sensible alternative way to check data. More formal statistical methods for detecting outliers can also be used (Barnett and Lewis 1994; Vardeman and Jobe 1999). The importance of using range checks is illustrated by a simulation in which different rates of entry error were introduced into a constructed dataset and simple range checks were used to identify and correct outliers. Even with a random entry error rate as high as 20%, population means remained very similar after the correction of unusual values, regardless of study sample size (Day et al. 1998). Error rates similar to those achieved with double data entry were achievable when extensive logic checking of fields was incorporated (Mullooly 1990; Neaton et al. 1990).

In instances where an unusual value is detected, a data quality query should be generated either manually or automatically. During study planning, a system for reporting and responding to such queries needs be conceptualized, along with the designation of individuals responsible for checking and responding to questions. The automatic generation of regular quality control reports including summary statistics such as the number of queries by form and data field, or the percentage of error-free forms, can aid the systematic processing of data. Section 14.4 of this chapter addresses the processing and resolution of error queries in more detail.

Comparing the number of forms that are edited using automated checks at the data-processing center to the number of forms recorded in the batch sent by the field center allows the identification of forms that are lost during keying. Additionally, a random sample of data forms should be compared to the electronic data submitted to check accuracy of data entry.

Once routine edits have been completed, the data form can be posted directly to a *master file* for smaller studies, or to a *distributor file*, for larger studies. In the Multiple Risk Factor Intervention Trial, the edited form was transferred to a distributor file, which held all the forms that were edited in a day. At the end of the day, forms held in the distributor file were transferred to one or more *transaction files*, which served as temporary storage until the next scheduled update of the master file. The use of transaction files allowed investigators the flexibility to resolve discrepancies before the data were added to the master file. Transaction files were generally copied to daily backup tapes so that data could be retrieved to the time of the last backup in case of processing errors, machine failure, or other accidents (DuChene et al. 1986).

14.3.7.5 Forms Posting

In general, it is best to keep the interval between data collection and entry as short as possible. If it is possible to process forms as they are generated, this is preferable (Meinert and Tonascia 1986). If batch processing is found to be more convenient, the scheduled time between subsequent postings of information from the study transaction files (raw data) to the master file should not be longer than 2 weeks. During forms posting, data fields from the transaction files are copied to the location in the master file(s) specified in the *data dictionary* (a database of information used to edit, document, and control the processing of forms through the computer system). The data management system should be programmed to reject the form if errors are detected in the data identifiers, or if data are found to already exist in the master file (unless the form to be entered is a correction form). Personnel at the data coordinating center can then review and resolve discrepancies in rejected forms. If fields need to be modified in the master file, changes should be explained and documented in the electronic file as well as on paper.

14.3.7.6 Backup of Raw Data

Once the forms have been posted to the master file, all transaction files containing the posted forms should be copied on to a tape or other electronic medium such as compact disc (CD), digital video display (DVD), or external hard drive, and stored offsite in a secure facility. In the event of a major system failure or destruction of the master file (in a building fire, for instance), the offsite copy will allow recreation of the master file.

14.3.7.7 Clearance

After the data are posted to a master file, computer edits of the master file allow consistency checks between fields on different forms. For example, an individual's height should remain constant over forms. It is informative to flag inadmissible values, as well as unlikely values. Additional within form checks can also be performed at this time.

14.3.7.8 Archiving

When within-form verification and across-form clearance are complete, and data on the master file are finalized, the master file should be copied on to at least two tapes and stored offsite. These tapes should be read regularly to check for deterioration. If a backup tape cannot be read, a new copy should be made.

14.3.7.9 Networks

With the emergence of networks or cohort consortia in large-scale epidemiological studies, data management becomes an increasingly complex issue. The need for standardization among study cohorts within a network requires an additional level of organizational coordination of data management and quality assurance practices. Some consortia establish steering committees to oversee quality assurance issues. Steering committees can serve to guarantee efficient and accurate data management while minimizing and streamlining administration. These activities are likely to involve harmonization of data that have been collected and/or coded in different ways. Reconciliation of disparate datasets may prove quite challenging. For more information on quality assurance in network settings, see Khoury et al. (2010).

14.3.8 Quality Assurance Committee

The most carefully designed quality assurance program cannot function efficiently without the assignation of responsibilities for various quality monitoring tasks to specific individuals and the existence of effective communication channels between study personnel. In many large studies, a quality assurance committee is formed to oversee the quality of data collection (Knatterud et al. 1998; The Chemical Manufacturers Association's Epidemiology Task Force 1991; US Environmental Protection Agency (EPA) 1989). The quality assurance committee addresses quality issues throughout the life of the study, from protocol development to the responsible archiving of data. The quality assurance committee is also responsible for reviewing study compliance with written quality assurance/control procedures and for evaluating interim analyses. For large studies, a data monitoring committee made up of external quality assurance auditors supportive of the protocol objectives and study design might be warranted (Fleming 1993; Khoury et al. 2010).

14.3.9 Communications

The effective resolution of study quality issues is highly dependent on the quality of communications between study personnel. Many of the quality assurance mechanisms already described in the chapter *contribute* directly to improved communication. Examples include the training of personnel and the definition of standard operating procedures. Other quality assurance mechanisms *depend* critically on communication for their implementation. In order for queries to be resolved effectively, study personnel need to know who to submit queries to and how these queries should be submitted. Structures for transmitting resolved data queries back to data entry personnel are also needed. The scheduling of regular meetings between study personnel is crucial for maintaining study communications. Emphasizing the rationale for quality control and the need for wholehearted support for quality control measures is important since quality control measures will fail if they are perceived as nit-picky and burdensome (Cooper 1986). One or more individuals should be designated responsible for preparing and disseminating the minutes of study meetings. More generally, communication structures should be in place to communicate the intent, conduct, results, and interpretations of the study to study personnel, study participants, and the scientific community. In certain situations, other parties that might need to be informed of study results include health care providers, policy makers, or the media.

In network or cohort consortia settings, communication among study groups is particularly important with regard to authorship and publications. Issues of authorship and publication policies should be established early to avoid confusion and dissent that may arise later.

14.3.10 Cost of Quality Assurance

Clearly, the implementation of quality assurance and quality control measures add to the cost of a study. While some expenses, such as the cost of routine data editing or the rechecking of statistical analyses may be impossible to estimate, cost information can be projected for other aspects of quality assurance, such as training, site visits, and external quality control programs (Knatterud et al. 1998). Considering the cost of various quality control measures early in the planning process allows for development of a realistic and feasible program that is more likely to be executed. Priorities for data quality should be set at this time. While certain aspects of data quality should not be sacrificed regardless of the expense, a compromise might be possible in other instances. For example, a costly, time-consuming measure of exposure might be collected for a subsample of study participants and this information can be used to validate a cheaper exposure measurement used for all study participants.

14.3.11 Ethical Considerations

Ethical considerations are perhaps the most important set of considerations in a study (for a general discussion, see chapter ▶Ethical Aspects of Epidemiological Research of this handbook). Epidemiological research should never lose sight of the fact that data are derived from human beings. Studies such as the Tuskegee Syphilis Trial (US Department of Health, Education, and Welfare (DHEW) 1973) which followed the progress of untreated syphilis in black men even after effective treatment was available may now seem shocking, but it is well to keep in mind that throughout most of the trial, the investigators did not find their research particularly objectionable. The thorough consideration of ethical issues raised by a study (mandated by law in most countries) will hopefully prevent a future generation of scientists from looking back at present-day trials with regret.

The human subjects section of the protocol must describe whether the study protocol imposes any physical or psychological risk to the participants. Potential benefits of the study should also be noted, with an explanation of whether benefits will be accrued by study participants themselves or whether the study is expected to benefit others in the future. The cost-to-benefit ratio should be weighed and discussed. Studies that involve primary data collection generally need to obtain informed consent from study participants. Consent forms should include, at a minimum, contact information for personnel available to answer questions about the research, the purpose of the study, eligibility requirements, the expected duration of participation, possible harm that the subjects could incur, expected benefits to subjects or to others, information on the voluntary nature of participation, and a statement indicating the right to withdraw from the study at any time (The Chemical Manufacturers Association's Epidemiology Task Force 1991). The study eligibility criteria are also subject to ethical considerations, both in terms of inclusions (different racial/ethnic groups and both sexes should be adequately represented) and exclusions (special justification is needed for study of vulnerable groups, such as pregnant women, children, or incarcerated individuals). Adequate provisions for maintaining data confidentiality and the privacy of individuals should be described. For example, investigators might plan to store hard copies of sensitive data in locked cabinets with limited access and remove personal identifiers from datasets used for analysis. Automated data management systems should have password control, users should be logged out after a period of inactivity, and the copying of data should be discouraged (Wyatt 1995).

Some of the most pressing ethical challenges to date arise from large-scale studies which rely on aggregating databases of biological specimens or "biobanks." Specimens included in biobanks may have been collected in the past with participant consent that does not meet today's standards of informed consent. In fact, the specimens may be used for assays and analyses that were not anticipated at the time of study initiation. Furthermore, participant consent may not apply to secondary uses of their data for future studies as yet unanticipated or for studies conducted by other investigators. Several recommendations have been made to address the ethical challenges of data sharing and aggregated databases, including ensuring the existence of data security mechanisms to protect participant privacy, accounting for the potential incorporation of data into aggregated databases when obtaining informed consent, and establishing data sharing rules (Karp et al. 2008).

14.4 Quality Considerations During Study Conduct

Before data collection is initiated, all data collection procedures should be reviewed and approved by the lead investigators. Data forms and equipment should have been tested and certified ready for use.

If rigorous quality assurance procedures have been planned prior to study initiation, quality control activities during study conduct mainly consist of the implementation of these procedures. The study protocol should be followed, personnel should be trained according to established standard procedures, and data collection should proceed with all quality assurances in place. Any deviation from a given standard operating procedure should be authorized by the steering committee.

The importance of periodic examination of data by study investigators, data coordinators, and data entry personnel while the data are being collected cannot be overstated. Examination of data trends by center, over time, or by technician (for example), can identify flaws in data collection early on. Even simple plots and graphs of data can identify sources of error. When data errors are identified, steps should be taken to correct the data in a timely manner. In some cases, statistical adjustment can be used to correct data drift. When this is not possible, data might have to be thrown out or completely reprocessed. In order to generate a written audit trail of data, any changes made in the data should be documented.

14.4.1 Training and Certification

The importance of training and certifying all study personnel has already been underlined in Sect. 14.3.3 “Personnel: Training and Certification.” While many study investigators are aware of the need for standardized operating procedures, information regarding these procedures is often lacking in study descriptions. While 244 original research articles in three emergency medical journals (1989–1993) described data collection by means of chart review, only 18% mentioned training of abstractors and periodic abstracter monitoring was reported in a mere 3% of these articles (Gilbert et al. 1996).

Detailed practical guidelines for training and quality control management for study interviewers, data abstractors, and biomedical technicians are available in the literature (Edwards et al. 1994; Fowler and Mangione 1986, 1990; Reisch et al. 2003). This section summarizes some of the main considerations.

14.4.1.1 Training

Training procedures should ideally involve all staff and procedures. While centralized training of all study personnel might be desirable in terms of increasing the comparability of data collection between sites and allowing study personnel from different sites to interact with each other, the expense of bringing personnel to a central training site for all their training can be considerable. Additionally, site-specific questions might arise that cannot be adequately addressed during centralized training. An optimum strategy might be to use both types of training. Table 14.4 provides an overview of the training process.

Table 14.4 Overview of training (Adapted from Reisch et al. (2003))

Steps in data processing	
Training manual	Educational training manual is sent to all sites for review The training manual consists of some or all of the following: a study overview, information on the relevant procedure, quality assessment procedures, data forms with instructions (e.g., for abstraction or interview), quick reference sheet for all variables, glossary of terms, standardized training examples, and relevant articles from the literature
Standardized training examples	Training examples should be prepared for key study variables. Study personnel might be asked to note blood pressure measurements from a training tape, for instance
Individual orientation	Two or more individual orientation sessions should be arranged with the onsite data collection team and with the lead study coordinator and/or study investigator. Additional sessions can be scheduled at the discretion of the site coordinators
Double-review of initial data	The first few examples of data collected (by chart abstraction, interview, or a biomedical procedure) should be repeated by a more experienced member of the data collection team. Discrepancies can then be reviewed Queries should be entered into an audit form and sent to the lead study coordinator to assist with later tracking of problematic data
Regular double-review	Performing regular double review for a small sample of data (e.g., once a month) can prevent data drift over time. Review of data at a later time is facilitated by audio or video taping of interviews or biomedical procedures
Regular conference calls/ meetings of field staff	Regular study conference calls can include a training component if examples of data collection problems are brought up for discussion during each call. An updated decision log containing a summary of discussions held and decisions made during these conference calls can be distributed among study personnel
Regular site visits	Review of data collection procedures during site visits by the lead study coordinator and/or lead investigator
Retraining	Retraining study personnel might be necessary if substantial time has passed since initial training, a systematic bias in data is detected, or the study protocol changes

14.4.1.2 Certification

Following initial training, study personnel should be certified to perform specific procedures. Regular retraining is desirable to prevent data drift. Retraining might also be necessary if a specific study technician is found to be introducing a systematic error into the data, or if the study protocol changes. Any retraining should be accompanied by recertification.

While the interval between retraining and certification varies from study to study, the Atherosclerosis Risk in Communities study (ARIC) used a 90-day interval since a 6-month interval was found to allow too much drift to recognize and correct digit preference. More timely feedback was also needed in the Cardiovascular Health Study (CHS) (Joel Hill, personal communication 2003).

14.4.2 Maintenance and Calibration of Equipment

Study equipment should be inspected and calibrated at regular intervals in accordance with the study protocol. In the event of equipment breakdown, equipment may need to be replaced. If the new equipment is similar to the equipment already being used, then calibration before use is sufficient. When replacement of existing equipment is desirable because a new model or instrument is more accurate or efficient than the existing equipment, data should be collected using both the old and the new instrument for a defined period of time, so that comparability of measurements can be established.

14.4.3 Implementing Data Management

The data management process has already been described in detail in Sect. 14.3.7. During study conduct, the planned data management system is implemented and refined as necessary.

14.4.3.1 Tracking and Monitoring of Data

The effective tracking and monitoring of data as data collection is in progress is essential to the timely detection and correction of errors. Monitoring should occur for subject accrual, data acquisition, and data quality. Automated tracking systems can greatly assist this process and have been used successfully in epidemiological studies as early as 1981 (McQuade et al. 1983). Data that are collected by hand should be recorded directly, promptly, and legibly in ink. Four different types of monitoring are recommended: *proactive efforts* to improve data, *observation of data collection*, *review of computer-generated checks and summary reports*, and *examination of data*.

When possible, data quality should be improved by *proactive efforts*. Automated reminders of when patients are due for study visits for time-dependent variables (e.g., levels of an exposure biomarker) can prevent the collection of data that is later deemed of poor quality or unusable. Target dates for follow-up visits can be defined by the participant's entry date rather than the date of the last visit, in order to prevent scheduling deviations from carrying over to future visits.

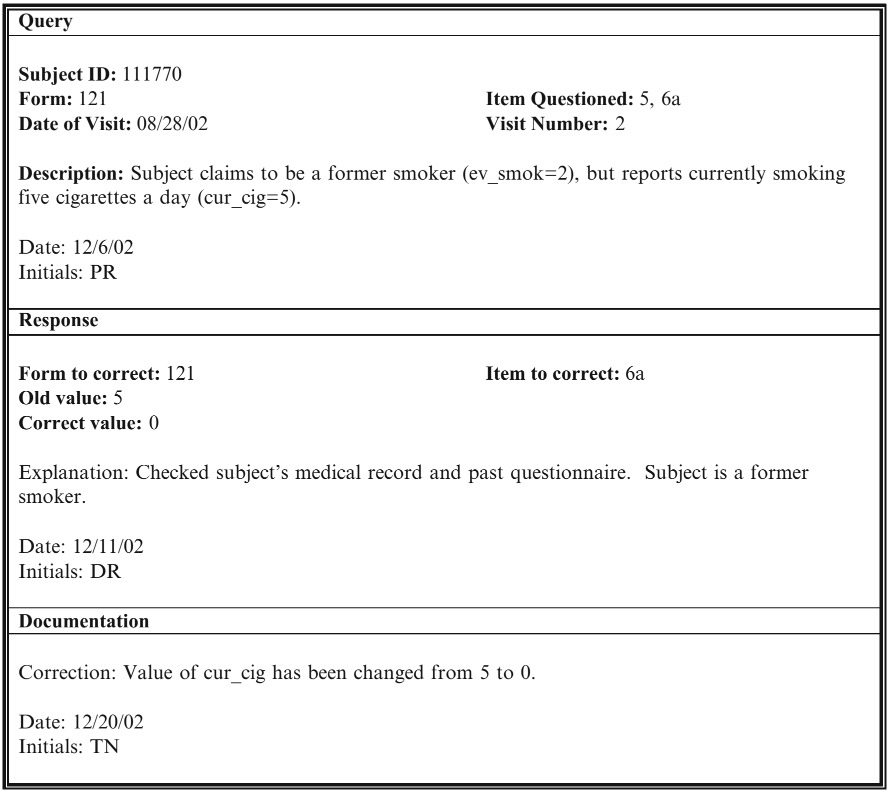
Direct or indirect *observation of data collection* can also identify errors in a timely manner. An unobtrusive way to monitor interviewers for delivery and adherence to protocol is to audio-record interviews. Measurement techniques for biomedical or laboratory technicians can either be video recorded or directly observed by senior technicians or other qualified study personnel.

Regular *review of computer-generated queries and summary reports* of data quality can alert the investigators to a variety of data errors, including participant ineligibility, data outside the expected range, and variation in data quality by data field, site, or technician. Active examination of data during collection is crucial. Summary statistics and plots of data by technician, site, or time can identify unusual trends. For example, an examination of data from the Hypertension Prevention Trial revealed that nearly 29% of the baseline systolic blood pressure readings from one clinic ended in the digit 2. This could be traced to measurements made by one technician, who recorded a number ending in the digit 2 for over 60% measurements (Canner et al. 1991). When a data collection flaw is identified, further error should be prevented by tracking down the source of the problem and taking corrective action.

Keying errors may be identified by periodic audits of the database against source documents. Rather than check all the data, a random sample of data fields can be selected to check for keying errors. When creating the test sample, it is important to ensure that a broad cross-section of data is included (e.g., both numerical and character fields should be checked). One method for sampling a variety of fields is to choose a random subsample of forms and look at all fields within those forms.

14.4.3.2 Corrective Actions

Moving back to the datascope for a moment, we recall that the identification of data errors is only the first step in data quality management. In order to reach the ultimate goal of valid data, these errors need to be corrected. The process for revising data should be as systemized and well documented as the process for locating errors. While the routine correction of careless mistakes while data entry is in progress need not be reported, data errors that are identified after initial data entry should not be changed by data entry staff until the query has been checked. A paper trail should be initiated for each problem, with the initial query describing the problem, and the date it was detected (Fig. 14.2). The individual(s) responsible for query resolution should then investigate the query and provide a response explaining why the problem occurred. Finally, the query documentation should indicate how and when the problem was resolved. If data from a form are found to be incorrect, they should be identified as incorrect rather than erased, and the correct values



Query

Subject ID: 111770
Form: 121 **Item Questioned:** 5, 6a
Date of Visit: 08/28/02 **Visit Number:** 2

Description: Subject claims to be a former smoker (ev_smok=2), but reports currently smoking five cigarettes a day (cur_cig=5).

Date: 12/6/02
Initials: PR

Response

Form to correct: 121 **Item to correct:** 6a
Old value: 5
Correct value: 0

Explanation: Checked subject's medical record and past questionnaire. Subject is a former smoker.

Date: 12/11/02
Initials: DR

Documentation

Correction: Value of cur_cig has been changed from 5 to 0.

Date: 12/20/02
Initials: TN

Fig. 14.2 Example of a data query form

should be inserted (Knatterud et al. 1998). In some cases, unusual values will be confirmed to be correct in which case they should be retained in the database with documentation.

Occasionally, errors identified during study conduct may lead to changes in the survey instrument or other study equipment. In such cases, it is crucial that the version of the form or equipment used to collect data is recorded in the database. If a new data check is added, either as a result of a query or as an additional precaution, old values in the database should be edited using the new rules in order to keep data consistent.

Tracking the time taken for corrective actions allows areas of delay to be identified and resolved for future queries. In most longitudinal studies, data are analyzed while data collection is still in progress. In such instances, one might want to exclude data that are under query from the master database until the problem is resolved. The inclusion of a "status" field for data would allow investigators to check whether values were acceptable or unacceptable (Gassman et al. 1995).

14.4.4 Site Visits

For multicenter studies, site visits to observe operations allow greater understanding of site-specific data collection issues and provide an opportunity to recognize and correct faulty systems (Gassman et al. 1995; Knatterud et al. 1998; Prud'homme et al. 1989). Scheduling site visits is recommended shortly after initiation of patient recruitment and when the data collection at the site is drawing to a close. Additional site visits should be scheduled for long-term studies.

The size of the site visit team can vary and is dictated by the nature and purpose of the visit. A typical site visit team might include the study principal investigator (or representative), the director of another field site, the data coordinating center director, the study project officer, and selected resource personnel. During the site visit, the site visit team would meet with the director and staff of the unit and hold private conversations with key support personnel. The site visit should include a thorough review of staffing requirements, recruiting, training and certification, and communication structures. Site visitors also have a chance to observe data collection, check data management, and review data quality monitoring. Specific activities might include observation of whether field technicians follow the study protocol, inspection of study records and documents storage, and review of the operation and maintenance of local data systems. Following the site visit, the leader of the site visit team should prepare a written report of the visit based on input from the entire team. The site visit report should describe any systematic errors that were identified in data collection and provide recommendations on how to rectify the situation. A formal response to the report should be prepared by the staff at the study site.

14.5 Quality Considerations After Data Collection

Once data collection for the study is complete, the task of analyzing and interpreting the data begins. The study investigator should yet again consult the datascope to check for possible biases and errors that need to be resolved in order to form a clear picture of the relationship under study.

14.5.1 Reporting Response Rate

If individuals who agreed to participate in the study were different in some important way from non-respondents, the study results could well be biased. For example, non-respondents to questionnaires might be of poorer health or more likely to be smokers than respondents (Shahar et al. 1996). Studies that have followed respondents and non-respondents to questionnaires have reported that non-respondents have a significantly higher risk of myocardial infarction, cancer mortality, and all-cause mortality (Bisgard et al. 1994; Heilbrun et al. 1991).

Calculating the study *response rate* gives a first indication of whether the investigator should be concerned about possible bias in the results. Generally, the higher the study response rate, the less need to worry about selection bias affecting the results. The simplest approach to response rate calculation is to divide the number of surveys received by the number of surveys sent. However, this does not account for factors that can affect the response rate such as undelivered questionnaires, ineligibility of subjects who completed questionnaires, or substitution of the intended recipient with another subject. Typically, the numerator and denominator of the response rate are adjusted to reflect such factors. Standard definitions and methods to calculate survey response rates are provided by the American Association for Public Opinion Research (2000) or the Council of American Survey Research Organizations (CASRO).

For cohort studies, the simplest way to estimate the *follow-up rate* is to divide the number of participants seen at the last visit by the number of participants initially enrolled. Again, different assumptions about individuals lost to follow-up yield different numbers for the follow-up rate.

Since different methods of calculating the response rate might be appropriate for different studies, the choice of the response rate formula is less critical than the identification and reporting of all the elements that enter the calculation (Table 14.5).

In general, response rates to questionnaires have been decreasing in the United States, and perhaps elsewhere (Kessler et al. 1995; Steeh 1981). Data from a nationwide survey in the United States (the Behavioral Risk Factor Surveillance System, BRFSS) indicate that response rates from random digit dialing have declined from a median of 68.4% in 1995 to a median of 55.2% in 1999 (Centers for Disease Control and Prevention (CDC) 1999). A review of 82 case-control studies published in the *American Journal of Epidemiology* (1988–1990), *Epidemiology* (1997–1999), and *Cancer Epidemiology, Biomarkers and Prevention* (1997–1999) reported a 0.2% and 0.44% decrease in reported response per year for cases and controls, respectively (Olson 2001). The same article reported an average response rate of 76.1% for cases and 71.5% for controls. A review of 321 distinct mail surveys published in a broader spectrum of United States journals in 1991 reported an average survey response rate of 62% (Asch et al. 1997).

Regardless of the exact value of the response rate, the characterization of non-respondents is crucial in order to assess whether a bias is present and, if it is, how the results of the analysis might be affected. Clearly, describing the non-respondents becomes more important when a study has a low response rate. Whenever possible, a brief survey should be administered to non-respondents to collect limited data for comparison with respondents. Otherwise, assessing available data on demographics, exposure, or outcome will allow some assessment of possible bias.

14.5.2 Analysis

Before proceeding to analysis, the study data should be tested rigorously to check for *residual errors* that remain after all data processing and routine quality assurance

Table 14.5 Reporting outcomes of recruiting respondents in case-control studies in a study of thyroid cancer in Western Washington (Adapted from Olson et al. (2002))

Units selected from sampling frame	Number
Random digit dialing screening phase	
Total	6, 741
Ineligible sampling unit	
Total	3, 589
Business, fax, government	1, 937
Non-working numbers	1, 436
Institution, group quarters, dataline	216
Unable to determine eligibility	
Total	431
Unknown if residential	274
Residential, unknown if individual eligible	157
Answering machine on all attempts	56
Refusal to answer questions on eligibility	76

Total	737
Not interviewed (refused)	163
Interviewed	574

activities are complete. Range checks provide one way to examine whether the data seem reasonable. Simple queries, for example, checking that the recorded age in years is consistent with the date of interview minus the recorded date of birth, can also help to detect errors.

Once the investigator feels confident that there are no obvious flaws in the data, the next step is to understand the data by conducting exploratory data analysis using univariate and bivariate summaries, as well as plots and graphs of the data. More complex exploratory analysis of the data should be guided by the data. If assumptions implicit in the planned analysis methods are violated, alternative statistical methods must be considered. Appropriate and careful statistical analysis is integral to good epidemiological practice. A description of basic methods of analysis for epidemiological study designs can be found in Part III (Statistical

Methods in Epidemiology) of this handbook and in most intermediate textbooks of epidemiology (Rothman and Greenland 1998; Szklo and Nieto 2000). Some of the key issues underlying the analysis of case-control and cohort studies are summarized in chapters ▸Cohort Studies and ▸Case-Control Studies of this handbook and in a two-volume series published by the International Agency for Cancer Research (Breslow and Day 1980, 1987). The finer points of analysis, however, are study specific. For this reason, it is crucial that data analysis be conducted by personnel with the necessary training and experience in statistical methods.

Once data analysis is complete, ways to check the analysis include independently reproducing the tabulations and statistical calculations from the original data and checking different tables for consistency of the denominators. All data reduction and statistical procedures should be documented to facilitate review at a later date.

The results of any study are associated with some degree of uncertainty. To the extent possible, these uncertainties should be quantified and accounted for or, at the minimum, characterized quantitatively. In an analysis of risk factors for coronary disease in the Framingham Heart Study, estimates of risk increased for factors measured with substantial error after correction for uncertainty (e.g., serum cholesterol), whereas risk estimates tended to remain unchanged for risk factors with little or no error, such as body mass index (Rosner et al. 1992).

The analysis of study data is followed by the task of interpreting the study results. An observed association might be due to statistical artifact, due to bias or confounding, or be truly causal. The use of statistical significance alone to guide inference is not recommended (Goodman 1999a, b). In a study exploring 100 associations, five would be statistically significant at the $\alpha = 0.05$ level by chance alone. Moreover, an association might be confounded by one or more variables or could be biased due to systematic flaws in the design or conduct of the study.

The capability of generating very large volumes of data from microarrays and other new technologies has led to new analytical challenges and the emergence of the field of bioinformatics. For example, genome-wide association studies (GWAS) currently explore associations of hundreds of thousands of single-nucleotide polymorphisms (SNPs) with disease status. Soon, researchers will be exploring the actual genetic sequences in people with and without disease, leading to even more massive datasets and analytical challenges. Not only is there a need for multiple comparisons adjustment but also for planning studies with sufficient power to detect small effects (Khoury et al. 2010). The planning of such studies necessarily involves a team that includes genetic epidemiologists, bioinformaticians, biostatisticians, and geneticists and clinicians.

Following adequate consideration of chance, confounding and bias (cf. chapter ▸Confounding and Interaction of this handbook), the determination of whether an association is causal will also depend on *temporality*, the *strength of the association*, the presence or absence of a *dose-response relationship*, *consistency* with prior literature, and *biological plausibility* (Gordis 2000; Hill 1965; US Department of Health and Human Services 2004).

If an exposure is believed to cause the disease in question, this exposure must occur before the disease develops. *Temporality* is easier to establish for prospective cohort studies in which exposure information prior to disease outcome is available. For cross-sectional or case-control studies, exposure information is usually collected concurrently with disease information or has to be recreated from historical records of exposure, making the assessment of temporality more difficult.

In general, the larger the magnitude of the association, the more likely it is that the relationship between the exposure and disease is causal. In epidemiological studies, the *strength of the association* is usually measured by the relative risk or odds ratio.

If it can be demonstrated that increasing the dose of an agent is associated with increased occurrence of disease in a well-defined relationship, this provides more evidence for causality. The absence of a *dose-response relationship*, however, does not preclude a causal relationship since it is possible that no disease develops until a certain exposure level is reached, after which disease can occur ("threshold effect").

Consistent replication of a finding in different study populations provides further evidence for a causal relationship. However, it is possible that an association only occurs in certain population subgroups, in which case it might be seen in some populations but not others.

Before concluding that an association is causal, it is important to consider *biological plausibility*. While it is possible that epidemiological studies can detect associations which are not yet understood on a biological level, attempting to understand how the exposure might cause the disease in question is nonetheless worthwhile.

Once the results of a study have been finalized, the investigators should consider how they plan to communicate the results and to whom. Groups that should be informed, in general, are the study personnel, study participants, and scientific community. If the results of a study warrant immediate action, health care providers and policy makers should also be alerted. While it is important that the media is informed of the results of studies that have relevance to the general public, it is generally prudent to wait until the study is published in a peer-reviewed journal since the process of critical review of a study allows for the identification and correction of key flaws.

A typical study report consists of the following sections: introduction, methods, results, and discussion (Table 14.6).

Regardless of the audience for the report, results should always be placed in context of the uncertainties and limitations associated with the findings. Describing results in terms of adjectives such as "definitive" or "conclusive" should be avoided. Too often, associations which receive much publicity to begin with have to be rescinded in light of further research.

Concise, simple language aids clarity of presentation. For written reports, adequately labeled tables and figures should be used to summarize information when possible. Information presented in tables should not be merely repeated in the text without additional interpretation.

It is important that results of well-designed studies are reported regardless of whether findings are negative or positive. The tendency for positive findings to be highlighted, both in terms of submission and final publication, biases the perception

Table 14.6 Guidelines for preparation of a study report (Adapted from Szklo and Nieto (2000))

Introduction	
Review study rationale	Describe importance of problem Biological plausibility How does this study add to existing literature?
State hypotheses	Specify interactions of a priori interest
Methods	
Describe study population	Methods of recruitment Inclusion and exclusion criteria
Describe data collection	Include accuracy and reliability of procedures, and quality control measures
State criteria for identification of confounders	
Describe statistical methods	Justify categorization of study variables State assumptions of selected model
Results	
Describe rates of participation or response	
Provide descriptive data	Frequency distributions, means, unadjusted differences Stratify by variables of interest, e.g., age, sex Quality control measures
Present results of model	Use most parsimonious model Additive and multiplicative interactions, if present
Tables and figures	Should be self-explanatory Use informative labels and units
Discussion	
Review main study results Describe strengths and limitations of study	Compare and contrast with published literature
Assess bias and confounding	How much would study results be affected by bias/confounding?
Address uncertainty	How precise are the study estimates, given misclassification?
Clinical, public health policy implications	If strength and impact of study results warrants
Future directions	How to improve on study, build on findings

of the true association between exposure and outcome. This is especially problematic in the context of meta-analyses (cf. chapter ►Meta-Analysis in Epidemiology of this handbook) which attempt to quantitatively summarize published studies. A bias toward publishing positive findings results in a biased estimation of overall risk (Easterbrook et al. 1991; Egger and Smith 1998; Ioannidis 1998; Thornton and Lee 2000).

Studies with substantive findings on a research question may have implications for policies related to public health. Researchers may appropriately highlight such findings in their reports, often at the conclusion of the discussion, commenting on the extent to which new knowledge has been generated with policy implications. There has been substantial debate among epidemiological researchers as to whether publications should also make policy recommendations (Samet 2000). In general, policy recommendations should not be made in publications providing research findings, particularly within the constraints of the policy expertise of most researchers and the space that can be devoted to such discussion in an article.

14.5.3 Storage and Retrieval of Data

Commitment to an epidemiological study does not end with the publication of the final papers. After the study is completed, sufficient material should be stored to allow future sharing of the data or auditing of the study. In fact, for some research funded by the US National Institutes of Health, submission of a fully documented dataset is required, although there are complicated issues related to assuring the privacy of all participants. An index of all stored study materials should be created, along with a description of where they can be located. Materials that could be archived include source data and specimens, laboratory or research notebooks, and the study protocol. Also included should be the final study report, computer data files, copies of computer programs and statistical procedures that were used in analysis, and any printouts of analyses that formed the basis of results included in the final report (Freedland and Carney 1992; The Chemical Manufacturers Association's Epidemiology Task Force 1991; US Environmental Protection Agency (EPA) 1989). If applicable, study forms and related forms should be destroyed in accordance with local statutes and medical records. In order to ensure safety and confidentiality of study materials, storage should be in a physically secure place with limited access.

Periodic checking of stored material is recommended to ensure that necessary updates have been made and to avoid unnecessary clutter. Original records can be transferred to microfilm for storage purposes to conserve space. If microfilm is used, the original records should be retained until the microfilm is checked for proper identification and legibility. For very large studies, electronic storage of study data might make sense given space and cost limitations.

14.6 Conclusions

The field of epidemiology has been growing rapidly, with a vast number of epidemiological studies published every year. A search for "epidemiology" in the PUBMED database yielded 2,028 references in 1964. A similar search for the year 2009 yielded 84,592 references (Fig. 14.3). The results of many of these studies, however, are inconsistent. These inconsistencies are sometimes due to chance, but

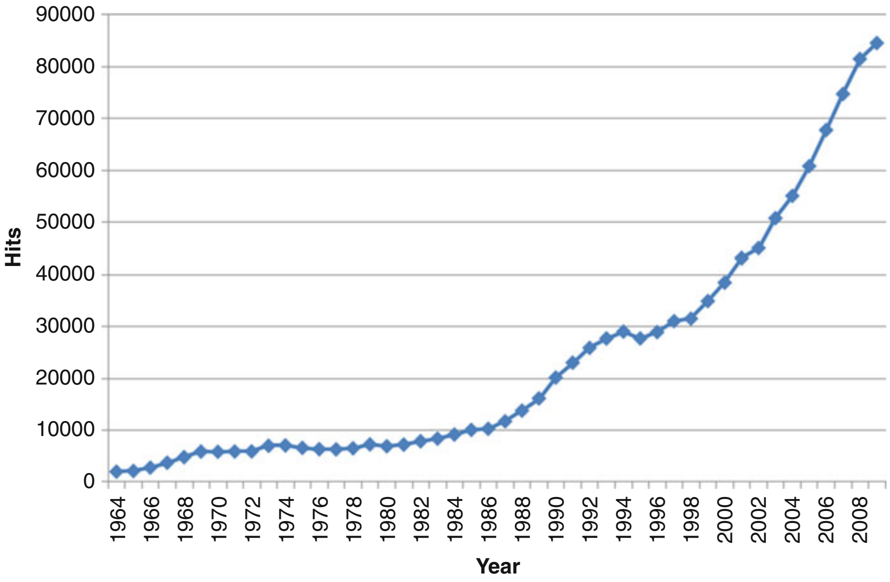

Fig. 14.3 Number of references to "epidemiology" in the PubMed database, 1964–2009

more often can be ascribed to the variable quality of studies with respect to design, conduct, analysis, or dissemination.

As a consequence of the inconsistent results reported by epidemiological studies, many consumers of epidemiological research including clinicians, policy makers, and the general public are dismissive of new findings. The importance of a widespread effort to follow good epidemiological practice and implement rigorous quality assurance and quality control procedures cannot be overstated.

Even as this chapter is being written, the methods of data collection, processing, and storage are changing rapidly as technological innovations emerge. However, the basic principles of good epidemiological practice, data quality assurance, and control will not change. The increasing use of e-mail, PDA, or web-based questionnaires may reduce data error due to data transfer from paper to electronic files, for example, but errors due to poor questionnaire design or data entry (to name just a few sources of error) will still exist. Similarly, electronic processing and storage of data might be helpful in identifying unusual values, but study investigators will still need to review, interpret, and correct these errors.

In this chapter, we have reviewed quality assurance and quality control activities pertinent to the planning, conducting, and reporting of a study. The mental exercise of "optimizing" the dials on the datascope can be useful while conducting epidemiological studies and when considering the results of already published studies. As high-quality research becomes the norm, the field of epidemiology will gain more respect among fellow scientists, policy makers, and the public.

15.1 Introduction

Field work in epidemiological studies consists of collecting data in natural and experimental settings to answer research questions or test hypotheses about the origins, distribution, and control of disease in populations. Field data can be collected directly and indirectly. Although direct data collection traditionally includes collecting biological samples such as blood and saliva, epidemiologists also collect data about the health of populations by contacting respondents through telephone, mail, or online. To study a community's use of preventative health services (such as influenza vaccinations), for example, a team of epidemiologists can conduct in-person or telephone interviews or administer written, computer-assisted or online surveys. Indirect data collection includes reviewing written, oral, and visual records of respondents' thoughts and actions and observing them in their natural or experimental environment. To study the extent to which a health care system's medical providers adhere to recommended guidelines for preventative health care, for instance, a team of epidemiologists might review a sample of medical records to identify which preventative services were used and by whom. If the team were interested in understanding why preventative services were (or were not) used, it might review transcripts of audio or videotapes of selected physician and patient encounters.

This chapter focuses on providing practical tips on the spectrum of techniques epidemiologists can use in designing and administering reliable and valid non-biological field measures. Although the chapter focuses on direct data collection, many of the principles apply also to indirect data collection.

15.2 Asking for Information: What are the Characteristics of Straightforward Questions and Responses?

Learning how to ask questions in written and spoken form is essential when collecting field data. A straightforward question asks for information in an unambiguous way and extracts accurate and consistent data. Straightforward questions are purposeful, use correct grammar and syntax, and call for one thought at a time with mutually exclusive questions (Sudman and Bradburn 1982; Fink 2002).

15.2.1 Types of Questions

Purposeful Questions Questions are purposeful when the respondent can readily identify the relationship between the intention of the question and the objectives of the study. If the objectives are to find out about the uses of health services, for instance, and some of the study's questions ask about education or place of birth, an explanation is needed of the relationship between questions and objectives. For instance, the introduction, can say something like: "We plan to compare people with differing backgrounds in their use of health services."

Concrete Questions A concrete question is precise and unambiguous. Adding a dimension of time can help make the question more concrete. For instance, rather than asking: "Has a physician *ever* told you that you have hypertension?" ask, "In the *past 12 months* has a physician told you that you have hypertension?"

Complete Sentences Questions should always be stated as complete sentences. Complete sentences express one entire thought, as in Example 15.1.

Example 15.1. Complete sentences
Poor: Place of birth?
Comment: Place of birth means different things to different people. I might give the city in which I was born, but you might tell the name of the country or hospital.
Better: Name the country in which you were born.

Make sure that experts and a sample of potential respondents review all questions even if you are using already existing and validated instrument. Respondents' reading levels and attention spans may vary across studies.

Open and Closed Questions Questions can take two primary forms. When they require respondents to use their own words, they are called open or open–ended. When the answers or responses are preselected for the respondent, the question is termed closed. Both types of questions have advantages and limitations.

An open question is useful when the intricacies of an issue are still unknown, in getting unanticipated answers, and for describing the world as the respondent sees it – rather than as the questioner does. Also, some respondents prefer to state their views in their own words and may resent the questioner's preselected choices. Sometimes, when left to their own devices, respondents provide quotable material. The disadvantage is that unless the team includes a trained anthropologist or qualitative researcher, responses to open questions are often difficult to interpret and compare.

Some respondents prefer closed questions because they are either unwilling or unable to express themselves. Closed questions are more difficult to write than open ones, however, because the answers or response choices must be known in advance. But the results lend themselves more readily to statistical analysis and interpretation. This feature is particularly important in most epidemiological studies which often rely on relatively large numbers of responses and respondents. Also, because the respondent's expectations are more clearly spelled out in closed questions, the answers have a better chance of being more reliable or consistent over time. Example 15.2 shows a closed question.

Example 15.2. A closed question
How often during the past week were you irritable? Circle one.

	Please circle one
Always or nearly always	1
Sometimes	2
Rarely or never	3

15.2.2 Types of Responses

The choices given to respondents for their answers may take three forms (Fink and Kosecoff 1998; McDowell and Newell 1996; Stewart and Ware 1992). The first is called nominal or categorical. (The two terms are sometimes used interchangeably.) Categorical or nominal choices have no numerical or preferential values. For example, asking respondents if they are male or female is the same as asking them to "name" themselves as belonging to one of two categories: male or female.

The second form of response choice is called ordinal. When respondents are asked to rate or order choices, say, from very positive to very negative, they are given ordinal choices. The third form of response choice results in numerical data such as when a respondent is asked to give his or her height or age at the last birthday.

A hypothetical study finding that uses nominal data results in numbers or percentages, as follows:

> Five hundred respondents were interviewed in a study of preventative health. All were asked to indicate whether or not they perform four health-related activities: (1) exercise at least 30 min most days of the week; (2) eat five or six servings of fruits or vegetables daily; (3) smoke; (4) drink no more than one to two alcoholic drinks daily. Of the 500 respondents, 25% reported that they smoked; only 10% stated that they drank no more than one to two drinks daily. None of the respondents reported exercising at least 30 min per day or eating five or six servings of fruits or vegetables.

Ordinal responses are made to fit on a scale that is ordered from positive (*definitely or probably important*) to negative (*definitely or probably not important*). Ordinal data thus are often characterized by counts of the numbers and percentages of people who select each point on a graded scale.

> Of 500 respondents completing the question, 250 (50.0%) rated each preventative health behavior as definitely or probably important.

Field studies often ask for numerical data as when respondents are asked for their birth date. From the date, you can calculate each respondent's age. Age is considered a numerical and continuous measure, starting with zero and ending with the age of the oldest person in the study. Numerical data lend themselves to many statistical operations. Typical findings might appear as follows: The average age of the respondents was 43 years. The oldest person was 79 years of age and the youngest was 23.

15.3 How are Field Study Measures and Questions Organized?

15.3.1 Length

The length of a measure depends upon what you need to know and how many questions you need to ask to get credible answers (Bourque and Fielder 2003a, b). Another consideration is the respondents. How much time do they have available, and will they pay attention? Relatively young children, for example, may only stay still for a few minutes, so shorter interviews, for example, may be better. You must also consider your resources: Longer measures may be more costly to design, validate and administer.

15.3.2 Question Order

All field measures should be preceded by an introduction, and the first set of questions should be related to the topic described in it (see Box 15.1).

Box 15.1. An introduction to a telephone interview and its first question

Hello. I am calling from the Health Clinic. We are surveying people who use the Health Clinic to find out whether it provides satisfactory services. Your name was selected at random from the Clinic's database. Our questionnaire will take no more than 4 min. You can interrupt me at any time. May I ask you the questions? [IF YES, CONTINUE. IF NO, SAY: THANK YOU AND HANG UP.] [CONTINUE HERE:]

The first question asks you about your overall satisfaction with the Health Clinic. Do you consider it [READ CHOICES]

a. Definitely satisfactory
b. Probably satisfactory
c. Probably not satisfactory
d. Definitely not satisfactory

[DO NOT SAY]

e. No opinion or don't know/wrong answer

Note that the interviewer starts off by saying that questions will be asked about satisfaction with the Health Clinic, and the first question calls for a rating of satisfaction.

In general, questions should proceed from easiest to answer and the most familiar to most difficult and least familiar. In a survey of needs for health services, items can first be asked about the respondent's own needs for services, then their family's, community's, and so on.

Questions of recall should also be organized according to their natural sequence. Do not ask very general questions such as: "When did you first start feeling dizzy?"

Instead, prompt the respondent and ask: “In the past 3 months, how often you felt dizzy? Think about the last time you felt dizzy. Was it in the morning, afternoon, or evening?”

Sometimes the answer to one question will affect the content of another. When this happens, the value of the measure may be diminished (Example 15.3).

Example 15.3. Ordering questions

Which question should come first?

a. How efficient is the nursing staff?

Or

b. Which improvements in nursing do you recommend?

Answer: Question b should come before Question a. If it does not, then the respondent might offer suggestions for the improvement of the nursing staff’s efficiency merely because it has been suggested.

Place a few relatively easy-to-answer questions at the end of the measure. When questionnaires, for instance, are long or difficult, respondents may get tired and answer the last questions carelessly or not answer them at all. You can place demographic questions (age, income, gender, and other background characteristics) at the end because these can be answered quickly.

Avoid many items that look alike. Twenty items, all of which ask the respondent to agree or disagree with statements, may lead to fatigue or boredom, and the respondent may give up. To minimize loss of interest, group the questions and provide transitions that describe the format or topic. For instance, say or print something like: “The next set of questions ask about your use of health services.”

Questions that are relatively sensitive should be placed toward the end. Topics such as grooming habits, religious views, and positions on controversial subjects such as abortion and assisted suicide must be placed far enough along so there is reason to believe the respondent is willing to pay attention, but not so far that he or she is too fatigued to answer properly.

Finally, questions should appear to reasonable people to be in a logical order. Do not switch from one topic to another unless you provide a transitional statement to help the respondent make sense of the order.

Here is a checklist of points to consider in selecting the order for the questions in your field measure:

Checklist to Guide Question-Order

✓ For any given topic, ask relatively objective questions before the subjective ones.
✓ Move from the most familiar topics to the least.
✓ Follow the natural sequence of time.
✓ See to it that all questions are independent.
✓ Avoid many items that look alike.
✓ Ask sensitive questions well after the beginning.
✓ Place questions in a logical order.

15.3.3 Aesthetics and Other Concerns

A measure's appearance is important. A self-administered questionnaire that is hard to read can confuse or irritate respondents who may not answer accurately or at all, reducing the reliability of the responses. A poorly designed interview form with inadequate space for recording answers will reduce the efficiency of even the most skilled interviewers.

15.3.4 Branching Questions or Skip Patterns

What happens when you are concerned with getting answers to questions that you know are only appropriate for part of your group? Suppose you were interviewing older adults in a general practice to learn about their medication use. You know that many of these patients are likely to be taking certain kinds of medications such as antihypertensives, NSAIDs, and aspirin. However, some people will be taking all of these medications each day, while others will be taking none.

If you want to ask about a topic that you know in advance is *not* relevant to everyone in the study, you might design a form such as the one in Example 15.4.

Example 15.4. Skip patterns or branching questions

- Do you take any of the following medications (a list is provided)?
  a. No [GO TO QUESTION 4]
  b. Yes
  [IF YES] How often do you take your usual dose (choices are given such as once a day; only when needed)?

OR

- Do you take any of the following medications?
  a. Yes [COMPLETE SECTION A]
  b. No [GO TO SECTION B]

Skip patterns may be confusing to people and should be avoided in self-administered printed questionnaires. Interviewers must be trained to follow skip patterns to ensure accuracy. Online questionnaires are effective vehicles for branching because you can design the software so that the respondent is automatically guided to the appropriate branch. For instance, if the questionnaire tells the respondent, "If no, go to question 6," the respondent who answers "no" will automatically be sent to question 6.

15.4 What Does It Take to Ensure Proper Administration of Field Instruments?

15.4.1 Self-Administered Questionnaires

Self-administered surveys can be designed for completion online or by "paper-and-pencil." They require a great deal of advance preparation and subsequent monitoring to get a reasonable response rate. These questionnaires are given or sent directly to people for completion. Advance preparation, in the form of careful editing and tryouts, is necessary in helping to produce a clear, readable self-administered questionnaire (Bourque and Fielder 2003a). You should always review the returns. Are you getting the response rate you expected? Are all questions being answered? The following is a checklist for using self-administered questionnaires:

Checklist for Using Self-Administered Questionnaires

✓ Mail respondents a letter or email them in advance telling them the purpose of your study. The letter should inform people to expect a questionnaire, explain the importance of the study and the respondent's role, list study supporters and sources of funding, and describe procedures to ensure confidentiality.

✓ Prepare a short, formal letter to accompany the questionnaire form. If you have already sent an advance letter, this one should be very concise.

✓ Offer to send respondents a summary of the findings so they can see just how the data are used. (If you promise this, allocate resources for it.)

✓ If you ask questions that may be construed as personal – such as gender, age, or income – explain why the questions are necessary.

✓ Keep the questionnaire procedures simple. Provide stamped self-addressed envelopes for written, mailed questionnaires. Make sure no special software is needed for online surveys (e.g., to download graphics). If special software is necessary, set up a system for ensuring that all respondents who are eligible for the survey have access to the software.

✓ Keep questionnaires as short as you can. Ask only questions you are sure you need and do not crowd them together. Give respondents enough room to write or check boxes and be sure each question is set apart from the next.

✓ Consider incentives. This may encourage people to respond. Incentives may range from certificates of appreciation, money, and stamps to pens, fuel, and food.

✓ Be prepared to follow up or send reminders. These should be brief and to the point. For mailed and online surveys, it often helps to send another copy of the questionnaire to non-respondents. Do not forget to budget money and time for these additional mailings.

15.4.2 Interviews

Finding Interviewers Interviewers should fit in as well as possible with respondents. They should avoid flamboyant clothes, haircuts, and so on. Sometimes it is a good idea to select interviewers who are similar to respondents in gender, age, or other demographic characteristics.

It is also important that the interviewers be able to speak clearly and understandably. Unusual speech patterns or accents may provoke unnecessarily favorable or unfavorable reactions. The interviewer's way of talking is of course an extremely important consideration in the telephone interview. The interviewer's attitude toward the study and the respondent will influence the results. If the interviewer does not expect much from the interview and sends this message, the response rate and reliability of responses will probably suffer. To make sure you are getting the most accurate data possible, you should systematically and frequently monitor the interviewers' progress (Bourque and Fielder 2003b).

Training Interviewers The key to a good telephone or face-to-face interview is training (Frey 1989). The overall goal of training should be to produce interviewers who know what is expected of them and how to answer questions and also know where to turn if problems arise unexpectedly in the field.

Whether you are training 2 interviewers or 20, it is important to find a time to meet. The advantage of meetings is that everyone can develop a standard vocabulary and share problems encountered in the field.

Once at the training site, trainees must have enough space to sit and write or perform any other activities you will require of them. If you want them to interview one another as practice for their real task, be sure the room is large enough so that two or more groups can speak without disturbing the others. You may even need several rooms.

Trainees should be taken step by step through their tasks and given an opportunity to ask questions. It is also essential to tell them some of the reasons for their tasks so they can anticipate problems and be prepared to solve them. The most efficient way to make sure the trainees have all the information they need to perform their job is to prepare a manual. Here you can explain what they are to do and when, where, why, and how they are to do it.

Conducting Interviews The following are suggested guidelines for conducting interviews:

- Make a brief introductory statement that will describe who is conducting the interview ("Dr. Mary Doe for Armstrong Memorial Medical Center"), tell why the interview is being conducted ("to find out how satisfied you are with our after-surgery program"), explain why the respondent is being called ("We're asking a random sample of people who were discharged from the hospital in the last 2 months"), and indicate whether or not answers will be kept confidential ("Your name will not be used without your written permission").
- Try to impress the person being interviewed with the importance of the interview and of the answers. People are more likely to cooperate if they appreciate the importance of the subject matter.
- Check the hearing and "literacy" of the respondent. Although it is important to stay on schedule and ask all the questions, a few people may have trouble hearing and understanding some of the questions. If that happens, reappraise the eligibility of the respondent (perhaps an interview is not the best method of obtaining reliable data from this respondent; other methods may be more appropriate). Another option is to speak more clearly and slowly.
- Ask questions as they appear in the interview schedule. It is important to ask everyone the same questions in the same way or the results will not be comparable.

Monitoring Interview Quality To make sure you are getting the most accurate data possible, you should monitor the quality of the interviews. This might mean something as informal as having the interviewer call you once a week, or something as formal as having them submit to you a standardized checklist of activities they perform each day. If possible, you may actually want to go with an interviewer (if it is a face-to-face interview) or spend time with telephone interviewers to make sure that what they are doing is appropriate for the study's purposes. To prevent problems, you might want to take some or all of the following steps:

Tips for Ensuring Quality

- Establish a hot line. This means having someone available to answer any questions that might occur immediately, even at the time of an interview. Consider obtaining a toll-free number.
- Provide written scripts. If interviewers are to introduce themselves or the study, give them a script or set of topics to cover. The script may have to be approved by an Institutional Review Board.
- Make sure you give out extra copies of all supplementary materials. If data collectors are to mail completed interviews back to you, for example, make sure to give them extra forms and envelopes.
- Provide an easy-to-read handout describing the purpose of the interview and the content of the questions.
- Provide a schedule and calendar so that interviewers can keep track of their progress.
- Consider providing the interviewer with visual aids. Visual aids may be extremely important when interviewing people in-person whose ability to speak or read may be limited. The preparation of audiovisual aids for use in an interview is relatively expensive and requires that the interviewers be specially trained in using them.
- Consider the possibility that some interviewers may need to be retrained and make plans to do so.

Computer-Assisted Telephone Interviews or CATI Computer-assisted interviewing is becoming increasingly accepted as a useful field work tool. With CATI, the interviewer reads instructions and questions to the respondent directly from the computer monitor and enters the responses directly into the computer (Bourque and Fielder 2003b). The computer, not the interviewer, controls the progression of the interview questions. No paper copies of the interview are produced, thus eliminating the need to find secure storage place for completed questionnaires.

CATI software programs enable the researcher to enter all telephone numbers and call schedules into the computer. When the interviewer logs on, he or she will be prompted with a list of phone numbers to call, including new scheduled interviews and callbacks. For example, suppose the interviewer calls someone at 8 a.m., but receives no answer. The CATI program can automatically reschedule the call for some other time. CATI programs are also available that enable specially trained interviewers to contact respondents with unique needs. For instance, suppose your study sample consists of people who speak different languages. CATI will allow multi lingual interviewers to log on with certain keywords; the computer will then direct them to their unique set of respondents.

The major advantage of CATI is that once the data are collected they are immediately available for analysis. However, having easy access to data may not always be a blessing. Some researchers may be tempted to analyze the data before the completion of data collection, and the preliminary results may be misleading. A main value of easy access to data, certainly in the early stages of data collection, lies in having the means to check on the characteristics of the respondents and to monitor the quality of the CATI interviewers in obtaining complete data.

Intensive interviewer training is crucial when using CATI in field studies. Interviewers must first learn how to use the CATI software and handle computer problems should they arise during the course of the interview. For instance, what will the interviewer do if the computer "freezes"? Further, the interviewer needs to practice answering questions invariably posed by respondents regarding the study's objectives, methods, human subjects' protections, and incentives. In fact, given the complexity of CATI, training may take up to a week. Thus, at the present time, use of CATI should probably be considered primarily when a study is well funded because it is a relatively expensive and specialized form of data collection.

CATI takes two forms. The first, which is most commonly used, consists of a lab or a facility furnished with banks of telephone calling stations that are equipped with computers linked to a central server. The costs of building the lab are extremely high and include assembling soundproof cubicles and having either a master computer that stores the data from the individual computers or linkage to a server. Additional resources are needed to cover the cost of leasing CATI software and hiring a programmer to install it. Training for this type of CATI is expensive, requiring a great deal of practice. There are also numerous incidental costs including those for headsets, seats and desks, instructional manuals, and service contracts for the hardware.

A second type of computer-assisted telephone interviewing system consists of CATI software programs that are run on laptops. With this type of CATI, the researcher only needs a laptop and access to a telephone connected to the Internet. In time, we can expect that the telephone will be superseded by wireless access to the Internet, making this type of telephone interviewing a desirable method for collecting data in the field and sending them to a central server. Moreover, this second type of CATI is appropriate for studies with a variety of funding levels because it is portable and relatively inexpensive. The portability of laptops, however, raises concerns about patient privacy. Laptops are sometimes shared or stolen, providing easy access to confidential respondent data. In anticipation of these concerns, laptops that are used for CATI should be dedicated to a single study, strict privacy safeguards must be enforced, and interviewers must receive special training to ensure proper CATI implementation and respondent protection. In the USA, patient privacy rules have become increasingly strict (e.g., through the Health Insurance Portability and Accountability Act or HIPAA), with costly penalties for violation.

Other Computerized Interview Methods Telephone interviews may not be appropriate for use in epidemiological studies with large populations who are geographically dispersed. These populations often differ in their linguistic, sociocultural, and ethnic traditions. Computerized interview programs are available that standardize the questions and also provide a mechanism for storing and retrieving data for analysis within and across large groups of people (Slimani et al. 2002).

15.5 How Can You Assure a Reliable and Valid Field Measure?

15.5.1 Pilot Testing

Once a field measure has been assembled, it should be tested to determine the ease with which it can be administered and to estimate the accuracy of the data. Pilot testing includes evaluating the logistics of administration as well as the ease of use of the form itself. The purpose of the pilot test is to answer these questions:

Questions Answered by Pilot Testing

- Will the measure provide the needed information? Are certain words or questions redundant or misleading?
- Are the questions appropriate for the respondents?
- Will information collectors be able to use the forms properly? Can they administer, collect, and report information using any written directions or special coding forms?
- Are the procedures standardized? Can everyone collect information in the same way?
- How consistent or reliable is the information?

15.5.2 Reliability and Validity: The Quality of the Measure

A ruler is considered to be a reliable instrument if it yields the same results every time it is used to measure the same object, assuming the object itself has not changed. A yardstick showing that you are 6 feet 1 inch tall today and 6 feet 1 inch 6 months from today is reliable.

People change over time. You may be more tired, angry, and tense today than you were yesterday. People also change because of their experiences or because they learned something new, but meaningful changes are not subject to random fluctuations. A reliable instrument will provide a consistent measure of important characteristics despite background fluctuations. It reflects the “true” score – one that is free from random errors.

A ruler is considered to be a valid instrument if it provides an accurate measure (free from error) of a person’s height. But even if the ruler says you are 6 ft 1 in. tall today and 6 months from now (meaning it is reliable), it may be incorrect, that is, invalid. This would occur if the ruler were not calibrated accurately, and you are really 5 ft 6 in. tall.

If you develop an instrument that consists of nothing more than asking a hospital administrator how many beds are in a given ward, and you get the same answer on at least two occasions, you would have an instrument that is reliable. But if you claim that the same instrument reflects the quality of medical care, you have a reliable measure of questionable validity. A valid measure is always a reliable one, but a reliable one is not always valid (Bernard 2000; Dawson and Trapp 2001).

15.5.3 Ensuring Quality: Selecting Ready-to-Use Measures

One way to make sure that you have a reliable and valid measure is to use one that someone else has prepared and demonstrated to be reliable and valid through careful testing. This is particularly important to remember if you want to survey attitudes, emotions, health status, quality of life, and health beliefs (Stewart and Ware 1992; McDowell and Newell 1996). These factors, and others like them, are elusive and difficult to measure. To produce a truly satisfactory measure of health, quality of life, and human emotions and preferences thus requires a large-scale and truly scientific experimental study.

15.5.4 Reliability

In reviewing a published field instrument (also, in assessing the quality of a homemade form) you should ask the following questions about four types of reliability: test-retest, equivalence, internal consistency, and interobserver reliability.

Test-Retest Reliability Does the instrument have test-retest reliability? One way to estimate reliability is to determine if someone taking the measure gives the same answers on more than one occasion. Test-retest reliability is computed by administering the measure to the same group on two different occasions and then correlating the scores from one time to the next to obtain a correlation coefficient or r value. Usually, to be considered reliable an instrument should obtain a correlation coefficient of at least 0.70 (Stewart and Ware 1992).

You can calculate test-retest reliability for single questions, subsets, or entire measures. For example, suppose you are studying the use of medications in a sample of older adults. The instrument you are using asks this question, "How many prescription medications do you usually take each day?" In order to assess the consistency of the respondents' answers, you would ask the same question twice: at baseline and then a second time, say 2 to 4 weeks later. Assuming medication-use rates in your sample tend to be stable over short periods of time, any differences in responses to the question can be assumed to reflect measurement error and not changes in the use of medications. To calculate test-retest reliability for an entire measure, you would administer its entire set of questions at two different points in time, score it, and then calculate the correlation coefficient for the two scores.

Equivalence Are alternative forms equivalent? If two different forms of a questionnaire are supposed to measure the same attitude, for example, you should make sure that people are likely to obtain the same score regardless of which one they take. If you want to use Form A of the instrument as a premeasured (before an intervention or treatment), for example, and Form B as a postmeasure (after the intervention or treatment), check the equivalence of the two forms to make sure one is not different from the other.

Equivalence reliability can be computed by giving different forms of the instrument to two or more groups that have been randomly selected. The forms are created either by using differently worded questions to measure the same attributes or by reordering the questions. To test for equivalence, you can administer the different forms (reordered or reworded) at separate time points to the same population, or if the sample is large enough, you can divide it in half and administer each of the two alternate forms to half of the group. In either case, you would first compute mean scores and standard deviations on each of the forms and then correlate the two sets of scores to obtain estimates of equivalence. Equivalence reliability coefficients should be at least 0.70.

Internal Consistency Another measure of reliability is how internally consistent the questions are in measuring the characteristics, attitudes, or qualities that they are supposed to measure. To test for internal consistency, you calculate a statistic called coefficient alpha, or Cronbach's alpha, named after the person who first reported the statistic (Anastasi 1982; Bernard 2000). Coefficient alpha describes how well different items complement each other in their measurement of the same quality or dimension.

Many researchers are not at all concerned with internal consistency because they are not going to be using several items to measure one attitude or characteristic. Instead, they are interested in the responses to each item. Decide if your instrument needs to consider internal consistency (see Example 15.5).

Example 15.5. Internal consistency

Internal consistency is important

A ten-item interview is conducted to find out patients' satisfaction with medical care in hospitals. High scores mean much satisfaction; low scores mean little satisfaction. To what extent do the ten items each measure the same dimension of satisfaction with hospital care?

Internal consistency is not important

A ten-item interview is conducted with patients as part of a study to find out how hospitals can improve. Eight items ask about potential changes in different services such as the type of food that might be served, the availability of doctors, nurses, or other health professionals, and so on. One item asks patients for their age, and one asks about education. Since this interview is concerned with views on improving eight very different services and with providing data on age and education of respondents, each item is independent of the others.

Interobserver Reliability: Kappa Kappa is a statistic used to measure interrater (or intrarater) agreement for nominal measures (Cohen 1960). What is a "high" *kappa*? Some experts have attached the following qualitative terms to *kappa*s:

0.0–0.2 = slight; 0.2–0.4 = fair; 0.4–0.6 = moderate; 0.6–0.8 = substantial, and 0.8–0.10 = almost perfect.

Here are some questions to ask about a published field instrument's validity:

15.5.5 Questions to Ask About a Published Instrument's Validity

- Does the instrument have predictive validity? You can validate an instrument by proving that it predicts an individual's ability to perform a given task or behave in a certain way. For example, a medical school entrance examination has predictive validity if it accurately forecasts performance in medical school. One way of establishing predictive validity is to administer the instrument to all students who want to enter medical school and compare these scores with their performance in school. If the two sets of scores show a high positive or negative correlation, the instrument has predictive validity.
- Does the instrument have concurrent validity? You can validate an instrument by comparing it against a known and accepted measure. To establish the concurrent validity of a new measure of quality of care, you could administer the new instrument and an already established, validated instrument to the same group and compare the scores from both instruments. You can also administer just the new instrument to the respondents and compare their scores on it to experts' judgment of the respondents' attitudes. A high correlation between the new instrument and the criterion measure (the established instrument or expert judgment) means concurrent validity. A concurrent validity study is only valuable if the criterion measure is convincing.
- Does the instrument have content validity? An instrument can be validated by proving that its questions accurately represent the characteristics or attitudes that they are intended to measure. An instrument that is designed to measure health beliefs has content validity, for example, if it contains a reasonable sample of facts, words, ideas, and theories commonly used when discussing or reading about the formation of beliefs about disease or health. Content validity is usually established by consulting the literature and by asking experts and prospective respondents whether the questions represent the knowledge, attitudes, and behaviors you want to measure.
- Does the instrument have construct validity? Construct validity means that the instrument measures what it purports to and not something else. Because of the difficulty of obtaining a true measure of the concepts and ideas that characterize epidemiological studies, construct validity must be established experimentally. One method of doing this is to administer the instrument to people who selected experts say exhibit the behavior associated with the construct. Usually, the experts based their judgments on theories that have empirical support and on clinical experience. If the people chosen by the experts to be exemplars of the behavior also obtain a high score (i.e., a higher score means greater evidence of the behavior), then the instrument is considered to have construct validity. This form of validity is usually established after years of experimentation and experience with the measure.

15.5.6 Suggested Guidelines For Pilot Testing

- Try to anticipate the actual circumstances in which the instrument will be conducted and make plans to handle them. For interviews, this means reproducing the training manual and all forms; for online surveys and mailed questionnaires, you have to produce any cover letters, return envelopes, and so on. Needless to say, this requires planning and time and can be costly.
- You can start by trying out selected portions of the instrument in a very informal fashion. Just the directions on a self-administered questionnaire might be tested first, for example, or the wording of several questions in an interview might be tested. This is sometimes called a "cognitive" pretest.
- Choose respondents for the pilot who are similar to the ones who will eventually complete the measure. They should be approximately the same age, with similar education, and so on.
- Enlist as many people in the trial as seems reasonable without wasting your resources. Probably fewer people will be needed to test a 5-item questionnaire than a 20-item one.
- For reliability, focus on the clarity of the questions and the general format of the instrument. Look for:
  - Failure to answer questions.
  - Giving several answers to the same question.
  - Writing comments in the margins.

Any one of these is a signal that the measure may be unreliable and needs revision. Are the choices in forced-choice questions mutually exclusive? Have you provided all possible alternatives? Is the questionnaire or interview language clear and unbiased? Do the directions and transitions make sense? Have you chosen the proper order for the questions? Is the questionnaire too long or hard to read? Does the interview take too long? For instance, you planned for a 10 min interview, but your pilot version takes 20.

Consider this: In a pilot of a self-administered survey of children's health behaviors, respondents were asked how often they washed their hands after eating. All six children between 8 and 10 years of age answered "always" after being given the choices "always," "never," and "I don't know." The choices were changed to "almost always," "usually," and "almost never." With the new categories, the same six children changed their answers to two "almost always" and four "usually."

15.6 Field Work Language and Culture

If you plan on translating an existing data collection instrument or measure, do not assume that you can automatically reword each question into the new language. Between the original language and the next language often lie cultural gaps. You may need to reword each question.

To avoid confusing people and even insulting them because you misunderstand their language or culture, you should follow a few simple guidelines. These involve enlisting the assistance of people who are fluent in the language (and its dialects) and pilot testing the measure with typical respondents. Suggested guidelines for translation always include the following.

15.6.1 Suggested Guidelines for Translation

- Use fluent speakers to do the first translation. If you can, use native speakers. If you can afford it, find a professional translator. The art of translation is in the subtleties – words and phrases that take years and cultural immersion to learn. If you use fluent speakers, you will minimize the time needed to revise question wording and response choices.
- Tryout the translated measure with three to five native speakers. Ask: What is this question asking you? Can you think of a better way to ask this question?
- Revise the measure with the help of the original translator.
- Translate the measure back into the original language. Use a different translator for this task. Does this "back translated" instrument match the original version? If not, the two translators should work together to make them match.
- Try the resulting measure on a small group (5–10) of target respondents. If the two translators could not agree on wording, let the group decide.
- Revise the measure.
- Pilot test the measure.
- Produce a final version.

15.7 Managing the Data

Data management consists of the methods used to store and organize information so that it can be analyzed. Data management (see also chapter ▶Data Management in Epidemiology of this handbook) starts with an analysis plan and ends with the final analytical operation. The analysis plan describes the hypotheses to be tested or research questions that will be answered. The plan is a guide to the data that will be collected, entered, and subsequently analyzed (Example 15.6).

Example 15.6. A portion of an analysis plan for an interview on health and alcohol use in the elderly
Hypothesis: More men than women will exceed drinking limits.
Variables: gender; drinking limits
Planned Analysis: Chi square to test for differences between numbers of men and women who exceed limits

Modifications to the original analysis plan can be expected, especially in large studies with a great deal of data.

A second data management activity is the creation of a code book. The contents of a code book may vary among researchers. Some researchers include in their definition only a description of the study's variables (such as [DRINK]) and how they are categorized or labeled (such as 1 = 1-2 drinks daily; 2 = 3 or more drinks daily; 9 = no data). Increasingly, many investigators are promulgating the view that code books should include all the information needed to reproduce the study. For example (Example 15.7), the Field Survey, a large California polling survey group, posts information such as below on its web site (http://field.com/fieldpoll/).

Example 15.7. Table of contents for a code book

I. Methods.

  A. Sampling.

    1. Sampling design to include eligibility criteria (e.g., 65 years of age and older; have had at least one drink in the past month.)
    2. Sampling strategies (e.g., stratified random sampling; convenience or opportunistic sampling; etc.)
    3. Sample size and justification.
    4. Recruitment and enrollment.
    5. Sampling statistics to include weight and sampling error calculations.

  B. Human subjects: Informed consent.

  C. Research design or how participants were assigned to groups (if appropriate); number and timing of instrument administration.

II. Data Collection.

  A. A copy of the instrument.

    6. The origins of the questions (e.g., adapted from a published instrument; created for this one.)
    7. Description of how each response is coded (e.g., 1 = yes; 2 = no; 9 = no data.)

  B. Training of data collectors; quality control.

  C. Information on reliability and validity.

III. A Data File Description.

The variable names [DRINK], labels (quantity and frequency) and values and value labels (1 = 1–2 drinks daily; 2 = 3 or more drinks daily; 9 = no data.)

A major problem in data management is how to handle missing data. Say, you mail 100 questionnaires and get 95 back. Is this a 95% response rate? Suppose that upon close examination, you discover that half the respondents did not answer question 5, and that none of the questions was answered by all respondents. With all that missing information, you cannot claim to have a 95% response rate.

What should be done about missing responses? In some situations, you may be able to go back to the respondents and ask them to answer the questions they omitted. In small studies, where the respondents are known, the respondents may be easily recontacted. But collecting information a second time is usually impractical, if not impossible, in most studies. Some studies are anonymous, and you do not even know who the respondents are. In institutional settings, you may have to go back to the Institutional Review Board to get permission to contact the respondents a second time. This may take too much time for your purposes.

Computerized questionnaires can be programmed so that the respondent must answer one question before proceeding to the next. Some respondents may find this approach frustrating, however, and refuse to complete the questionnaire. Although compelling respondents to answer all questions is touted as a major advantage of computer-assisted data collection, some researchers believe that forcing respondents to answer every question is coercive and unethical.

A key management activity is data entry, that is, the process of getting data into the computer. It usually takes three forms. In the first, someone enters data from a coded instrument into a database management program or spreadsheet. The data are then saved in as text or ASCII files, so that they can be exported into a statistical program like SPSS, SAS, or Stata. A second type of data entry involves entering data directly into a statistical program like SPSS, SAS, or Stata. In the third form of data entry, the respondent or interviewer enters responses directly into the computer. Data entry of this type is associated with computer-based measures including CATI and online surveys. The responses are automatically entered into database management systems or statistical programs (usually through special translation software). Programs are also available that will automatically convert one file format into another (say from SAS to Stata).

Database management programs, statistical programs and computer-assisted data collection with automatic data entry can facilitate accuracy by being programmed to allow the entry of only legal codes. For instance, if the codes should be entered as 001–010, then you can write rules so that an entry of 01 or 10 is not permitted. If you try to enter 01 or 10, you will get an error message. With minimum programming, the program can also check each entry to ensure that it is consistent with previously entered data and that skip patterns are respected. That is, the program can make sure that the fields for questions that are to be skipped by some respondents are coded as skips and not as missing data. Designing a computer-assisted protocol requires skill and time. No protocol should be regarded as error free until it has been tested and retested in the field.

Once the data are entered, they need to be cleaned. A clean data set can be used by anyone to get the same results as you do when you run the analysis. Data become “dirty” for a number of reasons including miscoding, incorrect data entry, and missing responses.

To avoid dirty data, make sure that coders or data enterers are experienced, well trained, and supervised. Check variable values against preset maximum and minimum levels, so that if someone enters 50 instead of 5, the maximum, you know there is an error. You can also minimize errors by making sure your coding scheme distinguishes truly missing (no response or no data) from don’t know and not applicable.

Run frequencies on your data as soon as you have about 10% of the responses in. Run them again and again until you are sure that the fieldwork is running smoothly. Frequencies are tabulations of the responses to each question. If your data set is relatively small, you can visually scan the frequencies for errors. For large databases with many records, variables, skip patterns, and open-ended text responses, you may need to do a systematic computerized check. All leading statistical programs provide for cleaning specifications that can be used during data entry and later as a separate cleaning process.

Several other problems may require you to clean up the data. These include having to deal with the complete absence of data because some questionnaires have not been returned, for instance, with missing data from questionnaire that have been returned, and with questionnaires that contain data that are very different from the average respondents.

15.8 What Are Reasonable Resources?

Fieldwork resources are reasonable if they adequately cover the financial costs of and time needed to conduct all activities in the time planned. This includes the costs of, and time for, hiring and training staff, preparing and validating forms, administering the instrument or measure, and analyzing, interpreting, and reporting the findings.

How much does it cost to conduct fieldwork? This question can be answered by obtaining the answers to seven other questions.

1. What are the major tasks?
2. What skills are needed to complete each task?
3. How much time do I have?
4. How much time does each task take?
5. Whom can I hire to perform each task?
6. What are the costs of each task?
7. What additional resources are needed?

Here is a checklist of typical field work tasks:

Field Work Task Checklist

✓ *Prepare the instrument for use in the field.*
  - Identify existing and appropriate instruments.
  - Conduct a literature review.
  - Contact other researchers.
  - Adapt some or all questions from existing instruments.
  - Prepare a new instrument.

✓ *Identify, enroll, and recruit subjects.*
  - Determine eligibility criteria (who should be included and excluded).
  - Determine sample size.
  - Identify sources for identifying respondents (e.g.., existing data bases, patients in a waiting room, patients with appointments).
  - Devise plans for coordinating respondents' willingness to participate and the study's field work needs. For instance, you may have to provide transportation for interviewers or participants.

✓ *Prepare documents for the IRB (Institutional Review Board).*
  - Develop procedures for insuring ethical principles of research. Such principles include respect for people and their autonomy, protecting people from harm and taking active steps to protect them, and balance potential risks with benefit from participation in the study.
  - Devise methods for ensuring the protection of the people who participate in field studies, including the preparation of fliers, recruitment letters, and informed consent forms.
  - Make provisions for protection against research misconduct including exaggerating findings or releasing them without permission.

✓ *Pretest the instrument.*
  - Identify a relatively small sample for the pretest.
  - Conduct a "cognitive" pretest by going over the instrument question by question with each respondent.

✓ *Pilot test the instrument.*
  - Identify the sample for the pilot test.
  - Obtain permission for the pilot test.
  - Analyze the pilot-test data.
  - Revise the instrument to make it final.

✓ *Administer the instrument.*
  - Hire staff.
  - Train staff.
  - Monitor the quality of administration.
  - Retrain staff.
  - Send out mail, supervise the questionnaire, conduct interview.
  - Follow up.

✓ *Manage the data.*
  - Code responses.
  - Prepare code book.
  - Consult with programmer.
  - Train data enterers.
  - Enter the data.
  - Run a preliminary analysis.
  - Clean the data.
  - Prepare a final codebook.

✓ *Analyze the data*.
  - Prepare an analysis plan.
  - Analyze the reliability and validity of the instrument.
  - Analyze the results of the study.

✓ *Report the results*.
  - Write the report.
  - Have the report reviewed.
  - Modify the report based on the reviews.
  - Prepare presentation.
  - Present the report orally.

15.8.1 Who Will Do It, and What Resources are Needed? Personnel, Time, and Money

Fieldwork happens because one or more persons are responsible for completing the required tasks. In a very small study, one or two persons may be in charge of developing field instruments, administering them, analyzing the data, and reporting the results. In larger studies, teams of individuals with differing skills are involved. Sometimes, a study is planned and conducted by the staff with the assistance of consultants who are called in for advice or to complete very specific activities.

First, you need to plan the activities and tasks that need to be completed. Once this is accomplished, you then decide on the skills required for each task. Next, you decide on the specific personnel or job descriptions that are likely to get you as many of the skills you need as efficiently as possible. For example, suppose your study design requires someone with experience in training interviewers and writing questions. You may just happen to know someone who needs a job and has both skills, but if you do not know the right person, knowing the skills needed will help you target your employment search.

The specific resources that are needed for each study will vary according to its size and scope and the number of skills and personnel needed to accomplish each task. Example 15.8 illustrates the types of skills and resources for a "typical" field study.

Example 15.8. Tasks, skills, and resources: an explanation

1. *Prepare the instrument for use in the field*

   If an instrument is to be adapted from an already existing instrument, expertise is needed in conducting literature reviews to find out if any potentially useful instruments are available. Sometimes, a reasonably good instrument is available: Why spend time and money to prepare an instrument if a valid one exists? It helps to have experience in the subject matter being addressed and to know who is working in the field and might either have instruments or questions or know where and how to get them.

   Selecting items or rewording them to fit into a new measure requires special skills. You must be knowledgeable regarding the respondents' reading levels and motivation and have experience writing questions.

   Preparing an entirely new instrument is daunting. A job description for an instrument writer would call for excellent writing skills and knowledge of all topics being assessed.

2. *Prepare materials for the IRB (Institutional Review Board)*

   US researchers cannot perform research with funds from the US government without approval from an Institutional Review Board or IRB – an independent group of people whose job is to evaluate if proposed research conforms to ethical principles (Brett and Grodin 1991, see also chapter ►Ethical Aspects of Epidemiological Research of this handbook). This is, however, not US specific. All high-resource countries have IRBs to ensure compliance with ethical principles. Most low-resource countries also have ethical reviews at the local or national level. The IRB typically requires a written explanation of the study plans (including rationale, purposes, and methods), the field forms, and one or more informed consent forms. The following informed consent form (see Box 15.2) has been approved by an IRB. As you can see, it provides potential respondents with descriptions of the study's purposes, the nature and characteristics of the tasks that will be required, and describes procedures for ensuring confidentiality.

Box 15.2. Sample consent form

The Prostate Cancer Network (PROCANE)

You are asked to take part in three telephone interviews and three self-administered questionnaires on your general health, your quality of life since being diagnosed with prostate cancer, and the quality of healthcare you have received while in the PROCANE Program. XXX MD, MPH is directing the PROCANE research study. Dr. XXX works in the Department of Urology at the University of YYYY. You are being asked to take part in the interviews and questionnaires because you are enrolled in the PROCANE program. You can choose to take part in this study or not. If you volunteer to take part in this study, you may stop taking part in the study at any time. This will have no effect of any kind on the health care you receive through the PROCANE program.

Disclosure Statement

Your health care provider may be an investigator in this research protocol. As an investigator he/she is interested in both your clinical welfare and your responses to the interview questions. Before entering this study or at any time during the study, you may ask for a second opinion about your care from another doctor who is in no way associated with the PROCANE program. You are not under any agreement to take part in any research project offered by your physician.

Reason for the Telephone Interviews and Self-Administered Questionnaires

The interviews and the questionnaires are being done for the following reason: To find out if the PROCANE program is meeting the needs of the patients enrolled in the program. During the telephone interview, a trained member of the PROCANE staff will ask you a series of questions about:

- Your health.
- Your quality of life since being diagnosed with prostate cancer, and
- The quality of the healthcare you have received while in the PROCANE program.

The self-administered questions will cover the same topics. But, you will be able to answer them on your own.

The PROCANE program will use your answers and the answers from other program participants to find out if the program is providing the right services to its participants and to find out if any changes need to be made to the program.

What You Will Be Asked to Do

If you agree to take part in this study, you will be asked to do the following things:

1. Answer three short (20 min) telephone interviews. The telephone interviews will ask you general questions about your health, your quality of life since being diagnosed with prostate cancer, and the quality of healthcare you have received while in the PROCANE program. You will be called to complete an interview when you first enroll in PROCANE, 6 months after your enrollment, and when you leave the PROCANE program. The interviews will be completed at whatever time is best for you.
   Sample questions:
   - How confident are you in your ability to know what questions to ask a doctor?
   - During the PAST 4 WEEKS, how much did pain interfere with your normal work (including both work outside the home and housework)? Would you say not at all, a little bit, moderately, quite a bit, or extremely?
   - How much of the time during the LAST 4 WEEKS have you wished that you could change your mind about the kind of treatment you chose for prostate cancer?

2. Answer three short (20 min) self-administered questionnaires. The self-administered questionnaires will ask you general questions about your health, your quality of life since being diagnosed with prostate cancer, and the quality of healthcare you have received while in the PROCANE program. The self-administered questionnaires will be mailed to you when you first enroll in PROCANE, 6 months after your enrollment, and when you leave the PROCANE program. The self-administered questionnaires can be completed at whatever time is best for you. A pre-paid envelope will be provided to you in which to return each questionnaire.
   Sample questions:
   - Over the PAST 4 WEEKS, how often have you leaked urine?
   - Overall, how big a problem have your bowel habits been for you during the LAST 4 WEEKS?
   - Overall, how would you rate your ability to function sexually during the LAST 4 WEEKS?

3. If you do not understand a question or have a problem with a self-administered questionnaire, you will be asked to call Ms. AAA at the PROCANE office at **1-800-000-000.** She will be able to assist you.

Possible Risks and Discomforts

You may be sensitive about answering questions that ask about your physical and emotional health or your experiences with the PROCANE program. However, you do not have to answer any question with which you are uncomfortable.

Potential Benefits to Subjects and/or to Society

The purpose of the telephone interviews and self-administered questionnaires is to improve the services that PROCANE provides to the men enrolled in the program. Your responses might lead to changes in the program that would improve the services that PROCANE provides.

Payment for Taking Part

No payment will be given to you for completing the telephone interviews or self-administered questionnaires.

Confidentiality

Any information that is collected from you and that can be identified with you will remain confidential. Your identity will not be revealed to anyone outside the research team unless we have your permission or as required by law. You will not be identified in any reports or presentations. Confidentiality will be maintained in the following ways:

- All interviews and questionnaires will be coded with a number that identifies you. Your name will not be on any of these materials.
- A master list of names and code numbers will be kept in a completely separate, confidential, password-protected computer database.
- All copies of the self-administered questionnaires will be kept in a locked file cabinet in a locked research office.
- All telephone interviews will be recorded in a confidential computer database.
- When analysis of the data is conducted, your name will not be associated with your data in any way.
- Only research staff will have access to these files.

Taking Part and Choosing Not to Take Part in Telephone Interviews and Self-Administered Questionnaires

You can choose whether to take part in this study or not. If you decide to take part in the telephone interviews and self-administered questionnaires you may stop taking part at any time. This will have no effect of any kind on the health care you receive through the PROCANE program. The investigator may withdraw you from this research if circumstances arise which warrant doing so.

Identification of Investigators

If you have concerns or questions about this study, please contact XXX, M.D., MPH, by mailing inquires to Box 000, Los Angeles, CA 900000-9990. He can be also reached at 1-800-000-000.

Rights of Participants

You may choose to end your agreement to take part in the telephone interviews and self-administered questionnaires at any time. You may stop taking part without penalty. You are not giving up any legal claims, rights or remedies because you take part in the telephone interviews and self-administered questionnaires. If you have questions about your rights as a research subject, contact the Office for Protection of Research Subjects, 2107 QQQ Building Box 951694, Los Angeles, CA 90095-1694, (310) 999-9999.

I understand the events described above. My questions have been answered to my satisfaction, and I agree to take part in this study. I have been given a copy of this form.

____
Name of Subject (Please Print)

____
Signature of Subject Date

Many IRBs also require detailed explanations of why each question on an instrument was chosen, how the study's participants were selected, and how you plan to ensure privacy for the respondent.

3. *Identify, recruit, and enroll patients*
Participants in field studies can be identified from existing databases (e.g., Medicare data base, physician specialty membership lists, patient appointment logs), and they can be approached in the field (e.g., a clinic's waiting room). To obtain a valid sample, the research must establish eligibility criteria that describe who will be included into and excluded from the study. Effective procedures must be devised to approach potential participants, screen for eligibility, inform eligible respondents about their role in the study, and enlist their cooperation. Often, these procedures need to be tested and retested until they achieve their desired goals. In the US as in most other countries, any contact with research subjects, including letters informing potential participants about a study or "scripts" to screen or enroll participants, must be approved by an IRB.
Recruitment letters (see Box 15.3) are often sent in advance of a study to inform respondents of the study and its purposes. The following is an example of a recruitment letter for a study of staffing and clinical policies regarding labor and delivery in all hospitals in a single US state. The letter was approved by an IRB and sent to the appropriate nurse manager at all hospitals in the state that delivered babies in a given year.

Box 15.3. Recruitment letter

<Letterhead and Logos>

Address
____
____
____

Date ____________

Dear Colleague (use name)

We are writing to invite you to participate in an exciting federally funded study of the range of clinical policies on Labor and Delivery (L&D) units in this state. Your participation includes taking part in a structured interview regarding policies and procedures on your (L&D) unit.

As you are well aware, much interest has been placed on nurse staffing policies in general, but to date most studies have centered on medical and surgical units. This will be the first study that is specifically designed to identify staffing patterns used on Labor and Delivery units, and to associate these staffing patterns with clinical policies and patient outcomes.

Likewise, there have been numerous isolated studies regarding the role of nursing support in labor, the effectiveness of doulas, nurse midwives, and various techniques of labor management (e.g. active management, "walking epidurals," hydrotherapy, etc). To date, however, there has been no systematic attempt to describe what is really happening on L&D units in the "real world." At the completion of our study, we hope to be able to answer the following types of questions:

- What does "active management" mean to you?
- How prevalent is hydrotherapy?
- What types of clinicians are trained in "teaching" hospitals?
- When do physicians need to be "in house"?
- How are L&D units staffing in the current environment of a nursing shortage?
- What strategies are being used to monitor cesarean rates?
- How are staffing and clinical policies related to maternal and neonatal outcome?

If you agree to participate, we will send you an advance copy of the L&D Clinical Policy Survey, and call to arrange a convenient interview time for you. You will be compensated $60.00 for your participation, which will take about 45 min to 1 h. Responses will be collated and serve as the first comprehensive overview of staffing and clinical policies on L&D units in this state. This project has been reviewed and approved by the Medical Center Institutional Review Board, and an information letter has been included for your review.

This project has been funded by the Agency for Health, and has been widely endorsed by representatives of agencies promoting a better understanding of healthcare practices, healthcare quality, and healthcare outcomes including, but not limited to the following:

- **Mary Smith**, Administrative Director of the Association of this State's Nurse Leaders
- **Tom Rodriquez**, CEO Medical Center, Current Board of the Hospital Association, and Past President of the State Hospital Association
- **Robert Johnson MD, MPH**, Center for Disease Control Director Division of Birth Defects and Developmental Disabilities

- **William Roberts, MD**, College of Obstetricians and Gynecologists, Chair District XXX

If you have any questions regarding this project, please feel free to contact us at 310 666-789. We thank you in advance for your participation in this exciting project.

Sincerely,

Yvonne Bree, RN, DrPH
Vice President & Chief Nursing Officer
YYY Medical Center

Mathilde Grun, MD, MPH
Director Maternal Fetal Medicine & Women's Health Services Research
YYYY Medical Center
Department Obstetrics & Gynecology

Recruitment letters tend to be most effective if they follow these suggestions:

1. Write the letter on letterhead. If possible place one or more logos on the stationery. The logos may be of the university or agency at which the study takes place and one or more of its supporters.
2. Personalize the letter, if appropriate. In the USA, "Dear John," is often handwritten over the "Dear Dr. Jones" to express collegiality.
3. Describe the purpose of the study. In this case, examples of study questions are included.
4. Describe the role each participant will play. This letter informs the respondent that joining the study means participation in an interview that may last up to 60 min.
5. Describe the incentives you are prepared to offer the respondent. In this case, the incentive is financial.
6. Inform the respondent about confidentiality. According to the letter, the Medical Center's Institutional Review Board has approved the study. An information sheet is to be included with this letter describing how confidentiality is to be ensured. If in doubt, or you do not have an information sheet, the letter should include a statement about protection of privacy.
7. Describe the source of funding for the study.
8. Give the names of any agencies or organizations that endorse or co-sponsor the study.

Sometimes, recruitment is done by telephone. As seen below (see Box 15.4), recruitment also means collecting data on refusers. Such data are used to determine if the recruitment approach is effective and to provide information on the similarity between persons who agree to participate and those who do not. If differences exist between participants and refusers, the external validity of the study may be compromised.

Box 15.4. Parent and child telephone recruitment script

Hello, my name is [FIRST AND LAST NAME] and I am calling on behalf of the LAUSD/UCLA study, *Finding Solutions Together*. May I speak to [NAME OF PARENT]?

1. [IF SOMEONE OTHER THAN RESPONDENT ASKS WHY YOU ARE CALLING, SAY:]

I'm calling about a research study being conducted by the school district. [CHECK ONE ANSWER]

a. No one by that name is at this number ⟶ ASK Q2
b. R not available ⟶ SKIP TO Q3
c. I am speaking to the parent or the parent comes to the phone ⟶ SKIP TO Q9
d. Refusal ⟶ SKIP TO Q8

2. [CONFIRM YOU HAVE DIALED CORRECTLY. ASK IF THE RESPONDENT WAS EVER AT THIS NUMBER AND IF THEY HAVE A NEW NUMBER FOR THE PERSON YOU ARE TRYING TO REACH. IF YOUR INFORMANT CANNOT GIVE YOU A NEW NUMBER, TRY DIRECTORY ASSISTANCE FOR A NEW LISTING. IF NO NEW NUMBER IS LISTED, NOTE AS NOT LOCATED.]
3. [SAY]: Is there a more convenient time to reach R?
   a. Yes ⟶ CONTINUE
   b. No ⟶ GO TO Q5
4. [SET CALL BACK APPOINTMENT]
   Date: ____________________
   Time: ____________________
   [SAY]: Okay. We will try back at that time. Thank you. [END CALL].
5. [SAY]: Is this the best number to reach R or do you have a better number for him/her?
   a. Yes ⟶ CONTINUE WITH Q7
   b. No ⟶ GO TO Q6
6. [RECORD NEW NUMBER]:______________________ ⟶ [SAY]: Okay, we will try him/her at this number. Thank you for your help. [END CALL].
7. [SAY]: Okay, thank you. We will try again another time. May I leave you my name and toll free number in case R wants to call me back?
   a. Yes ⟶ PROVIDE NAME AND TOLL FREE NUMBER. END CALL.
   b. No ⟶ THANK THE INFORMANT AND END CALL.
8. [SAY]: Thank you very much for your time. [END CALL. FILL OUT INFORMATION BELOW]:
   Refusal Information
   Who did you speak to? ____
   Reason for refusal?
   ____

Hello, my name is [NAME] (if not already introduced) and I am calling from [NAME OF SCHOOL]. I am calling you today because your child participated in the first part of our study and [NAME OF CHILD] reported on the questionnaire that [HE/SHE] has had difficulties related to stressful experiences that may benefit from our program. I am calling to see if you and your child are interested in participating in a program that can help children learn ways of coping with stressful experiences.

9. [SAY]: Are you interested in hearing more about this study?
   a. Yes ⟶ CONTINUE
   b. No ⟶ END THE CALL⟶ SKIP TO Q13

   We are conducting a study of youth in middle school who have experienced a very stressful event. The goal of the study is to find out ways that young people react to stressful life events, and whether a new program might help them feel better.

   If you and your child volunteer to be in this study, we would ask you to do the following things:

   - Your child would be given the opportunity to attend a group at school for children who have had stressful experiences and who could benefit from learning ways to improve the way that they feel and act. These groups will have five to ten students and a group leader and will meet once a week at school for 10 weeks. The group sessions will be audio taped for research purposes only. There will also be one meeting between your child and the counselor alone, about halfway through the program and four optional parent meetings for parents to learn more about how to help their child at home.
   - Not all children who qualify for this program will be in the program right away. Children will be chosen at random, like a flip of a coin, to start right away in the program or to receive the program in about 3 months. Those children who do not get into the program right away will also be offered other services to help them while they wait to start this school program.
   - In addition to the groups, we will ask that you and your child meet with an interviewer to answer questions about background about your child and family and how your child has been feeling recently. The parent interview will take about 1 h and will be set up at a time and place that is convenient for you. (Fill in description of questions) The child interview will take about 30 min at school (fill in descrip). We will ask you and your child to complete this interview before the program starts, and again at 3 months and at 6 months after starting the program, for a total of three times.
   - We will ask your child's teacher to complete a short checklist about your child's behavior at school before the program, at 3 months, and at 6 months.

10. [SAY]: Are you willing to meet with me to discuss your child's participation in this study in more detail, and if interested, complete the first parent interview?
    a. Yes⟶ GO TO Q11
    b. No⟶ GO TO Q13

11. [SAY]: Would you prefer to meet at the school or at your home?
    [CHECK ONE ANSWER]:

a. School
b. Home [IF HOME, OBTAIN ADDRESS]:
____
____
____

[SAY]: What is a good day and time for [YOU AND/OR YOUR CHILD] to do the interview?
Date:________________
Time:________________
[IF NECESSARY, OTHERWISE, GO TO Q13: SAY]: Do you think you and your child are able to understand and speak English well enough to participate in this program in English?

a. *Yes* ⟶ GO TO Q13
b. *No, cannot speak english well enough to participate* ⟶ SAY: I'm sorry to bother you. Thank you for your interest in participating in this study. Unfortunately, at this time we can only do this program in English. I would be happy to talk to you about other resources where your child can get help. Thank you for your time. [END CALL].

[SAY]: We would like to call you the day before the interview to remind you. Is it OK to call you at this number?
a. *Yes* ⟶ GO TO Q13
b. *No* ⟶ RECORD DIFFERENT NUMBER ⟶ GO TO Q12

12. [RECORD NEW NUMBER]
New number: (____) ______-________ ⟶ GO TO Q16
[SAY]: Thank you for taking the time to speak with me today. [END CALL].

13. [SAY]: Okay, thank you for taking the time to speak with me today. [END CALL. FILL OUT INFORMATION BELOW]:
Refusal Information
Who did you speak to? ________________________________
Reason for refusal? ________________________________
(Questions 14, 15, and 16 omitted to save space.)

4. *Pretest the field instrument*
Pretesting means identifying a relatively small sample of people who are willing to go through each question with you and tell you what it means to them. (This method is called "cognitive pretesting.") Do the participants agree with your interpretation of each question and response? Usually pretests are done using early versions of the study, and so glitches should be expected. You will need to find a secluded place to conduct the pretest, which is almost always an interview. A trained interviewer is needed. Strict rules are needed for recording participants' answers. Experienced personnel are needed to interpret pretest results and translate them into improvements.
5. *Pilot-test the instrument*
Pilot testing means having access to a group of potential respondents that is willing to try out an instrument that may be difficult to understand or complete. Expertise is needed

in analyzing the data from the pilot test, and experience in interpreting respondents' responses is essential. Additional knowledge is needed in how to feasibly incorporate the findings of the pilot test into a more final version of the instrument.

6. *Administer the instrument*

   Face-to-face and telephone or computer-assisted interviews require skilled and trained personnel. Interviewers must be able to elicit the information called for by the interview questionnaire and record or code the answers in the appropriate way. Interviewers must be able to talk to people in a courteous manner and listen carefully. Also, they must talk and listen efficiently. If the interview is to last no longer than 10 min, the interviewer must adhere to that schedule. Interviews become increasingly costly and even unreliable when they exceed their allotted time.

   Among the types of expertise required to put together a mail questionnaire is the ability to prepare a mailing that is user friendly (e.g., includes a self-addressed envelope) and the skill to monitor returns and conduct follow-ups with those not responding. Email surveys also require similar skills. The instrument used to collect data must be user friendly, and you need the skills to keep track of responses and then follow up non-respondents.

   If you plan to conduct online studies, you should consider becoming familiar with commercial software packages that guide survey preparation and analysis. Training in their use may be necessary for projects that do not have a specialist. If the study is being done at a local site (hospital, clinic), then privacy concerns associated with the Web may be especially daunting.

   Expertise is needed in defining the skills and abilities needed to administer the study's field measures and in selecting people who are likely to succeed in getting reliable and valid data. Training is the key. For example, a poorly trained telephone interviewer is likely to get fewer responses than a well-trained interviewer. Because of the importance of training, many large studies use educational experts to assist them in designing instructional materials and programs for training.

   In large and long-term studies, quality must be monitored regularly. Are interviewers continuing to follow instructions? Who is forgetting to return completed interviews at the conclusion of each 2-day session? If deficiencies in the process are noted, then retraining may be necessary.

7. *Manage the data*

   Managing data means programming, coding, and data entry. It also means setting up a database. Programming requires relatively high-level computer skills. Coding can be very complicated, too, especially if response categories are not precoded. Training and computer skills are needed to ensure that data enterers are expert in their tasks. Finally, data cleaning can be a highly skilled task involving decisions regarding what to do about missing data, for example.

8. *Analyze the data*

   Appropriate and justifiable data analysis is dependent on statistical and computer skills. Some studies are very small and require only the computation of frequencies (number and percentages) or averages. Most, however, require comparisons among groups or predictions and explanations of findings. Furthermore, measures of attitudes, values, beliefs, and social and psychological functioning also require knowledge of the statistical methods for ascertaining reliability and validity.

9. *Report the results*

   Writing the report requires communication skills, including the ability to write and present results in tables and figures. Oral presentations require ability to speak in public and to prepare presentations. It helps to have outside reviewers critique the report; time must be spent on the critique and any subsequent revisions. Expenses for reports can mount if many are to be printed and disseminated.

Use the following checklist as a guide in calculating costs and preparing field study budgets.

Costs of Field Work: A Checklist

- ✓ Learn about direct costs. These are all the expenses you will incur *because* of the fieldwork. These include all salaries and benefits, supplies, travel, equipment, and so on.
- ✓ Decide on the number of days (or hours) that constitute a working year. Commonly used numbers in the USA are 230 days (1,840 h) and 260 days (2,080 h). You use these numbers to show the proportion of time or "level of effort" given by each staff member. Obviously these numbers will vary from country to country.
  Example: A person who spends 20% time on the study (assuming 260 days per year) is spending 0.20 × 260, that is, 52 days, or 416 h.
- ✓ Formulate fieldwork tasks or activities in terms of months to complete each.
  Example: Prepare instrument during months 5 and 6.
- ✓ Estimate the number of days (or hours) you need each person to complete each task.
  Example: Jones, 10 days; Smith, 8 days. If required, convert the days into hours and compute an hourly rate (e.g., Jones: 10 days, or 80 h).
- ✓ Learn each person's daily (and hourly) rate.
  Example: Jones, US $320 per day, or US $40 per hour; Smith, US $200 per day, or US $25 per hour.
- ✓ Learn the costs of "benefits" (e.g., vacation, pension, and health) – usually a percentage of the salay.
  Example: Benefits are 25% of Jones's salary. For example, the cost of benefits for 10 days of Jones's time is 10 × 320 per day × 0.25, or US $800.
- ✓ Learn the costs of other expenses that are incurred specifically for *this* study.
  Example: One 2 h focus group with ten participants costs US $650. Each participant gets a US $25 honorarium for a total of US $250; refreshments cost US $50; a focus group expert facilitator costs US $300; the materials costs US $50 for reproduction, notebooks, nametags, and so on.
- ✓ Learn the indirect costs, or the costs that are incurred to keep the study team going. Every individual and institution has indirect costs. Indirect costs are sometimes a prescribed percentage of the total cost of the field work (e.g., 10%).
  Example: All routine costs of doing "business," such as workers' compensation and other insurance; attorney's and license fees; lights, rent, and supplies, such as paper and computer disks.
- If the fieldwork lasts more than 1 year, build in cost-of-living increases.
- Be prepared to justify all costs in writing.
  Example: The purchases include US $200 for 2,000 labels (two per student interviewed) at US $0.10 per label and US $486 for one copy of MIRACLE software for the data management program.

15.9 Conclusions

Fieldwork in epidemiological studies involves collecting information to describe, compare, or explain knowledge, attitudes, and behavior about the health and health care of populations. To assure reliable information, field work depends upon asking straightforward questions. Straightforward questions are purposeful, concrete and expressed as complete questions. Responses may be considered as nominal or categorical, ordinal, and numerical. Open questions allow the respondent to give answers in his or her own words. Coding open responses may be difficult. Closed questions provide the respondent with choices. They are easier to interpret and analyze than open questions but may not provide in-depth information. An instrument's length is dependent upon the resources available to develop and validate a questionnaire. Keep in mind that very long instruments may tire some respondents, thereby reducing the reliability and validity of the results. Questions should be ordered logically and each must be related to the expressed purposes of the study. Relatively simple questions should go first, hardest second. Demographic information is often called for in last place.

Make certain that respondents understand the purposes of the study and each question you plan to ask. If questionnaires are to be completed by mail, include self-addressed envelopes. Try to keep questionnaires as short as possible. For online surveys, avoid the need for the respondent to follow many steps: keep the questionnaire short and easy to use. For all self-administered questionnaires, make sure they are pretested and pilot tested; when possible look at preliminary data to check that all questions are being answered. Interviewing only succeeds with trained interviewers and a method for monitoring the quality of the process. Consider incentives to compensate respondents for their time. Pilot testing is essential to ensure the collection of reliable data. Reliability refers to the consistency with which questions are answered, while validity refers to the accuracy of the answers. Common types of reliability to consider include test-retest and internal consistency. Common types of validity are content, concurrent, predictive, and construct. To improve reliability and validity, check to see that the language and cultural assumptions of the field study are consistent with those associated with the population being studied. Consider using advance letters and incentives to encourage participation and improve response rates. Make certain all measures and the study's logistics are pretested and pilot tested. Regardless of the methods used to collect data in the field, be ever mindful of the need to ensure confidentiality of responses. Field work tends to be costly because of its dependence upon human capital including trained field workers and data managers.

16.1 Introduction

Accurate exposure assessment is a prerequisite for an efficient study design, more than ever before, because of the increasing challenges that epidemiology has to face to demonstrate low increases in risk, to disentangle mixed potential risk factors in disease causation, and to provide exposure-response relationships for policy makers.

Exposure assessment is the process that leads to establishing a dichotomy between exposed and non-exposed subjects and/or introducing a level of classification between subjects. A prerequisite for any epidemiological study is that there is variability of exposure to the agent of interest within a population and that this variability between subjects (inter-individual variability) will overcome individual variation of exposure (intra-individual variability).

This chapter describes what choices have to be made for a proper exposure assessment depending on the pathological process under study, gives an overview of the different instruments available for this assessment, and highlights some specific difficulties in this process (retrospective assessment, ecological measurement, or multiple exposures). Finally, measurement errors and ways for controlling them are described.

16.2 Definition of Exposure and Exposure Assessment

Exposure can be defined as a contact of an individual with an agent through any medium or environment. An agent can also be thought of as a susceptibility characteristic. The agent is not necessarily considered to be harmful (e.g., exercise or fiber in the diet). *Exposure assessment* aims to identify whether a person is exposed or not (a dichotomous classification) to a particular agent and, if the individual is exposed, to develop a ranking of subjects by exposure level.

16.2.1 Types of Exposure

An exposure may be to a chemical, a biological, a physical, or a societal agent in the external environment (e.g., cadmium, endotoxin, ionizing radiation, and the existence of a support system, respectively). It may be a characteristic of an individual (e.g., weight or physical activity) or a perception of an individual (e.g., lack of control in the workplace). Finally, it may be a biological agent in the body (e.g., herpes virus), a metabolite of an external agent (e.g., 1-hydroxypyrene, a metabolite of polycyclic aromatic hydrocarbons), a substance representing a pathway of action (e.g., DNA-PAH adducts), or the presence of a polymorphism (e.g., NAT wild type). In this chapter, we use the term exposure to apply to all of these, rather than separating external agents from internal agents. The concept of dose is discussed later in this chapter.

16.2.2 True Risk Factor or Surrogate

Ideally, an exposure assessment should focus on the "true" (or causal) risk factor, although it is acknowledged that complete knowledge of contributive causes is not necessary for an effective prevention. In many situations, however, a *surrogate* must be evaluated because the true risk factor has not yet been identified or only a surrogate can be measured. For example, the causal role of inhaled benzo[a]pyrene in the carcinogenicity of cigarette smoking for the lung may never be formally proven because the true risk factor (i.e., the total amount of inhaled benzo[a]pyrene over a period covering many decades) is impossible to measure (Rothman and Greenland 1998). The International Agency for Research on Cancer (IARC) has classified certain work environments as probably carcinogenic to humans, without identifying the specific compound(s) responsible for this health effect (e.g., the process of refining nickel). Thus, although the true risk factor(s) linked to a health effect may not yet be identified or quantified (e.g., nickel refining, tobacco smoking), measurement of a surrogate remains very useful for research and public health purpose. Protective measures and monitoring of exposure can then be implemented. Medical surveillance in the workplace, which usually includes some kind of biological monitoring of compounds known for their toxicity (e.g., urinary cadmium), may be required. A surrogate is useful for identifying factors of variation for the exposure, establishing presumptive causal associations and dose-response relationships, and narrowing the search for the true risk factor(s).

16.2.3 Dose Versus Exposure

The term *exposure* usually refers to contact with an agent in the external environment as indicated above, common nomenclature also may include agents in the body. Measuring an external agent should, but may not, take into account all the exposure sources (e.g., at home, at work, and leisure time), the time spent in each (i.e., activity patterns), and the individual susceptibility to this agent (e.g., due to physical exercise, diet, and physiological and genetic characteristics). These variables will affect the internal *dose* measured in human tissue or fluid. A biological marker of internal dose therefore comes closer to the relevant measure of exposure in some circumstances than an external exposure. This will be discussed more in Sect. 16.3.1. In the rest of the text, the term *exposure* will be used to describe agents that are being estimated for use in exposure- (or dose-) response relationships in an epidemiological study. Dose will be used to describe the level of the true risk factor at the target organ.

16.2.4 Selection of Metric

Once the agent or a scenario to be investigated in the epidemiological study has been selected, the relevant dimensions to quantify this exposure need to be determined. The appropriate quantification of exposure (metric) should reflect the toxic mechanism of action for the agent and disease of interest. The choice of this metric depends on the knowledge about the supposed biological mechanism inducing the health effect. Chronic diseases such as cancer, for example, are thought to be a result of lifetime exposure, so that the exposure metric often studied is *cumulative exposure*, whereas acute diseases such as asthma are thought to be due to recent high exposures, so that the metric often studied is *peak exposures*.

If there is a biological level above which detoxification processes of the organism are impaired (threshold), the *dose rate* (*average*) of an exposure or a peak exposure may be more relevant than cumulative exposure, because exposures below such a threshold would not cause any deleterious effect.

Oftentimes, however, the biological mechanism of the disease process is not known. In such cases, it is useful to explore multiple metrics such as cumulative (lifetime), highest, average (dose rate), highest short-term (peak) exposure, and components of these (e.g., cumulative exposure level or time above a particular exposure level). For example, the induction of carcinogenesis by a mutagenic compound is, theoretically, initiated at any dose, but the mechanism necessitates a long (sometimes several decades) induction period (*latency*). In this case, recent exposure (immediately preceding diagnosis) is not pertinent, and often measurement of past exposure is “lagged,” that is, exposure occurring in years just before diagnosis of the disease is not taken into account. The exposure metric, then, may incorporate a lagged latency. When an adverse effect is expected to occur only above a certain dose (*threshold*), for instance, in acute toxicity, a metric representing a quantitative level above the threshold would be more appropriate than a metric estimating the total exposure.

Often, the total exposure to a given compound received over a particular time period (cumulative exposure) is the relevant parameter in a pathological process. There are, however, several ways to receive the same cumulative exposure: a high intensity for a short period of time or a lower intensity over a longer period. For instance, the history of tobacco smoking is often summarized by a cumulative index (pack-years), that is, the number of years of smoking times the average number of packs of cigarettes smoked every day during the smoking period. This index, or any equivalent based on the product of duration of exposure by an intensity level, does not distinguish between the roles of *duration* of exposure, irrespective of the rate of exposure, and *intensity* of exposure at every instant.

Selection of an exposure metric that does not appropriately describe the pattern of exposure to the agent being investigated as it relates to the disease of interest will result in misclassification and loss of statistical power (see Sect. 16.5).

16.3 Exposure Data

Because exposures can have different natures, the sources of data used in exposure assessments differ. Exposure data can be thought to be of two types: measurement data (*direct*) and *indirect* information (e.g., questionnaire information, diaries, and records of surrogate information).

16.3.1 Measurement Data

Measurement data are generally considered the most accurate type of exposure data because they are objective measures of exposure. Measurement data include measurements of chemical hazards on the skin and chemical or radiation hazards in the food, air, or water in the general environment or in the workplace. They may be measures of quality of life, such as levels of stress. They also include measurements of human health, such as physical activity levels, physiological measurements, such as blood pressure or weight, or measurements of agents in biological tissues, such as drugs or nutrients. They also include measures of internal exposure or effect, such as blood lead levels and DNA adducts, respectively. For more examples of biological markers, please refer to chapter ▸Statistical Methods in Genetic Epidemiology of this handbook.

Measurements may be taken for purposes of an epidemiological study or may be available from existing records. Although individual measurement data are often thought to be the gold standard, they can be subject to substantial biases. Measurements may not represent the intensity of exposure during the relevant time window, for example, current levels of physical activity may not reflect earlier levels of physical activity. The number of measurements on any individual is generally small, and because the variability of some exposures is large (e.g., in air and in water), one or a few measurements may not reflect the metric of interest, such as long-term exposure levels.

In addition, historical measurement data in records may not represent the true exposure level, because the purpose of the data collection was taken for reasons other than to obtain an estimate of the exposure metric of interest to the study investigator. For example, measurements of agents in the workplace often have been taken to evaluate compliance with exposure regulations, and it has been speculated that such data may reflect higher exposures than the true long-term exposure level. Moreover, the analytical method may not have measured the true risk factor (e.g., historical measurements of cholesterol did not distinguish between high- and low-density cholesterol, and many historical measurements of dust in the air did not distinguish respirable dust from inhalable dust).

Biological measurements of exposure (e.g., carbon monoxide in the breath) *or of effect* (e.g., cholinesterase levels in the blood) are generally thought to be the gold standard, because they most closely reflect the dose received by the target organ. (Note that biological measurements can be both exposure data and the outcome, depending on the study design. Here, only biological measurements used as exposure data are discussed.) There are many limitations to this type of measurement, however. The variability of the concentration of an agent in the body is often greater than that seen in the external environment, so that if the number of measurements is limited, a mean of those measurements may not accurately reflect the average exposure. Some biological measurements may not reflect the dose at the target organ. Instead, they may reflect the amount of agent that was not received by the target organ (e.g., if the agent was measured in the urine) or the amount that was metabolized in the body (including by organs other than the target organ). In such cases, it is assumed that the amount measured and the amount in the target organ are highly correlated, but this correlation is likely to vary by agent or by organ and may vary considerably by individual. There are, in addition, no long-term biomarkers for most agents, and current levels may not reflect long-term exposure levels. Moreover, biological measurements reflect the body burden at one point in time. Even if the agent has a long half-life, the measurement may not be an accurate reflection of the total amount received due to metabolism and elimination over time (e.g., McGrail et al. 1995).

Biological measurements are often invasive and costly. For some known risk factors, only invasive techniques are available for biomonitoring, and exposure assessment, therefore, still relies on more traditional instruments. For example, asbestos is a recognized potent carcinogen. One way to evaluate asbestos exposure would be to measure the asbestos in broncho-alveolar lavage specimens. This invasive and expensive technique, however, is not routinely feasible, nor is it appropriate, because it does not reflect past exposure, which is the most relevant for cancer induction. In this example, exposure assessment must rely on indirect methods of measurement such as questionnaires or records.

If the measurement data were taken after the onset of disease (which is very difficult to determine because the onset may not be detectable), the measurements may be an effect of the disease, rather than a precursor. An example of such a measurement is serum levels of androgens and prostate cancer (Hsing 2001).

Because of their cost, biological measurements are used more often in case-control or cross-sectional studies or in a sample of a cohort, rather than for an entire cohort. In spite of these limitations, biological measurements can provide key insights into the toxicological mechanisms of the agent and can be useful in estimating exposure levels if used judiciously. They can be useful in estimating recent or chronic exposure levels that have low variability over time. In addition, they represent concentrations received from all sources of exposure, so that the total amount of exposure received is better estimated. This advantage is especially important when individual work practices, such as hand washing before eating, can affect internal concentrations.

Measurements of the external environment are thought to be a lower gold standard than biological measurements because they do not measure the internal dose received. They too represent only one point in time. This type of measurement often reflects only one source of exposure when several sources may be contributing to a study subject's overall exposure (e.g., pesticide exposures can occur from application at work, in the house and garden, from contamination of the soil from nearby farming operations, and from consumption of pesticide-contaminated food and water). Thus, measurement of only one source may cause other important sources to be missed. Measuring exposures from a single source, therefore, without considering other sources, can result in lower estimates of exposure and an overestimation of disease risk. In addition, external environmental measurements do not provide an estimate of internal dose. There are several advantages of this type of measurement over biological measurements, however. External environmental measurements are non-invasive and less expensive, and the number of agents for which there are analytical methods is larger. The variability of the concentration of an agent in the external environment usually is lower than the intra-individual variability in the body, meaning that when a small number of measurements is available, a small number of environmental measurements on a group of similarly exposed workers are likely to result in a better estimate of the true exposure level than a small number of biological measurements.

Finally, when measurements are taken for the purpose of an epidemiological study, investigators should ensure that the data are collected in a way to reflect the metric being investigated. The sampling strategy should be developed to reflect the goals of the study (e.g., randomly or randomly within strata). Strict quality control methods should be followed. When records of measurements are being used, investigators should review the collection, analytical, and quality control methods to determine the accuracy of the data and how the measurements compare to the metric being assessed in the epidemiological study.

16.3.2 Indirect Exposure Data

The second type of exposure information, indirect data, is derived from questionnaires, diaries, or records identifying measurements of exposure surrogates. Questionnaires may describe measurement data, for example, cigarettes consumed per week or more subjective measures, such as the perception of control at the workplace. Examples of indirect data from diaries or records of surrogates are the amount of milk products consumed or distance of a residence from a hazardous waste site, respectively. As with measurement data, information from questionnaires, diaries, or records may be problematic.

Questionnaires are developed by study investigators to ensure that information is collected in a structured, standardized approach to reduce differential questioning of cases and controls and to ensure that the data are as complete as possible.

The circumstances under which the questionnaire is administered (in person, telephone, mail, at home, or in a hospital) may reflect the level of response. Development and administration of the questionnaire and data entry and cleanup is costly and time-consuming. Computer-assisted personal and telephone interviews (CAPI and CATI, respectively) have substantially reduced data entry and cleanup costs, but their development is more expensive than using a paper copy. They can, however, include logic checks within the questionnaire to catch errors immediately, rather than long after the interview has taken place (cf. chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook). Questionnaires are usually administered by professional interviewers rather than by scientists knowledgeable of the areas being investigated, so that if a respondent asks for clarification or provides a response that is unclear or inappropriate, the interviewer may not be able to respond in a way to increase the quality of the data. Interviewer training and inclusion of probing questions are means to reduce this problem.

In spite of these limitations, oftentimes, questionnaires are the only way to collect information on exposures.

Designing a questionnaire consists of establishing a list of questions in a predefined order, aimed at eliciting the presence of and often the amount of a given exposure. A questionnaire is defined by its content, the time span it covers in a subject's life, and its format and wording. Common sense principles should guide the construction of a questionnaire. Thus, each question and the flow of the questionnaire should be clear and subject to minimal misinterpretation. Administration of the question should not be a substantial burden to the subject, either in regard to the amount of time spent answering the questionnaire, the complexity of the information being collected, or the sensitivity of the questions. One hour is usually considered the maximum amount of time that respondents retain interest, but it may be much less. Aids can be used to help the respondent accurately recall information, such as lists of pesticides, logos, trademarks of products used, and pictures of medication bottles.

The list of questions in the questionnaire should include only those that the respondent can answer and that will ensure an accurate assessment of exposures. As the questions are developed, an analytical strategy also should be developed on how the responses will be used. A minimum set of questions should be asked that ensure maximum efficiency, but a small number of additional questions may be included for cross-checking data. A few "red herring" questions (i.e., questions that are included to determine the accuracy of the responses, such as inserting in a list of real products, a product with a fake name) are often useful to evaluate the responses. More details on conducting interviews can be found in chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook.

The time span of the questionnaire is important. Respondents can more easily report on current exposures than historical ones. Past exposures, however, may be more important than current exposures in the etiology of chronic diseases, but collecting varying information over many years is problematic. Recollection of important life events at the earlier age can improve recall.

The format of the questions will determine the response rate to the question and the accuracy of the response. Open-ended questions (e.g., "What type of exercise did you do when you were in your twenties?") often gather more information than closed-ended questions because respondents can identify important exposures that are not anticipated by the investigator. Open-ended questions, however, require extensive coding, and some information collected is likely to be useless. Furthermore, important exposures may not be recalled. Close-ended questions (e.g., "Did you do any of the following in your twenties: walk? jog? play tennis? etc.") take more time, but the respondent is less likely to forget one of the identified exposures, making the information collected generally more accurate. If, however, the respondent had an important exposure to an agent not on the list, it may not be reported. Open-ended questions may be used in pilot studies to develop more standardized closed formats. Wording should be geared to the educational level of the respondents. In the USA, the reading level of a 14-year-old is generally considered appropriate for general population studies. When developing questionnaires, the investigator should consult one of the many references on questionnaire design (Sudman and Bradburn 1982; Armstrong et al. 1994; cf. chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook).

Screening questions are useful to minimize the time spent on answering inapplicable questions. Screening questions may require a simple yes or no (e.g., “Did you ever take birth control pills?”), or they may be formatted to screen out the lower exposed individuals (e.g., “Did you ever take birth control pills for at least one year?”).

Diaries are another source of exposure information and have been used most frequently for diet and to a lesser extent, physical activity. In a diary, the respondent reports the amount of exposure (e.g., red meat consumption) at some identified frequency (e.g., daily). Diaries are best used when exposure occurs frequently, because if the frequency is too low, the respondent is likely to forget to complete the diary. Time spent recording the information should be minimal (e.g., less than 1 minute), and the time covered by the diary should be short (e.g., 1–2 weeks) to maximize compliance. Diaries should be formatted in a way to ease data entry as much as possible (e.g., check boxes rather than open-ended questions).

Records are often needed for retrospective exposure assessment (see Sect. 16.4.3). Records of surrogate information (including geographic information systems (GIS)) are often used in ecological studies of the environment. Thus, amount of corn grown in various counties may be used to rank individuals with presumed exposure to herbicides. The data in such records may or may not have been accurately collected, but even if the data were accurately collected, the design of the data collection may impact the usefulness of the data in an epidemiological study. For example, the Toxic Release Inventory of the US Environmental Protection Agency collects emissions data from private businesses. These data can be used to identify geographical areas with significant releases of agents into the air, water, and ground. However, there is a minimum amount of contaminant that must be released into the environment before reporting is required. Companies releasing smaller amounts of agents into the environment are not identified. Thus, if there are many small companies of one type in an area, the emissions reported in the database may suggest very low levels that may not, in fact, be low at all. In such cases, there may be no better data available for use in a study, but the protocol and quality control measures for the data collection should be carefully evaluated prior to use of such data, so that the investigator is aware of the strengths and limitations of the data. It may be useful to compare such data to other records systems as well. For example, a study of farmers’ responses on pesticide use found reasonably good agreement with suppliers’ information on pesticides bought by the farmer (Blair and Zahm 1993).

In summary, the choice of a measurement instrument is determined by knowledge of the disease (what is the true risk factor?), the feasibility of the measurement (its invasiveness and the ease of use in the exposure assessment), the cost, and its validity and reproducibility characteristics (see Sect. 16.5).

16.4 The Process of Exposure Assessment

The process of exposure assessment aims at the construction of an individual exposure estimate, from exposure data available, in order to produce a valid and efficient classification of subjects. Exposure data are usually imperfect, however, and there is a need for exposure *assessment* (rather than measurement), in order to approach the relevant dose.

The main steps for building exposure estimates and classification of subjects are described below. The specific problems resulting from the retrospective character of exposure assessment, the use of ecological estimates and the handling of multiple correlated exposures will also be presented, where ecological estimate refers to estimating an exposure level for a group of individuals, rather than for each individual separately.

The process of exposure assessment can be straightforward to relatively complicated, depending on the level of detail and the accuracy of the exposure data (e.g., surrogates of exposure may warrant less-intensive exposure assessment efforts than accurate and detailed exposure information on the true risk factor), the goal of the study (e.g., hypothesis generating or hypothesis testing), and the resources of the investigator.

16.4.1 Creating an Exposure Estimate

Some exposure data need little processing such as information obtained directly from answers to a questionnaire, for example, smoking habits or intake of some kind of nutrients. In other investigations, some type of processing is needed. In the case of diet, for example, food composition tables allow the computation of the amount of nutrients across food groups (e.g., total vitamin A from various fruits, vegetables, meats). These tables take into account the mode of preparation and of preservation of the food. They are usually country-specific and need regular updating for an accurate translation from food groups into nutrients. For more details on assessment of micronutrients, we refer to chapter ▸Nutritional Epidemiology of this handbook.

Similarly, exercise can be measured using an accelerometer that measures movement, so that the total amount of energy expended can be estimated for an individual getting several types of exercise (Ainsworth et al. 1999).

In environmental studies (cf. chapter ▸Environmental Epidemiology of this handbook), the estimation process often is more complicated. These types of studies often make use of recognized pollutant dispersion models using exposure data reported by the subjects as well as exposure data from other records systems. Recently, various approaches relying on geographical-based information systems and land-use regression modeling have been developped to estimate eposure to traffic-related air pollutants (Wu et al. 2011). Estimates of trichloroethylene were developed for a municipal water system in a study of neurobehavioral effects using information on piping, flow input, water demand, and other variables, and a geographic information system (GIS) on the water distribution systems (Reif et al. 2003).

Occupational epidemiology (cf. chapter ▶Occupational Epidemiology of this handbook) also tends to estimate exposure, often retrospective (see Sect. 16.4.3), from multiple pieces of exposure information, but to date, there are no recognized methods. In the past, experts have based their estimates on job titles and industry with little documentation as to how these estimates were derived. Recently, more attention has been paid to identifying *determinants of exposure* (e.g., factors that affect exposure) (Vermeulen et al. 2002). Examples of determinants include the presence of ventilation, the use of protective equipment, and the quantity of the contaminant in the workplace. Models to estimate an exposure score can be developed by simply assigning weights to the values of the determinants. For example, for a study of man-made mineral fiber, type of emission (active, passive), handling of fibers, presence of controls, protective equipment, and other variables were identified as affecting exposures (Cherrie et al. 1996). Variations in these variables across jobs resulted in the assignment of different scores. Use of these determinants in statistical models allows for a more rigorous and transparent estimation process, however, such as for a study of paving workers where measurement data and determinants such as the type of paving (oil, mastic) and the use of tar were used to develop an estimation model for benzo(a)pyrene exposures (Burstyn et al. 2000). Summary estimates used in epidemiological investigations will then combine knowledge on duration, intensity, time since last exposure, in order to create relevant summary measures according to knowledge of the physiological process involved (Kriebel et al. 2007).

16.4.2 Establishing a Level of Classification

In deciding on a classification, a decision must be made as to whether it will be qualitative (yes/no or ever/never), semi-quantitative or ordinal (e.g., low, medium, or high, or scores of say, 1–3, with or without the quantitative levels associated with the categories identified), or quantitative (with units of measurements). This decision is usually based on the quality of the exposure data.

Continuous data (i.e., quantitative) have greater statistical power to find an association than categorical data. Continuous data, however, also provide an impression of higher quality of exposure data than categorical data do, so that if the exposure data are poor, it may be better to describe the exposures categorically.

Oftentimes, investigators believe that *categorical data* are more accurate than continuous data. In one sense, this may be true. It generally is easier to assign a study subject to one of three categories than to estimate a quantitative level. The use of categories, however, does not reduce the error of the exposure assessment because all individuals within the category are assigned the same value. To illustrate this point, when categories are used, either a score is assigned to the category or the median of the range the category represents is used. It would be rare, however, that all individuals within an exposure category actually have the same exposure level. There are likely to be some individuals exposed at the median level of the category who are therefore appropriately assigned. There are also likely to be some individuals on both the low and the high ends of the category who will be assigned the same value as those individuals at the median level. Moreover, the individuals on the edges of adjacent exposure categories (e.g., the individuals on the high end of the low exposure category and the individuals on the low end of the adjacent higher category) are assigned to different exposure categories and therefore to different median values, although they may be very similar in exposure levels. Thus, within any category of exposure, there is variability in exposure levels, and this variability will reduce the ability of the investigator to identify exposure-response relationships.

Another consideration in selecting the level of classification is the underlying assumption of the exposure-response relationship (cf. chapter ▸Analysis of Continuous Covariates and Dose-Effect Analysis of this handbook). Using a continuous measurement of exposure in regression modeling (cf. chapter ▸Regression Methods for Epidemiological Analysis of this handbook) assumes a linear increase of disease risk (or a transformed scale such as logit) for one unit of exposure. Use of categories of exposure, at least as a first approach, will, instead, fit observed values more closely without requiring any hypothesis about the shape of the exposure-response relationship. Categories must be developed, however, keeping in mind the limitations described above.

Grouping Strategies *Exposure groups* are subsets of the population being studied that are viewed as being similarly exposed and therefore assigned the same exposure level. Exposure groups may be defined during questionnaire development, the exposure assessment process, or the analytical stage. When developing questionnaires, exposure groups are defined when responses to the questions are provided in categories. For example, if the possible responses to “At what age did you get your first menstrual period?” are <10, 10–12, 13–14, and ≥15 years of age, these categories result in four exposure groups. In some studies, exposure groups are developed during the exposure assessment process. Thus, in an environmental study, a question may be asked, “How far did you live from the ABC waste site?” The exposure data that will be used in the exposure assessment may be described in three categories, for example, concentrations of an agent within a mile, 2–5 miles, and ≥5 miles. The investigator, then, may develop three exposure groups: one of subjects who report living ≤1 mile, one of subjects living 2–5 miles, and one of subjects living ≥5 miles. Alternatively, the exposure data may be continuous (e.g., concentrations at various distances). In this case, the investigator may leave the question open ended. Alternatively, he/she may prefer to use the same three response categories as indicated above because the investigator may believe that the subjects can more accurately identify the correct category than estimate a continuously measured distance. Finally, during the analytical stage, investigators may decide to group individuals into quartiles or other arbitrary or ad hoc categories. An advantage of this strategy is that categories can be developed using differing cut-points to allow comparisons with other studies.

The definition of exposure groups is important in an epidemiological study because the variability of exposure level within and across groups affects the power to observe an exposure-response relationship (see also Sect. 16.5). There are three types of variability in epidemiological studies. The first is *intra-individual* or day-to-day variability. For example, a subject with a mean alcohol consumption of two glasses a day may have no drinks some days and four drinks other days. The epidemiologist has no control over this variability, but it is important to appreciate that there is variability of most exposures of individuals, which could be important when investigating threshold effects.

Intragroup variability is the variability that occurs within the exposure group. Thus, within an exposure group consuming 2 to 4 drinks/day, there will be some individuals who average two, some who average three, and some who average four drinks/day. *Intergroup variability* is the variability across the groups (e.g., with categories of 0, $\leq$1–2, 3–4, 5–6, and $\geq$6, the range is 0 $\rightarrow$ 6 drinks/day). The more intragroup variability there is compared to the intergroup variability, the more likely that an exposure-response relationship will be missed. The goal, therefore, is to have narrow ranges of exposure levels within the groups (with little to no overlap across other groups due to misreporting) and as wide a range across groups as possible. For example, in a study investigating coal dust and change in lung function (forced expiratory ventilation in one second (FEV_1)), four different exposure groups were evaluated for intragroup and intergroup variability and the effect of variability on the FEV_1. The intragroup variance ranged from 0.18 to 0.35, and the intergroup variance ranged from 0.20 to 0.23 (Heederik and Attfield 2000). The FEV_1 coefficient (in ml per mg/m^3 of coal dust) ranged from -2.0 to -5.9. The exposure group with the lowest intragroup variance (0.18) and the highest intergroup variance (0.23) was associated with the highest loss of FEV_1 per unit of dust exposure (-5.9 ml/mg/m^3 of dust). Intragroup and intergroup variability can be evaluated using analysis of variance techniques (e.g., Burstyn et al. 2000).

16.4.3 Retrospective Exposure Assessment

The challenges of using instruments to measure current (i.e., recent) exposures are compounded when investigating chronic disease. Because historical measurements are often lacking, investigators may collect current measurements and assume that historical levels were similar or extrapolate historical level from the current measurements. Similarly, exposure information is often asked in questionnaires in reference to a single point in time (e.g., 20 years ago or when the subject was at a certain age), which is equivalent to having only one historical measurement. For example, in the area of nutrition, questionnaires used to investigate chronic disease have traditionally collected only information on current diet. Because diets have changed over time, current diet is not necessarily highly correlated to diets of 20 to 30 years ago.

In contrast, in the occupational investigations, however, complete work histories are often collected, which is likely to result in more accurately historical exposure estimates than using only current job. There is a whole body of literature relative to retrospective exposure assessment using job exposure matrices (JEM) or expert assessment from a panel of experts (Benke et al. 2001). A JEM is a cross tabulation of jobs (or job/industry combinations) and agents by time that automatically assigns the same exposure level to all individuals having the same job. Used in association with a subject's complete work history, JEMs or expert evaluation provide an individual probability or intensity of exposure to a given agent.

16.4.4 Ecological Versus Individual Exposure Assessment

Measurement data may not be available on the actual study subject, but rather on individuals thought to be similarly exposed as the individual under study. These types of measurements are called *ecological assessments*. In contrast, assessment of individual exposures takes into account the personal characteristics of the individual. An example of an ecological assessment is assigning the same level of trihalomethanes in a public water supply system to all individuals on that water supply, in spite of the recognition that the concentration of trihalomethanes can vary within a system. Assigning the same exposure level to individuals with different exposure levels will result in misclassification of study subjects because in the same (macro) environment, subjects are likely, in fact, to have different exposure levels. For example, subjects living in an area with a polluted public water supply will be exposed differently to a pollutant in the water depending on whether their water resources come from a public supply or from a private well, the amount of tap water they drink, their use of tap water for cooking, etc.

An ecological evaluation is used when exposure data or resources are limited. Ecological estimates are the rule in areas such as air pollution epidemiology, where individual exposures are often defined by atmospheric measurements at the sampling location nearest to the individual's residence, or more broadly, at the city level. Ecological estimates are also popular in occupational epidemiology, where job exposure matrices have been developed. In these examples, investigators of air pollution or workplace exposures usually do not have measurement data on the individuals or individual-specific parameters such as individual work practices and protective equipment. The ecological evaluation, therefore, assigns the same exposure value to a group of subjects sharing the same (macro) environment.

Ecological evaluations can result in substantial misclassification of exposure levels. In the field of occupation, even among individuals thought by occupational health professionals to have similar exposure levels, the exposure level can be up to three to six times larger or smaller than estimated, as indicated by geometric standard deviations often found (van der Woord et al. 1999). It seems reasonable to assume that similar degrees of misclassification occur among other types of environmental exposures. Extrapolation of measurement data from one individual to another or from a system to an individual therefore must be done with caution.

Ecological measurements are often derived from existing records (air quality monitoring records, occupational measurement surveys) and are much cheaper to obtain and estimate than individual measurements. Using ecological measurement instead of individual measurements makes sense if the contrast of exposure between the groups (e.g., cities or jobs) is greater than variability of exposures among individuals in the same group. Studies based on ecological measurements may also be useful for hypothesis generation.

Individual assessment generally requires a greater assessment effort but is likely to result in less misclassification. Considerations for selecting one approach over the other include the following: time and financial resources, availability of exposure data and its quality and quantity, and the purpose of the study (e.g., hypothesis generating or hypothesis testing and investigation of an exposure-response relationship).

16.4.5 Dealing with Multiple Exposures

In many situations, exposures to various potential risk factors in human populations tend to aggregate for an individual, due to individual behavior. An example is the correlated habits of smoking, alcohol, and coffee drinking among some individuals. Similarly, in the outdoors environment, humans are exposed to mixtures of compounds originating from the same source (e.g., mercury, polychlorinated biphenyls (PCBs), and other organochlorines from eating fish) or from various sources (e.g., carbon monoxide from automobile and truck exhaust).

Epidemiological studies have proved to be informative about many complex mixtures such as cigarette smoke or air pollution. However, identification of the component(s) responsible for the health effects (and their joint effects) observed is still required for a better understanding of disease causation, cost-effective monitoring of the hazard, and an efficient strategy of prevention of disease.

The situation of the mixed exposures cannot be treated as a classical problem of confounding because the exposures are highly correlated. Stratified analysis or multivariate modeling is, in general, inefficient because such analytical approaches do not allow the presence of a high colinearity among different exposures. In addition, the presence of one or several agents representative of mixed exposures or the occurrence of interaction among exposures is not merely a statistical problem. It also requires a strategy that recognizes the different underlying biological hypotheses of the various components of the mixtures. Much of the insight about multiple exposures comes from epidemiology (for instance, tobacco smoke or outdoor air pollution) because toxicological experiments often cannot replicate complex mixtures to which people are exposed across time, and such experiments are usually limited to single components or suitably chosen combinations.

To illustrate the problem of complex mixtures, we describe as an example environmental exposure to PCBs. Similar examples, however, are found in many other areas of study, including diet and occupational exposures. PCBs are a persistent type of industrial compound that includes 209 different chemical members referred to as congeners. The commercial product always is a mixture of correlated congeners, so that studying the toxicity of these compounds is not easy. For example, some PCBs act like dioxins by binding to the aryl hydrocarbon AhR receptor and may result in cancer (Longnecker et al. 1997). Experimental work has shown the highest dioxin-like activity occurs for congeners with no chlorine in the *ortho* position. It has been speculated that neurologic effects of PCBs, on the other hand, may be caused by congeners with chlorine in the *ortho* position.

Samet (1995) has proposed five general strategies for studying such complex mixtures efficiently: (1) treating the mixture as a single agent, (2) selecting an indicator component, (3) creating a summary index, (4) identifying the separate effects of the mixture's individual components, and (5) characterizing the independent and joint effects of the components. We review these strategies with application to the problem of the toxicity of PCBs.

(1) Treating the Mixture as a Single Agent The early studies in Japan and Taiwan that recognized the neurotoxicity of PCBs, and the later studies in Michigan, relied on total PCBs. At that time, congener-specific data were not available (Schantz et al. 2003). The exposure measurements taken in these studies were powerful enough to strongly suggest the neurotoxic potential of PCBs. There is still, however, a debate about discrepancies in health effects among studies in different countries. These discrepancies may be due to different analytical procedures, different patterns of congeners, or different co-exposures to other organochlorines, such as dioxins or furans, which have similar environmental pathways (Longnecker et al. 1997). In summary, treating the mixture of PCBs as a single agent has proved efficient for hazard identification in early work, but exposure misclassification limits the interpretation of the discrepant findings.

(2) Selecting an Indicator Component Several recent large studies have focussed on a small number of congeners present in relatively high concentrations (e.g., PCB 153). The congeners present in high concentrations, however, are not necessarily the most toxic. As a rule, "a single component of a mixture may be an appropriate index of toxicity if the component mirrors the dosimetry and toxicity of other components relevant to the health effect of concern" (Samet 1995).

(3) Creating a Summary Index Creating a summary index implies the attribution of some type of weighting to the individual concentrations of the different components of a mixture. The weight assigned to each congener is defined according to an underlying hypothesis about the biological activity of each component. If one assumes that endocrine disruption is a relevant biological mechanism of toxicity for PCBs, a measurement of the total estrogenic xenobiotic burden in adipose tissue could provide an integrated biomarker of xeno-hormonal activity resulting from exposure to a given mixture of compounds (Soto et al. 1997). Another example of biological activity, the dioxin-like activity of a PCB congener, can be calculated using a toxic equivalency factor (TEF) (Ahlborg et al. 1994), which is assigned relative to the toxicity of the dioxin 2, 3, 7, 8-TCDD. The total toxic equivalency (TEQ) of a mixture of PCBs can then be estimated by summing across all compounds, the product of the concentration, and TEF for each compound. It is likely, however, that the weighting is dependent on the state of knowledge about the relative potency of the different components at the time of calculation and that over time it would be necessary to modify the summary index as more information becomes available.

(4) Separating Effects of the Mixture's Components Creating one summary index does not reflect the heterogeneity of the mixture. There is a trade-off between measuring concentrations of the individual compounds in the mixture (which is usually time-consuming and expensive) and summarizing the mixture of highly correlated congeners. Analyzing concentrations of 38 PCBs congeners from 497 human milk samples from Canada in 1992, Gladen et al. (2003) distinguished three groups of congeners: one group of the congeners, including most of the major congeners, that were highly correlated, meaning that their individual biological effects realistically could not be separated in an epidemiological study; another group of congeners quantifiable in only a small fraction of the population by the assay methods used and therefore an epidemiological analysis would be uninformative; and a third group quantifiable in a reasonable fraction of samples and not correlated with the bulk of major congeners. The authors concluded the components of this last group are worth studying separately and are good candidates for individual determination and inclusion in epidemiological studies.

(5) Characterizing the Independent and Joint Effects of Components Measurements of selected congeners allow the evaluation of health effects related to single or joint exposures. Correlations, however, exist not only between concentrations of PCBs congeners but also with other common organochlorines, metals, and pesticides, and there are strong suspicions of possible interactions among these compounds at the molecular level that affect neurobehavioral function in particular (Carpenter et al. 2002). The strategies presented earlier provide some guidelines for studying these joint effects in epidemiological studies.

Two other points regarding mixtures are appropriate. It should be recognized that while some agents within a mixture may cause a disease, it is possible that other agents in that same mixture reduce the likelihood of the disease by deactivating the active compound. For instance, there is an active discussion around the beneficial impact on birth weight of seafood consumption during pregnancy, which brings high amounts of fatty acids and selenium, relative to the potential toxicity of seafood from contaminants such as mercury (Grandjean et al. 2001). This situation complicates the determination of causality in epidemiological studies. Also, individual characteristics of the study subjects (e.g., polymorphisms) may intensify or reduce the effect of the agent. Currently, our ability to tease out these situations is limited, but investigators should at least recognize that they may be possible.

Multiple exposures can be evaluated using interaction analysis but can also be grouped using hierarchical cluster analysis (e.g., see Hines et al. 1995 for an example). In this study, fabrication workers in a semi-conductor company were exposed to multiple chemicals. Hierarchical analysis allowed the investigators to identify groups of workers exposed to the same pattern of exposures (e.g., various glycol ethers).

16.5 Measurement Errors

All types of exposure assessment in every area of investigation will have some error. Chapter ▸Measurement Error of this handbook describes statistical methods to cope with measurement errors. Appreciation of the types and degree of error allows for a more appropriate interpretation of the study results. Knowing the sources of error can also provide areas for methodological investigation within the study to allow quantification of the error. This, in turn, can allow the investigator to estimate the effect of the error on the epidemiological findings.

16.5.1 Types of Measurement Errors

There are two types of errors that arise from measurements: random and systematic. Random error will result in the measurements being randomly distributed around the mean. Systematic error, or bias, will result in an overall mean that is erroneously high or low compared to the true mean. Both types of error are of concern in exposure assessment, and they are described in terms of precision and validity. *Precision* measures random error and refers to the reproducibility or reliability of the measure. *Validity* measures systematic error and refers to the distance between the exposure measured and the target variable (ideally, the true risk factor, but practically, the surrogate).

A measurement instrument must be *reproducible*. Under ideal conditions, this means that if the instrument is administered under the varying conditions, it should provide the same response within a reasonable level of variation. Generally, however, reproducibility more practically is defined as providing the same response within a reasonable level of variation under the same circumstances. Reproducibility is a necessary condition to accurately evaluate intra-individual and intragroup variability, but somewhat less necessary to accurately evaluate intergroup variability. In addition, to be useful, the measurement instrument must also be *valid* (i.e., it should measure the exposure it is supposed to measure and identify the true quantity present).

Historically, measurement error more often has been associated with categorical assessments than quantitative, probably because quantitative assessments have been limited in the past. Measurement error in either type of assessment will result in *misclassification error* when estimating the exposure levels of study subjects. For example, if a subject was assigned to a high fruit intake category, rather than a medium fruit intake category, the subject is misclassified. Misclassification of confounders can be also a serious problem since it will usually reduce the degree to which confounding can be controlled. For instance, in many studies it is essential to obtain a complete smoking history including detailed periods of smoking or quitting, and quantity smoked during each period, because tobacco smoking is a risk factor and therefore a potential confounder, for many diseases. When studying lifestyle factors associated with smoking, such as alcohol consumption, misclassification of smoking habits will result in incomplete adjustment and residual confounding. In the context of an epidemiological study, misclassification is characterized as non-differential or differential, depending on whether it affects the comparison groups (i.e., the diseased and non-diseased subjects) similarly. *Differential misclassification*, which results from there being a different amount of error for the diseased compared to the non-diseased, can lead to underestimation or overestimation of the association between the exposure and disease. In the latter situation, misclassification can induce spurious statistically significant results. *Non-differential misclassification* of exposure usually will bias estimates of relative risks toward the null. There are examples, however, occurring in extreme conditions, where non-differential misclassification of exposure can produce bias away from the null (Rothman and Greenland 1998). For more discussions about these concepts, see chapter ▸Misclassification of this handbook. Thus, both types of misclassification can result in incorrect conclusions.

16.5.2 Sources of Measurement Errors

Armstrong et al. (1994) classified sources of measurement error in five categories: faulty design of the instrument, errors or omissions in the protocol regarding the use of the instrument, poor execution of the protocol during data collection, limitations due to subject characteristics (e.g., poor memory of past exposures or day-to-day variability in biological characteristics), and errors during data entry and analysis. They have provided an extensive list of circumstances in which these errors may occur, and these sources should be carefully evaluated before attempting to use any type of instrument.

Measurement instruments and analytical methods (such as for an air or biological measurement, blood pressure) generally are designed to be as accurate and reproducible as possible when used under similar conditions, that is, with the same protocol. Two possible sources of systematic differences that can occur are from the measurement/analytical method itself and from the interference of other substances present in the measured environment. Reduction of these errors in the investigation of disease risks can be made by following the manufacturer's/laboratory recommendations, calibrating the instrument under the conditions being measured, using spiked and blank samples, and following other quality control procedures (cf. chapter ▸Quality Control and Good Epidemiological Practice of this handbook). Random error can arise from a lack of technical precision of the instrumentation, variation introduced by the laboratory technicians, and the analytical procedures themselves. This inherent limitation of the instrument and analytical methods, however, explains only part of the variability. Other sources of variation include weather conditions, presence of other exposures, the actual concentration being out of the range of the instrument's measurement range, and the timing of the instrument's response in the relation to a change in concentration. The sources of error need to be identified in order to decrease, or at least, recognize, and quantify the variability.

Questionnaires, because they also can suffer from the two types of misclassification, systematic and random, can be viewed similarly. Systematic differences can result from incorrect phrasing of questions (such that all respondents misinterpret the question similarly) or from inappropriate or misleading response categories. Random sources of misclassification can result from poor phrasing (such that different respondents interpret a question differently) and lack of interest on the part of the respondent. To collect quality data, questionnaires should be standardized, so as to ensure that all study subjects are asked the same questions. Questions must be clearly phrased, without ambiguity, and use terms that are understandable to respondents. Respondents must be able to remember the events being asked about and be able to correctly respond to the questions. Thus, reporting of events that took place many years ago or that require mathematical calculations (e.g., estimating average amount of foods eaten on a seasonal basis) is likely to be subject to more random error than reporting of more recent events or events that do not require calculations (e.g., Bradburn et al. 1987; Subar et al. 1995). Pilot testing of questions should be conducted on a group of individuals with the characteristics of the group who will be receiving the questions because respondents often interpret questions very differently from investigators, even if the questions were carefully developed. Questions should also be tested under the conditions that the questionnaire will be administered (e.g., in the home). Following these procedures should decrease bias and increase precision.

Diaries are prone to both systematic and random errors from the same sources as questionnaires. Records, in contrast, may have systematic and random error similar to measurement data or questionnaire data, depending on the type of record.

Both systematic and random errors may result from limited data. For example, systematic error could result in missing information from asking about sensitive issues, such as the number of sexual partners (Lindzey and Aronson et al. 1985). Subjects may be more inclined to respond with a "don't know" if the number of partners exceeds what they consider to be acceptable. Cases with workplace-induced cancer may be so sick that proxies are used as the respondents. Proxies generally know little about workplaces of the subject. In contrast, many of the control subjects would be able to provide detailed information about the workplace.

Having limited exposure information can result in misclassification of subjects by exposure level. In the environmental area, Brunekreef et al. (1987) illustrated the effect of limited data on misclassification in a study of the relationship between environmental exposure to lead and blood lead levels in children. He found that averaging four measurements of lead on home floors increased the regression coefficient explaining blood lead levels by 69%, compared to the model using a single home floor measurement. Having only one measurement, therefore, would have increased the misclassification of subjects. Generally, non-differential misclassification due to limited data will result in random error.

The problem of limited data also is evident in the use of questionnaires. For example, often investigators restrict the workplace exposure information collected to jobs, industries, and dates. From these limited data, they apply job exposure matrices to assign occupational exposure estimates. When applying the matrix, individuals holding a job are considered non-exposed if the exposure occurs only in a small proportion of workers in the job. This procedure will, however, inevitably result in classifying among the non-exposed individuals, a small proportion of workers who are, in reality, exposed. Similarly, individuals having jobs entailing a high probability of exposure will be considered exposed, even if they belong to the small proportion of non-exposed workers on this job. Detailed descriptions of tasks and work conditions of the jobs held by individual study subjects and evaluation of these data on the individual subject level are necessary for a better assessment. Thus, limited exposure data can contribute to misclassification, in that the available data (from which exposure is characterized) may not be representative of the individual's actual exposure level. This problem is more related to selection bias, is a general problem in epidemiology, and is not unique to exposure variables. The concept of bias is treated in chapter ▶Design and Planning of Epidemiological Studies of this handbook.

One can often recognize the circumstances in which differential misclassification may occur. Diseased subjects may have reflected more on their past exposures than the non-diseased (recall bias) or may take more care in providing correct responses. Differential bias will potentially occur when the exposure measurement instrument uses a human intermediary (e.g., the subject himself and/or an interviewer) aware of (or thinks he/she is aware of) the disease status. Thus, face-to-face interviews involve a substantial risk of producing interviewer effects. If a bias results from a different attitude of the interviewer toward the diseased compared with the non-diseased subjects, it is called interviewer bias. Self-administered questionnaires are generally believed to be less vulnerable to influences of response bias; however, the appearance of the questionnaire, the introductory letter, and the research group may all have an impact on response. The likelihood of bias from telephone interviews falls between these two data collection methods. Computer-assisted telephone interviewing has become the method of choice in many studies and often has a high response rate and few missing data (Nybo Andersen and Olsen 2002).

16.5.3 Quantification of Measurement Errors: Reproducibility Studies

Evaluation of the reproducibility of measurement instruments can be done by comparing the same instrument under the same conditions over time or by comparing various instruments under the same conditions at the same time. An example of the first type of study evaluated the reproducibility of a self-administered lifetime physical activity questionnaire (Chasan-Taber et al. 2002). Subjects reconstructed physical activity at four ages, starting at menarche, twice in the same mail questionnaire administered 1 year apart. All intraclass correlation coefficients used to measure reproducibility ranged from 0.78 to 0.87, with a value of 0.83 for total lifetime estimate of exposure.

The area of nutritional epidemiology (cf. chapter ▶Nutritional Epidemiology of this handbook) is one in which the design of proper questionnaire instruments has been extensively investigated. Subar et al. (2001) compared a new food frequency questionnaire and two widely used dietary questionnaires using telephone 24-h recalls. Despite substantial differences in the length and the design of the questionnaires, correlations obtained for dietary composition (i.e., total energy intake and 26 nutrients) were very similar. This comparison provides evidence that carefully designed self-administered food frequency questionnaires can provide reasonably reproducible measures of current nutrient intakes in epidemiological applications. There are still, however, questions about the validity of these instruments, and probably only the comparison of questionnaires with a truly uncorrelated error, such as a biochemical indicator of diet, will resolve these validity issues.

16.5.4 Quantification of Measurement Errors: Validation Studies

Ideally, an instrument should be evaluated by comparing it to a standard under the conditions the instrument is used. In evaluating the validity of any measurement instrument, the choice of the gold standard is a critical issue. Biochemical indicators of internal exposure provide an independent assessment for which measurement errors are not likely to be correlated with errors in air or water measurements or questionnaires. Biological measurements may represent historical exposures only if the chemical of interest has a sufficiently long biological half-life and may represent recent exposures only if the chemical has a relatively short half-life. In both cases, for the biological measure to be useful, the body burden cannot be affected by the disease or its treatment. In other situations, the biomarker may not measure the target agent of interest. Other challenges of biological monitoring can be found in Sect. 16.3.1 of this chapter. Biochemical indicators of dietary intake have a great appeal as the gold standard to assess the validity of dietary questionnaires (Willett 1990). There are limitations, however, in that the indicators may not reflect only dietary intake, and there are many dietary factors of interest for which there is no biomarker.

Practically, however, a gold standard often does not exist, especially when exposure has to be assessed retrospectively (e.g., historical tobacco consumption of individuals). For some exposures, a partial validation may be possible, by comparing questionnaire results to preexisting records. For example, reported jobs can be compared to employers' records, and smoking consumption can be compared to past medical records. Identification of gold standards that are alloyed and how to account for this error has been discussed (Wacholder et al. 1995). The validation of the instrument is also often measured by its ability to predict disease risk in prospective studies (Willett 1998). This approach is somewhat problematic, however, in that the epidemiological outcome is used to test the instrument. Nonetheless, a good instrument should produce better risk estimates than a poor one (Tielemans et al. 1998).

16.5.5 Methods for Correcting Measurement Errors

The effect of a systematic difference between the actual concentration and the concentration measured can be reduced or minimized simply by applying a correction factor reflecting the difference to the exposure estimate if the difference is known. Internal validation studies have been proposed to reduce the impact of measurement error. In one approach, exposure is measured, although imperfectly, from everyone in the study, and, simultaneously, a more accurate but more expensive measurement is collected on only a small subset of cases and controls selected randomly. Sophisticated statistical methods can then be applied in order to infer the corrected odds ratio from measurement error models fitted to the parallel exposure measurements from the validation sample (Stürmer et al. 2002). These so-called two-phase designs are among others investigated by Schill et al. (1993), Schill and Drescher (1997) and have been applied by Pohlabeln et al. (2002). This method, however, has not yet been routinely implemented, and further research is needed to establish the robustness of the procedures in realistic settings and to determine optimal designs for selecting a validation sample. As quoted by Chatterjee and Wacholder (2002) in a recent commentary, "The best way to reduce bias from measurement error is to improve tools for measuring exposures including biological markers, environmental samples and questionnaires."

A second approach that is gaining popularity is to conduct an uncertainty analysis (or sensitivity analysis; Rothman and Greenland (1998)). In this approach, investigators identify the uncertainty around a point estimate (e.g., two drinks of wine a day). For example, if the question "How many glasses of wine do you drink?" was asked and the responses were <1/day, 1–3/day, 4–5/day, and >5/day, the uncertainty ranges of these responses could be 0–0.9, 1–3, 4–5, and 6–10, respectively. Monte Carlo or other statistical simulations allow a better understanding of the uncertainty around the disease risk estimates.

16.6 Conclusions

The demand for accurate exposure assessment implies the need for development of validated and reliable tools in parallel with reduced costs and increased applicability in field studies. Sophisticated techniques are now available for direct measurement of chemicals in most mediums with excellent sensitivity and reproducibility. Similarly, questionnaires are being developed in various fields with considerable effort being put into their validation.

In some areas, such as occupational or environmental epidemiology, improvement is dependent upon additional knowledge on exposure determinants both at the personal and population levels and on objective comparisons of the quality of various available methods for exposure assessment (Liljelind et al. 2003). Quantitative estimates of exposure using statistical modeling are currently being developed, mainly for risk assessment purposes, but their applicability to epidemiological studies has not been fully explored.

To solve the problem of mixed exposures, the trend is toward building exposure indices summarizing several exposures according to biological hypotheses about their joint mechanisms of action. In the near future, new biotechnologies (e.g., genomics, proteomics) will contribute to the development of biomarkers of gene expression, intermediate between markers of exposure and markers of early effects that will summarize the joint action of mixed exposures at the molecular level (Henry et al. 2002; cf. chapter ▸Molecular Epidemiology of this handbook). The applicability of these techniques in epidemiological studies opens a whole new area of research.

17.1 Introduction

The convention in epidemiology and biostatistics is to divide the study of mismeasured variables into the areas of measurement error for continuous variables and misclassification for categorical variables. Although the topics overlap considerably, chapter ▸Measurement Error of this handbook focuses on measurement error, whereas the present chapter is devoted to misclassification. As a motivating example of a misclassified variable in an epidemiological study, say that a binary exposure is ascertained via subject self-report on a questionnaire. Given human memory limitations, we would usually expect a portion of responses to be erroneous. For instance, in the study of Kraus et al. (1989) on possible association between maternal antibiotic use during pregnancy and sudden infant death syndrome (SIDS), antibiotic use is self-reported by subjects via questionnaire. Examination of medical records of some subjects, however, indicates that the questionnaire responses are erroneous for some subjects. Thus, antibiotic use as determined via questionnaire is subject to misclassification. Moreover, this misclassification has implications when the association between antibiotic use and SIDS is inferred.

As another example, Natarajan (2009) considers whether carotenoid intake beyond a certain threshold correlates with blood pressure. Carotenoid intake is measured indirectly from dietary recall interviews conducted by nutritionists, and hence is subject to error both in recall and in the conversion from diet to nutrient data. Whereas carotenoid intake itself is a continuous variable subject to measurement error, the problem becomes one of misclassification when the focus shifts to the binary indicator of whether intake exceeds the threshold.

This chapter covers some of the main ideas and issues in dealing with misclassified variables in epidemiological contexts. Section 17.2 focuses on the impact of not dealing with misclassification, i.e., what happens if we proceed to analyze the data as if, contrary to fact, the exposure is measured correctly on all subjects. This starts with a basic case in Sect. 17.2.1, involving only a binary exposure and outcome along with a simple form of misclassification. More complex situations are then considered in Sect. 17.2.2. Section 17.3 turns to analyzing data while acknowledging the misclassification at play. After describing a simple situation in Sect. 17.3.1, the issue of where information about misclassification comes from is dealt with in Sect. 17.3.2. Then, different inferential strategies are contrasted in Sect. 17.3.3. Section 17.4 deals briefly with outcome and confounding variables subject to misclassification. Some summary remarks are given in Sect. 17.5.

17.2 The Impact of Uncontrolled Misclassification

17.2.1 The Basic Case

Consider a binary exposure X, with interest in how X is associated with a disease indicator Y that is correctly ascertained for all study subjects. *Exposure* *misclassification* results if the ascertained exposure W differs from the true exposure X for some subjects. The accuracy of the classification procedure is usually characterized by the sensitivities $Sn_{\mathrm{y}} = \Pr(W = 1|X = 1, Y = y)$ and specificities $Sp_{\mathrm{y}} = \Pr(W = 0|X = 0, Y = y)$; these are the probabilities that the ascertainment is correct for a given subject. These W probabilities should be contrasted with the X probabilities showing the correctness of the classification method when applied to a given population, the positive predictive values $\Pr(X = 1|W = 1, Y = y)$, and the negative predictive values $\Pr(X = 0|W = 0, Y = y)$. The predictive values can be derived from Sn_{y}, Sp_{y}, and the true prevalence $p = \Pr(X = 1)$ via Bayes theorem,

$$\Pr(X = 1|W = 1, Y = y) = Sn_{\mathrm{y}} \cdot p/[Sn_{\mathrm{y}} \cdot p + (1 - Sp_{\mathrm{y}}) \cdot (1 - p)] \quad \text{and}$$
$$\Pr(X = 0|W = 0, Y = y) = Sp_{\mathrm{y}} \cdot (1 - p)/[(1 - Sn_{\mathrm{y}}) \cdot p + Sp_{\mathrm{y}} \cdot (1 - p)].$$

It is important to note that our intuition tends to be poor in translating between classification probabilities and predictive values. As an example, say $Sn_0 = 0.95$, $Sn_1 = 0.90$, $Sp_0 = 0.88$, and $Sp_1 = 0.92$. These classification probabilities seem generally high, and we might characterize the misclassification as being somewhat modest. If, however, exposure is rare, the positive predictive values can be quite low. For instance, if $p = 0.1$, then Bayes theorem yields the positive predictive values as 0.47 (for $Y = 0$) and 0.55 (for $Y = 1$), whereas the negative predictive values are very high: 0.994 (for $Y = 0$) and 0.988 (for $Y = 1$).

Knowing the extent of misclassification alone does not suffice to characterize its impact on statistical inference since various constraints may apply. If only exposure is misclassified, the simplest constraint is that of *non-differential* misclassification, whereby the ascertainment of exposure status is completely independent of other variables. In the present setting, this is expressed as conditional independence between W and Y given X, i.e., $\Pr(W = w|X = x, Y = y) = \Pr(W = w|X = x)$, so that we may drop the "y" subscript from Sn_{y} and Sp_{y}. More involved settings would replace Y with "Y and other variables" in this conditional-independence statement.

On first glance, non-differential misclassification appears to be realistic whenever the ascertainment of W is carried out without knowledge of Y. Unfortunately, the situation is often not so simple, as discussed below. Nonetheless, the non-differential case is the typical starting point for analysis of misclassification effects since even with the constraint, we obtain an association between observables W and Y which differs from the association of real interest, between X and Y. Specific equations for describing and accounting for this phenomenon are given, for instance, in Sect. 3.3 of Gustafson (2003) and p. 356 of Greenland and Lash (2008). For binary variables with only exposure misclassified, the association between W and Y is always weaker than that between X and Y, resulting in the often-quoted maxim that exposure measurement error or misclassification biases results toward the null (i.e., pushes results toward no association). This maxim is often quoted outside of its rather limited domain of applicability, as will be discussed later on.

Table 17.1 Population odds ratio for misclassified exposure and disease, for various values of the odds ratio for actual exposure and disease, the exposure prevalence among non-diseased, and the sensitivity and specificity of the non-differential misclassification

		$OR = 1.25$		$OR = 2.0$	
Prevalence	Sp	$Sn = 0.95$	$Sn = 0.80$	$Sn = 0.95$	$Sn = 0.80$
0.01	0.95	1.04	1.03	1.16	1.14
	0.80	1.01	1.01	1.05	1.04
0.10	0.95	1.17	1.15	1.67	1.60
	0.80	1.08	1.07	1.34	1.27
0.20	0.95	1.20	1.19	1.80	1.71
	0.80	1.13	1.11	1.52	1.42

To provide some examples, Table 17.1 gives the population odds ratio between W and Y resulting from particular values for (i) the population prevalence of X among the non-diseased, (ii) the population odds ratio between X and Y, and (iii) the sensitivity and specificity of the non-differential misclassification. The attenuation of the odds ratio toward the null is seen to be more dramatic when either exposure ($X = 1$) or non-exposure ($X = 0$) is uncommon. For exposure prevalence below 50%, attenuation is seen to be driven more by imperfect specificity than by imperfect sensitivity; the reverse is true if exposure prevalence is over 50%. In practical terms, the discrepancy between the (W, Y) and (X, Y) associations can be very substantial under realistic values for exposure prevalence and misclassification magnitude. Thus, simply treating W as "the exposure" can be highly misleading. Valid estimation of the (W, Y) association will typically be highly invalid for the (X, Y) association.

17.2.2 More Complex Situations

As alluded to above, the "bias toward the null" maxim is often violated. It can be derived under special conditions such as non-differential misclassification of a binary exposure alone (Newell 1962) and generalizes to quantitative exposures under certain regression constraints (Weinberg et al. 1994). But in situations where exposure is not truly binary, errors depend on other variables, or data are grouped (ecologic), bias toward the null is no longer guaranteed even if non-differentiality holds (Walker and Blettner 1985; Dosemeci et al. 1990; Birkett 1992; Chavance et al. 1992; Kristensen 1992; Brenner et al. 1992; Weinberg et al. 1994).

To illustrate that non-differential misclassification does not always induce bias toward the null, consider a trinary exposure X with levels labeled "none," "low," and "high." Under non-differential misclassification, this gives rise to apparent exposure W, where this misclassification is described by a 3 by 3 matrix of probabilities of W given X. For a given misclassification matrix and a given joint distribution of actual exposure X and disease Y, it is a straightforward probability calculation to determine the joint distribution of apparent exposure W and disease Y.

Table 17.2 The effect of non-differential misclassification in a trinary exposure example. The left side of the table gives a joint distribution of actual exposure and disease, (X, Y). For the misclassification probabilities given in the text, the right side of the table gives the resulting joint distribution of apparent exposure and *disease* (W, Y)

	X			W		
	No	Low	High	No	Low	High
$Y = 1$	0.1	0.1	0.1	0.095	0.110	0.095
$Y = 0$	0.3	0.3	0.1	0.265	0.290	0.145

As a simple example, say that for each level x of X the probability of correct classification is $\Pr(W = x|X = x) = 0.7$. For the low level of X, suppose the probabilities of the two possible misclassifications (to none or to high) are 0.15 each. For both the none and high levels of X, suppose the probability of classification into the adjacent (low) category is 0.2, while the probability of classification into the distant category is 0.1. Thus, the probability of correct classification exceeds the probability being off by one level, which in turn exceeds the probability of being off by two levels. When applied to the joint distribution of (X, Y) given in the left side of Table 17.2, this non-differential misclassification yields the joint distribution of (W, Y) in the right side of this table. Note that the (X, Y) association in this example is described by a disease odds ratio of 1, contrasting the low level of X to none, and a disease odds ratio of 3 contrasting the high level of X to the low level. However, the (W, Y) association has odds ratios of 1.06 contrasting low to none and 1.73 contrasting high to low levels. Thus, we see slight bias *away* from the null in the first instance and (severe) bias toward the null in the second instance. This example underscores the lack of a simple general rule concerning the impact of non-differential misclassification when there are more than two levels of the exposure.

Another setting where often-seen rules do not apply is that of differential misclassification. In fact, for any given distribution of binary exposure X and binary outcome Y, one can find Y-dependent misclassification probabilities (sensitivities and specificities) for the misclassification from X to W which give any answer desired for the (W, Y) association. This in itself is not surprising. What is perhaps more surprising, however, is the frail nature of the non-differential assumption. Intuitively, non-differential would seem to say that the process by which X leads to W is blind to Y. However, many situations do not lend themselves to such blinding; moreover, some situations which appear on first glance to involve blind classification are seen upon closer inspection to be differential (Flegal et al. 1991; Wacholder et al. 1991).

Studies with retrospective ascertainment of exposures (e.g., questions based on recall of past events) are a prime example of settings where non-differentiality may be most dubious. This is particularly true when W arises as a response on a self-report questionnaire administered after diagnosis since subjects are necessarily not blinded to their own disease status. One can envision situations where a psychological tendency to blame a putative exposure for illness might induce non-exposed cases to declare themselves exposed more easily than non-exposed non-cases (so case specificity is lower than non-case specificity) or in which the awareness of the illness sharpens recall efforts and induces exposed cases to remember actual exposures at a higher rate than exposed non-cases (so case sensitivity is higher than non-case sensitivity).

On the other hand, in "denial" settings where exposure involves a behavioral choice that might be stigmatized, exposed cases might be particularly hesitant to admit that a behavior could possibly have contributed to their disease (so case sensitivity is lower than non-case sensitivity), or exposed cases might altruistically or fatalistically be less inhibited in admitting to these exposures than non-cases (so case sensitivity is higher than non-case sensitivity). Thus, retrospective ascertainment may be particularly fertile grounds for engendering differential misclassification, although psychological speculations may provide little guidance as to the direction or net impact of such differentiality (Drews and Greenland 1990).

Even when the misclassification process is physically independent of disease status, there may be mechanisms by which the non-differential assumption fails to hold.

As an example, suppose that the binary exposure X arises from thresholding a continuous exposure variable X_c. Similarly, the apparent exposure W might arise from thresholding W_c, which is a noisy measurement of X_c. A first intuition might be that if the process by which X_c gives rise to W_c is blind to Y, then the thresholded quantities would behave similarly. That is, non-differential measurement error of X_c might be thought to induce non-differential misclassification of X. Unfortunately, however, the situation is more complicated. If Y depends on X_c not just through X, then generally W and Y will not be conditionally independent given X. That is, if there is still a risk gradient with X even when conditioning on X being on a particular side of the threshold, then non-differential error in W_c as a measure of X_c gives rise to differential misclassification in W as a measure of X. This is then an example of an outward appearance of non-differential misclassification obscuring truth to the contrary.

For further discussion of misclassification arising from thresholding a poorly measured continuous variable, see Flegal et al. (1991), Gustafson and Le (2002) and Natarajan (2009). The latter article gives an example where the binary predictor X is an indicator of the log plasma carotenoid level exceeding a threshold (chosen to be one population standard deviation above the population mean level). Misclassification then arises because the measured carotenoid concentration W_c involves error relative to the actual level X_c.

17.3 Accounting for Misclassification

17.3.1 A Basic Case

Having discussed the manner in which the (X, Y) association for the actual exposure and disease can differ from the (W, Y) association for the assessed exposure and disease, we now turn to the issue of inferring the (X, Y) relationship from (W, Y) data. The feasibility of doing this is strongly governed by the form and extent of information about the misclassification. Simply put, moving from X to W corresponds to a distortion of the data, and we cannot expect to undo the impact of this distortion without some information on how badly W represents X.

As a simple but admittedly unrealistic starting point, if we have misclassification of a binary X into a binary W with known sensitivities and specificities, then inferential procedures are straightforward. In this case, the prevalences of apparent exposure, $\Pr(W = 1|Y = y)$ for $Y = 0, 1$, and the prevalences of true exposure, $\Pr(X = 1|Y = y)$, are completely determined by the system of equations

$$\Pr(W = 1|Y = y) = \Pr(X = 1|Y = y)Sn_{\mathrm{y}} + \Pr(X = 0|Y = y)(1 - Sp_{\mathrm{y}}). \quad (17.1)$$

Given Sn_{y}, Sp_{y}, and data on $(W|Y)$, (17.1) represents two equations (one for each Y value) in two unknowns $\Pr(X = 1|Y = 1)$ and $\Pr(X = 1|Y = 0)$. These equations can be solved explicitly, leading to odds ratio estimates relating X and Y. Considerable caution is needed, however, when applying this system with constraints, e.g., assuming non-differentiality (i.e., using the same values for Sn_{y} and Sp_{y} for cases and non-cases), as this can lead to estimates more biased than those from the uncorrected data (Brenner 1996). Fortunately, system (17.1) allows differential misclassification and generalizes straightforwardly to polytomous exposures and outcomes as

$$\Pr(W = w|Y = y) = \sum_{\mathrm{x}} \Pr(X = x|Y = y)\Pr(W = w|X = x, Y = y),$$

which can be solved for $\Pr(X = x|Y = y)$ via ordinary matrix inversion (Greenland and Kleinbaum 1983; Greenland and Lash 2008).

More generally, but with the same caveats, weighted least squares, maximum likelihood and Bayesian methods are readily applied to convert inferences about the (W, Y) relationship to inferences about the (X, Y) relationship. A technical difficulty for frequentist methods based on Eq. 17.1 however is that sampling variation can result in a sample prevalence of apparent exposure $(W = 1)$ which maps to a prevalence of actual exposure $(X = 1)$ that is less than zero or greater than one (Tu et al. 1994, 1995; Greenland and Lash 2008). As an example, suppose that classification probabilities $Sn_0 = Sn_1 = 0.8$ and $Sp_0 = Sp_1 = 0.85$ are known to the investigator. However, the investigator is unaware that $\Pr(X = 1|Y = 0) = 0.05$ and $\Pr(X = 1|Y = 1) = 0.10$, and consequently $\Pr(W = 1|Y = 0) = 0.183$ and $\Pr(W = 1|Y = 1) = 0.215$. Now say data in the form of W measurements on 200 controls and 200 cases are available. At these sample sizes, sample prevalences for W are likely within ±0.05 of the population prevalences. For instance, say the sample estimates for $\Pr(W = 1|Y = y)$ are 0.14 (for $y = 0$) and 0.22 (for $y = 1$). Now applying Eq. 17.1 in the other direction, our corresponding estimates for $\Pr(X = 1|Y = y)$ would be -0.016 and 0.108, for $Y = 0$ and $Y = 1$, respectively. The former (negative) estimate is clearly non-sensical and does not lead to a sensible estimate for the (X, Y) association. Gustafson et al. (2001) demonstrate that formal Bayesian analyses obviate this concern.

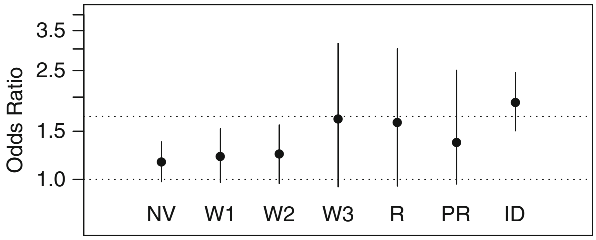

Fig. 17.1 Odds ratio inferences from a simulated dataset with 111 of 1,250 controls and 197 of 1,250 cases actually exposed, but 390 of the controls and 430 of the cases apparently exposed. Point and 95% interval estimates are displayed on a logarithmic scale. The ideal (ID) analysis uses the actual exposure data (X), while the other analyses use the apparent exposure data (W). The naive (NV) analysis simply treats W as if it were X. The "right" (R)-adjusted analysis correctly takes $Sn = 0.9$ and $Sp = 0.75$ as known. The three "wrong"-adjusted analyses ($W1$ through $W3$) incorrectly take (Sn, Sp) as known, with values (0.9, 0.9), (0.75, 0.9), and (0.75, 0.75), respectively. The adjustment based on a prior distribution (PR) for (Sn, Sp) uses the prior distribution described in the text. The *dotted lines* indicate the null and true values

Perfect knowledge of the sensitivity and specificity of exposure misclassification is unavailable in real problems. More realistically, one might hope to have some *validation data* available from which the relation between W and X can be estimated. This situation is discussed below. Absent such data though, one might have to rely upon more amorphous information, such as investigator-provided ranges of plausible values for the sensitivity and specificity of exposure classification. This puts the problem into the realm of sensitivity analysis, examining a range of answers corresponding to a range of assumptions about the severity of misclassification. Rather than provide hard constraints in the form of intervals for Sn_{y} and Sp_{y}, one might advocate softer, probabilistic constraints in the form of prior distributions for these quantities. That is, inference is still built upon (17.1), but with the acknowledgement that Sn_{y} and Sp_{y} are only known with some degree of uncertainty or vagueness, rather than exactly.

As an example, consider a population with an odds ratio between X and Y of 1.7, with 10% exposure prevalence among the non-diseased. A computer-simulated sample of 1,250 controls and 1,250 cases from the population produced 111 truly exposed controls and 197 truly exposed cases. However (again via computer simulation), non-differential misclassification with sensitivity $Sn = 90\%$ and specificity $Sp = 75\%$ resulted in the investigator observing 390 apparently exposed controls and 430 apparently exposed cases.

Point and interval estimates for the (X, Y) odds ratio arising from various Bayesian analyses of these simulated data are depicted in Fig. 17.1. These include the ideal (but unattainable in real settings) analysis arising from the (X, Y) data, and the naïve analysis arising from the (W, Y) data without any misclassification adjustment. Five adjusted analyses based on the (W, Y) data are also presented. Four of these are based on taking the (Sn, Sp) values as known (correctly in the first instance and incorrectly in the other three). A fifth adjusted analysis is based on a prior distribution for (*Sn, Sp*) which subsumes the different values specified. Particularly, this prior distribution has 5th and 95th percentiles for both *Sn* and *Sp* as 0.75 and 0.90. More technically, *Sn* and *Sp* are assumed independent and identically distributed *a priori*, each with a Beta (50.4, 10.2) distribution. This specification is somewhat unrealistic insofar as various forces may induce dependencies between *Sn* and *Sp*, but since these forces may be in either direction, independence is a simple starting point. Similarly, contextually realistic priors for the underlying (X, Y) distribution would be based on independent distributions for the odds ratio and the control exposure $(X = 1)$ prevalence; see Greenland (2001) and Greenland and Lash (2008, p. 369) for discussion. But, for the sake of simplicity, our analyses will use independent uniform distributions as priors for the case and control exposure prevalences.

In this example, we see that the inability to measure X precisely comes with a steep cost. The naïve analysis is biased, with a 95% interval estimate missing the true value. The adjusted analyses which use good information about misclassification (either correct knowledge of the values of *Sn* and *Sp*, or prior distributions that concentrate on sufficiently narrow ranges of values that include the correct values) are helpful in appropriately moving the naïve point estimate away from the null, and yielding interval estimates compatible with the true value. However, the widths of these intervals, roughly double that of the ideal analysis, show the severe loss of information entailed by the misclassification. Worse, in this particular case, the intervals cover the null, illustrating how misclassification induces a loss of power for detecting associations.

To emphasize that the behavior seen in Fig. 17.1 is typical in the 2 by 2 case, results for a further nine datasets, simulated under the same conditions described above, appear in Fig. 17.2. (To conserve space, only one of the three analyses with wrong values is presented.) This gives a slightly more nuanced view of how much power and precision is lost upon replacing X with W, even if the extent of misclassification is correctly known. Interestingly, in aggregate the interval estimates arising from the correctly known values of (*Sn, Sp*) appear to be slightly longer than those arising from the prior distribution applied to (*Sn, Sp*), i.e., less uncertainty *a priori* transmutes to relatively more uncertainty *a posteriori*. Gustafson and Greenland (2006) take up this curious issue in some depth.

Another related point is that the naïve analysis and the analysis using the correct values coincide in terms of which datasets yield interval estimates excluding the null. Thus, while adjustment for non-differential misclassification can be helpful for estimation purposes, it seems to have no impact for testing the null hypothesis other than loss of power from using the uncorrected (W, Y) data (Bross 1954). Greenland and Gustafson (2006) stress that this is a general finding for likelihood-ratio hypothesis testing under non-differential exposure misclassification, although Gustafson and Greenland (2006) show that the situation can be more complicated for Bayesian analysis.

It is worth noting that the severe bias from misclassification seen in the 2×2 case can be considerably worsened in matched analyses (Greenland 1982) and can lead to spurious appearance or masking of heterogeneity (effect-measure modification)

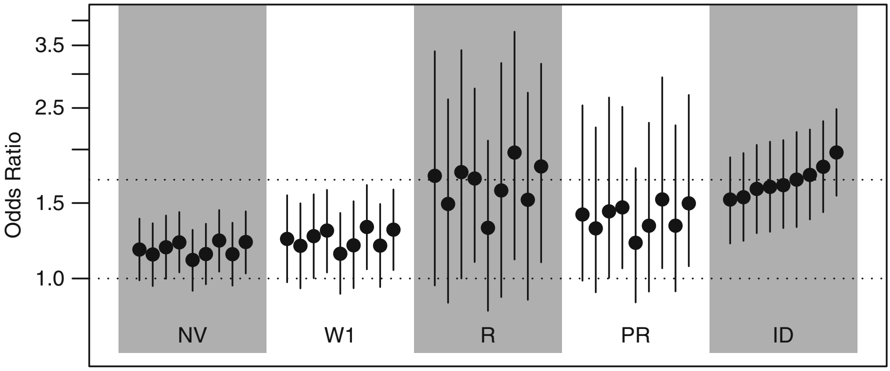

Fig. 17.2 Odds ratio inference for nine further synthetic datasets generated under the same conditions as in Fig. 17.1. These datasets are deliberately ordered to have ascending sample odds ratios for (X, Y)

in stratified analyses (Greenland 1980). Finally, as alluded to earlier, the non-differentiality assumption is more easily violated in practice than often realized (Wacholder et al. 1991), and its violation can play havoc with methods that assume it holds (Brenner 1996).

17.3.2 Sources of Information About Misclassification

A key concern in misclassification problems is how information about the extent of misclassification is derived. The previous subsection dealt with the somewhat amorphous case where the investigator has rough speculations about the extent of misclassification, which can be cast in the form of a prior distribution. In other cases, however, the data at hand may speak directly to the misclassification magnitude.

17.3.2.1 Validation Data

In some settings, it may be possible to measure the true exposure X, but these measurements are too expensive to make for all study subjects. This leads to the notion of *validation data*. Internal validation arises if the (W, Y) measurements for all study subjects are augmented with X measurements, ideally for a randomly selected subset of the subjects. The random selection could be undertaken as a random sample of all subjects, or it would also be permissible and could be more efficient to use stratified sampling with strata defined by the levels of W and Y. As an example of study data with a validation component, Kraus et al. (1989) consider antibiotic prescription during pregnancy (X) and sudden infant death syndrome (Y), where the noisy assessment of exposure (W) is self-reported antibiotic use on a questionnaire, recorded for all 797 controls and 775 cases.

Medical records were examined for 217 controls and 211 cases. Presuming these records to be accurate and complete, X itself is thus observed for these subjects.

Randomly sampled internal validation data lead to identified statistical inference – as the overall study sample size grows one learns the relationship between W and Y more precisely, as the size of the validation subset grows one learns the relationship between W and X given Y more precisely, and (if as here sampling is random within Y levels) one also learns directly about the odds ratio relating X to Y.

Conceptually, we can extract all the information from this form of data by using sample proportions based on *all* subjects with $Y = y$ to estimate $\Pr(W = w|Y = y)$ and using sample proportions based on *validated* subjects with $W = w, Y = y$ to estimate $\Pr(X = x|W = w, Y = y)$, i.e., to estimate the predictive values. Since

$$\Pr(X = 1|Y = y) = \sum_{\mathrm{w}} \Pr(X = 1|W = w, Y = y)\Pr(W = w|Y = y), \quad (17.2)$$

our estimates of the quantities on the right-hand side of the equation yield estimates of $\Pr(X = 1|Y = y)$ for y = 0, 1, and hence we can infer the (X, Y) association (Marshall 1990; Brenner and Gefeller 1993; Lyles 2002).

To illustrate with the data from Kraus et al. (1989), we estimate $\Pr(W=1|Y=y)$ as 134/797 for $y = 0$ and 173/775 for $y = 1$, which, incidentally, gives the sample (W, Y) odds ratio as 1.42. Then, we estimate $\Pr(X = 1|W = w, Y = y)$ as 16/184 for $w = 0, y = 0$; 21/33 for $w = 1, y = 0$; 17/160 for $w = 0, y = 1$; and 29/51 for $w = 1, y = 1$. Plugging these into (17.2), we estimate $\Pr(X = 1|Y = 0)$ as 0.179, and $\Pr(X = 1|Y = 1)$ as 0.209, yielding an estimated (X, Y) odds ratio of 1.21. Note that this is an instance where adjustment for misclassification pushes the point estimate toward the null, as can indeed happen under differential misclassification.

For planning a study, however, if the accuracy of W as a measure of X is poor, the statistical contribution of the non-validated data may be low; thus the cost-effectiveness of using W at all instead of obtaining X on everyone may be called into question if the cost of obtaining X is not considerably more than the cost of obtaining W (Greenland 1988). Furthermore, the naïve use of adjustment methods that assume no error in X can leave considerable bias, perhaps even more than there was before adjustment (Wacholder et al. 1993), and that bias is worsened by incorrectly assuming non-differentiality (Brenner 1996).

At the other extreme, it may be impossible to obtain X on the study subjects, leaving external validation data as the only alternative to speculation. It may be unreasonable to expect the predictive values in Eq. 17.2 to transfer across populations. If however we have (X, W, Y) values for subjects outside the main study, we might reasonably hope that the $(W|X, Y)$ distribution is similar in both populations, in which case Eq. 17.1 or its generalizations can be applied. In situations where the non-differential misclassification assumption can be invoked, it would suffice to have measurements of (X, W) values for subjects from the external population, which might be limited to only cases or only non-cases.

17.3.2.2 Multiple Surrogates

In lieu of validation measurements, another potential source of information about misclassification arises from multiple surrogates. For instance, say that data on

(W_1, W_2, Y) are available, where W_1 and W_2 are two different surrogates for X. For instance, in the example mentioned above, the review of medical records is in fact imperfect in assessing maternal *use* of antibiotics (as opposed to mere prescription, i.e., intent-to-treat). Thus, if X is now defined as antibiotic use rather than prescription, both the questionnaire and the examination of medical records only yield surrogates for the actual X. Under some assumptions, data on multiple surrogates plus disease outcome can be informative for the relationship between X and Y, even though X is never observed. Arguably, however, the assumptions are strong. In addition to the assumption that each surrogate arises via non-differential misclassification of X, an assumption that the surrogates are conditionally independent of one another given X is required, or at least that the dependency structure is precisely known. This is typically hard to justify. In many settings, one can imagine that subjects with a higher risk of W_1 being in error could also be at particular risk of having W_2 be in error.

Despite this caveat, there is some intuition as to why two conditionally independent surrogates suffice. The basic setup requires the estimation of six quantities: exposure prevalences among controls and cases, plus sensitivity and specificity for each surrogate. Without the conditional-independence assumption, there would be several further parameters at play. However, the data-structure identifies the conditional distribution of $(W_1, W_2|Y)$, which indeed permits the estimation of (at most) six quantities (Hui and Walter 1980).

One can relax the assumption that the two surrogates are conditionally independent (see, for instance, Dendukuri and Joseph 2001; Hanson et al. 2003). These approaches necessarily involve a non-identified model and typically a Bayesian analysis with a suitable prior on the extent of departure from conditional independence. More than two surrogates can also be used (e.g., Chu et al. 2009). Some technical investigation of the identification issues for multiple surrogate models is given by Jones et al. (2010) and Gustafson (2009).

Much of the work on multiple surrogates arises in the context of diagnostic testing or screening, where it is not exposure per se, but rather disease status, that is subject to misclassification. Moreover, the focus may not be on relating disease status to other variables, but may rather lie in disease prevalence or the classification probabilities for disease-status surrogates. Overviews of the statistical aspects of diagnostic testing are given by Pepe (2003) and Zhou et al. (2002); see Broemeling (2007) for a more Bayesian discussion. While diagnostic testing is outside the purview of the present chapter, many of the ideas from this literature carry relevance for the situation of misclassified exposure.

17.3.3 Different Inferential Approaches

While the example of Sect. 17.3.1 uses Bayesian methods to draw inferences about the relationship between actual exposure and disease, the literature describes a wide array of methods applied to misclassification problems. One surprising feature of the literature is that many methodological suggestions fall outside the realm of likelihood-based methods and emphasize intuitive appeal. For instance, Küchenhoff et al. (2006) extend the *simulation-extrapolation* (SIMEX) procedure originally devised for continuous X (Cook and Stefanski 1995) to the discrete X setting. The appealing intuition here is that one can add varying degrees of extra misclassification to the already misclassified data, to establish the relationship between the (W, Y) association and the extent of misclassification. This relationship can then be extrapolated back to the no misclassification case, though in practice there can be uncertainty about the appropriate functional form to be used for this extrapolation.

In continuous variable settings, likelihood-based procedures (i.e., Bayesian and maximum likelihood procedures) are sometimes argued against on the grounds that the required model specification is too arduous and prone to misspecification. In discrete-data settings, however, such arguments are typically obviated because discrete variables do not entail extra assumptions about distributional forms. Thus, problems of misclassification for discrete variables seem prime candidates for likelihood-based methods, given the general large-sample efficiency that accompanies such methods. Greenland (2008) finds that traditional external validation estimators based on Eq. 17.1 are indeed maximum likelihood estimators, although they were not originally derived as such, and that some proposed estimators which are not likelihood-based can be quite inefficient relative to those which are.

Within the realm of likelihood-based procedures, there are several general issues. First, the difficulty of implementation varies considerably with problem. A primary example of this arises with binary exposure and disease, along with internal validation. In the unconstrained case of differential misclassification, there are closed-form expressions for maximum likelihood estimators of all parameters (Lyles 2002). This arises because the model for $(X, W|Y)$ is *saturated*, with six unknown parameters in total in the binary case (parameterized, for instance, as exposure prevalence, sensitivity, and specificity, all of which may vary with Y). Analogously, a parameterization in terms of positive and negative predictive values along with prevalence of apparent exposure leads directly to closed-form estimators, for again it produces a saturated model. The maximum likelihood (ML) estimators of the parameters for the $(W|Y)$ distribution are the sample analogues of the corresponding cell probabilities based on all observations, while those for $(X\$|W, Y)$ are the sample analogues from the validation observations. On the other hand, imposing the assumption of non-differential misclassification reduces the number of unknown parameters to four, and the loss of saturation implies that numerical optimization is required to obtain ML estimates.

One way to obtain ML estimates when validation data are available is via algorithms for missing-data problems (Carroll et al. 2006). Very roughly put, such algorithms iterate back and forth between filling in (imputing) the missing data given the current estimated parameter values and updating the parameter estimates given the current filled-in (completed) data. For instance, with a random internal validation sample, the complete data would comprise (W, X, Y) observations for all subjects, whereas the observed data arise with X missing completely at random for some (usually most) subjects. The EM algorithm or any other optimization procedure can then be applied to the missing-data likelihood function (Little and Rubin 2002), as can more *ad hoc* but popular techniques like multiple imputation (Cole et al. 2006). Bayesian computation can be implemented via similar strategies, with Markov chain Monte Carlo (MCMC) sampling of all unobservables given all observables (see Carlin and Louis (2008) for a general introduction to MCMC, and Gustafson (2003) for application of MCMC to misclassification models). This devolves to iteratively generating Monte Carlo samples of complete data given parameters and incomplete data, and parameters given complete data.

There are a variety of computational approaches to problems in which a prior distribution is used to replace point constraints such as non-differentiality. While MCMC provides a theoretical guarantee of providing a fully Bayesian answer given sufficiently long computing time, reliable implementation can be difficult and it is not very accessible to non-experts. The approximate approach of Monte Carlo sensitivity analysis (Greenland 2003, 2005; Greenland and Lash 2008; Lash et al. 2009) is simpler and intuitive, and works well for many problems, although again it may suffer from range violations of the sort referred to in Sect. 17.3.1, i.e., combinations of sample W prevalences and misclassification probabilities can arise which imply X prevalences below zero or above one. An alternative that avoids these issues is to perform an approximate Bayesian analysis by representing the prior distribution as extra data points and then applying standard likelihood techniques to the augmented set of data (Greenland 2009a, b).

Setting aside the issue of implementation, many contexts involving misclassified variables do seem to require a Bayes or Bayes-like approach since the available information about the relationship between ascertained and actual exposure is amorphous and can only be captured via the specification of a prior distribution. We have already seen a stylized example of this form in Sect. 17.3.1, where the sensitivity and specificity of exposure classification were not known exactly, but were not completely unknown: They could be bounded probabilistically, i.e., plausible prior distributions could be specified. For instance, we could model suppositions such as "sensitivity is likely between 75% and 90%." This theme is explored in Greenland (2009a, b), who considers prior specification for classification parameters at length. An important feature of this work is that, if so desired, prior distributions need be specified explicitly only for those parameters that will not be strongly informed by the data; the remaining parameters are in effect left with improper ("non-informative") priors.

A different situation where Bayesian methods can be used to reflect amorphous assumptions arises in the context of validation data. Often, the assumption of non-differential misclassification seems unjustifiable, but at the same time large departures from non-differentiality are not thought plausible. Chu et al. (2010) investigate prior distributions which reflect this situation and consequently produce an analysis which compromises between those arising from the non-differential assumption and those arising when this assumption is omitted (i.e., allowing arbitrary differentiality). For instance, the joint prior distribution for sensitivity among controls and sensitivity among cases could be assigned such that the two quantities have the same distribution marginally, while also having a high correlation between them. This implies an *a priori* assumption that the two sensitivities are unlikely to be very far apart, with the details of this assertion being controlled by the specific choice of correlation in the prior distribution. The same style of prior can be applied to the two specificities.

17.4 Other Topics

17.4.1 Misclassification of Outcomes

In epidemiological contexts, questions of exposure classification are often paramount. In some settings, however, the outcome variable Y may be subject to misclassification. For instance, Y might be assessed via an imperfect diagnostic test. This leads to an interesting distinction. If Y is a continuous variable, then classical measurement error models for Y lead to no bias in estimators based on a surrogate U for Y. To see this, suppose $U = Y + \varepsilon_U$ where ε_U has zero mean and is independent of all variables including Y. Then, the regression structure is unchanged, i.e., the mean of U given X is the same as the mean of Y given X. In particular, if $Y = \mathrm{f}(X;\beta) + \varepsilon_\mathrm{Y}$, then $U = \mathrm{f}(X;\beta) + \varepsilon_Y + \varepsilon_U$, and so inferences on β from fitting $\mathrm{f}(X;\beta)$ to U are also inferences on the dependence of Y on X, albeit power and precision is reduced by the presence of the additional error ε_U in U. In contrast, the regression of Y or U on an unbiased surrogate $W = X + \varepsilon_X$ for X would produce an attenuated (flattened) regression function (Carroll et al. 2006), and so we should not ignore the measurement error in X. Thus, there is a fundamental asymmetry of X and Y under the simplest continuous error models.

In contrast to the asymmetric nature of regression when X and Y are continuous, when X and Y are binary and their odds ratio describes their dependence, X and Y do play symmetric roles. This symmetry is in part because of the use of a symmetric parameter (the odds ratio). But the fact that independent non-differential misclassification of Y cannot be ignored reflects in part that such misclassification cannot in general be represented in the independent additive form of classical continuous regression.

Put more broadly, apart from some special cases, misclassification of Y changes the regression structure. As a simple way to convey the essence of the situation, say that U arises from Y via non-differential misclassification. Then, the regression of U on X is an affine transform of the regression of Y on X,

$$\Pr(U = 1|X = x) = (1 - Sp) + (Sn + Sp - 1)\Pr(Y = 1|X = x),$$

and hence cannot be linearized exactly if Sn and Sp are unknown (here, X may represent any number of multiple exposures with different data types). Thus, we see a general sense in which a given change in risk of the outcome $Y = 1$ with X is weakened by a factor of $(Sn+Sp-1)$ to yield the change in risk of apparent outcome

$U = 1$ with X. While this multiplicative factor applies to the risk itself, Neuhaus (1999) considers the impact on other scales, such as logit-risk.

The consequence is that, for discrete outcomes, correction for outcome misclassification can be as imperative as for exposure misclassification. It should be noted however that attempts to correct for outcome misclassification in case-control studies can lead to serious bias if applied naively, without taking account of the fact that cases are sampled in a much higher proportion than are controls, i.e., that Y affects the sampling probability (Greenland and Kleinbaum 1983). Furthermore, studies that collect their own outcome data (instead of relying on records) may apply much more stringent classification procedures than used in ordinary clinical practice, making use of external validation data especially hazardous.

17.4.2 Misclassification of Confounders

Poor measurement can be a serious issue for confounding variables as well as for exposure and/or outcome variables (Greenland 1980; Savitz and Baron 1989; Brenner 1993; Marshall et al. 1999; Fewell et al. 2007). As a general rule, adjusting for a misclassified version of a confounder will only partially control for the actual confounder. To illustrate, suppose that binary exposure X and binary outcome Y are not subject to misclassification, but the binary confounder Z is unobserved, with non-differentially misclassified surrogate V taking its place. In the present context, the non-differential assumption corresponds to conditional independence of V and (X, Y) given Z. Thus, the misclassification can be described by the sensitivity *Sn* and specificity *Sp* of V as a surrogate for Z.

For simplicity, suppose that the (X, Y) odds ratio is homogeneous across the Z strata, i.e., $OR(X, Y|Z = 0) = OR(X, Y|Z = 1)$, so that Z may be a confounder, but does not modify the odds ratio. Necessarily then, as *Sn* and *Sp* both increase to one, $OR(X, Y|V = \mathrm{v})$ must tend to $OR(X, Y|Z)$, for both $V = 1$ and $V = 0$. In the other direction, however, as *Sn* and *Sp* decrease to the scenario in which V is completely random noise, whereby the distribution of V no longer depends on Z (i.e., $Sn = 1 - Sp$), stratification by V corresponds to an entirely random division of the population. Thus, for both $V = 1$ and $V = 0$, $OR(X, Y|V = v)$ must tend to the crude (unadjusted) odds ratio relating X to Y. Intuitively then, between the extremes of random and perfect assessment of Z, we should see stratification by V producing results in between the crude $OR(X, Y)$ and the fully adjusted $OR(X, Y|Z)$.

With differential misclassification, this argument no longer holds and it is at least theoretically possible for a V-stratum specific odds ratio to fall entirely outside the range of the crude and fully adjusted odds ratios. The argument can also break down for polytomous variables even if non-differentiality holds (Brenner 1993), although the deviations from it do not appear large in plausible examples.

For the non-differential binary case, Fig. 17.3 displays $OR(X, Y|V = v)$ as *Sn* and *Sp* vary, for specific choices of $(Z|X)$ and $(Y|X, Z)$ distributions. A setting where confounder misclassification leads to a spurious appearance of a relationship between X and Y is given, as is a setting where confounder misclassification

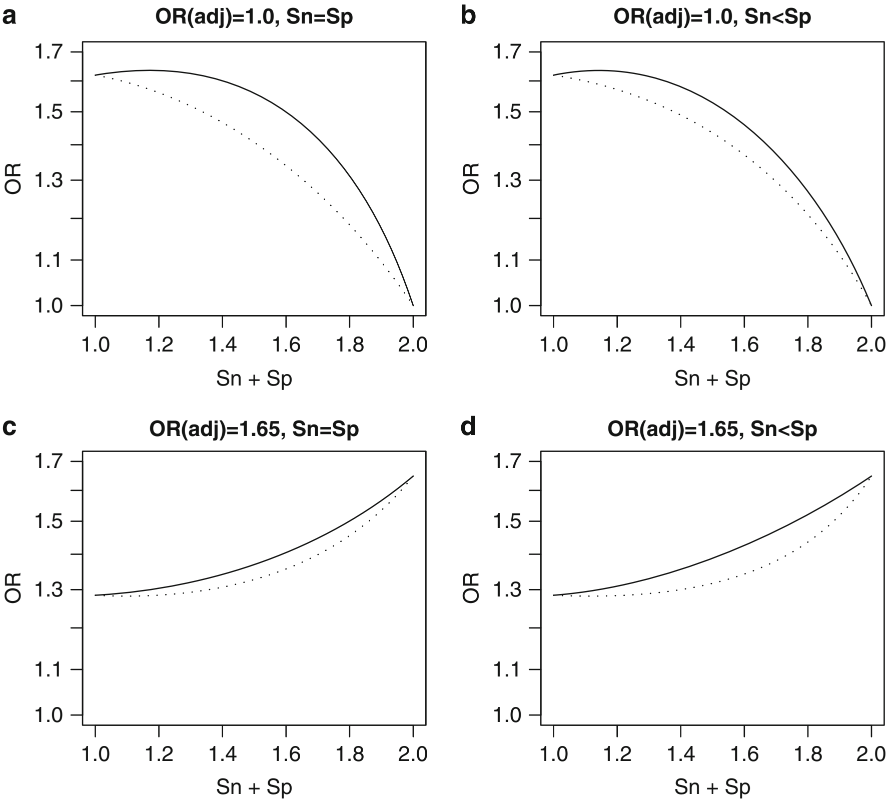

Fig. 17.3 Odds ratio for (X, Y) stratified by V, where V is a non-differentially misclassified surrogate for true confounder Z. Results are shown as the sensitivity and specificity of V vary, with the solid (*dotted*) curve corresponding to the $V = 0$ ($V = 1$) stratum. Note the use of logarithmic axis. In all cases, $\Pr(Z = 1|X = 0) = 0.25$ and $\Pr(Z = 1|X = 1) = 0.75$. In the upper panels, $\text{logitPr}(Y = 1|X, Z) = \text{logit}(0.1) + Z$, so X and Y are unassociated given Z. In the lower panels, $\text{logitPr}(Y = 1|X, Z) = \text{logit}(0.1) + 0.5X + 0.5Z$, i.e., X and Y have a homogeneous odds ratio of $\exp(0.5) \approx 1.65$ within levels of Z. In the *left-hand panels*, $Sn = Sp$. In the *right-hand panels*, Sp exceeds Sn, specifically $(Sn-0.4) = 1.5(Sp-0.6)$. In all situations, as the classification worsens to random ($Sn + Sp = 1$), $OR(X, Y|V = v)$ tends to the crude X-Y odds ratio. As the classification improves to perfect ($Sn + Sp = 2$), $OR(X, Y|V = v)$ tends to the fully adjusted $OR(X, Y|Z)$

attenuates the strength of the fully adjusted $(X, Y|Z)$ relationship. The figure also illustrates the fact that confounder misclassification can induce spurious heterogeneity (Greenland 1980). Starting with the homogeneous situation where $OR(X, Y|Z = z)$ is constant across Z, one sees that nonetheless $OR(X, Y|V = v)$ can depend on V even if the sensitivity and specificity for Z do not vary with X or Y. Analogous results apply to other measures of effect as well as odds ratios and show that confounder misclassification can also mask heterogeneity (Greenland 1980).

17.5 Conclusions

We have reviewed basic features and principles of misclassification, along with methods that attempt to account for it. As with its companion topic of measurement error, we would emphasize that typical adjustment methods are highly sensitive to underlying assumptions and models. In particular, simple assumptions such as non-differentiality, error independence, and error additivity often have no basis in fact and are easily violated, yet can have enormous impact on both the bias and precision of inferences. Thus, while an adjustment may often be better than no adjustment at all, we recommend sensitivity analysis, i.e., evaluation of how stable the results of adjustment are as the assumptions producing the adjustment are varied. Also, as illustrated in Sect. 17.3.1 and alluded to elsewhere, Bayesian techniques can be used to relax assumptions and thus better represent situations in which misclassification parameters are known approximately rather than exactly (such as when misclassification is thought to be close to, rather than exactly, non-differential). Such weakening of assumptions can (and we argue should) be made even if frequentist identification is sacrificed, for Bayesian identification can be maintained by using plausible priors in place of the questionable assumptions (Greenland 2009a, b; Gustafson 2009).

18.1 Introduction

All epidemiological studies are (or should be) based on a particular *source population* followed over a particular *risk period*. The goal is usually to estimate the effect of one or more exposures on one or more health outcomes. When we are estimating the effect of a specific exposure on a specific health outcome, *confounding* can be thought of as a mixing of the effects of the exposure being studied with the effect(s) of other factor(s) on the risk of the health outcome of interest. *Interaction* can be thought of as a modification, by other factors, of the effects of the exposure being studied on the health outcome of interest and can be subclassified into two major concepts: *biological interdependence of effects*, which includes concepts of synergism and antagonism, and *effect-measure modification*, also known as heterogeneity of a measure across the levels of another factor. Both confounding and interaction can be assessed by stratification on these other factors (i.e., the potential confounders or effect-measure modifiers). This chapter covers the basic concepts of confounding and interaction and provides a brief overview of analytical approaches to these phenomena. Because these concepts and methods involve far more topics than we can cover in detail, we provide many references to further discussion beyond that in the present handbook, especially to relevant chapters in Modern Epidemiology by Rothman et al. (2008).

18.2 Confounding

18.2.1 Basic Concepts

When estimating the effect of an exposure on those exposed, confounding occurs when the exposed and non-exposed subpopulations of the source population have different background disease risks, which is to say these subpopulations would have different disease risks even if exposure effects had been absent from both subpopulations (Greenland and Robins 1986; Greenland et al. 1999a, b; Maldonado and Greenland 2002; Rothman et al. 2008, Chap. 4). When we estimate the effect of exposure on the exposed by comparing the frequency of disease in the exposed and non-exposed groups, we assume that the disease frequency in the non-exposed group provides a valid estimate of what the disease frequency would have been in the exposed group if it had not been exposed. If this assumption is incorrect, that is, if the exposed and non-exposed groups would have had different disease frequencies in the counterfactual situation in which the exposed group had not been exposed, then we say that the comparison of the exposed group to the non-exposed group is confounded.

More generally, confounding can arise when the exposed and non-exposed groups are not completely comparable or "exchangeable" with respect to their response to exposure; that is, for at least one level of exposure, the exposed and unexposed groups would exhibit different risks even if they both had experienced that exposure level (Greenland et al. 1999b; Maldonado and Greenland 2002; Greenland and Robins 2009). Note that the earlier definition takes this level to be that of non-exposure because it is presumed there that the effect of exposure on the exposed is the effect of interest. If instead we were interested in the effect of non-exposure on the non-exposed (as might be the case in a study of a preventive factor), we would have confounding if the exposed group failed to exhibit the risk that the non-exposed would have had if they had been exposed.

This problem of non-comparability (non-exchangeability) can also occur in randomized trials because randomization may fail, leaving the treatment groups with different characteristics (and different baseline disease risk) at the time that they enter the study, or because of differential loss and non-compliance across treatment groups. However, there is more concern about non-comparability in observational epidemiology studies because of the absence of randomization. Randomization prevents certain sources of confounding (e.g., confounding due to physician selection of treatment based on patient characteristics, also known as "confounding by indication"); also, bias due to differential loss and non-compliance can be at least partially controlled by using the randomization indicator (the "intent-to-treat" variable) as an instrumental variable (Sommer and Zeger 1991; Greenland 2000a). These benefits of randomization are not available in observational studies, and in fact confounding should be expected to occur as a by-product of ordinary life events and choices.

As an example, if we compare the risk of lung cancer in people with a low dietary beta carotene intake compared with people with a high dietary beta carotene intake, it is very likely that these two groups will differ with respect to other risk factors for lung cancer such as tobacco smoking because people who are less health conscious are more likely to smoke as well as to neglect dietary recommendations. If this is the case (e.g., if a greater percentage of people smoke in the low beta carotene intake group than in the high beta carotene intake group), then smoking will confound the association between beta carotene intake and lung cancer: the higher smoking prevalence among those with a low beta carotene diet will lead to a higher lung cancer risk among them compared to those with a high beta carotene diet, even if beta carotene intake itself has no effect on lung cancer risk. This in turn will create a spurious inverse association between beta carotene and lung cancer if we do not or cannot fully adjust for smoking differences.

Any variable that affects disease in the absence of exposure has the potential to confound the exposure-disease relationship. It will confound that relationship among the exposed if, in the absence of exposure, it would have a distribution that is sufficiently different across exposure groups to produce a difference in risk across those groups even if exposure were absent. This was the case for smoking in the beta carotene example. A confounder, if not adequately controlled, will bias the estimated effect of exposure on disease. The bias will be upward if the higher-risk levels of the confounder occur more frequently among the exposed; conversely, the bias will be downward if the higher-risk levels of the confounder occur more frequently among the unexposed.

Confounding may even reverse the apparent direction of an effect in extreme situations. Confounding may also occur when the main exposure under study has no effect on the risk of disease – a spurious association may be observed which is entirely due to confounding. Factors associated with confounders can also act like confounders and serve as surrogates for confounders, provided that they are not affected by exposure or disease. For example, socioeconomic status may serve as a surrogate measure of causal factors (living conditions, lifestyle, lack of preventive care, etc.) that are potential confounders.

Three conditions are traditionally given as necessary (but not sufficient) for a factor to be a confounder of the exposure effect in the exposed (Rothman et al. 2008, Chap. 9). First, to produce confounding, a factor has to be predictive of disease in the absence of the exposure under study. Note that a confounder need not be a genuine cause of the disease under study, but merely "predictive" within exposure levels apart from chance relations. Hence, surrogates for causal factors (e.g., ethnicity, gender, socioeconomic status) may be regarded as potential confounders, even if they are not direct causal factors. It is not always clear from the data whether an observed relation between the factor and disease represents a genuine (replicable) predictive quality, as opposed to (say) chance. In making such a determination, prior information as opposed to statistical testing should play a dominant role (Greenland and Neutra 1980; Miettinen and Cook 1981; Robins and Morgenstern 1987). This is why one almost always sees adjustment made for age and sex: these factors are known to be predictive of risk of most diseases. When prior information is not available, one must of course turn to the data collected for the study as a guide as to whether the factor is predictive of disease in the source population; even in these cases, however, there are better strategies for confounder selection than those based on statistical testing. We will return to this topic below.

Second, a confounder has to be associated with the study exposure in the source population. It may occur that when participants in a case-control study are selected from the source population, then due to chance, a factor may be associated with exposure in the study, even though it was not associated with exposure in the source population. In this situation, the factor is not a confounder (Miettinen and Cook 1981; Robins and Morgenstern 1987). Although in practice it is common to use the data actually collected to decide whether a factor is associated with exposure, more commonly the data are used to decide whether adjustment for the factor makes an important difference in the estimated exposure effect, a practice we will discuss below.

In a case-control study, one should expect a confounder to be associated with exposure among the controls (at least if the controls are selected with no bias). If the factor is not associated with exposure among controls, an association may still occur among the cases simply because the study factor and a potential confounder are both risk factors for the disease, but this is a consequence of those effects and so does not cause confounding. A factor-exposure association will only indicate confounding by the factor if it reflects the association in the source population.

Third, a variable that is affected by the exposure or by the disease, for example, an intermediate in the causal pathway between exposure and disease, or conditions that are caused by the health outcome of interest, should not be treated as a confounder because to do so could introduce serious bias into the results (Greenland and Neutra 1980; Robins and Morgenstern 1987; Robins and Greenland 1992; Weinberg 1993; Cole and Hernan 2002; Rothman et al. 2008, Chap. 9). For example, in a study of obesity and death from coronary heart disease, it would be inappropriate to control for hypertension if hypertension was a consequence of obesity and, hence, a part of the causal chain leading from obesity to death from coronary heart disease. On the other hand, if hypertension itself was of primary interest, then it would be studied directly; obesity would be regarded as a potential confounder if it also involved exposure to other risk factors for death from coronary heart disease.

Similarly, we should avoid controlling for health outcomes that may be part of disease genesis, such as reduced pulmonary function following exposure to a respiratory hazard in a study of chronic obstructive lung disease (Checkoway et al. 2004). We would, however, be justified in controlling for baseline (i.e., pre-exposure) lung function if there were reasons to believe that baseline lung function was associated with subsequent exposure level. Evaluating whether certain factors are exposure or health outcome intermediates in causal pathways requires information external to the study. Intermediate variables can sometimes be included in the analysis, although special techniques are then required to avoid adding bias (Robins 1989; Robins and Greenland 1992, 1994; Robins et al. 2000). In no case would control of a variable affected by the disease be valid, however (Greenland et al. 1999a; Pearl 2009).

Assessment of confounding by a factor that is not an intermediate involves consideration of whether the exposed and non-exposed groups are "comparable" in the source population with respect to their disease risk in the absence of exposure. In practice, we often focus on specific potential confounders – variables that are risk predictive of disease in the absence of exposure (such as age and sex) and assess whether they are associated with exposure in the source population on which the study was based. If such an association is present, it is evident that the two groups are not comparable or exchangeable with respect to baseline risk. If such an association is absent, however, it does not mean that the groups are comparable because there may be other uncontrolled risk factors that confound the observed association, or the association may have been obscured by measurement error.

Because it involves judgments about causal as well as temporal ordering, the property of being a confounder cannot be determined from data alone (Greenland and Neutra 1980; Miettinen and Cook 1981; Greenland and Robins 1986; Greenland et al. 1999a; Robins 2001; Hernan et al. 2002; Pearl 2009). Once that ordering is established, however, it is common to assess confounding by seeing whether the main effect estimate changes when the potential confounder is controlled in the analysis. In this approach, near equality of the crude and adjusted effect estimates is taken as evidence that there is no confounding by the factor; conversely, an important difference is taken as evidence of confounding by the factor. Many epidemiologists prefer to make a decision based on the basis of this "collapsibility" or "change-in-estimate" criterion (rather than the criterion of "exchangeability"), although this approach can be misleading, particularly if (as usual) there is misclassification of the adjustment factors or the exposure (Greenland 1980; Greenland and Robins 1985; Savitz and Baron 1989; Marshall and Hastrup 1996, 1999) or if the outcome is common and the measure is an odds ratio or rate ratio (Miettinen and Cook 1981; Greenland and Robins 1986; Greenland 1996; Greenland et al. 1999b); also, this criterion does not exhibit good statistical properties, although it is no worse than significance-testing procedures (Maldonado and Greenland 1993).

The decision to control for a presumed confounder can be made with more confidence if there is supporting prior knowledge that the factor is predictive of disease, independent of its association with exposure. Such prior knowledge is usually available for well-studied factors such as age, sex, and tobacco smoking. At the very least, it is usually known if the factor cannot have been affected by exposure, for example, if the factor represents an event occurring before exposure. If even this much is uncertain, the decision to control or not control a variable may be controversial, in which case analyses both with and without its control may be presented (Greenland and Neutra 1980).

As a final caution, in studies involving aggregate-level effects (such ecologic and multilevel studies), a factor at one level may, if not controlled, confound effect estimates at another level, and a factor may modify and confound effects differently at different levels of aggregation. For example, both the income of an individual and the income of his or her neighborhood may separately predict risk of an outcome, possibly in opposite directions. Robbery rates are often higher in low-income neighborhoods, yet within neighborhoods it could still be that an individual's risk of robbery went up as his or her income went up. In that case, both neighborhood income and individual income could be confounders, but would confound effect estimates in opposite directions if both were positively and separately associated with the exposure under study. Thus, regardless of level of interest (e.g., country, neighborhood, individual), it is often essential to measure and adjust for variables on other levels (Greenland 2001).

18.2.2 Example of Confounding

Table 18.1 presents a hypothetical example of confounding in a cross-sectional study of asthma. Overall, one-half of the study participants are smokers and one-half are not. However, two-thirds of those in the exposed group are smokers compared with one-third of the non-exposed workers. Thus, although exposure is not associated with asthma either among smokers (the prevalence of asthma is 40% in the exposed and 40% in the non-exposed, prevalence ratio (PR) = 1.0) or in non-smokers (the prevalence of asthma is 20% in the exposed and 20% in the non-exposed, PR = 1.0), it is associated with asthma (PR = 1.25) when the two subgroups are combined. This occurs because smoking is associated with the exposure in the source population and is an independent risk factor for asthma. In this hypothetical example, each stratum-specific estimate is 1.00; thus the adjusted estimate will also be 1.00 whatever weights are used. Thus, the crude

Table 18.1 Hypothetical example of confounding by tobacco smoking in a study of occupational asthma

	Smokers		Non-smokers		Total	
	Exposed	Non-exposed	Exposed	Non-exposed	Exposed	Non-exposed
Asthma cases	800	400	200	400	1,000	800
Non-cases	1,200	600	800	1,600	2,000	2,200
Total	2,000	1,000	1,000	2,000	3,000	3,000
Prevalence (%)	40	40	20	20	33.3	26.7
Prevalence ratio	1.0		1.0		1.25	

prevalence ratio is 1.25, whereas the adjusted prevalence ratio is 1.00, indicating that confounding has occurred (provided that there has not been biased selection of the study participants from the source population).

18.2.3 Control in the Study Design

Confounding can be controlled in the study design, in the analysis, or both. There are three common methods for control at the design stage (Rothman et al. 2008, Chap. 11). The first is randomization – random allocation of participants to exposure categories. However, this is usually only an option for potentially beneficial exposures, for example, it would be impractical and unethical to conduct a randomized trial of the health effects of smoking, and as mentioned earlier, randomization may fail to prevent all confounding.

A second method of control at the design stage is to restrict the study to narrow ranges of values of the potential confounders, for example, by restricting the study to white males aged 35–54. This approach has a number of conceptual and computational advantages, but may severely restrict the number of potential study subjects and ultimately limit the generalizability of the study.

A third method of control involves matching study subjects on potential confounders. For example, in a cohort study, one could match a white male non-exposed subject aged 35–39 with an exposed white male aged 35–39. This will prevent age-gender-ethnicity confounding in a cohort study, but is seldom done because it is expensive and time-consuming. In case-control studies, matching does not prevent confounding but does facilitate its control in the analysis in that matching on a strong confounder will usually increase the precision of effect estimates. However, matching may reduce precision in a case-control study if it is done on a factor which is associated with exposure, but is only a weak risk factor for the disease of interest.

If a matching factor is not a risk factor, the matching process effectively turns it into a confounder that must be controlled in the analysis, thus reducing precision and increasing analytical complexity. For example, in a case-control study of power-frequency electromagnetic field (EMF) exposure and childhood cancer, choosing sibling controls (i.e., for each case choosing a sibling as a control) would mean that in almost every instance, the case and control would have lived in the same house and would have similar EMF exposure, resulting in almost no exposure-discordant pairs and almost no precision in the resulting matched-pair estimates.

As already mentioned, matching may be expensive and time-consuming. Finding suitable controls becomes increasingly difficult as the number of matching factors increases beyond two or three. Moreover, when it occurs, the increase in precision from matching is often modest, typically involving a 5–15% reduction in the variance of the effect estimate (Schlesselman 1982; Thomas and Greenland 1983). Therefore, although there are many discussions of matching stress issues of statistical efficiency, practical considerations (such as ease of finding controls) are often more important (Rothman et al. 2008, Chap. 11).

18.2.4 Control in the Analysis

Confounding can also be controlled in the analysis by adjusting simultaneously for all confounding factors or a sufficient subset of them. This presumes, of course, that a sufficient subset has been accurately measured, which is often not the case. Methods for controlling confounding in the analysis are discussed in more depth in the chapters on specific study designs (chapters ▶Cohort Studies, ▶Case-Control Studies, and ▶Intervention Trials of this handbook), in Part II (Methodological Approaches in Epidemiology) of this handbook, and in many textbooks (e.g., Rothman et al. 2008, Chaps. 15–21). In the simplest situation, control of confounding in the analysis involves stratifying the data according to the levels of the confounder(s) and calculating an effect estimate that summarizes the association across strata of the confounder(s). As an example, controlling for age (grouped into five categories) and gender (with two categories) might involve grouping the data into the 10 $(= 5 \times 2)$ confounder strata and calculating a summary effect estimate, which is a weighted average of the stratum-specific effect estimates. It is usually not possible to control simultaneously for more than two or three confounders in a stratified analysis, since finer stratification will often lead to many strata containing no exposed or no non-exposed persons. Such strata are uninformative; thus, too fine stratification is wasteful of information. This problem can be mitigated to some extent by the use of regression modeling (cf. chapter ▶Regression Methods for Epidemiological Analysis of this handbook), which allows for simultaneous control of more confounders by "smoothing" the data across confounder strata.

18.2.5 Assessment of Confounding

When one lacks data on a suspected confounder, and thus cannot control confounding directly, it is still desirable to assess the likely direction and magnitude of the confounding. In particular, it may be possible to obtain information on a surrogate for the confounder of interest. For example, social class is associated with many lifestyle factors such as smoking and may therefore be a useful surrogate for some lifestyle-related confounders. Even though confounder control will be imperfect in this situation, it is still possible to examine whether the exposure effect estimate changes when the surrogate is controlled in the analysis and to assess the strength and direction of the change.

As an example, suppose the relative risk relating low dietary beta carotene intake to lung cancer actually increases (e.g., from 2.0 to 2.3) or remains stable (e.g., at 2.0) when social class is controlled. This might be taken as evidence that the observed excess risk is not entirely due to smoking because social class is associated with smoking (Kogevinas et al. 1997), and control for social class involves partial control for smoking. The strength of this evidence depends of course on what exposure is being studied and what sort of classification errors or other sources of bias are present.

Even if it is not possible to obtain confounder information for any study participants, it may still be possible to estimate the likely strength of confounding by particular risk factors. This is often done in occupational studies, where tobacco smoking is a potential confounder, but smoking information is rarely available. In fact, although smoking is the strongest risk factor for lung cancer, with relative risks of tenfold or more, it appears that smoking rarely exerts a confounding effect of greater than 1.5 times in studies of occupational disease (Axelson 1978, 1989; Siemiatycki et al. 1988; Kriebel et al. 2004) (although this degree of confounding may still be important in some contexts).

There are several approaches to the assessment of potential confounding by factors such as cigarette smoking when data are lacking or incomplete. One approach is to conduct an analysis of smoking-related diseases other than the disease of primary interest (Steenland et al. 1984). If mortality from such diseases (e.g., non-malignant respiratory disease) is not elevated, this may suggest that any excess for the disease of interest is unlikely to be due to smoking. Similarly, one might be less inclined to attribute an excess of an alcohol-related cancer to unusually high drinking prevalence among the exposed if liver cirrhosis mortality is not elevated.

When detailed individual risk factor information is not available on a potential confounder, it may be possible to assess the impact of this factor on risk estimates by conducting a type of *sensitivity analysis* that estimates the potential direction and extent of confounding (Cornfield et al. 1959; Bross 1967; Axelson 1978, 1989; Schlesselman 1978; Checkoway and Waldman 1985; Axelson and Steenland 1988; Flanders and Khoury 1990; Rothman et al. 2008, Chap. 19; Lash et al. 2009; see also chapter ▶Sensitivity Analysis and Bias Analysis of this handbook). In this sensitivity analysis, the magnitude of the effect of the potential confounder on the disease should be known with some confidence, and the prevalence of the potential confounder among the exposed and comparison groups should be estimable, within reasonable bounds. Then, a range of confounding effects, including a "worst case scenario," can be calculated (Checkoway et al. 2004).

The overall incidence rate, I, of disease in a population can be written as the sum of incidence rates at the different levels of the confounder, weighted by the proportion of the population at each confounder level (Axelson 1978). For a confounder which has two levels (present, absent) whose presence multiplies the rate by the relative risk due to the confounder (RR_c), we have

$$I = I_0(1 - p_c) + RR_c(I_0)(p_c)$$

where:

I = incidence rate overall
I_0 = incidence rate among those who are confounder negative
p_c = prevalence of the confounder in the source population from which the cases arose

This expression can be expanded to include several levels of a confounder, for example, light, moderate, and heavy smoking. By applying the equation to two (or more) study groups (e.g., exposed and non-exposed subgroups) for which $\mathrm{p_c}$ is assumed to differ, one can calculate a confounding bias factor B_c for comparisons of these two exposed groups. If there is no effect of exposure, then B_c is the magnitude of effect one would observe due to differences in $\mathrm{p_c}$ alone. Then, if RR_{Obs} is the observed relative risk comparing exposed to non-exposed,

$RR_{Adj} = RR_{Obs}/B_c$ is the adjusted relative risk, controlling for confounding.

To illustrate, suppose that we observe $RR_{Obs} = 3.2$ for lung cancer and some dichotomous occupational exposure, and we are concerned about how much of this elevation is due to confounding by smoking, but there are no smoking measurements in the study. We might assume that smoking habits in the non-exposed approximate those of other typical blue-collar workers whose smoking habits have been studied. To estimate the most extreme confounding that might reasonably be expected, we might assume that the exposed were heavier smokers, with habits more like the 90th percentile of blue-collar workers. These assumptions would imply that the non-exposed might have been 50% non-smokers, 40% moderate smokers, and 10% heavy smokers, whereas the exposed were 20% non-smokers, 55% moderate smokers, and 25% heavy smokers. Assuming that moderate smoking confers a relative risk of smoking of 10 compared to non-smokers, and heavy smoking a relative risk of 20, the confounding due to smoking is $B_c = 1.65$. Thus, one would observe a relative risk of 1.65 comparing exposed to unexposed due to these smoking differences alone. One can then calculate that $RR_{Adj} = 3.2/1.65 = 1.9$ as a hypothetically "adjusted" exposure effect under a plausible, but unlikely, scenario for smoking differences among exposed groups. If RR_{Adj} is elevated, one might conclude that confounding is unlikely to be the entire explanation for the elevated risk (Checkoway et al. 2004).

This method allows one to place limits on the degree of confounding that can result from failure to adjust for an unmeasured risk factor that is associated with the exposure under study. Its application is restricted however to control for factors whose risks are well established quantitatively and for which the confounder prevalence in the population can be estimated fairly reliably. The relative risk that would result from differences in the prevalence of a covariate, such as smoking or alcohol consumption, may be quite limited, even in the absence of complete knowledge about the covariate (Cornfield et al. 1959; Bross 1967; Flanders and Khoury 1990). In particular, Flanders and Khoury (1990) showed that

$$1 \leq B_c \leq \min\{OR, RR_c, 1/p_c, RR_c/(q_c + RR_c * p_c), OR/(q_c + RR_c * p_c)\}$$

where B_c, RR_c, and p_c are as above, $q_c = 1 - p_c$, and OR is the odds ratio measuring the association between exposure and the covariate (both measured dichotomously in this example). Using this equation, rather severe limits can be placed on the range of possible values of B_c with information about p_c and RR_c alone, making no assumption about OR at all. For example, if $p_c = 0.5$, and RR_c for esophageal cancer from 1 pack/day smoking $= 5$, then $B_c = 1.7$. That is, given $RR_c = 5$, an observed RR_{obs} for an exposure effect is unlikely to be confounded by more than 1.7 times. With reasonable assumptions about the likely values of OR and RR_c, the association between exposure and the confounder, the maximum value for B_c could be lower or higher. This method can be extended for the situation in which there are multiple levels of exposure and multiple levels of covariates (Schlesselman 1978; Flanders and Khoury 1990) and to other measures of association such as odds ratios (Yanagawa 1984).

A more sophisticated version of sensitivity analysis places uncertainty distributions (priors) on the unknown quantities in the sensitivity formula, repeatedly draws values from these distributions and corrects the data or estimates based on the drawn values, adds in a random-error correction, and presents the resulting distribution of corrected estimates. Such Monte-Carlo sensitivity analysis has long been a staple of risk analysis and is now finding application in epidemiology, along with related Bayesian methods (e.g., see Greenland 2003, 2005; Steenland and Greenland 2004; Rothman et al. 2008, Chap. 19; Lash et al. 2009; see also chapter ▶Sensitivity Analysis and Bias Analysis of this handbook).

Sensitivity analysis can also be useful in certain situations in which confounder information has been collected, but the validity or precision of those data are weak. Sometimes smoking data are available on only a subset of the members of a cohort. One option is to conduct an analysis that controls for smoking directly on the subset with smoking data. However, the precision of this analysis and the generalizability of findings to the entire cohort may be questionable. Instead, one might apply the data relating the confounder to exposure among this subset in a sensitivity analysis for the entire cohort (Fingerhut et al. 1991). A third option is to adjust the entire cohort based on the data from the subset, using two-stage methods or missing-data methods (Rothman et al. 2008, Chap. 15).

18.2.6 Relationship Between Confounding and Other Biases

In this chapter confounding has been defined as non-comparability (non-exchangeability) of the exposed and non-exposed subgroups in the source population with respect to their risk of the disease outcome in the absence of exposure. Confounding is thus a property of the source population rather than of the specific group of study participants.

Selection bias involves biases arising from the procedures by which the study participants are selected (or select themselves) from the source population. Thus, selection bias is not an issue in a cohort study (or cross-sectional study) involving complete recruitment and follow-up because in this instance the study group is the entire source population. However, selection bias can occur if participation in the study or follow-up is incomplete. Selection bias is usually more of an issue in case-control studies in that it may occur if the case group does not include (or is not representative of) all cases in the source population or if the control group is not representative of the population at risk that the cases came from.

If control selection involves only sampling at random from the entire source population with complete cooperation, selection bias is a minor concern. More realistically, however, selection bias is likely if response rates differ according to exposure level and disease status. When controls are selected from among persons with other diseases, considerable care must be taken in specifying the diseases that form the control group. In particular, a specific disease may not correctly reflect the exposure pattern in the source population, especially if it is caused by the study exposure. One strategy is to include only diseases that are thought to be unrelated to the exposure(s) of interest (Rothman et al. 2008, Chap. 8), but this requirement may be difficult to satisfy in practice due to lack of adequate evidence for the absence of exposure effects (Axelson et al. 1982).

An alternative method is to select as controls a sample of all other diseases. This approach is reliable if one can be sure the factor under study does not markedly increase risk of numerous or the most common diseases. It has become common practice to exclude diseases known to be related to exposure from the pool of potential controls; however, even this restriction will not always eliminate bias (Pearce and Checkoway 1988).

Selection bias and confounding are not always clearly demarcated. In particular, non-response at baseline of a cohort can be viewed as a source of confounding, since it may produce associations of exposure with other risk factors in the study cohort and thus turn those factors into confounders (Greenland et al. 1999a). A similar phenomenon occurs in case-control studies when selection is affected by a factor that itself affects exposure. An example occurs when matching on a factor that is associated with exposure in the source population; even if the factor is not a risk factor for disease in the absence of exposure, matching may turn it into a confounder which must be controlled in the data analysis because matching will create the necessary factor-disease association if exposure affects disease (Rothman et al. 2008, Chap. 11). Unfortunately, as discussed earlier, if selection is affected by exposure and associated with case-control status (e.g., selection bias due to inappropriate selection of controls from persons with other diseases, or selection on factors affected by exposure), stratification on the selection-related factors will rarely produce valid estimates, and hence this type of selection bias should not be viewed as confounding.

Information bias is the result of misclassification of study participants with respect to disease or exposure status. Thus, the concept of information bias refers to those people actually included in the study, whereas selection bias refers to the selection of the study participants from the source population, and confounding generally refers to non-comparability of subgroups within the source population. There are many methods to adjust for misclassification, for example, (Copeland et al. 1977; Greenland and Kleinbaum 1983; Espeland and Hui 1987; Greenland 1988;

Armstrong et al. 1992; Thomas et al. 1993; Armstrong 1998; Carroll et al. 2006). These methods require estimates of sensitivity and specificity, predictive values, or the reliability of the measurement, based on prior information or validation data. Estimates based on prior information are often only best guesses that may not apply to the population under study. However, it is an informative exercise to conduct sensitivity analyses that explore the range of results that might have occurred under various scenarios (Rothman et al. 2008, Chap. 19), and again, Monte-Carlo sensitivity analyses and Bayesian analyses may be applied (Gustafson 2003; Fox et al. 2005; Greenland 2005, 2009a; Rothman et al. 2008, Chap. 19; Lash et al. 2009; see also chapter ▶Sensitivity Analysis and Bias Analysis of this handbook).

Some consider any bias that can be controlled in the analysis as confounding, but this definition is too general because any bias control requires background information for proper execution, and any bias can be controlled in the analysis given enough background information. Confounding is distinguished in that it represents a mixing or confusion of the effects of other factors with the effects of the study exposure, a concept that goes back at least as far as the writings of John Stuart Mill (Greenland et al. 1999b). Other biases are then categorized according to whether they arise from the selection of study subjects (selection bias), their classification (information bias), or misapplication of statistical methods.

Most observational studies suffer from more than one form of bias, and the effects of multiple biases may compound error. Perhaps the best-appreciated situation is when there is misclassification of a confounder, in which case attempts to control for the confounder will not fully control that confounder and may actually increase bias (Greenland 1980; Greenland and Robins 1985; Savitz and Baron 1989; Marshall and Hastrup 1996, 1999). When (as is often the case) multiple biases are present, many complex and counterintuitive phenomena can occur, and a clear picture of the net effects of bias will require analyses that account for these bias interactions (Greenland 2005; Rothman et al. 2008, Chap. 19; Lash et al. 2009).

18.3 Interaction

18.3.1 Basic Concepts

Concepts of *interaction* and *effect-measure modification*, also known as effect heterogeneity and effect variation, refer to conditions in which the effect of exposure on the outcome under study varies by some other factor. In other words, in order to know or estimate the effect of exposure on an outcome (such as a disease time, a disease risk, or a disease rate), we must first know whether or not another factor is present (or what the level of this other factor is). This concept can be subclassified into two major concepts: *biological interdependence of effects*, which includes synergism and antagonism, and *effect-measure modification*, also known as heterogeneity of an effect measure. With regard to the latter, all secondary risk factors modify either the rate (or risk) ratio or the rate (or risk) difference when an exposure effect is present, and uniformity over one measure implies non-uniformity over the other (Steenland and Thun 1986; Rothman et al. 2008, Chap. 4), for example, an apparent additive joint effect implies a departure from a multiplicative model.

A further source of ambiguity is that the term "effect modification" implies that one factor in some way biologically "modifies" the effect of the other factor, but this is not necessarily the case. For this reason, the terms "effect-measure modification" and "effect-measure variation" are more accurate terms and are logically equivalent to the definition of "interaction" used in most statistics books and computer programs (Rothman et al. 2008, Chap. 5).

The concepts of interaction and confounding are quite distinct. An effect-measure modifier may or may not be a confounder and a confounder may or may not be an effect-measure modifier (Miettinen 1974; Rothman et al. 2008, Chap. 5). For example, if we are comparing exposed and non-exposed subgroups of a population, and the percentage of people who smoke (and the intensity of smoking and the length of time that each person has been smoking) is the same in both groups, then smoking is not a confounder. However, the rate ratio for the exposure effect may still vary by smoking status, for example, the exposure may double the risk of disease in smokers but have no effect in non-smokers. In this situation, smoking would not be a confounder but would be an effect-measure modifier.

18.3.2 Example of Effect-Measure Modification

Table 18.2 presents a hypothetical example of effect-measure modification in a cross-sectional study of asthma. The overall findings are the same as for the study presented in Table 18.1, but the stratum-specific findings are different. Now there is no confounding by smoking because the percentage of smokers is the same in the exposed and non-exposed groups. However, there is effect-measure modification since the prevalence ratio (for the association of exposure with disease) is 1.5 in smokers and 1.0 in non-smokers. Thus, whereas the assessment of confounding involved the comparison of the crude and adjusted effect estimates, the assessment of effect-measure modification involves the comparison of the stratum-specific effect estimates with each other.

Table 18.2 Hypothetical example of effect modification by tobacco smoking in a study of asthma prevalence

	Smokers		Non-smokers		Total	
	Exposed	Non-exposed	Exposed	Non-exposed	Exposed	Non-exposed
Asthma cases	600	400	400	400	1,000	800
Non-cases	900	1,100	1,100	1,100	2,000	2,200
Total	1,500	1,500	1,500	1,500	3,000	3,000
Prevalence (%)	40	26.7	26.7	26.7	33.3	26.7
Prevalence ratio	1.5		1.0		1.25	

18.3.3 Concepts of Interaction

Although at first glance the assessment of interaction is relatively straightforward, there are considerable hidden complexities. Some of the analytical issues in studying effect-measure modification will be illustrated with data (Table 18.3) from a study by Selikoff et al. (1980) of lung cancer death rates per 100,000 person-years at risk in relation to exposure to cigarette smoke and asbestos (Steenland and Thun 1986). The rate difference due to asbestos exposure is 472 per 100,000 person-years in non-smokers and 736 per 100,000 person-years in smokers. Thus, the rate difference for the effect of asbestos exposure on lung cancer mortality is lower in non-smokers than in smokers. On the other hand, the rate ratio for the same effect is higher in non-smokers (asbestos rate ratio = 17.5) than in smokers (asbestos rate ratio = 4.7). Thus, both the rate difference and the rate ratio are subject to effect-measure modification in that the effect estimate depends on the presence or absence (or more generally, the level) of another factor (i.e., smoking), but the dependencies are in opposite directions: the rate difference is larger in smokers and the rate ratio is larger for non-smokers.

For the most part, statisticians have taken this dependence of modification on the underlying effect measure to imply that the assessment of interaction is "model dependent" (Kupper and Hogan 1978; Walter and Holford 1978), and in most of statistics, the term "interaction" corresponds to effect-measure modification. In contrast to these statistically based definitions, other authors adopt a definition of *biological* interaction in which two factors are said to exhibit interdependent effects or "synergism" if their presence is required by the same sufficient cause and "antagonism" if the absence of one and the absence or presence of the other is required (Rothman 1976; Rothman et al. 2008, Chap. 2). With this conceptualization, one can show that the presence and degree of effects and effect-measure modification depend to a large extent on the prevalence of causal cofactors of exposure, as well as the actual biological mechanisms at work (Rothman et al. 2008; see chapter ▶Basic Concepts of this handbook for further explanation).

A closely related conceptualization defines biological interaction to be present when individual patterns of response (the potential or counterfactual outcomes) to one factor changes when the other "interacting" factor is changed (Greenland and Poole 1988; Rothman et al. 2008, Chap. 5). Under this conceptualization, non-additivity of risks will imply the presence of biological interaction, and under

Table 18.3 Example of joint effects: lung cancer mortality rates per 100,000 person-years at risk in a cohort of asbestos workers compared to those in other blue collar occupations (Source: Steenland and Thun 1986)

	Rate in smokers (*RR*)	Rate in non-smokers	Rate ratio
Asbestos	935.8 ($RR_{11} = 32.7$)	500.5 ($RR_{01} = 17.5$)	1.9
Non-asbestos	199.5 ($RR_{10} = 7.0$)	28.6 ($RR_{00} = 1.0$)	7.0
Rate ratio	4.7	17.5	
Rate difference	736.3	471.9	

further often reasonable assumptions of no prevention by either factor (causal monotonicity), non-additivity will also signal the presence of synergistic sufficient-cause interactions (VanderWeele 2009a).

It should be noted that these concepts of no biological interaction are distinct from certain other biological concepts of no interaction. For example, some authors give a definition in which two factors have biologically independent effects "if the qualitative nature of the mechanism of action of each is not affected by the presence or absence of the other" (Siemiatycki and Thomas 1981). Unfortunately, this concept does not lead to an unambiguous definition of interdependent effects and thus does not produce clear analytical implications. In contrast, under the sufficient-cause and potential-outcome (counterfactual) conceptualizations cited above, the given biological model is itself evaluated in terms of the co-participation of factors in a sufficient cause or in terms of modification of individual response. For example, two factors which act at different stages of a multistage process have interdependent effects because they are joint components of at least one sufficient cause. This occurs irrespective of whether they affect each other's qualitative mechanism of action. They may not even need to be in the body at the same time, for example, if one risk factor affects an early stage of the process and the other affects a much later stage. Thus, whether or not two factors are synergistic or co-participate in a sufficient cause is a completely different issue from whether they affect each other's mechanism of action and can be empirically tested under a variety of scenarios (Rothman et al. 2008, Chap. 16; VanderWeele and Robins 2007, 2008; VanderWeele 2009a, b; VanderWeele et al. 2010).

18.3.4 Additive and Multiplicative Models

The sufficient-component and potential-outcome definitions of interaction (co-participation in a sufficient cause or change in response schedule) are attractive because they are based on an explicit causal model that leads to an unambiguous definition of independence of effects and because they lead to the additive model as the baseline for assessing interactions, just as obtained through public health (cost-benefit) considerations (Rothman et al. 1980, 2008, Chap. 5). However, the analytical implications of these concepts are not straightforward, since assessing independence of effects is usually only one of the analytical goals of an epidemiological study. There are several other considerations which often favor the use of multiplicative models.

One is that multiplicative models have convenient statistical properties. Estimation in non-multiplicative models may have problems of convergence, and inference based on the asymptotic standard errors may be flawed unless the study size is very large (Moolgavkar and Venzon 1987). Another is that, if it is desired to keep interaction (effect-measure modification, corresponding to product terms in a regression model) to a minimum, then a multiplicative model is often most effective. It is not uncommon for joint effects to appear closer to multiplicative than to additive (Saracci 1987). In this situation, there may be less masking of heterogeneity in calculating an overall rate ratio than in calculating an overall rate difference. Although departures from additivity need not be multiplicative (Selikoff et al. 1980; Saracci 1987), multiplicative-model summaries tend to be closer to a population-average (standardized) measure than are additive-model summaries (Greenland and Maldonado 1994). Finally, additive-risk models are not identical to additive relative-risk models when the model includes terms for confounder adjustment; unfortunately, in typical case-control studies, only the latter models can be fit, thus rendering it difficult or impossible to make unconfounded assessments of risk additivity (Greenland 1993a, b). In contrast, departures from multiplicativity can be assessed in the same fashion from cohort and case-control data.

18.3.5 Detecting Effect-Measure Modification

Determining whether or not a factor is an effect-measure modifier is often done by estimating an effect measure (e.g., relative risk) for the exposure of interest separately for each level of the presumed effect modifier and testing for equality of these measures across the modifier strata (Rothman et al. 2008, Chap. 15). This approach lacks power, however, and so it can be quite misleading to conclude modification is absent just because the test yields a large *p*-value. Because of such power problems and other problems due to sample size limitations, when there are multiple possible effect-measure modifiers (such as age, ethnicity, gender, or previous employment in a hazardous industry), effect modification is usually examined for each potential modifying variable separately or else through use of modeling methods that allow continuous modification by quantitative variables such as age. Prior selection of potential effect modifiers of greatest interest can simplify the task. Then, assessing effect-measure modification for a subset of modifying variables might be carried out, with adjustment made for other variables.

A major obstacle to modification as well as confounding assessment is misclassification. Misclassification of any of the variables in the analysis (whether the exposure, disease, confounder, or modifier) can make a measure appear to vary across strata when in reality it does not or make it appear nearly constant when in reality it does vary (Greenland 1980). Similarly, measurement errors can spuriously create or mask the need for product terms ("interactions") in a statistical model (Greenland 1993b; cf. chapter ►Regression Methods for Epidemiological Analysis of this handbook). In an analogous fashion, variation in a measure across strata may be spuriously created or masked by differences in other biases (such as residual confounding or selection bias) across strata. Again, such problems can be explored using sensitivity analysis.

Conventional statistical analysis strategies often assume that it is not appropriate to calculate an overall effect estimate if interaction is present. However, this principle is commonly ignored if the difference in stratum-specific effect estimates is not too great. In fact standardized rate ratios have been developed for precisely this situation, and will consistently estimate meaningful epidemiological parameters even under heterogeneity (Greenland 2004; Rothman et al. 2008, Chap. 15). And again, rate ratios estimated from multiplicative models often approximate these standardized ratios (Greenland and Maldonado 1994).

As mentioned above, concluding that there is no effect-measure modification because the p-value is high can be misleading. Most studies are not designed to examine modification, and as such, may have inadequate study sizes within strata of an effect-measure modifier to permit a useful statistical interpretation. Presentation of stratum-specific effect estimates and their confidence intervals can help to give a picture of whether the data allow any inference about effect-measure modification. Formal statistical tests may be most useful in situations where prior information suggests likely forms of effect modification (e.g., a harmful effect would only be anticipated among smokers) and the study is intentionally designed to accommodate an analysis of effect modification (e.g., sufficient numbers of smokers and non-smokers are selected).

Some authors (e.g., Kleinbaum et al. 1982) have developed modeling strategies in which the first step of an analysis involves testing for effect-measure modification, where the latter is represented by product terms in the model. In the most extreme application, this involves including all possible two-factor (and even three-factor) product terms in a preliminary model and retaining in subsequent analyses all products (and related lower-order terms) that meet the inclusion criterion (which might be having a p-value below a certain cut-off, such as 0.10, or having a point estimate larger than a particular magnitude). This approach often results in complex models with numerous product terms, which may lead to problems of convergence, bias in the parameter estimates due to data sparsity, and difficulties in interpretation.

In fact, there is no logical necessity for the assessment of effect-measure modification as the first step in an analysis, and there are several reasons why it can be preferable to evaluate confounding before considering modification. One reason is that the initial aim of most analyses is to determine if there is any overall effect of exposure. It is necessary to control confounding to do this, but it is not essential to evaluate modification when doing so. Although harmful effects in one stratum and protective effects in another stratum may yield an overall null effect, this phenomenon is presumably rare. A routine search may yield a high percentage of false-positives; on the other hand, if there were a relevant a priori hypothesis, then it would be appropriate to calculate stratum-specific effect estimates irrespective of the value of the summary effect estimate.

Another reason to begin an analysis with confounding evaluation is that inclusion of extra stratification variables or extra product terms involving the main exposure complicates confounder assessment. With extra strata or terms, changes in either stratum-specific or in summary fitted measures must be examined; the stratum-specific measures may be numerous and unstable, and the summary of these measures can be difficult to construct from a fitted model that has product terms involving the exposure, see (Rothman et al. 2008, Chap. 21) and (Greenland 2004) for example formulas. Ratio measures constructed from multiplicative models that omit product terms are often a reasonable approximation to the formally correct and more complicated measures that incorporate the terms, and so can be adequate for confounding evaluation (Greenland and Maldonado 1994).

Even if subsequent analyses concentrate on specific subgroups, it may be preferable to evaluate confounding in the whole data set, since this provides the greatest precision. If a factor is a confounder overall, then it is a risk factor, and is also associated with exposure. Thus it is necessarily a confounder in some specific subgroups, and there may be little loss of precision from control in any subgroups in which it is not a confounder (although this cannot be guaranteed). Hence, it may be preferable to evaluate confounding first, and then adjust for the same confounders in each subgroup analysis.

Some qualifications should be noted. First, confounding may be evaluated purely on contextual (subject-matter) considerations and, as mentioned earlier, has an inescapable a priori (causal) component in observational studies. Because of this causal component, purely statistical selection procedures such as stepwise regression can be even more misleading for confounder selection than they are in pure prediction problems (Greenland and Neutra 1980; Rothman et al. 2008, Chap. 12). Second, the entire selection process and the attendant problems can be avoided by switching to hierarchical regression methods (Greenland 2000b, c, 2008; Rothman et al. 2008, Chap. 21), which we discuss further below. For general principles of data analysis, we refer to chapter ▶Analysis of Continuous Covariates and Dose-Effect Analysis of this handbook and Chaps. 10 and 13 of Rothman et al. (2008).

18.3.6 Assessment of Joint Effects

The above considerations imply an apparent dilemma of how to conduct an analysis that combines the advantages of ratio measures of effect with the assessment of additivity, as implied by no interaction in the potential-outcomes framework. If an excess risk is found (and assumed to be causal) then attention shifts to elaborating the nature of the effect. This naturally comes toward the end of the formal presentation of the findings. Typically, the last few tables of a manuscript might examine the joint effects of the main exposure with other factors of interest, and the discussion might relate these findings to current etiological knowledge. As noted above, it often suffices to evaluate only those joint effects for which there is an a priori reason for interest.

As an example, when studying asbestos and lung cancer, interaction with smoking might be expected given the powerful effects of smoking. To examine the latter interaction, relative risks might be presented for smoking (in non-asbestos workers), asbestos exposure (in non-smokers) and exposure to both factors, relative to persons exposed to neither factor. These relative risks would be adjusted for all other factors (e.g., age) that are potential confounders, but not of immediate interest as effect modifiers. The relevant table (e.g., Table 18.3) can be derived from any form of model, including the statistically convenient multiplicative models, by including product terms as appropriate or by including separate variables for the mutually exclusive categories of exposure (asbestos alone, smoking alone, both).

The estimation of separate and joint effects may be difficult when the factors of interest are closely correlated. However, when it is feasible, this approach combines useful features of multiplicative models and additive interaction assessment; it also permits readers with other concepts of interaction to draw their own conclusions. Consider again the data in Table 18.3 on asbestos exposure, cigarette smoking, and lung cancer. The rate-ratio estimates (adjusted for age and calendar period) are 7.0 for asbestos exposure alone, 17.5 for smoking alone, and 32.7 for the joint effect of both exposures. Thus, the joint effect of asbestos and smoking is more than additive (the joint effect is 32.7 times, whereas it would be $1 + (7.0 - 1) + (17.5 - 1) = 23.5$ if it were additive).

This result is consistent with the hypothesis that asbestos and smoking are joint components in at least one sufficient cause; it might even be argued that the observed non-additivity refutes the hypothesis that asbestos and smoking never biologically interact (assuming as usual that there is no residual confounding or bias). If the joint effect were the sum of the separate effects, the result would have favored the hypothesis that they are not joint components of a sufficient cause and do not compete for a common pool of susceptibles. However, the latter interpretation is more restricted, since additivity could arise if two factors were components of the same sufficient cause, but also had antagonistic or competitive effects that balanced their synergistic effects. Thus, even in ideal circumstances, additivity does not definitively refute the hypothesis that asbestos and smoking interact biologically in some people (Greenland and Poole 1988, Chap. 5; Rothman et al. 2008). Furthermore, without further assumptions, sufficient-cause interactions may be absent and yet there may be departures from additivity (VanderWeele 2009a, b).

Nonetheless, if it is provisionally accepted that smoking and asbestos do act together in a sufficient cause of lung cancer, then attention may shift to elaborating the effect with mathematical models deduced from biological models of the interaction. For example, Doll and Peto (1978) suggested that smoking acts at both an early stage (probably the second) and the penultimate (fifth) stage of a six-stage carcinogenic process. Asbestos appears to act at one of the later stages, probably the fourth or fifth (Pearce 1988). If asbestos acted at the same late stage as smoking, then it could be expected that its effect would add onto the late-stage effect of smoking and multiply the early-stage effect of smoking. The resulting joint effect would be intermediate between additive and multiplicative. This pattern has been observed in several studies (Selikoff et al. 1980) although there are, of course, other models which predict the same result (Saracci 1987).

When interaction evaluation occurs as the last stage of an analysis, the routine evaluation (screening) of a large number of joint effects increases the number of tables but does not necessarily complicate other aspects of the presentation (Pearce 1989). It does however raise a number of statistical problems which have been the subject of much controversy and research. The first, lesser known problem is that exposure effect estimates may be biased away from the null when too many terms (such as product terms) are entered into a risk or rate regression (Greenland et al. 2000). The second is the multiple-comparisons problem. Although many epidemiologists have denied that such problems exist (e.g., Rothman 1990), their focus concerned situations in which despite many comparisons, the investigator was interested in just one or a few exposure-disease relations. Nonetheless, screening a large number of effects (whether main effects or product terms) implies interest in many relations and raises the issues of how one deals with the instability of the estimates and the high probability that some of the estimates are large simply because of large random errors (Greenland and Robins 1991; Greenland 1993c, 2000b, c; Steenland et al. 2000). Classical multiple-comparison procedures can be quite misleading, however, because they make no attempt to account for false-negative error (in fact they inflate it tremendously) and are arguably inferior to making no adjustment at all if one is less concerned about false-negatives than false-positives.

An analytical solution to both problems is to employ hierarchical modeling methods (also known as multilevel methods, penalized estimation, random-coefficient regression, shrinkage estimation, Stein estimation, empirical-Bayes regression, and semi-Bayes regression) (Greenland and Robins 1991; Greenland 1993c, 2000b, c; Steenland et al. 2000; Rothman et al. 2008, Chap. 21). Such methods are demonstrably superior to either extreme (of no adjustment versus classical adjustment) in these situations, as shown by theory, simulations, and performance in real epidemiological examples (Efron and Morris 1977; Greenland 1993c, 2000b, c, 2008; Steenland et al. 2000; Witte et al. 2000). Furthermore, these methods can also be applied to control for multiple confounders in place of confounder selection methods (Greenland 2000c) and can be carried out with standard software (Greenland 2008; Witte et al. 2000). Nonetheless, no analytical method can overcome the fundamental limits of precision and validity that afflict typical epidemiological data; such limits will usually mean that only substantial modification and interaction will be detectable in typical epidemiological research (Greenland 1993b, 2009b).

18.4 Conclusions
