The effect estimates used for indirect comparisons or the combination of different network paths may be based on fixed or random effects models. In the simplest case, independent estimates of different paths can be synthesized by an average, weighted by the inverse of their respective variances. Furthermore, Bayesian methods and hierarchical models can be used to analyze indirect comparisons as well as more complex data structures such as multiarm trials, especially when

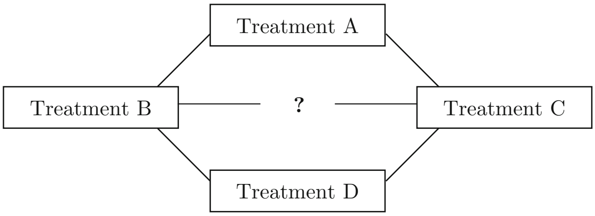

Fig. 36.8 Simple network meta-analysis

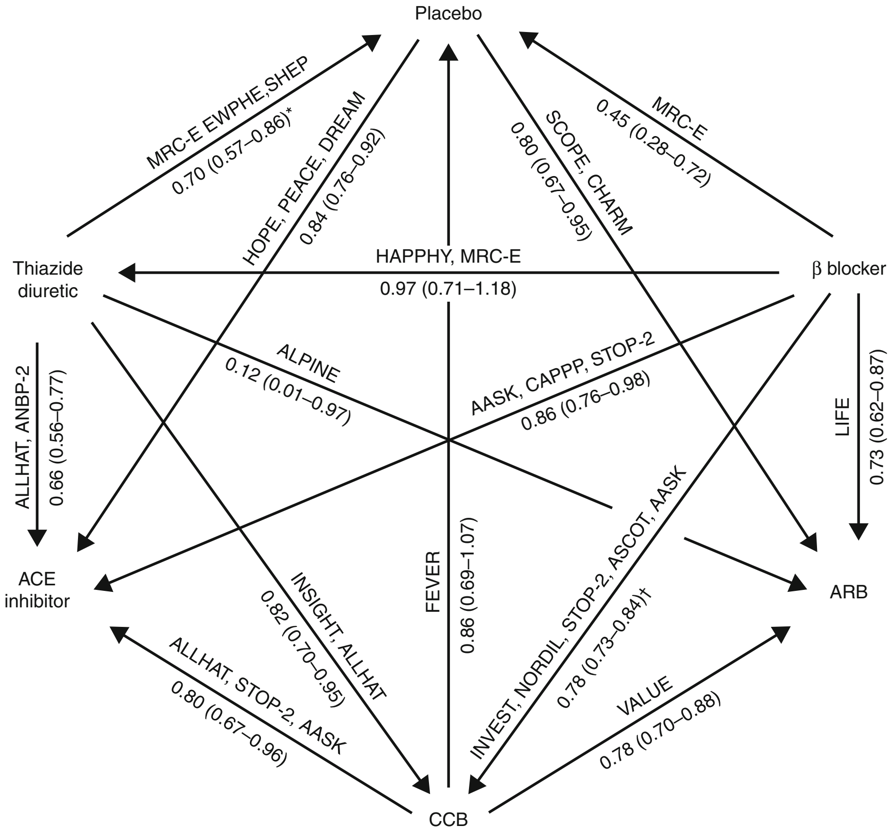

Fig. 36.9 A network of antihypertensive drug clinical trials (Reprinted from Elliott and Meyer 2007b, with permission from Elsevier)

additional information is available (Lu and Ades 2004). Adjustments for covariates and the use of meta-regression methods are also possible in network meta-analyses. Nixon et al. (2007) presented an MTC Bayesian meta-regression model to estimate the efficacy of biological treatments in rheumatoid arthritis adjusted for the both study-level covariates, disease duration and severity of disease.

36.7.2 Limitations

The reasons for potential bias, as already discussed for common meta-analysis, can also lead to distortions in network meta-analysis. But since an indirect comparison requires at least two meta-analyses, there is assumedly more scope for error.

For a valid indirect comparison, the studies should be methodologically and clinically comparable. Also, it is important to synthesize the evidence from different randomized clinical trials by comparing their treatment effects, such as log odds ratios. Considering only single treatment arms of the original controlled studies would break the randomization (Bucher et al. 1997). For example, the observations of treatment arm B and treatment arm C of the original by treatment A controlled studies (see Fig. 36.7) should not be pooled. Although the data originate from randomized controlled trials, they are reduced to the equivalent of those that come from an observational study. The comparison of effectiveness can therefore be biased by several confounders. Estimates of indirect comparisons based only on single treatment arms of randomized controlled trials are sometimes referred to as "unadjusted indirect estimates" and should be avoided.

In a network meta-analysis, not only the heterogeneity in treatment effects between studies of each pairwise contrast should be discussed, but also different network paths for the same comparison. For example, the estimations $\hat{\theta}_{BA} - \hat{\theta}_{CA}$ and $\hat{\theta}_{BD} - \hat{\theta}_{CD}$ in Fig. 36.8 can disagree. Particularly in MTC meta-analyses, inconsistencies in treatment effects obtained from direct and indirect comparisons of the same treatments may exist (Song et al. 2003). Baker and Kramer (2002) highlighted examples where the transitivity assumption between a direct and an indirect comparison is not given, for example, due to differences in patient or trial characteristics. In addition, imperfections in study design or analysis may lead to inconsistencies. For example, the observed treatment effect in open-label or ineffectively blinded studies might depend on whether the treatment is new or used as an active control which may alter the expectation of researchers and patients. This may in turn influence the observed treatment effect (see Lumley 2002). Song et al. (2009) surveyed systematic reviews published between 2000 and 2007 with indirect comparisons and investigated basic assumptions and methodological problems in the application. The assumption of consistency was explicitly mentioned in only 18 of the 30 included reviews where direct and indirect estimates were compared or combined.

The investigation of inconsistency, or also known as incoherence, is possible when there are closed loops such as in the connected polygonal network in Fig. 36.9. Independent estimates of different network paths can be tested, for example, with the simple χ^2-test like in the testing of heterogeneity (see Sect. 36.5.4 and Caldwell et al. 2009). Lumley (2002) offered a quantitative estimation procedure using linear mixed models, in which not only the heterogeneity but also the inconsistency can be fitted as a further random effect. Lu and Ades (2006) set the estimation of inconsistency in the framework of Bayesian hierarchical models. However, large inconsistency needs, as large heterogeneity, a closer look for possible reasons. The adjustment for covariates and the use of meta-regression methods are another

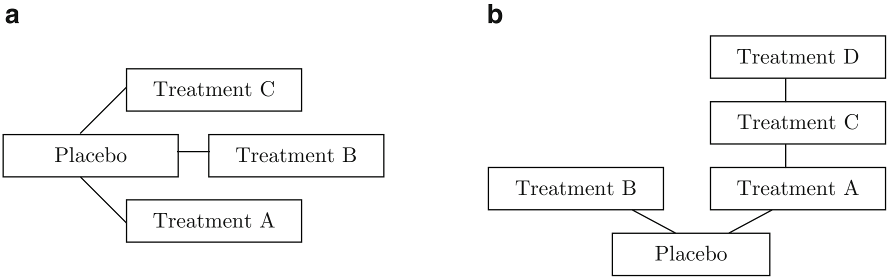

Fig. 36.10 Different network geometries: (**a**) radiating star (**b**) linear structure

possibility to address the inconsistency and also the heterogeneity within comparisons (Cooper et al. 2009). But since inconsistency is a property of loops, it is not easily possible to ascertain which specific contrast is responsible for the inconsistency, and it is an open question to which extent unexplained inconsistency is acceptable in an MTC meta-analysis. For a radiating or linear network meta-analysis structure, the estimation of inconsistency is impossible. Pattern (a) in Fig. 36.10 arises, for example, if there are only placebo-controlled studies and the active treatments are not compared to each other. If new treatments are tested only against the current standard, pattern (b) in Fig. 36.10 might result. Fewer cross-links and longer paths, for example, between treatment B and treatment C in Fig. 36.10, lead to greater uncertainty of the treatment effect estimation. But the information in these networks can be used, for example, in the planning of future trials to directly test the comparison where no direct evidence exists or to enhance the network. Salanti et al. (2008) discussed network geometry and asymmetry in this context, namely, that specific treatments or comparisons are represented more heavily than others.

Comparing the estimation accuracy between direct and indirect comparisons shows that under the assumption of statistical independence of different studies and consistent estimation accuracy, the variance of the effect estimator in indirect comparisons is greater than in direct comparisons. Assuming, for example, that the effect estimates of all studies have the same variance σ^2, the variance of the fixed-effect inverse variance estimator of the direct comparisons based on $2k$ studies would be

$$\text{var}(\hat{\theta}_{BC_{\text{direct}}}) = \sigma^2/2k.$$

However, the variance of the indirect comparison based on k studies for each comparison would be

$$\text{var}(\hat{\theta}_{BC_{\text{indirect}}}) = \text{var}(\hat{\theta}_{BA_{\text{direct}}}) + \text{var}(\hat{\theta}_{CA_{\text{direct}}}) = \sigma^2/k + \sigma^2/k = 2\sigma^2/k.$$

Thus, for the indirect approach, four times as many studies are needed to have the same power as the direct comparisons provide (Glenny et al. 2005).

Consequently, indirect comparisons are not preferable to direct comparisons, but they are useful in planning direct comparisons and where head-to-head comparisons are not possible. Both can be combined to include all the existing evidence and to obtain more precise estimates when direct comparisons are not sufficiently available (Higgins and Whitehead 1996). Song et al. (2008) hypothesized as to whether adjusted indirect comparisons may provide less biased results than direct comparisons under certain circumstances. For example, when an indirect comparison is based on studies with the same extent of bias, adjusted indirect comparison could counterbalance this. However, discrepancies between both approaches should be carefully investigated for potential explanations whenever possible.

36.8 Conclusions

Despite the many problems, there is an immense need to summarize current knowledge, for example, to assess the consequence of human exposure to environmental exposure. For this task, all available data and information will be needed, and meta-analysis is becoming increasingly influential. Particularly where the previously conducted epidemiological studies have provided inconsistent results, a meta-analysis may give some insight. As discussed, a major impediment for meta-analysis of epidemiological data is the heterogeneity across studies in their design, data collection methods, and analyses performed. The statistical combination of risk estimates should not be the central component of a meta-analysis using published data. An expert group in cooperation with the US Environmental Protection Agency was recently established to discuss the use of meta-analyses in environmental health studies. One of the objectives of this group was also to develop a consensus on "when meta-analysis should or should not be used" (Blair et al. 1995). There is always a danger that meta-analysis of observational studies produces precise looking estimates which are severely biased. This should be kept in mind as more and more public health regulators and decision-makers may rely on the results of a meta-analysis.

Appendices

A. Data

The listing shows the effect measure on the log-scale, the corresponding variance and the study type of each of the 36 studies analyzed in the meta-analysis by Sillero-Arenas et al. (1992):

```
data sillar;
input study or est type;

B. Elementary Analysis with SAS

SAS code for the elementary analysis using weighted least squares:

```
/* calculation of weights */
data sillar;
set sillar;
weight =1./est;
run;
```

```
/* intercept only */
proc glm data=sillar;           /* use proc GLM with data set sillar      */
model logor=/solution inverse ; /* Show  solution                         */
                                /* Show inverse of weighted design matrix */
weight weight;                  /*  weights 1./variance                   */
run;
```

This gives the following shortened output:

```
The GLM Procedure
Dependent Variable: logor
Weight: weight
               Sum of
Source     DF  Squares     Mean Square    F Value    Pr > F
Model       1   6.1683128  6.1683128       1.86       0.1813
Error      35 116.0756869  3.3164482
Un.Total   36 122.2439997

Parameter  df   Estimate     SE          t Value   Pr > |t|
Intercept  1    0.0559813731 0.04104847   1.36      0.1813
```

Please note that for performing a meta-analysis the standard error given by the program must be divided by the root mean square error in order to obtain the standard error of the pooled estimate. In order to avoid additional calculations the SAS output giving the inverse of the weighted design matrix gives the desired variance. The test of heterogeneity is given by the residual sum of squares as indicated by formula (36.4). This result can also be obtained using the SAS code for the fixed effect model based on maximum likelihood:

```
proc mixed method=ml data=sillar; /* Use proc mixed (ML
                                     estimation)              */
class study;                      /* Specifes study as 'classif
                                     icaton variable'         */
model or=/ s cl;                  /* Intercept only model, show
                                     solution and CI          */
repeated /group =study;           /* Each trial has its own
                                     within trial variance    */
parms /parmsdata=sillar           /* The parmsdata option reads
                                     in the variable EST indi
                                     cating the variances from
                                     the data set sillar.sd2 */
eqcons=1 to 36;                   /* The within study variances
                                     are known and fixed      */
run;
```

C. SAS Code for the Random Effects Model

The SAS procedure proc mixed requires the following manipulations of the data

```
data covvars;     /* data set containing the variances  */
set sillar;
keep est;
run;
data start;          /* include the starting value for the  */
input est;           /* heterogeneity variance              */
cards;
0.0
run;
data start;          /* Combine both data sets             */
set start covvars;
run;
```

Obtain the model with proc mixed

```
proc mixed method=ml cl data=sillar; /* CL asks for confidence intervals             */
                                     /* of covariance parameters                     */
class study;                         /* Study is classification variable             */
model or= / s cl;                    /* Intercept only model, Fixed solution and CI  */
random int /subject=study ;          /* Study is specified as random effect          */
repeated /group =study;              /* Each study has its own variance              */
parms /parmsdata= start              /* start contains starting value a. trial vars. */
eqcons=2 to 37;                      /* entries 2 to 37 are the fixed study vars.    */
run;
```

37.1 Introduction

37.1.1 The Nature of Geographical Epidemiology

Although, at first sight, geographical epidemiology may appear to differ substantially from other areas of epidemiology, it has many features in common. In particular, a major objective of epidemiology – to infer etiological relationships from observed associations – applies also in geographical studies. The distinctive characteristic is of course that geographical location is an important explanatory variable, either because it reflects an environmentally determined element of risk or because people with similar risk attributes live together, so that risk varies from place to place. The two-dimensional nature of geographical location means that the standard statistical techniques for handling sets of essentially univariate variables need to be augmented by more sophisticated methods.

There are practical limitations to the scientific value of geographical studies. The data quality tends to be low – not least because population censuses are relatively infrequent – and any real effects may be attenuated by factors such as mobility, often to the point where they are not detectable. Consideration of these difficulties may lead to the conclusion that a lot of geographical epidemiology is, in scientific terms, of very limited value. Historically, however, there have been some spectacular successes: to the famous observation of Snow (1855) on the source of cholera infection may be added a number of more recent and equally dramatic observations, for example, the identification of the cause of an outbreak of asthma in Spain (Antó and Sunyer 1992) and the implication of erionite fibres in the etiology of mesothelioma from the very high localized rates in the Cappadocian region of Turkey (Baris et al. 1992).

37.1.2 Scope of the Chapter

This chapter attempts to sketch the statistical principles of the subject, with an indication of the kinds of analyses to which these principles lead quite naturally. There is a large literature on the methodology of geographical epidemiology, much of it employing a Bayesian standpoint and exploring hierarchical models analyzed by Markov chain Monte Carlo methods. It would be impossible to give a comprehensive review of the latter field, and we adopt the less ambitious objective of outlining the fundamentals of the subject, in the hope that this will in any case provide insight into more sophisticated analyses. Nevertheless we have attempted to provide some examples of the techniques discussed and, where possible, to make recommendations for practitioners, though this latter goal is difficult in view of the large number of different analyses that have been proposed but whose properties are relatively unknown.

Our presentation will in fact be almost exclusively frequentist. To some extent, the choice between Bayesian and frequentist methods in statistics is a matter of philosophical standpoint. Frequentist arguments are undeniably limited in their scope and power and are frequently subject to misinterpretation. The limitations may, however, be argued to be intrinsic to the problem of inductive inference under uncertainty and such inference does not seem to this author to be more consistently clear-cut when derived from a Bayesian analysis. The modeling approach is admittedly more attractive than the mere detection of statistical significance, but it is not without its difficulties. For one thing, the amount of data in geographical studies may often not permit the estimation of numerous parameters, and to the extent that a model makes specific assumptions about underlying phenomena, there is a risk that it may inject spurious information into the analysis, leading to the overinterpretation of the data. The limitations of the hypothesis testing approach have not prevented its widespread use in practice, and an important part of the epidemiologist's role is to ensure that the tests that are carried out are chosen with due regard to maximizing their power against sensible alternatives. This at least is the standpoint from which we approach this topic here; in any case, the statistical framework underpins the more sophisticated analyses and forms a natural prerequisite for their understanding. See chapter ▸Statistical Inference of this handbook for a discussion of the fundamental distinctions between Bayesian and frequentist inference, and chapter ▸Bayesian Methods in Epidemiology of this handbook for an account of Bayesian modeling.

37.1.3 Chapter Contents

We start by considering (Sect. 37.2) the models that underlie statistical methods in geographical epidemiology in order to give insight into the justification for the methods that are discussed. A key feature is the duality that exists between the two approaches to epidemiological investigations generally. To be specific, we can elect to study either the occurrence of disease conditionally on case locations or vice versa, i.e., to regard case location as a random variable to be compared in fixed groups of affected and unaffected individuals. This duality precisely mirrors the distinction between the cohort and case-control approaches to epidemiological surveys. The case-control approach in geographical work has only recently been recognized and is particularly relevant for the analysis of data at the individual, as opposed to the areal, level. This important approach, though not yet fully exploited, has led recently to a number of new and interesting methodological developments.

In Sect. 37.3, we develop the way in which risk may be modeled in relation to geographically referenced data, distinguishing between the analysis of areal data and data at the individual level, for which it is assumed that individual locations are known. As with any statistical modeling exercise, the objective is to explain as much of the variation as possible, up to the point where heterogeneity can be attributed to chance. There are numerous ways of approaching this subject, even within the compass of frequentist analyses, and some of the issues as to the best analysis are unresolved.

Section 37.4 is concerned with mapping. From one point of view, mapping is an end in itself, and there are numerous methods available for producing maps. However, there is much scope for misinterpretation of data represented in this way, and we would argue that a map should be seen as the end product of some kind of modeling process, though possibly a very primitive one: no disease map can be constructed without assumptions about the underlying distribution of the disease it purports to represent.

Section 37.5 addresses the question of heterogeneity in the distribution of risk. To some extent, this involves issues bound up with the problems of modeling. But the simple question of whether there is any non-uniformity of risk is a valid one that can be at least partially answered without reference to underlying models or alternatives.

In Sect. 37.6, we address the problem of clustering. This may be seen as a violation of the twin assumptions of uniformity and independence discussed in Sect. 37.2. However, we may well be more interested in detecting small clusters of cases that are related to one another, and to this extent it may be appropriate to use different methods from those in Sect. 37.5.

Finally, Sect. 37.7 considers the rather more specific problem of detecting an increase in risk near a putative point source of risk, and it is argued that analyses of this kind are essentially one dimensional, and perhaps for this reason, it is somewhat easier to determine good methods for doing so. This is in fact a problem of considerable interest, and many investigations of "clustering" are really of this kind. The issue is illustrated by the incidence of childhood leukaemia around nuclear installations in the UK using data introduced in Sect. 37.3.2.

The concluding section summarizes the chapter and makes suggestions for further reading.

37.2 Statistical Models

In this section, we describe a statistical framework for the methods to be discussed. We start by explaining the elements that underlie the analysis of classical surveys and then show how the same starting point may be applied to geographical data.

37.2.1 A Statistical Framework for Epidemiological Observations

To describe a modeling framework for epidemiology, we start by supposing that the disease $\mathcal{D}$ in which we are interested is an essentially dichotomous entity, i.e., it is the binary outcome – affected/not affected – of some biological process applied to a finite set of individuals. Such a starting point will serve irrespective of the temporal nature of the events we are studying, be they deaths or incident cases of a disease $\mathcal{D}$ in a given time period or the prevalence of $\mathcal{D}$ at a given epoch. We will be primarily interested in the association between $\mathcal{D}$ and various covariates $\mathcal{C}$. Some of these may represent risk factors suspected of playing a causal role: we will describe these as exposure variables and denote them by $\mathcal{E}$. Others may be of interest in their own right or because they are potential confounding variables for $\mathcal{E}$. We will treat $\mathcal{E}$ as a subset of $\mathcal{C}$ when this is convenient.

To take a specific geographical example, we cite the famous study of cardiovascular disease $\mathcal{D}$ by Cook and Pocock (1983). The covariates $\mathcal{C}$ included water hardness $\mathcal{E}$, whose etiological relationship to cardiovascular disease was of primary interest, and also various indicators of socioeconomic status, which played the role of a confounding factor: the gradients of mortality, water hardness, and socioeconomic status are highly correlated with latitude in the UK. The data were analyzed for males and females together, but they could equally well have been stratified by sex, which would be a covariate of interest in its own right, since one might be interested in the mortality of males and females separately.

Next, we assume that occurrences of $\mathcal{D}$ are independent. This does not preclude the possibility that individuals have probabilities p of $\mathcal{D}$ that are related through their proximity, for example. Rather the condition stipulates that, *conditional on the values of* $\mathcal{C}$ *and* $\mathcal{E}$, the occurrence of $\mathcal{D}$ in one individual is independent of that in another, i.e., that the probability that individual A suffers from $\mathcal{D}$ is unaffected by the *fact* (as opposed to the probability) that some other individual B also suffers from it. In practice, this is a reasonable mechanistic assumption for nearly all chronic disease epidemiology. It clearly breaks down for infectious diseases, for which more sophisticated models would be appropriate. In fact, little theoretical foundation for modeling the epidemiology of infectious diseases at the individual level exists. This is partly because the theory is intractable, partly because it is not necessary in setting up the null hypothesis of no contagion for the purposes of testing. It is only for formulating alternative hypotheses in this situation that statistical models for a contagious mechanism are necessary. Important though this is, we will not consider the problem in this chapter.

Under this independence assumption, the individual outcomes of $\mathcal{D}$ are described by the very simple Bernoulli distribution. If all the probabilities p_i for the individuals in a group of n are the same, the number of occurrences out of the n will clearly follow the binomial distribution, while if all the p_i are different and supposed to depend on $\mathcal{C}$, we can model them through a (binary) logistic regression (Cox and Snell 1984).

Such analyses are becoming more common, but they require detailed information on individuals and are not without their technical difficulties. Much of epidemiology is in practice still conducted by the more traditional approach of grouping data according to disease status and to grouped values of $\mathcal{C}$. In this approach, the assumption is that the probabilities p_i within a particular group are indeed all the same, though in practice we know that this is unlikely to be true. However, this assumption is far less troublesome than appears at first sight. For one thing, as long as the p_i are small, the difference between a binomial distribution and that of a sum of slightly different Bernoulli variables will be negligible.

A typical analysis of epidemiological data proceeds by forming a cross-tabulation into a contingency table, whose rows, columns, and layers are labeled by components of $\mathcal{D}$, $\mathcal{E}$, and $\mathcal{C}$. The standard way of analyzing such a table is through a log-linear model, which implicitly assumes that the counts in the table are values of Poisson distributed variables, conditioned by the requirements that certain subtotals in the table are deemed to be fixed. For details on log-linear regressions please refer to chapter ▸Regression Methods for Epidemiological Analysis of this handbook.

The logistic regression and log-linear modeling approaches thus described have been constructed on the assumption that $\mathcal{D}$ is a random response and the covariates $\mathcal{C}$ are fixed, but we can also obtain useful analyses by conditioning on the numbers of "cases" affected by $\mathcal{D}$ and unaffected or disease-free "controls" in a suitable control group and regarding one or more of the covariates as a random response. This leads to the so-called "case-control" study (formerly termed a *retrospective* study), in distinction to a "cohort" (or *prospective*) study. Thus, for example, it might be appropriate to use a normal linear regression to model the exposure $\mathcal{E}$ of individuals to some risk factor – considered to be a continuous variable – as a function of the other variables, one of which would be an indicator for $\mathcal{D}$, the membership of the case or control group. We would then regard $\mathcal{E}$ as the factor of primary interest and the other covariates would be fitted in order to control for their possible confounding effects.

37.2.2 Statistical Models for Geographical Data

Most of the ideas outlined above carry over quite naturally to data in which geographical location plays a role. We will preserve the assumptions that $\mathcal{D}$ is a binary variable and that disease occurrences are independent conditionally on $\mathcal{C}$. We need to extend our conceptual notation to include geographical location, which we will denote by $\mathcal{G}$. There is a distinction between situations where we think of it as representing a pair of coordinates and those where it is an essentially two-dimensional location in the space representing a geographical region studied.

If $\mathcal{G}$ is thought of as representing coordinates, such as Easting and Northing, it may be meaningful to treat them like other quantitative variables, perhaps to detect a trend with latitude, for example. Alternatively, it might be meaningful to consider polar coordinates from a specified point $\mathcal{S}$ considered as a fixed origin, analyzing distance and direction from it. Typically, $\mathcal{S}$ would be a point of some etiological significance, such as a putative source of pollution. We return to this topic in Sect. 37.7 below.

However, this approach implicitly reduces our analyses to consideration of essentially one-dimensional variables, and it is useful to distinguish this from the *intrinsically spatial* case in which we regard two-dimensional space as a single entity. In this situation, a principal objective will be to depict the way in which risk varies over a region $\mathcal{R}$, usually by means of a map. It is unlikely that any kind of analytically determined trend surface, such as a polynomial, will be useful, though non-parametrically estimated surfaces might be. We return to the problems of mapping in Sect. 37.4 below.

The distinctions we made in Sect. 37.2.1 above apply for geographical data. For example, the majority of geographical analyses are effectively analyses of grouped data, in which observations have been grouped into k subregions $A_1, A_2, \ldots, A_k$ of

$\mathcal{R}$ (which we shall refer to as "areas"). Within each area, we would hope to know the population to serve as a denominator and the number of occurrences Y_i of the disease $\mathcal{D}$ would then follow a binomial or approximately a Poisson distribution, by the arguments outlined above. The areas may be regarded as analogous to the bins of a histogram, though they will nearly always be based on administrative areas with highly irregular boundaries, so that they do not share the attractive regularity properties of the more familiar histograms formed from quantitative variables. The identities of the areas themselves typically enter the analysis through the coordinates of their population centroids, and these may then be analyzed by incorporating them into the model as described above, though the analysis might well take account of spatial autocorrelation.

If instead of binning or grouping the observed cases into areas we record the exact locations of the occurrences of $\mathcal{D}$, we need a rather different modeling approach. The case-independence assumption implies that the cases are located according to a non-homogenous Poisson process (Diggle 2000), which is the standard probability model for events happening at random in a continuum, though not necessarily with a uniform pattern of risk. This model supposes that the probability of an event in a small area δA at the point (x, y) is $\lambda(x, y)\delta A$, where $\lambda(x, y)$ is the "intensity function" of the process giving the rate per unit area at (x, y); it also incorporates the crucial assumption that the occurrence of such a point is independent of occurrences outside δA.

It is well known, however, that when points occur according to a Poisson process in such a way that the total number is fixed at a value n, say, the pattern of points obtained is typically exactly the same as if we had sampled from a probability distribution with density function proportional to $\lambda(x, y)$. This enables us to describe the behavior in geographical space of a fixed sample of cases, with a view to estimating the risk at each point (x, y) or to compare the resulting risk function with that for a sample of controls. Thus we have moved to the "dual" or case-control approach, for we are effectively regarding the locations as realizations of a continuous bivariate random variable defined for our samples of cases and controls. Methods of analyzing data within this framework are discussed in Sect. 37.3.4 below.

37.3 Modeling Disease Risk in Relation to Geographically Referenced Factors

37.3.1 Areal Data

One of the commonest and most straightforward analyses of geographical data consists of modeling the counts Y_i of cases in areas A_i using a Poisson regression or, equivalently, a generalized linear model (GLM) with Poisson error and log link function; see McCullagh and Nelder (1989) and chapter ▶Regression Methods for Epidemiological Analysis of this handbook. We start by assuming that we can calculate “null expectations” e_i for the Y_i. In the simplest form, these could be obtained by multiplying some global reference estimate of risk p by the population sizes in the A_i. In practice, we will almost certainly wish to *standardize* for the age distribution and other known demographic factors such as socioeconomic status. Part of our objective is of course to modify the assumption that the risk is the same in every area, so we will incorporate a *relative risk* (*RR*) θ_i, to give the model for the counts as

$$Y_i \sim \text{Poisson}[\theta_i e_i] \; .$$

We then model the θ_i in the usual manner for a GLM through

$$\log \theta_i = \sum_{j=1}^{p} x_{ij} \beta_j \; ,$$

where the β_j are coefficients in the log-linear model and x_{ij} is the value of the jth covariate for the ith areal unit A_i.

Typical covariates in such an analysis might include intrinsically geographical features, such as altitude, geological composition, or levels of background radiation, or essentially demographic features, such as the age or socioeconomic composition of the population of each area. It should be emphasized that the units in such analyses are not the individuals with a disease $\mathcal{D}$ but the areas within which they reside, and the covariates are also necessarily attributes of these areas. The object of such an analysis, however, will generally be to make inferences concerning individuals, and to ignore the distinction is sometimes described as perpetrating the “ecological fallacy.” Covariate values for the area as a whole are implicitly imputed to each individual member of the population, and this has the potential for introducing a number of different kinds of bias known variously as “ecological” or “aggregation bias.”

A genuinely “ecological” or geographical imputation would arise if a geographical feature (such as latitude) were averaged spatially without regard to population density (Diggle and Elliott 1995), and any such averaging should as far as possible be density-weighted, perhaps by using the relevant measurement at the centroid of the population. Demographic variables, such as age or socioeconomic deprivation will usually be averaged over the population anyway, and in this case grouping into areas has much the same effect as grouping by other factors; the problem may then be seen in the wider context of aggregation bias. Such a bias can result from concealed within-group confounding, and it is difficult to take account of this without individual-level data. An intrinsic bias may also arise from the non-linearity of the model used, though this is likely to be small when the disease risk is itself small and relatively uniform, since the logistic (or any similar) transformation used in the model will be nearly linear.

Many papers have addressed the issue of ecological bias. An early contribution by Greenland and Morgenstern (1989) was influential but may have painted too pessimistic a view of ecological studies, which can be very valuable for providing pointers and which are often based on more objective data than case-control studies. Wakefield (2008) provides a useful overview and a review of the literature. Further discussion of the issues will also be found in chapter ▸Descriptive Studies of this handbook.

37.3.2 An Example of the Log-Linear Model for Areal Data

An example of this use of the log-linear model is provided by the application to childhood leukaemia data described by Bithell et al. (1995). The dataset analyzed was from the UK National Registry of Childhood Tumours (NRCT) maintained by the Childhood Cancer Research Group in Oxford and related to 5,359 children diagnosed with leukaemia or non-Hodgkin lymphoma under the age of 15 years between 1966 and 1987. Each of the cases was located in one of 9,831 electoral wards, which are administrative areas with an average population of around 5,000.

The explanatory variables fitted were "Standard Region," a classification of Britain into ten regions, and the Townsend Index, an areal index of social deprivation which is a function of unemployment, housing ownership, and other socioeconomic indicators. As shown in Table 37.1, there was a significant reduction in the deviance associated with each of these factors: the p-values shown in the first two lines are based on the chi-square approximation to the deviance reductions. It is interesting, incidentally, to note that the direction of the association is negative for the Townsend Index, i.e., the disease is slightly commoner in less deprived families. This is a feature of childhood leukaemia that differentiates it from most other diseases.

The goodness of fit of the model can in principle be tested by the residual deviance, but because the expected numbers of cases per ward in this analysis were small (less than half on average), the chi-square approximation is unreliable. However, the theoretical mean and variance of the deviance for Poisson observations with a specified set of expectations can be calculated straightforwardly. We can therefore obtain an approximate test of the residual deviance as follows:

1. Compute the values for the expectations predicted by the model for each ward.
2. Compute the mean μ and variance σ^2 of the deviance statistic D as defined by

$$D = 2\sum_i [Y_i \log(Y_i/e_i) - (Y_i - e_i)] \tag{37.1}$$

   as if the contributions to D were independent.
3. Refer the statistic $(D - \mu)/\sigma$ to the standard normal distribution.

Table 37.1 Analysis of deviance of childhood leukaemia data

Variation due to	d.f.	Deviance	p-value
Standard region	9	23.1	0.0060
Townsend index	1	23.6	10^{-6}
Residual	9,820	8610.6	0.025

The assumption of independence should be approximately true in view of the large number of degrees of freedom. Bithell et al. check the two-sided p-value by simulation of data from the fitted model and found a very good degree of approximation to the calculated value of 0.025. These results may be interpreted as meaning that the model fits much better than if the explanatory factors had not been taken into account (for which the equivalent p-value was 0.00042); though there is some evidence of residual heterogeneity, it must be remembered that this is a large data set and the level of significance observed is not indicative of a large degree of variation. We return to the issue of testing residual variation in Sect. 37.5.

37.3.3 Calculating the Expectations

The model described above involves the expectations e_i, which appear as an "offset" term in the model, i.e., $\log(e_i)$ is added to the linear function of the covariates defining $\log \theta_i$. These may be calculated from externally calculated rates, for example, from national statistics. If such rates are not easily available, the data can be internally standardized by supplying the sizes of the populations at risk; any factor representing the overall risk will appear in the intercept term of the model. The expectations predicted by the model can then be used as expectations for subsequent analyses, and this is a useful by-product of the modeling process. The method can be seen as an elegant and more consistent alternative to classical standardization, permitting the flexible inclusion of covariates according to their importance, as indicated by the modeling process.

Indeed, the analysis described by Bithell et al. is part of a larger one designed to produce expected numbers of childhood leukaemias for the areal analysis of incidence near nuclear installations; this is briefly described in Sect. 37.7.2.

37.3.4 Continuous Data

Following the discussion in Sect. 37.2.2 above, we suppose that we have a sample of exact locations of cases of disease $\mathcal{D}$ and that we denote their density function over $\mathcal{R}$ by $\psi(x, y)$. We need an analogue of the denominators in an areal analysis to serve as a measure of how many individuals there are at risk at each point (x, y) of $\mathcal{R}$. This is provided in principle by knowledge of the population density, which we will consider to be continuous and which we will denote by $\pi(x, y)$. Then our problem becomes one of comparing the density function for the incident cases with that of the population. For a rare disease, the population density (which strictly speaking includes diseased as well as healthy individuals) will be very similar to that for all non-diseased individuals, which can in turn be estimated by a suitable *sample* of controls. The natural way to make this comparison is through the ratio, and it is easily seen that this ratio

$$\theta(x, y) = \psi(x, y)/\pi(x, y)$$

defines a *relative risk function* (RRF) that gives the risk of being affected by $\mathcal{D}$ at each point (x, y) of $\mathcal{R}$ relative to the mean for the whole of $\mathcal{R}$ (see Bithell 1990).

A natural estimate $\widehat{\theta}(x, y)$ of $\theta(x, y)$ is provided by the ratio of estimates of $\psi(x, y)$ and $\pi(x, y)$. These may be obtained using one of the modern methods available for estimating a density function (see the books by Silverman (1986) and Scott (1992), e.g.). The process is not without difficulties but it can be used to provide meaningful estimates of the RRF over $\mathcal{R}$, in effect providing a map of it. We return to the problem of mapping in Sect. 37.4 below.

A more ambitious objective than merely mapping the RRF is to model it as a function of covariates $\boldsymbol{x}$, say. These may be geographically defined at every point of $\mathcal{R}$, or they may be attributes of the cases and controls in the samples. An elegant modeling approach is due to Diggle and Rowlingson (1994) and proceeds by analogy with classical case-control studies. We condition on the coordinates of the n cases and m controls and consider the probability that, under random allocation of the cases and controls to the $m + n$ locations, an individual sampled at a given location (x, y) is a case rather than a control. This probability can then be modeled logistically as a function of $\boldsymbol{x}$. If there appears to be unexplained variation in the RRF, it can in principle be modeled by adding a non-parametric function of (x, y) to the linear predictor. The numerical problems of the latter approach appear not to be trivial.

The inclusion of attributes of the individuals in the analysis is particularly attractive, since it provides the possibility of controlling for them within the geographical analysis. In practice, it is not always straightforward to obtain suitable controls for analyses of this kind, partly because the current emphasis on data protection makes it difficult to access individual records and partly because of the number of combinations of categories with respect to which we may wish to match. Nevertheless, this methodology, though still in its infancy, would seem to have considerable potential.

37.3.5 Spatial Structure in the Residual Variation

The object of fitting a model of the kind discussed is to obtain a satisfactory explanation of the data, i.e., a residual deviance that is not statistically significant. This is not always very easy, since the risk of disease may depend on factors that we have been unable to measure. Large data sets – for example, of national mortality rates – may also demonstrate a statistically significant deviance resulting from unobserved factors that are scientifically unimportant simply because of the large numbers of cases involved.

Unfortunately, conclusions about the importance of individual explanatory variables in a model are strictly valid only if the model fitted is correct. In practice, we will believe a model to be correct if it appears to fit reasonably well, i.e., if the residual deviance is not statistically significant. This raises the question of how to proceed if there is a degree of residual variation that we cannot explain.

In geographical studies, it is quite likely that such variation will be due to unobserved variables that are spatially autocorrelated, and in this case we can include terms in the model designed to reflect this autocorrelation. Typically, this is done for data in areal form using a conditional autoregression (CAR) model (Wakefield et al. 2000) while, for continuous data, Kelsall and Diggle (1998) use a generalized additive model (GAM) which effectively gives an extra term in the model estimating residual variation non-parametrically. These ideas are important but are somewhat beyond the scope of this chapter; see Pfeiffer et al. (2008) for an introductory account of spatial models and Diggle (2000) for a good overview of the field. We only remark that the issue may not always be as significant as some authors maintain. The deviances of the terms that are fitted in a model will still be a reliable indication of their importance unless they are confounded with the unobserved variables that are inflating the deviance; in this case, fitting a spatial model merely tells us that this confounding has a spatial structure – it does not help us to identify the variable or determine its scientific importance.

37.4 Mapping Disease Risk

The mapping of disease risk is a central endeavor of geographical epidemiology: a map is as convenient for portraying such location-specific information as it is for indicating the geography of the land to which it relates. It is therefore no surprise to discover that mapping has a long history predating any systematic development of the statistical principles that underlie it.

As with other areas of geographical epidemiology, many methods have been proposed. Broadly speaking, these can be divided into two classes, model-based and non-parametric. Methods in each of these classes can be applied to data in either areal or continuous form. It is important to appreciate, however, that, whatever method is applied, there is inevitably a degree of smoothing involved that is to some extent arbitrary and under the control of the investigator.

For example, the simplest form of map is the so-called choropleth map, which uses a gray or color scale to depict the risk of $\mathcal{D}$ in each of a number of areas, usually administratively defined so that denominators are easily available. Here, the degree of smoothing is determined by the size of the areas A_i, since the process represents the risk as being the same throughout each given area. An example of a choropleth map is given in chapter ▸Descriptive Studies of this handbook.

Similarly, data in continuous point form can be mapped using the methods described in Sect. 37.3.4 by plotting the RRF $\widehat{\theta}(x, y)$. Here, the smoothing is determined by the degree of smoothing used in the estimation of the densities: it is a commonplace of this methodology that some smoothing parameter always has to be used, though there are data-driven methods for estimating the most appropriate value. See Bithell (1990) for an early example of this method applied to small numbers of cases and controls, and Davies and Hazelton (2010) for a more recent development of the methodology.

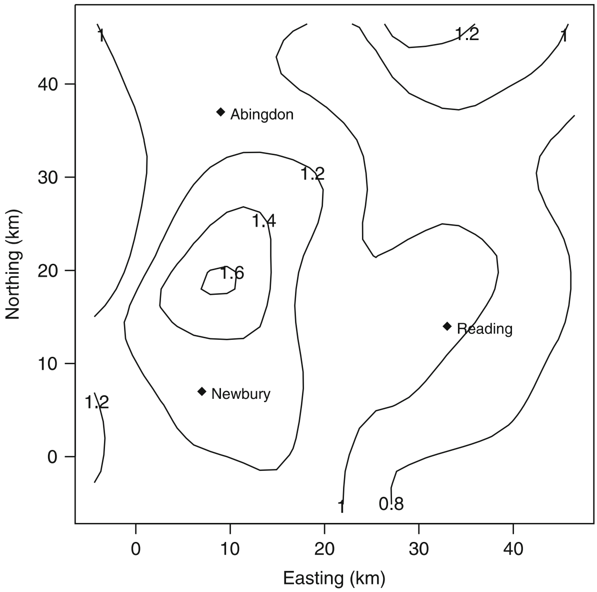

Fig. 37.1 Relative risk function for childhood cancer in a region of Oxfordshire, estimated from areal data. The three town centers are shown only approximately. The ASH smoothing parameter used was 8 (See Bithell 1999 for details)

It may be noted that the RRF method can easily be adapted to areal data by suitably modifying the customary density estimation methods (Bithell 1999). Figure 37.1 depicts the incidence of childhood cancer in a 50-km square region of Oxfordshire using data from the UK National Registry of Childhood Tumors maintained by the Childhood Cancer Research Group in Oxford. They consist of 279 cases of childhood cancer (other than leukaemia and non-Hodgkin lymphoma) registered under the age of 15 years between 1966 and 1987. Each case was located in one of 150 electoral wards for which expected numbers of cases were calculated using similar methods to those for the leukaemia data described in Sect. 37.3.2. The point observations for the cases were used to construct a density estimate $\widehat{\psi}(x, y)$ using the *average shifted histogram* (ASH) method due to Scott (1992). For the controls, the density estimate $\widehat{\pi}(x, y)$ was constructed by treating the centroids of the wards as point locations weighted by the expectations and using a version of ASH modified accordingly.

The basis of the ASH method is to count the numbers of cases in the cells of a square grid; these are then smoothed by slightly shifting the grid a number of times and averaging the resulting counts; this process effectively smoothes the surface by spreading out the contributions of the points through neighboring grid squares.

The RRF was then obtained by dividing the density estimates for the cases and controls to give $\widehat{\theta}(x, y) = \widehat{\psi}(x, y)/\widehat{\pi}(x, y)$. This is depicted in Fig. 37.1 as a contour plot with a scale in km and an origin located in South West Oxfordshire.

The methods sketched above may be regarded as empirical or non-parametric, in that there is nothing underlying them that is more sophisticated than the division of one number by another (specifically a count by a denominator or one density estimate by another). It is generally difficult to see how to determine the appropriate degree of smoothing by any objective process, as distinct from using intuitively plausible and aesthetically pleasing values.

The necessity for a degree of smoothing can easily be seen by considering a choropleth map, for which we have areas A_i with small numbers of cases, either because we have chosen small areas or because $\mathcal{D}$ has low incidence. In this case, the estimates of the risk in each A_i will be subject to large sampling errors; our belief about the true risk in A_i will be determined in part by the observed rate, but it will also rely on information from the region as a whole, to the extent that we believe there will be some comparability between the areas.

This idea has led to the development of model-based approaches using Bayesian arguments to integrate area-specific information with information from the whole region, using a statistical model for the underlying variation of the true risk. In a classical treatment of this problem, Clayton and Kaldor (1987) suppose that the true risk θ_i in A_i is distributed over the areas as a whole according to a gamma distribution with mean μ and variance σ^2. It can then be shown that the posterior distribution of θ_i has mean

$$\tilde{\theta}_i = \frac{y_i + \mu^2/\sigma^2}{e_i + \mu/\sigma^2},$$

where y_i is the observed value of the count Y_i in A_i. This formula can be seen to be a form of average of the maximum likelihood estimate $\widehat{\theta_i} = y_i/e_i$ of each θ_i and the overall mean μ, which can be estimated by $\sum y_i / \sum e_i$. The value of σ^2 can also be estimated from the data as a whole, though this requires an iterative method.

This method and variants of it provide *empirical Bayes* estimates, in that the prior distribution of the θ_i can be estimated from the data. The method is essentially non-spatial, in the sense that the true θ_i is supposed to vary independently. In practice, it is likely that rates in neighboring areas will be consistently more similar to one another than those in more separated areas. If this were not so, it would be essentially fruitless to attempt to produce a smoothly varying map. The Bayesian methodology has been extended to permit the prior distribution of the θs to depend on the values in neighboring areas. These more complicated models involve a greater number of arbitrary assumptions, however. They are gaining ground in popularity and appear to be used quite successfully. The reader is referred for more details and references to Clayton and Bernardinelli (1992) and to chapter ▸Bayesian Methods in Epidemiology of this handbook.

Attractive though these ideas are, the maps they produce need careful interpretation, since they have imposed a degree of spatial autocorrelation, and this process is capable of making adjacent areas look more similar than they really are. In a sense, this is true of all mapping methods and is a feature as intrinsic as the implicit smoothing itself.

In a challenging paper, Gelman and Price (1999) discuss the issue and illustrate the phenomenon of induced spatial pattern by means of simple modeling paradigms.

They point out that the probability that a particular area rate $\widehat{\theta_i}$ exceeds a given value increases with decreasing population size, n_i, say. The effect of this is that high observed rates of disease tend to be observed predominantly in low population areas; since these tend to be spatially aggregated – i.e., low population areas are more likely to occur next to other such areas – observed rates also appear to be spatially related even when in fact no such relationship exists for the underlying risk.

They further demonstrate that plotting the posterior means from a Bayesian analysis produces observed rates that are likely to exceed a particular value with probabilities that are *decreasing* functions of n_i, so that such plots overcorrect in some sense. Although scores exist – at least for continuous observations – that are not subject to these artifacts, they have no direct interpretation as estimates of the θ_i.

One is driven to the conclusion that disease maps are potentially misleading when used as anything except what Gelman and Price call "look-up tables," i.e., as a convenient way of depicting the rate in a given area *without reference to neighboring areas*. It is the temptation to use the map to generalize about the spatial pattern of rates that can be misleading, and it is probably better to formulate such questions within the context of a statistical model rather than to attempt to portray spatial relationship graphically. However, one suspects that this timely caution is unlikely to diminish the enthusiasm for constructing and overinterpreting disease maps.

37.5 The Detection of Generalized Heterogeneity

37.5.1 The Assessment of Heterogeneity in Areal Data

Heterogeneity is the key to epidemiology, in the sense that a uniform risk in observed data gives no possibility for associating differences with factors that may have etiological significance. We have already touched on the issue of modeling in Sect. 37.3.1, and our objective there is to find a model that appears to fit well in the sense that the residual deviance is not statistically significant – i.e., it is consistent with chance deviations from the predictions of the model.

As long as we have Poisson data with reasonably large means, we can assess the residual deviance as if it had a chi-square distribution with a number of degrees of freedom (d.f.) determined by the model – specifically the number of units minus the number of parameters fitted. It is important to remember, however, that this is based on asymptotic theory which, roughly speaking, supposes that the total number of cases is large compared with the number of units – areal or otherwise – in the analysis. A rule of thumb suggests that the expectations of the counts in a Poisson regression should mostly be in excess of 5. When the average expectation falls below this, we should expect the distribution of the deviance in a correct model to depart progressively from a chi-square distribution, which of course means that a corresponding statistical test of goodness of fit of the model based on the chi-square distribution would not be valid.

In this situation, we can obtain an approximate assessment of the value of the deviance – and hence the goodness of fit of the model – by simulation. Typically, we would generate, say, s new samples of data from Poisson distributions with means obtained from the model $\mathcal{M}_{\text{fitted}}$ fitted to the actual data. For each simulated sample, we would refit the same model and compute the residual deviance. The s values of the deviance thus obtained provide an estimate of the distribution of the deviance. This in turn provides a means of calibrating the deviance observed for our actual data. A formal test of goodness of fit would only be approximate since we are simulating from $\mathcal{M}_{\text{fitted}}$ rather than the true model with the true (unknown) parameter values. This situation is typical of "bootstrapping," and the theory of this subject could in principle lead to better approximations. For an account of bootstrapping see, for example, Efron and Tibshirani (1993).

37.5.2 Detecting Heterogeneity in Poisson Data

A special case arises when we have expectations, provided, for example, by some prior analysis or by simple calculation from population data and we merely wish to detect whether the Poisson distribution fits well with the assumed e_i, without reference to any model fitting. This is sometimes seen as a problem of detecting "clustering," though there are qualifications to this interpretation that we discuss below: for the moment, we prefer to regard this as the problem of assessing heterogeneity, i.e., variations in risk between areas without reference to a possible geographical origin for the phenomenon.

Relating this to the deviance of a Poisson model suggests that the deviance of the observations, defined in Eq. 37.1, Sect. 37.3.2, would be a sensible test statistic. The fact that this test is a likelihood ratio test means that it is *asymptotically* fully efficient – i.e., its power approaches that of the best possible test against a Poisson alternative in which the relative risks are different from unity.

Popular alternative contenders include Pearson's chi-square statistic

$$X^2 = \sum (Y_i - e_i)^2 / e_i \ ,$$

and the Potthoff–Whittinghill statistic (Potthoff and Whittinghill 1966)

$$PW = \sum Y_i (Y_i - 1) / e_i \ ,$$

which is regarded by some authors as a test of clustering. The former is, at least in simple cases, asymptotically equivalent to the deviance but is easier to compute and to study analytically. The asymptotic requirement, however, implies that the

Table 37.2 Expected significance levels (ESL) % and their standard errors for Pearson's X^2, the deviance, and the Potthoff–Whittinghill tests: k wards each with expectation e under H_0 and an alternative expectation dispersion with variance σ^2

e	σ^2	k		Pearson	Deviance	Potthoff
5.0	0.05	200	ESL	6.6	3.5	44.5
			s.e.	0.22	0.18	0.50
1.0	0.2	500	ESL	3.5	2.7	6.3
			s.e.	0.18	0.16	0.24
0.2	1.0	1,000	ESL	14.2	23.8	3.3
			s.e.	0.35	0.43	0.20

expectations should be large and the theoretical properties give rather little guidance on which test is best for small expectations.

Table 37.2 shows the results of a simulation study, designed to provide such guidance, in which the expected significance level (ESL) of each test has been estimated in each of three conditions. (The ESL is a convenient alternative criterion to power (Dempster and Schatzoff 1965): a smaller ESL corresponds to a more powerful test.) In each case, the ESLs were estimated from 10,000 simulations performed under varying conditions. These were chosen to produce values in a critical range corresponding to situations where the test would be quite likely to lead to different conclusions at conventional significance levels. In each case, a specific number k of wards were supposed to have the same expectations e under the null hypothesis, while under the alternative hypothesis, these expectations were multiplied by a set of RR factors θ_i sampled from a gamma distribution with mean one and variance σ^2.

In interpreting this table, we suppose that the key parameter is the size of the expectation e. Because the test statistic will be roughly proportional to the number of wards k, this latter parameter represents the amount of information and was chosen to bring the ESLs into an interesting range; it would not be expected to change the relative ordering of the three tests. The variance σ^2 represents the distance between the null and alternative hypotheses, and the values were chosen to be typical of the sort of discrepancy that one could reasonably expect to detect in practical situations. It could conceivably affect the relative properties of the different tests but is less likely to do so than e.

It will be seen that, with an expectation of $e = 5$, the deviance is indeed the best test, while the Potthoff–Whittinghill test trails behind Pearson's chi-square test. The difference between X^2 and D becomes marginal around $e = 1$ while, for smaller expectations, the ordering is reversed and the Potthoff–Whittinghill test appears to be superior. These results suggest that it would be wise to carry out simulations in particular marginal cases to determine the best test to use. It should also be emphasized that one should evaluate the significance of the chosen statistic using simulation when the e_i are small, since the Pearson and deviance statistics are then likely to have distributions markedly different from the chi-square.

37.5.3 Spatial and Non-Spatial Analyses

A test of heterogeneity in areal data of the kind described above provides only a non-spatial test of the heterogeneity of our observations. Whether this is appropriate depends on whether or not the areal units are defined by essentially geographical criteria. If, for example, they are defined by simply dividing our region $\mathcal{R}$ into urban and rural areas, then a factor associated with the degree of urbanization could be expected to induce heterogeneity into the areas irrespective of their spatial positions.

More frequently, however, areas are merely convenient administrative subdivisions of $\mathcal{R}$. In this case, we might expect a factor that raises the incidence in one area to do so in adjoining areas also. Then, a test that takes no account of the spatial relationship of the areas will be less powerful than one that does.

To take a simple hypothetical example, suppose that $\mathcal{R}$ consists of two subregions: $\mathcal{R}_1$ with n areas each having expectation $e_i = 9$ and $\mathcal{R}_2$ with n areas each having expectation $e_i = 11$. A dispersion test based on Pearson's chi-square statistic would use the variance of the observations to test the null hypothesis H_0 that all the expectations are the same:

$$X^2_{2n-1} = \sum_{i=1}^{2n} (Y_i - e)^2 / e \, ,$$

where $e = \sum_1^{2n} Y_i / n$ is the (estimated) expected count based on all $2n$ observations. To a good approximation, this statistic would have a chi-square distribution with $2n - 1$ degrees of freedom under H_0. If, however, we knew which areas belonged to $\mathcal{R}_1$ and which to $\mathcal{R}_2$, we would base the test on the equivalent statistic for testing the difference between the totals for the two subregions:

$$X^2_1 = \frac{\left(\sum_1^n Y_i - ne\right)^2 + \left(\sum_{n+1}^{2n} Y_i - ne\right)^2}{ne},$$

and it is fairly obvious that this would be a much more powerful test of H_0. This idealized situation is analogous to isolating sources of variation in an analysis of variance.

In practice, of course, we will almost certainly not be in a position to divide $\mathcal{R}$ into high- and low-risk areas a priori, but this example does suggest that the detection of non-uniformity of risk should take account of the spatial structure of the data. A classical account of tests of spatial autocorrelation is given by Cliff and Ord (1981), who establish some theoretical properties of their sampling distributions, particularly in the case of normally distributed observations. In one of the few comparative studies published, Walter (1993) examines the power empirically for three of the most popular tests against a variety of geographically plausible alternatives. The three considered were as follows:

- The I statistic of Moran (1948), which is analogous to a correlation coefficient and is defined by
$$I = \frac{n \sum_{ij} w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{\sum_{ij} w_{ij} \sum_i (x_i - \bar{x})^2}$$
- The c statistic of Geary (1954), which is similar to I
- A non-parametric test statistic which uses only the ranks of the observations

The first two statistics used as observations $x_i = y_i/e_i$, the standardized incidence ratios for the different areas, and spatial weights w_{ij} chosen to be one if A_i and A_j are adjacent and zero otherwise. Walter's Table II shows that, in each of the situations he considered, Moran's I had the highest power of the three, and it would seem that this should be the method of choice, at least for detecting generalized spatial relationship as opposed to isolated peaks in the risk. The question of whether higher power could be achieved by using more sophisticated weighting than a simple adjacency matrix, or by weighting the pairs of observations according to the amount of information they contain (in terms of sample size, for example), has not been much considered. Walter concludes that "the precise type of spatial pattern involved may have a major impact on the spatial power of the analysis" and that "more experience is needed to better understand the potential of these methods, and their limitations." Nevertheless this study was a useful contribution, and the use of Moran's I to detect spatial autocorrelation is probably a good choice.

37.5.4 Heterogeneity Tests Based on the Risk Surface

If we have continuous data – i.e., observations at the individual level – we can base a test of uniformity on the RRF $\widehat{\theta}(x, y)$ as estimated by the methods described in Sect. 37.3.4. We may regard a test statistic as being defined by a functional of $\widehat{\theta}(x, y)$, and there are various possibilities.

A natural choice is the weighted variance of $\widehat{\theta}(x, y)$:

$$T_{\text{var}} = \iint_{\mathcal{R}} \pi(x, y)\{\widehat{\theta}(x, y) - 1\}^2 \mathrm{d}x\mathrm{d}y \ .$$

In the absence of any reliable theory, it is necessary to resort to Monte Carlo methods to test the statistic. For case-control data, we use a permutation method that is straightforward though laborious:

1. Construct a map of the risk function $\theta(x, y)$ by a suitable method, using a degree of smoothing which is determined as a function of the data.
2. Evaluate the chosen test statistic for the observed data t_{obs}.
3. Choose a new sample of "cases" by choosing at random n points from the set of $m + n$ cases and controls combined.
4. Compute the value of the statistic t_1, say, for the simulated data, using the same procedure as in step 1.

5. Repeat steps 3 and 4 $s - 1$ more time so that there are s simulated values altogether.
6. Reject at level $\alpha = m/(s+1)$ the null hypothesis of uniformity of cases if t_{obs} is greater than all but $m - 1$ of the simulated observations.
7. Alternatively estimate the p-value of the test as the number of $\{t_i \geq t_{\text{obs}}\}/s$.

This general Monte Carlo procedure is applicable in very general circumstances, and it is especially useful in the analysis of spatial data, where construction of suitable models is difficult. We must remember, however, that a hypothesis test is, by itself, of very little inferential value without some idea of how probable the observed results would be under a plausible alternative.

The method can easily be adapted to a test based on a risk surface constructed from areal data as described in Sect. 37.4. The simulation would take the form of sampling areal counts from Poisson distributions with expectations e_i and computing the variance over a square grid as before. In either the continuous or areal data case, the degree of smoothing used in the density estimation process determines the scale of aggregation for which the test is most sensitive and is analogous to the choice of weights w_{ij} in Moran's statistics.

The use of tests of this sort is still in its infancy, but the underlying philosophy is attractive and increasing computing power is making them more practicable even for large data sets.

37.6 Clustering

Closely related to the idea of heterogeneity is the concept of clustering, with which much of geographical epidemiology is preoccupied. There is a large literature on the subject, not all of which is very clear on the issue of what we actually mean by the words "cluster" and "clustering." We may conveniently define a cluster as a localized aggregation of disease cases greater than can easily be explained by chance. Clustering may be regarded as the tendency to form clusters or, more generally, as any departure from the assumptions of uniform risk and independence of case occurrences as discussed in Sect. 37.2.1. We will continue to use the word heterogeneity to refer to a departure from uniformity and reserve the word clustering as far as possible to refer to mechanisms in which case occurrences are not independent. This kind of clustering may be supposed to act locally, whereas heterogeneity is more likely to be observed throughout $\mathcal{R}$ and is sometimes referred to as "generalized clustering." For further discussion of the issues the reader is referred to a useful paper by Diggle (2000).

We can give here only the briefest of accounts. We will distinguish between methods based on increased levels of risk and methods based on the proximity of neighbors. First, however, we make two general points about clustering.

In the first place, it is a well-accepted fact of spatial statistics that it is not possible to distinguish on the basis of a single realization of observed data from a spatial process whether any non-uniformity of the distribution of points (relative to an expected population distribution) is due to a variation of underlying risk, with cases occurring independently (i.e., points generated by a non-homogeneous Poisson process or its equivalent), or to a mechanism in which existing cases induce others nearby, such as would happen in a contagious process. Secondly, we remark that, from an abstract point of view, clustering may take place in any continuum and, in the geographical context, we may observe clustering in space, time, or the "product-space" of time and geographical space. This mathematical commonality means that tests can be adapted from one problem to another, with very fruitful consequences.

37.6.1 Methods Based on the RRF

Clustering is likely to be observed as an increase in risk in some locality and it follows that we can use the estimated risk surface $\widehat{\theta}(x, y)$ to provide an appropriate test. What functional of $\widehat{\theta}(x, y)$ we use will depend on the alternative we have in mind or, equivalently, the pattern we would most like to detect. If, for example, we are content to demonstrate a single cluster or aggregation of cases we could choose as our test statistic, the maximum of the $\widehat{\theta}(x, y)$ over the whole region $\mathcal{R}$:

$$T_{\max} = \max_{x,y \in \mathcal{R}} \{\widehat{\theta}(x, y)\} .$$

This does not, of course, preclude the possibility that we would detect multiple clusters, but it is likely that our test would be most powerful in the situation where there are in fact very few. We could of course extend the statistic to consider, for example, the mean of the r largest peaks in $\widehat{\theta}(x, y)$, but it is unlikely that we would have good a priori grounds for fixing r. Tests based on peaks of incidence must also be expected to be quite sensitive to the scale of the clustering phenomenon and to the degree of smoothing we employ in constructing $\widehat{\theta}(x, y)$.

A statistic likely to have similar properties to $T_{\max}$ is based on a scanning window, typically a square that moves over $\mathcal{R}$. At each point of a fine grid the observed number of cases is compared with its expectation; the test statistic is defined as the maximum discrepancy using a suitable criterion such as the incidence ratio. Here, the size of the window plays the role of a smoothing parameter; the main difference from $T_{\max}$ is that a peak incidence is weighted according to its radial extent; it seems likely that it behaves in a similar manner to $T_{\max}$ for suitably chosen smoothing parameters. Anderson and Titterington (1995) describe a version of this method that varies the window size to keep constant the expected number of cases under the null hypothesis. Much subsequent work describing similar tests has been published; see Tango (2010) for a recent summary. Some of these have considered windows of different shapes, notably elliptical, but the usefulness of these is limited, not least because we are unlikely to know a priori what shape a cluster might have.

In fact, the scanning window is a two-dimensional version of an approach originally used for detecting clustering in time; even this one-dimensional version is notoriously intractable analytically and simulations or other numerical methods would seem to be unavoidable.

37.6.2 Knox's Test

The use of what we may call pairing methods is historically older than the methods based on the risk surface discussed above; they have the attraction of being very simple to describe and understand.

The earliest such test is due to Knox (1964), who counted the number, Z, of pairs of children with leukaemia diagnosed within 60 days and 1 km of each other in Northumberland and Durham, two counties in the North East of England (see Table 37.3, taken from Knox (1964)). The study used local registration and hospital records, as well as death certificates to ascertain 185 children with an onset of leukaemia under 15 years of age between the years 1951 and 1960 inclusive. However, certain cases were excluded, and Table 37.3 refers just to children under the age of six, a restriction that needs to be borne in mind when interpreting the results; in fact, older children showed no effect.

The rationale for this test is explicitly related to the non-independence of the cases, namely, that a contagious mechanism passing a disease from one individual to another would be likely to lead to cases that are closer to one another in space and time than would be expected by chance. This in turn leads to the idea of considering pairs of cases.

Knox refers this statistic to its expectation calculated on the assumption that the spatial locations and times of occurrence of the disease are independent. This is given by

$$\mathbf{E}[Z] = \frac{N_T N_S}{\binom{n}{2}} \,,$$

where N_T, N_S are the numbers of pairs of cases close in time and close in space, respectively, and the denominator is the total number of pairs out of the n cases.

In effect, this becomes a test of the independence of these two variables, and it uses their *marginal* distributions to determine the null distribution of Z. Knox conjectures that Z should follow a Poisson distribution approximately; this is shown to be true in certain circumstances in work reported by David and Barton (1966), who give a formula for the variance of Z. It is wise to calculate this or to use a Monte Carlo test in which the times of occurrence of the cases are randomly permuted relative to the space coordinates, and the statistic Z is recomputed a large number of times. For Knox's data, the value of $\mathbf{E}[Z]$ is 0.83, for which $Z = 5$ has a p-value of 0.0017 when tested as a Poisson observation. David

Table 37.3 Pairs of cases of childhood leukaemia classified according to their closeness in space and time (see text)

		Distance apart (km)		
		0–1	Over 1	Total
Time apart	0–59	5	147	152
(days)	60–3,651	20	4,388	4,408

and Barton report an early simulation experiment for Knox's data carried out by M.C. Pike; the latter finds $Z \geq 5$ in 4 out of 2,000 simulations. This leads to an estimated significance level of 0.002 which is very close to that based on the Poisson approximation.

The choice of the critical distance and time separation is of course crucial. It determines the scale of clustering likely to be detected, and it should ideally be fixed in advance for the formal validity of the testing procedure. In particular, it is certainly not formally valid to test at a large number of different critical distances and times and then select the most significant result without allowance for this selection. If we really have no idea of the time and distance scales that would be appropriate, we need to use a data-driven method of identifying the most promising values (see Sect. 37.6.6).

37.6.3 Other Space-Time Clustering Methods

An alternative test based on the proximity in space and time of pairs of cases is proposed by Jacquez (1996). This is based on the number out of the l nearest neighbors in space of a given case that are also among the l nearest neighbors in time. Like the Knox test, it can be adapted to provide a test of space-only clustering. Jacquez claimed superior power to that of the Knox test, though in practice, this is likely to depend on the alternative being considered. Here, the parameter l serves as a kind of scale parameter since it determines how far we look for association between cases.

Knox's very elegant idea permits us to dispense with the need to estimate the marginal distributions, though only under the assumption that space and time are in fact independently distributed in the population. This assumption applies of course to Jacquez' test also. It will clearly be violated by population drift, i.e., a change of population distribution with time. Kulldorf and Hjalmars (1999) examine the size of this effect and conclude that it can be "a considerable problem." They recommend that space-time clustering should be tested using the joint space-time distribution of the population size, but this is of course rather hard to obtain with good accuracy and resolution. It seems likely that the use of the interaction tests will remain popular.

37.6.4 Space-Only Clustering

Knox's idea of counting pairs has been very fruitful and has been adapted to a number of related situations, including the use of a sample of controls to provide a reference distribution when testing for space-only clustering (Pike and Smith 1974). The essential idea here is to regard the controls as being similar to the cases, except that they are considered to have occurred at different "pseudo-times," while the cases are considered to have occurred simultaneously. The statistic computed is then the number of pairs of cases that are close in space, and it is not hard to see that this is formally equivalent to Z, with identical distributional statistical properties. Knox's test is not the only test that can be adapted to detecting space-only clustering using controls. Other possibilities are explored by Rogerson (2006) in a paper giving some analytical results but no power study.

37.6.5 Population Distance

One alternative to this adaptation of Knox's test for case-control data is a kind of dual approach due to Cuzick and Edwards (1990). This is based on the count of the number of individuals among the l nearest neighbors of each case that are also cases (as opposed to controls). The quantity l in the Cuzick–Edwards test serves as a determinant of the scale of clustering to be detected in this method. It is given in terms of the number of individuals likely to be within a region of contagion, rather than by a distance.

This may be seen as more relevant for some, though not for all, mechanisms of disease spread. Indeed, for any given pair, we can think of closeness in terms of distance or in terms of the number of other members of the population residing between the two members of the pair. The choice between these two metrics is crucial, though which is the more appropriate will presumably depend on the supposed etiology of the disease.

The idea of a population distance lies behind another method of testing, due to Besag and Newell (1991), who consider each case in turn and aggregate the areas around it that are necessary to include the rth nearest case. The expectation for the aggregate of these areas is then compared with r in the usual way. This can be regarded as a kind of inverse sampling, and again the number of cases considered, r, is a parameter that determines the scale of clustering to which the procedure is sensitive.

37.6.6 Choosing Scale Parameters

Every clustering phenomenon has an implied scale of the clustering effect and it is clearly desirable to have some idea of this before attempting to detect it. When we have no idea, the temptation to perform multiple testing arises and it is important to make allowance for this. A method for testing a range of distances and times in the Knox test is proposed by Abe (1973); effectively, this examines a multi-way table for association between space and time, making due allowance for the non-independence of the pairs. This statistic is sensitive to association over the whole range of distances and times rather than attempting to identify the most interesting scale. To identify the scale of maximal clustering effect, we can use a general data-driven procedure that can be constructed along the following lines:

1. Test the data at each of a number of critical space and time distance pairs.
2. Form a single test statistic, either using some aggregate over different values of the scale parameters or using some measure of the maximum degree of clustering; call this statistic t_{obs}.
3. Simulate further data sets under the null hypothesis: for Poisson data, this will probably involve sampling Poisson-distributed counts, while for case-control data, it may involve pooling all the cases and controls and randomly selecting a subset to serve as simulated "cases."
4. Rank the simulated values of the statistic $t_1, t_2, \ldots, t_s$ and compare the ranked values with t_{obs}.

This Monte Carlo procedure is of general applicability and provides a way of getting round the problem of unknown scale. It does of course sacrifice power by comparison with a test that correctly focuses on the true degree of clustering, so that the more carefully alternative hypotheses can be framed a priori the better.

Faced with this wide variety of tests, it is difficult for the researcher to know which to use. Each new test published typically is claimed to be more powerful than previously existing tests, but there is a wide variety of alternatives to uniformity of risk that could be considered, and it is certain that no one test is uniformly most powerful against all alternatives. In principle, it is open to the researcher to examine competing tests to see which would be best for the data and the alternative hypothesis in question, but this can be an arduous exercise. This is an area where we badly need more insight into which tests are preferable.

37.7 Predefined Sources of Risk

One of the epidemiological questions most often asked in a geographical context is whether there appears to be an aggregation of cases around a putative source of risk $\mathcal{S}$ such as an industrial plant. For example, there has been much interest in the UK, as in other countries, in the possibility of an elevated risk of childhood leukaemia around nuclear power stations. This results in part from the finding of an unusually large aggregation of cases near the nuclear reprocessing plant at Sellafield, which is situated on the coast of Cumbria in the North West of England. In fact, ordinary nuclear generating stations have little in common with the reprocessing plant and the experimental reactor at Sellafield, nor is there evidence of significant releases of radioactivity into the environment from generating stations. Nevertheless, public anxiety persists about the safety of the plants, partly perhaps because of the difficulty in comprehending the nature of nuclear power and partly because of sensational reporting in the news media. In fact, there is little evidence of a general increase in risk (Bithell et al. 1994), but it is highly desirable that the best statistical procedures are used to test the data that come under scrutiny. The public may not have a very sophisticated understanding of statistics, but it is obvious even to the uninitiated that some of the procedures used in the past have not been well-chosen from the point of view of maximizing the chance of detecting a real effect.

Aggregations around $\mathcal{S}$ are sometimes referred to as "clusters," but it is not generally supposed that the cases involved are related, only that the risk to individuals in the vicinity of $\mathcal{S}$ is elevated. Analyses could therefore proceed using the methods described in Sect. 37.3.1, with the obvious qualification that geographical variables clearly represent spatial relationship to $\mathcal{S}$. In practice, this nearly always means using distance from $\mathcal{S}$ or some function of it, so that the analysis is implicitly one-dimensional. Moreover, analyses are often required in situations where the number of cases is very small, and in this situation, the fitting of GLM's tends to be unstable and to lead to parameter estimates with large standard errors and unknown distributional properties.

37.7.1 Tests for Concentration of Risk

In this situation, it is probably better to rely on a formal significance test and the issue then becomes that of selecting the most powerful test against a suitable hypothesis or range of hypotheses. The resulting analyses are likely not to be very powerful in any case, but choosing the most powerful test at least increases the chance that a significant result can be attributed to a genuine departure from the null hypothesis of uniform risk.

The method of early investigators of simply comparing the risk in the area around $\mathcal{S}$ with a reference or "control" rate outside the area defines a test procedure that is in fact powerful only against an alternative hypothesis prescribing a uniform excess risk within the area, which drops to zero on the boundary. This is clearly implausible and critically dependent on the size of the area chosen; one inevitably concludes that a better test would be one designed for some systematic relationship between the risk and the distance from $\mathcal{S}$. We may reasonably suppose that this relationship is monotonic, but the rate of decay and the shape of the RRF (expressed now as a function of distance) will determine the power of the test.

An ingenious class of tests designed to be powerful against general monotonic alternatives was proposed by Stone (1988). His "MLR test" compares the ratio of the maximum of the likelihood under the null hypothesis of uniform risk against the likelihood of the observations maximized subject to the restriction that the risk is a non-increasing function of distance from $\mathcal{S}$, i.e.,

$$H_1 : \theta_1 \geq \theta_2 \geq \ldots \geq \theta_k \quad (\geq 1) \,, \tag{37.2}$$

where θ_i is the relative risk in the ith area in order of increasing distance from $\mathcal{S}$. Stone's test has become very popular in the UK epidemiological literature, though it is known that it is never the most powerful test against a specific hypothesis, this being provided by a *linear risk score* (LRS) test of the form

$$T = \sum_j \ln\left(\theta\left(d_j\right)\right) \,,$$

where d_j is the distance of the jth case from $\mathcal{S}$ and $\theta(d)$ is the risk at a distance d from $\mathcal{S}$ as specified by the alternative hypothesis (Bithell 1995).

Unfortunately, knowing the most powerful test against a specific alternative hypothesis does not greatly help if we do not know what that alternative is. However, it provides a benchmark against which we can judge other tests, and in particular, it enables us to determine the sensitivity of the power to variations in the alternative. It turns out that statistics of the form

$$T = \sum_j 1/\phi\left(d_j\right) ,$$

for monotonic functions $\phi(\cdot)$, define a class of *canonical* tests which can come close to optimal power in many circumstances. In particular,

$$\phi\left(d_j\right) = d_j \text{ and } \phi\left(d_j\right) = \sqrt{\text{rank}\left(d_j\right)}$$

behave well in areas with a reasonably uniform population distribution. However, the latter affects quite strongly which of the canonical tests actually is most powerful and it is wise to check the performances of the competing tests in each different study using simulation. In addition to their simplicity, the canonical tests have the great advantage that they are not dependent on any parameters in the RRF; the test based on the reciprocal of distance, for example, is most powerful against all alternatives for which the RRF is of the form $a \exp(b/d_j)$, for any parameters a (which governs the overall degree of risk) and b (which governs the rate of decay). The fact that risk is unbounded at zero is a small price to pay for this advantage, which means that there is no need to perform multiple tests with different values of a and b.

Because the LRS test statistics are sums, they should in principle have an approximately normal distribution, and it is easy to compute their moments. In small samples, this asymptotic normal approximation will not necessarily apply, and it is advisable to use simulation also to carry out the tests, i.e., to carry out Monte Carlo tests. In doing so, it is easy to see that the way the samples are drawn can be either to fix the total number of cases and use the multinomial distribution or to use unconstrained Poisson distributions to determine the counts in the areas A_i. Which of these two sampling schemes is used is very important and will typically affect the results quite substantially. The first method defines a conditional test which might be appropriate if the expectations e_i for the rates in the different areas are unreliable in absolute terms (though possibly still all right relatively); it is important to note though that, if the expectations are correct, a conditional test could reject the null hypothesis because of a deficit of cases near the boundary of the region rather than an excess near $\mathcal{S}$. The second, unconditional, test is appropriate if the rates are reliable and in this case the test statistic combines the evidence from the overall relative risk in the area with that from the spatial distribution. In this case, the appropriate form of Stone's test should also include the last (bracketed) inequality in Eq. 37.2 above.

Many other tests have been proposed for testing the concentration of risk around a point source; these are sometimes referred to as "focused tests." Some of these are in the class of LRS tests, though this is not always recognized. Some have been designed to use polar coordinates (Lawson 1993) and so to test for a directional effect; unfortunately no equivalent of the canonical test appears to be available for this problem, and so the maximal direction of the effect is a nuisance parameter that has to be estimated from the data unless there is a clear a priori reason for choosing one specific direction. Such tests have been applied to rather few datasets in practice. Tango (2010) gives a recent review of the field and reports extensive power calculations; these confirm that the canonical LRS tests do reasonably well for non-directional alternatives corresponding to a smooth monotonic RRF.

37.7.2 Example: Childhood Leukemia Around UK Nuclear Installations

The tests described above were developed partly in conjunction with analyses of the distribution of childhood leukaemia around nuclear installations. An analysis of all major sites in England and Wales is described by Bithell et al. (1994) using the data on leukaemia and non-Hodgkin lymphoma described in Sect. 37.3.2. The sites were examined separately using the LRS test with the reciprocal of distance rank as the primary test, though Stone's MLR test was also used for comparison. As remarked above, the results were largely negative.

However, public interest in the possibility of a raised risk persists, and two subsequent updated unconditional analyses have been published (COMARE 2005, 2011). In the first of these, the analyses were carried out in the light of a large simulation study that identified which of a number of tests would be most powerful at each of the sites. Experience of these analyses suggests that the power does indeed depend on the population distribution, but it has been found that, for the majority of test sites studied, the most powerful test against the alternatives considered was the LRS test based on $1/\sqrt{\text{distance rank}}$.

Table 37.4 shows the average power averaged over 75 alternative hypotheses and the significance levels achieved by each of five tests for one of the datasets from the 1994 analysis. It will be noticed that the smallest p-value was the Poisson maximum (often known as "Pmax"); this is in effect the maximum value of the cumulative relative risk as we move out from $\mathcal{S}$. The most powerful test, on the other hand, gives a non-significant result. This analysis is a timely warning against judging a test by the significance level achieved in a real dataset. More details and discussion of this analysis are given in Bithell (2003).

In the later study of nuclear power plants in Britain (COMARE 2011), the analysis was restricted to children under the age of 5 years and distances closer to the installations. This reduced the numbers to the point where it was necessary

Table 37.4 Average power of five tests and significance levels achieved for the 80 wards within 25 km of Hinkley Point, in which there were 57 cases observed against 57.2 expected

Test	MLR	Pmax	$1/\text{rank}$	$1/\text{distance}$	$\sqrt{1/\text{rank}}$
Power	0.359	0.204	0.421	0.649	0.630
p-value	0.150	0.020	0.108	0.357	0.341

to combine all 13 plants, and there were then sufficient cases to perform a Poisson regression on 1/distance. The resulting estimate of the risk coefficient was positive, but not statistically significant.

37.7.3 Summary of Recommendations

In summary, this is an area of geographical epidemiology where some progress has been made in identifying efficient procedures, perhaps because the problem is essentially one dimensional. Because data sets are usually small, it is an especially important aim to use tests of maximum power, and this criterion seems to be sensitive to the population distribution as well as the precise alternative considered. As far as areal data are concerned, it is recommended that a study should be guided by the following considerations:

1. First and foremost, thought should be given to the patterns of risk that it is desired to detect; these can be expressed in terms of the RRF and may reasonably be supposed to be monotonic decreasing unless special circumstances prevail. The more specifically this can be linked to a biological hypothesis, the more convincing a positive result will be.
2. Next, a circular region of radius R around $\mathcal{S}$ should be chosen and the observed and expected numbers of cases for the areas A_i in R obtained. There is no great advantage for testing purposes in calculating the numbers within fixed distance bands from $\mathcal{S}$. The magnitude of R is important since, if it is much greater than the distance of any conceivable risk, the analysis will inevitably lose power. As a guideline, it would seem sensible to choose the radius R so that the excess relative risk might reasonably be supposed to have declined to half its value at distance $R/2$.
3. A Poisson regression should be used only if the total number of observations is large enough to ensure convergence of the estimation procedure and to provide reliable estimates of the parameters. It is difficult to provide guidelines, but an analysis with fewer than 20 cases in R should be treated with caution. The alternative of a non-parametric test may then be preferable.
4. For a non-parametric test, the first choice to make is between the conditional and the unconditional versions. This will depend largely on the perceived reliability of the expectations and whether it is desired to detect an overall excess in the area as well as spatial pattern.
5. Among tests of either kind, the LRS canonical tests will be reasonably powerful against most monotonic hypotheses, and it is recommended that 1/distance or

$1/\sqrt{\text{distance rank}}$ be used unless the population distribution is very unusual or unless a very non-standard RRF is suspected. In either case, it is recommended that a simulation study be undertaken to determine the most powerful test for the suspected alternatives.

6. The analysis should then proceed with the test identified as best, using simulation to perform a Monte Carlo test unless the expectations are quite large, in which case normal approximations can be used for assessing the significance.

37.8 Conclusions

In this chapter, we have attempted to give a simple but unifying overview of the statistical methods that underlie geographical epidemiology. We have been able to refer to only a small proportion of the very large number of methods that have been proposed for different aspects of the subject. For further reading, we refer to edited volumes by Elliott et al. (1992, 2000), Lawson et al. (1999), and to the *Encyclopedia of Biostatistics* edited by Armitage and Colton (1998), for example the review article by Bithell (1998).

It will be clear that the rational choice of method is not an easy matter. Although the classical theory of statistics provides a number of principles leading to optimal procedures, there are areas of geographical epidemiology where they do not apply. In the first place, they apply essentially to the frequentist paradigm: the increasingly popular Bayesian methods raise essentially new optimality issues that are not easy to resolve. Secondly, many optimality results are asymptotic: when observations are effectively widely distributed throughout two-dimensional space, asymptotic results are less likely to be applicable even in moderately large datasets. Thirdly, many methods are essentially non-parametric and the classical optimality theory applies less directly to these. Lastly, the theoretical results apply mostly to situations where there is a large degree of independence in the structure of the data; they are therefore less applicable to models for the contagious processes needed to model alternatives to the null hypotheses in studies on clustering.

It follows that evaluating the relative merits of different methods has in practice to proceed by largely empirical methods, making extensive use of simulation. This makes appraisal difficult because of the large number of parameters that can be varied in the simulation experiments. It is important that any general principles suggested by the underlying theory are used to direct the empirical investigations, as exemplified, for example, by the discussion of methods for predefined sources of risk in Sect. 37.7. We conclude that geographical epidemiology, despite its practical limitations, can in principle provide useful pointers to the etiology of disease but that the methodology would be much more convincing if we knew more about its behavior in various plausible situations.

38.1 Introduction

Genetic epidemiology combines the scientific disciplines of human genetics, epidemiology, and biostatistics and has close relationships with the fields of medicine, molecular genetics, and molecular epidemiology. The latter traditionally has been concerned more with the study of molecular markers of exposure, susceptibility, and disease (see chapter ▶Molecular Epidemiology of this handbook). The field is also a specialized subdiscipline of biometry and mathematical population genetics with major biometrical contributions to human genetics and the development of statistical methods including segregation, linkage, and association analysis; simulation methods; and computer algorithms. Rather than focusing on cells or molecules (as in molecular genetics) or on individual patients (as in clinical genetics), genetic epidemiology research is conducted using populations or large series of systematically collected families (Khoury et al. 1993).

Genetic epidemiology aims to detect the genetic origin of phenotypic variability in humans (Vogel 2000) and unravel genetic components that contribute to the development or the course of a disease (or more generally a *phenotype*, the observed trait), along with environmental or other risk factors that may modify the effects of genes. Thus, the International Society of Genetic Epidemiology (IGES 2012) describes the field as a marriage between the disciplines of genetics and epidemiology, emphasizing the need to join the fields. Whereas genetics tends to focus on the genotype-phenotype correlation neglecting the environment and epidemiology tends to focus on environmental and demographic factors, a full understanding of the etiology of complex traits can only be achieved by considering both explaining how genes are expressed in the presence of different environmental contexts and how genetic and environmental factors act together in shaping a phenotype.

In contrast to classical risk factor epidemiology, the three main complications in genetic epidemiology are dependencies, large data sets, and the use of indirect evidence. The structure of chromosomes and families or populations leads to major dependencies within the data, thus requiring customized models and tests. Modern technologies can yield millions of genotypes per subject for many thousands of subjects at an affordable cost, and even higher density sequencing platforms are now becoming available, along with a plethora of other data types (e.g., expression, proteomics) and repositories of biological knowledge (*ontologies*). In many studies, the disease-related functionally relevant DNA variant(s) in a gene are not directly observed, and hence the evidence on them is only indirectly given through correlated variant(s).

This chapter is solely devoted to methods dissecting the genotype-phenotype correlation with a binary phenotype (affected/unaffected). It does not specifically cover quantitative phenotypes, although many of the techniques discussed below can be applied to such problems. Section 38.2 presents an overview of major study designs and types of analysis. Section 38.3 introduces the most important genetic models. Sections 38.4–38.6 cover the three major types of analysis, segregation, linkage, and association analysis. Section 38.7 describes recent developments and looks to the future. We offer some general conclusions in Sect. 38.8. Detailed information on diseases used as examples in this chapter may be found in the standard reference of McKusick (1998) or its online version, Online Mendelian Inheritance in Man (OMIM 2012).

38.2 Study Types

Genetic epidemiology investigations are usually triggered by epidemiological studies that demonstrate a positive family history as a risk factor for disease, suggesting the existence of genetic or shared environmental factors. Often the goal of initial studies is to estimate the *relative risk for relatives of affected individuals* compared to the general population, such as λ_S in the case of siblings of affected individuals, in order to support a genetic hypothesis.

To further investigate familial aggregation, a *segregation analysis* may be carried out in pedigrees. This aims to determine whether a *major gene* is influencing a given phenotype in these families and if so to estimate the parameters of the underlying genetic model. All methods for segregation analysis are based on probability calculations for the observed phenotypes conditional on hypothetical genetic model parameters and on family structure, that is *genealogies*. Parameter estimation is often based on likelihood-ratio tests in order to select the most plausible model nested within a hypothetical general model. Sometimes family studies are also used solely (twin studies) or jointly with a major gene to estimate the *heritability* h^2 of a trait, that is, the proportion of the variance explained by (additional) genetic components. Hence, λ_S or h^2 are often used to indicate the genetic basis of a phenotype in a population (or enriched families) before marker studies are performed.

The primary cause of a *monogenic disease* such as cystic fibrosis is a mutation within a single gene that segregates according to Mendelian laws (see below). The predisposing variants (the alleles carrying the risk) of this major gene are usually rare in the population. For *complex* or *multifactorial diseases*, there may still be Mendelian subforms such as breast cancer caused by the major gene *BRCA1*. For rare monogenic diseases and rare Mendelian subforms of complex diseases, segregation analysis and subsequent further analyses perform well. However, complex diseases in general require more sophisticated methods of analysis. For example, in Alzheimer's disease, there are at least three major genes and several susceptibility genes conferring moderate risk (*oligogenes*). Oligogenes can have relatively common alleles carrying the risk. *Polygenic* effects at many loci across the whole genome, each with a minor effect, may contribute to disease.

If there is evidence for the existence of genetic factors contributing to a disease, the next step is to identify susceptibility genes in order to quantify the genetic influence and to understand the underlying genetic model and pathway to the phenotype. To this end, measures of correlation between a *genetic marker* and the (unknown) *disease locus* are used. A genetic marker is a DNA segment for which the chromosomal localization is known and multiple alleles can be determined. In general, methods assume Mendelian segregation of the marker (see Sect. 38.3.2).

Frequently used markers are multiallelic *microsatellites* and biallelic *single nucleotide polymorphisms (SNPs)*. A marker is termed a *polymorphism* if the frequency of the most common variant is less than 99%.

Two types of correlation between a genetic marker and the susceptibility locus are used:

- *Linkage (cosegregation at the family level)*: Linkage is present if the transmissions of DNA at marker and disease susceptibility loci from a parent to a child are not independent. Relatives with a similar disease status (e.g., both affected) are then more similar at a marker close to the disease susceptibility locus than expected under independence.
- *Linkage disequilibrium (LD, association at the population level)*: LD is present if in a gamete the joint probability for a specific marker allele and a specific disease allele differs from the product of individual probabilities. In affected individuals, certain marker alleles will then be more or less frequent than in randomly selected individuals from the population.

Linkage analysis in families is based on linkage; *association analysis* in populations or families uses linkage disequilibrium. Some designs and corresponding statistical methods are capable of integrating both types of information into the analysis.

For the analysis of complex diseases with genetic markers, we can distinguish two major approaches: A *candidate gene investigation* focuses on genes (or genomic regions) whose function in the pathway to the phenotype is thought to be known. A prominent example of a candidate gene system is the HLA (human leukocyte antigen) complex on chromosome 6. HLA is involved in immune resistance and is thus a natural candidate gene region for all autoimmune diseases. The genotypes of the relevant functional component of the candidate genes are not always observed. In this case, we use the information on genetic markers that lie in or in close proximity to the candidate gene in question. In contrast, a *genome scan* – a systematic coarse grid search of the whole genome with genetic markers – aims to localize one or more regions harboring susceptibility genes. A typical scan might investigate approximately 350–700 microsatellites with an average distance of 5–10 cM (centiMorgan, see Sect. 38.3.3) or 500,000 or more SNPs along the genome, depending on the type of genetic information and design used (linkage or association, respectively).

38.3 Genetic Models

38.3.1 Terminology

The *genome* is the complete collection of an individual's genetic material present in every cell, consisting of *chromosomes* (long DNA strands). A *gene* is a piece of a chromosome coding for a function that can be seen as the heritable unit. The *locus* is the position of a piece along the chromosome. The locus might denote the position of, for example, a gene, a gene complex, or a marker. The different variants of a gene are called *alleles*.

The human genome is *diploid*, that is, chromosomes are paired *(homologous chromosomes)* with the exception of the sex chromosomes in males. Each human somatic cell contains 22 *autosomal* pairs and 1 pair of sex chromosomes. In a pair, the autosomal chromosomes contain the same gene with possibly different alleles at the same location. During *meiosis*, a diploid chromosome set is reduced to a *haploid* chromosome set of a germ cell, the *gamete*.

A pair of an individual's alleles at a locus is called a g*enotype*. If the alleles are identical, the individual is called *homozygous* at the locus, otherwise *heterozygous*. Two copies of a gene are called *identical by descent (IBD)* if both copies are identical and are copies of the same gene in a common ancestor. An individual is *homozygous by descent (HBD)* when its gene pair is IBD. When considering several loci simultaneously, the multilocus alleles inherited from the same parent constitute a *haplotype*.

38.3.2 Mendelian Single-Locus Model

Mendelian segregation (Mendel 1865) is the simplest and most commonly used model for the *mode of inheritance* for a single locus. An individual randomly and independently inherits one allele from father and mother, respectively. All segregation events from parents to offspring are independent. This implies that copies of some alleles are frequently present in offspring and other alleles are lost in subsequent generations, hence leading to random changes in population allele frequencies over time (*genetic drift*).

Consider the phenotype affected/unaffected by a certain disease. Let S denote a susceptibility gene with n alleles $S_1,\ S_2,\ldots,S_n$. The distribution of allele frequencies in the population is denoted by $p_r = P(S_r)$ $(r = 1,\ldots,n)$. Under Hardy-Weinberg equilibrium (HWE) (Hardy 1908; Weinberg 1980), the (unordered) genotype frequencies are given by

$$\begin{array}{ll} P(S_r S_s) = p_r p_s = p_r^2 & \text{for } r = s \\ P(S_r S_s) = 2 p_r p_s & \text{for } r \neq s \end{array}.$$

These frequencies follow from independence of the corresponding allele frequencies, combining two ordered genotypes for heterozygotes. Its maintenance in a population can be derived by applying Mendelian segregation to each possible parental mating type, assuming random mating (Khoury et al. 1993).

Penetrance describes the relation between genotype and phenotype. It is the conditional probability that an individual will be affected given its genotype: $f_{rs} = P(\text{affected} \mid S_r S_s)$.

Classical monogenic diseases are those caused by a single major gene, for which the penetrances take only the values 0 or 1. Often a locus S is assumed to be *biallelic*, that is, to have only two different alleles. Let S_1 denote the "susceptibility" allele (mutation) and S_2 the "normal" allele (wild type). For a classical *dominant* *disease,* all carriers of the susceptibility allele are affected ($f_{11} = f_{12} = f_{21} = 1$, $f_{22} = 0$); for a classical *recessive disease*, only homozygous carriers are affected ($f_{11} = 1$, $f_{12} = f_{21} = f_{22} = 0$).

Many classical hereditary diseases follow a Mendelian mode of inheritance. Often, the prevalence is below 1 in 1,000 live births. Examples are cystic fibrosis (autosomal recessive gene, cystic fibrosis transmembrane regulator (*CFTR*)) and Huntington chorea (autosomal dominant gene, *huntingtin* (HTT)). Both diseases can be caused by any of many different mutations. However, the assumption of a gene with a normal and a susceptibility allele (group) worked well in identifying these genes as disease causes, even though the true inheritance is much more complicated. The aim in statistical genetics is not to specify the correct and complete model but to address the scientific question adequately with a parsimonious mathematical model. If this model is too simple, then more complex or new biologically motivated models need to be considered.

The genotype-phenotype relation is complicated for many diseases. Individuals with a susceptible genotype can stay unaffected (*incomplete penetrance*) and those with a non-susceptible genotype can become affected (*phenocopies*). The penetrances at a specific gene locus may be different for different alleles and may depend on age, sex, environmental exposures, or other factors. For a general single locus with susceptibility allele S_1, we generally assume that $1 \geq f_{11} \geq f_{12} = f_{21} \geq f_{22} \geq 0$ and specifically for a recessive mode of inheritance that $f_{12} = f_{21} = f_{22}$ or for a dominant one that $f_{11} = f_{12} = f_{21}$. It is usually assumed that the parental origin of an allele has no influence on a disease, that is, $f_{12} = f_{21}$, although there is a growing literature on imprinting and parent-of-origin effects that violate this assumption (Zhou et al. 2010; Ainsworth et al. 2011).

38.3.3 Linkage

For the joint inheritance at two loci, independent Mendelian segregation does not generally hold, owing to crossover events and recombinations. *Gametes* (comprising one allele from each pair of chromosomes) are formed during meiosis, when homologous chromosomes are arranged next to each other and partly overlap. A chromosome breakage and a *crossover* – an exchange between homologous chromosomal segments – can occur. A *recombination* between loci A and B occurs when a gamete has a haplotype comprising a combination of alleles different from that on the same grandparental chromosome due to crossovers between the loci.

Consider the formation of gametes during meiosis displayed in Fig. 38.1. Between distant loci A and B (see Fig. 38.1a), a crossover is likely to result in a recombination of the haplotypes A_1B_1 and A_2B_2 to give the new haplotypes A_1B_2 and A_2B_1. If the two loci A and B are very close (see Fig. 38.1b), this is very unlikely. *Map distance* is defined as the expected number of crossovers between two loci (Haldane 1919). In expectation, the number of crossovers is roughly proportional to physical distance between two loci, so this distance measure

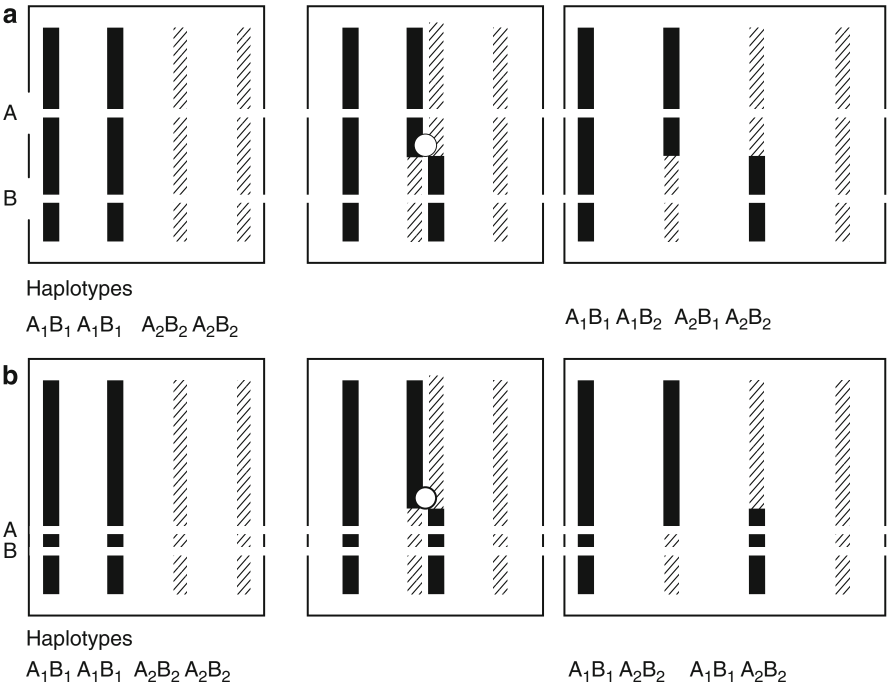

Fig. 38.1 Formation of gametes during meiosis from one parental pair of chromosomes with a single crossover. *Left*: parental chromosome pair, *middle*: crossover event (crossover point denoted by the *circle*), *right*: gametes for offspring formation. At the two loci A and B, the parent is double heterozygous A_1A_2 and B_1B_2. (**a**) The crossover occurred between locus A and B. The two middle gametes show recombination. (**b**) The crossover occurred above locus A and B so that the gametes do not show recombination

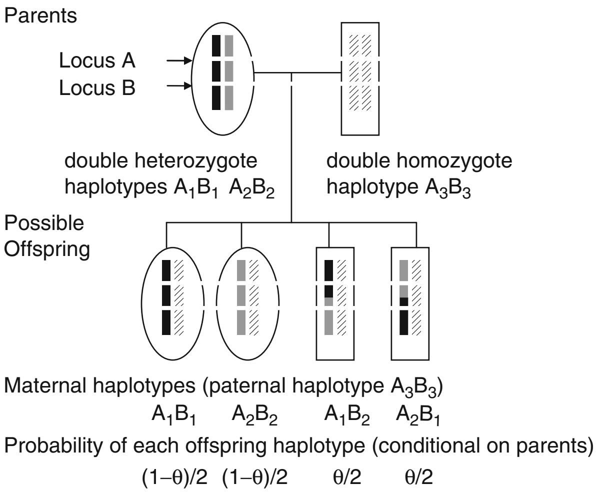
is additive, that is, for three (ordered) loci A, B, and C, the map distance between A and C is the sum of the distances between A and B and between B and C. The map unit is called a Morgan (M), named after T.H. Morgan, a Nobel prize winning geneticist (1866–1945), who discovered the importance of chromosomes for the inheritance process. The human genome contains approximately 3.3 billion base pairs with a total length of approximately 33 M, so as a rough guide, 1 centimorgan ($\text{cM} = 0.01\,\text{M}$) corresponds to one million base pairs in the physical map.

By genotyping, it is possible to observe recombinations between two loci, but crossovers are not directly observable. Figure 38.1a shows recombination due to a single crossover. For a double crossover (two chromosomal exchanges between loci), no recombination would be observed. This holds true for any even number of crossovers. Thus, a *recombination* is defined as an uneven number of crossovers between a pair of loci. The *recombination rate* θ – the ratio of the number of recombinant gametes to the total number of gametes formed – is used as a measure



Parents
Locus A
Locus B
double heterozygote haplotypes A_1B_1 A_2B_2
double homozygote haplotype A_3B_3
Possible Offspring
Maternal haplotypes (paternal haplotype A_3B_3)
A_1B_1 A_2B_2 A_1B_2 A_2B_1
Probability of each offspring haplotype (conditional on parents)
(1−θ)/2 (1−θ)/2 θ/2 θ/2

Fig. 38.2 Formation of recombinant and non-recombinant haplotypes by meiosis

of *genetic distance* between two loci. If loci are on different chromosomes or far away on the same chromosome, they segregate independently. By definition, there is *linkage* between the loci if $0 \leq \theta < 0.5$, and no linkage if $\theta = 0.5$. The closer loci are to each other, the less likely there will be crossovers and hence a recombination. Complete linkage (complete cosegregation) implies no recombination, and thus $\theta = 0$.

In Fig. 38.2, a double heterozygous parent with haplotypes A_1B_1 and A_2B_2 and a double homozygous parent with haplotype A_3B_3 are considered. For the double heterozygous parent, a meiosis can create the non-recombinant haplotypes A_1B_1 and A_2B_2 or the recombinant haplotypes A_1B_2 and A_2B_1. In order to determine recombination, a parent homozygous even at one locus is not informative. Given that recombination is present, each of the two recombinant haplotypes occurs with probability 0.5. Given that no recombination is present, each of the two non-recombinant haplotypes occurs with probability 0.5. For $\theta = 0.5$, there is independent segregation so that all four possible haplotypes are equally likely.

If three ordered close loci A, B, and C are considered, $\theta_{AC} \approx \theta_{AB} + \theta_{BC}$. In contrast to the map distance in Morgans, recombination distances are not additive. *Mapping functions* provide a translation of recombination distances into map distance in Morgans. In the majority of chromosomal regions, recombination rates for women are higher than for men.

The potential informativeness of a single marker chosen from an existing marker map (without consideration of the disease locus) is determined by its genetic variability, that is, allele distribution. A measure of marker informativitiy is the *heterozygosity* H, defined as follows (Weiss 1993; Ott 1999):

$$H = \sum_{r \neq s}^{n} p_r p_s .$$

38.3.4 Linkage Disequilibrium

Linkage and linkage disequilibrium (LD) are different concepts. As linkage describes the coinheritance at two loci, it can only be observed in families, and it is independent of the specific alleles. LD describes the relation between alleles at two loci in a population.

Let S denote a locus with n alleles $S_1, S_2, \ldots, S_n$ and allele frequencies $p_r = P(S_r)$ and M a locus with m alleles $M_1, M_2, \ldots, M_m$ and allele frequencies $q_i = P(M_i)$. A common measure of LD is the haplotype probability minus its expectation under no association. For two biallelic loci, it is denoted by D or δ. For multiallelic markers, the parameter δ_{ir} is often used to define the linkage disequilibrium between M_i and S_r as

$$\delta_{ir} = P(M_i, S_r) - P(S_r)P(M_i), \qquad i = 1, \ldots, m;\ r = 1, \ldots, n.$$

LD is present if $\delta_{ir} \neq 0$ for any pair of alleles M_i and S_r. Under LD, the allele distribution at locus M is dependent of the S allele present. Often used measures of LD are D' (Devlin et al. 1996), defined as δ divided by its theoretical maximum for the observed allele frequencies, that is, a rescaling of δ to range between 0 and 1, and R^2, the square of the correlation coefficient.

LD can arise in several different ways (Suarez and Hampe 1994). At linked loci, complete LD can be caused by a recent mutation at one locus. However, disequilibrium is also possible without linkage between the loci (the term *gametic disequilibrium* is preferable in this case). One important mechanism for the development of disequilibrium at unlinked loci, even on different chromosomes, is *population stratification*. For example, through immigration or non-random mating (e.g., by religion or social status), populations may admix with different allele distributions in the populations.

Under random mating, LD decays over generations g according to $\delta_g = (1 - \theta)^g \delta_0$, where δ_0 is the initial LD at generation 0 (Maynard Smith 1989). Thus, whatever the origin of LD, in the presence of tight linkage, it can stay strong during many generations. Without tight linkage, LD will degrade rapidly. Thus, LD provides indirect evidence for linkage.

38.4 Segregation Analysis

The aim of *segregation analysis* is to test for the existence of a major gene influencing a phenotype and to estimate its mode of inheritance. The pattern of inheritance may be investigated in a few large families or in many small families.

Consider a Mendelian single-locus model for a major gene with susceptibility allele S_1 and normal allele S_2. In the classical Mendelian disease model, the penetrances $P(\text{affected} \mid \text{genotype})$ are only 0 or 1, so the genotype directly translates to a phenotype, and the families segregating the S_1 display characteristic disease patterns.

The simplest segregation tests (see, e.g., Sham (1998)) are based on *segregation ratios*, the proportion of affecteds among offspring of particular parental mating types. For illustration, consider a rare autosomal dominant disease and matings between an affected and an unaffected individual. These will usually be $S_1S_2 \times S_2S_2$ *matings*. Let r be the observed number of affecteds among n offspring and q the probability for a child to be affected. Then the segregation ratio is the unknown parameter q of a binomial distribution with sample size n. If the null hypothesis $q = 0.5$ is not rejected, it may be concluded that the data are compatible with an autosomal dominant disease pattern.

For each of six possible mating types ($S_1S_1 \times S_1S_1, S_1S_1 \times S_1S_2, S_1S_1 \times S_2S_2, S_1S_2 \times S_1S_2, S_1S_2 \times S_2S_2, S_2S_2 \times S_2S_2$), the distribution of genotypes and phenotypes in the offspring is determined by various genetic models. However, families are often recruited non-randomly according to particular ascertainment criteria, such as enrichment for disease, yielding an oversampling for particular parental genotypes, so for a valid test, the probability distribution needs to be corrected for this *ascertainment bias*. For example, if all families with at least one affected offspring are recruited (*truncate ascertainment*), the distribution of the number of affected offspring can be corrected for ascertainment by considering a truncated binomial distribution conditioning on $r \geq 1$ per family. If instead each case has an equal probability of being ascertained (*single ascertainment*), then multiple case families are represented proportional to the number affected and simply excluding the proband from the analysis may suffice. In practice, ascertainment schemes may be complex or unsystematic (Elston 1995), and misspecification of ascertainment might cause serious bias in the estimation of genetic parameters (see, e.g., Shute and Ewens (1988)).

For an *extended pedigree* with N individuals, a numerical procedure is needed. Let L denote the likelihood for the observed vector of phenotypes $Y = (Y_1, \ldots, Y_N)$, given a genetic model and the pedigree structure. L can be calculated by summing over all possible genotype vectors $G = (G_1, \ldots, G_N)_i$, $i = 1, \ldots, N$, in a given family, a particular one denoted by $g = (g_1, \ldots, g_N)$. We assume that the phenotype Y_i only depends on genotype G_i of that individual i. Thus, we get

$$L(Y) = \sum_{g_1} \sum_{g_2} \cdots \sum_{g_N} P(Y|G = g)P(G = g).$$

The Elston-Stuart algorithm (Elston and Stewart 1971) provides an efficient recursive formula

$$L(Y) = \sum_{g_1} \sum_{g_2} \cdots \sum_{g_N} \prod_{j=1}^{N} P(Y_j|g_j) \prod_{k=1}^{N_1} P(g_k) \prod_{m=1}^{N_2} \tau(g_m|g_{m1}g_{m2})$$

where N_1 denotes the number of *founders* (individuals without specified parents in the pedigree, i.e., members of the oldest generation and married-in spouses) and

N_2 the number of *non-founders*. The parameters of the genetic model are (1) the genotype distribution $P(g_k)$, $k = 1, \ldots, N_1$, for the founders in the population for which HWE is usually assumed, (2) the transmission probabilities from parents m_1 and m_2 to offspring $m, \tau(g_m|g_{m_1}, g_{m_2})$, according to Mendelian segregation $(\tau(S_1|S_1S_1) = 1$; $\tau(S_1|S_1S_2) = 0.5$; $\tau(S_1|S_2S_2) = 0)$, and (3) the penetrances $P(Y_j|g_j)$ relating genotypes to disease. This recursive formula works well on a *simple pedigree* of arbitrary size. As several unrelated pedigrees are independent from each other, their likelihoods can be multiplied to yield the total likelihood of a sample of pedigrees. Computations on *complex pedigrees* with marriage chains and inbreeding loops (such as consanguineous marriages) are often only possible with approximation methods.

Segregation analysis works well for monogenic diseases. Due to the unclear genotype-phenotype relationship, they are much more difficult in complex diseases. Several genetic and non-genetic factors, such as age, sex, and exposure factors, may have an influence on disease. Genetic heterogeneity may be caused by different alleles of the same gene or different genes or modifying factors that lead to different phenotypes segregating within a family (Evans and Harris 1992). In addition, there are further types of genetic heterogeneity such as genomic imprinting. In the presence of heterogeneity, considering homogeneous subgroups (defined by, say, severity, age of onset, family history, ethnicity) can lead to a clearer genotype-phenotype relation and thus to identify a possibly Mendelian subform of the disease.

An example of a highly successful segregation analysis for a complex disease is breast cancer (Newman et al. 1988). The families were ascertained through a population-based cancer registry. The ascertainment criteria for index cases were women with breast cancer, Caucasian, diagnosed before the age of 55 during a specified period with a histologically confirmed primary tumor. There was no selection on family history. Thousand five hundred and seventy-nine nuclear families were recruited, along with one large extended pedigree. Complex segregation analysis was applied using the program POINTER (Lalouel et al. 1983). It models an underlying unobserved quantitative trait called *liability* as a mixture of three normal distributions with different means for each of the genotypes, allowing for polygenes and an environmental component, with disease corresponding to the liability exceeding a certain threshold (Morton and MacLean 1974). For a predisposing genotype, the mean liability is shifted compared to the mean for non-disposing genotypes such that more individuals will exceed the threshold. Evaluation by direct modeling of the transmission probabilities allows the identification of the major factor as a major Mendelian gene. Population-based liability classes were taken from cumulative incidence rates estimated from a large epidemiological study in the region.

Segregation analysis is based on likelihood-ratio tests comparing different models. First, one investigates the consistency of the data with a major gene model; next, one considers which mode of inheritance fits the data best. To avoid false-positive results, the likelihood for Mendelian transmission probabilities can be compared against more general models corresponding to environmental or cultural transmission. For breast cancer, an autosomal dominant major gene provided the best fit, although the general single-locus model with three penetrances resulted in a comparable fit, and the non-Mendelian transmission models were strongly rejected.

Segregation analysis for a disease without a single major gene but only a few oligogenes may not be particularly rewarding. Many genetic marker studies are nowadays carried out without specification of the genetic model, but it is still worth establishing that a disease has some genetic basis by estimating the heritability h^2 before embarking extensive marker studies.

38.5 Linkage Analysis

In *linkage analysis*, the cosegregation between marker and disease within families is investigated to find evidence for linkage and often to estimate the recombination rate θ. The classical *lod score method* (Morton 1955) is a test for linkage between a susceptibility gene and a marker (null hypothesis H_0: $\theta = 0.5$ vs. alternative H_1: $\theta < 0.5$) under a parametric model for the genetic effect, allowing estimation of θ. For a detailed description, see Ott (1999). Let $L(\theta)$ denote the likelihood for the observed phenotypes at a particular value for θ conditional on the (assumed) model, the marker allele distribution, and the given pedigrees. In the usual notation, the underlying conditioning is sometimes left out. The lod score function ("log odds") is the log likelihood ratio

$$Z(\theta) = \mathrm{LOD}\,(\theta) = \log_{10} \frac{L\,(\theta)}{L\,(0.5)}$$

as a function of θ. $Z(\theta)$ compares the likelihood under linkage with recombination rate θ with the likelihood under no linkage, that is, $\theta = 0.5$. $Z(\theta)$ will be maximized over all possible values for θ, that is, $0 \leq \theta \leq 0.5$, to yield $Z_{\max}$. Values of $Z_{\max} > 3$ are taken as evidence for linkage. The recombination rate is estimated by $\theta_{\max}$, the θ-value corresponding to $Z_{\max}$. If $Z_{\max} < -2$, linkage can be excluded. The limits 3 and -2 are based on a sequential Wald test, such that the posterior probability for linkage when rejecting H_0 is 95% for a single alternative θ. As logarithms of base 10 are used, the limits correspond to stopping limits of 1,000 and 0.01 in the sequential testing procedure yielded by setting the probabilities of types I and II errors at $\alpha = 0.001$ and $\beta = 0.01$ (Morton 1955).

The likelihood $L(\theta)$ for linkage between two loci A and B for a sibship can be derived easily when the genotypes at both loci are directly observable. Let the mothers' genotypes be A_1A_2, B_1B_2 and the fathers' A_1A_1, B_1B_1; here, only the double heterozygous mother is informative. Without knowing the maternal grandparent's genotypes, one cannot determine the *phase*, that is, whether the mother's haplotypes are A_1B_1 and A_2B_2 (phase I) or A_1B_2 and A_2B_1 (phase II). If the phase were known, $L(\theta)$ would be given by a binomial distribution with

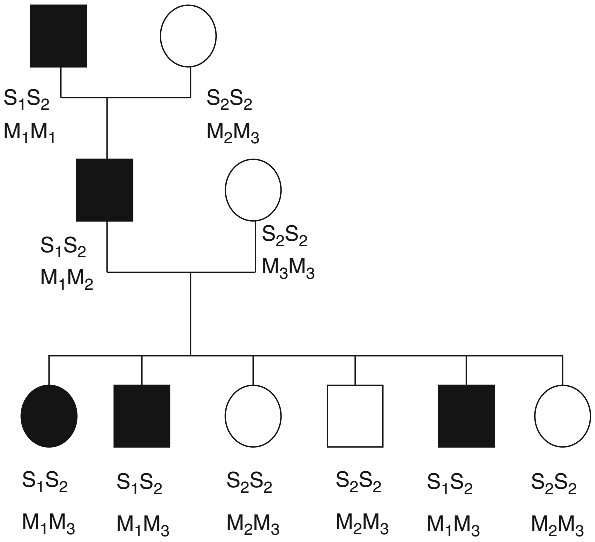


Fig. 38.3 Pedigree with a sibship of size six with marker information and with genotype information concerning the susceptibility locus, owing to the clear-cut rare autosomal dominant mode of inheritance (individuals: square = male, circle = female, black = affected, white = unaffected)

parameters n and θ, where n is the number of informative meioses. For an unknown phase, consider first phase I: Let n_x and n_y denote the number of meioses from the mother to the n children, of which n_x are non-recombinants (A_1B_1 or A_2B_2) and n_y are recombinants (A_1B_2 or A_2B_1). Under phase II, let n_x and n_y denote instead the number of recombinants and non-recombinants. Assuming LD phases I and II are both equally likely, then

$$L(\theta) = \binom{n_x + n_y}{n_x} \left[\frac{1}{2} (1 - \theta)^{n_x} \theta^{n_y} + \frac{1}{2} \theta (1 - \theta)^{n_x} \theta^{n_y} \right].$$

For the sibship in Fig. 38.3, let us now determine the likelihood $L(\theta)$, the lod score function $Z(\theta)$, $Z_{\max}$, and $\theta_{\max}$. Assume an autosomal dominant gene S with a rare susceptibility allele S_1 and a normal allele S_2. Thus, the affected father and all affected siblings have genotype S_1S_2. The marker M has alleles M_1, M_2, and M_3. The mother is homozygous and uninformative for linkage. She will not be considered further.

As a result of the genotyped grandparents, the father's haplotypes are known: S_1M_1 and S_2M_2. Thus, the phase is known and the likelihood is

$$L(\theta) = \binom{6}{0} (1 - \theta)^6 \theta^0 = (1 - \theta)^6 .$$

The lod score function is

$$\begin{aligned} Z(\theta) = \mathrm{LOD}\,(\theta) = \log_{10}\tfrac{L(\theta)}{L(0.5)} &= \log_{10}\tfrac{(1-\theta)^6}{(0.5)^6} \\ &= 6\log_{10}(1-\theta) + 6\log_{10}2 \\ &= 6\log_{10}(1-\theta) + C \end{aligned}$$

where C denotes a constant independent of θ. The maximum of the lod score function is $Z_{\max} = 1.8$ for $\theta_{\max} = 0$. This corresponds to complete linkage as supported by no observed recombinations.

Missing information on grandparental genotypes in Fig. 38.3 results in an unknown phase. Then the lod score function would be

$$\begin{aligned} Z(\theta) = \mathrm{LOD}\,(\theta) &= \log_{10}\tfrac{L(\theta)}{L(0.5)} = \log_{10}\tfrac{0.5\theta^6+0.5(1-\theta)^6}{(0.5)^6} \\ &= \log_{10}\left(\theta^6 + (1-\theta)^6\right) + 5\log_{10}2. \end{aligned}$$

In this case, the maximum of the lod score function is $Z_{\max} = 1.5$ for $\theta_{\max} = 0$. Due to the uncertain phase, the maximum lod score is reduced. However, the estimate for the recombination rate stays at $\theta = 0$.

In Fig. 38.3, assume now that the second affected child has the genotype M_2M_3 (and the genotype S_1S_2). With the phase as indicated in the figure, one recombination needs to be taken into account now. Thus,

$$\begin{aligned} Z(\theta) = \mathrm{LOD}\,(\theta) &= \log_{10}\tfrac{L(\theta)}{L(0.5)} = \log_{10}\tfrac{6\theta(1-\theta)^5}{6(0.5)^6} \\ &= \log_{10}\theta + 5\log_{10}(1-\theta) + 6\log_{10}2. \end{aligned}$$

With one recombination, the maximum of the lod score function is $Z_{\max} = 0.63$ for $\theta_{\max} = 1/6 = 0.17$. Now linkage is estimated as incomplete, and $Z_{\max}$ is markedly reduced.

If in Fig. 38.3 the genotypes of the father and his parents are unknown, the father's genotype can be inferred as either M_1M_1 or M_1M_2. If HWE can be assumed, the likelihood of the recombination rate $L(\theta)$ can be calculated as a function of the marker allele frequencies in offspring. A detailed calculation will show that in this case, a rare marker allele M_1 will result in a high lod score and a more common marker allele M_1 will result in a lower lod score.

For a larger pedigree, $L(\theta)$ can be computed by the Elston-Stuart algorithm (Elston and Stewart 1971) described earlier, where now the g_j are the joint genotypes formed by the two loci S and M and θ is part of the transmission probabilities for the formation of gametes as recombinants or non-recombinants. Across families, the segregation process is independent, so $L(\theta)$ is simply the product of the individual family-specific likelihoods.

The lod score method has been very successful in localizing major genes, such as *BRCA1* for breast cancer (Hall et al. 1990), which was facilitated by focusing on early-onset families for which the genetic relative risk (*RR*) is strong and by having available a good segregation model. However, in complex diseases, the mode of inheritance is usually unclear, leading to false-positive and false-negative results as well as biased estimation of θ (Risch 1991; Lander and Schork 1994; Terwilliger and Ott 1994; Ott 1999). Joint segregation and linkage analysis often leads to biased parameter estimation, particularly if families are not systematically ascertained or the segregation model is misspecified. In MOD-score analysis (Risch 1984; Clerget-Darpoux et al. 1986), the LOD score is maximized over θ and the parameters of a biallelic single-locus model, that is, allele frequency and three penetrances. *Non-parametric methods* or *model-free methods* have been developed to avoid assumptions about the underlying genetic model. Their aim is to provide evidence for linkage without specifying the parameters of the underlying mode of inheritance and without estimating the recombination rate (Lander and Schork 1994; Elston 1998). They are often based on the *identity-by-descent (IBD)* status (Penrose 1953). For example, the IBD status of a patient and one of his/her siblings can take on the values 0, 1, or 2, according to the number of marker alleles that have been transmitted to both siblings from exactly the same grandparental copy of a parent's gene and are thus identical.

Allele sharing methods test whether relatives with a similar disease status (e.g., both affected) are more frequently similar in IBD at the marker than expected in the absence of linkage. In the *affected-sib-pair (ASP) method* (Day and Simons 1976), the observed counts of n ASPs with 0, 1, or 2 marker alleles IBD are compared with the expected ones assuming no linkage ($0.25n$, $0.5n$, or $0.25n$) using a χ^2-goodness-of-fit-test.

The literature on IBD methods is extensive and more powerful methods have been developed (e.g., Holmans 1993; Whittemore and Tu 1998). To determine IBD unambiguously, the marker must be sufficiently polymorphic, and the parents must be genotyped, or neighboring loci must be genotyped to yield sufficient information on the grandpaternal inheritance of the alleles. Often, IBD needs to be estimated. Sometimes, the *identity-by-state* (*IBS*) status (the number of identical marker alleles without considering ancestry) is used instead. In the Lander-Green algorithm for multipoint linkage analysis (Lander and Green 1987), the inheritance vector and thus the IBD status at a particular locus can be determined much more precisely even when some parents are not genotyped. The algorithm calculates the inheritance vector using a hidden Markov model walking from marker to marker, where pedigree size that a software can handle is limited by the length of this vector determined by the number of founders and non-founders in the pedigree (Lander and Green 1987; Kruglyak et al. 1996).

38.6 Association Analysis

The aim of *association studies* is to provide evidence for association or linkage disequilibrium in a population. LD results in an association between marker alleles and alleles of a susceptibility gene, such that certain marker alleles will be present more often in affected individuals than in a random sample of individuals from the population.

In classic *case-control studies,* marker allele frequencies or genotype frequencies in a group of unrelated affected individuals are compared to those in a group of unrelated unaffected individuals. Numerous associations have been identified with case-control studies, for example, associations of autoimmune diseases (e.g., diabetes, multiple sclerosis) with the HLA system or of apolipoprotein E (*APOE*) allele ε4 with Alzheimer's disease (Corder et al. 1993). The *APOE* ε4 allele frequency is approximately 35% in Alzheimer's patients, but only 15% in the older population not suffering from dementia. If a positively associated marker allele is frequent in a population, such as *APOE* ε4, then it is by itself not a good predictor for disease status, and the proportion of homozygotes for the allele is high. Linkage analysis methods are in general not very powerful in this situation.

Besides the usual limitations of classical case-control studies in epidemiology (cf. chapter ▸Case-Control Studies of this handbook), case-control studies to investigate linkage disequilibrium in genetic epidemiology must take a particular form of confounding known as population stratification into account. Population stratification denotes the presence of different ancestry populations, that is, discrete subpopulations or admixture of populations. If individuals are descended from populations with different allele frequencies and this is not taken into account, then spurious associations can be induced. To avoid this confounding, cases and controls must originate from the same homogeneous (including ethnically homogeneous) source population, or an appropriate design and analysis strategy needs to be employed.

If an association is found that is not considered spurious, this may have two causes (Lander and Schork 1994):

- The disease-associated allele is the susceptibility allele itself. If so, this association is expected to occur in all populations harboring this allele.
- The associated allele is in linkage disequilibrium with the susceptibility allele at the disease locus. If this is the case, then different associations can occur in different populations due to different haplotype frequencies at the two loci.

In the first case, marker and disease loci are identical, so $\theta = 0$, and LD is complete. In the second case, marker and disease locus are in general very close to each other. For this reason, association studies are highly valuable for the investigation of candidate genes.

As mentioned above, uncontrolled population stratification can result in spurious associations. For case-control studies, there are methods for taking the existence of subpopulations into account during statistical testing. All methods require many markers along the genome to be genotyped. In the *genomic control* method (Devlin and Roeder 1999), a variance inflation factor is used to adjust the test statistic, taking into account correlations between individuals in subpopulations. The *structured*

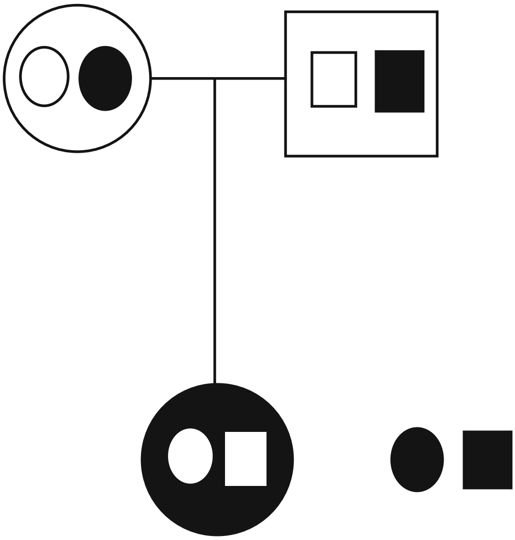

Fig. 38.4 Nuclear family with one affected child. Alleles transmitted from the parents to the affected child are denoted in *white*. Alleles not transmitted from the parents to the affected child are denoted in *black* (individuals: square = male, circle = female, black = affected, white = unaffected, inside: alleles)

association method (Pritchard et al. 2000) estimates the population structure and either assigns individuals to the most likely subgroup or better, estimates the proportion of each individuals' genome derived from each subgroup. Association is subsequently tested within subgroups or adjusted for ancestral source proportions. Both methods typically use panels of hundreds of "ancestrally informative" markers. *Principal component analysis* (Price et al. 2006) generally uses all the markers from a genome-wide scan and adjusts the association of any particular marker for the first few dozen principal components.

Family-based association studies avoid bias due to inadequate controls and population stratification by design. The concept of *internal controls* was first proposed by Falk and Rubinstein (1987). For the original design, nuclear families with at least one affected child are recruited, and the two parental alleles not transmitted to the affected child are used as internal controls (Fig. 38.4). With this design, information on both linkage and association between a marker and the susceptibility gene is used.

For a biallelic marker, the data resulting from this study design can be presented in various ways as 2 × 2 contingency tables and analyzed with standard statistical tests to investigate whether certain alleles are transmitted from the parents to an affected child more often than not (Terwilliger and Ott 1992; Schaid and Sommer 1994). Although in principle, all these procedures test for association (H_0: $\delta = 0$ vs. H_1: $\delta \neq 0$) and most for linkage as well, the most appropriate test respecting the matched nature of the transmitted and non-transmitted allele data is the McNemar test, which in this context is known as the *Transmission/Disequilibrium Test* (*TDT*)

Table 38.1 2×2 contingency table for family-based association studies based on a sample of N families with one affected child and both parents showing the matching of the two alleles of a parent. Consider a biallelic marker with alleles M_1, M_2. Small letters (a, b, c, d) denote allele counts. $2N$ denotes the total number of parental genotypes (i.e., of pairs of transmitted and non-transmitted alleles) to the affected child from the $2N$ parents

	Non-transmitted allele of one parent		
Transmitted allele of one parent	M_1	M_2	Total
M_1	a	b	$a+b$
M_2	c	d	$c+d$
Total	$a+c$	$b+d$	$2N$

(Spielman et al. 1993). The TDT is a haplotype-based analysis of the matched sample (Table 38.1). The test statistic is

$$\text{TDT} = (b-c)^2/(b+c).$$

The TDT compares whether the M_1 allele is more often transmitted to an affected child (b) than the M_2 allele (c) from heterozygous parents or vice versa. The test only considers M_1M_2 parents, since homozygous parents are not informative for preferential transmission of either allele.

The literature on family-based association analysis is vast (see, e.g., Whittaker and Morris (2001)). Important extensions of the above methods allow the application to multi-allelic markers, to tightly linked loci, and to quantitative traits. In addition, the design also allows for other types of nuclear families, such as sibships with affected and unaffected individuals (Spielman and Ewens 1998; Laird and Lange 2006). If a particular mode of inheritance is suspected, specialized versions of the TDT or related likelihood methods may yield higher power (Schaid 1999). If a candidate gene is to be investigated in detail, then a haplotype analysis can be carried out considering several biallelic polymorphisms (SNPs) in the same gene. The first step in a haplotype analysis is the estimation of the haplotype frequency in a population or the estimation of the most probable haplotype pair in an individual. For cohort or case-control studies, see Excoffier and Slatkin (1995), Stephens and Donnelly (2003), and Browning and Browning (2009); for family samples, see Rohde and Fuerst (2001) and Qian and Beckmann (2002). In the second step, linkage disequilibrium is investigated on the basis of the estimated haplotypes or haplotype frequencies. Some of these LD measures have already been described above (Devlin and Risch 1995).

Besides the analysis of main effects, gene-gene and gene-environment interactions can also be investigated in association analysis using standard tools. For gene-environment interaction, the case-only design enables the analysis of multiplicative interactions of factors, required to be independent in the population, on the basis of a sample of diseased individuals (Albert et al. 2001). If the independence assumption is valid, it is very efficient; if it is violated, such as for smoking-addiction genes and smoking, results can be severely distorted.

38.7 Current Methods and Outstanding Challenges

Genetics – and all its subdisciplines – has been an amazingly fast-moving field, with outstanding developments in both technology and biological insights. Methodological developments in statistical genetics and bioinformatics have had to scramble to keep pace; not the least of these challenges has been the daunting computational challenges posed by the massive data sets these advances have provided. In the remainder of this chapter, we review the current state of the art in the design of modern genetic epidemiology studies and the analysis of ultra-high-dimensional data and attempt to anticipate some of the novel developments that will be required in the foreseeable future.

38.7.1 Genome-Wide Association Studies

Fifteen years ago, Risch and Merikangas (1996) published a farsighted article in *Science* on the failure of traditional linkage analysis to uncover the genetics of complex diseases and made the then-radical suggestion that it would soon be possible to explore the entire genome by direct association methods. Their prediction came true, enabled by two developments in particular. The first was the advent of chip-based genotyping platforms that made it possible to assay hundreds of thousands to millions of SNP genotypes at a cost of under $1,000 per sample with high reliability. The second was a concerted effort by the public and private sectors to map the entire human genome (the Human Genome Project) and then to assemble a catalogue of known variants in a sample of Caucasian, African, and Asian populations (the International HapMap Project). In combination, these two advances provide a feasible way to directly genotype a large proportion of common variants and to predict many variants located next to the genotyped markers that are not typed directly.

It was nearly a decade before the first success of this approach was published in the form of a trio of papers on age-related macular degeneration in *Science*, one using this approach (Klein et al. 2005), which implicated a gene *CFH* in the complement pathway, a finding that has subsequently been confirmed numerous times. Since then, associations of about 210 diseases or quantitative traits and 1,300 genetic loci at genome-wide levels of significance ($p < 5 \times 10^{-8}$) have been published that have been independently replicated; the most recent version of the catalogue of published GWAS is available at the website of National Humane Genome Research Institute (NHGRI), National Institutes of Health (Hindorff et al. 2012; see also Hindorff et al. 2009). Study design and statistical analysis methods for such genome-wide association studies (GWAS) have been discussed in greater depth than is possible here (Hirschhorn and Daly 2005; Wang et al. 2005; Kraft and Cox 2008; McCarthy et al. 2008; Thomas 2010a, b; Witte 2010). Instead, we briefly review some of the recurring themes.

Multistage study designs. Early on, it was recognized that the multiple comparisons burden might be alleviated by some kind of staged design, in which only a portion of the sample would be used for screening the entire genome using one of the expensive high-density commercial platforms offering a fixed array of SNPs, followed by genotyping the remainder of the sample using a custom panel of only the most promising SNPs (Satagopan and Elston 2003). The final analysis then combined the information from both stages rather than treating it as a discovery and independent replication design (Skol et al. 2006); furthermore, it was possible to optimize the allocation of subjects to the two (or more) stages and the selection of the threshold for selecting SNPs to be genotyped in the later stages (Wang et al. 2006; Skol et al. 2007). With rapidly declining costs and increasing density of coverage of commercial panels, the interest in multistage designs has declined as investigators have recognized the advantage of having genome-wide data on the entire available sample as a resource for testing a broad range of hypotheses. However, the basic concept remains in spirit in the requirement for independent replication, as discussed in Sect. 38.7.3, and with the need for selecting a manageable number of individuals for next-generation sequencing technologies (Thomas et al. 2009).

Multiple testing and replication. With hundreds of thousands, if not millions, of associations being tested in a single study, there is an obvious need to avoid false-positive claims by adopting a stringent level of significance. A simple Bonferroni correction for one million SNPs would suggest a threshold of $0.05/10^6 = 5 \times 10^{-8}$, which has become the conventional criterion for claiming genome-wide significance, nominally ensuring a 5% probability of making at least one false-positive (family-wise error rate). This calculation fails to take into account the correlation among these tests due to linkage disequilibrium but is not a bad approximation for even the more recent platforms that allow testing of 2.5–5 million SNPs, as 1 million turns out to be roughly the effective number of independent tests in populations of European descent (or roughly double that in African-descent populations) (Pe'er et al. 2008). Fast asymptotic approximations have been developed (Conneely and Boehnke 2007) that allow for LD within a region, or permutation tests can be used as a gold standard for more complex dependency structures.

Despite the stringency of the genome-wide significance threshold, there are many factors than can lead to increased false-positives, some of which are discussed further below. But the key point is that a single study, however significant, is not usually considered convincing evidence of a genuine association without independent replication (Ioannidis 2007). Such replication is not simply to guard against chance variation (which can always be avoided simply by adopting an even more stringent significance threshold) but due to various sources of uncontrolled bias. Hence, real scientific replication should involve some elements of validation in different populations, by different investigators, using different methods. This is already demanded by the standard Bradford-Hill criteria in epidemiology used to establish validity of the association and strengthen belief in causality. This is not always possible in practice, however, such as for rare diseases where the discovery comes from a consortium of virtually all the available data or for studies conducted in unique settings (suggesting a need for some flexibility in the replication demands of granting agencies and journal editors!). Here in particular, the support by additional biological evidence is highly warranted.

Population substructure and study designs. One of the most pervasive sources of bias in GWAS is population substructure, as discussed in Sect. 38.6. Most GWAS therefore adjust instead for either an estimate of global ancestry from a finite set of founding populations using ancestry informative markers, typically using the STRUCTURE program (Pritchard et al. 2000) or using the top principal components from all or a subset of the markers, typically using the EIGENSTRAT program (Patterson et al. 2006). Either of these approaches tends to be quite effective at controlling the overall false-positive rate at least in homogeneous populations such as those of European descent. As a diagnostic for whether residual overdispersion due to uncontrolled population substructure remains after such adjustment, Quantile-Quantile plots of observed versus expected p-values of the single marker test statistics are generally used, and the genomic control overdispersion factor (Devlin and Roeder 1999) is checked to see if it is close to one. Control of population substructure can be more difficult in admixed populations like African-Americans and Hispanics, but these offer the advantage of being able to use within-individual comparisons for admixture mapping (Patterson et al. 2004; Freedman et al. 2006). For conventional GWAS scans in admixed populations, further adjustment for local ancestry (i.e., the ancestral origins of individual's chromosomes in the specific region of interest) may be necessary; the LAMP (Sankararaman et al. 2008) and HAPMIX (Price et al. 2009) programs can be used for this purpose.

Imputation. From the beginning, it has been understood that most associations discovered in a GWAS were unlikely to be directly causal, because only a small fraction of the genetic variation in the genome was being tested, but would hopefully reflect indirect associations with nearby causal variants through linkage disequilibrium between the causal and the marker loci. With the availability of the much more extensive catalogue of variation from the HapMap project, it has now become possible to infer the genotypes for most of the common variants in the genome by using imputation techniques from one of these standard reference panels (Li et al. 2010; Marchini and Howie 2010). Although programs such as MACH provide an assessment of the most likely genotype at each untyped locus, their use in association analysis would fail to account for the uncertainty in these imputations, essentially a form of measurement error leading to biased tests. A more appropriate procedure is therefore to use the estimated genotype probabilities or (under an additive model) the expected "gene dosage" as a continuous variable in a logistic regression analysis (Hu and Lin 2010).

Reporting. Given the potential range of problems and the approaches different investigators might take to addressing them, there is a need for some systematic guidance for how GWAS should be reported, if only to avoid subsequent problems in synthesizing the literature. Several authoritative statements have been issued by various groups to address this need, without imposing a straightjacket that would stifle investigators' creativity (Ehm et al. 2005; Chanock et al. 2007; Ioannidis et al. 2008; Hudson and Cooper 2009; Khoury et al. 2009; Little et al. 2009).

GWAS Summary. Over roughly the last 5 years, a consensus has emerged that most of the discovered novel associations of common, complex disorders with common SNPs have been relatively weak, with odds ratios typically in the range of about 1.2–1.6. Furthermore, even in the aggregate, these associations account for only a small portion of the total heritability estimated from classical twin or family studies (McCarthy and Hirschhorn 2008). While it is possible that these heritability estimates may be somewhat biased, it is certain that there remains a large portion of undiscovered genetic variation ("dark matter") to be accounted for (Hindorff et al. 2009; Manolio et al. 2009). Even for such a strongly related genetic and well-measured quantitative trait as height, the 180 loci that have so far been discovered based on meta-analysis of studies totaling over 183,000 individuals account for only about 10% of the total variability. Furthermore, it has been estimated that even with astronomical sample sizes, the number of loci of comparable effect sizes might rise to 600 but would still account for only about 20% of the heritability, which has been estimated at greater than 80% of the total phenotypic variation (Lango Allen et al. 2010). A variety of hypotheses have been advanced to account for this unexplained heritability, including rare variants, copy number variants, gene-environment and gene-gene interactions, and epigenetic effects, which will feature prominently as we move into the "post-GWAS" era.

38.7.2 Post-GWAS

Meta-analysis. Given the small effect sizes being sought and the enormous multiple comparisons penalty, most successful GWASs have required thousands of subjects. Nevertheless, as the experience with height demonstrates, no one study is likely to uncover more than a small fraction of the loci involved in a complex trait, and even larger sample sizes will be needed. Hence, the field has moved into a "Big Science" era, in which many investigators studying a given trait have formed consortia to pool all the available data for analyses of tens or hundreds of thousands of subjects (de Bakker et al. 2008; Zeggini and Ioannidis 2009). Some of these consortia have functioned simply to meet the replication requirement for each other's discoveries, but the more important purpose is to try to identify additional and weaker associations through a much larger sample size. This could in principle be accomplished by either a reanalysis of their combined raw data ("mega-analysis") or by meta-analysis of their summary statistics (Lin and Zeng 2010). In practice, the latter is usually much easier to accomplish, particularly if the different studies have used different genotyping platforms but can effectively impute genotypes for a larger, common set of HapMap SNPs (Zaitlen and Eskin 2010).

Fine mapping. Having identified one or more genome-wide significant and replicated regions, one might proceed to try to localize the region where a causal variant or variants might lie before attempting deep sequencing or functional studies. Here, the obvious strategy is simply to retest the available samples (or better, additional samples) with a higher density of markers in the region(s) of interest, but there are obvious trade-offs between sample size, number of regions that can be fine-mapped, region sizes, and density of markers (or criteria for selecting specific markers). These issues are amenable to methodological research, but there does not seem to be any generally agreed guidelines as of this writing. Given the speed the field is moving and the rapidly dropping costs of sequencing, many groups have decided to proceed directly to sequencing, bypassing the intermediate step of fine mapping.

Interactions and pathway analyses. Following an initial scan for main effects of SNPs (in either a single study or meta-analysis of several), much more remains to be explored. One possibility is that there could be larger gene-environment or gene-gene interaction effects that do not produce significant marginal effects. The obvious problem is that the number of possible interactions can be very much larger than the number of main effects: For a GWAS of one million SNPs, for example, there are half a trillion possible pairwise interactions. A simple Bonferroni correction for multiple comparisons would thus require a significance level of 1×10^{-13}, and of course, interaction tests would require much larger sample sizes than main effects even at the same significance level (Marchini et al. 2005). Power can be enhanced by "case-only" analyses based on an assumption of independence of the interacting factors in the source population. For example, a reanalysis of cleft palate data obtained substantially narrower confidence limits on the interaction between smoking and the *TGFα* gene (odds ratio $(OR) = 5.14$, 95% confidence interval $(\mathrm{CI}) = (1.68,15.7)$ for the case-only analysis compared with $OR = 6.57$, 95% $\mathrm{CI} = (1.72,20.0)$ for the case-control analysis), equivalent to a 30% reduction in sample size required for the same precision (Umbach and Weinberg 1997). Case-only analyses are, however, biased if this assumption is violated, as might arise due to LD among nearby pairs of loci, population stratification, or behavioral factors that induce an association between genes and environmental factors. To overcome these difficulty, various staged or hybrid approaches have been introduced (Evans et al. 2006; Kooperberg and Leblanc 2008; Mukherjee and Chatterjee 2008; Li and Conti 2009; Murcray et al. 2011). Although power will still be much lower than for main effects, these various methods generally yield much better power than a simple exhaustive search (Cornelis et al. 2012; Mukherjee et al. 2012). To make systematic study of gene-environment interactions of adequate sample sizes possible in the future, it is essential that investigators planning new GWAS design their studies to have appropriate environmental measurements and appropriate population-based sampling schemes. For example, the recent US National Institutes of Health (NIH) "post-GWAS" initiative aimed at synthesizing all the available data on five cancer sites, replicating findings, and characterizing genetic risks and their modification by environmental exposures has been limited by the fact that many of the available studies have not collected any environmental exposure data, and if collected, the choice of measurements was highly variable and ranged from very crude to very detailed assessment.

Another possibility is that there could be many SNPs that individually fail to be genome-wide significant but that jointly contribute to a common pathway. A variety of methods have been developed for identifying subsets of genes in known pathways that collectively are overrepresented among the top GWAS associations. Of these, the technique of Gene Set Enrichment Analysis (Wang et al. 2010), originally developed for gene expression data, has been most widely used. Hierarchical Bayes methods provide a more flexible regression-based approach to incorporate external knowledge about genomic, pathway, or functional annotation into the analysis of GWAS data (Lewinger et al. 2007). Cantor et al. (2010) provide an extensive review of these and other approaches to prioritizing GWAS associations for further investigation. Key to all these methods is the extent and quality of external databases such as the Kyoto Encyclopedia of Genes and Genomes and the Gene Ontology, which can be used for annotation in a systematic manner (Thomas et al. 2007). It is an interesting phenomenon that, after the failure of most candidate gene studies to yield replicable findings, the enthusiasm for the "agnostic" GWAS approach is now drifting back toward a synthesis of pathway-based and agnostic reasoning!

Functional studies. A somewhat unexpected finding from many GWAS is how few of the discovered associations lie in coding regions of genes (Hindorff et al. 2009). While some of the SNP associations could reflect LD with nearby coding variants that have not yet been discovered, it seems more likely that the majority will reflect variants in promoter regions of genes or long-range enhancers. Molecular techniques for functional characterization of causal associations will depend on the nature of the postulated effect, a topic which is beyond the scope of this article; for a recent set of recommendations, see Freedman et al. (2011). Nevertheless, there is a growing interest in "integrative genomics" approaches that can combine information across different types of data, such as SNPs, mutations in tumor tissues, transcriptomics, methylomics, metabolomics, and proteomics (Schadt et al. 2005; Hawkins et al. 2010).

38.7.3 Targeted, Whole-Exome, and Whole-Genome Sequencing

GWASs are based on an underlying "common disease, common variant" hypothesis (Reich and Lander 2001), which postulates that complex diseases are caused, at least in part, by common variants that can be effectively tagged by other SNPs in the region. The SNP panels used in most GWAS, based on one million or fewer SNPs, indeed are generally effective at tagging most "common" variants (conventionally defined as those with minor allele frequencies (MAF) of at least 5%). Newer generations of 2.5–5 million SNP panels will enhance the coverage of "uncommon" variants (those in the range of 1–5% MAF), but even these are not expected to provide good coverage of "rare" variants (less than 1% MAF). To discover these, direct sequencing will be necessary. The advent of several different massively parallel and fast "next-generation sequencing" (NGS) technologies (Davey et al. 2011) has now made this cost-effective, at least for targeted regions such as those around selected GWAS hits or the whole-exome. At the time of this writing, costs are typically around $1,000 per sample for whole exome sequencing and $5,000 for the whole genome, but the "$1,000 genome" (Mardis 2006) is anticipated in the near future. However, the data management and data analysis challenges are formidable. In addition to the storage problems of terabytes of raw data produced for even a single subject (petabytes for a typical study), NGS does not directly yield genotype calls but rather a random set of short sequence reads that must be aligned to cover the region of interest. The number of reads at any specific location is thus randomly distributed (with a mean given by the average depth of coverage), so the genotype can only be inferred probabilistically, taking into account possible errors in the reads themselves. Thus, in addition to the trade-offs mentioned earlier about region size and sample size, a further dimension to the design challenge is the necessary depth of sequencing, subject to a constraint on total cost (Sampson et al. 2011). The optimal design will depend upon the purpose – whether for discovery of rare variants or for testing association. One promising option is to perform the sequencing on pooled DNA samples (Futschik and Schlotterer 2010), which can considerably reduce costs, but this adds complexity to the optimization of the numbers of subjects and numbers of pools.

Multiple Rare Variant Analyses. One of the first analytical issues that arises concerns testing of association with rare variants. For feasible sample sizes, it is virtually impossible to test association with any single rare variant, both because of their rarity and the massive multiple comparisons penalty – for a typical whole-genome sequencing study, for example, one might expect to discover on the order of 20 million variants, most appearing only a few times. Interest has therefore tended to shift to tests of the "multiple rare variants" hypothesis (Price et al. 2010). The most commonly used technique is some form of "burden" test, which simply compares the total number of rare variants at a particular locus carried by cases and controls, possibly weighted in some fashion by their frequency or other characteristics (see Basu and Pan (2011) for a comparison of the available methods), but hierarchical Bayes methods that take account of model uncertainty offer a flexible and attractive alternative (Quintana et al. 2011).

Study designs for assessing causality. Most GWASs have used a case-control design with unrelated subjects for greatest statistical power. However, family-based designs offer two important advantages for studying rare variants. First, the sample can be enriched for rare variants by targeting cases with a strong family history. But more important is that looking at the pattern of cosegregation of variants with disease within families offers great potential for distinguishing causal variants from private polymorphisms that are simply circulating in the family but have nothing to do with the disease (Zhu et al. 2010; Shi and Rao 2011). This is essentially a form of linkage analysis, which has long been recognized as the design of choice for mapping rare major genes.

38.7.4 Risk Models and Translational Significance

Finally, as the number of genetic associations grows, it is natural to ask whether they can be used for genetic risk prediction. For genetic risk prediction, the purpose for the test must be distinguished, for example, a screening test for the general population or a high-risk population or a confirmation or exclusion test for a particular mutation for a particular family member of a disease-enriched family.

For major genes, segregation models as described above, using available genetic and non-genetic information and possibly indirect LD measures, can be used for prediction. For screening in populations, clearly a single SNP with relative risk less than 1.5 has very little value, but in the aggregate, one might consider a risk index based on all the known variants. For prostate cancer, for example, there are now more than 50 known GWAS associations, and a substantial portion of the population will carry several of these variants. Unfortunately, attempts to do this so far have not been particularly encouraging (Jostins and Barrett 2011; MacInnis et al. 2011; So et al. 2011; Newcombe et al. 2012). For prostate cancer in African-Americans, Haiman et al. (2011) reported a twofold gradient in predicted risk across quartiles of risk using 40 GWAS SNPs and 3.5-fold using only the 27 that were significantly associated among African-Americans, but the latter comparison may be subject to some overfitting. A clinically useful screening test should have both high sensitivity and high specificity (Kraft and Hunter 2009; Kraft et al. 2009; Janssens et al. 2011). Since both depend on where one draws the line between "normal" and "elevated" risk, a widely used measure of the overall performance of a screening test is the Area Under the Receiver Operating Curve (AUC) (Sanderson et al. 2005; Zou et al. 2007), obtained by plotting sensitivity against one minus specificity across the range of possible cut-points of the index (here, the predicted genetic risk score). For breast and prostate cancer, Machiela et al. (2011) found AUCs of 0.53 and 0.57, respectively, compared with 0.50 for an index that was no better than chance. Clinically useful risk indices would require an AUC of the order of 0.80 or better. For Crohn's disease, this appears attainable (Pharoah et al. 2002), but not at this point for most cancers (Chatterjee et al. 2011). Perhaps a more important question is what is the additional predictive value of genetic test results on top of established risk factors, including family history (Pencina et al. 2008; So et al. 2011). With the proliferation of direct-to-consumer genetic testing kits, some based on rather flimsy scientific evidence or with somewhat misleading advice about possible lifestyle changes to improve their risks, this question becomes of immediate translational significance (Hudson et al. 2007; Kaye 2008). See Levy et al. (2007) for a discussion of the scientific and ethical significance of the publication of the first complete human genome sequence. (The United States Genetic Information Non-discrimination Act (May 5, 2008) and a similar law in Germany (Gendiagnostikgesetz vom 31. Juli 2009 (BGBl. I S. 2529, 3672)) were enacted to protect individuals from discrimination based on genetic test results.) Although genetic risk prediction for the general population may still be some ways off, there is potentially greater utility in predicting genetic variation in response to treatments because these effects are likely to be much stronger due to the lack of time for evolution to eliminate deleterious variants, considering the recentness of most drug exposures (Altshuler et al. 2008).

38.8 Conclusions

The field of genetic epidemiology is in the midst of a fundamental paradigm shift. Originally based on methods for describing familial aggregation, testing for the existence of a genetic basis (segregation analysis), and localizing genetic causes (linkage analysis), the mainstay has become testing association with directly measured genotypes. A decade ago, this was feasible only for a modest number of variants in candidate genes, an approach that is now widely viewed as not having been particularly rewarding because of our lack of success in picking good candidates. With the advent of high-density genotyping platforms, agnostic scans for common variants across the entire genome have become popular and have led to many unexpected discoveries, albeit generally with rather small effect sizes that even in the aggregate account for only a modest proportion of the total estimated heritability of most complex diseases. These data are now being mined with sophisticated algorithms in the hope of identifying novel pathways across many of the suggestive, if not genome-wide significant, associations. Future directions are aimed at trying to identify the cause of the remaining unexplained heritability by targeted, whole-exome, or (soon) whole-genome sequencing – technologies that will pose formidable statistical and computational challenges – and by understanding the biological basis of the observed associations through regulatory, epigenetic, or other mechanisms.

39.1 Introduction

A directed acyclic graph (DAG) can be thought of as a kind of flowchart that visualizes a whole causal etiological network, linking causes and effects. In epidemiology, the terms causal graph, causal diagram, and DAG are used as synonyms (Greenland et al. 1999). DAGs are considered to be of use for embedding causality in a formal causal framework (Hernán and Robins 2006; Robins 2001; Hernán et al. 2004). In probability theory, there is a somewhat different understanding of DAGs, which we will discuss later. This chapter aims to demonstrate how DAGs can help to formalize the search for answers to different research questions in epidemiology.

In the first section of this chapter, we review the application of DAGs in epidemiology. Data collected in the framework of observational epidemiological studies are usually insufficient in one way or another, for example, due to missing information, misclassification, or due to some other form of bias (see chapter ▸Basic Concepts of this handbook). Even when there is little doubt that an association found in observational epidemiological studies represents a true causal mechanism, such as in the case of smoking and lung cancer, information obtained may be biased, leading to a biased estimate of the strength of the association under study. A DAG is useful to determine confounding factors that bias the association between a risk factor and disease.

The second section of this chapter deals with probabilistic DAGs in the framework of Bayesian networks. Bayesian networks are graphical representations of a probability distribution over a set of variables. They are useful to identify the association structures among all variables under investigation and to visualize conditional relationships among these variables. Bayesian networks are appropriate in situations where we deal with complex or unknown association structures. Their key concept is to identify conditional independencies, where the study variables are symbolized as vertices in a DAG and edges between them reflect associations. That means, if two vertices are unconnected in the DAG, the corresponding variables in the probability model are conditionally independent given the remaining variables. We will introduce the probability theory behind Bayesian networks as well as data-driven inference to estimate the unknown parameters of the underlying statistical model. We also deal with model selection to search for the DAGs that best reflect the pattern of the data at hand. In the final sections, we discuss advantages and limitations of the DAG concept and give an outlook.

39.2 Causal Graphs: Concepts

Causal graphs associate events with other events. Causes necessarily precede their effects, and this temporal relation is part of the definition of a cause. Causal graphs provide a supportive approach to visualize causal links between exposures and outcomes in epidemiological research. Formal rules are used to develop the graphs and to derive appropriate analytical approaches. The theoretical framework for using DAGs in epidemiology has been developed only recently, motivating health scientists to work with DAGs in planning their investigations and analyzing their data. DAGs and probability theory can be incorporated into Bayesian networks to be applied to real data problems. Pearl (2009) specified the threefold role of graphs in probabilistic and statistical modeling as follows:

1. To provide convenient means of expressing assumptions
2. To facilitate economical representation of joint probability functions
3. To facilitate efficient inferences from observations

Causal graphs move away from purely mathematical language to an alternative way of communicating, understanding, and evaluating causality in empirical sciences.

As pointed out by Greenland et al. (1999), the theory of DAGs offers the benefit of compact graphical as well as probabilistic representations of assumptions, for example, about confounding, in epidemiological studies. In addition, the evaluation of confounding especially in the presence of multiple potential confounders is aided through a graphical approach when traditional textbook criteria of confounding fall short. Graph theory can help to identify the set of confounders for which adjustment is required, whereas other potential confounders can be discarded according to the DAG. Causal graphs should be understood as tools rather than as independent novel concepts. They help to clarify network structures and enforce thinking about the relationships between variables which may otherwise remain vague or totally omitted. For non-mathematicians, causal graphs provide an opportunity to derive conclusions from a diagram developed through the application of a set of formal rules (Glymour 2006).

39.2.1 History and Development

Causal graphs were first used almost a 100 years ago in the field of genetics and later in the social sciences, econometrics, physics, and many other areas. Graphs usually represent deterministic functional relationships between cause and effect, where probabilistic elements indicate unobserved variables in the equation. Linking a probabilistic perspective with the aim to deduce deterministic causal relationships from empirical data was at the core of developments in the field of causal graphs towards the end of the last century. A formal framework of the causal graph concept was first developed in the early 1990s, later published in a book by Spirtes et al. (2001). The underlying mathematical theory is that of Bayesian networks (see Sect. 39.3), which represent probabilistic assumptions about the associations between different components of the network. The rapid emergence of artificial intelligence systems since the 1980s was a major input to the development of Bayesian network theory. These systems allow for the efficient ordering and interpretation of new observations, searching for associations while accounting, both, for prior information and the new set of observations in a coherent way (Pearl 2009). This is not possible without advanced computer technology, as the amount of data, for example, in medical research, climate sciences, but also in the framework of epidemiological studies, grows rapidly.

39.2.2 DAGs and Other Methods of Causal Modeling

A prominent causal model in epidemiology is the sufficient-component cause model by Kenneth Rothman (see chapter ▶Basic Concepts of this handbook; Rothman 1976; Rothman et al. 2008). This model uses pie charts to represent causes, with the different pieces of the pie standing for component parts of the overall cause. Once the causal mechanism is deemed to be complete in the sense that the minimal set of conditions and events that lead to the effect are present, a cause is described as sufficient. All the components of the cause are required for the effect to occur. If a specific component needs to be always present in the set of component causes because the effect never occurs without it, this component is called necessary. The component approach is easily reconcilable with the common understanding of multifactorial diseases in modern medicine. While conceptually helpful to understand causation, the specification of sufficient-component cause models in defined situations requires in-depth knowledge of biological mechanisms or other information that are often not available (Greenland and Brumback 2002). Causal graphs as well as the sufficient-component cause model have their strength in a qualitative description of causal relations. Two other causal modeling approaches also build on aspects of qualitative description of causal relations but provide quantification of specific exposure-disease relations. These are the counterfactual (or potential outcomes) models (see Rothman et al. (2008) for more details) and structural equation models (Greenland and Brumback 2002).

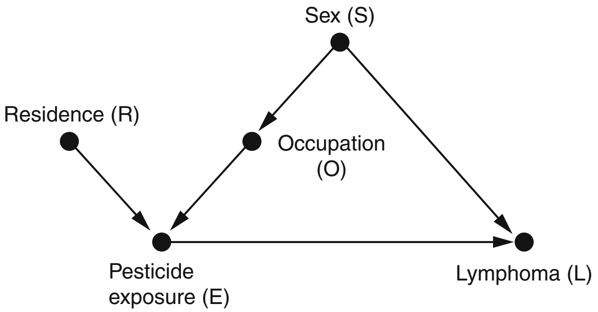
Within the realm of counterfactual models (Rubin 1974), g-estimation (Robins et al. 1992) and marginal structural modeling (Robins et al. 2000) are more recent developments. Structural equation modeling has a long tradition in the social sciences (Pearl 2009). One logical link between the different models is given through their focus on alternatives or contrasts in the representation, either graphical or probabilistic, of causal structures between exposures (or interventions) and outcomes.

39.2.3 DAGs in Practice: Some Introductory Notations

Directed acyclic graphs are directed in that they symbolize the associations between different components of a supposed causal network through arrows pointing from a cause to its effect. They are acyclic since no path of directed arrows is allowed to form a closed loop. There are other versions of graphs that employ undirected graphs and cyclical associations, but these are not of interest here since the investigation of causality implies direction from cause to effect (see Greenland et al. 1999). The principles of DAGs are illustrated by the following example which we will revisit throughout this chapter.

Example 39.1a.
Suppose we want to investigate the association between pesticides and the occurrence of lymphoma in adults employed in various industrial plants, with the underlying hypothesis that pesticide exposure increases the risk of lymphoma. In a graph, a line with an arrowhead

Fig. 39.1 DAG of the lymphoma example



pointing from *pesticide* (exposure) to *lymphoma* (outcome) symbolizes this situation. Further, we assume that *sex* affects exposure probability only through *occupation*, while *sex* is directly related to *lymphoma* risk as the outcome. *Residence* also affects *pesticide exposure* probability. Figure 39.1 gives the full picture for this simple situation and is used to introduce first definitions and concepts, which will be referred to later.

In explaining the notations used for constructing the graph, we refer to the basic paper by Greenland et al. (1999). A line connecting two variables in a causal diagram is called an arc or edge. Adjacent variables are those in direct neighborhood to each other, connected by an edge. A (causal) directed association is indicated by a single-headed arrow, pointing from cause to effect.

Example 39.1b.
In Fig. 39.1, the line linking *pesticide exposure* (E) and *lymphoma* (L) corresponds to an arrow, indicating in this example the assumption that pesticide exposure causes lymphoma, which in epidemiology translates to "modifies the risk of lymphoma," given the absence of bias and confounding.

Arrows, arcs, or edges end up in nodes or vertices, which are the points in the graph representing the variables considered, as, for example, *residence* (R), *pesticide exposure* (E), *occupation* (O), *sex* (S), and *lymphoma* (L) in our example. A directed path is a line made up of arrows all pointing in one direction and connecting adjacent vertices, for example, the path from R to L passing through E. When a path leads through a vertex, this vertex intercepts the path. A succession of edges that simply connect adjacent vertices, regardless of their direction, is simply called path – it is not directed. Ancestors or causes E and S of the variable L are those vertices on a directed path that leads into L. Conversely, L is named descendant of E and S. Looking only at two adjacent vertices, E is called a parent of L (child) if an arrow originates in E and leads to L.

A more general notation for DAGs denotes X as exposure, Y as outcome, and $Z_1, \ldots, Z_K$ as measured covariates. This will be used in Sect. 39.2.6 where the essential steps for the construction and interpretation of graphs are outlined.

39.2.4 DAGs and Confounding

An exposure-outcome association can be confounded by a third factor if this factor independently causes the outcome and is associated with the exposure under study. Failure to adjust for such confounding factors may lead to bias (see chapter ▸Confounding and Interaction of this handbook). Factors that are intermediate steps on the assumed causal path between exposure and outcome should, however, not be adjusted for. There are also situations, as initially pointed out by Weinberg (1993), where a factor that changes the exposure-outcome association and thus appears to be a confounder should not be adjusted for as this would actually introduce bias in the risk measures. This may be the case if this third factor is itself partly caused by the exposure. Furthermore, in specific situations, adjustment for a confounding factor may in turn introduce confounding by another factor previously not regarded as confounder of the exposure-outcome association under study.

DAGs help to graphically describe such situations and call for explicit consideration of the factors to be included (or not) in analyses of epidemiological studies. DAGs can therefore be applied as tools to identify variables that have to be adjusted for in order to attain an – ideally – unbiased estimate of the association between an exposure and an outcome.

39.2.5 Constructing a DAG to Identify and Control for Confounding

Before starting to build a DAG, one needs to assess which variables might be important for answering the research question. The choice of potentially relevant variables, for example, to explain the etiology of a disease, is based on one or several of the following considerations:

- Subjective assumptions, common sense
- Other studies, previous research
- Other information (e.g., theoretical considerations, expert opinions)

A DAG provides a formal way to organize the covariates based on the best possible assumption about the causal structure of these variables. The DAG leads to one (or several) so-called "minimally sufficient adjustment set" of covariates to be adjusted for in order to obtain an unconfounded estimation of the association. The following introduction to the rules for constructing a DAG is based on Glymour and Greenland (2008), Greenland et al. (1999), Hernán et al. (2002), and Glymour (2006).

39.2.6 Formal Rules for Constructing a DAG

As mentioned before, each arrow in a directed acyclic graph has only one arrow head and each arrow points from one variable to another variable, without closed loops. If there is an unmeasured (latent) variable that might influence the causal association between exposure and outcome, it has to be represented in the DAG as an unmeasured covariate. In most epidemiological studies, weak associations are unlikely to introduce major bias. Thus, the influence of these variables on the causal pathway is probably negligible, and therefore, omission of these variables from the DAG is recommended. The following notations are used to construct a DAG in order to identify confounders that have to be controlled for:

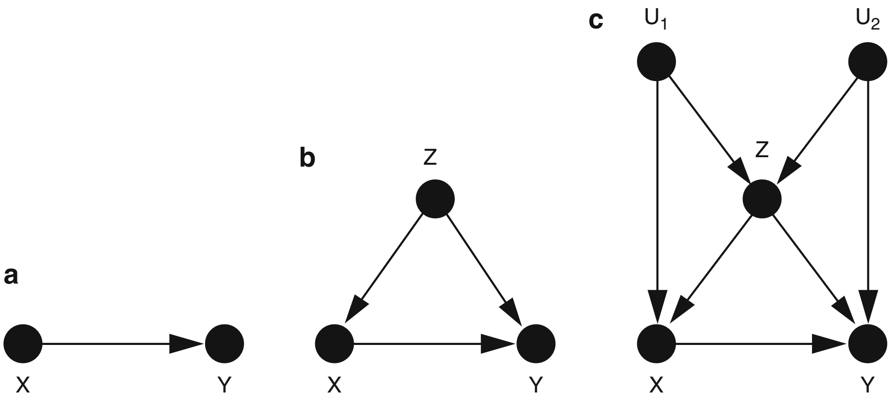


Fig. 39.2 (**a**) Exposure-outcome relationship (Step 1); (**b**) add measured covariates (Step 2); (**c**) add unmeasured covariates. X: *first delivery at older age* (exposure); Y: *breast cancer* (outcome); Z: *family history* (measured covariate); U_1: *SES* (unmeasured covariate); U_2: *BRCA I/II* (unmeasured covariate) (Step 3)

- Exposure: X
- Outcome: Y
- Measured covariates: $Z_1, Z_2, \ldots, Z_K$
- Unmeasured covariates: $U_1, U_2, \ldots, U_L$

Every covariate is a variable and not the manifestation of a variable, e.g., sex (male/female) and not male. For every association, a directed arrow is drawn.

Example 39.2.
We will explain the construction of a DAG step by step using a hypothetical study of the association between the dichotomous variable *first delivery at older age* (X) and risk for *breast cancer* (Y).

1. **Draw exposure and outcome:** In the first step the exposure-outcome relationship is constructed (see Fig. 39.2a). Remember that,
   - Each vertex is a variable
   - The graph must be directed
   - The graph must be acyclic.

   In Fig. 39.2a the exposure X is *first delivery at older age* pointing to the outcome Y, which is *breast cancer.*
2. **Include measured covariates** *Family history* of breast cancer (Z) is a measured covariate which might influence (i) *first delivery at older age* (i.e., women with a family history of breast cancer might become pregnant at a younger age) and (ii) the risk of *breast cancer* (see Fig. 39.2b).
3. **Include unmeasured covariates** In our example, *socioeconomic status* (SES) and *breast cancer early onset gene type I or II* (*BRCA I/II*) are unmeasured covariates (U_1, U_2, respectively). *SES* is associated with *first delivery at older age* and might be associated with *family history* due to a higher proportion of women who were screened for a family history in higher SES groups or due to another reproductive behavior in higher SES groups, while *BRCA I/II* is associated with *family history* and *breast cancer* (see Fig. 39.2c).
4. **Prepare a list of all covariates affected by the exposure** In this step all children of X are listed. Children are those vertices where the arrow from X is heading to. In this

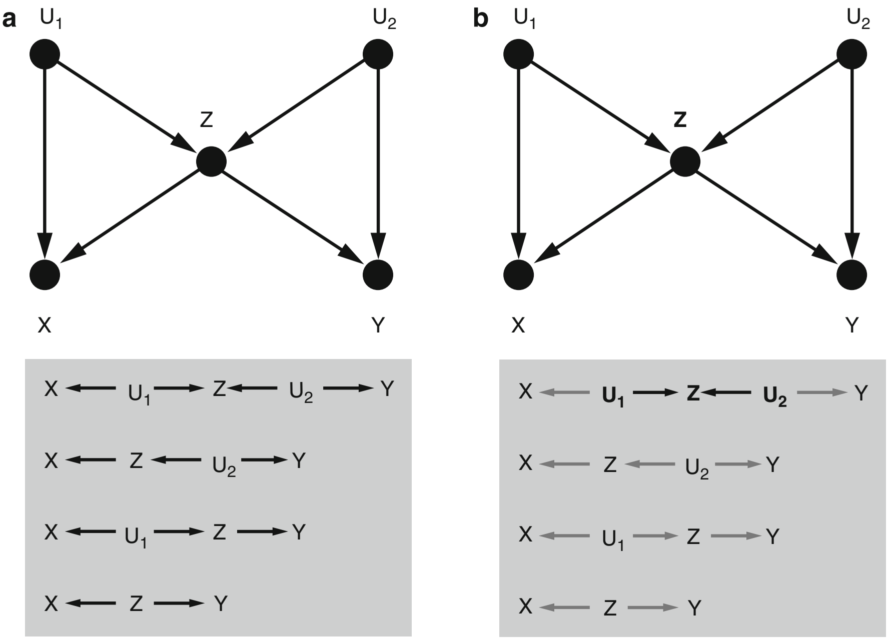

Fig. 39.3 (**a**) A list of backdoor paths after eliminating the exposure-outcome relation (Steps 4 and 5); (**b**) finding colliders (Step 6)

example, there is only one arrow originating in X: $X \rightarrow Y$. Eliminate this arrow to remove (for now) all assumed direct exposure effects (see Fig. 39.3a).

5. **Find all backdoor paths** For this purpose, arrow directions are not considered. Confounding is present if exposure and outcome are still connected after the elimination of all direct exposure effects. In this example, four pathways from X to Y exist after elimination of the direct exposure effects. These open pathways from X to Y are called backdoor paths (see Fig. 39.3a).
6. **Disregard the backdoor paths already blocked by a collider** Colliders are "collisions" of two paths, identifiable by covariates that have two arrows pointing towards them. Z is a collider in the example, because U_1 and U_2 point to Z (see Fig. 39.3b). Backdoor paths containing a collider are blocked because the pathway ends in the collider (here Z) and not in the outcome Y, and thus this backdoor path can be erased. In our example the first backdoor path $X \leftarrow U_1 \rightarrow Z \leftarrow U_2 \rightarrow Y$ can be deleted.
7. **Identify sufficient adjustment sets** List all unblocked, open backdoor paths and find a set of covariates that would block all still existing open backdoor paths by adjusting for this set. In our example the minimal sufficient adjustment set (MSAS) would include only Z. Adjusting for Z would block all open backdoor paths (see Fig. 39.4).
8. **Looking for associations induced by adjustment (or stratification)** Adjusting for the covariates that were identified as a MSAS might introduce new associations between covariates that have not been present before adjustment. In our example, no association between U_1 (*SES*) and U_2 (*BRCA I/II*) was existing prior to adjustment. However, adjusting for Z (*family history*) introduces an association between these two covariates, for example, a higher risk for carrying *BRCA I/II* among persons with a high *SES*. This phenomenon of an induced spurious association was first described by Berkson (1946).

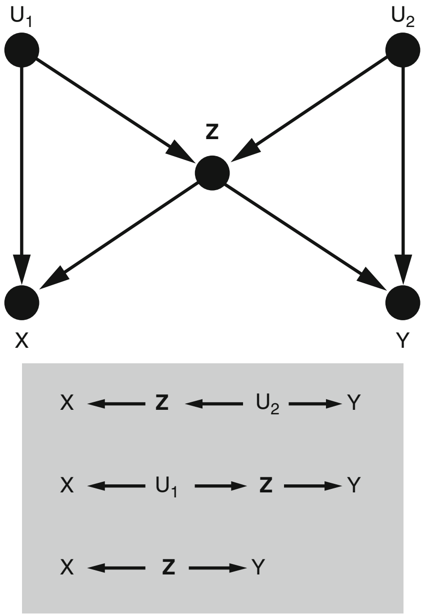

Fig. 39.4 Find potentially sufficient adjustment sets (Step 7)

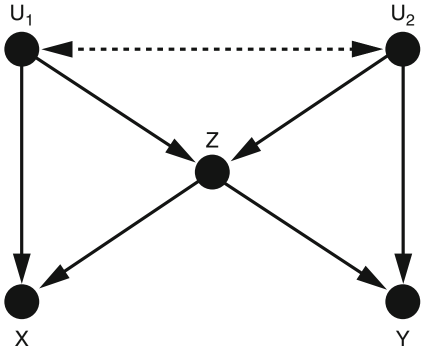

Fig. 39.5 Induced associations are expressed as a *dotted line* with *doubly headed arrow*, here between U_1 and U_2. The two minimal sufficient adjustment sets are $\{U_1, Z\}$ and $\{U_2, Z\}$ (Step 8)

The newly induced association is drawn as a dashed arrow with two heads while introduces a new, unblocked backdoor path (see Fig. 39.5).

9. **Repeat Steps 5–7 and find a new minimal sufficient adjustment set, preferably composed of measured covariates.** In our example, the final minimal sufficient adjustment sets are $\{U_1, Z\}$ or $\{U_2, Z\}$. Adjusting for U_1 and Z or U_2 and Z results in a situation in which the association between X and Y is not confounded by Z, U_1 or U_2.

The DAG does not allow to assess the quality or strength of the influence of a confounder; it only allows to state whether a covariate is a confounder or not. Drawing a DAG might, as in our example, end with the uncomfortable situation that in the minimal sufficient adjustment set, an unmeasured covariate is included. Inclusion of this covariate in statistical analyses is not possible. Generally, MSAS that include unmeasured covariates do not allow to correctly estimate the association between exposure and outcome.

DAGs help to determine whether a set of measured variables is sufficient for analyzing the association under study, for example, for identifying the causal effect of first delivery at older age on breast cancer risk. When there are confounding paths between exposure and outcome, it may be possible to close these paths by adjusting for other variables.

In practice, there may be several distinct sufficient sets and even several distinct minimal sufficient sets for controlling confounding. Researchers may sometimes wish to adjust for more variables than necessary. Identifying an MSAS can be valuable, because adjusting for more variables than needed implies the risk of introducing confounding and reducing precision. In addition, measuring unnecessary variables can be difficult and expensive.

Although the MSAS can quickly be identified by paper and pencil for small graphs, it can be a laborious task for complex graphs. Computer programs may help to identify the appropriate adjustment sets. `DAGitty` (Textor et al. 2011; Textor 2012) is an easy-to-use browser-based program; the `DAG` program (Knüppel and Stang 2010; Knüppel 2011) works with input and output files but cannot visualize the DAG; the `R` package `dagR` (Breitling 2010) provides a set of `R` functions to find the MSAS, however, also without graphical visualization.

39.3 Probabilistic DAGs and Bayesian Networks

In the previous sections, we introduced DAGs as a visual tool to identify a minimal sufficient adjustment set of factors that might bias the association in order to assess causal relationships. In this section, we consider probabilistic DAGs that describe probability statements and associations between random variables but without claiming to infer causality.

The key concept of probabilistic graphs is to interpret graphs in terms of conditional independencies and probabilities. In the following, we will focus on Bayesian networks as probabilistic DAGs in order to perform estimation and model selection. Bayesian networks are probability models to analyze and visualize the usually complex association structure that underlies any multivariate dataset by applying the theorem of Bayes and the concept of conditional independence.

If the so-called Markov properties are fulfilled, and the joint distribution can recursively be factorized into conditional probabilities according to a DAG, it is possible to read conditional independencies off the graph. Since the computation of the joint probability would be intractable in most situations, the factorization helps to simplify computations. Furthermore, the application of graph theory allows to decompose the DAG into smaller subgraphs which again helps to make computations efficient.

Taken together, this tight linkage between probability theory and graphical representation has three advantages (Bishop 2007):

1. A DAG visualizes and defines the structure of a probabilistic model.
2. Conditional independence properties can be read off the graph.
3. Algorithms exploit the graph structure to make inference and model selection in complex graphs possible by breaking down the graph into subgraphs that allow to carry out calculations.

Contrary to the DAGs discussed in the previous sections, probabilistic DAGs do not necessarily require prior knowledge to postulate the DAG. However, they need data for reasoning and decision-making under uncertainty, or when the existence of an edge between two vertices in a DAG has to be estimated. Generally, for interpretation we distinguish the following three purposes of probabilistic networks (Kjærulff and Madsen 2008, p. 18):

1. Deductive reasoning (also referred to as predictive or causal inference) follows the network from the cause to the effect, for example, $P(E \mid O = \text{farmer}, R = \text{rural})$ (see Fig. 39.1).
2. Abductive reasoning (also referred to as diagnostic inference) follows the arrows in reverse order, that is, from the effect to the cause, for example, $P(O \mid E = \text{yes})$.
3. Inter-causal reasoning (also referred to as explaining away) is the ability to make inference on one cause of two independent causes of a known common outcome. This is possible because the outcome is a collider for the two independent causes, which induces an association between the two variables pointing on the collider (see Fig. 39.5). As a result of this induced association, knowing the outcome and having confirmation of one of the causes changes belief in the other cause. This property distinguishes probabilistic networks from other logical systems and is the key feature for making probabilistic networks powerful.

In the next section, we introduce key concepts, formalisms, and some graph terminology, which is required to understand Bayesian networks. Then we discuss how unknown parameters of Bayesian networks and unknown graph structures can be estimated. Beyond this introduction, we recommend the books by Lauritzen (1990), Husmeier (2005), Jensen and Nielsen (2007), Kjærulff and Madsen (2008), Darwiche (2009), and Koller and Friedman (2009) for further reading. Readers who are especially interested in decision-making are referred to the literature on influence diagrams (e.g., Kjærulff and Madsen 2008).

39.3.1 Concepts for Bayesian Networks

For the purpose of a Bayesian network, a directed acyclic graph is defined as follows: A DAG $\mathcal{G}$ is a pair $\mathcal{G} = (V, E)$ with $V = \{1, \ldots, K\}$ the set of distinct vertices and $E \subset (V \times V) \backslash \{(v, u) | v, u \in V, v \neq u\}$ the set of directed edges forming no cycles. Any ordered pair of vertices $(v, u) \in E$ denotes a directed edge and is visualized as arrow $v \rightarrow u$ where v is a parent of u and u is a child of v. The set of all parents and children of a vertex u is given by $pa(u) = \{v \in V | (v, u) \in E\}$ and $ch(u) = \{v \in V | (u, v) \in E\}$, respectively. A directed path of length n from

v_0 to v_n is a sequence of distinct vertices $v_0, \ldots, v_n$ such that $(v_{i-1}, v_i) \in E$ for all $i = 1, \ldots, n$. A directed path is denoted by $v_0 \mapsto v_n$ and a directed cycle is a path of length greater than two and with $v_0 \mapsto v_n$ and $v_n \mapsto v_0$. The vertex u is an ancestor of v and v is descendant of u if there is a directed path $u \mapsto v$. The set $de(u)$ contains all descendants of u and all non-descendants are given as $nd(u) = V \backslash (de(u) \cup \{u\})$. The set of ancestors of u is denoted by $an(u)$ and the ancestral set of u is $An(u) = an(u) \cup \{u\}$. A figure such as $v \mapsto w \mapsfrom u$, where a vertex has unconnected ancestors is called v-structure. For disjoint subsets A, B, S of V, A is separated from B in $\mathcal{G}$ by S if every path between A and B intersects S (see, e.g., Koller and Friedman (2009, p. 35ff.) or Lauritzen (1990, p. 6) for further graph terminology).

Probabilistic DAGs build on the statistical concept of conditional independence and make extensive use of the Bayes' theorem (see chapter ▶Bayesian Methods in Epidemiology of this handbook), also called the chain rule of probability in the context of probabilistic DAGs, where the joint probability of the variables in a DAG is decomposed into products of conditional probability distributions. In the following, let $p(x, y, z)$ denote the probability mass function $P(X = x, Y = y, Z = z)$ in case of discrete random variables and the probability density function if variables are continuous. The chain rule states that the joint probability distribution over a set of variables decomposes into

$$p(x, y, z) = p(z|x, y)p(x, y) = p(z|x, y)p(y|x)p(x).$$

More generally, let us suppose we have K variables. Then the joint probability distribution can be factorized as follows:

$$p(x_1, \ldots, x_K) = \prod_i^K p(x_i|x_{i+1}, \ldots, x_K). \tag{39.1}$$

Example 39.1c.
We assume that *lymphoma* (L), *occupation* (O), and *pesticide exposure* (E) are associated with each other. According to Eq. 39.1, their joint probability distribution can be factorized as

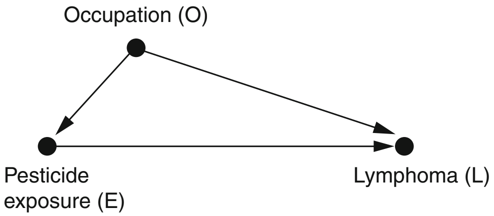
$$p(L, O, E) = p(L|O, E)p(E|O)p(O).$$

The chain rule allows to generate different but interchangeable probability factorizations, as, for example,

$$\begin{aligned} p(L, O, E) &= p(L|O, E)p(O|E)p(E), \\ p(L, O, E) &= p(E|O, L)p(O|L)p(L), \\ &\ldots \end{aligned}$$

Figure 39.6 shows one possibility to construct a DAG representing this joint probability. As we will see later, the DAG in Fig. 39.6 reflects exactly one factorization.

Fig. 39.6 A DAG encoding the joint probability $p(L, O, E)$ between the variables *lymphoma* (L), *occupation* (O), and *pesticide exposure* (E)



The advantage of factorizing the joint probability into a product of conditional probabilities is to make the calculations computationally (more) feasible. A further decomposition is possible if we take advantage of the conditional independencies between the random variables of the random vector $\mathbf{X} = (X_1, \ldots, X_K)'$ (see Box 39.1).

Box 39.1. Conditional independence of random variables

Let X, Y, Z be random variables with joint probability function $p(x, y, z)$. Then X is conditionally independent of Y given Z (written $X \perp\!\!\!\perp Y | Z$) if in the discrete case

$$p(x, y|z) = p(x|z)p(y|z)$$

for all values x, y and for all z such that $p(z) > 0$. If $p(x|z) = p(x)$, $p(z)>0$, then X and Z are marginally independent and we write $X \perp\!\!\!\perp Z$.

The relation $X \perp\!\!\!\perp Y | Z$ means that for every level of Z, Y does not offer any new information to understand X. The conditional independence $X \perp\!\!\!\perp Y | Z$ can also be expressed in slightly different ways as:

$$\begin{aligned} p(x|y, z) &= p(x|z), & p(z) &> 0 \\ p(x, z|y) &= p(x|z)p(z|y), & p(y) > 0, p(z) &> 0. \end{aligned}$$

Example 39.1d.
Suppose in the lymphoma example that we have additional information about the subject's *residence* (R) and we can assume that R is independent from *lymphoma* (L) given information about *occupation* (O) and *pesticide* exposure (E). The joint probability of these four random variables can in general be factorized according to the chain rule as

$$p(L, E, O, R) = p(L|E, O, R)p(E|O, R)p(O|R)p(R)$$

but also as

$$p(L, E, O, R) = p(R|O, E, L)p(O|E, L)p(E|L)p(L).$$

If we make additional use of the conditional independence $R \perp\!\!\!\perp L | \{E, O\}$, the first equation simplifies as follows,

$$p(L, E, O, R) = p(L|E, O)p(E|O, R)p(O|R)p(R).$$

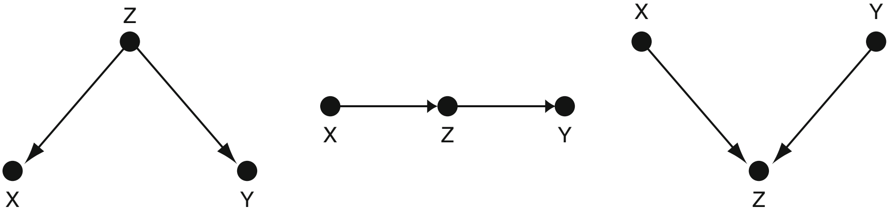


Fig. 39.7 Graphical representation of a fork $(X \perp\!\!\!\perp Y|Z)$, a chain $(X \perp\!\!\!\perp Y|Z)$, and a collider $(X \not\!\perp\!\!\!\perp Y|Z$, but $X \perp\!\!\!\perp Y)$ representing conditional (in)dependence. The fork and the chain represent blocked paths and the collider illustrates an unblocked path

Since conditional independence does not imply any order, it also leads to the following simplification:

$$p(L, E, O, R) = p(R|O, E)p(O|E, L)p(E|L)p(L).$$

These simple rules about factorization and (conditional) independence can be used to reflect (in)dependencies among random variables in a graph as vertices represent random variables, and missing arrows between components of a random vector $\mathbf{X} = (X_1, \ldots, X_K)'$ symbolize (conditional) independencies.

Generally, a conditional independence between three variables X, Y, and Z can be visualized in a DAG in different ways. The fork (see Fig. 39.7) displays a situation where Z regulates X and Y, and hence, X and Y are conditionally independent from each other given Z. The conditional independence $X \perp\!\!\!\perp Y|Z$ can also be represented by a chain in which Z blocks all information flowing from X to Y. In both situations, Z blocks the path between X and Y. If two independent causes X and Y are pointing on a common effect Z, then Z is a collider (see Sect. 39.3.2.2). A collider blocks the path between the marginally independent variables X and Y. However, if we condition on the collider Y, it opens the path and we create an association between X and Y, which implicates the conditional dependence $X \not\!\perp\!\!\!\perp Y|Z$. As Rothman et al. (2008) stated, conditioning on non-colliders closes the path (as the path between X and Y in the chain structure) and conditioning on a collider opens the path (see Sect. 39.2.6).

However, a collider structure also enables to predict values for a parent variable given the knowledge about the other parent and the child. Let us therefore come back to the lymphoma example.

Example 39.1e.
Suppose *occupation* (O) and *residence* (R) are independent causes of *pesticide exposure* (E) as shown in Fig. 39.1. The knowledge about someone working in a chemical plant provides a very good explanation that this person was exposed to pesticides and "explains away" living in a rural region as a possible cause for pesticide exposure. Here, we condition on the collider E, which opens the path between R and O and induces the inequality

$$\begin{aligned} &P(O = \text{chemical industry}|E = \text{yes}, R = \text{rural}) \\ &\qquad\qquad \neq P(O = \text{chemical industry}|E = \text{yes}, R = \text{urban}). \end{aligned}$$

This property is often referred to as "explaining away" effect or "inter-causal inference" (Kjærulff and Madsen 2008). Without conditioning on E, O and R are marginally independent and hence, the information of living in a rural region provides no additional information:

$$P(O = \text{chemical industry}|R = \text{rural}) = P(O = \text{chemical industry}).$$

A further component in the theory of probabilistic DAGs is that the joint probability distribution can be rewritten to combine graph terminology with probability theory by recursively factorizing it as a product of conditional probability distributions (see Box 39.2).

Box 39.2. Recursive factorization

A distribution P allows a recursive factorization according to the structure of a DAG $\mathcal{G} = (V, E)$ if P can be expressed as a product over the local probability distributions of each vertex $v \in V$:

$$p(\mathbf{x}) = \prod_{v \in V} p(x_v|\mathbf{x}_{pa(v)}).$$

Example 39.1f.

The set of parents of the DAGs depicted in Fig. 39.8a are $pa(L) = \{E, O\}, pa(E) = \{O, R\}, pa(O) = \{R\}, pa(R) = \emptyset$ and in Fig. 39.8b $pa(L) = \emptyset, pa(E) = \{L\}, pa(O) = \{E, L\}, pa(R) = \{E, O\}$. Both sets of parents characterize exactly the specific decomposition of their joint probability (see also Example 39.1d). The DAGs illustrated in Fig. 39.8 represent the independence $R \perp\!\!\!\perp L|\{E, O\}$ indicated by the missing edge between R and L. The direction of the arrows between the vertices corresponds to the factorization of the joint density. An arrow points from L to O, that is, $L \rightarrow O$, if $P(L, O)$ factorizes into $P(O|L)P(L)$ and vice versa, that is, $O \rightarrow L$ if $P(L, O) = P(L|O)P(O)$.

So far, we called the link between a DAG and a probability model a probabilistic DAG, whose network structure coincides with a set of conditional probability

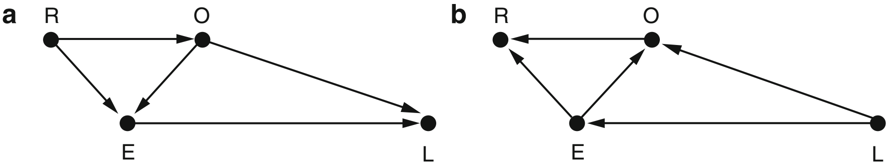

Fig. 39.8 The DAG in (**a**) visualizes the factorization $p(L, E, O, R) = p(L|E, O)p(E|O, R)p(O|R)p(R)$ in contrast to the DAG in (**b**) that represents $p(L, E, O, R) = p(L)p(E|L)p(O|E, L)p(R|O, E)$. Both DAGs encode the conditionally independency $R \perp\!\!\!\perp L|\{E, O\}$

distributions. Since these probabilistic DAGs make use of Bayes' theorem, they are called Bayesian networks (see Box 39.3).

Box 39.3. Bayesian network (cf. Kjærulff and Madsen 2008 p. 65)

A Bayesian network $\mathcal{B} = (\mathbf{X}, \mathcal{G}, P)$ consists of the following:

1. A DAG $\mathcal{G} = (V, E)$ with vertices $V = \{v_1, \ldots, v_K\}$ and directed edges (arrows) E, which describes the dependence structure and implies an ordering of the variables
2. A set of random variables $\mathbf{X} = (X_1, \ldots, X_K)'$, represented by the vertices of $\mathcal{G}$
3. A family of conditional probability distributions P with parameters $\boldsymbol{\theta}$ that admit recursive factorization according to $\mathcal{G}$ where each random variable $X_v \in \mathbf{X}$ is described by one local probability distribution $p(x_v|\mathbf{x}_{pa(v)})$

There are two definitions to assure that the conditional independence statements can be read off the DAG. One of them is the d-separation criterion that is formally defined as in Box 39.4.

Box 39.4. *d*-separation (Pearl 2009, p. 16ff)

A path between v and u is d-separated (or blocked) in a DAG $\mathcal{G} = (V, E)$ by a set of vertices $S \subset V\backslash\{v, u\}$ if and only if at least one of the following conditions hold:

- The path contains a chain $v \mapsto w \mapsto u$ or a fork $v \leftarrow\!\dashv w \mapsto u$ such that $w \in S$, or
- Neither the vertex w nor any descendant of w is an element of S, and w is a collider on the path $v \mapsto w \leftarrow\!\dashv u$.

The sets A and $B \subset V$ are d-separated by $S \subset V\backslash(A \cup B)$ if every path between A and B is blocked by S.

The other definition includes the directed Markov properties (Lauritzen et al. 1990) that require the "moralization" of the graph. The moral graph $\mathcal{G}^m$ is obtained by (i) "marrying," that is, connecting, every pair of non-adjacent parents and then (ii) replacing all arrows with undirected edges. A formal definition of the directed Markov properties is given in Box 39.5.

Box 39.5. Directed Markov properties (Lauritzen 1990, p. 47, 50)

Let $G = (V, E)$ be a DAG and $\mathbf{X} = (X_1, \ldots, X_K)'$ a set of random variables with joint distribution P factorizing recursively according to $\mathcal{G}$ and be $\mathbf{X}_A$ a subvector with components $(X_v, v \in A)$, $A \subset V$. P obeys:

- The *local directed Markov property* if for any vertex $v \in V$

$$X_v \perp\!\!\!\perp \mathbf{X}_{nd(v)\setminus pa(v)} | \mathbf{X}_{pa(v)}$$

- The *global directed Markov property* if for any disjoint sets $A, B, S \subset V$

$$\mathbf{X}_A \perp\!\!\!\perp \mathbf{X}_B | \mathbf{X}_S$$

whenever A and B are separated by S in the moral graph $(\mathcal{G}_{An(A \cup B \cup S)})^m$ induced by the smallest ancestral set containing $A \cup B \cup S$

The local and global directed Markov properties are equivalent under the above assumptions.

The d-separation and the directed Markov properties assure that if the joint probability distributions factorize according to the DAG $\mathcal{G}$, then the DAG represents the independence properties of this distribution.

Example 39.1g.
Suppose we want to know whether *residence* (R) and *sex* (S) are conditionally independent given *pesticide exposure* (E) illustrated by the lymphoma DAG in Fig. 39.9a. If we want to read independencies out of the graph, we can apply the global directed Markov property, which requires the moralization of the graph. In the first step, we have to build the DAG that is induced by the ancestral set of R, S, and E, which additionally includes *occupation* (O) as ancestor of E but not *lymphoma* (L), because L is no ancestor of E, R, and S. In the moral graph $(\mathcal{G}_{An(R \cup E \cup S)})^m$ a new edge is needed between *residence* and *occupation* (they have to be "married"), because conditioning on E opens the path between *residence* and *sex* and expresses *residence* and *occupation* as dependent $(R \not\perp\!\!\!\perp S|E)$. It follows that *occupation* has to be additionally included in the separating set modifying the independent statement into $R \perp\!\!\!\perp S|\{E, O\}$. Note that in this example, the subsets R, E, and S contain only one vertex each. However, the concept can be also applied to sets including several vertices. The local directed Markov property gives us the independencies for a specific variable. Suppose we are interested in all independencies regarding *residence*. Applying the above definition, we have to build the set of non-descendants of R without its parents $nd(R)\setminus pa(R) = \{S, O\}\setminus\emptyset = \{S, O\}$. Since the set of parents is empty, we can deduce the following marginal independencies: $R \perp\!\!\!\perp S|\emptyset = R \perp\!\!\!\perp S$ and $R \perp\!\!\!\perp O$.

Each DAG encodes explicit (conditional) independencies that can be translated into the respective factorization of the joint probability using the d-separation or the directed Markov properties. However, different DAGs can induce the same set of conditional independence statements. These DAGs are called Markov-equivalent if and only if they share the same sets of skeletons (graph after replacing all directed edges by undirected edges) and the same sets of v-structures (Andersson et al. 1997; Pearl 2009). Although Markov-equivalent DAGs can look quite different at first glance, they are statistically indistinguishable. Thus, if the aim is to infer the structure of a DAG from given data, many different DAGs may be possible. Even with large amounts of data we cannot determine the "true" structure of the

underlying causal graph, but rather (at best) a Markov-equivalent graph. Causal interpretations relying on the direction of an edge can therefore be problematic.

Example 39.1h.
The graphs in Fig. 39.8 share the same skeleton and have both no v-structures. Thus, they both induce the same conditional independence $R \perp\!\!\!\perp L | \{E, O\}$ and are Markov-equivalent, although their arrows point in the opposite direction.

39.3.2 Modeling

The DAG of a Bayesian network is a compact and intuitive representation of uncertain associations between well-defined variables, expressed in (conditional) probabilities. The local probability distribution of each variable $X_v, v \in V$ given its parents defines the conditional distribution as, for example, multinomial, Gaussian, or otherwise. Discrete Bayesian networks contain only discrete variables where the local probability distribution is a set of multinomial distributions parameterized by a probability vector $\boldsymbol{\theta}$ for each configuration of the values corresponding to the parents.

Example 39.1i.

In the lymphoma example, the parents of the binary variable *lymphoma* are *sex* (S), with the states female and male, and *pesticide exposure* (E) with states yes and no. In the framework of a case-control study, the local distributions of L are hence $p(L = \text{case}|S = \text{female}, E = \text{yes})$, $p(L = \text{case}|S = \text{male}, E = \text{yes})$, $p(L = \text{case}|S = \text{female}, E = \text{no})$, and $p(L = \text{case}|S = \text{male}, E = \text{no})$ analogously for $L = \text{control}$ with the same configurations for the parents S and E.

Gaussian Bayesian networks consist only of continuous variables that follow a multivariate normal distribution where the conditional mean depends on the parents' values while the conditional variance does not (Markowetz and Spang 2007). Hybrid Bayesian networks can be applied if discrete and continuous variables have to be modeled simultaneously. These models can be described by the conditional Gaussian distribution (Lauritzen 1992), which assumes that the conditional distribution of the continuous variables given the discrete ones is multivariate Gaussian. Although this distribution allows efficient inference (Cobb et al. 2007), it has the major limitation of restricting the DAG structure too much since discrete vertices cannot have continuous parents. More general models have been presented, including mixtures of truncated exponential models (Moral et al. 2001), mixtures of polynomial models (Shenoy 2011), or Bayesian networks assuming non-parametric distributions (Imoto et al. 2002, 2003). Almost all of these, however, are not implemented in available software yet. Most popular in practice are the multinomial and the multivariate Gaussian distribution.

In contrast to "causal" DAGs, which as discussed earlier are postulated to the best of an epidemiologist's knowledge, Bayesian networks are used when the focus is on (semi-)automatic data-driven modeling. Data analysis applying Bayesian networks may address three different situations:

1. *Expert systems* are fully specified Bayesian networks, including the DAG structure and the parameter vector $\boldsymbol{\theta}$, that is, the probability distribution is completely defined. The aim of expert systems is usually prediction or decision-making under uncertainty in very complex networks. They exploit the graph structure to efficiently compute marginal and conditional probabilities, which otherwise could lead to intractable calculations. Expert systems help to answer questions given some available evidence for one or more variables in the DAG. In the lymphoma example (Fig. 39.1), we could query the likelihood of getting lymphoma for white-collar workers and whether additional information about residence would help to substantially improve the prediction. Expert systems rely on the assumed probabilities and do not necessarily need data, but new data can be used to sequentially update the parameters.

   Lauritzen and Spiegelhalter (1988) developed the probability propagation algorithm to answer those questions in discrete Bayesian networks. Exact inference, however, is an exception and Markov Chain Monte Carlo (MCMC) methods allow for approximate calculations. Expert systems will not be covered in this chapter. For more information, we refer to Cowell et al. (1999), Jensen and Nielsen (2007), or Darwiche (2009).

2. *Parameter learning* aims to estimate the parameters of the local probability distributions. For making inference, we need data and we assume a DAG $\mathcal{G}$ as well

as an underlying distribution with unknown parameters. Recursive factorization over the DAG helps to make these computations feasible in complex systems. Approximate methods for estimating the unknown parameters are needed when missing cases or unmeasured (latent) variables have to be coped with.

3. *Structure learning* aims to find a set of conditional independencies and hence one or more DAGs that describe the data best. For this purpose, a specific distribution, for example, multivariate Gaussian, is assumed without specifying the parameters. In the statistical community, this procedure is referred to as model selection.

Regardless of the aim which Bayesian networks want to achieve, the computations of the conditional probabilities are an exhaustive task due to the large number of parameters in a Bayesian network. A dataset with only 15 binary variables leads to a contingency table with $2^{15} = 32,768$ cells. The calculation of the joint distribution is intractable in such complex situations. Making use of the DAG structure simplifies the complexity since the joint probability factorizes according to the DAG but also because computer algorithms enhance efficiency by exploiting several mathematical properties of these subgraphs for the calculations.

If the dataset is sufficiently large, that is the number of vertices is much smaller than the number of observations, and the dataset does not contain missing values, then exact inference may be possible. Real datasets generally do not fulfill these requirements. Bayesian networks with missing observations (i.e., missing values and unmeasured variables) require approximate estimation techniques where data are expressed as likelihoods rather than as certain values (Borsuk 2008). Computer scientists have developed many algorithms, usually based on optimization methods, to handle missing values and complex association structures. In the following, we will describe inference making and model selection using discrete Bayesian networks in more detail.

39.3.2.1 Parameter Learning: Estimation of the Parameters of a Bayesian Network

This section deals with the estimation of the parameters of the local distributions of a Bayesian network. Parameter learning requires two assumptions: firstly, the structure of the DAG is known, and hence, parameter learning does not aim to estimate the direction of an arrow between two variables and secondly, a complete random sample $\mathcal{D} = (\mathbf{x}_1, \ldots, \mathbf{x}_N)$ from the joint probability distribution of $\mathbf{X}$ is given.

If the dataset comprises enough data, we can use the principle of maximum likelihood to infer the parameters $\boldsymbol{\theta} = (\theta_1, \ldots, \theta_K)'$. Let $\mathcal{B} = (\mathbf{X}, \mathcal{G}, P)$ be a Bayesian network which is characterized by its graph structure $\mathcal{G}$ and a set P of local probability distributions associated with each variable, and let $\mathcal{D}$ be a dataset of complete observations. The likelihood $L(\boldsymbol{\theta}, \mathcal{G}|\mathcal{D}) = p(\mathcal{D}|\boldsymbol{\theta}, \mathcal{G})$ is maximized with respect to the parameters $\boldsymbol{\theta}$ of the local probability distribution $p(x_v|\mathbf{x}_{pa(v)})$ exploiting the DAG structure $\mathcal{G}$ to obtain the maximum likelihood (ML) estimator as

$$\widehat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta}}{\arg\max}\, L(\boldsymbol{\theta}, \mathcal{G}|\mathcal{D}).$$

Let us assume the data are discrete to demonstrate the basic idea. Each variable $X_v \in \mathbf{X}$ has r_v possible categories and each local distribution is a set of multinomial distributions, one multinomial distribution for each parent configuration according to $\mathcal{G}$:

$$p(X_v = j|\mathbf{X}_{pa(v)} = l, \theta_v, \mathcal{G}) = \theta_{vjl} > 0,$$

where $\theta_v = \left(\left(\theta_{vjl}\right)_{j=1}^{r_v}\right)_{l=1}^{q_v} = (\theta_{v11}, \ldots, \theta_{vr_K q_K})$ are the parameters under the constraint $\sum_{j=1}^{r_v} \theta_{vjl} = 1$ with q_v denoting the number of possible parent configurations of vertex v.

The recursive factorization property (see Box 39.2) is applied to decompose the likelihood of a Bayesian network to get K independent and less complex estimation problems:

$$L(\boldsymbol{\theta}, \mathcal{G}|\mathcal{D}) = p(\mathbf{x}|\boldsymbol{\theta}, \mathcal{G}) = \prod_{v=1}^{K} p(x_v|\mathbf{x}_{pa(v)}, \theta_v, \mathcal{G}) = \prod_{v=1}^{K} L(\theta_v, \mathcal{G}|\mathcal{D}).$$

The ML estimator of $\theta_{vjl} = p(X_v = j|\mathbf{X}_{pa(v)} = l, \theta_v, \mathcal{G})$ for multinomially distributed data is given as

$$\hat{\theta}_{vjl} = \frac{N_{vjl}}{\sum_{l=1}^{q_v} N_{vjl}} = \frac{\sharp \text{ subjects with } X_v = j \text{ and } \mathbf{X}_{pa(v)} = l}{\sharp \text{ subjects with } \mathbf{X}_{pa(v)} = l}. \tag{39.2}$$

Example 39.2a.
Consider a collider structure (Fig. 39.10) corresponding to a mechanism where genetic (G) and environmental (E) factors independently influence a disease (Y). In this setting, the genotype of the genetic factor G is considered as either "common" or "rare," and a person is either "exposed" or "unexposed" to the environmental factor E. We want to calculate the prevalence of Y given the ML estimates of the multinomial local probability distributions. Table 39.1 shows the ML estimators $\hat{\theta}_{vjl}$ for each vertex in the DAG obtained from a sample with $N = 2,307$ observations. We omit the results for the state "healthy" of the

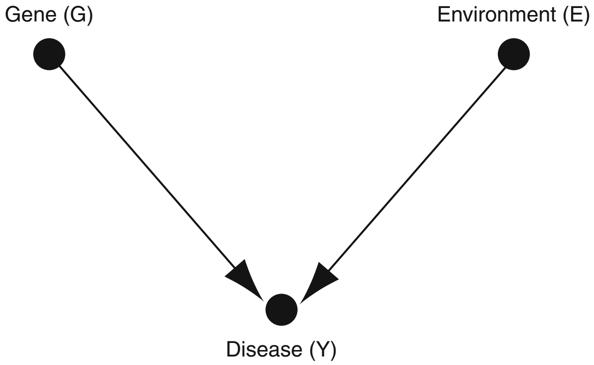

Fig. 39.10 Graphical representation of Example 39.2a

Table 39.1 ML estimates for the local probability distributions of G, E, and Y using Eq. 39.2. The ML estimators are based on the value j of the vertex v and the combination l of the values of v's parents. The vertices G and E have no parents and hence, their ML estimator simplifies to $\hat{\theta}_{vj} = \frac{N_{vj}}{N}$

v	j	l	N_{vj}	$\hat{\theta}_{vj}$
G	Common	–	2, 147	0.931
	Rare	–	160	0.069
E	Unexposed	–	2, 091	0.887
	Exposed	–	261	0.113
			N_{vjl}	$\hat{\theta}_{vjl}$
Y	Diseased	Common – unexposed	13	0.131
	Diseased	Common – exposed	128	0.269
	Diseased	Rare – unexposed	7	0.045
	Diseased	Rare – exposed	8	0.008

variable Y. G and E have no parents, and the parent configuration of Y are the four possible combinations of the values common/rare and exposed/unexposed.

The estimator $\hat{p}(Y =$"diseased") is computed using recursive factorization according to the DAG structure as

$$\begin{aligned}\hat{p}(Y) &= \sum_g \sum_e \hat{p}(Y = y|G = g, E = e)\hat{p}(G = g)\hat{p}(E = e)\\ &= (0.131 \cdot 0.069 \cdot 0.113) + (0.269 \cdot 0.931 \cdot 0.113)\\ &\quad +(0.045 \cdot 0.069 \cdot 0.887) + (0.008 \cdot 0.931 \cdot 0.887)\\ &= 0.00103 + 0.02837 + 0.00276 + 0.00664 = 0.03880\end{aligned}$$

which yields $\hat{p}(Y =$ "diseased"$) = 0.0388$, that is, the prevalence is about 4%.

ML estimation has the disadvantage of being sensitive to small sample sizes. Consider a problem, where we have sparse data and many discrete variables that can be arranged in a large contingency table, which will probably have many cells with zero entries. In the discrete example, ML estimation relies on frequency counts and will therefore give cells with zero counts also a probability of zero, which has a (misleading) strong influence on the outcome. An alternative to ML estimation is Bayesian inference that assumes $\boldsymbol{\theta}$ also as unknown, yet not fixed. Bayesian estimation treats $\boldsymbol{\theta}$ as a random vector and takes prior knowledge about each parameter into account to estimate the posterior distribution $p(\boldsymbol{\theta}|\mathcal{D}, \mathcal{G})$.

Let us consider a given DAG $\mathcal{G}$ and data with likelihood $L(\boldsymbol{\theta}, \mathcal{G}|\mathcal{D})$. Additionally assume a prior distribution $p(\boldsymbol{\theta}|\mathcal{G})$ of the parameters $\boldsymbol{\theta}$ for a given graph $\mathcal{G}$ to derive the posterior distribution of the parameters

$$p(\boldsymbol{\theta}|\mathcal{G}, \mathcal{D}) = \frac{p(\boldsymbol{\theta}|\mathcal{G})p(\mathcal{D}|\boldsymbol{\theta}, \mathcal{G})}{p(\mathcal{D}|\mathcal{G})} \propto p(\boldsymbol{\theta}|\mathcal{G})L(\boldsymbol{\theta}, \mathcal{G}|\mathcal{D}).$$

Applying Bayes' theorem, the posterior is proportional to the product of the prior distribution and the likelihood. The normalizing denominator $p(\mathcal{D}|\mathcal{G})$ reflects the average probability of the data under a given DAG, but it does not depend on $\boldsymbol{\theta}$, and thus its computation is not of interest. The influence of the prior information on the posterior distribution will decrease with increasing sample size, that is, when the evidence from the data overrules the prior information or if the prior information is uninformative (see chapter ▶Bayesian Methods in Epidemiology of this handbook). A proper factorization of the posterior distribution depends on the choice of the distribution for the priors $p(\boldsymbol{\theta}|\mathcal{G})$. A suitable prior is the conjugate prior, that is, when the posterior distribution is of the same family as the prior distribution. The conjugate prior for multinomial data is the Dirichlet distribution. If no conjugate prior distribution can be found, it is impossible to compute the posterior exactly, and the posterior distribution has to be approximated.

To make computations generally feasible, that is, also for large networks, it is desirable that the parameters do not have to be learned simultaneously but rather that each component θ_{vjl} of the parameter vector $\boldsymbol{\theta}$ can be learned individually, which needs the assumption of no missing data in the random sample $\mathcal{D}$ and the assumption of parameter independence (Spiegelhalter and Lauritzen 1990). This means that (a) the parameters θ_v of each local distribution are independent of each other (global independence), allowing the decomposition $p(\boldsymbol{\theta}|\mathcal{G}) = \prod_{v=1}^{K} p(\theta_v|\mathcal{G})$, and (b) that the parameters θ_v are independent for each parent configuration $\mathbf{x}_{pa(v)}$ (local independence), meaning for each variable v it follows $p(\theta_v|\mathcal{G}) = \prod_{j=1}^{r_v} \prod_{l=1}^{q_v} p(\theta_{vjl}|\mathcal{G})$. If global and local independence hold, then the joint distribution factorizes as follows:

$$p(\boldsymbol{\theta}|\mathcal{G}) = \prod_{v=1}^{K} \prod_{j=1}^{r_v} \prod_{l=1}^{q_v} p(\theta_{vjl}|\mathcal{G}).$$

Example 39.2b.
Figure 39.11 shows a Bayesian network representation for Example 39.2a using a Bayesian approach. Nodes for the prior distributions are placed outside the gray box and parameter independence holds since they are all independent from each other. The observations $X^1, \ldots, X^N$ are conditionally independent given θ_v.

Up to now we assumed a dataset without any missing data points or unobserved variables. Real data, however, are frequently incomplete, so that some variables show missing values or certain variables remain unmeasured. In such situations, the posterior distribution factorizes into components that are not well known anymore, which leads to analytically intractable calculations and high computational complexity. Hence, we need approximative and more complex solutions in order to make inference.

ML estimation with data missing at random (see chapter ▶Missing Data of this handbook) is generally achieved by the Expectation-Maximization (EM) algorithm (see Lauritzen (1995) for Bayesian networks). Applying the idea of Bayesian

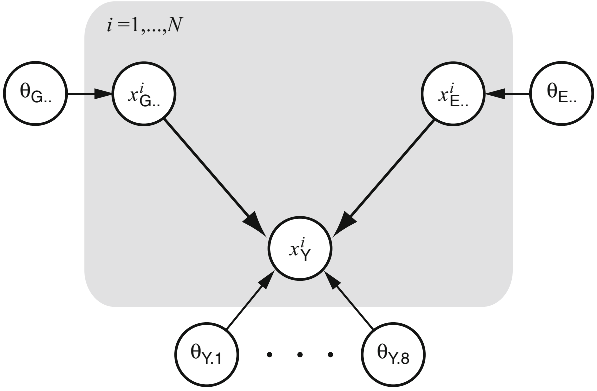

Fig. 39.11 Graphical representation of Example 39.2a using a Bayesian approach under the assumption of parameter independence. Parameters are unknown and marginally independent having the joint probability $p(\mathbf{x}, \boldsymbol{\theta} | \mathcal{G}) = \prod_{v \in V} p(\theta_v | \mathcal{G}) \prod_{i=1}^{N} p(x^i_v | \mathbf{x}^i_{pa(v)}, \theta_v, \mathcal{G})$

inference, the most popular approaches for approximative inference are based on MCMC techniques. An example is the Gibbs sampler (e.g., Gilks et al. 1996).

Since with increasing sample size the influence of the prior decreases and the posterior approaches the likehood, frequentist and Bayesian inference are asymptotically equivalent when estimating unknown parameters. However, Bayesian approaches are generally less computationally expensive than frequentist approaches (Husmeier 2005, p. 26). Beyond that, Chickering (1996), Chickering et al. (2004), and Dagum and Luby (1993) have shown that exact as well as asymptotic probabilistic inference in Bayesian networks is NP-hard (non-deterministic polynomial-time hard). This means that no general algorithm exists that can perform a solution to this problem in less than exponential time (exponential with respect to the number of variables in the DAG). Suitable algorithms are therefore those that can reduce the required (possibly exponential) time and present even so adequate estimates. See Daly et al. (2011) for an overview.

39.3.2.2 Structure Learning: Model Selection of a Bayesian Network

In epidemiology we are often confronted with situations where we neither know the “true” causal graph structure of the target population nor the parameters that describe this structure. The aim is then to learn a Bayesian network from data where the graph and the parameters are unknown. The selected DAG with its probabilistic model or learned Bayesian network should explain the association structure among a given set of random variables and data $\mathcal{D}$ as best as possible.

A naïve optimization method to identify the DAG with the best fit would be to compare the fit of every possible DAG and then select the Bayesian network with the best fit. This intuitive model search strategy is too exhaustive as the number of possible DAGs g_K is super-exponential in the number of vertices K in the DAG.

The number of possible DAGs can be calculated with Robinson's recursive formulae (Robinson 1977) as

$$g_K = \sum_{v=1}^{K} (-1)^{v-1} \binom{K}{v} 2^{v(K-v)} g_{K-v} \quad \text{with } g_0 = 1$$

which points out that exhaustive search is infeasible. In Example 39.1a with five vertices, we would have to calculate $29,281$ networks; ten vertices would already imply approximately $4.8 \cdot 10^{18}$ DAGs. The goal is hence to identify one or more DAGs with a good fit in acceptable time.

Two types of search strategies are typically distinguished to achieve this: (i) score-based algorithms that follow a scoring approach to differentiate between several Bayesian networks and (ii) constraint-based algorithms that apply tests of independence to decide about acceptance of an edge. Sometimes this strategy tries to follow causal semantics to select a DAG. There are also hybrid search strategies that combine score-based and constraint-based algorithms. Once the DAG is selected, the parameters of the Bayesian network can be estimated using, for example, the methods mentioned in Sect. 39.3.2.1.

Score-Based Algorithms Score-based algorithms usually consist of two components. The first component involves a scoring criterion that measures the degree to which a selected graph fits the data given prior knowledge (if any) and assigns a value to that DAG. The second component is a search strategy to identify DAGs with high scoring values.

Using the method of maximum likelihood, the best fit for a given graph is achieved by maximizing the likelihood $L(\boldsymbol{\theta}_{\mathcal{G}}, \mathcal{G}|\mathcal{D})$ of its parameters $\boldsymbol{\theta}_{\mathcal{G}}$ given the data $\mathcal{D}$. An ML score for a graph $\mathcal{G}$ is then given as

$$\text{ML}_{\text{score}} = \max_{\boldsymbol{\theta}_{\mathcal{G}}} \log L(\boldsymbol{\theta}_{\mathcal{G}}, \mathcal{G}|\mathcal{D}) = \log L(\hat{\boldsymbol{\theta}}_{\mathcal{G}}, \mathcal{G}|\mathcal{D}).$$

The ML score usually suffers from overfitting as the score increases with the number of parameters in the model. Generally, it will judge the saturated model (each vertex is a parent of all its non-parents) as the best fit, which is useless. Most scoring criteria combine therefore model fit and model complexity to avoid overfitting. One example is the Bayesian information criterion (BIC). It determines the model fit based on the ML method from above and controls overfitting by penalizing the maximum likelihood by the number of model parameters d:

$$\text{BIC} = \log L(\hat{\boldsymbol{\theta}}_{\mathcal{G}}, \mathcal{G}|\mathcal{D}) - \tfrac{d}{2} \log N,$$

where the sample size N calibrates the penalty.

Another ML-based scoring criterion is the Akaike information criterion (AIC) that penalizes the ML estimator only by the number of parameters.

The BIC is a consistent scoring criterion (Geiger et al. 2001; Chickering and Meek 2002). This means that under the assumption that the true model is one of the candidate models, the BIC will assign the true model the highest score with probability one for N tending to infinity. The AIC is not consistent but is an efficient scoring criterion. The AIC is a good choice for high-dimensional settings where the true causal graph is not believed to be in the set of candidate models and the aim is to adequately describe the unknown DAG. Graphs selected by the AIC are typically more complex, that is, the DAG contains more edges than those selected by the BIC, which in turn tends to be more parsimonious, yet in smaller graphs also too parsimonious. Although motivated from a Bayesian point of view, the BIC does not reflect a Bayesian approach since it does not depend on a prior distribution for the parameters.

The Bayesian score (BS) is an often preferred alternative to frequentist methods. Suppose that $\boldsymbol{\theta}_{\mathcal{G}}$ and $\mathcal{G}$ are random variables with the structural prior $p(\mathcal{G})$ and parameter prior $p(\boldsymbol{\theta}_{\mathcal{G}}|\mathcal{G})$. The posterior distribution of a graph $\mathcal{G}$ given data $\mathcal{D}$ is then

$$p(\boldsymbol{\theta}_{\mathcal{G}}, \mathcal{G}|\mathcal{D}) = \frac{p(\mathcal{D}|\mathcal{G})}{p(\mathcal{D})},$$

where $p(\mathcal{D}|\mathcal{G}) = \int p(\mathcal{D}|\boldsymbol{\theta}_{\mathcal{G}}, \mathcal{G})p(\boldsymbol{\theta}_{\mathcal{G}}|\mathcal{G})d\boldsymbol{\theta}_{\mathcal{G}}$ is called the marginal likelihood of the graph $\mathcal{G}$. It expresses the averaged likelihood over all possible parameters of the local distributions. The parameters are marginalized out of $p(\mathcal{D}|\mathcal{G})$ by integrating the marginal likelihood with respect to $\boldsymbol{\theta}_{\mathcal{G}}$. The denominator $p(\mathcal{D})$ neither depends on $\mathcal{G}$ nor on $\boldsymbol{\theta}_{\mathcal{G}}$ and can be treated as constant which is the same for all models and has therefore not to be computed for model selection. The marginal likelihood can be computed under reasonable assumptions, that is, assuming a random sample from the unknown data-generating causal graph with no missing values and no missing variables, parameter independence, and a conjugate prior. The Bayesian score of $\mathcal{G}$ is defined as

$$\text{BS} = \log p(\mathcal{G}, \mathcal{D}) = \log p(\mathcal{D}|\mathcal{G}) + \log p(\mathcal{G}),$$

which avoids overfitting by averaging over the parameters $\boldsymbol{\theta}_{\mathcal{G}}$ and not maximizing the likelihood.

The structural prior $p(\mathcal{G})$ is mostly chosen as uniform (each DAG has equal probability). However, it is also possible to choose a prior distribution to account for biological knowledge by excluding graphs or assigning them different probabilities. It should be noted that sometimes the optimal model can only be detected by searching through some impossible models. With increasing sample size, $p(\mathcal{G})$ plays a minor role as it remains constant while the marginal likelihood grows linearly.

Different scoring criteria exist to compute the posterior probability. The K2 scoring function (Cooper and Herskovits 1992) is, for example, a possible choice if among others a Dirichlet distribution is assumed as conjugate prior for multinomial data as well as parameter independence and complete data.

The score was further developed by Heckerman et al. (1995) to the Bayesian Dirichlet equivalence (BDe) metric, which is score equivalent in contrast to K2. Score equivalence means that Markov-equivalent DAGs will be assigned the same score value.

The accuracy of a model selected based on the Bayesian score criterion is higher than if it is selected based on the BIC. However, the model selection procedure using the Bayesian score is also more computationally expensive. Liu et al. (2012) empirically evaluated different scoring criteria for Bayesian network model selection and concluded that the BIC consistently outperforms other scoring functions.

The choice of the search space (e.g., network structures, equivalence classes of network structures), a proper scoring criterion, and a strategy how to search through the space of graph structures are important. Score-based algorithms use one of the above-mentioned scoring criteria to rank different models by maximizing the scoring function over some search space to identify the Bayesian network with the highest score.

A popular search strategy is heuristic greedy search. It aims to find a satisfactory solution in reasonable time by choosing a graph that offers an immediate improvement without considering future consequences. This approach does not identify the global optimal graph, that is, the DAG with the highest score of all possible DAGs, but rather finds a local optimal graph meaning that each modification of one (or just a few) edge promises no higher score.

One well-known score-based greedy algorithm is the hill-climbing algorithm. It starts with an initial graph and modifies it stepwise by adding, deleting, or reversing an arrow until the score of the final model cannot be improved. Hill climbing has the disadvantage that it may stick at a plateau or at a local maximum and does not find the global maximum. As explained before, all neighboring graphs (graphs with one modified arrow) show either the same or a lower score, although the current model score is not the highest of all possible models. Solutions to avoid local maxima and plateaus include simulated annealing (Kirkpatrick et al. 1983; Darwiche 2009) or the repetition of the model selection with random initial models. Another possibility is to use tabu search (Glover 1989, 1990) instead, which enhances the performance by memorizing visited networks.

Some algorithms reduce the search space by searching among Markov-equivalent classes of Bayesian networks. DAGs within a Markov-equivalent class determine the same probability model and will therefore be assigned the same score. Several researchers (Chickering 1996; Andersson et al. 1997) prefer to search in the space of equivalence classes rather than in the space of all DAGs.

Fundamental general techniques of structure learning algorithms were developed by Heckerman et al. (1995) and Chickering (1996) and further improved (see Markowetz and Spang (2007), Daly et al. (2011), and Koller and Friedman (2009) for more information).

Constraint-Based Algorithms The aim of constraint-based approaches is to determine DAGs that entail the directed Markov properties (or equivalently the d-separation relations) corresponding to the independencies among the components of the random vector $\mathbf{X}$. A sequence of (conditional) independence tests is applied to establish a set of (conditional) independencies that are used to construct the graph edge by edge. Algorithms first form an undirected version of the DAG before the directions of the arrows are included in the next step.

Some algorithms optimize their selection strategy by limiting the search space to the *Markov blanket* of each vertex. The Markov blanket of a vertex v contains the parents, children, and all vertices that share a child with v (Scutari 2010). The final graph then specifies the constraints of the Markov property for the data. Again, heuristic algorithms are necessary since exhaustive search is computationally infeasible.

Statistical hypothesis tests detecting (conditional) independence for discrete data include association tests like Pearson's χ^2-test or deviance-based tests. Conditional independence tests for continuous variables are based on the partial correlation coefficient of X and Y given Z. For many tests, exact and asymptotic versions are available.

Some algorithms search for "causal" DAGs. The inductive causation (IC) algorithm by Verma and Pearl (1991, 1992) is an intuitive example. The procedure can roughly be summarized as follows (Jensen and Nielsen 2007, p. 231ff.):

1. Find the *conditional independencies* and learn the skeleton of the graph, that is, the graph contains only undirected edges.
2. *Identify all v-structures* For triplet-structures $X - Y - Z$, check if Y is in the separating set S of $X \perp\!\!\!\perp Z | S$. If $Y \in S$ then X and Z are conditionally independent given Y. If $Y \notin S$ then introduce the v-structure $X \rightarrow Y \leftarrow Z$ in the graph.
3. *Avoid new v-structures* If there are missing directions in a directed path, like $X \rightarrow Y - Z$ and Z is not adjacent to X, then orient $X \rightarrow Y \rightarrow Z$.
4. *Avoid cycles* If $X \rightarrow Y$ introduces a directed cycle in the graph, then reverse the arrow $X \leftarrow Y$.
5. *Choose direction randomly* (optional) If none of Steps 2–4 can be applied, choose an undirected edge and direct it randomly.

Example 39.1h.
Figure 39.12a shows the skeleton of the lymphoma example with the found (conditional) independencies. Applying Steps 2–4 of the IC algorithm results in the graph in Figure 39.12b. The graph containing the edge $O \rightarrow S$ instead of $O \leftarrow S$, however, is Markov-equivalent.

Although the IC algorithm is simple to understand, it is not specific enough for practical application. The first successful implementation of a causal discovery algorithm was developed by Spirtes and Glymour (1990). Their PC algorithm relies on conditional independence tests to build a preliminary undirected graph and a systematic procedure to remove unnecessary edges and adjust directions by applying the directed Markov properties or the d-separation. The output of the PC algorithm is an acyclic, partially directed graph, that is, some edges are undirected. DAGs with undirected edges represent an equivalence class, where all DAGs within that equivalence class are Markov-equivalent and represent the same set of independence properties (see Fig. 39.13). The PC algorithm is consistent if the distribution P is faithful with respect to a graph $\mathcal{G}$, meaning that the conditional independencies of the distribution can be transferred to $\mathcal{G}$ ($\mathbf{X}_A \perp\!\!\!\perp \mathbf{X}_B | \mathbf{X}_S \Rightarrow A \perp\!\!\!\perp B | S$), and all conditional independencies have been correctly identified. Under certain assumptions, the PC algorithm is a consistent estimator for causal effects,

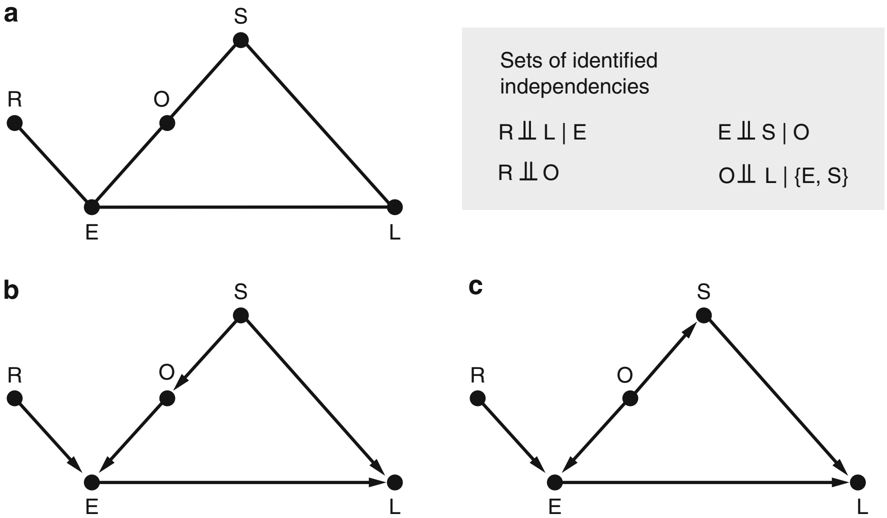

Fig. 39.12 (**a**) Skeleton encoding the (conditional) independencies; (**b**) graph after introducing all v-structures and chain structures, according to the IC algorithm; (**c**) a Markov-equivalent graph

although there might be unobserved confounders and/or unknown time order. Robins et al. (2003) showed that the type of consistency is not uniform, implying that the PC algorithm selects the true graph with an infinite sample size. That means, even in very large finite samples, the true graph will not necessarily be selected.

There are several modifications of the PC algorithm. The PC* algorithm significantly reduces the number of performed independence tests and is therefore quicker than the PC algorithm (Spirtes et al. 2001, pp. 84–89). The CPC algorithm (Ramsey et al. 2006) uses a more sensitive test for orientation of colliders, and the JPC algorithm (Ramsey 2010) is restricted to continuous variables which tries to improve accuracy. Kalisch and Bühlmann (2007) have shown that assuming Gaussian data, the PC algorithm is applicable to high-dimensional data.

It is important to remember that with data-driven model selection based upon conditional independence tests, it is only possible to construct a DAG up to its Markov equivalence class (Kalisch et al. 2012). To direct undirected edges is then only possible with prior knowledge about causal directions.

Some limitations of statistical hypothesis tests also need to be considered in this context. An independence test is constructed to prove statistical dependence. However, statistical independence is accepted when the data shows no evidence against independence. This does not mean that the true data-generating process implies independence. Additionally, each statistical test has a probability for false-positive or false-negative decisions. False decisions have the consequence that edges in the DAG are erroneously added or deleted. The selected DAG then represents independence statements that are at least partly untrue. The accuracy of

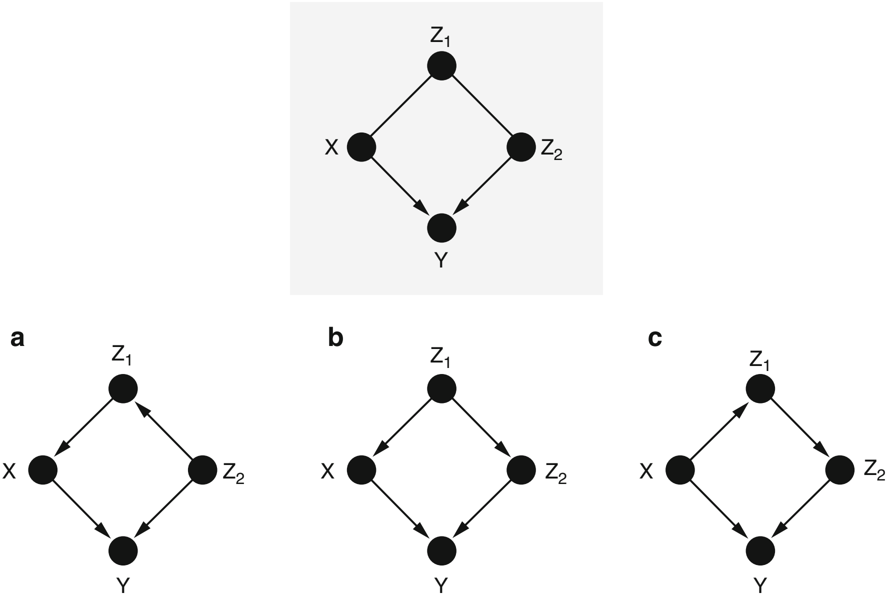

Fig. 39.13 The graph in the *gray box* illustrates the Markov equivalence class of the three Markov-equivalent graphs (**a**)–(**c**)

constraint-based methods is discussed by Fast et al. (2008) in a more general setting. Li and Wang (2009) developed a procedure to control the false discovery rate of the learned graph using the PC algorithm.

Score-based and constraint-based methods have each their advantages. Constraint-based algorithms are more efficient when the graph is sparse. They can deal better with latent variables and even work in the presence of selection bias. However, the most serious disadvantage is their insufficiency to adequately cope with the problem of simultaneously testing multiple hypotheses. Score-based techniques, on the one hand, show a better performance, especially for dense graphs and with less data, they favor parsimonious models and thus avoid overfitting, and they are superior in dealing with missing data. On the other hand, they "only" find a good model but do not identify the best one. Hybrid algorithms have been developed to combine the advantages of both methods (e.g., Wong et al. 2002; Tsamardinos et al. 2006; Wang et al. 2007). In a first phase, the hybrid procedures usually apply a constraint-based algorithm to learn an initial skeleton. In a second phase, the score-based algorithm searches in the reduced search space for the Bayesian network with the highest score. The inclusion of latent variables or the consideration of selection bias in the network requires specific algorithms (Friedman 1997; Spirtes et al. 1995).

Our discussion about Bayesian networks is far from comprehensive. Beside the monographs mentioned earlier, the tutorial by Heckerman (1999) represents a good introduction into the topic, especially on parameter learning. In Daly et al. (2011), a good review of existing algorithms for learning parameters and structure can be found. Darwiche (2010) gave a broad overview of applications of Bayesian networks. Issues of robustness and sensitivity are, discussed, for example, by Kjærulff and Madsen (2008, Chap. 10), Husmeier (2003), and Friedman et al. (1999b, a). Genetic and biological aspects are covered in the reviews by, for example, Friedman (2004) or Markowetz and Spang (2007). Applications in epidemiology outside genetic epidemiology are rare to date (Getoor et al. 2004; Nguefack-Tsague 2011; Nadathur and Warren 2011; Stefanini et al. 2009).

39.3.3 Software

As the previous discussions show, a major issue in working with Bayesian networks is the choice and availability of appropriate software. Numerous software applications are available (Korb and Nicholson 2011; Murphy 2007) which we describe roughly. `R` (R Development Core Team 2012) offers several packages to deal with Bayesian networks. One of them is the `gRbase` package (Dethlefsen and Højsgaard 2005), which is a platform for a more general framework of graphical models. `gRain` (Højsgaard 2012) uses this platform to compute expert systems. The book by Højsgaard et al. (2012) introduces graphical modeling using `R` but focuses mostly on `gR`-packages. The package `bnlearn` (Scutari 2010) includes several algorithms for learning Bayesian networks with either discrete or continuous data and provides parallel computing. The package `pcalg` (Kalisch et al. 2012) implements the PC algorithm and other constraint-based algorithms. Bayesian networks with mixed variables can be handled by `deal` (Bottcher and Dethlefsen 2011). Popular standalone software packages include the commercial software `Hugin` for building and making inference from expert systems (Madsen et al. 2003), OpenBugs for parameter learning using MCMC methods (Lunn et al. 2009), or `Tetrad IV` (Glymour et al. 2012) for building and calculating Bayesian networks applying the PC algorithm and many other algorithms described in Spirtes et al. (2001). An updated, but not complete list of software packages for Bayesian networks is maintained by Murphy (2012).

39.4 Conclusions

In epidemiology, DAGs are typically applied as a tool to visualize an etiological network. Ideally, this visualization allows to efficiently identify potential confounders that have to be adjusted for in the estimation of the effect of a risk factor on the outcome under study. DAGs are usually constructed on the basis of single hypotheses since the entire etiological network is usually unknown. The construction of a DAG therefore requires a comprehensive understanding of the etiology to develop the optimal DAG. However, when not data-based, the construction of a DAG relies on assumptions which are always incomplete and may lead to different DAGs. In situations where edges or directions are uncertain, Shrier and Platt (2008) recommend to postulate alternative, equally plausible DAGs for the situation under study. These alternative DAGs should be tested to evaluate whether they generate the same adjustment set of covariates, and results of these alternative DAGs should also be published. Such sensitivity analyses help to assess the robustness of the estimated effect measures (Geneletti et al. 2011).

A considerable limitation of DAGs, if only considered as a graph and not as a probability model, is the fact that the arrows in the graph itself do not indicate the type (protective or risk-enhancing) and strength of the associations. While the (likely) presence of bias is identifiable from a well-developed graph, no information on the extent and direction of the bias and its relative importance in mathematical terms can be derived from the DAG alone. The use of Bayesian networks can be helpful in this respect as estimation of parameters is possible here. So far, DAGs cannot represent interactions or effect modification (Hernán et al. 2004), and some authors are very skeptical whether DAGs will ever provide a reasonable solution to disentangle the complexity of causal networks (Weinberg 2007). In spite of this criticism, VanderWeele and Robins (2007a, b) have started to deal with effect modification in DAGs, but their models require stringent assumptions.

The main difference between a causal DAG and a probabilistic DAG is the fact that the construction of the causal DAG relies on adding an arrow $X \rightarrow Y$ whenever we think about a causal (dependent) flow from X to Y, while the second approach is built upon (conditional) independencies. This admittedly is a somewhat complicated way of thinking. It reveals the association patterns embedded in the data particularly when no reliable background knowledge exists. A further difference between causal and probabilistic DAGs is the fact that cause-effect relationships are non-symmetrical. Arrows indicate the direction of an association, whereas probabilistic independence associations are symmetrical and the connection between two vertices symbolizes "no (conditional) independence" between two vertices without implying a direction. Moreover, from a statistical point of view, it is a challenge to distinguish association from causality. DAGs have become increasingly popular to postulate causal relationships, but data-driven modeling of DAGs can at best assist to explore causal dependence networks. This results from the fact that, so far, a single DAG cannot accomplish probabilistic and causal interpretations simultaneously (Dawid 2010a). For example, we showed earlier that Markov-equivalent DAGs encode for the same conditional probabilities but have different "causal" interpretations. Markov-equivalent graphs can therefore not be distinguished based on the data alone.

An overall problem is that probability distributions are well defined, whereas the concept of causality has no common understanding in epidemiology. Therefore, how to draw causal conclusions from non-experimental data remains a key challenge for epidemiologists, especially when confounding is not fully understood. As a consequence, prominent researchers in this field (Pearl 2009; Spirtes et al. 2001; Dawid 2010b; Didelez and Sheehan 2007) have been arguing for a formal language for causality. Pearl's *do*-operator (Pearl 2009) or counterfactuals (Rubin 1974) are examples of this formalization. Here, causality is generally viewed as an intervention effect in a given system, and DAGs help to clarify the assumptions of these concepts. A formal language is also necessary to improve and invent causal algorithms for causal discovery using Bayesian networks.

40.1 Introduction and Brief History

Life course epidemiology is the study of long-term biological, behavioral, and psychosocial processes that link adult health and disease risk to physical or social exposures acting during gestation, childhood, adolescence, and earlier or adult life or across generations (Kuh and Ben-Shlomo 2004). Life course epidemiology was one of several new conceptual models of epidemiological thinking that began to emerge in the 1980s and 1990s and that are now mainstream paradigms in social epidemiology (Susser 1985; Susser and Susser 1996a; Krieger and Zierler 1997; McMichael 1999), though its concepts have been applied more generally to chronic disease etiology. They parallel the emergence of causal models (Greenland et al. 1999; Hernán et al. 2002) for epidemiology during the same period.

Life course epidemiology started in the United Kingdom, when a group of epidemiologists and social scientists[1] started to meet regularly at the London School of Hygiene and Tropical Medicine to evaluate the new empirical evidence on the role of early life influences, particularly fetal development, on chronic disease risk that was emerging from the Medical Research Council (MRC) Environmental Epidemiology Unit (Southampton) under the leadership of Prof. David Barker. This body of work, initially known as the "Barker" hypothesis, fundamentally asserted that the causes of many, if not all, chronic diseases were established by "programming" of processes during embryological development and this in turn was influenced by nutritional influences acting either in pregnancy or prepregnancy through the development of the mother during her childhood or adolescence (Barker 1998). The programming hypothesis itself evolved into a more generalized developmental model that extended into the postnatal and childhood period (Gluckman and Hanson 2004). Initial reactions within epidemiology to these new ideas were either skeptical or at best agnostic, although their challenge to existing conventional life style models of chronic disease was welcomed. We (YBS and DK), with our colleagues, seized the opportunity to provide a critical overview of these new ideas and review of the research findings. This led to the first edition of the Oxford University Press publication "A life course approach to chronic disease epidemiology" (Kuh and Ben-Shlomo 1997) which is currently in its second edition (Kuh and Ben-Shlomo 2004) and has led to a series of other life course books on women's health (Kuh and Hardy 2003), methodology (Pickles et al. 2007), family-based designs (Lawlor and Mishra 2009a) and healthy ageing (Kuh et al. 2014). We coined the term "life course epidemiology" to reduce the polarization that was occurring between epidemiologists supporting either the early-life or adult-life hypotheses on the development of chronic disease risk,

[1] The group included Mel Bartley, Yoav Ben-Shlomo, David Blane, Derek Cook, George Davey Smith, Jonathan Elford, Diana Kuh, Dave Leon, Ivan Perry, Chris Power, David Strachan, and Peter Whincup

arguing that the relative importance of exposures across life needed to be investigated and underlying processes examined.

In the course of putting together the first book and a related editorial (Ben-Shlomo and Kuh 2002) and glossary (Kuh et al. 2003), two of us (YBS, DK) were forced to specify a clear conceptual framework behind some of our rather loose terminology and causal thinking. We proposed several potential models or pathways through which early or later life exposures may work in either an additive or interactive fashion to increase individual and population risk of disease. These models, based on ideas of critical and sensitive periods or of risk accumulation from other disciplines (see Sect. 40.2), were our first attempt to establish a conceptual foundation for others to extend and/or reformulate. As such, they provided a useful stepping stone for hypothesis formulation.

This chapter allows us to develop these models as well as acknowledge and synthesize the ideas of other researchers. We place life course epidemiology within an historical and interdisciplinary perspective. We restate our initial models as well as define and clarify key terminology used in life course epidemiology and often a source of confusion between epidemiologists and other disciplines. Discussion of the uses and misuses of life course models in the published literature then helps us to refine our initial models. We discuss both design and analytical issues for those who wish to undertake life course research and devote a section around the less commonly used but long-established family-based designs explaining how they help infer causality. We illustrate some of our ideas with two case studies around life course influences on an age-related disease and trait.

We have encountered three common criticisms to life course epidemiology. The first is “Haven’t we always been doing this?” As we shall describe below, the broad ideas behind life course epidemiology are not new and have been considered in some guise or other for at least a century both within public health and other social sciences. However, the theoretical specifications and empirical data supporting these ideas are indeed contemporary. The second criticism is “Isn’t it obvious that all disease must stem from exposures acting across the life course?” This is also a truism for any multifactorial chronic disease, but as we have previously noted, “it is insufficient to glibly state that all health and social outcomes are due to life course influences. This is analogous to stating that all health is a function of genetic and environmental exposures. Whilst factually correct it does not further our understanding of etiology or help policy formulation” (Ben-Shlomo and Kuh 2004). We feel that this asks the wrong question. Instead, as is elucidated in our models, the key questions relate to whether certain time periods are more relevant for some exposures, whether exposure duration is the main determinant, and how exposures may be interrelated as part of causal pathways. The third criticism is “These models are too complex. Is it realistic, either in terms of data availability or statistical models to truly test them?” This last criticism is the most challenging. We hope that the examples provided at least partially answer this criticism and will enthuse other epidemiologists to build on our ideas and state their life course hypotheses in a more thoughtful manner.

40.2 Life Course Epidemiology Within Its Wider Historical and Inter-Disciplinary Perspectives

Epidemiology and public health have historically gone through various eras or phases of development from the nineteenth century until today (Hamlin 1992; Susser and Susser 1996b), each emphasizing a different notion of health, a different notion of cause or set of causative factors, different research settings, and different intervention strategies to prevent or reduce risks to health. We have suggested (Kuh and Davey Smith 1993, 2004; Kuh et al. 2009) that in one of these eras, at the beginning of the twentieth century, health was seen as fitness or vitality, and there was concern that the fitness of the population was degenerating. The contemporary debate centered around whether fitness was inherited or could be nurtured by a good early environment, especially by "maternal efficiency" (Pearson 1919; Paton and Findlay 1926). Public health officials who believed that "the health of the adult is dependent upon the health of the child" and that "the health of the child is dependent upon the health of the infant and its mother" (Newman 1914, p. 16) argued that the new maternal and infant welfare services would improve national fitness; the geneticists argued that these services would keep "weaklings" alive and lead to reduced national fitness. There was little epidemiological evidence for either side. Rather support for the importance of the early environment came from the biological and psychological sciences where ideas of developmental critical periods were gaining ground (Stockard 1927; Freud 1955). Later, it came from early cohort analysis that showed birth cohort effects on mortality risk (Kermack et al. 1934), although the importance of these has been recently challenged (Murphy 2010).

In epidemiology and public health, interest in early life influences of adult health waned as early post war cohort studies of middle aged men successfully identified more proximal biological risk factors, such as high blood pressure, and adult lifestyle factors, for adult chronic disease. In contrast, early life continued to dominate the psychological sciences into the 1970s and then gave way to a life-span perspective. Some emphasized the role of continuing adult development on later life outcomes (Baltes et al. 1998), and others showed discontinuity as well as continuity between childhood and adult psychopathology and demonstrated the presence of "chains of risk" and how they could be broken (Rutter 1989; Rutter et al. 2006). The modern revival of the life course perspective in human biology and biological anthropology linked early development to aging and emphasized how the early as well as the later environment influences individual variation in structure and function at every age. The notion of risk accumulation, while present in early public health and demographic literature (Ciocco et al. 1941; Riley 1989), has become more prevalent with the transcendence of the disposable soma theory of biological aging where aging is seen to be caused by the accumulation of molecular and cellular damage from insults experienced by the organism throughout life (Kirkwood and Holliday 1979).

Epidemiologists were relatively late in reviving a life course perspective. The catalyst was the growing empirical evidence of a multiplicity of links between the postnatal as well as the prenatal environment and developmental characteristics with respect to adult health, function, disease, and aging. Evidence came from population studies, initially from the maturing birth cohort studies (Wadsworth 1991; Power and Elliott 2006) and the revitalized historical cohort studies (Barker 1992) and more recently from intergenerational studies (see Sect. 40.5). Systematic reviews and meta-analyses have also strengthened the evidence base (Huxley et al. 2000, 2002).

In recent years, this epidemiological evidence has been harnessed in support of the biological processes of developmental plasticity. The fundamental assumption is that multiple phenotypes can arise during development from a single genotype, which enables production of a range of phenotypes better suited to the prevailing environmental conditions than would otherwise be possible (Gluckman et al. 2007, 2008) but may lead to disease or disadvantage if environmental boundaries are exceeded. Epigenetic mechanisms are thought to mediate these processes (Gluckman et al. 2009). Developmental plasticity is seen as an evolutionary process that helps to explain how organisms become matched to face environmental challenges. This occurs on several time scales: across multiple generations (natural selection), across the life course (developmental plasticity), and across shorter time periods (homeostasis).

Epidemiologists thus have an increasingly rich set of theories of human development and aging on which to draw to explain as well as describe the phenomena they observe. These theories should underpin the building of conceptual epidemiological models that hypothesize the relationships between risk factors across life and health outcomes in later life. Epidemiologists must then find study designs to operationalize these relationships into testable hypotheses and, ideally, to distinguish causal relationships. If empirical evidence supports the hypothesis, scientists must then explain the phenomena in ways that are compatible with or further develop these underlying theories. Research hypotheses and findings are often not refined sufficiently to distinguish between competing theories, and a number of interpretations may be plausible. Or they represent only pieces of the jigsaw that can be reinterpreted or more fully interpreted when other jigsaw pieces are available (see Sect. 40.6). As many studies simply do not have data across the whole of life, findings from different studies may need to be pieced together using advanced statistical modeling (Wills et al. 2011). This can be facilitated by standardized and repeated measures of biological function (such as blood pressure, muscle strength, lung function, or cognitive function) that exhibit age-related change across the life course and are thus dynamic tools for investigating links between development and aging across life and the biological imprint of physical and social exposures (Kuh 2007).

Life course epidemiologists who wish to explain how a distal risk factor, such as father's social class, in childhood may affect lifetime biological function and the development of adult chronic disease risk can draw on several theoretical disciplines: sociological or economic theories to explain the social and economic structure of society, psychological theories to explain individual agency and behavior, and biological theories to explain how social and psychological phenomena "get under the skin." More often than not, they focus on one pathway of interest (the "direct" pathway) and ignore the others.

40.3 Life Course Models

“All models are wrong; the practical question is how wrong do they have to be to not be useful” (cited from Box and Draper (1987) in Collins and Altman (2010)).

40.3.1 Basic Concepts

The pathways which link an exposure such as poor socioeconomic conditions in childhood to a pathological entity such as a cerebrovascular accident many years later are complex and may involve factors acting at both societal, area, neighborhood, family, individual, and ultimately physiological and cellular levels (Susser and Susser 1996a). While the models we propose below are gross simplifications of these complex processes, they support the empirical test of alternative or counterfactual models of disease risk.

We initially proposed a simple dichotomous classification of life course models which conceptualized the origins of chronic disease to belong to either a critical period or accumulation of risk pathway (we shall criticize this classification below). Within these two subdivisions, we further elucidated various alternative models to be considered. We illustrated the latter set of models using simple graphical illustrations (more formally referred to as directed acyclic graphs – DAGs) but did not do this for the first set as we were uncertain as to the best way to illustrate these graphically (the problem of illustrating interactions in DAGs has only been recently addressed) (Vanderweele et al. 2010). We use hypothetical or empirically based examples to illustrate each of these models.

1. *Critical Period Model* (see Box 40.1 for definitions of key terms). In this model, it is assumed that an exposure, e.g. a specific viral infection, acting within a predefined time window, e.g. first trimester of pregnancy, may result in a specific disorder, e.g. schizophrenia. This model does not preclude other causes of schizophrenia that are unrelated to viral infection, e.g. genetic factors, or that other exposures, e.g. expressed familial hostility, cannot also increase risk of schizophrenia. It does assume that maternal exposure after the first trimester or if a subject is exposed postnatally is not associated with any increased risk compared to an unexposed subject.
2. *Sensitive Period Model*. An obvious variant of the above scenario is that exposure in the second trimester is associated with a milder form of the disease and that exposure in the third trimester is associated with a schizophreniform type of personality but not overt clinical disease. This is what is meant by a sensitive rather than a critical period model, namely, that exposure within specific time windows has a greater or lesser risk of disease. Both these models can be regarded as examples of age interaction whereby the effect of viral infection is modified by the time window (as measured by gestational age) of exposure. In a critical period model, the effect is all or none by time strata, while in the sensitive period model, it is simply that the strength of the relationship is stronger in one time period than another.

Box 40.1. Glossary of key concepts

Accumulation of risk – The notion that life course exposures or insults gradually accumulate through episodes of illness and injury, adverse environmental conditions, and health-damaging behaviors.

Chain of risk model – A chain of risk model refers to a sequence of linked exposures that raise disease risk because one bad experience or exposure tends to lead to another and then another. Social, biological, and psychological chains of risk are possible and involve "mediating factors" and often "modifying factors." The sequential links are probabilistic rather than deterministic.

Critical period – In the natural sciences, a critical period of development refers to a time window when intrinsic changes in the organization of living systems or subsystems toward increasing complexity, greater adaptivity, and more efficient functioning occur rapidly and may be most easily modified in a favorable or unfavorable direction. In life course epidemiology, a critical period is a limited time window in which an exposure can have adverse or protective effects on development and subsequent disease outcome. Outside this developmental window, there is no excess disease risk associated with exposure.

Interaction – Interaction or effect modification is the process whereby a third variable ("effect modifier") alters the relationship between an exposure and an outcome so that the effect of an exposure may only be seen, for example, in those who are also exposed to the effect modifier. It is known as "synergism" if the modifying variable enhances the effect of the exposure or "antagonism" if it diminishes it.

Sensitive period – Like critical periods, sensitive periods are also times of rapid individual change, but there is more scope to modify or even reverse those changes outside the time window. Thus, a sensitive period in life course epidemiology is a time period when an exposure has a stronger effect on development and subsequent disease risk than it would at other times. Outside the time period, any excess risk will be weaker.

Adapted from Kuh et al. (2003)

3. *Critical/Sensitive Period Model with Later Effect Modification*. Even though the timing of an exposure may be essential to have any effect or a stronger effect on a disease outcome, this does not mean that it is inevitable that disease will always emerge. Unrelated exposures in later life that are not themselves secondary to the initial insult could still modify disease risk either through independent or interactive effects. For example, if maternal undernutrition in pregnancy, as seen in the Dutch Hunger Winter (Stein et al. 1975), was associated with a permanent reduction in the number of muscle cells at birth, this could be compensated by

increased physical activity in later life resulting in muscle hypertrophy. In this case, reduced grip strength would only be observed in small babies who were relatively inactive as adults or with aging, and there may be no effect in those with high activity levels.

4. *Accumulation of Risk with Uncorrelated Exposures.* We live in an associational world whereby many non-genetic exposures are correlated to varying degrees due to social patterning of exposures (Davey Smith et al. 2007). It is therefore rare to have environmental associations that are truly randomly distributed. In such a scenario, the risk of being exposed to A is unrelated to B and C so that unexposed individuals are equally as likely to be exposed to B and C (see Fig. 40.1a). For example, the risk of depression may be associated with a genetic variant (A), death of a father due to military conflict, and unemployment in adult life (C) due to the subject's employer going bankrupt. In this example, there is no reason to believe any of these exposures are correlated with each other. If each exposure increases risk (though this may be to varying degrees), then individuals exposed to more than one factor will have a greater risk than those exposed to fewer factors. In this case, we are assuming that these exposures do not interact with each other and the effects are additive.
5. *Accumulation of Risk with Correlated Exposures.* Exposures are more commonly correlated because of risk clustering (see Fig. 40.1b). For example, living in a poor neighborhood may be associated with being exposed to a less healthy diet, reduced opportunities to exercise, and greater peer influences on smoking. Each of these factors may additively increase risk of coronary heart disease, but in this case, one exposure will be associated with the others due to the common factor of neighborhood poverty which is an upstream determinant of the other mediating factors.
6. *Chain of Risk Additive Model.* In this scenario, each exposure increases risk, but A is itself a determinant of B which in turn increases the risk of C (see Fig. 40.1c). Hence, a chain effect may be established whereby an exposure may only have a modest effect directly on outcome, but its overall effect, including the indirect pathways, may be much larger. For example, smoking may directly result in subclinical atherosclerosis through an inflammatory effect on the arterial wall, but it also reduces exercise behavior due to respiratory symptoms. This in turn results in reduced aerobic capacity but also increases obesity. This in turn results in insulin resistance syndrome and is a risk factor for coronary heart disease. In this case, intervening on obesity alone would have health benefits, but obese individuals who have followed this pathway would still be at increased risk due to their life course history compared to non-obese individuals.
7. *Chain of Risk Trigger Model.* In contrast to the previous model, the trigger model is only associated with risk due to the last exposure in the chain (see Fig. 40.1d). For example, poor childhood socioeconomic environment results in overcrowding which in turn increases exposure to *Helicobacter pylori*, and this is associated with peptic ulcer. In this scenario, eradication of *H. pylori* will eliminate the risk, and there will no longer be any residual risk associated with the socioeconomic environment. Such pathways are interesting as they may

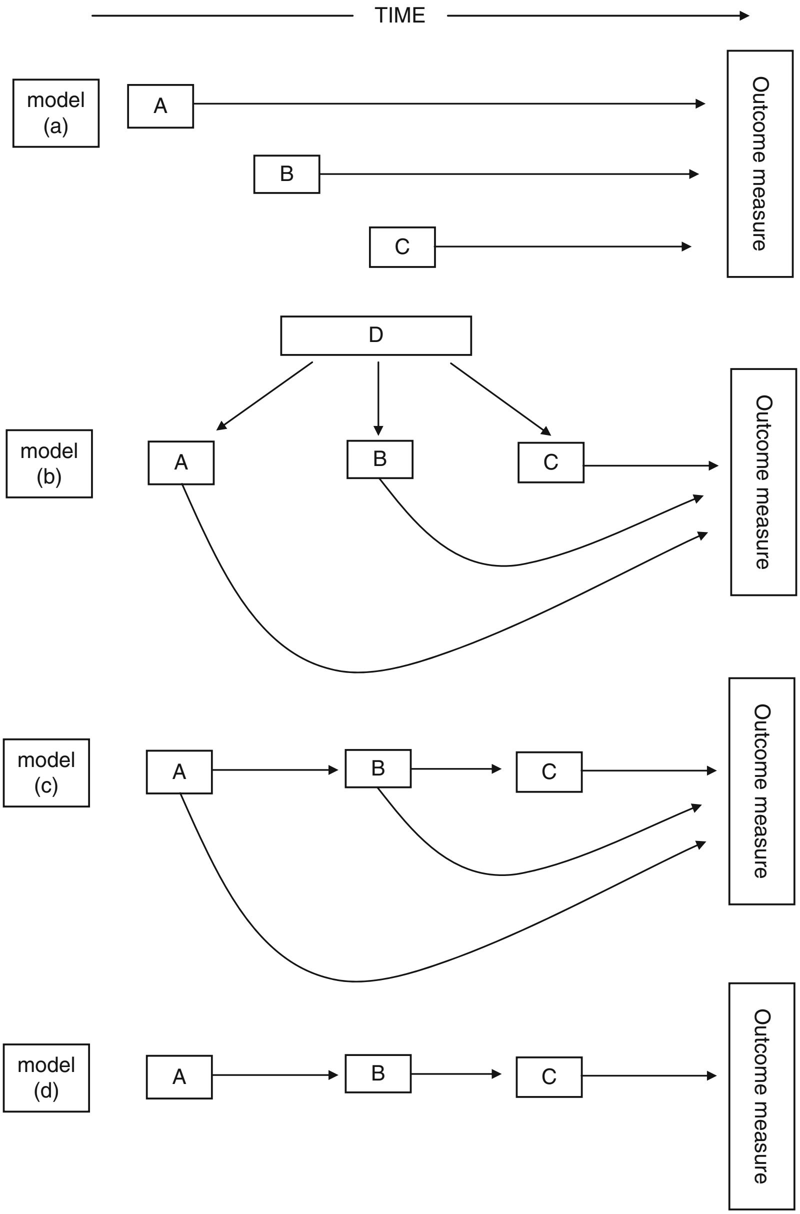

Fig. 40.1 Graphical illustrations of various life course models: (**a**) accumulation of risk with uncorrelated exposures, (**b**) accumulation of risk with correlated exposures, (**c**) chain of risk additive model, and (**d**) chain of risk trigger model (Taken from Kuh et al. 2003)

explain why some epidemiological studies show marked heterogeneity of effects (assuming this is not due to random variation). In these pathways, variations in temporal or cultural differences can abolish associations. So, for example, the association of socioeconomic conditions with any smoking-mediated disease can legitimately vary by time and place due to cultural or temporal changes in smoking behavior.

We did not invent the concepts of accumulation and chains of risk but rather adopted them from existing ideas. The demographer John Riley proposed the idea of accumulation as one of the driving forces behind patterns of mortality, so that countries with greater adverse exposures exposed individuals to an accumulation of adversity and this resulted in higher mortality (Riley 1989). Similarly, the eminent child psychiatrist Sir Michael Rutter coined the term chains of risk so that "the impact of some factor in childhood may lie less in the immediate behavioral change it brings about than in the fact it sets into motion a chain reaction in which one 'bad' thing leads to another, or, conversely, that a good experience makes it more likely that another one will be encountered." (Rutter 1989).

40.3.2 Misunderstandings Behind Life Course Epidemiology

The ideas behind life course epidemiology have been embraced to varying degrees across a wide range of topic areas from cardiovascular, cancer, mental health, and aging. Common misunderstandings frequently occur around careless use of the terminology, for example, the use of the term "critical period" when in fact the term sensitive period may be more appropriate. For example, it has been argued that the elasticity of the arterial vessels is determined in both pre- and postnatal life (Martyn and Greenwald 1997), and so an adverse exposure acting in this period could result in stiffer arteries which in turn result in adult hypertension. In such a scenario, poor prenatal growth (a proxy measure of an adverse exposure) may be more sensitive than poor postnatal growth, but the intrauterine period cannot be critical if effects of adverse development and growth can still be seen due to postnatal exposures. If one expanded the biological time window to include both pre- and postnatal life, assuming no influences outside this time window, then by definition this would be a critical period. However, this is unhelpful, and the a priori definition of what time windows one should select should be based on either biological evidence and/or differences in the determinants of pre- and postnatal growth and hence the ability to potentially intervene.

Similarly, the demonstration of a stronger association in an earlier period conditional on the same exposure in a later time period does not necessarily support a "programming effect" in the earlier period. This issue was initially highlighted in relation to the inverse association between birth weight and later cardiovascular outcomes in some cases only after conditioning on a measure of later adiposity. We shall discuss this example further in relation to modeling trajectories.

40.3.3 Social Mobility and Life Course Models

When we conceptualized our models, we had assumed that the critical/sensitive period models applied to a single exposure that could occur across different time windows. In this case, the question is whether the timing of exposure has additional effects over and above the duration of exposure. In contrast, our accumulation models were based on different exposures acting either in an additive or chain of risk fashion. However, the accumulation model has most often been applied to the same exposure, e.g. socioeconomic position (SEP), over time so that the risk of an outcome has been compared by simply adding the number of periods of poor SEP and examining if risk increases in a simple linear fashion (Davey Smith et al. 1997). Given that earlier SEP is a strong predictor of future SEP, this would better fit an additive chain of risk model than the other types of model. However, sociologists have had a long interest in the process of social mobility so it was not surprising that a publication attempted to address whether the effects of critical period, accumulation, and social mobility in terms of CHD risk could be disentangled (Hallqvist et al. 2004). Hallqvist and colleagues examined SEP (which was dichotomized into manual vs. non-manual) over three time periods (childhood, young adulthood, and midlife). They then identified eight possible patterns which were classified as consistent with either a critical period, accumulation, or social mobility model. However, given that the social mobility trajectory was consistent with both the critical period and accumulation trajectories, they concluded that it was impossible to disentangle these different models analogous to the problem of trying to disentangle age period and cohort effects. We support this conclusion but feel that this problem occurred because they added social mobility as an additional model. As can be seen in Table 40.1, the phenomenon of social mobility is consistent with a critical/sensitive period or accumulation model depending on which of many empirically based patterns emerge from the data analysis. We would argue that social mobility is better limited to a descriptive term regarding inter- and intra-general variation in SEP as opposed to an etiological model which tries to understand how the process of mobility is embodied into pathophysiology. A more recent approach has systematically tried to test whether one can differentiate between these different models having explicitly operationalized each model in

Table 40.1 The association between social mobility and disease risk operating under different life course models

Early SEP	Late SEP	Effect estimates				
High	High	1.0	1.0	1.0	1.0	1.0
Low	High	1.5	2.0	1.0	1.8	1.5
High	Low	1.5	1.0	2.0	1.3	1.0
Low	Low	2.0	2.0	2.0	2.0	5.0
Life course model		Accumulation	Early critical period	Late critical period	Early sensitive period	Interaction model

algebraic terms (Mishra et al. 2009). This later paper also used three measures of SEP over time but importantly defined social mobility in a specific manner so that it reflected an interactive effect of mobility, thus resolving the intractable problem seen in the earlier paper. In this paper, the authors included an adult-life critical period model, though it is less likely from a biological perspective that exposures in adult life would be critical as in general terms this reflects a degenerative rather than a developmental phase of the life span.

This approach has been an important advance in helping researchers formally test different models where exposures are categorized. Other approaches are required for trajectories of continuous measures (see below). One simple problem that has already been identified is that the timing of the measurement points could artefactually favor one model over another. In a recent publication examining SEP and physical performance measures, only two time points were available: childhood and adult life. Simple multivariable analyses suggested that the effect of adult SEP was a stronger determinant of poor performance than childhood SEP supporting an adult-life sensitive period model rather than a simple accumulation chain of risk model (Birnie et al. 2010). Formal tests however did not reveal a significantly better fit between these two models probably due to insufficient power. However, the adult SEP exposure was based on a measure that covered a much longer time period than the childhood measure. This was not an issue in the original paper by Mishra and colleagues, as it used measures that spanned three relatively equal-spaced time periods. In the latter example, the greater effect of adult SEP may not reflect any greater sensitivity but merely a better measure of exposure as it captures socioeconomic conditions that operate over a longer time period.

A similar problem has also been encountered when trying to tease out sensitive and accumulation models in relation to the duration of effect. A publication from the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort examined whether pre- and postnatal maternal anxiety predicted asthma risk. It found that children whose mothers reported anxiety in both periods had a greater odds ratio of asthma than those only reporting anxiety in either period alone (odds ratio for both periods 1.46, 95% confidence interval (CI) = 1.20–1.78; prenatal only odds ratio 1.30, 95% CI = 1.04–1.64; postnatal only odds ratio 1.18, 95% CI = 0.89–1.57) (Cookson et al. 2009). At first glance, these results appear to be most compatible with an accumulation effect: however, further exploration of this relationship suggested that duration of anxiety symptoms was actually a marker of prenatal severity. Women reporting both pre- and postnatal anxiety symptoms had higher anxiety scores at 32 weeks gestation than those with just prenatal anxiety. The duration of symptoms across both time periods was thus a measure of prenatal severity, and conditioning on prenatal anxiety abolished the association with postnatal anxiety, more consistent with a critical or sensitive period model.

Even without some of the issues highlighted above, there is a danger that applying these statistical approaches without any understanding of the biological basis of disease may still produce misleading results. A paper examining smoking habits in women in relation to breast cancer suggested that initiation of smoking in puberty may be related to a greater risk of breast cancer after taking smoking duration

into account (Band et al. 2002). In the illustrated hypothetical example, we have partitioned exposure time into 10 pack-year blocks (Fig. 40.2). A naive analysis would conclude that a simple accumulation model was the best fit of the data given the steady increase (dose response effect) in risk of breast cancer. However, by comparing the subgroup of women with 30 pack-years who started smoking around the time of puberty with those who started after puberty, we would now conclude that puberty may be a sensitive period where, conditional on the total pack-years of exposure, women may have an additional greater risk possibly due to the enhanced carcinogenic effects of tobacco exposure on rapidly dividing breast tissue.

It is clear that if one thinks of accumulation in terms of the same rather than different exposures, then the critical and sensitive period models are not qualitatively different but could be considered to be embedded (Fig. 40.3) within a hierarchical framework. Thus, a sensitive model is a variation of the accumulation model whereby exposures accumulate risk over time, but the effects are differential and the critical period model is a special form of a sensitive period model whereby you have an all or none effect. It may therefore be more helpful to consider an accumulation model as the default model with sensitive and critical period models considered as special types accumulation models.

40.3.4 The Importance of Trajectories

We have described above how patterns of a dichotomous variable over time may have differential effects on disease risk. The same applies to continuous measures such as anthropometry. The initial birth weight chronic disease/risk factor associations which stimulated such huge interest in biological programming were mainly based on only examining intrauterine growth through the proxy variable of

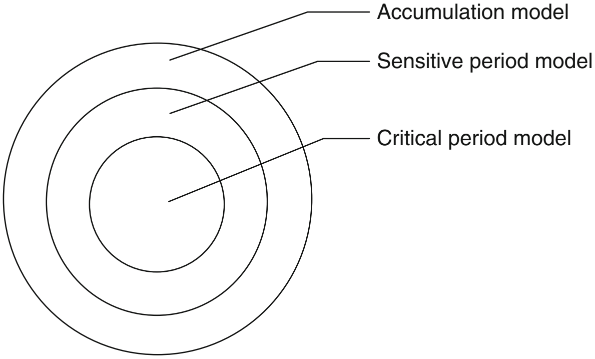

Fig. 40.3 A hierarchical representation of life course models

birth weight, length, or ponderal index (though the original Hertfordshire cohort did also examine anthropometry at 1 year). However, growth does not stop at birth and may be considered a life course process until maturity. Because fetal growth is so fundamental to embryological development, it is seductive to only consider this period as “critical” which may be true for some outcomes, e.g. thalidomide and limb development, but not for others, e.g. lung function, arterial elasticity, and synaptic density where postnatal influences are also important. The interpretation of the original inverse association between birth weight and later life outcomes as an effect of intrauterine development was criticized as in many (but not all) publications: this association only became clear after statistical adjustment for a later life measure of anthropometry such as weight or body mass index. This conditional association suggested that postnatal centile crossing or catch-up growth may be the important pathway rather than intrauterine development, which has rather different policy implications if true (Lucas et al. 1999). The biological interpretation of this statistical finding is more complex. It is possible that centile crossing is itself driven by poor intrauterine growth. This may be through an acute phenomenon, e.g. infants whose mothers smoked in pregnancy may develop suboptimally but once born catch up to their genetic potential. Alternatively endocrine and/or metabolic pathways may be reset having a longer term chronic effect on growth trajectories. Another alternative explanation is that both pre- and postnatal growth may be determined by genetic factors which in turn may be related to later disease (Hattersley and Tooke 1999). This example highlights the importance of understanding trajectories over time rather than examining one or two arbitrary time points that are available in individual datasets.

The analysis of repeat measures to model trajectories is complex and open to various different analytical strategies. Initial publications from the retrospective Helsinki cohort used a simple summary measure approach so that standardized differences in anthropometry, measured on an annual basis between 6 and 16 years, were compared between CHD cases and the whole cohort (Eriksson et al. 1999). Such patterns are useful descriptive starting points but may be misleading as they imply an individual trajectory from what are repeat cross-sectional measures. Repeat longitudinal measures of the same individuals can be used to derive summary measures. For example, a study examining growth between 9 and 18 years and with up to 65 repeat anthropometric measures was able to construct individual growth velocity curves and hence derive from the inflection point of maximal growth velocity, the age at peak height velocity, which was used as a valid surrogate for the timing of puberty (Sandhu et al. 2006). A more sophisticated reanalysis of the same data using a multilevel model approach was able to explain 99% of the variance in growth patterns. This SuperImposition by Translation And Rotation (SITAR) model (Cole et al. 2010) derived three parameters (starting point size – equivalent to the intercept, growth tempo – a left-right shift in the spline curve and growth velocity – a scaling parameter that reflects the duration of the growth spurt making the curves steeper or shallower) that were able to capture how individuals deviated from the overall mean growth curve. This method ideally requires repeat data closely spaced together. Multivariable models have also been used to model growth velocities over more widely spaced time periods which have the advantage of being less correlated than the crude anthropometric measures measured over shorter periods (Kuh et al. 2006); these can show very high correlation coefficients. Other approaches have used latent variable models or spline regression models. In each case, these models are testing whether deviations from a "normative" trajectory are associated with an outcome of interest. The spline approach has one useful advantage in that it allows periods of time to be partitioned, a priori, based on biologically driven changes in growth patterns (Ben-Shlomo et al. 2008). For example, postnatal growth is non-linear, and there are transitions or inflection points of deceleration or acceleration. Having modeled such points, the effect of each period independent of the earlier period can be investigated. The use of directed acyclic graphs can also highlight the direct and indirect influence of each period, as normal regression models will only present the direct estimates conditional on other parameters.

The ability to test various trajectories is however limited by the degree of variability within any dataset. A recent study examining the associations between the age at onset of obesity and later blood pressure found evidence, particularly in men, that earlier onset of obesity was associated with both higher body mass index at 53 years and higher blood pressure (Wills et al. 2010). However, given the strong tracking of body mass index (BMI) (among individuals who first became obese at 26 years, 82%, 91%, and 95% were obese at 36 years, 43 years, and 53 years), they could not test patterns that included weight loss subsequent to obesity in earlier life as there were few individuals in these trajectories. While one could argue that this may not matter if few individuals demonstrate these trajectories, the counterfactual still exists, and if an effective intervention was to be implemented (assuming it has equal benefits at all time periods), then we would still remain unclear as to its optimum timing.

We have briefly mentioned some of the statistical challenges to be considered within a life course framework (for a fuller discussion, see Pickles et al. 2007). A review of the statistical issues around life course analyses concluded that there was no one “correct” approach to conduct a specific analysis but that the method should be driven by the specific question being tested and the available data (De Stavola et al. 2006). However, life course analyses have the same problems as any longitudinal analysis, that is loss to follow-up bias and missing data, and these too need careful attention.

40.4 General Design Issues

Ideally one should have access to a multigenerational birth cohort to test life course hypotheses. While in the United Kingdom, we are fortunate to have several birth cohorts (NSHD, NCDS, ALSPAC, millennium cohort), and it is possible to link family members across generations in several European countries, none contain the ideal dataset. For example, the oldest birth cohort studies may not have biological samples from earlier periods, and more recent birth cohorts are still relatively young and hence only have intermediate surrogates of disease risk. There is therefore no perfect and complete life course study, and even if there was, its generalizability could be limited because of the effects of social change. Therefore, life course hypotheses can be tested, and valuable insights gained using historical cohorts, case control studies, and rarely but more convincingly through the follow-up of natural experiments (Lumey et al. 1993; Stanner et al. 1997) or randomized controlled trials, usually set up for other short-term outcomes. In addition, combining trajectories from several cohorts using multilevel models is also starting to reveal valuable insights on the lifetime trajectories of biological functions such as blood pressure which are important drivers of disease risk (Wills et al. 2011).

We highlight a few examples of these approaches for illustrative purposes. The role of perinatal risk factors has played a prominent role in ideas around programming. However, exposures such as maternal diet and smoking during pregnancy will be heavily confounded by other socially patterned variables. One approach to this problem has been to compare maternal-offspring to paternal-offspring associations (see Sect. 40.5 below for more details) on the basis that intrauterine effects should be specific to the former while effects due to confounding will find associations with both parents (Brion et al. 2007). However, an alternative strategy is to break the confounding using a natural experiment. In a developing world context, this can be explored by examining season of birth as this relates to conception and fetal development during dry or rainy seasons that have a large effect on maternal nutrition. A subtle variant of this approach has examined the effects of day-time fasting during Ramadan on the birth weights of offspring and other abnormalities. This is particularly clever as the Muslim calendar varies by season so that in some years, the duration will be shorter or longer depending on whether it falls during winter or summer. Thus, mothers who fasted during the first trimester were more likely to have lighter birth weights, a reduction of male offspring, and a greater risk of disability (Almond and Mazumder 2008). An extreme version of this approach can be seen in studies that have followed up offspring of mothers who conceived during a period of starvation, e.g. Dutch Hunger Winter, Leningrad siege, and Chinese famine. Any nutritional hypothesis is severely challenged if such studies fail to find effects, even though one can question the generalizability of these experiences.

Another approach has been the longer term follow-up of past randomized trials. Such an approach is dependent on several key factors: (a) does the intervention relate to an a priori hypothesis, (b) did it actually have an effect, (c) can the original participants be traced, and (d) is follow-up sufficiently complete and unbiased to enable valid comparisons, ideally as an intention to treat analysis, by random group allocation. For example, Singhal and colleagues have developed the "growth acceleration hypothesis" (Singhal and Lucas 2004) on the basis of their follow-up studies of premature babies who were randomized to either breast versus formula feeding or high versus low nutrient feeds. In these studies, the response rate at follow-up was low (around 20%), and though there do not appear to be major differences at baseline between those who reattended compared to those who did not at baseline, there remains a concern that confounding may still be present though to a lesser degree. However, many of their reported associations are using the data as a cohort rather than using the initial randomization thereby losing the benefits of the trial design. One of us (YBS) has been involved in the follow-up of village-based cluster trial in India where a nutritional intervention was introduced to exposed villages while this was delayed for several years in the control villages (Kinra et al. 2008). Follow-up of the children from all the villages has enabled a pragmatic analysis of whether intervention was associated with better or worse cardiovascular risk markers. Reassuringly, children from the intervention villages were taller at follow-up, indicating some effect on development, and had better insulin function as well as less stiff arteries, though the differences were modest. Whether these observations translate into more meaningful differences in future risk of hypertension and diabetes remains to be seen, and further more detailed phenotypic follow-up has just been completed.

40.5 Family-Based Designs

Families lie at the center of life course epidemiology, but their role is only beginning to be reflected sufficiently in our understanding of individuals not as isolated beings but as lives that unfold within collective structures that shape our health over and above individual characteristics (Merlo et al. 2009). As has been discussed in previous sections, maternal influences during gestation can play a key role in human development, but mothers alongside other family members also characterize the experience of childhood and adolescence. Once in adulthood, partners, pregnancies, and offspring will condition an individual's health and health-related behaviors. The effects on health and well-being due to relationships with adult offspring and grandchildren may also extend into later life. Thus, family-based studies may be seen as representing another opportunity for life course epidemiology in moving beyond associational epidemiology to multilevel analyses that address questions of causality in the absence of randomized control trials, disentangling genetic and environmental factors, and the role of timing of exposures.

The theory and practice of family-based studies are set out in a recent publication from the life course series entitled "Family matters: Designing analysing and understanding family-based studies in life course epidemiology" (Lawlor and Mishra 2009a). This examines the three key aspects of how family-based analyses can contribute to life course epidemiology. "First, family will directly affect health by determining many of the biological, environmental and social exposures across the life course. Secondly, different family members will exert their impact on ones health by different degrees at different times in the life course, and hence detailed studies of family influences could help to understand the importance of timing of exposures across the life course. Lastly, comparing statistical relationships within and between families can help to clarify the mechanisms underlying associations in life course studies and help to determine causality" (Lawlor and Mishra 2009b).

Family-based studies are those designs that incorporate purposeful data collection on family members. They include the long-established design of twin studies, which have provided first estimates for effects of heredity compared with environmental influences, as well as sibling studies where the effects of different exposures can be examined for individuals who are genetically very similar but not identical. Over recent years, there has been an increasing focus on the use of large population-based studies that cover multiple generations, for instance, by providing prospective data on parents and offspring from registry records. Thus, these studies present opportunities for investigating causality by allowing us to examine intra-familial correlation of outcomes, such as for birth weight over generations, while accounting for shared environments.

As discussed in the previous sections regarding the developmental origins hypothesis, a key aspect is the possibility of maternal exposures during pregnancy having a direct biological effect of offspring outcomes. Findings, however, can be heavily confounded by social and environmental factors. One approach to this issue using intergenerational studies has been to compare maternal-offspring to paternal-offspring associations for the effect of smoking on offspring birth weight and childhood BMI (Davey Smith 2008). Epidemiological findings have established that smoking during pregnancy by the mother, but not paternal smoking, leads to lower birth weight and thus provide evidence for an intrauterine mechanism (Lawlor and Mishra 2009b). Maternal smoking during pregnancy is also linked with childhood obesity (Oken et al. 2008), but elsewhere higher (rather than lower) birth weight has been associated with childhood obesity (Baird et al. 2005), implying that a distinct mechanism exists for the effect of smoking on birth weight. Moreover, from the Avon Longitudinal Study of Parents and Children, the effect of maternal smoking on childhood obesity has been shown as similar in magnitude to paternal smoking (Leary et al. 2006). This suggests that maternal smoking does not have a direct intrauterine effect on childhood obesity but may be due to the confounding effects of other lifestyle factors (such as diet and exercise) of parents who smoke. Further research is needed, but study sample size is an issue in having sufficient numbers of families with either or both parents smoking, including those where mothers (temporarily or permanently) gave up smoking during pregnancy.

Even with family-based studies, causality remains difficult to nail down. In a German longitudinal study of substance use and mental disorders, findings confirmed previous results that major depression among parents was associated with increased offspring risk for depression (Lieb et al. 2002). While such results support the potential role of genetic and various shared environmental factors leading to mental disorder, the study was unable to eliminate the possibility for the association to operate in the other direction, for instance, psychopathology in offspring leading to depression in their parents. The analysis to support specific mechanisms for depression is further complicated since mental disorders often do not occur singularly but as a group of comorbid disorders.

Family-based studies pose a number of methodological challenges beyond those of representativeness normally encountered in life course epidemiology, such as missing data and attrition. Considerable caution needs to be applied in generalizing results from long-term birth cohort studies, since cohort effects may limit the extent that older individuals in the sample are representative of the contemporary population, especially of younger generations. But in addition, we need to consider the various ways that families – and the social environment they provide – may have changed over decades, including the increased prevalence of single parent families, the rise of working mothers, and even the decline in the number of siblings. Assumptions that siblings have the same fixed familial socioeconomic position may break down in countries, cultures, and populations where one child is “favored” over others, such as in their diet or for further education, based on their gender, birth order, early signs of promise, or other characteristics (Mishra and Lawlor 2009). It is also important to consider the validity and potential bias of using proxy informants in family-based studies, whereby the respondent gives information about other family members, such as when a mother provides data about her offspring or vice versa. Moreover, when family structure and/or interrelationships are central to a particular analysis, missing data from one family member may mean that available data from other family members should not be used.

Sample size and statistical power are often an issue in the design of family-based studies. When they are used to test causal hypotheses or disentangle causal pathways, they typically involve comparing variations in the associations within and between different family structures, for example, comparing maternal-offspring associations to paternal-offspring associations or comparing within and between siblings or twins. Such analyses require considerably greater sample sizes than studies concerned with a single association, and they are prone to type 2 errors (Mishra et al. 2009). In cases where family-based studies are analyzed as Mendelian randomization studies (Davey Smith and Ebrahim 2003) (where genetic variants that are known to be robustly associated with a non-genetic risk factor of interest are treated as an instrumental variable for that risk factor), the maternal genotype is often used as an instrumental variable for an intrauterine exposure. These studies require very large sample sizes, typically tens of thousands of families depending on the prevalence of the genetic variant under investigation, in order to have the statistical power to provide estimates that would be useful in translating research into public health policy or clinical practice.

The increasing focus on family-based studies in life course epidemiology has seen existing cohort studies augmented with data collection on family members or through record linkage of registry data as well as medical records (for instance, cancer registry, DNA data, and health-care utilization). The designs of some new cohort studies address family associations from the outset, such as the Generation Scotland study which will recruit adults over a 6-year period, to form a total of 50,000 individuals that comprise of siblings and parent-offspring groups (Smith et al. 2006). In another example, the *China Children and Families Cohort Study* has enrolled 300,000 families with recruitment occurring even prior to conception of the main participant for some couples (Brown et al. 2007). The LifeLines project aims to recruit 165,000 individuals in the Netherlands over three generations including partners and siblings (Stolk et al. 2008). Thus, the future for family-based studies lies both in the prospect of new family data from existing studies and the commencement of studies with younger cohorts – especially those now being initiated in low- and middle-income countries. If studies are conducted mindful of the diligence and methodological rigor gained from existing cohort research, then over time this should allow for cross cohort comparisons to test and verify key epidemiological findings and disease mechanisms across generations and populations with diverse cultural, socioeconomic, and environmental conditions.

40.6 Life Course and Aging: Two Case Studies

This section will use two examples relevant to understanding lifetime influences of aging to highlight some of the interesting questions raised by a life course approach. Aging toward the end of life is commonly associated with the phenomenology of “frailty” defined as a syndrome with some or all of the following manifestations: weakness, fatigue, weight loss, decreased balance, low levels of physical activity, slowed motor processing and performance, social withdrawal, mild cognitive changes, and increased vulnerability to stressors. A multiplicity of etiological factors have been suggested for frailty (Hogan et al. 2003), including the potential role of the growth hormone (GH) and insulin-like growth factor (IGF) axis. IGF is a nutritional-driven peptide that is an insulin analogue and has pleiotropic actions including positive effects on mitogenesis, cytodifferentiation, and anti-apoptosis. It is the last role that has generated much interest in relation to cancer etiology, with a meta-analysis highlighting its potential role in premenopausal breast cancer and possibly prostate cancer (Renehan et al. 2004).

The GH-IGF axis also plays an important role in both fetal and postnatal growth, and animal studies show marked reductions in genetic mutation models. For example, mutations in the IGF-I and IGF-II genes can reduce birth weight by 35–40% and adult body size by 60–70% (Veldhuis et al. 2006). Therefore, this axis may be an important link between development and aging, in that more rapid growth and early maturation will be associated with shorter life expectancy given prominent evolutionary drive for reproduction. We have previously shown that earlier puberty is associated with higher IGF-I levels in adulthood measured 40 years later (Sandhu et al. 2006), using a historical cohort design. However, in this study, we had no measure of IGF during childhood so we could not differentiate as to whether higher childhood IGF-I triggered earlier puberty and then tracked into adulthood or whether the timing of puberty itself had an effect on the GH-IGF axis. The modifiability of the system as well as its potential long-term patterning however was seen in the follow-up of the Barry Caerphilly milk supplementation trial (Elwood et al. 1981). This study randomized women in pregnancy and their offspring to additional free household milk and measured growth up to 5 years. While intervention was associated with higher birth weight, there was no demonstrable effect on childhood height at 5. However, follow-up at 25 years found that adults in the intervention group had lower IGF-I levels suggesting that supplementation may have downregulated the GH-IGF axis (Ben-Shlomo et al. 2005). This complemented a report from the Dutch Hunger Winter where women who were exposed to nutritional restriction as children had higher IGF-I levels in middle age, suggesting an upregulation of the GH-IGF axis (Elias et al. 2004). A similar finding was seen in the Boyd Orr cohort where subjects whose family reported greater consumption of milk had lower IGF-I levels in adulthood (Martin et al. 2007). These findings were unexpected as one would have predicted, a priori, the opposite results: acute supplementation or restriction is associated with an increase or decrease of IGF-I levels, respectively. However, acute changes may reverse over the longer term as evidenced by a small follow-up of children who had IGF measured in the first year of life and then again at 17 years (Larnkjaer et al. 2009). This study observed an inverse association between postnatal levels and IGF levels at 17 years. This observation may explain the earlier paradoxical findings. An alternative explanation is that subjects with higher IGF-I simply mature faster and have already reached the declining phase of IGF-I levels that is associated with deceleration of the pubertal growth spurt so that they appear to have lower IGF-I levels in early adulthood in comparison to those who are maturing more slowly and reach their peak IGF-I level at a later age. This observation may no longer be true in much later life.

IGF-I levels may provide one possible mechanism that explains a series of observations relating to breast cancer and measures of physical performance (one constituent of the frailty syndrome). A meta-analysis of birth weight and breast cancer found a continuous positive association (dos Santos Silva et al. 2008), and a large historical cohort study found that independent of birth, taller stature at 8 and 14 years and more rapid pubertal growth increased risk of breast cancer (Ahlgren et al. 2004). Similarly, data from the MRC National Survey of Health and Development has found that childhood weight gain before age 7 years, in contrast to adult weight gain, was generally beneficial for midlife physical performance (timed tests of balancing on one leg or rising from a chair and sitting down ten times), though this finding was seen in men and not in women (Kuh et al. 2006). This finding is consistent with a meta-analysis of studies that show that better childhood SEP is associated with better performance measures over and above adult SEP (Birnie et al. 2011) and lower IGF-I is associated with lower SEP both at birth and in adulthood

(Kumari et al. 2008). Data from the Caerphilly Prospective Study (CaPS) has also shown that higher IGF-I predicts better physical performance (as measured by the get up and go test) almost 2 decades later (Birnie – personal communication).

This example shows how these findings from different studies are like pieces of a jigsaw puzzle that, if put together with the help of an underlying conceptual and theoretical model, can reveal some of the potential pathways linking development and aging. Given the complexity of most endocrine systems and their ability to change due to negative feedback and up/downregulation, it is perhaps not unsurprising that there may be early life effects on the GH-IGF axis with short-term implications for development and long-term implications for aging and age-related diseases.

Our second example also demonstrates the need to consider developmental trajectories. In almost all societies, it is recognized that systolic blood pressure increases with age. This effect is even more marked if one examines pulse pressure (difference between systolic and diastolic pressure) or pulse wave velocity (McEniery et al. 2010a), a more direct measure of arterial stiffness. This is unsurprising as the wall of arteries consists of smooth muscle, collagen, and elastin tissue, and every time the heart beats, the arterial wall expands and recoils which puts stress on its constituent structures. A recent 20-year follow-up from CaPS found that the best predictor of arterial stiffness was the combined product of heart rate and systolic blood pressure measured over 25 years, and most of the usual cardiovascular risk factors had only modest effects if at all (McEniery et al. 2010b). In this example, one might regard the increase of stiffness with aging as a simple accumulation effect so that the more cardiac cycles one experiences at greater pressure, the more likely there will be physical damage to the arteries and hence greater stiffness, though this is still modifiable to some degree due to greater physical fitness and pharmacological lowering of blood pressure and heart rate. However, it is also clear that the development of the arterial tree, which is both a pre- and postnatal phenomenon, could contribute to future stiffness by altering the ratio of collagen to elastin tissue (Martyn and Greenwald 1997). One way to examine this idea is to look at another physiological measure that declines with age and also develops during the same time period. Tests of lung function, as a measure of the pulmonary tree, may be one such measure, and these are inversely correlated with arterial stiffness so that subjects with better lung function have less stiff arteries. What is more surprising is that a past measure of lung function in CaPS was a better predictor of pulse wave velocity than a cross-sectional measure taken at the same time (Bolton et al. 2009) and that rate of decline in lung function had little predictive effect. This suggests that there are common developmental origins of lung function and arterial structure that could influence both and that these may be more important than smoking history on arterial stiffness. In this example, both sensitive and accumulation models probably fit the data, but they operate through different mechanisms. These findings illustrate the importance of thinking about both risk factors that determine the development of a function as well as those that may determine its decline. In this hypothetical figure (Fig. 40.4), we have illustrated four population groups: a normative group who live up to a 100 years without

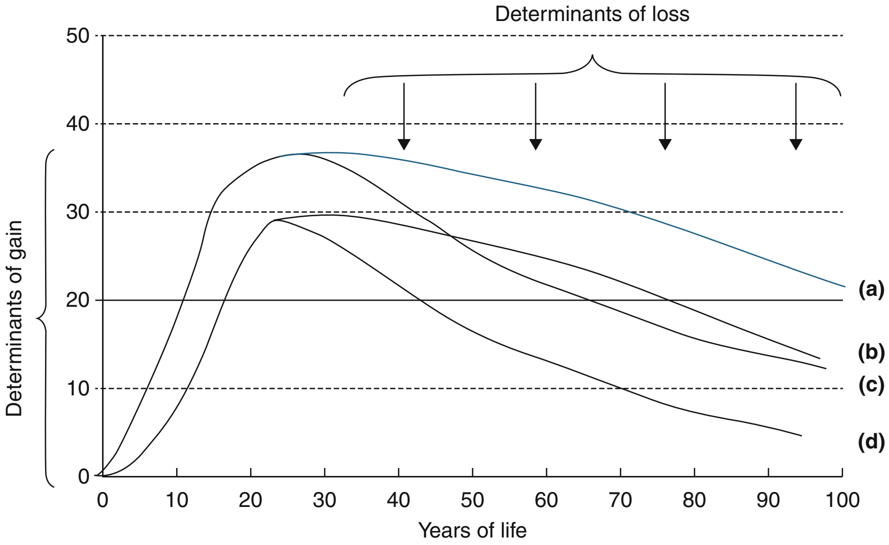

Fig. 40.4 Population trajectories of traits across the life course illustrating four potential groups: (*a*) normative, (*b*) suboptimal development, (*c*) accelerated decline, and (*d*) combined developmental and decline group

reaching the threshold for disease (a), a suboptimal developmental group (b), an accelerated decline group (c), and a combined group (d). By only studying disease or a phenotype at the end of these various pathways, one will attenuate associations. Other than the combined group which will have an earlier age at onset, the pathways (b) and (c) will be clinically indistinguishable unless one has longitudinal data over the life course that can identify which pathway has been followed. Thus, a risk factor that acts on suboptimal development (groups b and d) will appear to have an attenuated effect when combining groups (b and c) depending on their respective frequencies in the sample. The longitudinal approach is therefore more powerful to elucidate different classes of risk factors.

40.7 Conclusions and Policy Implications

Life course epidemiology is predicated on the idea that what happens to individuals early in life can have long-term effects for later health, disease, and aging. Understanding the lifetime influences on health, disease, and aging will require an interdisciplinary life course approach which is being fostered across the UK research councils. For too long, the various life course perspectives across the disciplines have traveled parallel but separate paths. There have been growing calls for life-span psychology and life course sociology to integrate ideas of social structure and individual agency (Settersten 2009), but more attention by these disciplines needs to be paid to relevant biological theories. Biologists and epidemiologists have generally tried to control out the social and psychological pathways and in the UK at least have focused on specific diseases, rather than underlying traits or disease-related trajectories.

Life course ideas have stimulated not only academics but policy makers, and various NGOs (such as the World Health Organization and specific disease charities) (Aboderin et al. 2002; National Heart Forum 2003) have embraced these concepts. This has surprised us as many questions remain unanswered especially in relation to cost-effectiveness of interventions. In addition, most life course interventions will only demonstrate benefits over a long time frame, usually of little interest to politicians. However, they do allow policy makers some flexibility as interventions at any point across the life course can be argued to have long, medium, or short-term benefits. In particular, the degree to which inequalities in health can be reduced by life course models has received some attention. A commentary in the Journal of the American Medical Association argued that "from both basic research and policy perspectives, confronting the origins of disparities in physical and mental health early in life may produce greater effects than attempting to modify health-related behaviors or improve access to health care in adulthood" (Shonkoff et al. 2009). The Marmot Review of Health Inequalities *Fair Society, Healthy Lives* (Marmot Review Team 2010) highlighted the importance of interventions in early life but took a more long-term accumulation perspective. "Central to the Review is a life course perspective. Disadvantage starts before birth and accumulates throughout life,... Meanwhile, there is much that can be done to improve the lives and health of people who have already reached school, working age and beyond .... Services that promote the health, well being and independence of older people and, in so doing, prevent or delay the need for more intensive or institutional care, make a significant contribution to ameliorating health inequalities." As we have argued above, both approaches may be correct in some respects. Given our current state of knowledge in relation to human intervention studies, we are operating in a "speculation rich, data sparse" environment. The beginning of the twenty-first century offers many challenges and exciting opportunities to develop life course perspectives for a greater understanding of the etiology of disease and health and for the rationale development of public health prevention programs.

41.1 Introduction

Social epidemiology has been defined as the branch of epidemiology that studies the social distribution and social determinants of health (Berkman and Kawachi 2000). As all aspects of human life are inextricably bound within the context of social relations, every conceivable epidemiological exposure is related to social factors. In this broad sense, all epidemiology is social epidemiology (Kaufman and Cooper 1999) with perhaps the latter discipline making explicit the analysis of the social determinants of health. However, the term "social" has also been used to contrast with the "individual" and especially individualist theories of society. And so for some, social epidemiology and its social theories of disease distribution stand in contrast to individualistic epidemiology, which relies on individualistic theories of disease causation (Krieger 2001a).

The idea that social conditions influence health is not new. Chadwick (Flinn 1965) wrote about the insanitary conditions of the working classes and how overcrowding, damp, and filth contributed to their lower life expectancy. Durkheim (1897) wrote about how social norms and conditions affect risks of suicide in the population. Social epidemiology builds and expands on this literature by posing new research questions, utilizing new research methods and influencing government policy agenda. The rest of this chapter will discuss each of these three developments in social epidemiology.

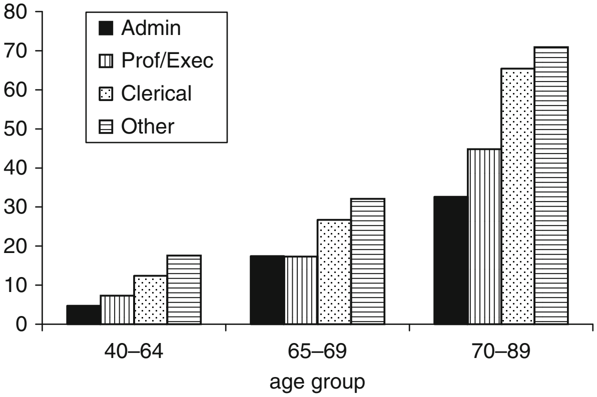
41.2 Research Questions

41.2.1 The Social Determinants of Health

If the social environment is an important cause of health, this is likely to be manifested as social inequalities in health. People from better social environments with greater access to socioeconomic resources are likely to have better health. Supporting this view, social inequalities in health have been documented for most countries, for most causes of deaths and diseases, and in most age-groups. People from lower socioeconomic backgrounds are more likely to be unhealthier and have lower life expectancies, even in the richest countries. In Fig. 41.1, from the first Whitehall study on the health of civil servants in the United Kingdom (Marmot and Shipley 1996), men in the lowest, office support employment grades have mortality rates four times that of men in the highest administrative grade in the youngest age-group. This difference in mortality between hierarchies in the civil service remains even after retirement among men in the oldest age-group. What remains unclear are the pathways leading from the social structure to health or the social determinants of health.

There have been a number of attempts to delineate the pathways underlying the social determinants of health. One such example is illustrated in Fig. 41.2 (from the Commission on Social Determinants of Health (CSDH) 2008). The socioeconomic

Fig. 41.1 All-cause mortality per 1,000 person-years by employment grade: Whitehall men, 25-year follow up (From Marmot and Shipley 1996)



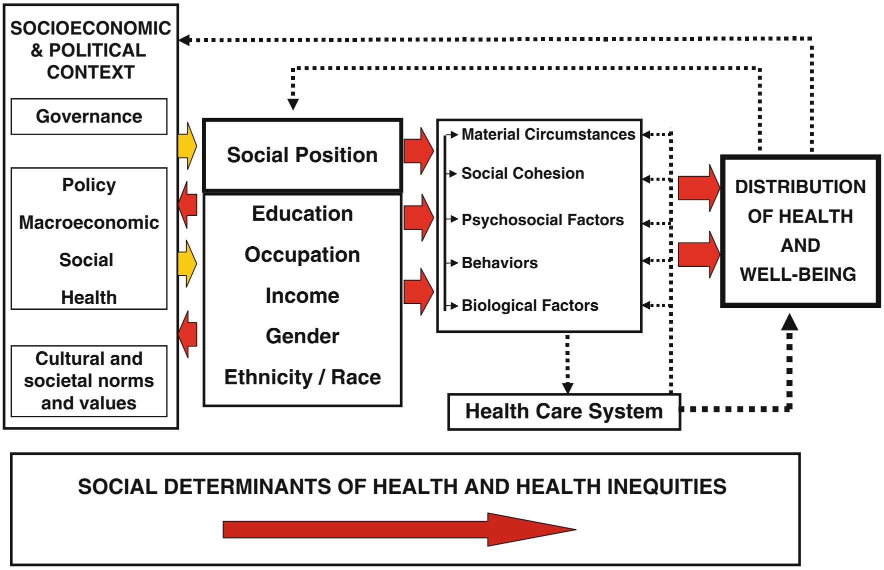


Fig. 41.2 Conceptual framework on social determinants of health. Commission on Social Determinants of Health Final Report (CSDH 2008)

and political context influences the structural determinants of inequalities (social class, gender, race, education) which in turn affect the conditions in which people live, work, and grow, resulting in an unequal distribution of health in the population. In this conceptualization, taking action on the social determinants of health requires action at different levels. On an individual and household level, these include taking action on material and stressful living and working conditions, changing unhealthy behaviors and increasing access to quality health care. On a social level, these also include taking action on the macropolitical and macroeconomic processes that result in unequal employment and educational opportunities and gender and racial discrimination.

There has been relatively little testing of these pathways between social structure and health, primarily because to date, there have been little data available to test all these pathways. However, a few studies have examined some of these pathways and their contribution toward understanding social inequalities in health. The rest of this section will highlight some of the research on the search for the social determinants of health.

41.2.2 Health Behaviors

People from lower socioeconomic groups are more likely to smoke, drink alcohol excessively, and have less physical exercise and unhealthier diets. It is likely that such unhealthy behaviors form part of the pathways underlying social inequalities in health. Poor people in the UK are less likely than those who are well-off to eat a good diet, more likely to have a sedentary lifestyle, more likely to be obese, and more likely to be regularly drunk (Fig. 41.3, from Colhoun and Prescott-Clarke 1996).

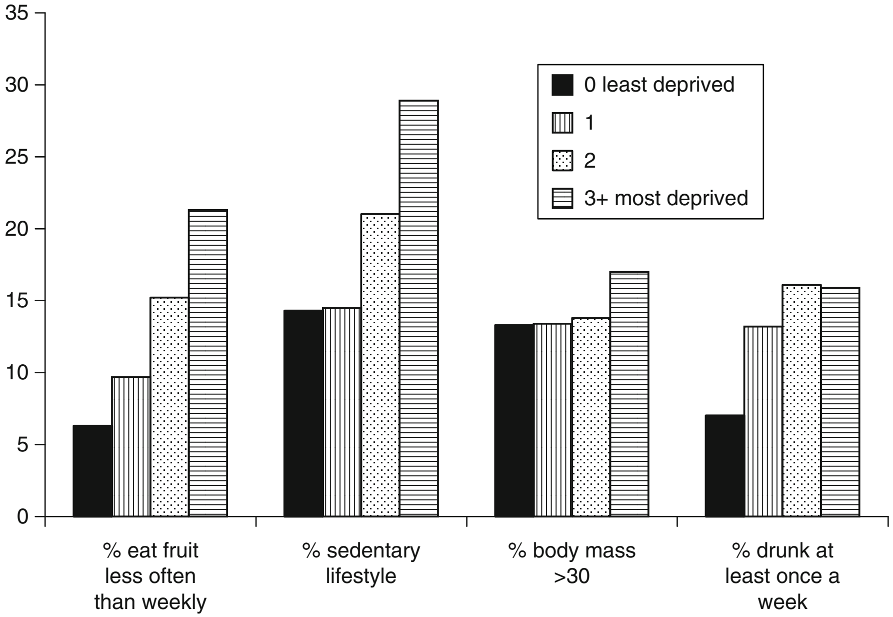

Fig. 41.3 Distribution of some health behaviors among men by level of socioeconomic deprivation (From Colhoun and Prescott-Clarke 1996)

Some studies have analyzed the contribution of such health behaviors to explaining the social gradient in health and have found that a substantial social gradient in health still remains even after adjusting for such (un)healthy lifestyles (Marmot et al. 1978). So there may be other social determinants of health not directly related to health behaviors, as suggested by the pathways through work and material factors in Fig. 41.2. Some evidence of these other pathways is discussed in Sects. 41.2.3–41.2.7.

Lynch et al. (1997) argue that we still need to understand why poor people behave poorly. Without some understanding of how the social environment influences behavior (through, e.g., social norms or environments which may be health damaging or health promoting such as workplace restrictions on smoking or stressful environments for which smoking may be an effective, albeit temporary coping strategy), interventions to modify behavioral risk factors may not be successful.

41.2.3 Material, Economic and Political Determinants of Health

The link between health and material or socioeconomic circumstances has been observed at least since mid-nineteenth-century Britain, if not earlier. Chadwick (Flinn 1965) wrote about how overcrowding and damp and filthy living conditions contributed to the lower life expectancy of working class men. In 1848, partly through fear of cholera and partly through pressure from Chadwick, the British parliament passed the first Public Health Act. This, in addition to the pioneering work of the epidemiologist Snow (1855), set in motion the public health movement in nineteenth-century Britain which saw improvements in housing, sewage and drainage, water supply, and contagious diseases and provided Britain with the most extensive public health system in the world.

It has also been argued that much of the decrease in the mortality rate in the nineteenth and early twentieth century was primarily due to better nutrition in the population which led to increased host resistance to opportunistic infections (McKeown 1979). The driver behind better diets in the general population can be traced to economic growth which made nutritious foods more easily affordable by most of the population. Others, like Szreter (1988), argue that the public health movement of the mid nineteenth century in the UK also played an important role in combating deaths due to infectious disease. It is likely that a combination of macroeconomic factors (economic growth) and public policies (public health measures) led to the overall decreases in mortality rates due to infectious diseases and increases in life expectancy.

In twentieth-century industrialized societies, infectious diseases played an increasingly smaller role in causing deaths, while chronic diseases such as heart disease and cancers caused the majority of deaths. Although people from poorer social classes are more susceptible to such chronic diseases (repeating the patterns of infectious diseases like cholera in nineteenth-century Britain), the mechanisms underlying this social patterning of chronic diseases are not easy to specify. A single infectious agent such as a bacterial agent which thrives in unhygienic circumstances is unlikely to account for why poorer, less advantaged people have more heart attacks.

Some authors argue that, even today, economic and political processes are the fundamental determinants of health and disease (Coburn 2000; Navarro and Shi 2001). Determinants of health can be analyzed in terms of who benefits from specific government policies and practices. Economic and political institutions and decisions that create, enforce, and perpetuate social inequality also create and maintain social inequalities in health. For example, neoliberal (market oriented) policies which favor the dismantling of the welfare state may help to widen existing social inequalities in health. Navarro and Shi (2001) found that countries with more economic and social redistributive policies (Sweden, Finland, Norway, Denmark, and Austria) were more successful in improving the health of their populations (reducing their infant mortality rate). In contrast, neoliberal countries (Canada, United States, United Kingdom, Ireland) where the market reigns supreme and the welfare state is the weakest had the lowest rates of improvements in the infant mortality rates. The substantial decline in life expectancy in Russia in the 1990s has been linked to its transition to a neoliberal economy (Walberg et al. 1998).

41.2.4 Life Course

The idea that a person’s experiences over a lifetime can have a cumulative effect on their health is a central idea within social epidemiology. The study of long-term effects of physical and social exposures during gestation, childhood, adolescence, young adulthood, and later adult life on the risk of chronic disease has been defined as a life course approach to chronic disease epidemiology (Ben-Shlomo and Kuh 2002; see also chapter ►Life Course Epidemiology of this handbook). Such studies include biological, behavioral, and psychosocial pathways that operate over an individual’s life course, as well as across generations, to influence the course of chronic disease. However, it is only in fairly recent years that adequate data and appropriate statistical methods have been made available to test the hypotheses associated with a developmental and life course perspective.

A systematic review on the evidence of different ways in which socioeconomic position over the life course could affect cardiovascular health described four common life course models (Pollitt et al. 2005). The first is a latency model (or “critical period”) of early socioeconomic disadvantage which affects cardiovascular health later on in adulthood independent of intervening socioeconomic circumstances (Power and Hertzman 1997). Barker found evidence that birthweight and other indicators of fetal growth in the newborn are related to fibrinogen and insulin resistance 50 years later (Barker 1991, 1997). Low birthweight is also associated with poorer childhood health which some researchers have linked to lower social position in adulthood (Illsley 1986). Others suggest that there are “sensitive periods” during a child’s development when exposure to socioeconomic advantage or disadvantage is critical for later life health (Hertzman et al. 2001).

The second is the pathway model (Kuh and Ben-Shlomo 1997) in which exposure to socioeconomic disadvantage influences later life socioeconomic position resulting in “social chains of risk.” For example, childhood circumstances may not affect adult risk of ill health and disease directly. It is possible that parental social class and educational qualifications are important because they help to determine the social circumstances in which the offspring lives and works in adult life, and it is these circumstances that give rise to social inequalities in disease. Some studies have found the relationship of education on adult health can be explained in terms of occupational class and income (Davey Smith et al. 1998).

The third is a social mobility model in which upward or downward social mobility affects health, although there is disagreement over whether such social mobility results in wider (West 1991) or narrower (Bartley and Plewis 1997) social inequalities in health. The fourth is a cumulative model in which the accumulation (but not the interaction) of socioeconomic disadvantage throughout the life course affects health (Davey Smith and Lynch 2004), but the timing of exposure to disadvantage (whether in childhood or in adulthood e.g.) is not important.

These four models of life course socioeconomic factors overlap conceptually. For example, the pathway model is a special case of the accumulation model in which early socioeconomic position does not have a direct effect on later life health independent of later life socioeconomic pathways. Similarly, the social mobility model is analogous to a critical period model with later life effect modification, where the exposure to early life disadvantage is either enhanced or diminished by later life socioeconomic position (Mishra et al. 2009). The review by Pollitt et al. (2005) found moderate support for the role of socioeconomic disadvantage in childhood as a critical period for risk of cardiovascular disease, little support for the effect of social mobility, and consistent support for the accumulation model of socioeconomic disadvantage. From a social epidemiological perspective, the lack of evidence for the social mobility model is perhaps a little disappointing, as evidence for these models could potentially provide a way of reducing the negative health consequences of exposure to early life disadvantage. However, the Pollitt review also mentions considerable methodological issues in the analyses of all life course models and advocates the use of multiple socioeconomic measures and multiple life course analytical approaches in understanding chronic disease epidemiology.

41.2.5 Social Biology

Human beings are both social and biological, and understanding the interaction between the two is crucial to understanding the social determinants of health. The biological processes that underlie the social determinants of health make explicit the pathways from psychosocial factors to biological responses. Psychosocial factors may affect health in two distinct ways – they may directly cause biological changes which predispose to disease, or they may, indirectly, influence behaviors such as smoking and diet, which in turn affects health (Brunner 2000).

The direct effect of psychosocial factors on biology may be through the experience of chronic stresses which in turn modify neuroendocrine and physiological functioning (Selye 1956). Humans are adapted to meet the challenge of short-term threats. However, frequent and prolonged activation of the fight-or-flight response or defense reaction appear to be maladapted (Sapolsky 1993). The main axes of the neuroendocrine response appear to be the sympathoadrenal and hypothalamic-pituitary-adrenal (HPA) systems (Brunner 2000). The former, the sympathoadrenal system, is characterized by the rapid release of adrenaline from the adrenal medulla and noradrenaline from the sympathetic nerve endings, which produces, among other things, cognitive arousal, raised blood pressure, and glucose mobilization. There is evidence of wide variations between individuals in the size and duration of these endocrine responses attributed to individual differences in psychological coping resources (Grossman 1991). The HPA system involves cortisol release from the adrenal cortex. Like the sympathoadrenal system, functioning of the HPA axis also appears to be conditioned by psychosocial factors (Hellhammer et al. 1997). Lower social position is associated with prolonged elevations or cortisol release or blunted responses from a raised baseline (Suomi 1997). These patterns of cortisol secretion differ from the normal sharp response and rapid return to a low baseline. A comparison of Swedish and Lithuanian men given a stress test revealed higher morning cortisols and blunted reactivity among the low-income group drawn from the higher coronary risk Lithuanian population (Kristenson et al. 1998). Low socioeconomic position among British civil servants (the Whitehall II cohort) is associated with blunted cortisol reactivity in terms of a flatter slope in the diurnal cortisol profile (Kumari et al. 2010).

There is some evidence for the hypothesis that psychosocial factors directly affect neuroendocrine mechanisms which result in social inequalities in coronary heart disease. Hostility and anxiety have been linked with reduced heart rate variability (HRV) which refers to the beat-to-beat alterations in heart rate (Hemingway et al. 1998). HRV appears to be sensitive and responsive to acute stress as well as a marker of cumulative wear and tear. HRV has been shown to decline with the aging process which has been attributed to a decrease in efferent vagal tone and reduced beta-adrenergic responsiveness. By contrast, regular physical activity (which slows down the aging process) has been shown to raise HRV, presumably by increasing vagal tone.

The metabolic syndrome is a well-known precursor state to coronary heart disease (CHD) and is linked with increased risk of type 2 diabetes. The main components of the metabolic syndrome are impaired glucose tolerance, insulin resistance, and disturbances of lipoprotein metabolism characterized by raised serum triglycerides and low HDL cholesterol (Seidell et al. 1990). Although the link between the metabolic syndrome and CHD is well established, the association between psychosocial factors and the metabolic syndrome is less certain. Central obesity and other components of the metabolic syndrome are consistently related to low socioeconomic position in industrialized countries (Brunner et al. 1993; Kaplan and Keil 1993). It is possible that chronic psychosocial stresses result (directly) in the metabolic syndrome pattern of abnormalities through the activation of the HPA axis. Increased HPA activity results in redistribution of body fat, leading to central obesity, hypertension, and type 2 diabetes, as found in Cushing's syndrome (Howlet et al. 1985). The alternative explanation is that psychosocial stresses lead to unhealthy behaviors (smoking, inappropriate diets).

However, in the Whitehall II cohort, adjusting for health behaviors did not change the social gradient in the metabolic syndrome, suggesting a direct neuroendocrine effect (Brunner et al. 1997).

Infectious disease may also contribute to social differences in morbidity. *Helicobacter pylori* infection, acquired in childhood, is linked with deprivation and overcrowded housing and may produce long-term low-level systemic inflammatory responses which enhance atherogenesis. In Whitehall II, lower employment grade in the civil service is linked to raised fibrinogen (Brunner et al. 1995) and higher concentrations of CRP and IL-6 (Gimeno et al. 2007).

41.2.5.1 Epigenetic Changes in Relation to Social Conditions

While it is unlikely that there are social position differences in genetic structure (Holtzman 2002), how genes are expressed may be related to social conditions. Whether a gene makes its product (gene expression) can be influenced by "epigenetic" processes, so called because the change in gene expression occurs without a change in DNA structure. In many cases, the epigenetic process is the methylation of DNA – the DNA molecule is chemically modified by the addition of methyl residues which confer a change in gene expression. Pertinent to the latency life course model, one of the best-known examples of this phenomenon in humans is the demonstration of persistent epigenetic differences associated with famine in utero. In this example, individuals aged 58 on average who were exposed to famine in utero in early pregnancy had different rates of methylation of a gene involved in growth (IGF-2) compared to non-exposed siblings (Heijmans et al. 2008).

After birth, studies focus on the maternal/neonatal interactions and their association with long-term changes in gene expression. In animal studies, experiments have focussed on long-term changes in neuroendocrine function, specifically in the hypothalamic-pituitary-adrenal axis and a receptor within this system, the glucocorticoid receptor. For example, a number of studies have demonstrated that the epigenetic status of the glucocorticoid receptor gene promoter is regulated by parental care during early postnatal development in rats (Meaney and Szyf 2005).

Data in humans are currently lacking, but early evidence may suggest that the social environment early in life has a long-lasting biological and health impact via epigenetic marking of specific genes. For example, methylation profile of the glucocorticoid receptor is different in those that have committed suicide associated with childhood maltreatment relative to controls (McGowan et al. 2009). DNA methylation is potentially reversible (Weaver et al. 2004), making this process subject to a number of life course processes; however, these remain to be determined in human studies.

41.2.6 Ecological Perspectives

In the UK and elsewhere, there are marked differences in health between areas. People living in areas with higher levels of poverty have poorer health on average and lower average life expectancy. However, explanations for these area differences in health remain debatable. Some argue that excess mortality in deprived areas can be wholly explained by the concentration of poorer people in those areas (Slogett and Joshi 1994; Duncan et al. 1993). In other words, the compositional or aggregate effect of poor individuals (each of whom has lower than average life expectancy) in an area explains the lower average life expectancy for the area. Others argue that such compositional effects cannot entirely explain area differences in health (Diez-Roux et al. 1997). They point out that even after adjusting for the composition of individuals living in an area (such as their income and wealth levels), significant area differences in health remain. They argue that there may be contextual or ecological reasons for area differences in health, explanations which may not be reduced to an aggregation of the individuals living in the area. For example, particular characteristics of an area such as its pollution levels or its lack of medical services may have an impact on the health of everyone living in that area (Macintyre et al. 1993). Research from the United States has found that states with lower levels of trust have higher rates of violent crime, including homicide (Kawachi et al. 1999a). Such contextual effects may also interact with an individual's characteristics, and this combined interaction may alter their risk of disease. For example, the lack of medical services may have a greater impact on the health of poor people living in an area compared to richer people who may have the resources to travel or access medical services outside their local area. Such ecological or contextual characteristics clearly form part of the social determinants of health and may play some role in explaining social inequalities in (individual) health.

Ecological approaches were disfavored for many years in social epidemiology (Macintyre and Ellaway 2000). Although public health practitioners in the nineteenth and early twentieth centuries focused on dealing with health damaging and promoting environments such as sewage, clean water, housing, and physical working conditions, the decline in infectious diseases led to less emphasis being placed on such ecological factors. The rediscovery of social inequalities in health toward the end of the twentieth century focussed primarily on the role of individual health-risk factors such as behaviors, low income, lack of employment and education, and a relative neglect of contextual or environmental determinants of health. This neglect has been explicitly addressed in the most recent literature with multilevel analyses that explicitly take into account compositional and contextual social factors that affect health (Macintyre and Ellaway 2000).

41.2.7 General Susceptibility to Disease

According to the general susceptibility hypothesis (Syme and Berkman 1976), social factors influence disease by creating a vulnerability or susceptibility to disease in general rather than to any specific disorder. This idea was built on the observation that many social conditions are linked to a broad range of diseases. While behavioral, environmental, biological and genetic factors influence specific diseases, these factors may interact with socially stressful conditions in the development of these diseases, resulting in illness and early mortality.

As discussed above, research from social biology shows that some stressful experiences activate multiple hormones, affecting multiple systems and potentially producing wide-ranging organ damage. The cumulative experience of stress may affect a variety of chronic and infectious diseases through neuroendocrine-mediated biological pathways. There are a number of different sources of stressful experiences, some of which are discussed below. The linking of such stressful experiences (often measured using psychological concepts) to wider social circumstances has been called a psychosocial approach to understanding the social determinants of health.

41.2.7.1 Social Support

The effect of social support and social networks on health has been researched (at least) since the late nineteenth century when Durkheim investigated the links between social integration and suicide. He explained suicide in terms of social dynamics, arguing that suicide is not an isolated individual tragedy but a reflection of social conditions such as the lack of attachment and regulation in society. Attachment is also a core concept for Bowlby (1969) who argued that marriage is the adult equivalent of childhood attachment between mother and child. Secure attachment, whether in terms of parent-child or marital relationships, provides for successful and healthy development. Men who have never married or have recently divorced have a significantly greater risk of dying from both cardiovascular and non-cardiovascular diseases than married men (Ebrahim et al. 1995). Married women are generally healthier than unmarried women as well, although the health benefits of marriage may not be particularly strong for employed women (Waldron et al. 1996).

Throughout the 1970s and 1980s, a series of studies appeared which consistently showed that the lack of social ties or social networks predicted mortality from almost every cause of death (Berkman 1995). Social ties and networks were measured in terms of numbers of close friends and relatives, marital status, and membership in religious or voluntary associations. Since then, studies have gone on to focus on the provision of social support rather than on the elaboration of the structural aspects of social networks. Not all social ties or networks are supportive, and there is variation in the type, frequency, and extent of support provided. Social support, in theory, can be divided into emotional support (usually provided by a confidant or intimate other), instrumental support (or help in kind, money, or labor), appraisal support (help in decision making), and informational support (provision of advice or information). Lack of emotional support has been linked to early cardiovascular disease mortality among both men and women and younger and older people (Berkman et al. 1992). Other studies have found that social integration, particularly operating though emotional support, influence recovery from strokes (Berkman and Glass 2000). However, this is contradicted by evidence from a randomized control trial aimed at improving social support and reducing depression in postmyocardial infarction patients. The ENRICHD study found no difference in survival between the control and intervention (which had increased social support and lower depression) groups (Berkman et al. 2003).

41.2.7.2 Social Disorganization

Social scientists have puzzled over why some societies seem to prosper, possess effective political institutions, and have better health outcomes compared to other societies. One of the hypotheses that has been proposed to explain this difference between societies is the amount of social capital or cohesion (and its converse – social disorganization) in a particular society (Coleman 1988; Putnam 2000). Social cohesion refers to the extent of connectedness and solidarity among groups in society. A cohesive society has greater amounts of social capital (higher levels of interpersonal trust, reciprocity, and mutual aid) than a disorganized society. There is emerging evidence that greater social capital is linked to lower mortality rates as well as better self-rated health (Kawachi and Berkman 2000). As mentioned in Sect. 41.2.6, states in the United States with lower levels of trust have higher homicide rates (Kawachi et al. 1999a). Even after adjusting for individual risk factors for poor self-rated health (e.g., low income, low education, smoking, obesity, lack of access to health care), individuals living in US states with low social capital were at increased risk of poor self-rated health (Kawachi et al. 1999b). Such results suggest that there are contextual explanations for area differences in health, as discussed in the section on ecological perspectives.

Social capital may be linked to health through a number of different mechanisms. We have already discussed two types of explanations for understanding area differences in health – compositional and contextual explanations. Socially isolated individuals (not having contacts with friends or relatives, not belonging to any groups) are more likely to be living in communities with lower social capital, so the association between social capital and health may be the compositional effect of the aggregation of socially isolated individuals. However, there may be other pathways by which social capital affects health (Kawachi and Berkman 2000):

1. Through health-related behaviors. Social capital may influence the health behaviors of neighborhood residents by exerting social control over deviant behaviors such as adolescent smoking, drinking, and drug abuse.
2. Through access to services. Socially cohesive neighborhoods are more successful at organization access to services such as transport, health services, and recreational facilities
3. Through psychosocial processes. Socially disorganized neighborhoods with low social capital could have higher levels of fear of crime and other stressors which could negatively impact on the residents' health.

41.2.7.3 Work Stress

One of the more established results in epidemiology has been the link between physical working conditions and health. Reports on occupational health have highlighted the link between emphysema and other lung disease with coal mining, musculoskeletal disorders, and accidents with certain types of manual work. In recent years, there has been increased research on work-related stress and how that affects both physical and mental health.

There are two dominant models of work stress in the literature. The first, the job strain model is based on the concepts of job control and demands (Karasek et al. 1981). Workers with low levels of job control and high levels of demand are said to have high levels of job strain (or work stress). In addition, workers with job strain who have unsupportive managers or colleagues (isolated job strain or iso-strain) have particularly high levels of work stress. Job control (or decision latitude) consists of whether or not workers are able to utilize and develop skills (skill discretion) and their authority over decisions. Job demands consist of qualitative emotional demands as well as quantitative demands specifying output per unit of time. Prolonged and repeated exposure to job strain is hypothesized to increase sympathoadrenal arousal and decrease the body's ability to restore and repair tissues which in turn affects health (Chandola et al. 2008). Civil servants in the UK with greater duration of exposure to job strain and iso-strain have higher risks of cardiovascular disease (Chandola et al. 2006, 2008).

The other model of work stress, the effort-reward imbalance model (Siegrist 1996), hypothesizes that the degree to which workers are rewarded for their efforts is crucial for their health. When a high degree of effort does not meet a high degree of reward, emotional tensions arise and the risk of illness increases. Effort is the individual's response to their job demands, and this response may be extrinsic effort (referring to the individual's effort to cope with external job demands) and intrinsic effort (referring to the individual's drive to fulfill their goals). Reward can be measured through financial rewards, self-esteem, and social control. While there is some overlap between the job strain and effort reward imbalance models, the former is entirely focussed on the organization of the structure of work, while the latter includes the individual's way or coping methods of handling difficulties (through the concept of intrinsic effort).

There is some evidence that both models of work stress contribute independently of one another to predicting coronary heart disease events (Bosma et al. 1998). The cumulative adverse health impact of low job control and effort-reward imbalance indicates that both job stress factors provide supplementary information on the relevant stressors in the psychosocial work environment.

41.2.7.4 Unemployment and Job Loss

There has been considerable research into the effects of unemployment and job loss on health. However, this is an area of research that is particularly sensitive to the claims of "health selection," that the reason why unemployment is associated with ill health is because ill health selects people out of employment. The reverse argument is that a disadvantaged socioeconomic position has an effect on a stable job career (and the risk of unemployment) as well as health. It is therefore important to disentangle the causal narrative in studies about unemployment and health and find out which comes first.

The evidence on unemployment and health supports both the social causation and health selection interpretations. In a review of the effect of unemployment on health, Kasl and Jones (2000) summarized the evidence as follows:

1. Unemployment is associated with a 20–30% excess in all-cause mortality in most studies.
2. There is some evidence of the impact of unemployment on physical morbidity but with results that are more difficult to interpret.
3. Unemployment is linked to biological indicators of stress reactivity.
4. Unemployment is associated with behavioral and lifestyle risk factors, although the direction of causality is hard to disentangle.
5. Unemployment clearly increases psychological distress.
6. Threatened job loss (job insecurity) is associated with physical and psychological morbidity and cardiovascular risk. The anticipation of job loss affects health even before changes in employment status (Ferrie et al. 1995).

41.2.7.5 Depression and Affective States

Depression is one of the most common psychiatric problems and is also common in patients with chronic medical conditions. Some depressive episodes are brought upon by physical illness, but many depressive patients have depressive episodes long before they develop any physical symptoms of illness. Furthermore, depression may alter the course and outcome of physical illness (Carney and Feedland 2000).

Depression has been associated with immunological dysfunction. Patients with major depression have been found to have blunted natural killer cell activity (Maes et al. 1994), increasing their risk for many acute and chronic illnesses. There is also some evidence that depression may play a causal role in the development of heart disease. There is some evidence of a social gradient in depression in a healthy, working population – it appears to be more common among those from poorer, more disadvantaged social positions (Stansfeld et al. 1998) and may originate from their lower control over aspects of their work and home environment (Griffin et al. 2002).

Another set of psychological pathways by which social conditions may affect health is through emotions and the physiological, cognitive, and behavioral responses they evoke. Emotions may be transitory states brought on by specific situations or traits, i.e., stable and general dispositions to experience particular emotions (Spielberger and Krasner 1988). Much of the research on emotion and health has been carried out in relation to coronary heart disease. Much of this literature has focussed on type A behavior (which includes a free-floating but well-rationalized hostility, hyperaggressiveness, and a sense of time urgency), chronic anger and hostility, anxiety, and a mixture of emotions associated with depression including hopelessness, loneliness, guilt, and shame (Kubzansky and Kawachi 2000).

There is some evidence of a social patterning of emotions (Bradburn 1969; Mroczek and Kolarz 1998). Kemper (1993) suggests that many emotions are responses to power and status differentials embedded within social situations. Potentially stressful events can be associated with a variety of different emotions. Emotions can be considered as products of stress as well as mediators of its effects, thus representing a crucial link in the chain of causation from social stressors to individual biological responses (Spielberger and Krasner 1988). Evidence from animal studies suggests that additional to hypothalamic control of the stress response, areas of the brain involved with emotional or affective responses such as the limbic system also play a major role in stress responses (Menzhaghi et al. 1993) and adaptation to the stress response (Sapolsky et al. 1986).

41.3 Research Methods

41.3.1 Applying a Population Perspective

Rose (1992) proposed that an individual's risk of illness cannot be considered in isolation from the risk of disease of the population to which they belong. For example, the distribution of cholesterol levels in the Finnish population is shifted to the right of the Japanese distribution – on average, Finnish people have higher cholesterol levels than Japanese people. The level of "normal" cholesterol for the Finnish population would be "abnormal" for the Japanese population and would be a risk factor for CHD in the latter population. Applying the population perspective into epidemiological research means asking "why does this population have this particular distribution of risk factors," in addition to asking "why did a particular individual get sick?" (Berkman and Kawachi 2000). Answering the second question has been the focus of clinical medicine, while answering the first question is the key to the largest improvements in the health of the population as it focuses attention on the majority of cases of illness within the bulk of the population. Medical care can prolong survival after some serious diseases, but the social and economic conditions that affect whether people become ill are more important for health gains in the population as a whole.

41.3.2 Better Measures of Social Exposures

There is no simple relationship between social-structural conditions such as income distribution and welfare state regimes on the one hand and health inequalities in the population on the other. The different pathways by which social factors can have an effect on different health outcomes implies that there is no single measure of socioeconomic position that can represent all of these social dimensions. However, it is common for epidemiological studies to state they have taken account of the confounding effects of socioeconomic position by adjusting for a single crude measure of socioeconomic position (SEP). The possibility that the measure of SEP does not adequately measure the different dimensions of SEP in the population, at different stages of the life course, is seldom considered in standard epidemiological analyses.

Measures of socioeconomic position are not interchangeable. The Commission on Social Determinants of Health (Kelly et al. 2007) identified the structural determinants of health inequalities as the social processes by which inequalities are generated and reinforced; these include social (occupational) class, power, status, and education.

Many epidemiological studies only measure a single measure of socioeconomic position, most commonly education. Although education is relatively easy to measure (either in terms of years spent in education or in terms of highest qualifications obtained), it has the major limitations. Education is largely invariant over the adult life course, and it is hard to conceptualize of downward social mobility in terms of education (hence, it is not really a measure of "position"). Education predicts but does not directly measure adult socioeconomic position, thus resulting in biased estimates of adult socioeconomic position in many epidemiological studies.

Income, wealth, and assets are good indicators of a person's position in the labor market as well as their material standards of living. Higher levels of income and wealth enable greater access to and greater consumption of health promoting resources and services. Accurate measurements of income require detailed information from multiple income streams from all individuals in the same household which is not always possible in surveys. Data on income are often sensitive. People are not willing to disclose how much they earn, resulting in a large proportion of non-response or missing data from surveys on income. Many studies use proxy measures of material living standards such as entitlements to social security benefits, possession of consumer goods and assets, wealth, car ownership and house ownership, (or "consumption" measures) which are less prone to non-response bias. Wealth represents the total value of a person's or household's assets. These can be a wide variety of assets and require valuation of non-monetary assets such as land and housing, which are difficult to estimate and measure. Some argue that consumption expenditure is a more accurate representative of long-term economic status than income (Friedman 1957). This is because income is subjective to greater fluctuations, whereas individuals and households may base their consumption decisions on their planned and anticipated ("permanent") income rather than their current income levels.

In the developed world, some authors argue that occupational class is the key measure of SEP (Rose and Pevalin 2002). A review of measurement of social circumstances concluded that a classification based on occupation was essential to understanding social inequality (Rose and Pevalin 2002). Some argue that occupation is the key variable in the accumulation of advantages and disadvantages over a person's life course. Occupation can be regarded as the means by which a person's principal resource (education) is converted into an important reward (income). As occupation links these two sets of advantages, it is a greater measure of accumulated advantages than either one alone.

Different countries often have national occupational class schemas which makes cross-country comparisons difficult. However, the International Labor Organization has developed the International Standard Classification of Occupations based on two main concepts: the kind of work performed and the skill involved. Another limitation of occupational class is the lack of comprehensive population coverage – vulnerable groups such as children, women, and the elderly often have to be classified by proxy measures of social class in which case, these social class measures no longer reflect differences in employment conditions, but rather they reflect differences between households in membership of particular occupations.

41.3.3 Better Measures of Health

The concept of health is multidimensional (the WHO definition states that health is a state of complete physical, mental, and social well-being), including hard to measure concepts like quality of life. Research in social epidemiology does not just focus on clinically measured disease outcomes because the absence of disease is not sufficient for health. Rather, one of the main focuses of social epidemiological research is the use of health-related quality of life measures as valid measures of health outcomes (Fitzpatrick et al. 1992). Population mortality statistics tell us little about the health of general populations in developed countries. The use of standardized health-related quality of life measures in different countries (Ware and Gandek 1998) enables international comparisons of physical, mental, and social well-being.

Subjective health status covers a wide variety of areas, including role functioning (e.g., the ability to perform domestic and work tasks), the degree of social and community interaction, psychological well-being, pain, tiredness, and satisfaction with life (Bowling 2003). Health-related quality of life has come to mean a combination of subjectively assessed measures of health, including physical function, social function, emotional or mental state, burden of symptoms, and sense of well-being (Coulter 1993). Some of these patient-based measures of health status are reviewed in chapter ▸Health Services Research of this handbook. Concepts of health-related quality of life adjusted measures of life expectancy such as disability-adjusted life years (DALYs) and quality-adjusted life years (QALYs) are also reviewed in this chapter.

41.3.4 Better Measures of the Association Between the Social Structure and Health

Social epidemiology has typically relied on observational studies to describe the effect of social factors on health such as social inequalities in health. As associations described in observational studies may be subject to confounding bias, especially from unmeasured confounders, it is hard to draw causal inference from most social epidemiological studies. There are many examples of how results from observational studies in social epidemiology have not been replicated in randomized control trials (Berkman 2008), although there have also been examples where randomized control trials have replicated results from observational social epidemiology studies (Howden-Chapman et al. 2007).

Methodological advances in social epidemiology in using propensity score matching (Oakes and Johnson 2006), natural experiments and instrumental variables (Glymour 2006), and controlled community trials (Hannan 2006) offer new ways of building causal and explanatory models. Standard multiple regression procedures do not necessarily advance a causal understanding of the social determinants of health. For example, as different measures of the social structure may have different pathways to different health outcomes, the reduction of such differences into a single regression model may obscure rather than elucidate the pathways underlying the social determinants of health. Furthermore, different dimensions of the social structure may influence people's health at different time points of the life course. For example, in industrialized societies, the period of the life course when compulsory education is completed may be a crucial time for the health of the population, not because young adults are at a particular high risk of disease or illness at that stage in life but because educational qualifications are a strong determinant of social position in later adult life which in turn appear to be strongly linked to health outcomes later on in life. It is important to take account of the life course temporal and causal ordering of the various measures of social position and use methods that make explicit the various underlying causal pathways between different measures of social position and health.

41.3.5 Analyzing Population Surveys, Birth Cohorts

One of the defining characteristics of research methods in social epidemiology is the use of population representative sample surveys in analyzing the social determinants of health. Research in social epidemiology tends to use non-experimental observational studies, both cross-sectional and longitudinal. All observational studies suffer from problems of causality – it is hard to determine and separate out cause from effect (cf. chapters ▶Basic Concepts and ▶Confounding and Interaction of this handbook). This drawback has necessitated the use and development of complex study designs and analytical methods to disentangle the causal pathways underlying the social determinants of health.

Studies with good methodological designs (e.g., Ferri et al. 2003) in social epidemiology tend to rely on data from large-scale population representative sample surveys because of the complexity of the social structure and the different pathways to health. The representativeness of data is crucial in order to apply a population perspective in social epidemiological research. Smaller-scale samples may not be representative of the broader population.

Birth cohort studies are a special type of such large-scale population representative samples which incorporates a life course approach to epidemiology. The UK has taken a prominent role in the development of such longitudinal studies. The British birth cohort studies of those born in one week of 1946, 1958, and 1970 link data from one part of the life course (from birth onward) to another (childhood, adolescence, adulthood) for a large number of individuals. Comparisons between different birth cohort studies enable the disentangling of age, period, and cohort effects, which could be problematic when analyzing most cross-sectional and even longitudinal sample surveys. For example, in the book, “Changing Lives, Changing Britain” (Ferri et al. 2003), *cohort* effects that might be attributed to socioeconomic change impacting differentially on people born at different times can be differentiated from *age* differences reflecting the different changes between the stages of life, which in turn can be differentiated from the prevailing socioeconomic context at the time of data collection – the *period* effect. Such analyses of this unique set of longitudinal data, incorporating a life course perspective, are very promising for future research into social epidemiology.

41.4 Setting Government Policy Agenda

One of the goals of epidemiology has always been to use what we learn to improve public health. The science of social epidemiology has repeatedly shown evidence that social conditions are a major determinant of health. However, the translation of the research findings of social epidemiology into public policy has not been straightforward. Unlike results from some branches of epidemiology which can be more easily implemented into government guidelines (such as recommended alcohol intake) or public policy (reduction in smoking prevalence), programs to implement findings from social epidemiology need to take into the account the complexity of the pathways from the social structure to health.

Some authors argue that policy interventions are most effective when they are closest to the root causes of disease (Rothman et al. 1998). Interventions at the upstream, social level may not be as efficient as interventions closer to disease occurrence. So, for example, policy interventions on reducing the social gap in smoking-related diseases should focus on interventions on smoking cessation rather than interventions on the social causes of smoking. Others argue (such as Coburn (2000), mentioned in Sect. 41.2.3) that interventions need to be upstream, at the societal and macroeconomic level, in order to successfully reduce health inequalities.

41.4.1 Reports on Inequalities in Health

The Black Report (DHSS 1980) into inequalities in health in the UK had a number of wide-ranging policy recommendations for reducing such inequalities. However, the lack of implementation of these policies by the British government in the 1980s and early 1990s was due, in part, to a lack of political will and the high cost of these policy recommendations.

The change in government in Britain in 1996 (from Conservative to Labor) paved the way for the publication of the Acheson Report (Acheson 1998) on inequalities in health in 1998 with another list of recommendations for reducing health inequalities. The recognition that inequalities in health are evident in every country led the WHO to commission a report on the social determinants of health (CSDH 2008). The commission was established to support countries and global health partners to address the social factors leading to ill health and health inequalities. This has led to many countries commissioning their own reviews of health inequalities and the social determinants of health (http://www.who.int/social_determinants/thecommission/countrywork).

The very fact that social epidemiology deals with the social structure necessitates policies aimed at changing the social structure as well as the intermediate pathways to health. Such policies are not always easy to specify, detail, and enact. Furthermore, the diffuse ownership of such policies between government departments (such as education, health, and treasury departments) makes their implementation harder. In recognition of the complexities of policies aimed at reducing health inequalities, the UK government set up a crosscutting spending review (across various government departments) on tackling health inequalities. This report (Department of Health 2002) explicitly acknowledges that policies on reducing health inequalities need to be coordinated across a wide range of government departments and bodies (not just the national health service), including local government and health organizations and sets in process the institutional framework for such coordination. An evidence-based strategy for reducing health inequalities that includes policies and interventions that address the social determinants of health inequalities has been commissioned in England: the Strategic Review of Health Inequalities in England Post 2010 (The Marmot Review 2010). However, even with evidence-based policy recommendations, political will is also needed for action on health inequalities.

41.4.2 Collating Evidence for Policies Through Intervention Studies and Cross National Comparative Studies

One of the ways of ensuring appropriate policies for reducing inequalities in health are implemented is by studying the results from intervention studies. However, social epidemiological research does not easily lend itself to intervention studies, mainly because the complexity of the social structure makes it hard to disentangle the pathways to reductions in health inequalities. For example, it is hard to disentangle changes from behavioral change interventions from secular trends in society (Susser 1995). It is also difficult to separate out the influence of secondary support (from support groups organized around behavioral interventions) from the intended influence of the behavioral intervention (Spiegel et al. 1989). Social support interventions have had mixed results partly because as relationships develop and change slowly, the benefits of support interventions may be missed in the short term (Glass 2000).

Another method of analyzing policy recommendations for health inequalities is through international and longitudinal comparisons of health inequalities. Changes in taxation and income redistribution policies within a country may be hypothesized to have an effect on health inequalities. Furthermore, cross national longitudinal comparisons of different tax policies and their effect on health inequalities may be another way of analyzing the effect of policies on health inequalities (Navarro and Shi 2001). However, to date, there has been little research in this area which means that current policies on reducing inequalities in health may not be entirely appropriate or well targeted.

41.5 Conclusions

Perhaps, the major contribution of social epidemiology to epidemiology in general has been in rediscovering and analyzing the role of social factors in producing health and illness. This has primarily come about by the literature on social inequalities in health and, consequently, research into the social determinants of health. The search for the pathways between the social structure and health has led to innovations in longitudinal research methodology. While social epidemiology shares common epidemiological problems of reliance on observational studies and problems in interpreting causality, the incorporation of a life course perspective by analyzing and comparing birth cohort studies holds great promise for future studies. Research into social epidemiology has influenced wide ranging government social policies because of the macrosocietal-level interventions that are needed to reduce inequalities in health.

Although there is some debate over the usefulness of the specialization of social epidemiology within the medical sciences (Zielhus and Kiemeney 2001), others have argued that the overall contribution of social epidemiology toward understanding current and changing distributions of population health have been striking (Krieger 2001b; Muntaner 2001). The interdisciplinary nature of social epidemiology has led to the incorporation of research questions, methods, and policy agendas that have enriched our understanding of the social determinants of health.

42.1 Introduction

Occupational epidemiology has the same main goal as the broad field of epidemiology: to identify the causes of disease in a population in order to intervene to remove them. Occupational epidemiology is an exposure-oriented discipline; it is thus the systematic study of illnesses and injuries related to the workplace environment (Checkoway et al. 2004).

The first concern about occupational causes of disease may have been that of Hippocrates, who wrote about the lifestyle habits and environment of populations and patients. Nevertheless, it was the Italian physician Bernardino Ramazzini who recommended that doctors add questions about occupation to those recommended by Hippocrates, and it was Ramazzini who made the first systematic description of occupational diseases and their causes in his book *De Morbis Artificum* (Ramazzini 1964). His descriptions included different characteristics of skin ulceration in freshwater and sea fishermen, silicosis among stonemasons, ocular disorders among glassblowers, and neurological toxicity among tradesmen exposed to mercury. It is noteworthy that he not only described the diseases but was also deeply concerned about the ethics of harmful work practices and the need for preventive measures, such as good ventilation and protective clothing.

Classic historical reports, such as those about scurvy in sailors in 1753, scrotal cancer in chimney sweeps in 1775, respiratory cancers in underground metal miners in 1879, and bladder cancer in dye workers in 1895, are clear examples of the importance of reports of case series by clinicians and by the workers themselves (Carter 2000). New occupational hazards came to light incidentally even in the mid-1900s, when the methodological landmark of the historical cohort study was designed (Doll 1952, 1955; Case et al. 1954) and occupational epidemiology developed as a discipline. Indeed, Case and coauthors suspected that rubber workers would have an elevated risk for bladder cancer while conducting a study on the high incidence of bladder tumors among dye manufacturers (Doll 1975). While reviewing hospital records of bladder cancer patients in Birmingham, England, chosen as a control area because it did not have a dye industry, they noticed that many workers had been employed in a rubber factory. Subsequent investigation confirmed the association with rubber production and showed that it resulted from exposure to an antioxidant containing the carcinogen 2-naphthylamine (Case and Hosker 1954; Coggon 2000).

Occupational epidemiology has contributed to the development of both study designs (such as the historical cohort study) and analytical methods that are now part of the broader field of epidemiology and of other exposure-oriented disciplines. For instance, quantitative and qualitative methods for assessing exposure, such as job-exposure matrices and job-specific questionnaire modules for assessment by experts, were developed by occupational epidemiologists and industrial hygienists. They have now been adapted and used in other disciplines, such as nutritional and environmental epidemiology, and are central to ensuring the validity and informativeness of epidemiological research in general.

Prevention is the final goal of all epidemiological research and findings. Occupational exposure was one of the first causes to be identified of diseases such as cancer and pulmonary illness, and epidemiological study of such exposures often led to the identification of specific causal agents. Occupational hazards are known causes of disease that are amenable to regulatory control and thus especially suitable for prevention. This is in contrast to aspects of lifestyle, such as smoking and dietary habits, for which control requires modification of cultural and personal behavior patterns. Free choice may contribute to some diseases attributable to environmental causes; for instance, the large majority of cases of lung cancer are attributable to tobacco smoking and can be prevented by avoiding the habit. The reason for interest in preventing occupational hazards is more subtle: As personal choice plays little or no role in occupational exposure, the protection of workers warrants special attention. Furthermore, while industrial effluents and products might cause illness in the general population, exposed workers are likely to be the first and most severely affected. Prevention at the level of the working environment will by the same token result in prevention in the general population.

This chapter will address issues in study designs and epidemiological methods as applied in the specific field of occupational epidemiology. They will include dose-response analysis, healthy worker effect, and exposure assessment. Finally, how occupational epidemiology can help to evaluate the need and effectiveness of primary prevention interventions and policies will be described using the example of occupational cancer.

42.2 Study Designs

Classic epidemiological studies, such as cross-sectional (see chapter ►Descriptive Studies of this handbook), case-control (see chapter ►Case-Control Studies of this handbook), and cohort studies (see chapter ►Cohort Studies of this handbook), are commonly carried out in occupational settings. The principles of study design and data analysis are derived from general epidemiological methods; however, some specific aspects are worth addressing.

42.2.1 Cross-Sectional Studies

Cross-sectional studies are generally used to investigate symptoms, sub-clinical outcomes, and physiological functions that are (or are suspected to be) related with an exposure of interest. Examples are wheezing and other respiratory symptoms in relation to exposure to different types of metal-working fluids (Greaves et al. 1997), urinary mutagenicity and DNA adducts in peripheral blood mononuclear cells and urothelial cells in relation with urinary 1-hydroxypyrene levels (Peters et al. 2008), and forced expiratory volume in one second (FEV_1) and diesel exhaust exposure (US Environmental Protection Agency 2002). Cross-sectional studies are also useful in the study of potentially reversible and non-fatal diseases, such as musculoskeletal disorders. For all of such conditions, longitudinal studies are either inappropriate or not practically feasible, and cross-sectional studies are the best study design applicable. It must be born in mind, however, that they measure the prevalence of the outcome of interest, or assess a dose-response relationship, in groups that are often an opportunistic, rather than a representative, random sample of the ideal target population (e.g., all metal or all rubber workers), being made up of the individuals still active at the time of the survey and willing to participate. Therefore, associations between exposure and disease are difficult to interpret, as they could depend either on an increased incidence or on a longer duration of disease among a subgroup of cases. For this reason and for problems of reverse causality arising from measuring exposures and diseases at the same time, which prevents the time sequence between exposure and outcome to be clearly established, the causal nature of an association can be weakly addressed using a cross-sectional approach.

Cross-sectional studies allow the researchers to examine on an ad hoc basis the target population, or a sample of it, and by doing so to study health outcomes that cannot be investigated in longitudinal studies of mortality or incidence. At the same time, they are vulnerable to the effect of non-response, particularly when they are carried out with the main aim of estimating the prevalence of diseases or their symptoms. Diseased workers may participate in the study differently from those who are not diseased, and their willingness to participate may depend on their exposure status. Occupational studies of fertility and sperm quality are an example of studies in which non-response is a critical problem. Since the observation of the toxic effects of 2,3-dibromo-3-chloropropane on testicular germ cells (Potashnik et al. 1978), the fertility of exposed male workers has been investigated in several studies. In one study, groups of traditional and organic farmers were selected randomly from the database of the Danish Ministry of Agriculture in 1995–1996 and invited to participate in a study on semen quality, including total sperm count, sperm concentration, other indices, and serum concentrations of sex hormones (Larsen et al. 1999). A questionnaire eliciting information on previous exposure to pesticides was posted to 1,124 farmers, of whom 86% answered and 256 provided semen samples. This low participation proportion was not unexpected, as the examination required by the study was somewhat demanding.

A further limitation of cross-sectional studies, which is specific to occupational epidemiology, is that only active workers are usually investigated, because the study base is defined as workers employed in a specific industry or exposed to a specific occupational factor. It follows that workers who have terminated their employment cannot be included in the study.

Let us consider the example of the cross-sectional studies on the health effects of exposure to diesel fumes (US Environmental Protection Agency 2002). Acute respiratory effects were investigated in several studies by measuring FEV_1 and other indicators of pulmonary function twice, at the beginning and at the end of a work shift, in workers employed in mines and garages. Chronic respiratory effects were studied through a single survey and a medical examination in workers with different levels of cumulative occupational exposure to diesel exhausts. Individuals who are susceptible to diesel exhaust exposure tend to move from jobs with a high level of exposure. Therefore, a cross-sectional study on the acute effects of exposure is presumably carried out among a selected group of workers, resulting in a possible underestimate of the effects. Regarding chronic effects, which are manifest a long period after the exposure has occurred, there is an underestimate of the association between exposure and disease, if the termination of employment is determined by the disease or its early symptoms.

Notwithstanding these limitations, cross-sectional studies have been successfully carried out on the association between certain exposures and long-term effects, taking advantage of the fact that this study design offers the opportunity to investigate exposures thoroughly. A group of French talc millers received a respiratory health examination in 1989, including a standardized questionnaire on respiratory symptoms, lung function testing, and a chest radiograph (Wild et al. 1995). Systematic measurements of dust concentrations had been made in 1986 and 1989, and, based on the results of the measurement campaigns and of an accurate retrospective reconstruction of past working conditions, a quantitative job-exposure matrix had been developed. The cumulative exposure of all workers included in the respiratory health survey was estimated, by applying the matrix to their work histories. A dose-response relationship between cumulative dose and decline in lung function, prevalence of dispnoea, and chest X-ray opacities could be shown.

The initial survey of a cross-sectional study may become the first phase of a longitudinal study. In the investigation of French talc millers, the same group of workers included in the 1989 respiratory health survey received a second chest X-ray in 1993. An increase was observed in the number of workers with profusion of opacities >1/0, but the increase was not associated with cumulative exposure to talc (Wild et al. 1995).

42.2.2 Cohort Studies

To investigate long-term effects, the cohort study is a valid, but sometimes expensive and time-consuming, design. Nevertheless, the availability of employment records and trade union registries often permits straightforward identification of past occupational cohorts. It is therefore not surprising that historical cohort studies have long been the method of choice in occupational epidemiology, and they have contributed significantly to the identification of occupational hazards.

Researchers usually identify a factory in which the exposure of interest occurs – to specific chemicals and substances or specific working conditions and job tasks – and select the members of the cohort from registries available at the factory. Alternatively, a study population can be identified from similar departments in different factories. Thus, when a single facility does not provide a sufficient number of workers or the time of follow-up is not long enough, a collaborative study can be conducted in similar factories in several centers.

The cohort study of workers employed in the man-made vitreous fiber (MMVF) industry in Europe, coordinated by the International Agency for Research on

Cancer (IARC) (Boffetta et al. 1997, 1999; Sali et al. 1999), is an example of such collaboration. The cohort was assembled in 1977 and consisted of approximately 22,000 workers who had ever been employed in 13 factories producing at least one of three types of MMVF, namely, glass wool, continuous filaments of glass fiber, and rock or slag wool, at any time between the year of starting production of MMVF and 1977. The follow-up ended between 1990 and 1995 in different factories, depending on subsequent updating.

Exposure was assessed on the basis of individual work histories, obtained from employment registries in 1977. It was known that important technological changes had taken place in the production of MMVF over the study period, so that the period of MMVF production was divided into three "technological phases": early, intermediate, and late. As the ambient levels of exposure to MMVF were estimated to have decreased with evolving production processes, the year in which each of the three phases began in each factory was assessed. Information on possible concomitant exposure to other agents, such as asbestos and bitumen, was also obtained for each factory. The researchers thus knew the duration of employment for each worker, by factory, technological phase, and job task.

National mortality rates were used to calculate standardized mortality ratios (*SMR*s) (cf. chapters ▸Rates, Risks, Measures of Association and Impact or ▸Descriptive Studies of this handbook) for neoplastic and non-neoplastic causes of death, and cancer-specific standardized incidence ratios (*SIR*s) were estimated for the subcohorts in countries where cancer incidence rates are available from cancer registries. The effect of duration of employment was estimated in internal comparisons within the cohort, the reference group including workers employed for less than 5 years. Data were also analyzed according to type of MMVF, job task, technological phase, and time since first employment. Data on workers who had been employed for less than 1 year were analyzed separately, as short-term workers might be high-risk individuals with particular lifestyles or occupational exposure to agents other than MMVF (see also Sect. 42.4.2).

In general, MMVF production workers did not have an excess risk of mortality or cancer incidence, although a small excess risk for lung cancer was found among rock- and slag-wool workers, and increased mortality from heart diseases and non-malignant renal diseases was suggested. It is important to note that no information on lifestyle factors was available, which is a limitation of almost all historical cohort studies.

In countries where good, computerized population registries with a long history of registration exist, large occupational cohort studies can be carried out by linkage of information on occupational status from censuses with individual data on, for example, mortality, cancer incidence, and hospital discharges. The strength of record-linkage studies is the very large sample size. An occupational record-linkage study of cancer incidence was conducted in the Nordic countries among persons aged 25–64 years who were listed in the 1970 censuses (Andersen et al. 1999). Overall, about ten million persons were included in the study, and more than 500,000 incident cases of cancer occurred during the follow-up period, which ended between 1987 and 1990, depending on the country. Occupational exposure was evaluated for 54 occupational groups. Many cancer-specific associations were estimated, and they cannot be discussed here; however, the general finding was that risk of cancer is associated with occupation.

This record-linkage study shows clearly that cohort studies can provide risk estimates for many outcomes and some of the findings might be unexpected. For instance, in a historical cohort study of 8,226 workers employed in an aircraft manufacturing factory in northern Italy between 1954 and 1981, an unexpected excess of melanomas was found (6 observed, 1.02 expected cases) (Costa et al. 1989). When an unexpected association is found, the characteristics of the cases, including age, sex, period of employment, factory, and job task, should be explored carefully in order to identify any clusters of jobs or operations that suggest a common exposure. In the example of melanoma, the characteristics of the six cases were described in detail, but no cluster could be identified.

There are two major limitations to the use of data from existing records rather than from ad hoc questionnaires and environmental or biological measurements: lack of detailed information on exposure and lack of information on possible relevant confounders.

With regard to exposure, maximum cooperation between researchers and management, trade unions, occupational physicians, and industrial hygienists is crucial to obtain information on the nature of both industrial processes and working environments. Basic information on the exposure of each worker should include the starting and ending dates of employment at the factory. Unfortunately, important information, such as the job task of each worker and changes in industrial processes over time, is often missing. Even when the job task is recorded, one would like to evaluate also the variability of exposure levels among workers carrying out the same job. The general lack of information may reduce the quality of the data on exposure, whatever approach is used to assess exposure, and finally bias the results of the study because of misclassification. Although it is theoretically possible to measure factory-specific levels of exposure at the time a study is conceived, strong assumptions should hold for a reliable imputation of past exposures.

In some studies, plant-specific ambient measurements had been recorded over time and were available for assessing exposure. A historical cohort of more than 74,000 workers employed between 1972 and 1987 in 672 factories in jobs that entailed exposure to benzene was assembled in China (Hayes et al. 1997). The cohort was followed-up for death from all causes and for incidence of hematological tumors, with an analogous cohort of approximately 36,000 unexposed workers for comparison. For the purposes of assessing exposure, information on the factory and department of employment and on the starting and ending dates of each job was obtained, for each worker, from employment records available at the factories (Dosemeci et al. 1994a). Moreover, information on production activities and changes in processes over time was obtained at each factory and for each job type. Importantly, the results of all past air monitoring (more than 8,400 measurements) for benzene and other solvents were also obtained. Therefore, whenever possible, the exposure level was assigned to each worker on the basis of monitoring results either for specific combinations of job task, department, and calendar period or for adjacent calendar periods or similar job tasks.

Detailed information on exposure and confounders can obviously be obtained in concurrent cohort studies, which can be efficiently carried out when the induction period between exposure and disease is short. If the cohort is followed-up prospectively, temporal variations in exposure can be ascertained either at individual level, from questionnaires, personal dosimetry data, or use of biomarkers of exposure, or at aggregate level, from environmental measurements and monitoring of changes in industrial processes.

42.2.3 Case-Control Studies

Studies in Industrial Populations Nested case-control studies (see chapter ▸Modern Epidemiological Study Designs of this handbook) might solve some of the limitations inherent in the cohort design. As a nested case-control study covers fewer persons than a cohort study, the nested approach is efficient when the exposure assessment is not straightforward, as, for instance, when it is based on experts' judgment. The nested approach is also more efficient when worker-specific levels of exposure are estimated from biological samples or by direct interview with the workers or their next-of-kin. Measurement of biomarkers can result in accurate assessments of current exposure, but assumptions must be made about past exposure. Conversely, interviews allow detailed reconstructions of working histories and provide information on possible confounders. Information on actual exposure levels may nevertheless be rather imprecise, and the subjects are difficult to trace, especially when the follow-up period is long.

The historical cohort study of workers employed in MMVF production coordinated by the IARC, described above, includes a clear example of a nested case-control design (Boffetta et al. 1997). The analyses of the cohort revealed a small excess risk for lung cancer among rock- and slag-wool production workers, but no information was available on possible confounders; furthermore, occupational histories were available up to 1977 only and were limited to the information in the employment registries. The researchers therefore conducted a case-control study of 196 cases of lung cancer, and 1,715 matched controls nested in the cohort (Kjaerheim et al. 2002). The index subjects or their next-of-kin were traced and interviewed to obtain information on lifetime smoking habits, residential history, and lifetime occupational history, both within and outside the MMVF industry. As anticipated by the study design, the proportion of completed interviews with the selected subjects was low: 68% for cases and 35% for controls. Two industrial hygienists evaluated the individual occupational histories for exposure to each of several occupational agents known or suspected to be associated with lung cancer. Moreover, an expert panel was formed to evaluate individual cumulative exposure to MMVF on the basis of the new information obtained at the interview. The smoking-adjusted estimates and the analyses by quartiles of cumulative level of exposure in the nested study did not support an association between exposure to rock- or slag-wool and lung cancer risk.

Quite often, a nested case-control design increases the efficiency of the computerization, cleaning, and handling of data, even though information on exposure is available. Grayson (1996), for example, conducted a case-control study on brain cancer nested in a cohort of approximately 880,000 US Air Force members to evaluate the effect of occupational exposure to electromagnetic fields. The workers had to have been employed between 1970 and 1989. At the end of the follow-up period, 230 incident cases of brain cancer were found, and four controls for each case were randomly selected among cohort members. Information on past exposure to electromagnetic fields was obtained from several sources, including employment records, records of events exceeding existing limits, and some personal dosimetry data. The final analysis was based on 1,150 persons instead of more than 800,000 in the original cohort.

Studies in the General Population Population- or hospital-based case-control studies have frequently been used to investigate the health effects of occupational exposures. In the early 1980s, a multicenter case-control study was carried out to investigate the associations between laryngeal and hypopharyngeal cancer and smoking, alcohol, dietary habits, and occupational factors (Tuyns et al. 1988). The study, coordinated by IARC, was population-based and included six centers in northern Italy, France, Spain, and Switzerland. Information on occupational history and lifestyle factors was obtained by face-to-face interviews with cases and controls. Specifically, each person was asked to report all jobs held for at least 1 year since 1945, specifying their starting and ending years, a short description of specific tasks, the name of the company, the company's activity, and the specific products of the department in which the interviewed person had worked. The occupational histories of 1,010 interviewed cases and 2,176 interviewed controls were coded, without knowledge of case or control status, according to standard international classifications of occupations and industries. Then, smoking- and alcohol-adjusted odds ratios for occupational factors were obtained by two approaches. First, an exploratory analysis was carried out on 156 occupations and 70 industrial activities in which at least nine individuals had been ever employed (Boffetta et al. 2003). Second, a working group created a job-exposure matrix (JEM) to categorize each combination of job and activity in terms of levels of probability, intensity, and frequency of exposure to 16 occupational agents for which there was some a priori evidence of an association with laryngeal cancer risk (Berrino et al. 2003). The agents investigated included asbestos, solvents, formaldehyde, and polycyclic aromatic hydrocarbons. The JEM was used and evaluated in ad hoc studies (Merletti et al. 1991; Ahrens et al. 1993; Luce et al. 1993; Orlowski et al. 1993; Stengel et al. 1993; Stucker et al. 1993). An account of its validation, based on a comparison between the results of the JEM and the experts' evaluation of the jobs as described in the questionnaires, is given in Table 42.1. Generally, the specificity and sensitivity of the JEM was agent-specific. The first analytical approach, based on job titles and industrial activities, provided risk estimates for several occupations, an advantage

Table 42.1 Validation of the job exposure matrix (JEM) of the IARC case-control study on laryngeal and hypopharyngeal cancer: percentage of jobs not entailing an exposure to specific agents according to an expert's assessment compared with the results from the JEM

	JEM categories of intensity/probability of exposure[b]							
Agent[a]	No. of job periods	1	2	3a	3b	3c	4	5
Asbestos	3220	96	83	79	73		68[c]	
Solvents (1)	2712	96	92	89	70	47	58	16
Solvents (2)	929	87	83	62	67	35	37	9
Formaldehyde	884	75	90	59	47	50	29	–[d]
Wood dust	863	95	–[d]	50	50	–[d]	8	0
PAH	2571	98	68	88	85	98	74	39

[a] Agents were evaluated in the following studies: asbestos, Orlowski et al. (1993); solvents (1 = bladder cancer study, 2 = glomerulonephritis study), Stengel et al. (1993); formaldehyde and wood dust, Luce et al. (1993); *PAH* polycyclic aromatic (hydrocarbons), Stucker et al. (1993)

[b] Categories: 1. Job-related exposure is not higher than for the general population; 2. job entails or may entail a cumulative exposure slightly higher than for the general population; 3. job may entail exposure definitely higher than for the general population, but the coded information is not sufficient to discriminate between exposed and not exposed workers (3a: few workers are thought to be exposed, and 3b: some workers are thought to be exposed, 3c: the majority of workers are thought to be exposed); 4. job entails exposure to the specific agent at definitely higher level than the general population; 5. job entails exposure to the specific agent, and there are instances in which the exposure is known to be particularly high

[c] Categories 3c, 4, 5 were considered jointly

[d] Category with no jobs according to the JEM

facilitated by the heterogeneity of the study subjects' working histories due to the multicenter design. Conversely, the second approach directly tested etiological hypotheses. In both instances, the case-control design made it possible to control for the confounding effects of smoking, alcohol drinking, and diet.

Mortality Odds Ratio Studies Mortality odds ratio studies have a case-control design and are a valid alternative to proportionate mortality studies, which have been widely used in occupational epidemiology (Miettinen and Wang 1981; Boyd et al. 1970). In proportionate mortality studies, the frequency of death for the diseases under study among exposed workers is compared with the corresponding figure calculated for a reference population (proportionate mortality ratio, *PMR*). *PMR*s are limited by the fact that they must add up to unity; therefore, elevated *PMR*s for some diseases are, by definition, counterbalanced by decreased *PMR*s for other diseases. Moreover, *PMR*s are biased if ascertainment of deaths is incomplete in a different proportion among exposed than unexposed subjects. These drawbacks are overcome in mortality odds ratio studies where the case-control approach is applied. In such studies, the cases comprise deaths from the specific cause of interest, both exposed and unexposed, while the controls are other deaths, selected on the basis of a presumed lack of association with the exposure. The principle of selecting the control causes of death for inclusion in the study is therefore the same as selecting a control series for any case-control study: Controls are selected independently of exposure and with the aim of representing the proportion of exposure in the study base (Rothman et al. 2008). In practice, however, avoiding bias may prove difficult, as many causes of death, even when unrelated with the exposure under study, are associated indirectly with occupational exposures via the socioeconomic status.

Concluding Remarks Case-control studies can be used efficiently to investigate long-term outcomes represented by rare diseases, or by diseases caused by widespread occupational exposures, which cannot be localized to a specific industry. This study design also permits the researcher to focus on minorities and on subgroups of the population that have often been poorly investigated. For example, at the first international conference on occupational cancer in women, in 1993, it was recognized that most of the information on occupational hazards had been obtained from studies on men: A survey showed that less than 10% of published epidemiological studies included and reported detailed results on women (Zahm et al. 1994). Although this picture has changed, efforts to study the effects of occupational exposures on women are still needed (Zahm and Blair 2003). A case-control approach is often used in occupational epidemiology for exploratory studies. As in the study on laryngeal and hypopharyngeal cancer described above, an occupational history may be classified by several groups of job titles and industrial activities. As multiple comparisons are made, a Bayesian approach with semi-Bayes or empirical-Bayes adjustments might help to decrease the impact of false-positive results (Greenland and Poole 1994; Corbin et al. 2008). For a formal explanation and practical examples of Bayesian approaches in occupational epidemiology, see Greenland and Poole (1994) and Steenland et al. (2000a).

42.3 Exposure Assessment

Exposure assessment (see chapter ▸Exposure Assessment of this handbook), a critical step in any epidemiological study, is central in occupational epidemiology. The most recent developments in the design of both cohort and case-control studies of work-related diseases rely on identification of exposure to specific agents, such as chemicals, rather than on the use of surrogates of exposures, such as being employed in a given industrial activity or holding a certain job. Furthermore, an attempt is often made to compute some measure of dose, such as cumulative exposure or average exposure, which in turn requires estimation of the level (intensity) of exposure and its variation over time.

42.3.1 Exposure Assessment in Industry-Based Studies

Two general strategies, statistical and deterministic modeling (Kauppinen et al. 1994), are available to assess exposure on the basis of the primary information collected in a study. Such information usually does not include satisfactory measures of exposure to the agent(s) of interest and is often limited to a description of the work setting, the operations performed by workers, and the materials they handled. When suitable data are available, however, on the concentration of the agent of interest in the workplace, exposure assessment will be based on a stochastic (statistical) approach, in which a model is fitted to the results of past industrial hygiene measurements by plant, job title, and work area; missing data will be estimated from the model (Kauppinen et al. 1994). When statistical modeling is applied to industry-based studies, such as cohort, cross-sectional, and nested case-control studies, workers are classified into "homogeneous" groups on the basis of combinations of plant, work area, job title, and period. The available industrial hygiene measurement series are broken down into the same groups (de Vocht et al. 2008; Lavoué et al. 2007). The main limitations of the statistical approach are that (1) trends in exposure over time are often unknown, either because measurements were not made for previous processes and working conditions or because of difficulties in the interpretation of historical measurements, and (2) the interindividual variation of exposure within a homogeneous group can be wider than that between groups, which may make the correct identification of homogeneous groups difficult (Kromhout et al. 1993). Furthermore, it must be born in mind that, when only limited data exist, they will also be distributed unevenly by job. There is, thus, the danger of overestimating exposures due to oversampling worst case scenarios, especially when measurements were initiated upon complaints of workers, for example, in response to spills. Conversely, measurements done by the companies or measurements made to assess compliance with exposure limits may lead to underrepresentation of the highest exposures.

In historical cohort studies, the availability and quality of industrial hygiene data are often different for the various settings included in the work histories of the study subjects; good data may exist for some periods and not for others. In these circumstances, the maximum achievable goal is a semiquantitative approach in which jobs are compared according to materials handled and tasks performed. The jobs are then ordered in terms of assessed exposure, which is placed onto a semiquantitative scale (e.g., high, intermediate, low).

Because comprehensive data on exposure are rarely available, less accurate methods have thus to be used. If the factors that determine the level of exposure can be identified, they can be used to construct a deterministic model (Kauppinen et al. 1994). In deterministic modeling in industry-based studies, the most significant factors that affect exposure intensity, such as type of plant and machinery, presence of local exhausts, and workers proximity to sources, are identified. Their relative importance is then assessed, either on the basis of historical industrial hygiene data – even if such data are insufficient for complete modeling – or, in their absence, through the theoretical evaluation of how different tasks, operations, and procedures could have affected exposure. In rare circumstances, it has been possible to improve the assessment by reproducing experimentally some past working conditions and to estimate the concentrations of the agents of interest by applying modern measurement techniques to such reconstructed working places and procedures. It has been shown that, by combining such approaches, complex industry-specific exposure matrices can be built on the basis of detailed knowledge of plant-, job-, and time-specific factors (Kauppinen and Partanen 1988). Semiquantitative exposure levels can then be established for each study subject applying the matrix to the information on the jobs they held and the tasks they performed.

The main limitations of the deterministic approach are that (1) the relative importance of the various determinants may prove difficult to assess, and agreement among experts may be poor, and (2) the quality of information on the determinants may be highly variable across study subjects; for some, the tasks involved in their job might have been recorded, while for others barely the job title or the department of assignment is known.

In some recent multicenter or pooled industry-based studies, considerable advances have been made in exposure assessment, by combining the statistical and deterministic approaches. Quantitative industry-specific exposure matrices were thus built and applied to the workers' individual job histories (Burstyn et al. 2000, 2003; t'Mannetje et al. 2002; Harber et al. 2003). Alternatively, Bayesian decision analysis may be applied: Experts will create a "prior" probability distribution of exposure, based on their knowledge of processes, jobs, etc., which will be combined with available measurements to obtain "posterior" distributions (Ramachandran 2001). Current standards of practice imply that when good industrial hygiene data are available, at least for some historical periods, and the relative influences of changes in plant, process, and activity can be evaluated, exposure will be assessed quantitatively and extrapolated to periods or plants for which no original quantitative information was available. With this method, quantitative data on a given job, in a given industrial activity, and during a given period provide a baseline estimate of both the average exposure and its variation. Known differences in the presence and characteristics of determinants provide multiplicative weighting factors to be applied to the baseline estimate. Few validation studies of industry-specific exposure matrices are, however, available (Dosemeci et al. 1994b, 1996).

42.3.2 Exposure Assessment in Population-Based Studies

In population- and hospital-based case-control studies, statistical modeling has been used to set up job-exposure matrices (JEM) (Hoar et al. 1980; Macaluso et al. 1983). A JEM can be defined as a cross-classification of a list of job titles with a list of agents to which the workers performing the jobs might be exposed (Kauppinen and Partanen 1988). Deterministic modeling has been used in the interpretation and assessment of job histories by industrial hygiene experts when occupational questionnaires including job-specific modules (JSM) were developed to obtain the detailed information necessary for the experts' judgment (Siemiatycki et al. 1981; Macaluso et al. 1983; Ahrens et al. 1993). Researchers at the US National Cancer Institute showed that a deterministic approach can be used not only in expert- and JSM-based assessment but also to create and use more detailed and improved JEMs that might allow semiquantitative or even quantitative exposure assessments (Dosemeci et al. 1990a). The same group suggested that the JEM-based assessment strategy should be abandoned in favor of the JSM-based expert assessment

(Stewart et al. 1996). Use of JEMs has been reported to result in loss of both sensitivity and specificity in exposure assessment, in comparison with the use of a JSM-based individual assessment (Rybicki et al. 1997). Simulation studies suggested that use of JEMs may lead to loss of precision in odds ratio estimates, whereas expert-based assessment resulted in relatively low levels of misclassification (Bouyer et al. 1995).

Although it is somewhat difficult to assess the validity of expert-based exposure assessment in the field, some studies suggest that the agreement within and between experts might be satisfactory when experienced teams of raters are available (Siemiatycki et al. 1997; Fritschi et al. 2003). Two studies addressed the issue of expert-based exposure assessment validation by means of an objective index of past exposure to asbestos.

The first study (Pairon et al. 1994) comprised 131 cases of mesothelioma. The probability, level, and frequency of exposure were assessed by using qualitative ordinal classifications of the job in which each person had maximum exposure. Combinations of assessed probability, level, and frequency were summarized in four classes: (1) unexposed or possibly exposed, (2) probable or definite exposure at low level, (3) probable or definite exposure at levels higher than low, with sporadic frequency, and (4) probable or definite exposure at levels higher than low, with more than sporadic frequency. No attempt to build up a cumulative dose index was made. A limited correlation between the exposure assessment and objective indices of exposure to asbestos was observed, particularly with counts of asbestos bodies per gram of dried tissue. This study suffered from some shortcomings. Intensity and frequency were not used to compute a combined dose estimate, which prevented the calculation of a cumulative dose index. Frequency was used to discriminate between the third and the fourth summary class, but variations in frequency might actually be less important than those in intensity to determine the average exposure level. Only the highest exposure job was used in the assessment, so that other possible exposures have not been taken into account. The sensitivity of objective indices of asbestos exposure in mesothelioma cases may be low.

In the second study (Takahashi et al. 1994), 42 cancer cases for whom necropsy material was available were assessed for exposure from a JSM-based questionnaire and by analysis of lung tissue fibers. A good correlation was found between the JSM-based exposure assessment and asbestos fiber counts, although some cases were found to have had exposure but had no asbestos in the lung. The main shortcomings of this study are its rather limited dimension and a potential necropsy selection bias; the heterogeneous nature of the cases as to their cancer site makes it difficult to extrapolate its results to a mesothelioma series.

Expert-based assessment with deterministic modeling in the hands of experienced raters has resulted in quantitative assessments in some population- and hospital-based case-control studies (Iwatsubo et al. 1998; Brüske-Hohlfeld et al. 2000; Rödelsperger et al. 2001; Pohlabeln et al. 2002).

Recently, nationwide databases of past measurements have been created by public institutions involved in health and safety at work, like Colchic at INRS (France), MEGA at Berufsgenossenschaften (Germany), or the National Exposure Database at the Health and Safety Executive (UK). The availability of large amounts of industrial hygiene data, going back in time to the 1970s and 1980s and earlier, is stimulating the development of quantitative JEMs (Kauppinen et al. 2009; Preller et al. 2010; Peters et al. 2012).

42.3.3 Consequences of Errors in Exposure Assessment

The consequences of errors in exposure assessment are discussed extensively in the chapters on exposure assessment (chapter ▸Exposure Assessment) and measurement error (chapter ▸Measurement Error) in this handbook. When exposure is measured as a continuous variable at the individual level, random, non-differential errors in assessment, such as those deriving from errors in measurement, generally lead to attenuation of the exposure-disease association and diminish the goodness of fit of regression models (Armstrong 1998). When measurements are constrained by a lower limit, such as a detection limit, however, inflation of the exposure-response association can occur under certain circumstances (Richardson and Ciampi 2003). When exposure is measured as a continuous variable, but at the group level, a rather different situation occurs: The exposure level is the average for a sample of individuals in the group, and all individuals are assigned this average exposure. This leads to what is referred to as "Berkson error." In a "classical" error, an individual is assigned a measured exposure, affected by random variability. In Berkson error, the group average exposure is affected by a considerably smaller random error, but the actual exposure of each individual in the group will be different from the group average. Berkson error usually entails small, if any, bias of the exposure-response association (Armstrong 1998), even if in certain circumstances a substantial over- or underestimation of the quantitative relationship may occur (Steenland et al. 2000b).

In many, probably most, study designs, exposure is scaled as a discrete variable on a dichotomous or a polytomous scale. When the exposure variable is dichotomized, non-differential misclassification will always bias the effect measure toward the null; however, when the exposure variable is polytomous, non-differential misclassification will bias the effect measure toward the null only if misclassification occurs between adjacent exposure categories. When it involves non-adjacent categories, bias away from the null may also occur (Armstrong 1998; Dosemeci et al. 1990b).

Quantitatively, misclassification is a function of (a) the sensitivity of the assessment method, that is, the proportion of all truly exposed subjects correctly classified as exposed and (b) its specificity, that is, the proportion of all truly unexposed subjects correctly classified as unexposed. The relative importance of sensitivity and specificity in overall misclassification bias depends on exposure prevalence: When exposures are rare, like most occupational exposures in population- and hospital-based case-control studies, even small losses in specificity may strongly bias the relative risk estimate toward the null. Such effect is clearly depicted in Fig. 42.1, where a true relative risk of 4.0, sensitivity in exposure assessment of 0.9, and a range of commonly found exposure prevalences (from 0.001 up to 0.2) are assumed. The estimated relative risk is plotted against different specificities in exposure assessment.

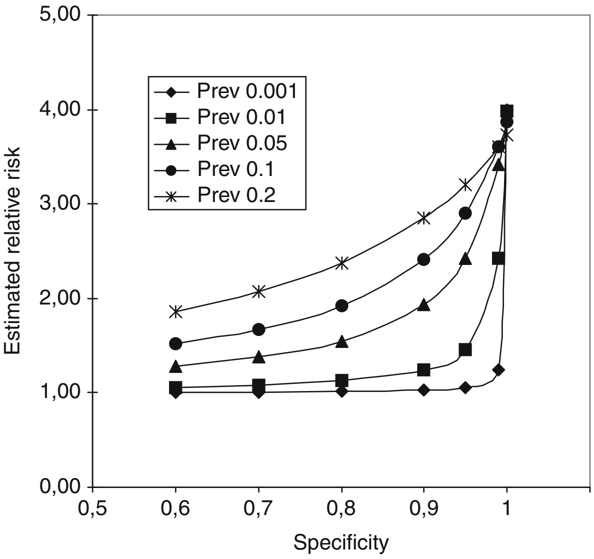

Fig. 42.1 Bias toward the null of estimated relative risk due to loss in specificity in exposure assessment. True relative risk = 4 and exposure assessment sensitivity 0.9 are assumed. Estimated relative risk is plotted against different levels of specificity of exposure assessment, for exposure with prevalences (Prev) ranging from 0.001 to 0.2 (Modified from Ahrens 1999)

This consideration does not of course imply that sensitivity is not important: When exposures are rare, low sensitivity in exposure assessment causes loss in power and requires substantial increases in sample size to compensate for it.

42.4 Special Issues in Occupational Epidemiology

42.4.1 Confounding

A general discussion of confounding is given in chapter ▸Confounding and Interaction of this handbook). Information on several known possible confounders and on other occupational and non-occupational exposures of interest is almost always lacking for historical occupational cohorts. Methods to deal with confounding in historical cohorts include use of internal comparison groups, with general characteristics assumed to be similar to those of the exposed subjects, and use of available statistics on the distribution of confounders in the population from which the cohort originated. The first approach is commonplace in occupational epidemiology, although it is seldom possible to verify whether the comparison group has the assumed characteristics. Internal comparisons have the advantage of controlling part of the bias introduced by the "healthy worker effect," that is discussed below. In a historical cohort study conducted in the Nordic countries to investigate the risks for cancer among airplane pilots (Pukkala et al. 2002), national cancer registry data were used to calculate standardized incidence ratios (*SIR*s). Since airplane pilots belong to a higher social class than the general population, however, the *SIR*s were possibly biased. In this study, cosmic radiation was the main exposure of interest; therefore, a cumulative dose of radiation experienced by each member of the cohort was calculated. This made it possible to check the main findings from the external comparison by analyzing the effect of the exposure, using pilots with the lowest cumulative dose as the reference group. Such a comparison is unlikely to be confounded by social class.

The second approach, the use of available population statistics, was applied in the Norwegian part of the occupational record-linkage study in the Nordic countries, described in Sect. 42.2.2, with occupation-, sex-, and birth-cohort-specific information on smoking habits in the population obtained from external surveys (Haldorsen et al. 2004). The Norwegian study evaluated 42 occupational groups for risk of lung cancer in comparison with twelve other occupational groups assumed to be without exposure to occupational lung carcinogens. The magnitude of the associations of proportion of current and former smokers and amount of cigarettes smoked with lung cancer risk was estimated among the twelve reference groups, using data from the external surveys. Then, the smoking-adjusted SIRs for the 42 occupational groups were calculated and compared with the non-adjusted estimates. Limitations of this approach are that (1) the quality of the information on the confounder depends on the quality of the surveys and (2) the magnitude of the association between confounder and disease is not directly estimated at an individual level. The magnitude of the association can be either obtained from the best available studies or from ad hoc studies conducted in the same population, or estimated, as in the Norwegian study, using aggregate data.

When a study is conducted to determine whether an occupational exposure is associated with a disease, with no specific interest in the dose-response relationship, and when the estimate of the association is large, adjusted and unadjusted estimates are often similar. This has been shown in studies of occupational lung cancer risk, for which smoking is a strong potential confounder. In particular, using an indirect approach that is a type of sensitivity analysis, Axelson calculated that the confounding effect of smoking can hardly explain relative risks greater than 1.5 or below 0.7 when national rates are used for comparison (Axelson 1978; Axelson and Steenland 1988). He made sound assumptions about the proportions of moderate smokers (40%) and heavy smokers (10%) in the population used for calculating the number of expected cases and also about the effects of moderate smoking (relative risk, 10) and of heavy smoking (relative risk, 20) on lung cancer risk. Then, the adjusted relative risks were calculated for different scenarios of association between smoking and being employed in specific occupations (Table 42.2). Axelson's suggestion that, under common circumstances, strong risk factors have weak confounding effects was investigated further and supported (Gail et al. 1988; Siemiatycki et al. 1988; Flanders and Khoury 1990).

In developing a protocol for a case-control study on the risk of female breast cancer associated with occupational exposure to magnetic fields, a simulation study was carried out to evaluate the potential confounding effects of several risk factors (Goodman et al. 2002). Twelve potential confounders, including a family history of breast cancer, country of birth, age at menopause, and obesity, were selected on the basis of recent reviews on breast cancer epidemiology and evaluated both in

Table 42.2 Risk ratios for lung cancer in relation to the fraction of smokers in various hypothetical populations (Source: Axelson 1978; Axelson and Steenland 1988)

	Type of smokers in the population (percentages)		
Non-smokers (risk of 1)	Moderate smokers (risk of 10)	Heavy smokers (risk of 20)	Rate ratio
100	–	–	0.15
80	20	–	0.43
70	30	–	0.57
60	35	5	0.78
50[a]	40[a]	10[a]	1.00[a]
40	45	15	1.22
30	50	20	1.43
20	55	25	1.65
10	60	30	1.86
–	–	100	3.08

[a] Compared to reference population with 50% non-smokers, 40% moderate smokers, and 10% heavy smokers

univariable analyses and with combinations of two to five risk factors. Estimates of the strength of the associations between the risk factors and breast cancer risk and the prevalences of the risk factors in the general population were obtained from the literature. The aim was to identify confounders that, under different scenarios of their prevalence among cases, could increase a true odds ratio of 1 up to a distorted value of 1.5. In the univariable analysis, no risk factor was a strong confounder, unless an unrealistic increase in its prevalence among occupationally exposed women was assumed. Interestingly, the scenario in which the prevalences of several risk factors were increased also did not have a strong confounding effect. For instance, a twofold increase among exposed women in the prevalence of first-degree relatives with breast cancer, a history of cancer in one breast, benign proliferative breast disease, obesity, and consumption of at least two drinks per day inflated the odds ratio from unity to 1.38.

The similarity between adjusted and unadjusted estimates has also been shown empirically, in both cohort and case-control studies. *SMR*s of cancers of the lung, bladder, and intestine, unadjusted for smoking, strongly correlated with smoking-adjusted estimates in analyses of occupational factors in a cohort of US veterans (Blair et al. 1985). Analogously, smoking was found to be a weak confounder in a review of several occupational case-control studies on lung cancer (Simonato et al. 1988). When selecting the final model for analyzing a case-control study on occupational factors and lung cancer risk in two areas of Italy in 1990–1992 (Richiardi et al. 2004), we evaluated several models for addressing smoking as a confounder. Table 42.3 shows the results of an evaluation for two occupational categories, one positively associated and the other negatively associated with smoking. The evaluation showed that a simple model in which smokers are classified as current, former, and never can accommodate for most of the potential confounding effect.

Table 42.3 Odds ratio and 95% confidence intervals of lung cancer for two selected job titles, obtained using seven different methods to model smoking in an Italian case-control study on lung cancer (Source of data: Richiardi et al. 2004)[a]

	Retail trade salesmen (54 exposed cases)	Mail distribution clerks (58 exposed cases)
Model	*OR* (95% CI)[b]	*OR* (95% CI)
1	1.56 (1.04–2.35)	1.47 (1.00–2.17)
2	1.41 (0.93–2.15)	1.62 (1.07–2.45)
3	1.30 (0.85–2.01)	1.65 (1.08–2.52)
4	1.30 (0.84–2.03)	1.63 (1.06–2.51)
5	1.26 (0.81–1.95)	1.70 (1.10–2.61)
6	1.28 (0.82–2.00)	1.70 (1.10–2.63)
7	1.26 (0.81–1.98)	1.70 (1.10–2.65)

[a] All models were adjusted for age and study area. Model 1: no smoking variables; Model 2: smoking status categorized as ever/never smoker; Model 3: smoking status categorized as current/former (since at least 2 years)/never smoker; Model 4: same as model 3 with three levels for current smokers: 1–9, 10–19, 20+ pack-years; Model 5: same as model 3 with number of pack-years introduced as a continuous variable; Model 6: same as model 5 with 4 levels for time since cessation: 2–5, 6–10, 11–15, 16+ years; Model 7: same as model 6, using b-spline cubic regression with knots at 10, 20, 30, and 40 pack-years to model the cumulative number of cigarettes smoked

[b] *OR*, odds ratio adjusted for age, study area; CI, confidence interval

42.4.2 Healthy Worker Effect

Workers are not a random sample of the general population as the employment status is positively associated with the health status. First, relatively healthier people are more likely to seek a job and to be hired. Second, as sick people tend to leave their jobs, healthier workers remain employed longer. The two health-related selection forces cause a well-known selection bias in occupational epidemiology, known as the "healthy worker effect" (Fox and Collier 1976; McMichael 1976). The first phenomenon is known as the "healthy hire effect," whereas the second, associated with duration of employment, is known as the "healthy worker survivor effect" (Arrighi and Hertz-Picciotto 1994). The magnitude of the phenomena depends on the type of work, general social conditions (e.g., unemployment rate), the disease under study (e.g., studies of cancer are generally less biased than studies of diseases with shorter induction period), and the study design (Choi 1992). The healthy worker effect is also seen as a traditional confounding problem, as employment status is associated at the same time with the health status of workers and disease risk (Checkoway et al. 2004). Because of the healthy worker effect, cohorts of workers may have lower mortality rates than the general population. Negative results in occupational epidemiological studies may therefore hide harmful exposures. Moreover, an increase in risk of a disease may artificially plateau at the highest level of cumulative exposure, at which workers have the longest duration of employment (Stayner et al. 2003).

A logical approach for controlling, or at least decreasing, the bias introduced by the healthy worker effect is to use an appropriate internal or external comparison group, namely, a group of unexposed workers who possibly underwent similar health-related selection at the time of employment. Use of such a comparison group does not, however, imply unbiased estimates, as the healthy worker survivor effect may still persist. Indeed, as reviewed by Checkoway and colleagues (2004), four time-related factors should be considered: age at first employment, duration of employment, length of follow-up (members of a cohort can be followed-up also after they have left the job), and age at risk. Arrighi and Hertz-Picciotto (1996) evaluated four suggested methods for controlling the healthy worker effect: (1) restricting analyses to long-term survivors; (2) excluding recent exposures, introducing a lag of 10–20 years; (3) introducing current employment status as a confounder in the models; and (4) modeling employment status simultaneously as a confounder (the same as in the third approach) and as an intermediate time-dependent variable (if the risk factor for the disease under study is also a determinant of job termination and, therefore, of change in employment status). The latter technique uses the so-called G-method as suggested by Robins and colleagues (1986, 1992). This approach has the strongest theoretical support and was considered the most appropriate after empirical evaluation, although there are difficulties in its implementation. Lagging exposure is a valid, straightforward alternative that can be implemented when the induction period between exposure and disease is not short.

Case-control and cross-sectional studies are not free from the healthy worker effect. In case-control studies, it can result in differential sampling of controls from the exposed and the unexposed population. For instance, if controls are selected from hospitalized patients and individuals with a particular occupational exposure tend to be healthier, then the proportion of exposed controls is artificially decreased. The odds ratio would, therefore, be overestimated, a bias that reverses the usual underestimation of SMRs introduced by the healthy worker effect in cohort studies.

In a cross-sectional study, workers with higher exposure may have a paradoxically lower prevalence of diseases or symptoms known to be associated with exposure, because diseased workers would tend to leave jobs entailing the exposure.

42.4.3 Dose-Response Analysis

As discussed in chapter ▶Exposure Assessment of this handbook), the dose is the level of the risk factor at the target organ, while exposure refers to the level of the risk factor in the external environment. Although the dose is the biologically relevant measure, the amount of exposure, as a surrogate of the dose, is usually the only available information in occupational studies, so that a dose-response analysis is in fact an exposure-response analysis. In some studies, the actual dose can be estimated from measurements of exposure and knowledge of the specific agent uptake and clearance (US Environmental Protection Agency 2002).

Exposure can be measured using different metrics, namely duration, intensity, and cumulative level (cf. chapter ▶Exposure Assessment of this handbook). The selection of the metric should be based on the – often unknown – mechanism of disease development and on the nature of the exposure itself. Importantly, the choice of the metric influences the magnitude of the estimates and the shape of the dose-response (Blair and Stewart 1992). Cumulative exposure, that is, the product of intensity and duration, is a correct metric for several types of diseases where risk is directly proportional to dose. Duration of employment is a valid surrogate for cumulative exposure when intensity of exposure has been relatively constant over time, through working areas of the plant and across tenures (Checkoway 1986). Peak exposure is more important than duration in the study of diseases for which a threshold exists, such as back pain or acute toxicity.

A dose-response analysis is commonly carried out in occupational epidemiology for at least three main reasons. First, occupational exposures are time- and place-specific, implying that assessment of an association between an occupational exposure and a disease necessarily takes the level of exposure into account. Second, a dose-response relation is one of the well-known Bradford Hill's criteria for establishing causality (Hill 1965). When the risk for a disease increases continuously with increasing exposure, whatever the shape of the trend, the likelihood of a causal association is higher. However, on the one hand, a dose-response relation does not prove causality; on the other hand, the lack of such a relation does not imply lack of a causal association, as clearly demonstrated by threshold phenomena. Third, the dose-response analysis is one of the steps in risk assessment, which aims at quantifying the health effects of environmental and occupational exposures that can be modified by new policies and technologies. Risk assessment comprises (1) hazard identification, on the basis of evaluation of the available evidence on the health effects of the agent; (2) exposure assessment, identifying the nature of the exposure in the population, the characteristics of the exposed individuals, and the behavior of the agent in humans; (3) identification of the exposure-risk model, which implies a dose-response assessment; and (4) risk characterization, determining the exposure level-specific health effects in the population (Nurminen et al. 1999; Checkoway et al. 2004).

Often, data on exposure in occupational epidemiology are summarized as qualitative or semiquantitative indices. For instance, JEMs usually produce indices of intensity and probability of exposure on an ordinal scale. Such information offers little basis for a dose-response analysis. In other instances, if quantitative information is available, cumulative exposure can be estimated for each study subject; it must be born in mind, however, that quantitative estimates are affected by measurement errors, falling in the two broad categories of classical and Berkson error already discussed in Sect. 42.2.3. Among many possible examples, we cite here the dose-response analysis carried out by Steenland and colleagues (1998) on occupational exposure to diesel exhaust in the trucking industry and the risk for lung cancer, which was used for quantitative risk assessment by the Health Effects Institute (1999). Steenland and colleagues conducted a case-control study, obtaining information on lifetime work histories from interviews with the study subjects' next-of-kin and from retirement registries. Then, for the purpose of exposure assessment, workers were assigned to the category in which they had been employed the longest. Contemporaneously, an industrial hygiene survey was conducted to measure levels of exposure to elemental carbon (a marker of exposure to diesel exhaust, which is a complex mixture of gases and particulates) in the main job categories within the trucking industry (Zaebst et al. 1991). Combining the lifetime work histories with the results of the survey and making several assumptions, in particular with regard to past exposure, the cumulative exposure of each worker was estimated. Although quantitative data were obtained, the level of misclassification of exposure was still presumably high, albeit non-differential. In particular, each subject's true exposure in each job category was a random variation of the exposure level that was assigned to that job based on the industrial hygiene survey.

There are several approaches to dose-response analysis, including simple parametric models, categorical analysis, biological-based models, polynomial regression, spline regression, and non-parametric models, such as generalized additive models (cf. chapters ▶Analysis of Continuous Covariates and Dose-Effect Analysis and ▶Regression Methods for Epidemiological Analysis of this handbook). We will not describe and compare these techniques, but we highlight some aspects that are specific to occupational epidemiology. Interested readers may refer to the above chapters or one of the several available thematic textbooks (Härdle 1990; Hastie and Tibshirani 1990).

Categorical analysis, in which the exposure variable is subdivided into a certain number of categories on the basis of cut-points chosen a priori, is usually the starting point for a dose-response assessment, as it allows researchers to observe the shape of the dose-response relationship. The shape is obviously strongly influenced by the choice and number of the cut-points that can be decided upon according to biological considerations, if available, or other criteria, including established standards or the percentile method. Evidence that an association is limited to the highest exposure levels should not lead to disregard causality without careful consideration of the possibility of a threshold for the effect of interest.

When the exposure variable is continuous, the simplest approach consists in fitting a regression model with a term for the exposure (e.g., cumulative exposure). This implies assuming a priori a shape of the dose-response curve that seldom reflects biological knowledge, if any is available. When the exposure variable is not transformed, the assumed shape is usually log-linear or logistic. In occupational epidemiology, a leveling off in the increasing trend in risk for chronic diseases is often observed at the highest levels of exposure (Stayner et al. 2003). The explanations for this leveling off can be either biological (e.g., saturation phenomena, depletion of susceptible individuals) or methodological (e.g., misclassification of exposure, healthy worker effect), and a log transformation of the cumulative exposure variable is an option to consider.

Among the more complex alternatives, spline regression and its variants (b-splines and loess among the most popular) can be implemented quite easily with common software packages. It is therefore being used increasingly in occupational and environmental epidemiology (Greenland et al. 2000; Steenland et al. 2001; Thurston et al. 2002; Steenland and Deddens 2004). Spline regression, which is based on piecewise polynomials, has the advantage of providing a smoothed dose–response curve, although it does not always produce easily interpretable estimates (Harrell et al. 1988; Greenland 1995). Figure 42.2 shows an example of a dose-response analysis of data from men included in a case-control study on occupational factors and lung cancer risk that we carried out in two areas of northern Italy in

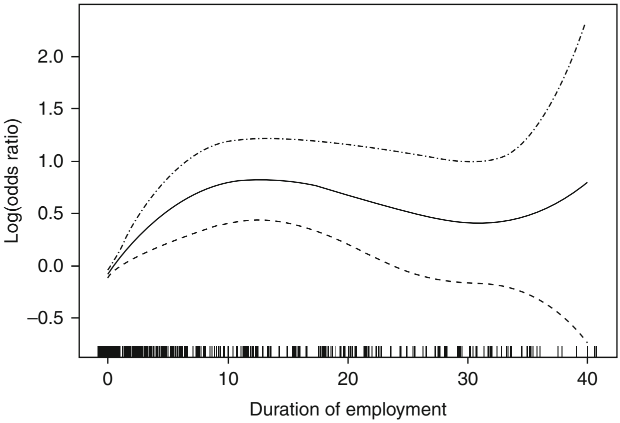

Fig. 42.2 Association between duration of employment in occupations known to entail exposure to lung carcinogens and risk of lung cancer modeled using a generalized additive model with cubic b-splines (four degrees of freedom), adjusted for study area, age, and cigarette smoking (current/former/never smokers) (Source of data: Richiardi et al. 2004)

1990–1992 (Richiardi et al. 2004). The odds ratio (plotted on the log scale) of lung cancer increased with duration of employment until 10–15 years and slightly decreased after that. Estimates for the durations of employment above 30 years are not interpretable because of few observations and consequent large confidence intervals. This shape in dose-response is not entirely unexpected when duration of exposure is used in the analysis, as subjects with longer duration of employment may be those with lower intensity of exposure and better health status.

42.5 Primary Prevention

How can occupational epidemiology help evaluate the need and effectiveness of primary prevention interventions and policies?

Sound epidemiological studies are typically needed to produce evidence of toxicity for occupational agents when long-term effects are present such as in occupational cancer that we use here as an example (Merletti and Mirabelli 2004). Complex mixtures entailing occupational exposures were among the first causes of cancer to be identified and finally led to the identification of specific causal agents. Thus, the study of occupational cancers offered precious insights and paradigms for occupational epidemiology at large.

Agents currently established as causes of occupational cancer and occupations with sufficient evidence of increased cancer risk according to the International Agency for Research on Cancer can be found in this textbook (see chapter ▶Cancer Epidemiology of this handbook; IARC 2011).

In appraising the body of evidence on occupational hazards and its relevance for control of occupational exposures, consideration must be given to the problem of who should bear the burden of proof and what the proof should consist of: whether evidence of benefit from intervention or evidence of harm from exposure. Occupational exposures are imposed upon individuals who have little, if any, personal choice, freedom, and responsibility in accepting or avoiding them. Furthermore, they often lack the basic necessary knowledge. As consequence, the burden of proof is on the employer, to demonstrate that the production process is safe. Evidence that exposure may be harmful is sufficient to require intervention to eliminate it.

Primary prevention, in the field of exposure to carcinogens as well as of other chemical and physical hazards at work, is based on the application of basic industrial hygiene strategies at the industry level: (1) substitution with agents intended not to be as dangerous, (2) fully enclosed processing, and (3) strict control of exposure by reduction of amounts used, by local exhaust, by personal protection, by cleaning practices, etc. This means to reduce the number of potentially exposed workers and their exposure level. Exposure control is better implemented by embedding it in the project of plants and processes, aiming to workers' protection as well as to that of neighboring communities.

At the community and country level, primary prevention entails adopting regulations intended to favor preventive measures or to enforce them. The first country to forbid the manufacture of certain chemicals because of their carcinogenicity was the United Kingdom, with the Carcinogenic Substances Regulations in 1967, prohibiting beta-naphthylamine, benzidine, 4-aminobiphenyl, and 4-nitrobiphenyl (UK 1967). The EC regulation on carcinogens at work has been developed starting with the 90|394|EEC Directive, but still today the only carcinogenic agents whose production and use is forbidden, apart from asbestos, are the same four as in the UK Carcinogenic Substances Regulations. In the USA, no formal ban has been put on any carcinogenic agent, production, or process on grounds of workers' protection. Permissible exposure levels (PELs) have been established by the Occupational Safety and Health Administration (OSHA) largely on the basis of the 1987 list of the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit values (TLVs), with the result that (1) the TLV's list has been updated and expanded by ACGIH, but the list of PELs is unchanged, and (2) certain agents are commonly recognized carcinogens, but their PELs were established without taking their cancer-causing properties into account (Smith and Mendeloff 1999).

Despite these limitations, OSHA and EPA in the USA and the EC in its regulation on classification, labeling and packaging of dangerous substances publish lists of substances officially recognized as carcinogens. The availability of lists of carcinogenic, and in general of toxic, chemicals is a useful tool for hazard identification, even if limited to intentionally used agents.

Workers' information on their exposures and on the risks entailed by them is a fundamental issue. It is the first step in their empowerment to verify that appropriate measures have been taken. The EC regulation requires that specific information is given to exposed workers, including special instructions on how to deal with accidents and emergencies.

Provided local regulations have been adopted, like all EC Member States should have done, law enforcement through technical public services specialized in inspecting workplaces is another key issue. Further, workers should be able to stand in courts not only when they are affected by work-related conditions but just because they are exposed, and their cases should be fairly settled, which does not seem to occur currently even in large EC Member States (Editorial 2003).

It may be surprising that systematic reviews on the effectiveness of interventions and/or implementation activities aimed at exposure control are generally lacking. In the area of occupational cancer, an exception may be the review by Kogevinas and coworkers in 1998 on the rubber industry (Kogevinas et al. 1998), where some changes in overall technology and chemistry were considered along with evidence on the persistence of previously observed cancer risks. This review is useful to point out the many and different difficulties we are confronted with while trying to gather evidence of effectiveness in occupational cancer prevention:

1. The long induction period of most human cancers prevents driving conclusions from early observations after changes are introduced, since workers first employed after intervention are not yet at risk, or fully at risk, of developing the disease.
2. Longer-term observations, however, are difficult to carry out; they are also difficult to interpret because of changing patterns of incidence/mortality in the disease of interest, and of possible complex interactions with other exposures.
3. Often, the exposure characteristics are not well understood and recorded, so it may become impossible to assess the quantitative relationship between exposure level and disease occurrence, which is precisely what is needed when exposure levels are reduced, but the agent is not completely eliminated.
   (a) Sometimes, the nature of the relevant exposure is not understood, so that a carcinogenic agent may be withdrawn, but its substitutes may be as dangerous, or almost as dangerous.
   (b) Both industry-based and community-based epidemiological studies have major limits in exposure assessment, due to lack of suitable exposure data, and this is the origin of major uncertainties and controversies in the interpretation of epidemiological evidence.

This picture explains why it is difficult to obtain evidence of cancer risk reduction following the adoption of control measures and why reports of this kind of evidence are rare.

Within the limits of the above-mentioned uncertainties, some widespread occupational cancer risks (Cruickshank and Squire 1950) seem to have disappeared from industrial and agricultural settings in Europe and in the USA. Furthermore, some carcinogenic exposures also disappeared or have been reduced to lower levels in developed countries. The subsequent reduction of the fraction of cancers attributable to occupation can be estimated, provided adequate data are available (Armstrong and Darnton 2008), and has to be the object of future scientific investigations.

Some contradictory experiences occurred either: Agents have been substituted with others now seemingly entailing the same risks, carcinogenic contaminants have been eliminated from agents used in certain industries only to be introduced in agents used in other processes, and only partial elimination of risk has been achieved when relevant exposures were to complex mixtures rather than to simple chemicals (Evanoff et al. 1993). Therefore, workers' exposure to carcinogens in industrialized countries is still not controlled as completely as it should be, given our current knowledge of the carcinogenic properties of chemical and physical agents. The most critical point, however, is continuation of productions and processes entailing exposure to carcinogens in developing countries, often lacking experience in the management of industrial hazards and power to enforce sound control strategies (Jeyaratnam 1994).

42.6 Conclusions

Attempts have been made to estimate the global burden of disease and injury due to occupational factors (Leigh et al. 1997, 1999; Ezzati et al. 2002; Rushton et al. 2010). Although such global statistics are of difficult interpretation, given the very large number of assumptions underlying them, two major conclusions can be drawn: (1) The problem is still an important one throughout the world, including developed regions; (2) the burden is shifting to the developing world, which accounts to 70% of the world's workforce and where the globalization of industry is resulting in increased exposure to occupational agents. The situation is exacerbated by unsafe technology, transfer of hazardous industries and wastes from developed to developing countries, use of agents banned or restricted elsewhere, poor health and nutritional status of the workforce, and ineffective legislation on occupational safety and health. Although prevention of exposure to occupational hazards will come from political and economic changes in the world, just as political and economic interests are the determinants of the present situation, much can still achieved, even in the current international situation (Pearce et al. 1994).

The applications of occupational epidemiology in public health decision-making are broadening, providing inputs to risk assessment, evaluation of occupational guidelines, and extrapolation of findings from occupational settings to communities with the aim of setting policies at population level. These multiple applications mean increasing responsibility to ensure ethical scientific conduct and clear, thorough communication of the assumptions, limitations, and uncertainties, of the results of research and of risk assessment (Kriebel and Tickner 2001).

Recent discoveries in molecular biology and genetics have made it possible for researchers to examine how genetic characteristics affect responses to occupational and environmental exposures. The use of genetic biomarkers in epidemiology has provided potential understanding of the underlying mechanisms of disease and therefore ultimately contributes to public health. Despite the potential benefits of genetic information, its collection in epidemiological studies, particularly in occupational settings, presents ethical, legal, and social challenges. Clarifying gene-environment interactions will have implications for difficult regulatory questions, such as protecting the most susceptible members of the population and its subgroups, but in the case of workers, genetic information could be used to discriminate them (Christiani et al. 2001). The challenge of identifying and applying genetic information in the study of human diseases in instances in which it will make a difference to prevention and public health (Millikan 2002; Merikangas and Risch 2003; Schulte 2004) may well also apply to occupational epidemiology.

43.1 Introduction

43.1.1 Issues of Environmental Epidemiology

The human environment – "the aggregate of surrounding things, conditions, or influences especially as affecting the existence or development of someone or something" (Webster's Encyclopedic Unabridged Dictionary of the English Language 1989) – is a topic of ever-increasing public awareness. Concern about the safety of the environment has stimulated controversial debates both in the general public as well as in the scientific community. Environmental safety has to meet defined standards for the protection of public health, and epidemiological knowledge has to be gathered on the impact of risk factors on human health.

Environmental epidemiology may be defined as "the study of the effect on human health of physical, biological, and chemical factors in the external environment. By examining specific populations or communities exposed to different ambient environments, environmental epidemiology seeks to clarify the relation between physical, biological, and chemical factors and human health" (NRC 1991).

Although this is a modern definition of the relation between environmental hazards and humans, the ideas of environmental epidemiology are linked to medical history. Environmental hazards were observed in ancient times. For example, Locher and Unschuld (1999) cite the antique scripts of Hippocrates, "De aere aquis locis" or Aristotle, recommending that cities have to be located in a healthy environment and that air and water should be clean so as not to impair human well-being.

Another example of an environmental issue is the radon problem, which was first addressed in 1492 by Paulus Niavis in his essay, "Ludicium Iovis" oder *Das Gericht der Götter über den Bergbau*:

> Wie man vom Schneeberge und von den Gruben zu sprechen hat: Die arbeiten darin, und die Luft im Berge, die sehr ungesund ist, nimmt ihnen die natürliche Farbe, sehr oft geschieht es auch, dass sie frühzeitig mit Tod abgehen. (cited by Schüttmann 1992)

More than 500 years ago, the very first observations were made of a possible relationship between "the air within the mine" (*die Luft im Berge*) and symptoms of disease and early mortality in the area of ancient ore mining around the village of Schneeberg in Saxony, Germany. Writings by famous early modern physicians like Agricola, *Bermannus oder über den Bergbau* (1555) and *De Re Metallica* (1556), or Paracelsus, *Von der Bergsucht und anderen Bergkrankheiten* (1567), report cases of a special disease and describe disease clusters in Schneeberg, in Joachimsthal, and in other villages in this area. The disease was thus called Schneeberg lung disease (*Schneeberger Lungenkrankheit*) (Schüttmann 1992).

Agricola and Paracelsus did not know the real cause of the disease; it was more than 300 years until the *Schneeberger Lungenkrankheit* was identified as lung cancer in the year 1879. With this the occupational causality was stated, but the real source of exposure was not known until the processes of radiation were discovered at the beginning of the twentieth century. In 1909, the mines around Schneeberg were investigated and radioactivity was measured. Based on this, a director of the mines formulated in 1913 the hypothesis of an exposure-effect relationship between the

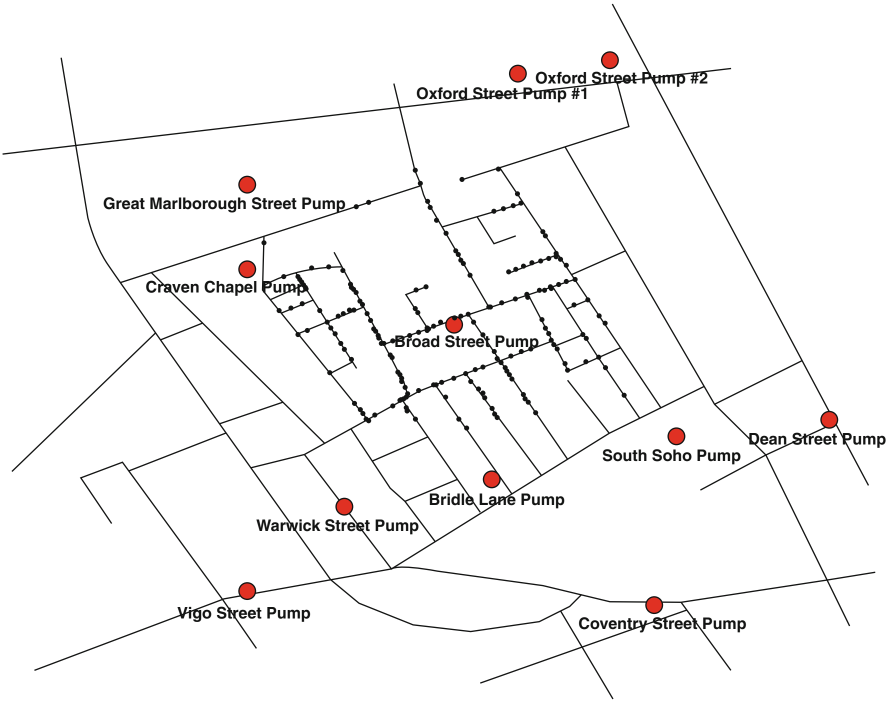

Fig. 43.1 John Snow's map of cholera cases in Soho, London (Figure modified from EpiInfo^{TM} 2000)

"radium emanation" or radon and lung cancer. Although the real nature of the dose-effect relationship was not known, the *Schneeberger Lungenkrankheit* was officially recognized in 1925 as an occupational disease in Germany in cases of diseased workers that had been extensively exposed in the mines. These observations led to the question of whether radon is a common risk. Due to the ubiquitous presence of the gas, it can be extrapolated that radon constitutes an environmental hazard in the general population (Schüttmann 1992).

Another classical example of environmental epidemiology is the famous risk map of John Snow, who reported cases of cholera in Soho, London, in the middle of the nineteenth century (Fig. 43.1).

The increasing number of cholera cases in London in 1849 and 1853/1854 caused a great awareness of the real reasons for the epidemic. John Snow's map can be considered as one of the initial steps in spatial statistics and spatial epidemiology (cf. chapter ▶Geographical Epidemiology of this handbook). It identified the source of the epidemic in the contaminated water of the Broad Street Pump. Additional research was carried out, and it was discovered that cholera incidence differed substantially in the water supply areas of the Lambeth water company and the Southwark and Vauxhall water companies. While in "Lambeth's area," 461 cases were observed in a population of 173,748, 4,093 cases occurred in a population of

266,516 in the “Southwark and Vauxhall area.” The risk ratio of 5.8 indicated a serious problem with water contamination in the “Southwark and Vauxhall area.”

These classical examples illustrate that the impact of the environment on human health was realized very early and that this impact depends on the social and political situation of a population. Nowadays there are different environmental health concerns in the developed and the developing countries. With the foundation of modern epidemiology by Sir Richard Doll and others in the middle of the twentieth century, the general focus of public and scientific concern was first on risk factors like smoking, occupation, and nutrition and their association with cancer and cardiovascular diseases. Many methods of modern epidemiology were developed as applications on these associations.

In the developed world, environmental issues of public and scientific concern are ambient air pollution, radiation (from the general environment as well as from nuclear power plants and facilities), environmental tobacco smoke (ETS), or special agents known as hazardous from occupational exposures like lead and mercury and their impact on human health. In contrast, in the developing world, the major concerns are clean air, sanitation, and clean water. Infectious diseases (cf. chapter ▸Infectious Disease Epidemiology of this handbook) in particular are a part of this problem as well as severe environmental pollution and exposures to chemical agents.

Incomplete understanding of causes of many common diseases in both developed and developing countries focuses interest on identifying environmental hazards and incorporating this knowledge in strategies of risk management.

43.1.2 Concepts of Environmental Epidemiology and Toxicology

The concept of common risk analysis has been suggested as an approach to gaining basic comprehension of all processes necessary to understand and manage risks on human health (cf., e.g., Graham 1997). Risk analysis could be defined as a three-stage process including risk assessment, risk management, and risk communication. Risk assessment may be understood as a purely scientific process, in which information is collected to describe risk factors and their impact on human health, while risk management and risk communication describe the political and social process to put this information into population-relevant actions, rules, and laws.

The general principles of a scientific environmental risk assessment may be described as a four-step process:

- Hazard identification, that is, does the agent have the potential to cause an adverse effect?
- Exposure assessment, that is, what exposures are experienced or anticipated under relevant conditions?
- Exposure-outcome assessment, that is, what is the relation between exposure and outcome in humans?
- Risk characterization, that is, what is the estimated incidence and severity of an adverse effect in a given population?

The basic scientific methodologies to deal with environmental risks and to answer the questions of risk assessment are environmental epidemiology and environmental toxicology. Both concepts should be recognized as scientific partners within a common risk assessment.

The risk assessment process in environmental toxicology usually comprises several steps of in vitro and animal experiments over a broad range of exposure intensities, leading to a NOEL (no observed effect level) in a sensitive animal species and the ADI (acceptable daily intake) that incorporates an appropriate safety factor, usually 10, 100, or higher. This process of risk assessment to protect humans works well for numerous compounds, but it also has a number of shortcomings.

First, many agents like cancerogenic, genotoxic, and allergenic chemicals are not considered to have a threshold exposure level and may induce cancer or an allergic reaction at extremely low exposures. Second, usually single compounds are tested, although we are exposed to numerous agents simultaneously. The possibility of both synergistic and antagonistic interactions between agents greatly complicates the risk assessment process. Of particular importance are synergistic reactions that have been demonstrated in vitro and in experimental animals in some instances. Here, a single agent does not induce any – or only minor – adverse effects, while the simultaneous administration of two agents elicits a strong toxicological effect. Obviously, the NOEL-ADI approach using single-agent administration does not incorporate the possibility of agent interactions. Therefore, additional methods must be developed to approach this problem. Third, the current concept does not take previous exposure into account. That is of special relevance for persistent bioaccumulative compounds like heavy metals. For these compounds, the ADI should be based on estimation of human body burdens and body burden-response relationships.

Another problem is the difficulty of extrapolation to very low doses. The restriction in the number of animals per group that can be used and the paucity of data on the mechanistic action of agents are the main reasons for these difficulties. Much effort is being spent, and more should be on the development of alternative methods in risk assessment to reduce the use of experimental animals. A number of cell and organ cultures of animal and human origin have been developed. The relative simplicity of these systems in comparison to whole animal models can be both advantageous and disadvantageous. However, few in vitro systems available at present are accepted as alternatives to whole animal models both in the scientific community and in regulatory agencies. It is clear that in vitro systems cannot reflect the entire organism and thus can reduce and refine, but not entirely replace, animal experiments. However, in vitro systems can be of enormous help to understand the mechanisms of toxic action.

These limitations of in vitro and animal experiments in toxicology call for human data from observational epidemiological studies. In general, epidemiological investigations of environmental hazards have to be conducted with the same care as in other fields, but in environmental studies, some special features have to be considered.

On the one hand, an environmental risk factor may cause severe diseases such as cancer or strong respiratory symptoms; on the other hand, these outcomes are also induced by many other risk factors; therefore, the relative impact of the environmental agent is small. This is true for many environmental problems, for example, the effects of air pollution on respiratory health, the effects of water contaminated with heavy metals and subsequent permanent damage to children's intellectual potential, and the effects of residues in food on human health. Furthermore, there are only a few situations in which high concentrations of an environmental agent affect a large part of the population. These cases may be related to "special sources" and often result from an accident like the Chernobyl disaster or from exposure of a population within a restricted area as a consequence of chronic pollution of the soil, for example, by an industrial plant.

Investigation of small risks is one of the main characteristics of environmental epidemiology. At this point it has to be noted that a small relative risk does not mean that the risk is not important. Many environmental risk factors are ubiquitous, and large proportions of a population can be exposed. This may cause population-attributable risks that cannot be neglected and may therefore be an important task for risk management. The dimension of this problem is demonstrated in several reports of the (environmental) burden of disease (cf., e.g., Prüss-Üstün et al. 2003). In assessing the health risk of environmental tobacco smoke (ETS), Heidrich et al. (2007) calculated the attributable risk (*AR*) for coronary heart disease and Heuschmann et al. (2007) calculated the *AR* for stroke in the entire German population (approx. 80 million). Although the association of ETS with both diseases is weak, that is, the corresponding relative risk is in the order of 1.2, ETS causes more than 2,000 additional deaths due to coronary heart disease and more than 700 deaths due to stroke per year.

But addressing small risks for multifactorial diseases leads to several problems in conducting an epidemiological investigation. First, all possible risk factors linked to a disease outcome should be incorporated into a study to avoid bias due to confounding and to study the possible interactions among all risk factors. This in turn requires that a large number of parameters be incorporated into a risk model. Therefore, large sample sizes are necessary to provide sufficient statistical power. Besides financial constraints, the logistic requirements are a major issue of the fieldwork in an environmental epidemiological investigation.

Second, the overall power of an investigation will be influenced by the definition of exposure itself. For example, "air pollution" is a mixture of hundreds of agents. If for this purpose an exposure-disease relationship has to be detected, the definition of exposure has to be clarified in advance. There are many different possibilities to assess the exposure and to conduct measurements, and each of them may contribute to the real exposure-disease relationship. As a consequence, a proper exposure assessment is of substantial importance, and much effort has to be made to conduct a powerful investigation.

Therefore, special methodological issues have to be taken into account in environmental epidemiology. Before these are described, special research situations need to be addressed in more detail as typical examples.

43.2 Examples of Research Fields in Environmental Epidemiology

There are numerous exposures and disease outcomes in environmental epidemiology, and there are many bibliographies, dictionaries, and structured databases with detailed information on the risks of environmental exposures. Only a few of them can be discussed further here.

43.2.1 Outdoor Air Pollution

From the earliest times, the impact of air pollution has been a major public health issue of interest in environmental epidemiology. For example, as early as 1294, the mayor of Venice is reported to have given orders to manufacturers of metals like mercury or tin to change the company's location to avoid exposing the population to "unhealthy smoke" (Locher and Unschuld 1999).

Industrial air pollution, coal burnt in domestic hearths, and traffic in combination with special weather conditions were the reasons for the London smog episode in early December, 1952. Smoke and sulfur dioxide pollution increased dramatically during this time. The visibility in central London dropped to a few meters, and there was an up to ten-fold increase of ambient air concentrations of sulfur dioxide. Traffic and general public life were strongly restricted. More than 4,000 deaths were attributed to the air pollution during that time, and mortality increased upon the average even in the months after this environmental disaster.

The London smog episode may be considered the beginning of quantitative risk assessment of the effects of air pollution on human health; it continues to influence the ideas and methods of environmental epidemiology today, as is shown, for example, by reanalysis of the 1952 data (e.g., Bell et al. 2004). As a political and social consequence, the British government introduced its first "Clean Air Act" in 1956 to reduce air pollution. As a scientific consequence air pollution was first defined by the level of sulfur dioxide and the concentration of particulate matter. Afterward, it was possible to make a more detailed analysis of the relationship between air pollution and human health by looking more closely at the diameter of particles, nitric (di)oxide, ozone, and other constituents.

The outcome of concern during the London smog was daily mortality, which was approximately four times above the average daily mortality during December. The deaths attributed to the smog were primarily linked to pneumonia, bronchitis, tuberculosis, and cardiovascular failures. This caused a controversy on whether these deaths occurred only among people with previous severe illness or whether the smog caused additional deaths. Another problem is the aggregation of cause-specific mortality rates by day. In such aggregated data, there may be perfect correlation between the exposure in question and other health risks like smoking which might confound the association. Individual-based studies are better suited for the investigation of multifactorial diseases, because perfect correlation between variables is very unlikely and it is thus feasible to separate their effects.

Since then, many studies have been conducted to resolve this debate. One of the most famous is the "Six City Study" conducted as follow-up study by the Harvard School of Public Health in the US cities Watertown, Massachusetts; Portage, Wisconsin; Topeka, Kansas; Kingston/Harriman, Tennessee; St. Louis, Missouri; and Steubenville, Ohio. In this concurrent cohort study with a 14- to 16-year mortality follow-up, the effects of air pollution on mortality were estimated, and individual risk factors were monitored for 8,111 adults. The Harvard group found that higher levels of fine particles and sulfate were associated with an increase in mortality by 26% (95% confidence interval: 8–47%), when the most polluted city was compared to the least polluted city. A positive association of mortality with concentrations of fine particles was found for cardiopulmonary disease. The authors therefore concluded: "Although the effects of other, unmeasured risk factors cannot be excluded with certainty, these results suggest that fine-particulate air pollution, or a more complex pollution mixture associated with fine particulate matter, contributes to excess mortality in certain U.S. cities" (Dockery et al. 1993).

Other studies corroborated the finding that long-term residence in cities with elevated ambient levels of air pollution is associated with an increase in mortality (e.g., Pope et al. 1995; Anderson et al. 1996; Katsouyanni et al. 1997; Samet et al. 2000; Vedal et al. 2003), but many questions still remain open. For example, a reanalysis of the "Six City Study" suggested that there is a modifying effect of education on the relationship between air quality and mortality (Krewski et al. 2004).

The epidemiology of air pollution is a highly complex and grave public health issue: On the one hand, mortality is only the endpoint of one possible health outcome; respiratory and cardiovascular disease or cancer are other serious issues. On the other hand, additional agents may be identified as characterizing parts of air pollution. Not surprisingly, the number of epidemiological studies of the impact of air pollution on human health is overwhelming (cf. WHO 2000; Brunekreef and Holgate 2002).

43.2.2 Residential Radon

A major issue of epidemiological research during the last decades has been the development of exposure-risk functions between radiation and different (cancer) outcomes. The main sources of the average annual radiation exposure in industrialized countries are medical examinations and therapies, inhalation of radon and its progeny, ingestion of natural radiation sources, and cosmic and terrestrial radiation (UNSCEAR 2000). Other sources, like the fallout from nuclear weapon experiments, the Chernobyl disaster, or the occupational exposure of workers in the nuclear industry, are low or affect only a very small part of the general population.

Worldwide the average annual effective dose from radon and its decay products is estimated at 1.15 millisievert (UNSCEAR 2000). Therefore, natural radon seems to be an environmental risk factor of great interest. Its harmful character was recognized very soon after the discovery of radiation at the beginning of the

Table 43.1 Individual and pooled results of 11 cohort studies in miners on radon exposure and lung cancer (Lubin et al. 1994)

Study	# cases	(ERR/WLM)%	CI

twentieth century and its identification as the real cause of the *Schneeberger Lungenkrankheit* (cf. Sect. 43.1.1).

In the history of radiation research, many (animal) experiments and measurements have been undertaken, with the usual uncertainties in extrapolating the results to humans. However, in the middle of the twentieth century, cohort studies in (uranium) miners were started to investigate the true exposure-disease relationship between radon and lung cancer. These studies confirmed that exposure to the radioactive gas radon (^{222}Rn) and its progeny increases the risk of lung cancer among workers in the uranium and other mining industries (Lubin et al. 1994; NRC 1999; IARC 2001; Table 43.1).

The study results in Table 43.1 are reported with exposures in working level month (WLM). This cumulative measure was developed historically with the idea of there being a safe threshold for radiation exposure of workers. This was defined as 1 working level (WL) and was stated as 100 picocuries per liter, which in today's SI units is equivalent to 3.7 kilobecquerel per cubic meter (kBq m-3; 1 becquerel per cubid meter is 1 radioactive decay per second in 1 cubic meter air). With an average time of occupation of 170 hour per month, this cumulates to 1 WLM.

Overall a strong exposure-effect relationship was observed. When the occupational-related exposure scale is transformed from WLM in usual Bq·m^{-3} (for details on the assumptions and calculations of the transformation cf., e.g., NRC 1999), the overall estimate of the excess relative risk per WLM was estimated as 0.49 (Table 43.1). As 1 WLM corresponds to 170·3.7 kBq·m^{-3}, we get an estimate of 0.49/(170·3.7) = 0.08 per 100 Bq·m^{-3}, that is, per additional average exposure of 100 Bq·m^{-3}, the lung cancer risk will increase by 8%. This exposure-effect relationship is further influenced by the time since exposure (TSE), the age at exposure, and other risk factors like the exposure to arsenic or other dusts and the smoking habits of the workers. These factors were not investigated deeply within the cohorts, and therefore uncertainties remain about the dose-response relationship.

The public health concern about major radioactive exposure, however, is the long-term exposure of the general population to the much smaller concentrations of radon in homes. When the exposure-effect relationship from the miner studies is extrapolated to the level of radon exposure in homes, an average population-attributable risk of lung cancer of 5–15% can be estimated in industrialized countries (Lubin and Steindorf 1995; Steindorf et al. 1995; Darby et al. 2001; Menzler et al. 2008). If this extrapolation is true, exposure to residential radon is the most hazardous environmental risk factor for cancer in the general population, and risk management strategies need to be developed.

However, a direct transfer of the risk estimates derived from miner studies or animal experiments to residential environments may not be appropriate due to substantial differences in the levels of radon exposure; other physical factors such as breathing rate; the distribution of aerosol particles size; the unattached fraction of radon progeny; confounding factors such as smoking, asbestos, and other occupational risks; nutrition; leisure time activities; social conditions; genetic susceptibility; and age, gender, and regional circumstances.

In the past 20 years, a series of well-conducted epidemiological case-control studies investigated the risk of lung cancer in relation to indoor radon exposure in the general population (Schoenberg et al. 1990; Blot et al. 1990; Pershagen et al. 1992, 1994; Létourneau et al. 1994; Alavanja et al. 1994, 1999; Ruosteenoja et al. 1996; Auvinen et al. 1996; Darby et al. 1998; Field et al. 2000; Kreienbrock et al. 2001; Lagarde et al. 2001; Tomášek et al. 2001; Oberaigner et al. 2002; Wang et al. 2002; Barros-Dios et al. 2002; Kreuzer et al. 2003). Two collaborative analyses of these studies (Darby et al. 2005; Krewski et al. 2006) supported the hypothesis of an association, despite some heterogeneity among single studies, and concluded that residential radon exposure increases the risk of lung cancer, particularly in smokers, and recent ex-smokers.

43.2.3 Non-Ionizing Radiation

Exposure to electric and magnetic fields (EMF) in the occupational as well as in the residential environment is a matter of public concern in the developed world. The debate on health consequences is widespread, and there is speculation on possible effects of exposure ranging from the development of cancer to headaches, depressions, or general malaise.

A first investigation of Wertheimer and Leeper (1979) brought EMF and childhood leukemia to the special attention of the public. The authors conducted a case-control study with 155 cases and the same number of controls, and found a risk ratio of around three. So-called wire codes of distances to electric power lines were introduced as a measure of exposure to EMF.

Further studies followed. Greenland et al. (2000) and Ahlbom et al. (2000) summarized the results of these studies by pooling them into two joint analyses in the USA and in Europe (Fig. 43.2).

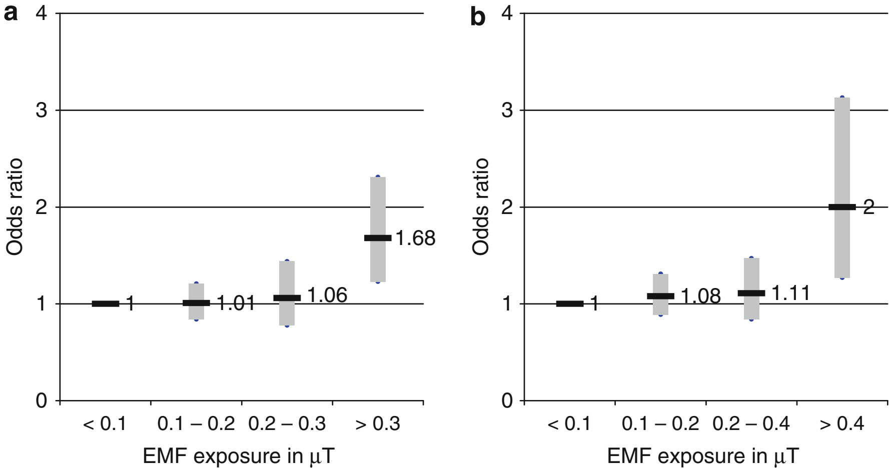

Fig. 43.2 Leukemia risk in children due to EMF exposure: odds ratios and 95% confidence intervals by EMF exposure in μT from pooling studies (**a**) in the USA (Greenland et al. 2000) and (**b**) in Europe (Ahlbom et al. 2000)

Figure 43.2 suggests a similar risk pattern in the USA and in Europe, with an overall statistical significance in the highest exposure group. However, the discussion on EMF risks is ongoing, primarily due to limitations of exposure assessment for the use of wire codes as well as for recent techniques of (personal) measurements and exposure assessment.

Habash et al. (2003a) therefore stated: "Currently, the evidence in support of an association between EMF and childhood cancer is limited, although this issue warrants further investigation. Evidence of an association between EMF exposure and adult cancers, derived largely from occupational settings, is inconsistent, precluding clear conclusions. There is little evidence of an association between EMF and non-cancer health effects. . . . Further research is needed to clarify the ambiguous findings from present studies and to determine if EMF exposure poses a health risk."

43.3 Special Methodological Issues in Environmental Epidemiology

Although there is great variation in study designs and in measurement techniques, methods of exposure assessment and statistical analyses used in environmental epidemiology share common features that will be summarized in the following.

43.3.1 Principles of Study Design

As mentioned above, one of the major problems in studying an environmental risk factor is often the low risk associated with it. Therefore, the overall power of a study has to be large to increase the chance of identifying health hazards. The proper choice of the study design is thus a basic step in conducting an investigation in environmental epidemiology.

43.3.1.1 Standardization of Study Designs

The power of an epidemiological study is related to two major components, namely, the sample size and the precision of all instruments used. The number of available cases and the financial budget are constraints that determine the limitations of every investigation. Therefore, it is desirable to standardize study designs to increase the precision of the results and to establish a basis for comparisons between different studies.

For example, the designs of studies of the impact of residential radon developed gradually over time. In a very first step, ecological studies were performed to investigate the numerical correlation between radon concentration and lung cancer mortality with aggregated data, for example, on the basis of administrative districts (Stidley and Samet 1993). This type of study design is very popular in environmental epidemiology but is strongly influenced by different types of biases, especially confounding bias (cf. chapter ▶Descriptive Studies of this handbook). Figure 43.3 shows an example of an ecological analysis for radon data in West Germany.

Figure 43.3 shows a typical problem which occurs in ecological studies in environmental epidemiology when the environmental risk factor is associated with a low risk and the disease is influenced by a strong risk factor that is itself associated with the risk factor under study. On the one hand, in Germany – as in other industrialized countries – smoking is much more popular in cities and urban areas (e.g., the major cities Berlin, Hamburg, Düsseldorf, Bremen) than in rural areas (e.g., the rural districts Niederbayern, Oberpfalz, Tübingen in the south

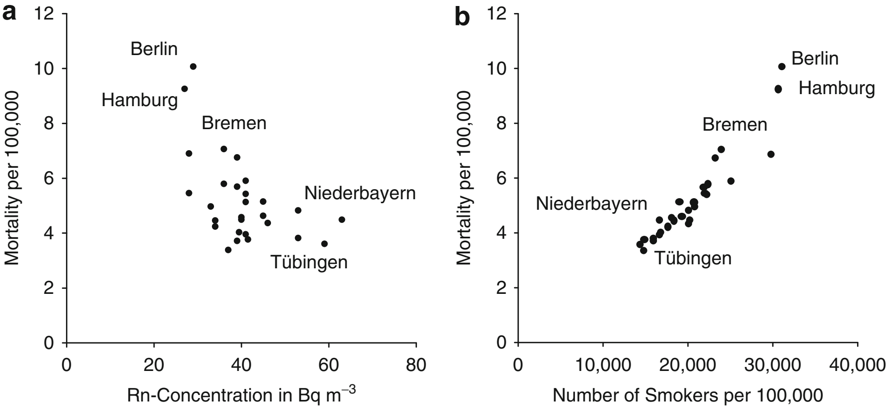

Fig. 43.3 Lung cancer and radon in West Germany. (**a**) Lung cancer mortality in women by average radon concentration in West German districts (*Regierungsbezirke*). (**b**) Lung cancer mortality in women by average smoking prevalence among females in West German districts (Kreienbrock et al. 2012, modified)

Table 43.2 Three generations of radon studies with individuals (Pershagen 1993, personal communication)

Generation	Characterization
I	– Conducted in the early 1980s – Small sample sizes – No or crude Rn measurements – No or only small control for confounding
II	– Conducted in the late 1980s – Small sample sizes – Rn measurements in one house – Some control for confounding
III	– Conducted in the 1990s – Big sample sizes – Rn measurements in all homes – Control for confounding

of Germany). In addition, smoking prevalences decrease from north to south. On the other hand, radon concentration is low in cities and urban areas, while higher measurements are much more likely in rural areas. This pattern causes a "protective radon effect" if the smoking habits are neglected.

This type of misleading findings in ecological studies is known as the ecological fallacy and can be observed in many studies on radon (Cohen 1993, 1997) as well as on other environmental risk factors. Therefore, ecological studies are only reasonable as a starting point for discussion. Causal relationships could not be concluded from this type of study design.

Study designs based on individuals are necessary to investigate the causal role of environmental risk factors. For studies on the radon-related lung cancer risk in the general population, Pershagen (1993, personal communication) described three generations of studies following the ecological studies (see Table 43.2).

The studies from the first and second generations were very small and therefore did not have the power to detect the radon-related lung cancer risk, which is expected to be low. Thus, in 1989, 1991, and 1993, workshops were organized with all principal investigators of ongoing studies during that time to develop "Guidelines for Conducting Radon Studies" (Samet et al. 1991). These workshops led to a standardization of study protocols and formed a basis for future pooling of studies.

Although this process of standardization cannot be established as a general rule in environmental epidemiology, it should be recognized as a strategy that may enhance the overall power of investigations.

Because the risk ratio of an environmental risk factor is usually low and many of the diseases under study are not frequent, a case-control study is the type of study design that is most appropriate to investigate an environmental risk factor within the common population. This is usually done for studies on radon and lung cancer as well as for most of the studies investigating the impact of environmental agents on cancer. For example, of the 20 studies on residential radon mentioned in Sect. 43.2.2, only the Czech study was conducted as a cohort study in which a case-control study is nested (Tomášek et al. 2001).

In contrast, at first glance cohort studies seem to be rare in environmental epidemiology due to the extensive efforts they require. Nevertheless, there are well-known examples of this study design, such as the "Six City Study" on air pollution and mortality (Dockery et al. 1993, cf. Sect. 43.2.1), and other longitudinal designs, studying long-term effects of the relation between air pollution exposure and public health (Brunekreef 2003). Therefore, the use of cohorts is increasing in different fields of environmental interest. For example, cohorts are now being used in investigations on the impact of nutrition on human health, like the EPIC project (European Prospective Investigation into Cancer and Nutrition), which studies more than 500,000 participants in ten European countries (Slimani et al. 2002). However, the establishment of large cohorts for environmental research is often facing financial restrictions limiting the proper assessment of exposure (see below).

43.3.1.2 Selection of Study Participants and Choice of the Study Area

The first step in planning an investigation in environmental epidemiology is the choice of the study area. For this purpose, monitoring data of measurements is very helpful to find out whether the risk factor is present within a defined region and which variation it shows. This is necessary to distinguish between exposed and non-exposed populations or to evaluate an exposure-effect relationship for a common range of possible exposures.

However, areas with high average concentrations or with a greater proportion of elevated values do not by definition guarantee a proper environmental study. If the risk factor is distributed equally, cases and controls of the study region will be exposed to a similar degree, and no effect of the risk factor can be observed in the study. This problem is known as "overmatching on the exposure factor." It can be avoided by separating areas with different levels of the risk factor. This problem is commonly discussed in studies on the possible impact of outdoor air pollution as a risk factor (e.g., Dockery et al. 1993; Pope et al. 1995; Heinrich et al. 2000; Hoek et al. 2000).

A different problem occurs in studies on the indoor environment: The concentration in homes is influenced by outdoor air, geology, or other factors related to the outside environment but will be modified by the type of house and the (ventilation) habits of the inhabitants. This may result in low measurements even in areas with a great impact of outdoor air or geology on increased concentrations of the agent under study. Taking into account the fact that measurements are only one component of the exposure assessment (see below), it is possible that both cases and controls will be exposed at a very low level. This effect was observed, for example, in many radon studies, for instance, in the study in Winnipeg, Canada (Létourneau et al. 1994), or the study in West Germany (Kreienbrock et al. 2001), where measurement programs showed areas with high radon concentrations on average, while exposures of study participants were low. This was mainly due to the mobility of the population that resulted in low average exposures of individuals (Warner et al. 1996).

Therefore, the choice of the study area has to be influenced both by the presence of a monitoring program indicating areas with elevated concentrations of the risk factor and by a population density that yields a sufficient number of study participants.

The selection of cases within the study area is dependent on the health system within this area. If national or regional registers are available, cases will usually be recruited from these registers; if not, case recruitment from hospitals will be the usual sampling strategy. The problem of a proper selection of a group of cases is similar in all kinds of epidemiological applications, but if measurements on environmental agents have to be conducted, this causes additional problems, especially if the cases are to be recruited in hospitals and the measurement campaign is (technically) complicated. This will decrease the response proportion in the case group, and the rates may be differential by disease stage and thus may cause a selection bias. On the other hand, even in studies with registers, this type of problem is present, especially if next-of-kin interviews have to be conducted instead of interviews of cases.

Similar problems due to selection procedures and exposure assessment may be present for the control group in environmental studies. As in any other epidemiological study, the different types of bias may occur, but these may be strongly influenced by the type of measurement to be conducted. This problem can be observed mainly in "special circumstances studies," where recent environmental problems of great public interest are studied. This may cause different response proportions among subgroups within the general population, which may introduce a severe selection bias and impair comparability between subgroups.

An example of a special circumstances situation was described by Oberaigner et al. (2002) for radon epidemiology. In 1989, high lung cancer mortality rates were reported for the District of Imst, Tyrol, Austria, in an alpine region without any industry. First investigations in this district (Ennemoser et al. 1994a, b) identified one village with extremely high radon concentrations; the highest concentrations measured in residences were above 100,000 Bq·m^{-3}. In the meantime, detailed cross-sectional investigations have examined both the radon gas concentrations and the geology. In fact, only half of the village was affected, and about 40 residences were identified with concentrations above 1,000 Bq·m^{-3}. There were only few and isolated high concentrations in the other villages of this region. In fact, the scientific interest in this area was linked to population's interest and response. While in the beginning the whole population was interested, in cross-sectional measurement programs, there was a gradual decrease in response proportions linked, unfortunately, with increasing exposure.

Decreasing response proportions were also observed during the 1990s after the reunification of Germany, when many environmental measurement programs identified numerous areas with elevated levels of environmental agents of scientific interest in the former German Democratic Republic (Heinrich et al. 2002; Frye et al. 2001). One may call this effect a possible bias due to "over-examination."

These examples indicate that selection bias is of special interest in environmental epidemiology and special efforts have to be undertaken during fieldwork to avoid possible selection effects. Besides an exact definition of inclusion and exclusion criteria of study participants, selection effects are mainly dependent on a proper documentation of the reasons for response and non-response combined with an additional investigation on the non-responders. Moreover, it is necessary to make corrections for selection bias.

43.3.1.3 Sampling Procedures and Correction for Non-Response Bias

Usually the recruitment of study participants is described as a process of selecting a study population from a target population by means of a defined sampling scheme. If the study population is a representative sample of the target population, the study results should be unbiased; otherwise, a selection bias may occur which will have to be discussed. For studies in environmental epidemiology, these biases may be described from two different perspectives.

On the one hand, different selection procedures for the exposed and the non-exposed populations are possible, as observed in many environmental studies. Heinrich et al. (2002) described studies on air pollution and respiratory health and allergies in the former German Democratic Republic, where response proportion decreased with increasing exposure. On the other hand, response proportions may differ between cases and controls of a study. This effect is often due to the fact that controls are less motivated so that their response proportions are lower than that of the cases who want to know whether environmental hazards are responsible for their disease.

Investigation of the non-response patterns seems to be necessary to investigate these processes and to establish a basis for an adjustment for possible selection effects caused by non-response. The general principle of a non-response investigation was initially outlined by Hansen and Hurwitz (1946) and is illustrated in Fig. 43.4. It may be assumed that study response is a characteristic of the members of the target population that partitions the population in two strata, N_1 responders and N_2 non-responders. An epidemiological study of study size n may be interpreted as a stratified random sample from the target population, that is, a stratified sample of real responders n_1 and non-responders n_2. This process can be interpreted as a first phase of a sampling plan. In a second phase, a real sample of size n_2^* is drawn from the n_2 non-responders, and all efforts are made to get information from this second-phase subsample of size n_2^*, for example, by conducting additional telephone interviews. The final study population n^* will be calculated as the sum of these subsample sizes.

If a non-responder investigation is conducted, adjustment for non-response will be possible in a straightforward way. For simple linear statistics like prevalences or means (of exposures), an adjusted estimator can be computed as a simple weighted mean of the two strata means of responders, denoted as $\bar{y}_1$, and non-responders, say $\bar{y}_2$, that is,

$$\bar{y}_{\text{adj.}} = \frac{n_1}{n^*} \cdot \bar{y}_1 + \frac{n_2^*}{n^*} \cdot \bar{y}_2. \tag{43.1}$$

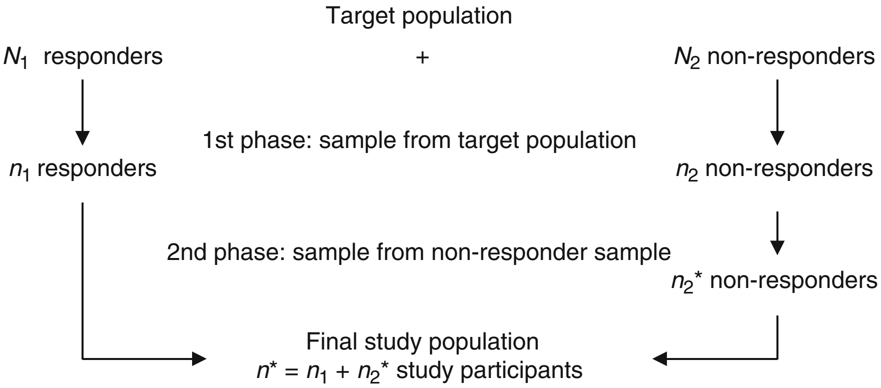

Fig. 43.4 Two-phase sampling scheme for collecting sampling information on non-responders

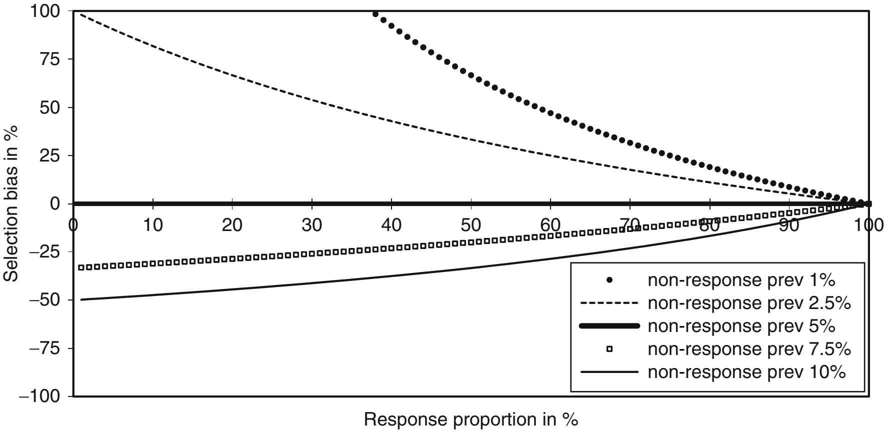

Fig. 43.5 Selection bias in % due to non-response for estimating a prevalence in the target population of 5% for varying exposure prevalences among non-responders

This type of adjustment (Eq. 43.1) is useful in environmental epidemiology, especially if diseases or exposures under study are rare and therefore prevalences are low. Figure 43.5 displays the impact of selection bias due to non-response on the estimation of a prevalence of 5% by comparing the adjusted estimator from Eq. 43.1 with the usual estimator, namely, the average $\bar{y}_1$, that is calculated without adjustment for non-response. This situation may occur, for example, in a cross-sectional study investigating the impact of air pollution on respiratory symptoms like asthma in boys. It can be shown that selection bias increases with increasing non-response, depending on the magnitude of the difference of the exposure prevalences between responders and non-responders.

Table 43.3 Realization of study subjects n_{ij} as sample with probability W_{ij} from the members N_{ij} of the target population, $i = D$ for diseased and $\bar{D}$ for non-diseased subjects, $j = E$ for exposed and $\bar{E}$ for exposed and non-exposed subjects

	Exposed	Non-exposed
Diseased	$n_{DE} = W_{DE} N_{DE}$	$n_{D\bar{E}} = W_{D\bar{E}} N_{D\bar{E}}$
Non-diseased	$n_{\bar{D}E} = W_{\bar{D}E} N_{\bar{D}E}$	$n_{\bar{D}\bar{E}} = W_{\bar{D}\bar{E}} N_{\bar{D}\bar{E}}$

A linear adjustment is not suitable for estimating ratios, and the strata of responders and non-responders have to be split up into the exposed and the non-exposed subpopulations. Kleinbaum et al. (1982) therefore introduced the 2×2 table of an epidemiological study as the selected outcome from the target population that results in a 2×2 table of selection probabilities for subjects from the entire target population (Table 43.3).

If selection of study participants is outlined as in Table 43.3, an epidemiological study to estimate a population odds ratio is unbiased if the odds ratio of the selection probabilities $W = (W_{DE} W_{\bar{D}\bar{E}})/(W_{D\bar{E}} W_{\bar{D}E})$ is equal to unity. If W is greater than unity, the study will be biased away from the null, else the bias is toward the null.

Investigations in environmental epidemiology may be very sensitive to selection bias. The odds ratio of the selection probabilities W may be used both for a quantitative and a qualitative assessment of the possible bias. If, based on the study design and the sampling techniques applied, the sampling probabilities can be computed, a quantitative adjustment for selection bias will be possible by multiplying the study odds ratio with the inverse W^{-1}.

If sampling probabilities are not available, a qualification of the direction of selection bias is possible. Examples for a qualitative assessment of the bias can be adopted from cross-sectional studies of the impact of air pollution on respiratory health. Here, the motivation of the study subjects may be influenced by the disease and by the exposure situation. In contrast, subjects who are not ill and who are not exposed may not be motivated to participate. This will decrease the selection probability $W_{\bar{D}\bar{E}}$; hence, $W < 1$, and the study odds ratio will be biased toward the null.

In contrast, if the same study is conducted in a “special circumstances area,” the effect may be vice versa if the healthy exposed population is unwilling to participate. This will decrease the selection probability $W_{\bar{D}E}$; hence, $W > 1$, and the study odds ratio will biased away from the null.

43.3.2 Measurements and Exposure Assessment

The measurement of an environmental agent such as the risk factor under study is the primary issue of an investigation in environmental epidemiology. Such measurements can be used directly or as a basis of an exposure assessment. The main problems to be addressed in any investigation in environmental epidemiology

Table 43.4 Examples of short-term and long-term exposure-effect relationships in environmental epidemiology

Exposure-effect relationship	Example
Short-term exposure/short-term effect	Traffic-related agents – acute respiratory symptoms Smog episodes – mortality
Short-term exposure/long-term effect	Fallout from nuclear weapon tests – cancer incidence Contaminated food – new variant of Creutzfeldt-Jacob disease
Long-term exposure/long-term effect	Environmental tobacco smoke – lung cancer Residential radon exposure – lung cancer

are an appropriate choice of the measurement technique, the method of exposure assessment, and the statistical evaluation to model the exposure-effect relationship.

Numerous types of exposures may be distinguished in environmental epidemiology. One useful categorization is to distinguish between short-term and long-term exposures and between short-term and long-term effects. The time interval between exposure and effect is often called time since exposure (TSE). Table 43.4 shows typical examples that may occur in environmental epidemiology within these categories.

The relationship of short-term exposures to short-term effects as well as the relationship of long-term exposures to long-term effects may be postulated as the typical situations under study in environmental epidemiology, while the situation in which a short-term (single) exposure causes a long-term effect seems to be rare. It may be argued that it is much more complicated to assess long-term exposures and that short-term exposures may be described by the measurement itself. However, this is not a general rule.

For radon and for many other agents, residential exposure is a long-term exposure starting at birth and ending with the study recruitment, for example, by the index date of diagnosis or the date of a standardized personal interview. The outcome under study is lung cancer as a long-term effect. Taking into account the fact that residential exposure is characteristic of the homes a study participant has lived in during his or her life, the overall exposure can be outlined as in Fig. 43.6.

The exposure pattern depicted in Fig. 43.6 seems to be typical for a long-term exposure to an environmental agent, that is, that individuals are exposed to different average levels with varying intensities around these levels in different time windows over their lifetimes. In the radon example, different levels of exposure are related to different dwellings the study participants have lived in during their lives. Each of the resulting time windows covers many years, a typical situation in many studies where the exposure conditions are linked to locations and these exposures are more or less constant over time. Additional examples for this situation are found in all studies investigating the impact of indoor or outdoor residential exposures on human health like the different agents responsible for air or soil pollution.

Sometimes the time windows of different exposure levels may be subdivided if there is additional knowledge about external circumstances and about the habits

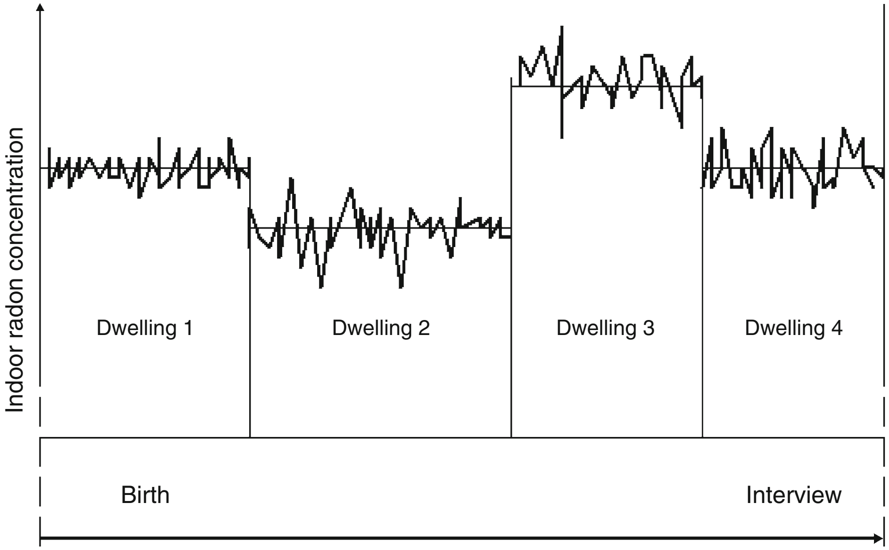

Fig. 43.6 Residential radon exposure during a participant's life (fictitious participant's biography) (Wichmann et al. 1998, modified)

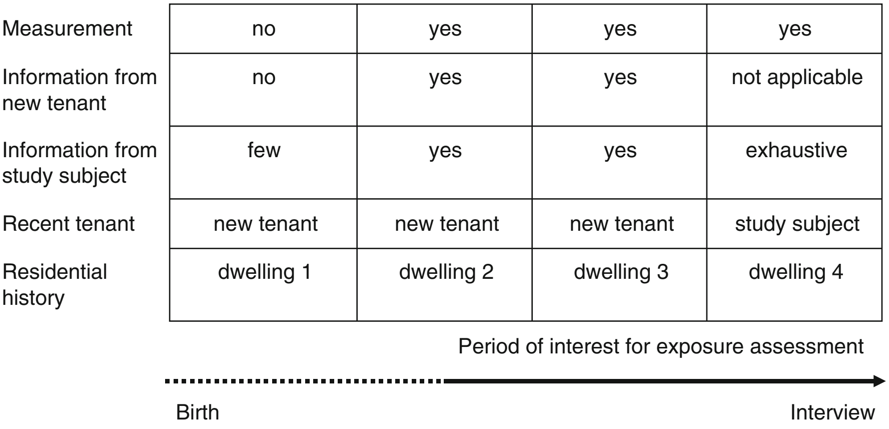
of the participants. For the radon example, these modifications of exposure can be summarized as follows. It is known that radon concentrations in homes differ due to temperature and air pressure, resulting in different concentrations over the seasons (on average, the concentration in winter is twice as high as in summer) as well as over the day (higher concentrations during the night than in the daytime). From this point of view, time windows on a monthly or even on an hourly basis have to be considered. But the living habits of the participants will also influence the exposure pattern. For example, the time spent indoors during the day as well as during the year will be an important factor for an individual's exposure. In addition, exposure will be modified by living habits like ventilation behavior, by the existence and pattern of utilization of different rooms within the homes, and by other individual habits.

The combination of both dimensions of exposure windows due to the external circumstances and to the habits of the participants may provide a sophisticated structure of the exposure windows, which on the one hand will decrease the variation of exposure around an average exposure within a time window. On the other hand, the process to obtain proper information and measurements within these time windows will be much more complicated and difficult.

Different strategies to model an exposure-disease relationship are suitable in environmental epidemiology. As a very rough strategy, the real exposure may be extrapolated by means of a (categorical) variable that is used as a surrogate. Such variables and scores are widely used because no measurements have to be made and information can often be collected easily by means of a questionnaire or even by simple observation. Thus, classical categorization into exposed and



Measurement	no	yes	yes	yes
Information from new tenant	no	yes	yes	not applicable
Information from study subject	few	yes	yes	exhaustive
Recent tenant	new tenant	new tenant	new tenant	study subject
Residential history	dwelling 1	dwelling 2	dwelling 3	dwelling 4

Fig. 43.7 Information and measurement sampling scheme for a residential radon exposure (fictitious participant's biography) (Wichmann et al. 1998, modified)

non-exposed groups can be used, for example, by definition of areas with high or low industrialization or by geology. For example, early studies of the impact of radon on cancer tried to assess the exposure by categorizing the type of house as a surrogate.

Such scores are insufficient to assess an exposure pattern as in Fig. 43.6, and measurements of the agent under study should be carried out. Besides technical and financial restrictions, for epidemiological purposes it has to be clarified whether these measurements are suitable for a population-based study. Continuous measurement of the agents under study for every study subject will be rare, and the most frequently applied technique uses short-term or cumulative passive samplers. For example, for radon exposure assessment, passive sampling techniques were utilized by applying an information and measurement sampling scheme as outlined in Fig. 43.7.

The information and measurement sampling scheme given in Fig. 43.7 was used in modified versions in many studies investigating the impact of residential radon on the general population. In a personal interview with trained interviewers, the following information was recorded using a standardized questionnaire for each dwelling inhabited over a given period relevant for exposure assessment (e.g., 30 years before date of interview):

- Average time spent in each room per day, ascertained separately for each dwelling inhabited during the exposure assessment period
- Average periods of regular absence from the residence in each residence period, such as holiday; weekly absence due to occupation; etc.
- Persistent characteristics such as type of house, year of construction, type of construction, and type of basement
- Changeable characteristics such as insulation of basement and windows, heating system, and ventilation habits

- Calendar years of residence periods in each dwelling inhabited
- Calendar years of alterations of building characteristics within a residence period

This information was not collected in detail for dwellings outside the period relevant for exposure assessment. Measurements of radon concentrations were carried out by means of so-called alpha track detectors placed both in the living room and in the bedroom of the present and former dwellings of the participants. The relevant information gathered from the participants and the subsequent tenants of the former dwellings were recorded according to their periods of residence.

These data provide the basis for different methods of exposure assessment. The most popular one integrates the several measurements as a time-weighted average exposure representative of the period of exposure assessment. In addition, the exposure assessment has to adjust the current measurements for alterations of living habits and for occupancy times in the present and previous residences as well as for seasonal effects if the measurement took place in a non-typical season.

In the first approach, the exposure has to be calculated as a usual linear weighted average in the same scale in which measurements are reported. For radon concentrations, this is in $\mathrm{Bq{\cdot}m^{-3}}$. The second approach considers the cumulative exposure for a defined period before the interview. This exposure window should be the most relevant time interval with respect to the disease under study. For the lung cancer risk due to radon, time windows from 5 to 15 up to 5 to 30 years prior to diagnosis are under discussion (ICRP 1993; Lubin et al. 1994). Here, the measurements in the present homes are supplemented by measurements in the previous homes, corrected by changes due to reconstruction of the house or different ventilation habits of the study subjects and the present inhabitants and by seasonal adjustment. This cumulative exposure can be expressed in $\mathrm{Bq{\cdot}m^{-3}}$ per year.

To evaluate corrections of measurements due to changes between subjects and present inhabitants in all rooms measured (e.g., living room and bedroom), a bivariate version of a multiplicative model of the following type can be assumed:

$$rn = \mu \times \beta_1 \times \beta_2 \times \beta_3 \times \ldots \times \beta_J \times \exp(\varepsilon), \tag{43.2}$$

where rn denotes the observed radon concentration; μ is an overall baseline radon concentration; $\beta_1, \beta_2, \beta_3, \ldots \beta_J$ are J categorized effect parameters corresponding to the factors of house characteristics, ventilation habits, reconstructions, and so on; and ε is an error term from a normal distribution with zero mean.

The univariate version of Eq. 43.2 is well established in the context of radon surveys (Gunby et al. 1993; Kreienbrock and Siehl 1996). It is based both on the physical model that changing habits will lead to an exchange of a specific fraction of indoor and outdoor air and on the usual figure that indoor radon concentrations have been found to follow a log-normal distribution (Bäverstam and Swedjemark 1991; Gunby et al. 1993; Miles 1994; Lubin et al. 1995).

The log transformation of Eq. 43.2 leads to a bivariate normal distribution of the transformed radon measurements both in the living room and bedroom, which is required for standard MANOVA (multivariate analysis of variance, Anderson 1984).

An additive model can be computed which estimates final model effects $\beta_{jk}^{(i)}$, for each category k of a factor j in room i, with $k = 1, \ldots, K_j$, number of categories of factor j, $j = 1, \ldots J$, factors in the model, and $i = 1, 2$ rooms.

With $K = 1$ as the reference category for each factor j, correction factors for the measured radon concentrations of present inhabitants can be defined as

$$\text{Correction}\,{}_j^{(i)} = \frac{\exp\left(\beta_{jk_j}^{(i)}\right)}{\exp\left(\beta_{j\ell_j}^{(i)}\right)}, j = 1, \ldots, J, i = 1, 2, \tag{43.3}$$

where the participant's category is k_j and present inhabitant's category is ℓ_j relating to factor j, $j = 1, \ldots, J$ (cf. Gerken et al. 2000). These factors may be estimated from the above linear model by an ordinary least square algorithm and are then used for calculating the corrected average cumulative radon exposure per year and individual.

A correction for all measurements has to be applied to evaluate adjustments of measurements for seasonal effects. It can be assumed that the logarithm of the radon concentration in a given house follows a sine-cosine curve over 1 year. Then, the cumulative measurement obtained from the alpha track detector involves a time integral over the sine-cosine curve, that is,

$$\ln(rn_i) = \mu_i + 1/(t_{i2} - t_{i1}) \int_{ti1}^{t_{i2}} s_t \mathrm{d}t + \varepsilon_i \tag{43.4}$$

with rn_i being the observed radon concentration, μ_i the mean radon concentration in room i over the entire year, t_{i1} and t_{i2} the first and last day of measurement, ε_i an error term, and s_t the sine-cosine curve given as

$$s_t = \alpha_1 \cdot \cos(2\pi/365 \cdot t) + \alpha_2 \cdot \sin(2\pi/365 \cdot t) \text{ for } t = 1, \ldots, 365, \tag{43.5}$$

where α_1 and α_2 are parameters that can be estimated from the data within the framework of a standard linear model (Pinel et al. 1994; Oberaigner et al. 2002; Baysson et al. 2003). A result of an adjustment process like Eq. 43.4 and Eq. 43.5 is outlined in Fig. 43.8 for a radon study in Austria, where the maximum radon concentration was reached in mid-February (2.62 times the mean concentration), and the minimum concentration in mid-August (0.38 times the mean concentration).

Overall the exposure assessment may be summarized as a weighted cumulation of several stages of information based on measurements, questionnaire data, and modeling (see Fig. 43.9).

This process of exposure assessment (cf. chapter ▸Exposure Assessment of this handbook) can be considered as a very typical situation in environmental and in other fields of epidemiology. Additional examples of the calculation of cumulative exposures are the concept of working level month as a cumulative measure of the exposure to ionizing radiation among workers in the uranium mining industry (cf. Sect. 43.2.2; NRC 1999), the concept of fiber-years for the cumulative exposure

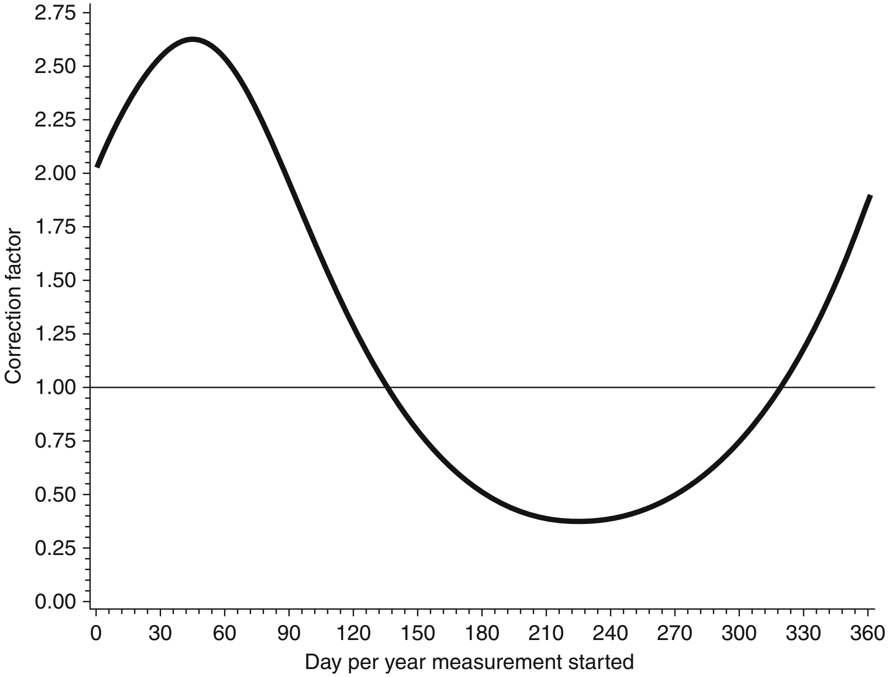


Fig. 43.8 Seasonal correction of radon measurements (Oberaigner et al. 2002, modified)

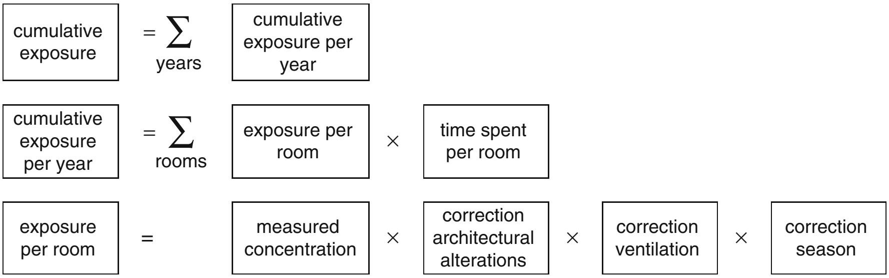

cumulative exposure = $\sum$ years cumulative exposure per year

cumulative exposure per year = $\sum$ rooms exposure per room × time spent per room

exposure per room = measured concentration × correction architectural alterations × correction ventilation × correction season

Fig. 43.9 Assessment of residential radon exposure

to asbestos, or the pack-year concept that summarizes all cigarettes smoked during the lifetime (1 pack-year = 1 pack of 20 cigarettes a day for 1 year = 7,300 cigarettes).

Although these concepts are very popular, and sophisticated solutions of integrating exposures are available, a cumulative exposure quantification may lead to substantial problems in evaluating a risk model. These strategies need retrospective information and may therefore be influenced by information bias. This is especially true if information is based on interviews and participants' memory. As a famous example, the British Doctors' Study showed that there was a large gap between the initial reporting of the smoking habits of study participants and the same subjects' answers to the same questions on his or her past habits some years later (Doll and Peto 1976).

Besides this general problem, the real nature of an exposure-risk relationship may not be well described for an agent if integrated exposures are used. It is known that the risk may differ in different exposure patterns even if cumulative exposure is constant. These effects are sometimes addressed as the inverse dose-rate effect that results in higher risks if the same cumulative exposure is reached with a low dose rate in contrast to the same cumulative exposure reached by a high dose rate over a shorter time interval. This effect was reported in cancer epidemiology for smoking as well as for exposure to asbestos or ionizing radiation. To evaluate such effects, this has to be taken into account by the risk model used.

Influenced by studies of the effect of a single exposure in a very short time interval, studies of the impact of environmental agents make use of the concept of time since exposure (TSE) that generally leads to the effect that risk decreases or even disappears if TSE is increased. This effect is able to modify the response to a cumulative exposure. If a single point in time is indicated when the an exposure occurs, TSE can be well defined. This is possible for several studies when a point in time is well defined, for example, studies of the health impact of the exposures to the atomic bombs of Hiroshima and Nagasaki, for many occupational exposures, or for exposure due to medical examinations.

However, for most of the exposures in environmental research, as for radon exposure, the concept of a single point in time is not applicable, since continuous exposures have to be taken into account (see Fig. 43.6). Therefore, additional strategies on modeling exposure have to be used.

Finkelstein's approach makes direct use of the time window structure to better understand the influence of a special risk factor over time (cf. Finkelstein 1991). This exploratory method can be described as a series of risk models that include total cumulative exposure and an additional covariate for exposure received during a fixed time interval. Characteristics of the fitted models provide insight into the influence of exposure increments on disease risk at different points in time.

Let Y_i denote the disease status of individual $i(i = 1, \ldots, n)$, and let $x_i(t)$ denote the exposure of the ith individual at time t before interview ($t \in [0, T]$), where T depends on the length of collected exposure histories. Additional covariates $z_i = (z_{1i}, \ldots, z_{mi})$ are used to adjust for confounding.

Then a time window approach sequentially fits models that include cumulative exposure to attained age, A, and cumulative exposure received over a time interval of fixed width k as covariates. Intervals of various width k can be considered. For the time window centered at time c before interview, where $c \in [k/2, T - k/2]$, a model M_c of the form

$$\text{logit}\,\Pr(Y_i = 1|z_i, ; x_i(t), t \in [0; T]) = \alpha_0 + \alpha' z_i + \beta_1 \int_0^{A_i} x_i(t)dt + \beta_2 \int_{c-k/2}^{c+k/2} x_i(t)dt \tag{43.6}$$

may be fitted, and the likelihood ratio test statistic can be computed as

$$LR_c = -2 \log \frac{\max_{\alpha,\beta} L(M_c|\beta_2 = 0)}{\max_{\alpha,\beta} L(M_c)}, \tag{43.7}$$

which compares model (43.6) with the corresponding "null" model without the time window exposure variable, that is, $\beta_2 = 0$. The value of c is then varied over its range. For fixed c, the parameter β_1 represents the increase in the log odds ratio per unit exposure, while β_2 represents the additive effect on a log scale of a unit exposure that occurred during the specific time window of length k centered at time c. The likelihood ratios between the models with and without the time window, LR_c, can be compared to assess the significance of the additional exposure variable. In this way, a continuous weighting of the impact of the exposure over time is possible (see Fig. 43.10; Hauptmann et al. 2000a, b).

Overall it may be stated that the process of sampling information and measurements to conduct an exposure assessment is the major issue in an investigation of the impact of an environmental agent on human health. Besides technical and financial constraints, several types of information bias and uncertainty influence this process, and uncertainty of exposure measurements still remains, even if detailed descriptions of the exposures are available. This should be considered during the statistical analysis of a study.

43.3.3 Statistical Analysis

As in all other fields of epidemiology, classical concepts of risk models like the categorical analyses of (stratified) contingency tables or modeling approaches like logistic regression or Cox' proportional hazards models are used in the study of the risk of environmental agents on human health to describe the relationship between exposure and disease (cf. chapter ▶Regression Methods for Epidemiological Analysis

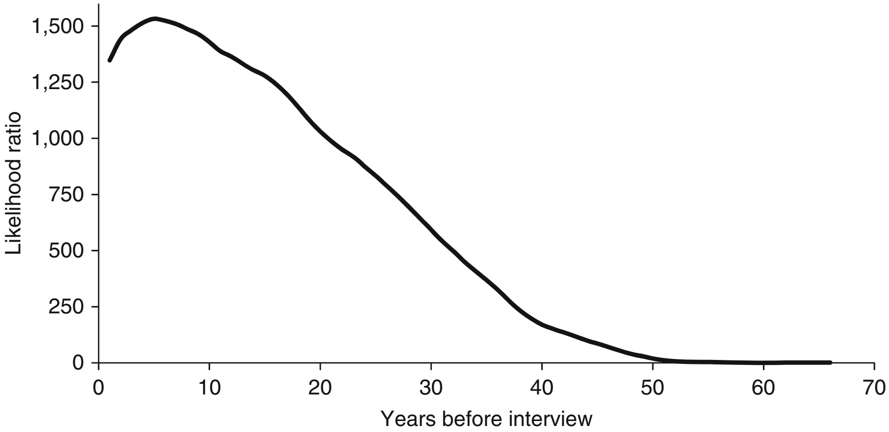

Fig. 43.10 Continuous time weighting of exposure and its impact on risk (Modified from Hauptmann et al. 2000a)

of this handbook). In general, low risks, the problem of strong confounding with other major risk factors, the problem of proper exposure assessment, and the basic assumption of the nature of the exposure-disease relationship lead to additional strategies for statistical modeling that are of special importance for environmental epidemiology.

43.3.3.1 Modeling the Exposure-Disease Function

One basic issue in the study of environmental risks is the choice of an exposure-disease function to describe the real nature of the response of an environmental hazard on human health. Two main strategies may be distinguished. If, based on former studies, on animal experiments, or on general toxicological considerations, a class of functions between exposure and disease can be specified, then a parametric version of a risk model will be suitable. This strategy may be appropriate if exposure is measured on a continuous scale, as in studies on the risks of ionizing or non-ionizing radiation or in air pollution studies. The functional type specified will be related to the preliminary considerations, but linear and log-linear parameterizations of the risk ratio are very popular in environmental studies, at least as a starting point.

The linear (excess) relative risk model may be introduced as

$$\frac{p}{1-p} = \mu \cdot (1 + \beta x), \tag{43.8}$$

where p is the risk of an interesting disease under study, μ is a multiplicative intercept, x specifies the exposure quantity, and β is the excess odds ratio, that is, the increase of the odds ratio in percent. In model (43.8), the true odds ratio equals $1 + \beta x$.

In contrast, the log-linear model may be stated as

$$\ln\left(\frac{p}{1-p}\right) = \alpha + \gamma \cdot x, \tag{43.9}$$

where p is the risk, α is an intercept, γ is the log odds ratio, and x the exposure. Model (43.9) corresponds to the usual logistic regression model where the odds ratio is given as $\exp(\gamma \cdot x)$.

Both models (43.8) and (43.9) are very popular in environmental epidemiology for reasons of easy interpretation as well as for an easy model fit in statistical and epidemiological software packages. Likelihood-based confidence intervals as well as tests on statistical hypotheses on the parameters can be computed straightforwardly.

However, based on the range of possible exposures in the human environment, both models have to be considered very carefully. For very small exposures x, it holds that $\exp(x) \approx 1 + x$, and therefore Eq. 43.8 and Eq. 43.9 yield similar results for large parts of a general population. The risk models (43.8) and (43.9) will differ substantially for the part of a population which is exposed to a higher degree. This is demonstrated in Fig. 43.11 for the risk of residential radon and lung cancer as an example.

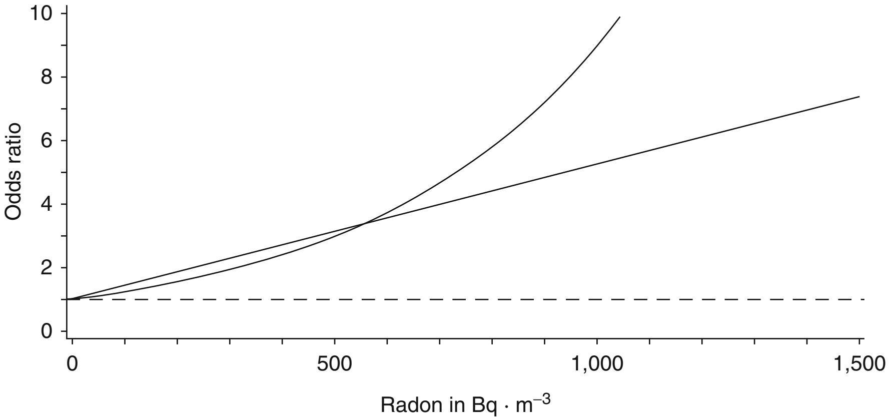

Fig. 43.11 Lung cancer risk due to residential radon; comparison of linear and log-linear risk (Modified from Oberaigner et al. 2002)

As an example, let us come back to radon exposure. It can be assumed that the exposure to radon is low for large parts of the population and that concentrations above 500 Bq·m^{-3} are unusual in the residential environment. Within this lower range, both models, the linear and the log-linear approaches, yield a similar magnitude of risk. For exposures above 500 Bq·m^{-3}, the two models will give different results that may lead to different consequences for risk management.

Therefore, non-parametric approaches are applied, especially if the real nature of the relationship is not known. On the one hand, these types of risk models may be based on categorical exposures using ordinary contingency tables. On the other hand, continuous exposure-effect relationships may be described via spline functions or fractional polynomials (cf. chapter ▶Analysis of Continuous Covariates and Dose-Effect Analysis of this handbook, Royston and Sauerbrei 2008).

There are numerous examples of this strategy, even in situations in which exposure assessment was conducted on a continuous scale and categories of exposure were defined afterward. Studies on EMF-related risks are a typical example of the use of this type of model. Figure 43.12 shows the results of a study on this topic conducted in Germany (Schüz et al. 2001).

Studies on EMF risks are usually influenced by many factors, and exposure assessment has to be conducted carefully. According to Fig. 43.12, the advantages of a model fit using categories instead of a continuous exposure assessment are obvious. While Fig. 43.12a suggests a strong increase in risk in the upper exposure category, Fig. 43.12b shows a smoother increase from one exposure category to the next. Thus, models using exposure categories increase the degrees of freedom, and any kind of exposure-disease relationship may be estimated. But this strategy is fully data-driven, and exposure-disease relationships may occur which are not plausible in any situation. For example, Ahlbom et al. (2000) reported results from a meta-analysis on EMF exposures with the same exposure categories as

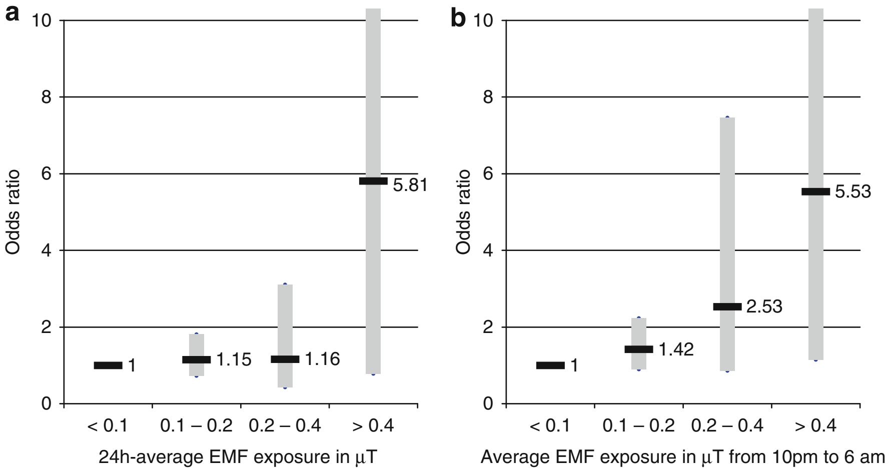

Fig. 43.12 Leukemia risk due to EMF exposure in Germany; odds ratios and 95% confidence intervals by EMF exposure in µT; (**a**) average exposure during 24 h; (**b**) average exposure during the night from 10 p.m. to 6 a.m. (Schüz et al. 2001)

in Fig. 43.12. Ahlbom et al. (2000) reported odds ratios of 1.58, 0.79, and 2.13 for the categories 0.1–0.2 μT, 0.2–0.4 μT, and more than 0.4 μT, respectively, compared to the reference category of less than 0.1 μT. These results do not agree with a monotonous exposure-disease relationship, and evidence for its true nature will be hard to obtain. However, the general strategy of using non-parametric approaches is well established in all kinds of epidemiological studies and can be considered as a basic tool for estimating risk coefficients in environmental studies.

43.3.3.2 Confounding and Interaction and Their Impact on Low Risks

Selecting the type of statistical model for investigations in environmental epidemiology is also influenced by further risk factors that may confound or modify the association under study. Given that most environmental risk factors will cause a low risk, these potentially distorting influences need careful scrutiny to avoid biases and misinterpretations of the results.

The influence of smoking in relation to the effects of environmental exposures on respiratory health may be used as a classical example. The smoking-related relative risk (RR) of lung cancer is reported to be in the order of 10 or more, in contrast to the RR of residential radon or air pollution, with RRs of less than two (Pershagen et al. 1994; Boffetta et al. 1998; Kreienbrock et al. 2001). The effect of smoking on respiratory symptoms like strong cough or obstructive bronchitis is in the range of around two to three but only in the order of 1.3 for the comparison of areas that are polluted differently (Dockery et al. 1993; Pope et al. 1995; Wolf-Ostermann et al. 1995). On the one hand, these examples suggest that it is necessary to incorporate these strong risk factors into a common risk model. On the other hand, these risk factors may dominate the model, requiring the development of proper strategies for the process of model and variable selection.

Following Greenland (1989), the selection of variables in epidemiological studies is based on two concepts: classical selection procedures such as backward or forward selection in regression models (cf. chapter ▶Regression Methods for Epidemiological Analysis of this handbook) and a sophisticated analysis of the associations and interacting mechanisms of the variables under study made in advance.

These in-advance analyses have to be conducted carefully. Sensitivity analyses can be considered as an appropriate way to deal with this problem. Here, sensitivity analyses have to be carried out of both the disease variable as well as the different risk factors under study.

Studies on respiratory health and air pollution may serve as a typical example. First, respiratory health has to be defined precisely. Often very different definitions are possible. The definition of asthma is a classical example: The US National Heart, Lung, and Blood Institute defines asthma as “a chronic inflammatory disorder of the airways [that] causes recurrent episodes of wheezing, breathlessness, chest tightness and coughing, particularly at night or in the early morning, usually associated with widespread but variable airflow obstruction that is often reversible, either spontaneously or with treatment.” In contrast the American Lung Association defines asthma as “a chronic disease of the lungs in which the airways overreact to certain factors by becoming inflamed or obstructed, making it difficult to breathe comfortably” (JHSM 2004).

This shows that varying definitions of a disease may result in a large variety of measures that will influence prevalence and incidence measures and also affect the dependent variable under study in a regression model. Therefore, it is helpful to calculate the same risk models for different definitions of the outcome to compare the patterns of the exposure-disease relationship.

If, as in most cancer studies, a symptom is defined in a clear and unequivocal way, sensitivity analyses of (concurrent) risk factors are worthwhile. Risk models can be calculated by systematically omitting one of the risk factors to assess the influence of the omitted factor by comparing the reduced model with the full model. This type of sensitivity analysis is a basic method in meta-analysis to assess the impact of each single study (cf. chapter ▶Meta-Analysis in Epidemiology of this handbook).

If a large number of risk factors and/or strong and weak risk factors are incorporated simultaneously into one model, this may yield cross-classifications with only small numbers of observations, even if the overall sample size of the study is large. This causes a reduced statistical power due to a loss of precision, as can be demonstrated by studies on the interaction of smoking and residential radon, like the Swedish nationwide study conducted by Pershagen et al. (1994) (Table 43.5).

This substantial study included 1,281 cases and 2,576 controls. Assigning these subjects to the exposure categories and especially dividing them into sub-strata related to both smoking and environmental exposure yield small sample sizes in

Table 43.5 Lung cancer risk due to smoking and residential radon in Sweden: number of cases and controls (*subj.*), odds ratios (*OR*), and 95% confidence intervals (*CI*) (Pershagen et al. 1994)

	Radon exposure in Bq m^{-3}									
	<50		50–80		80–140		140–400		>400	
Smoking status	Subj.	*OR* (CI)	Subj.	*OR* (CI)	Subj.	*OR* (CI)	Subj.	*OR* (CI)	Subj.	*OR* (CI)
	64	1	36	1.1	35	1.0	38	1.5	5	1.2
Never smoked	443	–	240	(0.7–1.7)	252	(0.6–1.5)	198	(1.0–2.3)	31	(0.4–3.1)
	35	2.6	21	2.4	24	3.2	27	4.5	1	1.1
Ex-smoker	105	(1.6–4.2)	69	(1.3–4.3)	63	(1.8–5.6)	48	(2.6–8.0)	8	(0.1–9.0)
	103	6.2	60	6.0	62	6.1	53	7.3	12	25.1
Current <10 cig. a day	128	(4.2–9.2)	79	(3.8–9.4)	79	(3.9–9.5)	59	(4.5–11.7)	4	(7.7–82.4)
	168	12.6	85	11.6	94	11.8	83	15.0	16	32.5
Current >10 cig. a day	102	(8.7–18.4)	63	(7.4–18.0)	71	(7.7–18.2)	42	(9.4–24.0)	4	(10.3–102.1)
	82	4.7	66	5.9	57	5.3	45	5.4	9	8.8
Unknown	174	(2.9–7.7)	110	(3.5–10.0)	103	(3.1–9.2)	89	(3.1–9.5)	12	(3.3–23.7)

special subclasses. For example, the number of subjects is small in the highest exposure category (more than 400 Bq·m^{-3}). Stratifying this group into subgroups by smoking status results in small numbers and leads to less precision in estimating the related effects, as is reflected by the wide confidence intervals shown in Table 43.5.

Sensitivity analyses of all possible risk factors have to be a combination of an exploratory process of exposure assessment and of the analyses of the association, confounding, and interaction mechanisms between these factors. The etiology of pediatric asthma may serve as a consolidated example of this processes as summarized by Johnson et al. (2002) (see Fig. 43.13).

The outcome of persistent (pediatric) atopic asthma has to be recognized as a complicated process involving different steps of development of the disease and common and interacting influences by different risk factors. Environmental agents may play a role as independent risk factors or as interacting and confounding variables. For example, most of the possible risk factors in the areas "residence" and "environmental hygiene" in Fig. 43.13 are more or less associated, and confounding bias may be present if this is not adequately described or modeled in an epidemiological investigation. Some studies report such associations (Weiland et al. 1994; Ponsonby et al. 2000), although the majority of studies do not support a strong relationship between air pollution and atopic asthma.

The Committee on the Assessment of Asthma and Indoor Air, Division of Health Promotion and Disease Prevention, Institute of Medicine, concluded that there is sufficient evidence for a causal relationship between exposure to allergens produced by cats, cockroaches, and house dust mites and exacerbations of asthma in sensitized individuals and between environmental tobacco smoke exposure and exacerbations of asthma in preschool-aged children. Besides these findings it was suggested that there is sufficient evidence of associations between several exposures and exacerbations of asthma, like the exposure to biological allergens produced by dogs, fungi, molds, and rhinovirus and to chemicals such as high levels of NO_2 and NO_x. Limited evidence of an association was suggested for exposures of children and adults to the biological allergens domestic birds, *Chlamydia pneumoniae, Mycoplasma pneumoniae*, or respiratory syncytial virus (RSV) or to the chemicals environmental tobacco smoke, formaldehyde, or fragrances (IOM 2000).

The evaluations of the Institute of Medicine are a synopsis of hundreds of studies on this topic. But the overall evidence of a single risk factor is influenced by a "network of associations of risk factors," from which some are identified as causal and some as associated. For example, allergens related to pets like cats and dogs may be measured and separated as factors. However, strong associations of behaviors in pet holding have to be taken into account, and it is difficult to separate them from the exposure factors above, especially if there is a large association between factors.

Therefore, powerful studies are needed both in terms of sample sizes as well as in terms of high quality in exposure assessment. Synopses like the asthma studies mentioned above, systematic reviews, meta-analyses, and pooling of studies may be useful to avoid biased conclusions about the effect of weak risk factors in environmental epidemiology.

43.3.3.3 Correction for Errors in Exposure Assessment

As outlined in Sect. 43.3.2, one major problem of an investigation in environmental epidemiology is the categorical or the continuous assessment of an environmental exposure. The statistical inference on this risk factor is linked to the problem of information bias if misclassification (for categorical exposures) or uncertainty (for continuous exposures) in the exposure assessment occurs.

There exist numerous examples for information biases due to misclassification in exposure assessment. Misclassification is often due to recall bias, which is typical in case-control studies. It may occur if cases report environmental exposures more often than controls, who do not care so much about environmental exposures because they are not diseased. In this situation a bias away from the null is introduced and variables may be erroneously identified as risk factors. The same direction of bias may result if interviewers tend to ask more detailed questions on exposures in cases than in controls.

Biases due to misclassification should be avoided by the design of a study and during data collection, for example, by standardization of interview techniques (cf. chapter ▶Epidemiological Field Work in Population-Based Studies of this handbook). Under certain assumptions they may be corrected by appropriate methods of adjustment for misclassification. This is usually done by estimating the sensitivity and the specificity of the categorical exposure assessment and adjusting the observed measures of disease by these estimators (cf. chapter ▶Measurement Error, see also chapter ▶Misclassification of this handbook).

But even the continuous measurement of environmental exposures may lead to uncertainty in the exposure assessment. The sources of error are numerous, like the accuracy of the detectors, the laboratory procedures, the positioning of the measurement devices, extrapolations to past exposure, or gaps in the exposure history.

These errors have to be incorporated into the statistical models used to estimate risk coefficients similar to the procedures of adjustment for misclassification. Statistical models that take uncertainty in exposure assessment into account are related to special computational efforts, and therefore different techniques were developed especially during the 1990s thanks to the overall availability of high-capacity computers (cf. also Tosteson et al. 1989; Armstrong 1990, 1998; Carroll et al. 1995; Michels 2001). Often the development of these techniques was motivated by examples from environmental epidemiology. Here, the exposure assessment is based on measurements, and the ordinary assumption of a continuous risk factor with uncertainty is fulfilled. For example, Thomas et al. (1993) applied special techniques for studies of the impact of EMF on childhood leukemia. Lagarde et al. (1997); Reeves et al. (1998), and Heid et al. (2002) investigated models for proper incorporation of the uncertainty of radon exposures and its impact on lung cancer risk. Zeger et al. (2000) and Dominici et al. (2000) examined the impact of errors in the particulate matter on mortality.

These studies show that the impact of information bias tends to increase the impact of usual random error. It is therefore of major importance to incorporate the error in the exposure assessment into the risk model. Correction for errors in

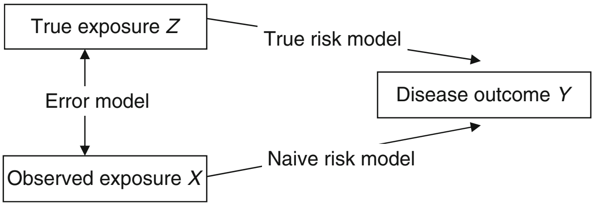

Fig. 43.14 True exposure Z and observed exposure X and their relationship to the disease outcome Y

exposure generally requires several models (cf. chapter ▶Measurement Error of this handbook): the model for the true exposure, the true exposure-disease model linking true exposure and disease, and the error model linking true exposure and measured exposure. Given these models, the exposure-disease model accounting for errors in exposure measurement can be derived by linking measured exposure and disease (Fig. 43.14).

As a general strategy, the variable X, which represents the observed result of an exposure assessment (cf. Sect. 43.3.2) is not fixed but has an error structure. The variable X has to be contrasted with the true value Z of the exposure. Following Heid (2002) in describing the deviation between X and Z, five classifying characteristics of error models may be considered: (1) random vs. systematic error, (2) non-differential vs. differential error, (3) homoscedastic vs. heteroscedastic error, (4) additive vs. multiplicative error, and (5) classical vs. Berkson error.

A random error is generally considered as a measurement error. It is characterized by an unsystematic deviation below or above the true value that average to zero. Usually all laboratory devices used in environmental measurements are prone to this error. In contrast, systematic errors lead to an overestimation or an underestimation of all individual measurements and do not average to zero. This problem may occur, if measurements were conducted on different technical levels, which is a special problem in multicenter studies or in meta-analyses. Here, intercomparison exercises of the different methods will give a deeper insight into the problem (Hollander et al. 1990; Kreienbrock et al. 1999; Wellmann et al. 2001; Bochicchio et al. 2002; Janssens 2004).

Similar to the effect of non-differential misclassification of categorical exposures, it can be assumed that error in the exposure assessment will attenuate the true exposure-disease relationship as long as this error is non-differential. A non-differential misclassification of the exposure is present if the error has the same magnitude and direction among diseased and non-diseased study participants. Otherwise (differential error), the direction of bias is not obvious in advance, and any direction is possible (cf. chapter ▶Measurement Error of this handbook). Figure 43.15 shows the effect on non-differential error for studies of lung cancer risk due to residential radon in the UK and in Sweden, where the reported excess relative risk increases by approximately 50% after adjustment for measurement error. This situation may be considered as typical in environmental epidemiology.

The problem of homoscedastic vs. heteroscedastic errors and the problem of additive or multiplicative errors are related to the nature of the statistical distributions

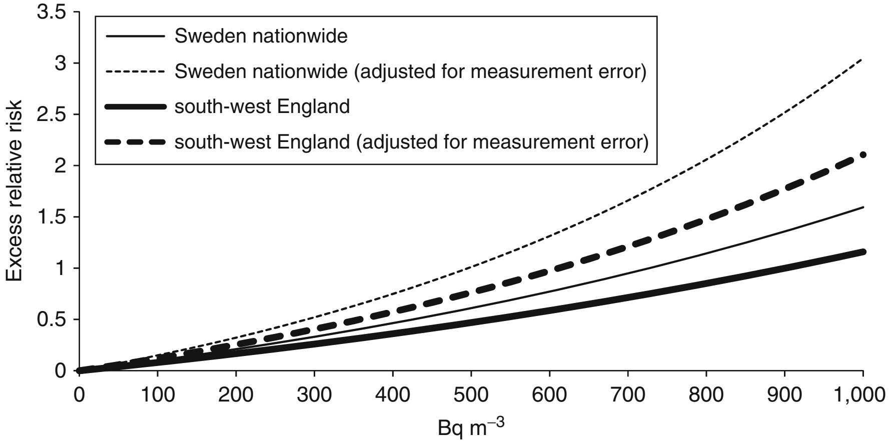

Fig. 43.15 Excess relative risk due to residential radon in the UK and in Sweden; results of classical log-linear models and adjustment for measurement error (Darby et al. 1998; Lagarde et al. 1997)

which are stated for the measurements or for the exposure in general. For an additive error, the spread of the true exposure given the measured exposure is constant for the full range of the exposure. In this situation a normal distribution is often appropriate. In contrast, for a multiplicative error, the spread increases proportional to increasing exposure. Therefore, multiplicative errors usually are assumed to be log-normal, which often is evaluated by measurement and monitoring programs on the population level. This is more or less true for many environmental agents like radon (Bäverstam and Swedjemark 1991; Gunby et al. 1993; Miles 1994; Lubin et al. 1995), classical pollutants of outdoor air (Ebelt et al. 2001; Wallace et al. 2003), endotoxin levels (Park et al. 2000), and many more.

Finally, errors of the classical type arise, if a quantity X is based on measurements by some device and repeated measurements would vary around the true value Z. This situation can be assumed for all kinds of laboratory devices, for which a measurement error is reported.

In contrast, error of the Berkson type occurs if the exposure, which is assigned to each individual, is derived from an overall group characteristic. The same approximate exposure value (proxi) X is used for all members of the group, and the true exposure Z varies randomly around this proxi with mean equal to it. This type of error may occur in a study on the effects of air pollution on respiratory health, if all study participants of a defined region are assigned to the same proxi X, for example, the result of a single measurement station. Thus, Berkson error may occur if exposure is measured via (locally) fixed monitors instead of personal detectors or if exposures have to be approximated due to missing values in the measurements (cf. chapter ▸Measurement Error of this handbook; Lagarde et al. 1997; Armstrong 1998; Reeves et al. 1998).

An overwhelming variety of models exists to estimate the effects of uncertainty of exposure assessment. Regression calibration is one of these (cf. chapter ▸Measurement Error; Rosner et al. 1989; Carroll et al. 1995). The main advantage of regression calibration is that it can be used in rather complicated measurement error models. The method includes three steps: first, find a mean (calibration) model for the true regressors Z depending on the exposure assessment X; second, fit the main model by plugging in the estimates from the calibration model. The third step is the correction of the variance estimation of the main model. Although this method was developed for multiple logistic regression accounting for errors in more than one variable, application is usually restricted to account for errors of the primary risk factor of interest. The error model, that is, the mathematical formulation of the deviation of the measured exposure X from the true exposure Z, is the most important model assumption, upon which all of the correction methods rely. In fact, assumptions about the error model are a particular source of concern regarding correction of measurement error (Michels 2001).

Therefore, substantial effort was devoted to evaluate these assumptions about the different model characteristics as well as in the different fields of applications. This was done by theoretical considerations, by simulation studies, as well as by applying different techniques on selected studies (Armstrong 1990; Thomas et al. 1993; Ibibarren et al. 1996; Lagarde et al. 1997; Reeves et al. 1998; Carrothers and Evans 2000; Dominici et al. 2000; Zeger et al. 2000; Heid et al. 2002; Field et al. 2002; Heid et al. 2006).

In conclusion, a clear distinction between the components of classical and Berkson error is essential in the assessment of error sources and for establishing an error model. This differentiation is crucial due to the different impact of these two error types. The classical error is able to induce severe bias on the risk estimate; multiplicative classical error may even distort the dose-response curve. This bias can be reduced by using the mean of multiple measurements in the analysis that require internal replicate measurements for each individual, or it can be corrected for by using the information from (internal or external) replicate measurements of a subgroup. Also the spuriously narrow confidence intervals for uncorrected risk estimates in the presence of classical error can be adjusted. Therefore, it can be recommended that more internal repeated measurements in future epidemiological studies should be conducted, for example, by using more than one detector per study participant.

At first glance, the Berkson error is less problematic in environmental epidemiology, since usually it does not induce notable bias of the risk estimates. However, Berkson error weakens the precision of the estimates and therefore leads to a loss of power that should be avoided, for example, by a proper individual exposure assessment. This will, however, introduce the classical error which may be reduced by replicate measurements, but this does not hold for the Berkson error. Simplified, classical error is related to the measurement process, whereas Berkson error is often a matter of defining the exposure groups. Using stationary monitors (e.g., using the distance of a home to the next emitter of an environmental agent instead of individual measurements) or using a person's affiliation to a group in order to use the exposure assigned to this group (e.g., using job-environment-exposure matrices instead of personal monitors) is a question of how to define the exposure group; this induces Berkson error.

The general statement that non-differential, random, and homoscedastic errors attenuate regression coefficients applies only to the classical error. To assume the sum of both error type's sizes as known and to vary the percentage of the Berkson error are one option (cf. Mallick et al. 2002). An additional option is a two-dimensional view to the measurement error, that is, a classical-type dimension and a Berkson-type dimension, where the size of each dimension needs to be studied separately. The full error is represented in the continuum of a two-dimensional space (cf. Zeger et al. 2000). Exposure assessment should therefore not only aim to be as accurate and precise as possible but also provide a model of the measurement errors that unavoidably remain even with clear differentiation of classical and Berkson components.

43.4 Conclusions

By definition, environmental epidemiology focuses on health problems due to the environment where individuals live rather than due to their personal characteristics or lifestyles. During the past centuries, there has been a remarkable discourse on environmental health and environmental epidemiology, and a huge number of individual studies as well as pooling of individual studies and meta-analyses have contributed to a large overall knowledge base on environmental hazards. As a consequence, many public health issues have been addressed by reducing contamination of air, water, soil, and food to the benefit of many parts of the world's population. One of the most prominent interventions during the last decade was the prohibition of smoking in public buildings, restaurants, and even pubs for reducing environmental tobacco smoke.

However, many multifactorial diseases are not yet fully understood, and the scientific focus has changed during the last decade, as developments in epidemiology have kept up with those in molecular biology and genetics.

A typical example is the discussion on the health impact of air pollution on respiratory diseases. One such issue is atopic asthma, and studies were conducted to find a relationship between air pollution and the incidence of the disease. But the studies failed or observed only little environmental influence. Therefore, the focus was shifted to the nature of allergic disease itself, and techniques of molecular biology and genetics have now been widely used to deepen our knowledge on this topic (cf. Johnson et al. 2002).

Therefore, the study of gene-environment interactions has been and will continue to be a major subject of epidemiological investigations, for example, for asthma, for cancer, and for other diseases to which modern molecular and genetic approaches can be applied. A serious disadvantage of all these studies is that investigations in molecular and genetic epidemiology tend to be very expensive, so that study sizes have to be restricted. For example, Kalayci et al. (2004) compared plasma levels of MCP-4 in 30 patients who presented for emergent treatment of asthma with levels in 90 subjects with chronic-stable asthma matched for age, sex, and ethnicity within an entire cohort of 596 subjects. Nowadays, however, genome-wide association studies make the necessary genetic information affordable, but the collection of environmental information is usually not part of these studies. This impedes the inclusion of genetic data in environmental studies on a broad scale.

Thus, there is a contradiction between the original idea of an environmental study with large sample sizes and extensive measurement of environmental agents on the one hand and a study in molecular and genetic epidemiology with genetic information only on the other hand. Therefore, the information content of studies on gene-environment interactions is often limited because of their insufficient ability to account for confounding.

This situation may be referred to as the "restricted information problem" in the analysis of gene-environment interactions. Two major ways may be identified for further research on this topic. To increase power, all possible measures have to be taken to improve the precision of molecular and genetic techniques and the assessment of exposures (cf. Sects. 43.3.2 and 43.3.3 and chapters ▸Molecular Epidemiology and ▸Statistical Methods in Genetic Epidemiology of this handbook). For example, first studies on the impact of environmental tobacco smoke (ETS) on respiratory diseases used urinary cotinine concentrations as a biomarker (Ehrlich et al. 1992). However, cotinine levels in the urine reflect only recent exposures and can therefore not replace exposure histories obtained via questionnaires that give a good estimate of the long-term cumulative exposure.

The second approach to cope with the "restricted information problem" is directly linked to the design and the statistical analysis of the investigation. In practice it is often impossible to detect an effect of a single agent because the various exposures are strongly correlated and the exposure that has been measured may actually act as a surrogate to the whole mixture of agents. Therefore, it is necessary to find statistical models which make use of the correlation of all possible independent risk factors, as well as all modifying and confounding variables. For example, in a study on the health impact of toxic substances ingested with food, strong correlations have to be made explicit that are due to nutritional habits, like the consumption of special types of seafood. Therefore, this has to be addressed in detail during the phase of constructing a final risk model and by appropriate specification of statistical methods (cf. chapter ▸Regression Methods for Epidemiological Analysis of this handbook).

The development of these models, besides the molecular and genetic view on a special health issue, is ordinarily linked to the personal exposures of an individual recruited for the study. On the other hand, many environmental exposures act on an aggregated level. For example, outdoor air pollution is the same, drinking water is the same, or contaminated soil often is the same for major parts of a population, for example, all inhabitants of a particular area. From the statistical point of view, this yields a Berkson-type error and a correlation of the exposures between the study participants, or even more extremely, it yields sub-classes of participants exposed in the exact same way. On the one hand, classes of hierarchical models may be used to find a proper risk model in this situation. On the other hand, the extraordinarily large number of possible environmental hazards may even force epidemiologists to conduct ecological studies to find rough estimates of risk.

In regard to the complex nature of possible environmental hazards, Pekkanen and Pearce (2001) pointed out that increasing emphasis on individual exposures, susceptibility and disease mechanisms, puts environmental epidemiologists in danger of losing their population perspective of disease causation and prevention. To avoid this and to continue the successful work of environmental epidemiology and public health, environmental health problems should be approached on four different levels: the molecular, the individual, the population, and the ecosystem level. Within and between these levels, research and development of new methods is needed, but it will be crucially important to choose the most appropriate level of research for a particular environmental problem. For example, the health impact of climate change will be one of the most important health problems of the future requiring research, but ordinary designs and exposure assessments may not be adequate to give answers to the underlying questions.

This may initiate new methodological concepts in study designs, in biological and genetic markers, in exposure assessment, as well as in the statistical analysis of studies in environmental epidemiology. In the last decades, new analytical methods in molecular biology and genetics have enriched designs and techniques in epidemiological investigations on environmental hazards. The challenge for further work is to exploit these new areas of scientific cooperation.

Summarizing, it must be determined whether there is

– Sufficient evidence of an association
– Limited or suggestive evidence of an association
– Inadequate or insufficient evidence to determine whether or not an association is present
– Limited or suggestive evidence of no association
– Evidence of no association

This judgment should be combined with an evaluation of the public health impact of an environmental problem. For this purpose, assessment of the etiological fraction due to the exposure in question may give an important input.

Acknowledgements The author likes to thank Michael Gerken, Michael Hauptmann, Iris Heid, Michaela Kreuzer, Wilhelm Oberaigner, Angelika Schaffrath Rosario, H.-Erich Wichmann, and Jürgen Wellmann for their substantial help in preparing this manuscript and Judith McAlister-Hermann for her work in reviewing. A very special gratitude for their help and patience has to be offered to the editors of this handbook, Wolfgang Ahrens and Iris Pigeot, and to the reviewers for their helpful comments.

44.1 Introduction

> The main objective of nutritional epidemiological research is to provide the best possible scientific evidence to support an understanding of the role of nutrition in the causes and prevention of ill-health
>
> Margetts and Nelson (1997)

Basic textbooks describing the field of nutritional epidemiology were available in the 1990s (Margetts and Nelson 1997; Willett 1998), and one of these (Willett 2013) has recently been updated. It is not the intention of this chapter to repeat all that is available in these textbooks but to highlight some key concepts and recent developments relevant to readers of a general epidemiology textbook.

Nutritional epidemiology primarily seeks to describe the distribution and variation in the nutritional behavior of individuals and relates that behavior to health outcomes. Nutritional epidemiological approaches are appropriate for a number of different purposes. Primarily, nutritional epidemiological studies seek to understand the role that nutritional factors play in causing various health outcomes. In generic terms, the aim is to explore exposure-outcome relationships. Outcomes can be defined in many different ways but include the occurrence of measures of well-being, or a disease, or intermediate disease markers, or measures of metabolic disturbance, or even measures of nutritional status such as body composition (body mass index used to define obesity, and stunting and wasting related to age-specific weight and height). Nutritional exposure is a generic term used here to describe different aspects of dietary and nutritional behavior and can include dietary intakes, dietary habits, knowledge and attitudes about food, biochemical markers, body composition, or even clinical signs of nutritional problems.

The principles of nutritional epidemiology can also be applied to studies that seek to monitor the population for the purposes of identifying individuals at risk of deficiency or excess or for describing the proportions of the population at risk. Such studies provide a basis for deciding public health actions and for informing progress on policies aimed at reducing nutrition-related problems.

Nutritional epidemiological studies follow the general principles of all epidemiological studies to develop a clear and testable research question and to provide an unbiased answer to that question. These general principles are covered elsewhere in Parts I (Concepts and Designs in Epidemiology) and II (Methodological Approaches in Epidemiology) of the handbook. The issue with assessing outcomes is not specific to nutritional studies and will not be discussed in this chapter.

The aim of this chapter is to focus on the challenges and best practice around assessing nutritional exposures. The best approach depends on the purpose of the study, and methods used to derive measures need to be fit for purpose. For example, if an individual level of accuracy is required, where within-person variation can be characterized, a simple questionnaire that assesses usual intake will not be adequate. On the other hand, if all that is required is an estimate of the population average, a less precise measure may suffice, provided the sample size and sampling frame are appropriate. Whenever nutritional data are collected, a measure of the relative validity of that measure for the purpose intended should be provided. As in all epidemiological studies, the key challenge is to avoid bias, both in terms of information and sampling, while managing measurement error that is unavoidable because of the nature of variation in behavior and the imprecise methods available.

An evidence-based approach to the development of future research priorities and public health actions depends on that evidence being available and being of sufficient quality to be useful. Similarly monitoring the effectiveness of interventions or actions aimed at improving nutrition depends on the appropriate use and availability of reliable measures in the population and among vulnerable groups. Methods that provide measures may not be suitable for all sectors of a population, and this needs to be taken into account when developing and using nutritional epidemiological tools. It is the aim of this chapter to shed some light on how best to provide this evidence.

This chapter describes the measurement of dietary exposure, the definition of nutritional exposures, measurement error and calibration of dietary intake, the statistical approaches to obtain proper estimates of dietary intake data, and relative risk estimates including energy adjustment and dietary pattern analysis. It also illustrates the organization and presentation of dietary data including implications for meta-analysis and reviews and depicts the challenge of nutrition surveys and nutritional epidemiology in public health practice.

General Considerations in Measuring Exposure The most commonly used measure of nutritional exposure is the assessment of diet. The measure may be dietary patterns, intake of a particular food, the nutrient content of a food or the whole diet, or consumption of supplements or other added substances such as additives or preservatives. Where nutrient intake is required, the relevant food composition data must be available.

The level of detail required to assess dietary exposure depends on the exposure of interest, and this in turn determines the level of accuracy required to derive the relevant measure of exposure. In selecting the approach to measuring dietary exposure, it is important to consider the relevant time frame for the assessment; is it usual long-term intake, or total life time exposure, current exposure or immediate past exposure, or exposure at a critical point in time based on some biological insight about causation? It is also necessary to consider how the measure will be expressed, as the average exposure for the individual or population or proportion above a threshold or cut-off for either the individual or the population.

Before deciding on a method of assessment, it is thus critical to have a good idea of the question being asked and the level of detail required to correctly characterize the relevant exposure. The within-person variation in exposure behavior, the between-person variation, the measurement error of the instrument, and method itself all need to be appropriately taken into account.

It is essential to develop and use a written protocol to ensure that methods are used appropriately. Observers should be trained prior to the study beginning. Part of this training should ensure that within- and between-observer error is within acceptable limits (maximum 10%) and that there is no bias in the way observers use the instruments. If there is unmeasured between-observer variation, it will be impossible to disentangle this from center-to-center variation. Advanced computer programs that guide the interview such as the multiple-pass method developed in the USA (Convey et al. 2004) or EPIC-Soft developed in Europe (Slimani et al. 2000) have helped to minimize between-observer effects.

Practical considerations of time and money may limit the choice of methods used and the impact that this may have on the results obtained needs to be taken into account. Small, but important differences may be missed by imprecise methods.

44.2 Measuring Dietary Exposure

Individual Level of Assessment When the exposure of interest is at the level of the individual, the key question is whether the measure required is for usual intake or current intake (Illner et al. 2010). Usual intake refers to average long-term habitual intake, often expressed as diet over a year. From the statistical point of view, it is sufficient to capture a limited number of days from that period to represent usual intake (see Sect. 44.4). These days should be selected at random (Fig. 44.1). The length of time required to assess both usual and current intake depends on the variety of foods consumed by the population group of interest and a consideration of determinants of dietary intake that may have changed over time.

The more the diet and the more the eating behavior vary over time, the longer the time frame that is required to capture these variations. Where it is known that environmental factors have influenced access to food at a particular time this needs to be taken into account if exposure at that time is considered to be critical. This might be the case when food supply was impaired, e.g., by drought or war. Urbanization may also affect dietary behavior. Moving from rural areas where people mostly rely on foods they have grown themselves, to urban areas where they will mostly be buying foods will have a major impact on dietary behavior. Where foods are prepared and consumed away from the home, this may also alter the composition and quality of the diet. Other important considerations may be personal characteristics of the subjects being investigated. An important aspect on which information should be obtained is the literacy of the subjects to ensure that the chosen method is suitable for the target population. In studies with deprived populations, for example, interviewer-based methods could be selected instead of self-administered questionnaires.

For current intake, the key challenge is to decide how many days of recording are required to capture the true within-person variability. Where food patterns are changing rapidly, and where the composition of the foods being eaten is changing, the methods used to assess behavior must be sensitive to these dynamics.

Population Level of Assessment Where the primary requirement of the measure of exposure is to assess population or subgroup average exposure, the main consideration will be having a suitable large and representative sample to characterize the variation of behavior in the population. The recorded exposure for any one individual will not accurately reflect their true long-term exposure, but the assumption is made that on average those overreporting exposure will be balanced out by those underreporting their exposure. This assumes random error only; if

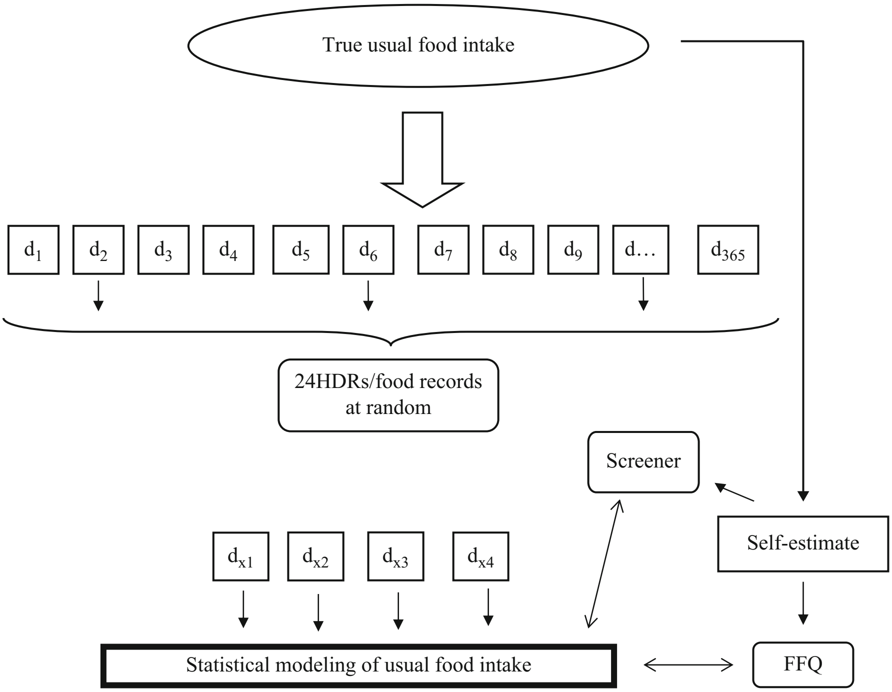

Fig. 44.1 Approaches of dietary assessment. Food and nutrient intake is realized by intake per day over life (24 HDR = 24 hour dietary recall). Usually, in studies, a year is of interest. This can be considered as true usual intake. We can estimate this intake by selecting a number of days at random in which intake is recorded. Another approach is to estimate usual intake directly via self-report. The food frequency questionnaire (FFQ) is such an instrument. Screeners are tools that address only a specific aspect of intake but not the total diet. They may be designed to assess day-to-day behavior but also to self-report usual diet. Statistical tools are now available to model usual food intake from day-to-day information. Some of them are also utilizing self-estimates in addition to day-to-day information to estimate usual food intake

individuals with certain characteristics systematically under- or overreport their true behavior, then the measured population average exposure will be biased. One such factor that may distort the measure of exposure is a person's body mass index. How to explore this will be covered further in a later section.

There is a large body of statistical data on national food availability and food availability on retail and household levels (Table 44.1). These are aggregate data to characterize regions which may serve ecological comparisons. The national statistics on food availability are systematically collected from the national statistical offices in a standardized way and prepared by the FAO in Rome. They provide an excellent overview of the global situation of food availability in the regions of the world over time (FAO 2013). Similarly, data on purchases at the household level have been used to describe the level of food security. In the European countries, household data have also been used to describe dietary practices (Naska et al. 2007).

Table 44.1 Methods of dietary assessment by type of epidemiological study (Modified from Margetts et al. 2003)

Epidemiological study	Level of aggregation required; expression of information (comment)	Method (comment)
Population or household level		
Aggregate population/ecological	• Average per capita intake compared across countries or regions or households • Trends over time within a country or region or household	Food disappearance data Food balance sheets from statistical offices Household budget surveys
Community experiment or intervention	Group level of analysis: compare outcomes for different exposures	Household budget surveys or sentinel assessment of representative individuals
Individual level		
Cross-sectional (prevalence survey)	Absolute amount	Food records or recalls (multiple days to describe within-person variation; number depends on measure required) Biochemical markers in blood and urine (check dose-response relationship with diet)
	Ranking	Food records (usually single days) 24-h recall (single or multiple days) FFQ, screeners Nutritional biochemical markers
Case-control	Past exposure at time of initiation or as proxy for past; usually categorized but may use continuous measure. (Absolute accuracy not required; assess misclassification and take into account)	FFQ of present or past diet Diet history Screeners
Cohort	Subjects intake at start of study ranked and categorized (expressed as exposed, not exposed) but may use continuous measure (absolute accuracy not required; assess misclassification and take into account, unless absolute risk to be described)	Food records 24-h recall FFQ Screeners Nutritional biochemical markers in blood or urine (does it relate to diet in sensitive manner?)
Experimental study	Individual level (usually needs to be accurate at absolute level)	Food records (multiple days to assess within-person variation) 24-h recalls FFQ (for patterns or group level comparison) Diet quality indices Nutritional biochemical markers

FFQ food frequency questionnaire

Impact of Study Design There is also a relation between type of study design and the dietary assessment instruments to be used. The major difference is between prospective and retrospective study designs. Retrospective study designs such as the case-control study need to apply retrospective dietary assessment methods since diet before onset of the disease is to be measured. Corresponding estimates of nutritional exposure are quite limited with regard to validity and accuracy of quantitative dietary intake measures.

In the next paragraphs we will summarize the key issues in assessing diet using different methods. Since there is an increasing interest in novel technologies and the use of web-based instruments (Illner et al. 2012), each section contains a description of the traditional approach and novel techniques. New information technologies will enable nutritional epidemiologists to rethink the way they currently measure diet, and this may lead to better quality information. However, most methods still require the active participation of the study subject and nutritional exposure assessment has to rely on self-reported information rather than on objectively measured parameters.

Dietary assessment methods with emphasis on novel approaches have recently been reviewed (Ngo et al. 2009; Illner et al. 2012). Particularly helpful is also the website of the risk factor monitoring and methods branch of the National Cancer Institute (NCI) as part of the National Institutes of Health of the USA (National Cancer Institute 2013) and the website of the Medical Research Council (MRC) of the UK (Medical Research Council 2013).

44.2.1 Food Record

The food record usually seeks to register prospectively all the food, drink, and supplement intake consumed over a period of time, usually broken down to 24-h periods. For some studies, where there are very specific foods of interest, the recording may be restricted to these foods or food groups. The required number of days of recording depends on how the data are to be used. For population estimates, two recorded days per person will suffice as long as the sampling covers all days of the week and all weeks of the year. Where an accurate estimate of individual exposure is required more recorded days will be needed depending on the sources of variation in the population and the exposure of interest (see Sect. 44.3). For example, if the exposure of interest is a nutrient found in a limited number of foods that are rarely eaten, then many days of recording in a large sample are required.

In theory, a major advantage of food records is that the open-ended nature of the collection allows many different exposure measures to be derived. When new exposures of interest arise, these can be derived from the records provided that such details were recorded.

Ideally consumption is recorded as it occurs, not recalled at the end of the day. It is generally the aim to record all foods eaten with a detailed description including quantity and method of preparation. Greater accuracy is usually obtained when the foods are weighed before they are consumed (weighed food record), rather than this amount being estimated or weighed before preparation.

A food record, if properly conducted, is often considered as the reference method against which less accurate methods are compared (see Sect. 44.2.4). Caution is required when making the assumption that a food record represents true intake. People often change their diets when asked to record their intake, either because the method is too time-consuming and people thus eat simpler foods or because they preferably choose foods that are socially desirable. The method relies on the participant being honest and retaining his/her usual food choices. Otherwise, it may be that technically accurate measures are obtained which are, however, biased in comparison to what a researcher would observe with an unobtrusive method.

44.2.1.1 Traditional Food Record

The food record is an open-ended method, either self-completed or administered by an interviewer. Traditionally the method requires the individual to write down what they have consumed over 24 h, either on a blank sheet or sometimes structured around meal-times or times of the day, depending on what is most appropriate for the target population. The interview approach may be conducted face-to-face or over the telephone. The researcher does not have to make assumptions as to which foods to include. This is also a disadvantage since correct assignment and coding of the foods are a major time-consuming effort, in particular if the subject has not given the respective details and/or has consumed many composite dishes. Technically, a food record can be collected, stored, and analyzed later (Bingham et al. 2003).

As an alternative to writing down what was eaten, it is possible to ask subjects to use a voice recorder; the recoding has then to be transcribed and to be processed further (Kohlmeier 1995; Illner et al. 2012).

If the study aims to record group mean intake and assuming the errors in the study sample are randomly distributed, a 1-day record will provide a reasonable estimate of the group mean. Where the requirement is to measure an individual's dietary intake and/or distributions, then more days of recording per subject will be required, depending on the extent of the within-person variability of the nutritional exposure of interest. Micronutrients that are found in large amounts in foods rarely eaten (vitamin A in organ meats) will require more days (perhaps up to 30 days) of recording to capture those days when the nutrient-rich foods are eaten. Macronutrients are generally supplied from a wide range of foods, and an individual's usual intake can probably be derived from 3 to 4 days of recording. In practice, researchers tend to ask participants to record more than 1 day, such as 4- or 7-day records, at one occasion. Often, it seems useful to discard the first day due to the fact that this day often differs from the remaining days. Also in terms of the statistical properties, a day from a consecutive record is not a random selection of possible days because a day out of a series of days has a high chance of being correlated with the other days, including the error (one day with a large intake, the other day with a small intake).

In order to improve the precision of food identification, barcode reading could be used for commercial foods. In some regions such as the European Union, each commercial food bears a barcode that can be read by a barcode reader. With the help of the barcodes, the food can be exactly identified, and information from nutrient labels can be directly used. However, it is still necessary to estimate the portion size of this intake in a proper way and to link the recorded data with reliable food composition data.

44.2.1.2 Standardization and Web-Based Approaches of Food Recording

Food records have been standardized and simplified by some groups (Koebnick et al. 2005). Paper versions were developed in which predefined categories of foods and portion sizes, often covering several days, are offered. The participant marks the respective items if the food has been consumed. Compared to the original method, this type of standardization reduces variability between the individuals in the study. The advantage of this simplification is the restriction to specific food items. The disadvantage is that it may miss foods that may later be considered important.

Computer-based versions of food records including their standardized and simplified versions can be found on the Internet. Often, they are directly linked to national food composition tables, among others, to allow nutritional counseling (e.g., Nutrition Analysis Tool (NAT) 2013). Users can enter their data using common web browsers. Such food records could also be used in the wider context of monitoring lifestyle changes in health programs, for example, weight loss programs. Computer-based versions of food records allow the rapid calculation of energy and nutrient composition and enable tailored guidance to be provided based in this information to foster behavior change. The aim in such circumstances is not so much accuracy as ease of use in affecting behavior change. Reliability and validation studies of these novel form of food records are rarely found in the international literature (Illner et al. 2012).

Major efforts have been undertaken at the beginning of this millennium to make use of new interactive devices such as mobile phones and personal digital assistants (PDAs)/tablets in order to record food intake (Illner et al. 2012). The advantage of these tools is that they allow direct and immediate reporting of food intake, even during a meal or directly after it. This method may not generate better results than paper-based food records; however, it has the advantage that food coding can be organized interactively using computer program-based analyses. As with the computer programs of recording diet from the Internet, the interest of those providing the mobile phone and PDA programs is often less research but more about dietary counseling and monitoring of dietary changes. This is well accomplished by an interactively communicated report of the energy and nutrient intake during recording. With the new generation of mobile phones, apps are available that ask to record food intake and calculate energy and nutrient intake.

44.2.1.3 Food Recording by Photographs

Within the US program, "Technology Assisted Dietary Assessment," mobile telephones of the new generation will facilitate a completely new way of collecting food records with the aim to obtain data with a much higher accuracy and validity than before (Daugherty et al. 2012). The idea behind this approach is not to record the meals but to produce images of all foods eaten. Photographs of meals on a plate can be taken before and after eating to allow subtraction of uneaten foods. The images are sent to a server of the institution and immediately analyzed by computer programs in terms of foods being used and the quantity ingested. It is the aim to train the computer programs to identify the foods properly and to calculate quantity even if the food is partly or mostly covered by other foods. Some companies and institutions have already established this method in a semiautomatic way in that dietitians assign foods and quantities from the pictures supported by computer programs. The semiautomatic approach is of commercial interest since the user may be willing to pay for the result. In the research environment, it is the aim to reduce the human factor as much as possible and to rely on powerful self-learning computer programs.

The current challenge is the quantification of foods. Initially, each image has to contain a standard that gave information about size and color. This might be a complication that makes the method less easy to conduct. Other ideas favor taking pictures from several predefined angles allowing producing three-dimensional images from which the quantity is derived.

With the progress in information technology and computer science, food recording by photographs seems to be the most promising novel approach to assess individual diet.

44.2.2 Food Recall

Unlike the food record techniques that record current intake, the food recall methods estimate past intake, sometimes referred to as a retrospective method. The most commonly used time frame for the recall is the intake at the past day, and as such, although it is a retrospective method, it is designed to cover current intake. The food recall can be done either by the respondent him/herself or by an interviewer. If only the past day is covered, the method is called a 24-h recall. A 24-h recall starts with an overview over the meals of the past day and works through each meal in detail by identifying each food being eaten including specifications such as brand name, cooking method, and fat content. Recall of the portion sizes may be aided by photographs and food models.

The main concern with this approach is that it relies on subjects accurately recalling what they ate. As with the record techniques, people may either deliberately or accidently exclude certain foods. Bias due to change in diet is thought to be less likely to occur if subjects are given no notice of the request for information. Otherwise, the 24-h recall will be as vulnerable to under-eating and social desirability as the food record. The risk of underreporting of foods when conducting 24-h recalls can be ameliorated by training of interviewers, use of standardized computer programs with meal orientation and tiers of questions with increasing details regarding the food being eaten, probing questions regarding in-between meals, and rechecks when a low-energy consumption has been reported.

The method of 24-h recalls is also considered similar to the method of food records to serve as a reference method for other less accurate methods. However, the retrospective and self-reporting nature of the 24-h recall can also induce bias and misreporting. As with the food record, about 10 to 15% of the consumed energy will not be reported, if compared with objectively measured energy expenditure (Poslusna et al. 2009).

Computer-based 24-h recalls can be linked to the latest national food and nutrient databases, where facets such as brand name, preparation, cooking method, and fat content can be incorporated for all foods or for specific food groups.

44.2.2.1 Interviewer-Administered 24-h Recalls

Traditionally, 24-h recalls are conducted by face-to-face interview, although telephone interviews rather than face-to-face are becoming more common particularly for large studies. Comparison studies did not reveal any statistically significant difference between face-to-face and telephone interviews (Tran et al. 2000; Brustad et al. 2003). The interviewer can use a computer program and ask about the diet of the previous day. Such an interview takes about 20 to 40 minutes. This type of 24-h recall has been applied in some of the calibration studies (see Sect. 44.5.2.) when a study participant was in a study center for examination. In some of these studies, home interviews were conducted if more than one 24-h recall was required per subject.

In order to obtain several 24-h recalls from a subject for randomly chosen nonconsecutive days, the telephone interview is the preferred method. In this case, the participant may receive a book with portion sizes at the beginning of the study, mostly during physical examination at a study center (and eventually coupled with a first face-to-face interview) and may then be waiting for the call by the interviewer on subsequent days.

44.2.2.2 Web-Based 24-h Recalls

Web-based 24-h recalls for self-administration have been developed and follow the same principles as the 24-h recall administered by interviewers. A good example of such an approach is the NUTRINET-SANTÉ Study, conducted in France (l’Étude Nutrinet-Santé 2013). The 24-h recall of this study is self-administered and web-based, developed in a long tradition of experience. In France, the first approaches to collect detailed dietary data by self-administration have been started in the early teletext times. Other web-based programs for self-administration have been developed by a Californian group (Arab et al. 2011) and by the NCI (Subar et al. 2012). The US programs have been organized similarly as the interviewer-based multiple-pass method, developed for the surveys of the US Department of Agriculture, and has shown to be feasible. A special tool was developed for adolescents in the HELENA study (Vereecken et al. 2008) which was adapted for young children in the framework of the IDEFICS study. This program is still computer-based but will soon be available as a web-based instrument (SACANA) for self-completion instrument (Börnhorst et al. 2013). However, it is still unclear whether there is a loss of information by the self-administration compared to interviewer-conducted 24-h recalls and how large the loss may be. Some loss of information by self-administration might be expected due to the complexity of current diet and skipping of probing questions. Therefore, the web-based versions of 24-h recalls cannot be regarded as quantitative reference methods yet.

A further simplification of 24-h recalls, designed for self-administration via Internet or touch screen, is done by keeping the meal-based structure but to offer only a selected number of foods and ask for their portion size and frequency of intake at that day (Biobank UK 2013). The time to fill in one questionnaire takes about 11.5 min on average. The questionnaire has been developed by an Oxford research group and is currently used in the UK-Biobank study (Liu et al. 2011).

Another modification of the 24-h recall has been done in Germany with the aim to have a self-administered instrument that focuses on the use of a selected number of foods on a specific day. This instrument has been designed to be applied as a web tool but can be also printed out and used as a paper version to be filled in at home (for the past day) after a telephone call (Boeing, personal communication; German Institute of Human Nutrition (2013) "Simplified 24-h-recall"). Filling-in time is about 8 min per single day. The simple self-administered 24-h recall allows repeated application without much time effort for the participant but needs further data on portion sizes from interviewer-conducted 24-h recalls and frequency per day information from a FFQ for those foods eaten daily.

44.2.3 Dietary History Method

The dietary history method goes back to Burke (1947) who proposed to use a habitual instrument to capture individual diet in addition to food records estimating current diet. The diet history is a retrospective method with the aim to obtain a detailed picture of the usual dietary intake of an individual. By this method, the individual has to describe usual food and supplement intake, organized according to meals, for a relatively long period, e.g., 4 weeks, 6 months, or 1 year. The method usually requires the administration by an interviewer. The face-to-face situation allows the use of common household measuring containers to estimate portion sizes. The method is popular particularly in the Scandinavian countries and has also been used in the health surveys of Germany, conducted by the Robert Koch Institute. The method has been the dietary assessment method of choice in a larger European study on the elderly (van Staveren et al. 1996).

Bälter from the Karolinska Institute, Sweden, has developed a web-based version of a diet history for a large-scale prospective study (Bälter et al. 2005). This web-based dietary history combines the meal orientation of food intake during a day and the focus of the food frequency (see Sect. 44.2.4) on habitual diet and is asking about habitual meal structured food intake.

As with other retrospective methods asking for habitual diet, social desirability and overestimation of healthy foods are one of the problems when compared with reference methods (see Sect. 44.5.1). Estimating habitual diet by the respondents themselves and not by statistical methods from short-term quantitative instruments (see Sect. 44.4) is usually prone to many biases due to the considerable intellectual effort of the participant to recall precisely the habitual diet during a certain time period.

44.2.4 Food Frequency Questionnaire (FFQ)

The method of the food frequency questionnaire (FFQ) became prominent with the first large-scale cohort studies, comprising more than 100,000 subjects, at the end of the 1970s. At that time, also the first data processing centers based on large computer units had been established, and it was logical to make use of the "new" technologies to collect data on dietary intake. For this purpose, the method of asking for the habitual eating frequency of portions of selected foods over a defined retrospective time period in a self-administrative manner was ideal and thus, the food frequency questionnaire became the leading dietary assessment method for all types of studies in which the diet of cases are intended to be compared with the diet of controls. This could be used prospective studies as well as retrospective case-control studies. The response categories in the first versions of the FFQ were initially confined to nine options, in order to optimize computer storage place. The FFQ is primarily a ranking instrument developed for comparing groups and less an instrument by which diet is exactly quantified.

The selection of foods to be included depends on the research question in general and the type of dietary exposure of interest. An FFQ designed for general purposes should be able to measure key dietary components related to health and energy intake. Key dietary components include foods and food groups as well as nutrients. The development of an FFQ requires a survey type of dietary data collection by reference methods in the source population in which the FFQ should be applied. Key foods, explaining most of the variance of the nutritional exposure, can be identified by methods such as stepwise regression and specific programs for that purpose such as Max-R and MOM (Mark et al. 1996). Also foods contributing to a specific nutritional exposure in high absolute amounts should be identified. Both types of considerations, variability of food intake in the source population and the contribution of foods to the nutrient and energy intake, finally result in the list of foods selected to be included in the FFQ. Usually, the number of food items in an FFQ is about 130 to 180. Each FFQ needs investigations in as much the FFQ is able to reflect true dietary intake (see Sect. 44.5.1) and whether calibration strategies (see Sect. 44.5.2.) could be applied to assure that the dietary intake values reflect the intake in the source population (Nöthlings et al. 2007).

The focus on food items makes the FFQ very attractive to compare subjects and populations regarding the pattern of dietary intake. Some FFQs have already been developed to be applied in a multicultural setting, for example, in the multiethnic cohort of Hawaii. This study consists of subjects of Hawaiian, Japanese, Caucasian, and black origin (Kolonel et al. 2000). Also, an FFQ was developed for estimating diet in different European countries (Illner et al. 2011). In view of worldwide trends toward a unified food supply which is usually accompanied by a reduction of specific cuisine traditions, multicultural FFQs asking for the use of commonly available foods as well as some specific traditional foods in all study subjects might be feasible and give a first insight into still existing differences in eating habits of subjects and groups on a wider scale based on one instrument.

44.2.4.1 Traditional FFQ

From its beginning, the paper version of an FFQ was designed for optical scanning. Often, the requirements for optical scanning dominated the design of the instrument, for example, that the frequency scale for each food item was displayed in lines. The number of lines per page, in turn, followed the number of sensors of the scanner.

In the FFQ usually the frequency of intake of a standard portion over a year is requested. For case-control studies, the time period to be covered is usually extended, for example, to 5 years before onset of the disease or the last 5 years. Seasonal variations and specifications regarding facets of the food such as fat content (dairy foods) were often included into the FFQ. Further research revealed that the frequency scale should be vertically organized instead of horizontally. Most individuals preferred this type of presentation in a feasibility study (Thompson et al. 2002). It is still a question as how to incorporate the portion sizes into an FFQ. Since the frequency scale always makes reference to a portion, the assessment of the individual portion size improves the ranking of a subject and increases the comparability between subjects. Thus, in traditional FFQs, questions on the portion size of a food item, categorized in small, medium, large – often illustrated by pictures – are asked. Portion size information usually accounts for 10 to 20% of the variation in food intake (Noethlings et al. 2003). It is still the question whether such portion size information is reflecting true behavior. Research in recollecting and proper assignment of portion sizes revealed that portion size information has some validity (Haraldsdóttir et al. 1994; Ovaskainen et al. 2008).

44.2.4.2 Food Propensity Questionnaire (FPQ)

In connection with considerations of combining information of 24-h recalls with FFQ information (see Sect. 44.4), it was suggested to reduce the information requested in the FFQ to the frequency scale and to omit the questions on portion sizes (Subar et al. 2006). This step would reduce the burden for the study participant but could still make use of most of the information a FFQ is providing.

44.2.4.3 Screeners for Dietary Exposure

The selection of foods for the FFQ can be limited to only a few or even one dietary exposure. The resulting questionnaires are called "screeners" since they only screen and rank subjects according these (this) exposure(s) (Thompson et al. 2004). Screeners are particularly interesting if in a study only one or a few hypotheses are of interest and time and resources are limited to collect dietary data. However, since the screeners lack the information on energy intake, adjustment for energy intake allowing to control for the different energy needs of the study subjects and to improve the validity of the estimate of the dietary exposure is not possible (see Sect. 44.5.2).

44.2.4.4 Web-Based Versions of the FFQ, FPQ, and Screeners for Dietary Exposure

From the beginning, the use of FFQs as a self-administered instrument facilitates its application as a web-based tool (García-Segovia et al. 2011). With the Internet, study participants can now fill in the questionnaire at home on the computer or directly in the study center. In the study center, the questionnaire can be offered as a touch screen program. Studies comparing the traditional paper versions with the Internet versions did not find differences in the performance of the instrument. Many research groups now offer paper as well as Internet versions of their FFQs.

44.2.5 Nutritional Biomarkers

Nutritional exposure can also be expressed as nutritional status defined through biomarker measurements. Nutritional status reflects the dynamic balance between dietary supply, body pools, and the metabolic demands. Measuring food intake does not represent a nutritional status. At the same level of dietary intake, a subject may be able to function well or poorly, depending on the demands being placed upon him/her. If an individual is growing or fighting an infection, the dietary supply of a nutrient may or may not be adequate to enable and maintain optimal function. However, the available nutritional substrates for function at a certain time period not only are coming from the diet but can also been mobilized from the body pools. Where there is competition for these metabolic substrates, one function may be compromised by another one. In an epidemiological study, it is often assumed that a reported measure of intake reflects the functional availability. However, this assumption is rarely true. Nutritional biomarkers are primarily obtained from blood or urine to estimate nutrient status and/or to validate nutrient intake obtained by (self-reported) dietary assessment.

In this chapter, we will not address assessing nutritional status by biomarkers or the development of appropriate methods to identify new biomarkers of nutritional status. Novel -omics techniques allow a completely new and comprehensive approach with simultaneous determination of thousands of metabolites. Thus, biomarker studies with this type of data will play a prominent role in the future regarding the search for a better characterization of a subject regarding nutritional status. Here, we address which biomarkers are useful to validate dietary assessment instruments. Biomarkers have a major advantage of being independent from all self-reported diet with respect to their error structure. This is a major statistical advantage when statistical models are built to identify measurement error (see Sect. 44.5.1).

Nutritional biomarkers can be divided into three categories: (1) recovery biomarkers which are considered to capture true dietary intake and are measured in the same units as dietary intake by dietary assessment methods such as nitrogen in urine, (2) concentration biomarkers which correspond to dietary intake but do not reflect total dietary intake and are not measured in the same units as dietary intake such as vitamin C, and (3) replacement biomarkers that should be used instead of measuring intake by dietary assessment, i.e., when it is difficult to capture dietary intake due to limited information in nutrient databases, widespread occurrence in foods, or very difficult measurement procedures by questionnaires such as selenium.

For validation purposes, the recovery biomarkers are the primary choice. However, the number of true recovery biomarkers is small and refers to energy expenditure and nitrogen excretion in urine, followed by the minerals potassium and sodium, also excreted in urine. With the exception of energy expenditure measured by doubly labeled water, urine is the biomaterial of choice for recovery biomarkers. Less suitable than recovery biomarkers for validation purposes are concentration biomarkers. They are usually determined in blood such as vitamins and bioactive compounds, e.g., vitamin C, folic acid, vitamin D, or carotenoids. Concentration biomarkers usually lack a linear relationship with intake over the whole range of exposure, and their concentrations in blood are the result not only of intake but of metabolic activities including genetic makeup.

Urine samples for the determination of recovery biomarkers require 24-h collections. The collection of complete 24-h urines is laborious for participants and researchers since it requires the permanent availability of collection containers with preservatives and their storage and a pickup service. Some researchers also favor the use of 4-aminobenzoic acid (PABA) or other markers to verify the completeness of urine collections (Murakami et al. 2008). With PABA as a standard, correction factors for incompletely collected urines can be applied.

44.3 Defining Dietary Exposures

In a research setting, the hypothesis is framed in terms of how the exposure influences the outcome. In this sense, the measure of dietary exposure needs to reflect the relevant exposure in the formulated hypothesis. Nutritional status refers to measures of diet, body composition, and biochemical and clinical states. All can be used as measures of exposure. In this section, we characterize dietary exposure in more detail. Diet is a general term and comprises all that we eat. Food describes the individual items that make up a diet. The dietary assessment methods record these individual items (and also supplement intake). Food intake can be converted into intake of nutrients, other food compounds and energy by multiplying it with the average concentration of these compounds in the food. In rare occasions food intake could also be duplicated and one half ingested and the other half chemically analyzed for particular constituents, including, e.g., products formed by different cooking methods. Intake of individual foods, nutrients or dietary patterns may be the relevant exposure, depending on the hypothesis being tested.

Food composition tables are the means to convert food intake to nutrient intake. A normal supermarket can offer several thousand different food items and the overall number of available foods in a country approaches 200,000. Food-composition tables are usually hierarchically organized from major food groups to subgroups down to single food items. Food composition tables usually do not contain brand names but are structured according to foods. They are food-oriented and thus contain information on the processing, e.g., raw, cooked, pickled, and canned. They also include ingredients and foods we never eat as described. Complex dishes and recipes pose a problem for food coding. Sometimes, the conversion into ingredients is done, and sometimes a general food code is used. Thus, it is important to follow in each study the same strategy in order to make dietary assessments comparable. The different strategies of food coding and the use of different food composition tables also make it difficult to compare data from different countries directly.

Food composition tables link the nutrient content or the content of other food constituents with a given food item. The contents or concentrations of the constituents are often generated as a combined effort of several institutions and laboratories (Bell et al. 2012). Application of standardized laboratory methods and quality control measures are essential to compile meaningful food composition tables. Often, an analytical method is changing with technical progress and laboratory data nowadays are not directly comparable with older data on food constituents. A particular problem for researchers could be the variation of the constituents within a food. Species differences, ripening status, and soil condition are a few of the factors that could increase the variation of the constituents. An example is selenium in grain which heavily depends on soil concentration which is quite different in the USA compared to Europe. Selenium concentration in grain therefore depends on the annual import and export figures between the USA and Europe. If the variation of a given constituent in a food is very high and if this constituent is contained in many foods, one might conclude that the use of biomarkers might be a better choice to rank subjects.

44.3.1 Defining Reference Categories and Cut-Points

In statistical models, nutrient or food intake data are commonly used as categorical variables rather than as continuous ones (see also Sect. 44.6). Categorical variables are created by dividing the continuous data of the study population into tertiles, quartiles, or quintiles. The categorical approach makes no assumptions about the underlying shape of the association between the nutrient and the outcome. Even if intakes are used as continuous variables, analyses based on categories should be done to check whether the assumptions made for the continuous approach are justified. For example, in logistic regression, the assumption of a linear trend can be assessed by examining the variable in categories (Hosmer and Lemeshow 1989; cf. chapter ▸Regression Methods for Epidemiological Analysis of this handbook). One reason in favor of the categorical approach is that it expresses the results for dietary factors in the same way, independent from the instrument being used and the random and systematic biases in estimating intake. Categories describe the measured ranges of intakes among the individuals in the study group in an identical manner. The relative risk estimates for the highest versus the lowest category can be directly compared to assess the relative impact on the outcome of interest. Nevertheless, caution may be required in comparing results from different studies where the range of intakes covered in the top or bottom third, for example, may be quite different. For example, comparing tertiles of intake of red meat between Germany and China, the intake in the highest third in China will probably be included in the bottom third for Germany.

Using external criteria might be an alternative to build categories. For example, one could use published dietary recommendations such as 30% of energy from fat or 30 grams of dietary fiber per day. The use of external criteria, however, requires that the dietary estimates in the study are not biased. Otherwise, the public health message coming out of the study might be grossly misleading. The same applies to the labeling of the categories. The values used to label categories should be meaningful to the readers. Otherwise, it would be better to label categories according to an ordinal scale.

Where data are recorded and reported as continuous variables any associated disease risk is expressed per unit of exposure. Thus, it is important to assess the exposure in terms of absolute amounts consumed. The respective unit of exposure can then be selected to express the change in relative risk. For some exposures, units of 1 g are biologically meaningful, while for others units of 10 g or 100 g are of relevance. The exposure units can also be chosen according to external knowledge, for example, from dietary recommendations.

44.3.2 Measurement of Dietary Behavior

Dietary behavior can be an important aspect of dietary exposure. Dietary behavior can be asked directly in questionnaires. Corresponding questions address, for example, for cooking methods, food preparation, food sources, or food knowledge. For health outcomes, food preparation and in particular cooking methods may be important. In this respect, meat preparation has gained the highest interest so far. Some groups such as from the NCI developed and validated specific questionnaires with pictures about the way a subject is preparing and eating meat in order to estimate the intake of carcinogenic compounds (Sinha 2002).

The long-term observation of dietary behavior in countries that are in transition or in specific groups that undergo major cultural changes seems to be of high scientific interest in order to understand the impact of changes in dietary behavior on health outcomes. In these instances, the consumption of commercial foods, eating out of home, and sources of food supply are repeatedly assessed and analyzed in the population of interest.

44.3.3 Dietary Pattern Analysis

There has been a growing interest in approaches to summarize the dietary data by forming patterns and by investigating their association with disease risk. Dietary patterns can be assessed for foods as well as for nutrients. Most of the dietary pattern analyses are still devoted to foods. Dietary patterns can be derived in different ways (Hu 2002). One method is to use some a priori understanding of the way in which people should eat. Based on this understanding, indices are formed which describe how well an individual is following the prescribed dietary pattern.

Examples for such indices are the Healthy Eating Indices developed for the USA, the Mediterranean Diet Index, or the Nordic Healthy Eating Index. Other ways of forming dietary patterns are based on exploratory statistical methods such as principal component analysis, reduced rank regression, and cluster analysis. The latter methods make use of the existing empirical data collected in a study and utilize the correlation or covariance matrix between the dietary exposures. They are also called a posteriori methods in contrast to the a priori methods.

44.4 Methods to Calculate Habitual Diet Based on Short-Term Food Records and Recalls

For a long time, it was discussed how data from 24-h recalls and food records can best be incorporated into studies aiming at habitual diet. Some researchers argued that time periods of collecting data of only a few days are not sufficient to characterize the habitual diet of individuals. They highlighted that day-to-day variation and seasonal intake might make such methods less suitable for epidemiological studies that relate diet with disease risk or other personal characteristics. Nowadays, it seems possible to collect several 24-h recalls per individual at random over a year, for example, by telephone (see Sect. 44.2.2). Further, statisticians have developed complex programs that allow an estimate of the habitual diet based on these 24-h recalls. In this section, the aim is to describe how to calculate habitual diet from short-term instruments with their major research lines.

Dietary data, derived from 24-h recalls and food records, include two types of variation. One type of variation is the daily variation of dietary exposure in an individual (within-person or intraindividual variation) and the other type of variation is the variation of dietary exposure between the individuals (between-person or interindividual variation). The total variation of dietary exposure data of a study is therefore the sum of the intra- and interindividual variance. In a study with many study subjects, the interindividual variation is usually causing the major part of the variation. The extent to which the intraindividual variation contributes to the total variation of the dietary exposure depends on the number of days recorded for an individual. Each individual has a true mean value per day around which the single-day values vary. With increasing days recorded per individual, the estimate of the true mean of the individual becomes more precise. If all 365 days of an individual would have been recorded unbiased, the true mean intake per day of all individuals can be defined precisely. With fewer days, the individual mean values still vary around the true mean.

The existence of the two types of variation has several consequences. One consequence is that the distribution of the mean intake in a study population does not reflect the true distribution of the means among the individuals. This may be important when public health measures are derived from such distributions (see Sect. 44.7). The deviation from the true mean of an individual increases when the number of days per individual decreases. The distribution of dietary intake data with only one recorded day per individual is usually much flatter than the true distribution due to the additional intraindividual variation. With more recorded days per individual, the estimated distribution in the population becomes more narrow. Another consequence is the dependency between the ratio of the two types of variation and the number of days needed to characterize an individual regarding a specific dietary exposure. The more stable the daily dietary intake is, the smaller is the intraindividual variation, and the fewer days are required to characterize the dietary intake of an individual. Protein, for example, is a dietary constituent with only a comparatively small day-to-day variation. On the contrary vitamin A has a high intraindividual variation due to occasional intake of vitamin A-rich foods. For example, liver is rarely eaten (see Sect. 44.2.1.1).

The implication of the different types of variation within a dietary data collection with 24-h recalls or food records on the practice of nutritional epidemiology was intensively discussed in the 1980s (Beaton et al. 1979, 1983). It was proposed to use variance component analysis to calculate the two types of variation and to remove the intraindividual part of the variation in order to obtain the true variation between the individuals (Beaton et al. 1979, 1983). Traditional variance component analysis requires a normal distribution of the intake data which is only rarely found. Perhaps this is why this procedure does not improve the estimate of dietary exposure for the individual but does so for the whole study group.

Progress has been made during recent years to develop the statistical framework further in order to identify and control for the intraindividual variation properly. The aim of such statistical procedures is to estimate the true study distribution based on only the interindividual variation. The estimated true study distribution also provides the best estimate for each individual. An introduction to the statistical background of such methods can be found on the NCI website (National Cancer Institute 2013) as well as links to their statistical program. The statistical method transforms any type of intake distribution into a normal distribution, removes the intraindividual variation by variance component analysis, and back-transforms the new values to the original scale. Further, the analysis has been split into the part of estimating the probability of intake (i.e., of a day) and of the amounts eaten at each occasion.

Further efforts try to extend the approach to the multi-exposure situation, since one exposure correlates with other exposures in terms of error structure and variance components (Zhang et al. 2011). Such statistical tools for the multi-exposure situation, particularly if energy is included (see Sect. 44.6.1), will result in even better estimates of the distributions compared to only considering one exposure at a time.

The use of such methods is straightforward when nutrient data are investigated. Nutrients are consumed almost always every day, and non-zero consumption is not an issue. If foods are investigated, non-consumption might take place at the day on which the data are collected. Even if the recall spans several days, no consumption of a food might be recorded despite the individual has eaten the food outside the recorded time period. Thus, it is proposed to make use of the frequency information of an FFQ if such data are available. The FFQ provides information of the habitual use or non-use of a food. A habitual non-user of a food should have a zero intake. In contrast, a habitual user of a food even if no data are available on the 24-h recalls or food records should have an intake value even if it is small. Some of the statistical programs take this into account and simulate the intake of foods not reported in 24-h recalls.

The estimates for each individual, calculated by such programs, can be regarded as the best estimate of the habitual diet derived from the short-term dietary assessment instruments (George et al. 2012). These estimates are not identical with the mean intake over the days which are usually calculated for each individual from food records or 24-h recalls. The estimation of the habitual intake of an individual can be further improved by considering covariate information such as age, sex, BMI, and habitual frequency information of a food. It has been calculated that 4 to 6 days per individual might be sufficient to capture most of the food and nutrient intake of an individual correctly (Carroll et al. 2012). It has also been found that often the individual estimates improved when the FFQ information is added (Carroll et al. 2012).

In view of the advantage of short-term methods such as 24-h recall and food record with regard to their precision and quantity, their use to calculate habitual intake is considered an important step further. The new statistical programs might facilitate up the widespread use of quantitative assessment methods in future epidemiological studies.

44.5 Quantification and Correction of Measurement Error

Different study designs use different methods to assess diet, often for reasons of cost, time, and effort. However, it should be the aim of nutritional epidemiology to assess and utilize dietary data that are close to true intake (Fig. 44.2).

Therefore, a great deal of research and effort has gone into the validation or calibration of methods used in nutritional epidemiological studies (Table 44.1). The aim of such studies is less to improve the method itself but to define, and then correct for, the type and amount of measurement error (calibration studies). The validation of a method is usually done by comparing the empirical data from the dietary assessment with a measure of true intake. However, true intake (truth) is nearly impossible to measure. True intake should be considered more as a construct or latent variable than the result of a direct measurement. As a compromise, researchers take the best possible methods, usually 24-h recalls or food records, and compare their results with the results from the study instruments such as FFQs, diet histories, and screeners. This type of validation is also called relative validation (or some prefer to comparative study), since the reference method still contains measurement error compared to the truth. The reference method is often labeled as the relative reference method compared to a gold standard reference method. In this comparison, it is assumed that the errors of each method are not correlated and that any agreement observed between both measurements derived is not due to this correlation of errors.

Including a biomarker may provide further refinement to the validation of dietary methods. It is assumed that the error associated with the collection of biomarker information is independent from the errors of self-reports of dietary intake. This assumption allows the use of complex statistical methods to estimate true intake. This framework is also known as the method of triads (Daurès et al. 2000). In the method of triads, the correlations between questionnaire data, reference data, and

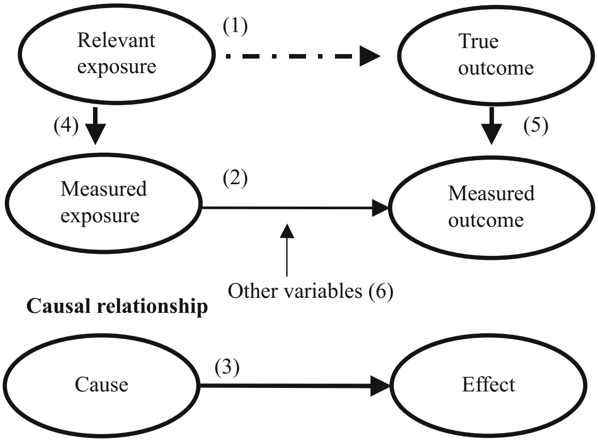

Fig. 44.2 Relationship between exposure and outcome, cause and effect. (1) This represents the true relationship between relevant exposure and outcome. (2) This represents the observed relationship between measured exposure and measured outcome. (3) This represents the true causal pathway. The cause must precede the effect. (1) and (3) are the same if other variables (6) (confounders) are either absent (no residual confounding) or taken account of (by stratification or statistical adjustment). (4) This represents the relationship between relevant exposure and measured exposure. (5) This represents the relationship between true outcome and measured outcome. (6) Variables that should be measured and reported that may influence the relationship between exposure and outcome.
The extent to which the measured exposure and outcome deviates from the true and relevant measures should be described in a validation study that presents the measurement errors

biomarker data are used. In its most advanced form, the statistical framework of the method of triads includes repeated measurements of all three assessment methods (Rosner et al. 2008).

44.5.1 Quantification of Measurement Error

The way that measurement error is assessed needs to be appropriate as to how the data derived from the method will be used in the main study. It should also be clear that the sample of people used to assess the measurement error should be similar to the study population in terms of characteristics. In broad terms, the comparison study assumes one method is a better estimate of the true exposure (reference method) and is often denoted by Q, while the test method is denoted by R. Ideally Q equals R in any comparison. There are a number of different ways to assess and express the relationship between R and Q. For example, the relation between R and Q can be described by correlation coefficients. Validation studies also established cross-tables between R and Q and described the relation between R and Q with a categorical association measure such as kappa or chi-square. The decision of the way to describe the validity of a method depends on the statistical approach of the

Table 44.2 Probabilities of misclassification of a reference ranking in fifths using an imperfect alternative that has various correlations with the reference (From Walker and Blettner 1985)

Absolute difference in quintile ranks	Correlation coefficient between the reference and alternative			
	0.9	0.7	0.5	0.3
0	0.573	0.403	0.321	0.263
1	0.378	0.400	0.379	0.355
2	0.047	0.156	0.203	0.225
3	0.002	0.037	0.081	0.118
4	0.000	0.003	0.017	0.038

main study. Alternatively, the validity can be described by using several approaches in parallel to generate various types of validity coefficients. If the study aim is to compare the relative risk of one level of exposure with the relative risk of another level, then the validation study should also assess how well the selected method can distinguish these levels compared to the reference method.

A regression approach allows a more sophisticated analysis of the relationship between Q and R.

The respective relation can be described with

$$R = \alpha + \lambda Q + \varepsilon,$$

where α describes the systematic bias, the parameter λ the ability of Q to measure the range of intake in R, and ε describes the random error. A small value of λ indicates a low ability of the instrument Q to assess existing differences between study subjects. The estimates of λ are sometimes used to correct the observed relative risks for measurement error (Spiegelman et al. 1997). It is difficult to get measures of α, and it is often assumed to be zero. If this assumption is not true, then a distorted estimate of agreement will be derived.

Table 44.2 shows the proportion of people who are classified into the correct quintile by the reference method but into a different quintile by the alternative/test method (Walker and Blettner 1985). For a measure with a correlation of 0.5, only 32.1% of individuals are placed into the correct quintile, another 37.9% are one quintile too high or low, while the remaining individuals are misclassified by two quintiles or more. This table also shows that extreme misplacement over four quintiles is rare. The impact of the measurement error on the study result is profound. Assuming a cohort study with a "true" incidence of 2% in the lowest quintile and 6% in the highest (i.e., a relative risk of 3.0), using the alternative method with a correlation of 0.5 with the reference method would lead to incidences of 3.1% and 4.9% in the lowest and highest quintile, respectively, and result in a relative risk of 1.58 instead of 3.0 (Walker and Blettner 1985).

A particular concern is whether those who misreport their intake are different in other important characteristics from those who do not. Most work has been done on misreporting energy intake by individuals with different levels of body mass index.

The data suggest that overweight people tend to underreport their fat intake. Another issue is misreporting due to social desirability and established norms. Recent work showed that fruit intake is overreported by low consumers because they know they should eat a certain amount of fruit (Amanatidis et al. 2001). This phenomenon was particularly observed among more educated individuals. Before a study begins, it may be possible to take a tendency to differential over- or underreporting into account in the design of the study, for example, by excluding overweight people. However, if this is done, it could mean that the study results cannot be generalized to the whole population.

Even if a validity study has not been conducted, the test-retest correlation (reliability) (cf. chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook) can provide an indication for the maximum level of validity. The correlation between the test and reference measures cannot be greater than the correlation of repeat measures of the test measure (Walker and Blettner 1985). Low test-retest reliability clearly indicates also low validity.

This initial concept of validation with a reference measure was extended toward measurement models that included objective measurements such as biomarkers. Biomarkers can be used as the only reference method or as a second reference method. The use of biomarker information as a second reference method leads to the method of triads and latent variables (see Sect. 44.5). A second reference method gives also a sense of how well the first reference method may be in measuring the underlying truth.

Some of the biomarker information can be considered to provide gold standard information on the nutritional exposure of interest (see Sect. 44.2.5). In contrast to the relative reference methods, the gold standard information provides a measure of nearly the truth. However, we still have to be aware that this term gives a false sense of accuracy due to the often short-term recording periods of the gold standard reference. One of the gold standard reference methods is the measurement of energy expenditure as a proxy for energy intake by doubly labeled water (DLW). DLW provides an integrated measure of components of energy expenditure, usually over 7 to 14 days. The technique involves ingestion of a small amount of water with hydrogen replaced by deuterium, where both the deuterium and the oxygen are isotopically labeled. As water molecules are split during energy metabolism, oxygen binds to carbon and is exhaled as CO_2. The excretion of deuterium is then measured in urine. The rate of loss of these labeled elements can then be used to provide an estimate of energy expenditure (Goran and Astrup 2002). Apart from DLW, urinary nitrogen is also considered as a gold standard method. Aside the two, there are only a few other robust independent measures that are relevant (see Sect. 44.2.5). Most of the biomarkers of nutritional status lack a linear dose-response relationship with the level of dietary intake (which is the relevant exposure) (Bates 1997a, b). If there is a curvilinear relationship, the question is important how the intake of the study population fits into this relation. If the intake of the study population is either at the lower or higher end of the distribution, the comparison of the dietary and the blood measure may show poor agreement and lead to the erroneous conclusion that the dietary assessment is poor.

Studies with DLW seem to suggest that there is no or only a low relation between energy intake assessed by an FFQ and energy expenditure derived from DLW, particularly in overweight or obese subjects. It seems that, based on DLW, many overweight people underreport their energy intake (Subar et al. 2003). A further refinement is to express energy intake as a function of the resting or basal metabolic rate (BMR). If energy intake is less than the BMR, it would seem reasonable that subjects who are not losing weight underreport their dietary intake. Usually a factor is added to the BMR to allow for some level of physical activity (PAL). A PAL value of 1.2–1.5, reflecting low to moderate physical activity, is often used. If multiplied with BMR, the estimated required energy intake is obtained. In the national diet and nutrition surveys of British adults, using a 7-day weighed food record, about 40% of the subjects underreport their intake, assuming some degree of moderate activity (Black et al. 1991). However, underreporting has been found across all PAL. Thus, underreporting is not completely compensated when individuals with an energy intake below a certain BMR to PAL level are excluded from the study (Tooze et al. 2012). In case of the diet and nutrition survey of British adults, excluding 40% of subjects due to underreporting energy intake reduces the power of the study and may cause selection bias but may be necessary to reduce information bias.

One of the important studies with biomarker information was the Observing Protein and Energy Nutrition (OPEN) Study conducted in the USA from 1999 to 2000 due to its design and size. This study assessed the dietary measurement error of two self-reported instruments: a semiquantitative FFQ and a quantitative 24-h recall (Subar et al. 2003). Doubly labeled water and urinary nitrogen were used as biomarkers of energy and protein intake in nearly 500 men and women. In this study, the self-administered dietary assessment instruments were only able to pick up a minor part of the true variation between individuals as compared to the objective measures. The FFQ used in this study reflected 4–16% of the true variation in energy intake and 30–40% of the variation in protein density. The four 24-h recalls reflected 20–37% of variation in true energy intake and 35–50% of the variation in protein density.

44.5.2 Correction of Measurement by Calibration of Dietary Data and Measurement Error Models

The main idea behind calibration of the dietary data in a study is to improve the estimates of dietary exposure of all study subjects by using data from a validation substudy collected within the main study. A validation study in a subgroup of the main study should be regarded as a general advantage independent from using the results for calibration since validity is assessed under real study conditions. The population of the sub-study should be representative for the study population, and the collection of the additional data should follow the rules of the method of triads.

Calibration means that the information obtained by the dietary instrument of the main study is corrected using the information from the validation study with the better method in a measurement error model. Usually, a weak dietary assessment leads to a loss of power and the attenuation of the risk estimate toward the null value. Calibration should reduce the attenuation of the relative risk. The concept of calibration is closely related to the concept of validation. Simulation studies could show that calibration in most instances fulfill the purpose to improve the estimate of the diet-disease relationship (Freedman et al. 2011).

There are several ways to establish the measurement error model. An often used approach is regression calibration, in which the relation between the self-reported diet and the biomarker information is described by regression equations (Freedman et al. 2011). These equations include regression terms for the characteristics of the participants that influence the estimate of the observed dietary data compared to the truth. For all subjects that are not part of the sub-study, an estimate of the true intake is calculated given the self-reported intake and the personal characteristics of that subject.

44.6 Statistical Approaches in Nutritional Epidemiology

In principle, the statistical risk modeling of dietary data is not different from the modeling of other data. They are usually used as continuous or categorical data (see Sect. 44.3) in Cox proportional hazard or logistic regression models.

In the past, most of the nutritional epidemiological studies presented relative risks for ordered categories such as quartiles or quintiles. Usually, the lowest category was selected as reference category, and the relative risk was estimated for the other categories of intake. Since the FFQ was considered as a ranking instrument, the use of categories seemed to be appropriate. The use of intake categories instead of a continuous measure also allows investigating non-linear relationships and thresholds (see Sect. 44.3). With more precise data, there is increasing interest to describe the relation between dietary intake and risk of a disease in a continuous manner. This trend is further supported by the estimate of habitual intake from short-term reference instruments (see Sect. 44.4) and the use of calibration and measurement error models with objective measures (see Sect. 44.5.2).

Thus, this section concentrates on those concepts that cover analytical approaches based on continuous data.

44.6.1 Adjustment for Confounding by Energy Intake

The requirement of energy depends on individual factors such as growth in children, body weight, and physical activity. The nutrients that provide energy include fat, carbohydrates, protein, and alcohol. There is high interest on the role of these energy-providing nutrients, particularly of fat, for disease risk. However, the amount of intake of energy and the intake of the energy-providing nutrients is highly correlated, and it is necessary to separate the effect of energy from the effect of the nutrient providing that energy. Further, with increasing energy intake, the proportions of the energy-providing nutrients change. With increasing energy intake, more fat is usually consumed due to its higher-energy content per unit of intake compared to other nutrients. Thus, energy intake is a confounder for the energy-providing nutrients. In respect to disease risk, energy intake itself does not seem to be an important exposure to be studied. Energy intake is a direct consequence of other important lifestyle factors for disease risk such as body weight and physical activity, which should thus be taken into account in the modeling strategy.

For many years, it was believed that calculating nutrient density would protect against the phenomenon of confounding by energy. Nutrient density means that the nutrient content of a food is put in relation to the energy content of a food by dividing units of nutrient by units of energy. However, energy is still indirectly included in the nutrient density term but as denominator. If for any reason energy intake is associated with the disease of interest – e.g., due to inadequate control of energy related risk factors – residual confounding by energy intake remains when using nutrient density. The only protection against this type of bias is the inclusion of energy intake in the statistical model in addition to the nutrient density term.

In 1986, Willett and Stampfer (1986) proposed to overcome the problem of confounding of the energy-providing nutrients through energy by calculating energy-adjusted nutrients and to use this term in the statistical modeling instead of the nutrient itself. Energy-adjusted nutrients were obtained by taking the residuals from a regression of energy to the energy-providing nutrient. The residuals of this regression reflect the amount of the nutrient which is consumed by the individual compared to the average consumed at a specific amount of energy. Energy adjustment by the residual method removes the variation due to energy intake from the variation of the nutrient. As a consequence, the original variance of the nutrient is reduced compared to the variance of the nutrient without considering energy intake. This will affect the observed range of nutrient intake in the study population. This range will be much smaller for energy-adjusted values compared to the original values. Residuals, however, have a mean of zero and contain negative values if individual consumption was less than the average. In order to obtain interpretable energy-adjusted nutrient data, a constant should be added to the residual, usually the mean or median intake.

Kipnis et al. (1993) showed that identical beta-coefficients should be obtained in a logistic regression for a nutrient when a standard model is applied by using energy and nutrient intake in the same regression equation compared to using the energy-adjusted nutrient. A different beta-coefficient for a nutrient is obtained in a logistic regression with a nutrient but without energy adjustment. The beta-coefficient of a nutrient in a logistic model with adjustment for energy reflects the relative risk which is obtained when a nutrient is substituted for "other" nutrients (energy is kept constant) and the beta-coefficient of a nutrient without energy in the model represents the relative risk when a nutrient is added to the diet.

In the measurement error models derived from studies with gold standard measurements such as in the OPEN study, often low correlations between measured and true energy intake were observed (Subar et al. 2003). Thus, without energy adjustment also the nutrient will be affected by this type of measurement error. It is therefore not surprising that in validation studies energy-adjusted dietary exposure variables show better correlations than the original variables (Subar et al. 2001).

Including energy in a regression model results in a model in which the energy is kept constant. Thus, increase or decrease of a dietary variable containing energy (fat, carbohydrates, protein, and alcohol) can only be done at the expense of another dietary variable also containing energy. Having energy in the regression equation with disease risk as outcome would result in investigating an isocaloric situation. Such a design is comparable with isocaloric intervention studies, in which one dietary component is exchanged with another dietary component in energy equivalents. Since the energy variable is in the ideal situation a linear combination of all nutritional variables contributing energy, not all energy-providing variables and energy could be in the regression equation. The variable which is exchanged needs to be left out of the regression equation. It is also of advantage to express each nutrient variable in energy units such as percent energy. The nutrient variable which is usually left out of the regression equation is the variable contributing most of the energy, often the carbohydrates. Isocaloric modeling is also called performing a substitution model. One energy-providing nutrient variable is substituted by another energy-providing nutrient variable in the risk model. Substitution models can also been run with other parameters being held constant. For example, if the overall fat content is held constant, one type of fat such as saturated fat could be substituted by another type of fat such as polyunsaturated fat. Other substitution models can refer to the amount of food. If the overall amount of food is included in a regression model with single foods, change in one food can only been done at the expense of other foods not being in the regression equation but contributing to the overall amount of food.

Some researchers have investigated substitution models for risk of a disease. For example, Daniel et al. (2011) showed that increasing poultry intake does not affect risk of colorectal cancer but decreases the risk if poultry replaces meat. Meat was associated with increased risk in that study.

44.6.2 Linear and Non-Linear Relationships

In their simplest form, statistical models assume and describe a linear relationship when continuous data are used. It is important to be aware of the fact that the models calculate the change in relative risk per unit change of dietary exposure. If the units are small, the relative risk unit will also be small. Thus, it is useful to rescale the original units into meaningful units, based on the level of consumption and feasible changes in consumption in the target population. As a guiding rule, a 10% change in dietary behavior would be considered as reasonable and worthwhile. Thus, for example, a change in fat intake from 100 to 90 g per day would be useful to know, whereas to assess a change in risk from 100 to 10 g per day would not, as this degree of change is hardly ever achievable.

There are many instances in which the assumption of a linear model can be wrong. First hints of such a situation can be obtained by using categories. However, in principle, it would be better to test whether a deviation from the linear model exists. The easiest way to test whether a non-linear relationship exists is the use of power terms for the variable of interest or of the spline technique. Power terms higher than the linear term can be tested for significance. There are several ways to apply the spline technique. The most commonly used method in the dietary field is to model restricted cubic splines. This means that simultaneously linear, quadratic, and cubic terms of the dietary exposure are modeled, and the extreme ends of the distribution are restricted to be linear. In addition, the exposure needs to be divided into sections by the definition of knots (cut-points).

A further technique to investigate non-linear relationships is by using fractional polynomials (Royston and Sauerbrei 2008). In a simulation study, the fractional polynomial technique seems to perform even better than the cubic spline approach to detect non-linear relationships (Binder et al. 2013).

44.7 Organization and Presentation of Data: Implications for Meta-Analyses and Reviews

We distinguish meta-analyses based on literature (MAL) from meta-analyses using pooled data (MAP). MAL is based on aggregated data taken from published studies, while MAP uses the raw data from individual studies and combines (pools) them into one single dataset. Both approaches to summarize the evidence help to understand the role of nutritional exposures for the occurrence of diseases and to plan potential prevention measures (cf. chapter ▸Meta-Analysis in Epidemiology of this handbook). The organization and analysis of published data as quantitative meta-analysis is facilitated by the recent editions of the Stata program (Stata 2013) which has established routines for statistical analysis and graphical presentations of such data. In the recent years, the conduct of meta-analyses in the field of nutritional epidemiology has increased considerably compared to the past. This development is facilitated by the many nutritional epidemiological studies generated from the cohorts established around the beginning of this century. It is important to recognize that a meta-analysis is not necessarily based on a systematic review of all available literature, thus the possibility of bias may still arise.

It is nevertheless often not easy to summarize the evidence by the MAL approach. It was shown that the presentation of results from risk analysis for dietary exposure can be very different. Usually, the researchers present the data in such a way that the main message can be well captured by the readers under the usual space restrictions of journals. We have shown in the previous sections that many ways exist to describe the relation between a dietary exposure and outcome. Depending on the aim of a meta-analysis, the metric of interest has to be chosen. This will determine whether a study is included or not.

A nice example for summarizing the evidence by meta-analysis has been provided by the World Cancer Research Fund (WCRF) in its second report on Food, Nutrition, Physical Activity and the Prevention of Cancer and the subsequent systematic literature reviews (WCRF 2007). Particularly, in the material from the systematic literature reviews published along with the book, several metrics were used to describe the association: (1) by categories (comparing the lowest vs. the highest), (2) by using units of exposure, and (3) by displaying association along the range of exposure from the various studies.

Published data regarding dietary exposure are still liable to gross biases compared to the truth and thus even carefully conducted meta-analyses of nutritional epidemiological studies cannot be directly transformed into quantitative recommendations. Meta-analyses are providing hints regarding the direction of an effect but currently the data are not solid enough for immediate quantitative public health advice.

Pooled analyses have the advantage that the original data can be calibrated and uniform quality criteria can be applied to all studies included. A recent example of this is the analysis of trials of the effects of supplementation with multiple micronutrients compared with iron and folic acid supplementation during pregnancy (Margetts et al. 2009). Having access to the raw data makes it possible to apply the same inclusion and exclusion criteria and to adjust for gestational age in a comparable manner across all studies (Margetts et al. 2009). There are several initiatives to establish large databases with data from nearly all cohort studies, particularly those conducted in the USA and Europe, for pooled analyses. Depending on the degree of quality control and calibration efforts, such joint analyses could provide meaningful quantitative summary estimates in the future.

44.8 Nutritional Epidemiology in Public Health Practice

Here, we discuss the use of nutritional epidemiology methods for descriptive epidemiology and public health nutrition practice rather than research. In particular, we focus on national dietary surveys and the assessment of population intakes with respect to external references because there have been several important changes in methodological approach and terminology in recent years.

44.8.1 Nutrition Surveys: Assessing the Usual Intake of a Population

With the notable exception of the UK, countries that have conducted national surveys investigating dietary intake have generally collected 1 day of intake from participants, usually as a 24-h recall but occasionally as a 1-day record. In the UK, 4–7 days of records have been collected in all national diet and nutrition surveys (recent cycle began in 1986 with adults and has covered all age groups, up to repeating adults in 2002).

The external references (see below) are based on the assumption that usual intake has been assessed in the individuals participating in the survey. If national survey data collected a single day of information from each individual, it will be difficult to compare such data to a reference due to lack of information on the intraindividual variation and wrong conclusions about the prevalence of specific exposures might

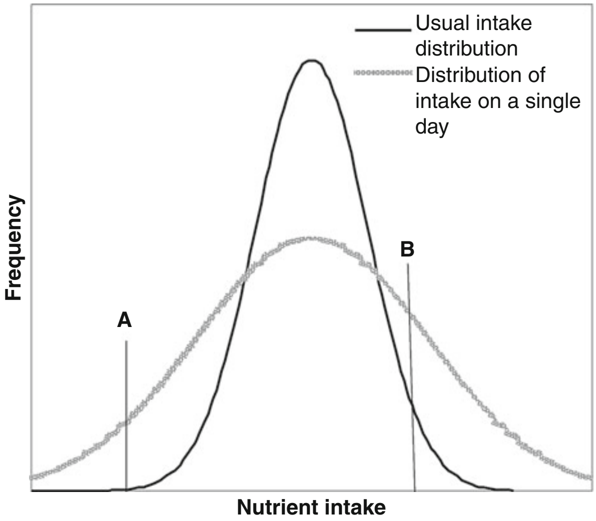

Fig. 44.3 The distribution of the usual intake of individuals has a narrower standard deviation than the intake on a single day. When cut-offs (e.g., *A* or *B*) are based on the assumption that usual intake has been measured, the incorrect prevalence will be obtained if single-day data is used

be drawn. If the aim is, for example, to describe the proportion of the population with low intakes, then using single-day data will overestimate the true prevalence when the population average lies above the cut-off (cut-off A in Fig. 44.3), but will underestimate the true prevalence if the population average lies below the cut-off (cut-off B in Fig. 44.3). Conversely, if the interest is in describing the proportion with high intakes, then single-day data will underestimate and overestimate the true prevalence, respectively. The extent of the error will depend on the location of the cut-off with respect to the population average and also the ratio of the standard deviations of the single day and usual intake distributions. This ratio is lower for those nutrients found in a wide range of foods which are eaten frequently (e.g., macronutrients such as protein) and highest for those nutrients which are found in a small range of foods where the alternatives have different nutrient contents (e.g., the vitamin A content of vegetables varies enormously).

There are two alternative ways of dealing with this problem. One is to take the strategy used in the UK and obtain multiple days of intakes from all participants in a survey. This increases the cost, logistical complexity, and respondent burden. The second way is to obtain an estimate of the ratio of the standard deviations of the two distributions and to correct the distribution obtained from all participants using the ratio (Sempos et al. 1991). As dietary intakes and patterns vary with age and sex, it would be important to do this work for all important subgroups in the population and not to obtain one ratio, for example, in adults that is then applied to all other groups. This method is obviously cheaper. Its main drawback is the fact that the usefulness of the survey data for other purposes is limited.

Table 44.3 Data from other studies showing the range of intakes across fourths or fifths for different ways of expressing nutrient intakes

Author	Fifths				
Nutrient and method	Lowest	2	3	4	5
Willett et al. (1987) – data from 4 one-week diet records in 179 women					
Total fat					
Mean absolute (gram)	47	59	68	75	98

Median absolute (mg)	201	291	362	487	–
Median energy-adjusted (mg)[a]	249	312	357	442	–
Median mg/1,000 kcal	127	144	157	181	–
Fiber					
Median absolute (g)	4.3	6.5	8.2	11.1	–
Median energy-adjusted (g)[a]	4.8	6.7	8.2	10.4	–

[a] Each person's residual has been added to the mean for the population for that nutrient

One-way analysis of variance allowing for random effects and repeated measures can be used to separate the between-person variance (s_b) from the total variance (s_{total}) in the subsample with multiple measures (Mackerras 1998). Then the ratio can be used to adjust each individual's single-day value (x_i) in the main survey relative to the sample mean ($\overline{X}$) (Sempos et al. 1991):

$$\text{adjusted value} = \overline{X} + (x_i - \overline{X})(s_b/s_{total}).$$

Depending on the nutrient, the 10th to 90th centile range of the corrected distribution could be as little as 66% of the 10th to 90th centile range of the uncorrected distribution (cf. Sect. 44.3.3 and Table 44.3). It is important to note that although the corrected population distribution was created by applying a factor to each individual's data point, the resulting values for each individual cannot be interpreted as each individual's true usual intake (Guenther et al. 1997; Murphy 2003). They are only correct on average, and this is sufficient to generate the corrected population distribution. If the usual intake has to be estimated for each individual (for addressing other purposes of the survey), multiple days of intake data must be collected from each individual.

Just as nutrient intake varies from day to day, so does the intake of foods and non-nutrient food components. Given current recommendations to increase intake of foods such as fruit and vegetables, it is important for dietary surveys that collected single-day data are corrected using the same approach for each food. Although there are a number of studies describing the extent of the variability of nutrient intake (e.g., Beaton et al. 1979, 1983; Nelson et al. 1989), there are few reports supplying the same information for food intake (Palaniappan et al. 2003).

44.8.2 Measuring Nutritional Exposures in Specific Groups

The characteristics of the target population and the circumstances in which they live influence the approach that has to be taken in gathering information about nutritional exposures. An approach that works in one community, or sector of society, may not work in another one. People from different cultures have different ways of conceptualizing and expressing what is important for them. For example, people who gather their food from the wild will often have very detailed names for all the edible foods but often have only one name that describes all the other foods that they do not eat.

44.8.3 References for Assessing Dietary Intake in Populations

For many years, “recommended” intakes of nutrients have been promulgated by various national bodies. However, the correct use of these figures has never been very clear. This situation is probably related to the general problem that diagnostic criteria for assessing individuals are often misinterpreted as indicators for population surveillance, or vice versa. A typical use of national dietary surveys is to compare the results to external references such as “recommended intakes.”

It is important to realize that all committees agree that the “recommended” figures they produce are expressed as daily amounts for convenience only. All committees agree that it is long-term diet that is important and that the “recommended” figures should never be compared to a single day of intake for either populations or individuals. As shown in Fig. 44.3, the incorrect prevalence will be found if they are compared to single-day data. The following discussion assumes that usual intake distributions are available for the population.

Until about 10 years ago, most countries have set up only one type of dietary reference figure for each age-sex group for each nutrient. At present, this figure is called the Reference Nutrient Intake (RNI) in the UK, the Population Reference Intake in the European Union, the Recommended Dietary Allowance in the USA and Canada, and the Recommended Dietary Intake in Australia (Department of Health 1991; The Scientific Committee for Food 1993; Food and Nutrition Board 2000; Truswell et al. 1990). We will refer to all of them as the RNI. The RNI is generally set well above the average requirement so that, if everyone ate this amount, there would be a low probability of deficiency in the population. Sometimes, there was enough information to set the RNI at two standard deviations above the Estimated Average Requirement (EAR). Often, the committees just added a large safety margin. As the margin added varied by nutrient, it was not possible to express the RNI as a constant multiple of the underlying average requirement.

The UK was the first country to set multiple values when it revised its dietary references (Department of Health 1991) and specified the location of the EAR in addition to the RNI which is referring to the 97th centile value, not the average. The European Union then followed, naming its equivalent figures Average Requirements (The Scientific Committee for Food 1993) and more recently the USA and Canada have also described the EAR that their recommended dietary allowances were derived from (Food and Nutrition Board 2000).

Advising individuals to have intakes that meet the RNI is sensible because this advice carries a low probability of suggesting inadequate intakes for that person. However, could the RNI be used to assess the adequacy of population intakes? In earlier times when the EAR was not specified, two methods were used quite commonly. They were to determine whether the mean intake is equal to or above the RNI or to determine the proportion falling below the RNI. Neither of these approaches is satisfactory (Beaton 1999).

Because the standard deviation of the population intake distribution is generally much wider than the standard deviation of the requirement distribution (Beaton 1999), many people will appear to have intakes below their requirements when the median population intake lies on the RNI (RNI(a) in Scenario 1, Fig. 44.4). The extent to which this happens depends on how the RNIs were set up in the past. If they were set up by adding a safety margin that was larger than twice the $\text{SD}_{\text{requirement}}$ (SD = standard deviation), then the greater margin will lead to less prevalence of inadequate intake (RNI(b) in Scenario 1, Fig. 44.4). It is true that, if everyone has an intake above the RNI, the prevalence of inadequate intake will be essentially 0 (Scenario 2, Fig. 44.4). However, many people will be consuming much more than their personal requirements, and it is clear that there could be some overlap between the two distributions that is still consistent with a low probability of inadequate intake.

A third approach that has been used in the past is to calculate the proportion of the population with intakes below 70% of the RNI based on the assumption that the requirement distribution had a coefficient of variation of 20%. As this was rarely the case, this approach would overestimate the true prevalence of inadequate intake for some nutrients and underestimate the true prevalence for other nutrients. Consequently, this approach would not necessarily reveal which nutrient is in shortest supply in the population.

So the question is how much overlap there can be between the requirement and intake distributions before the prevalence of inadequate intakes is unacceptably high? A method for multiplying the two probability distributions was described in 1986 (Subcommittee on Criteria for Dietary Evaluation 1986), and the powerful computers of today can do the calculations easily. However, if the requirement distribution is symmetrical and the intake distribution is approximately normal, then a shortcut method can be used: if the intake mean is at least $\text{EAR}+2{*}\text{SD}_{\text{intake}}$

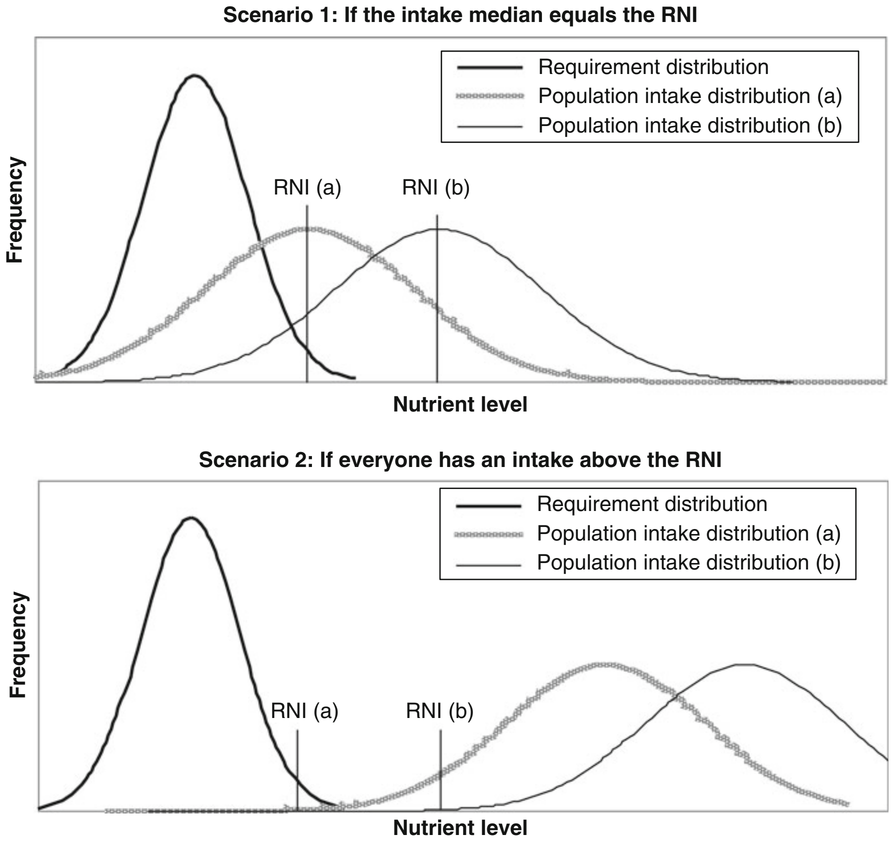

Fig. 44.4 Illustration of how the Reference Nutrient Intake (RNI) has been used in the past to assess population intakes, assuming two different RNIs that had been set in different ways (Adapted from Beaton 1999)

(with 2 being approximately the 97.5% quantile of a standard normal distribution) higher than the EAR, then the prevalence of inadequate intakes will be 2.5% or less (Fig. 44.5). In other words, if the assumptions are met, the proportion below the EAR is the proportion with inadequate intakes, although no definite statements can be made about the individuals with intakes below the EAR. Other multiples of the SD_{intake} could be used if other criteria are desired. Note that the standard deviation in this formula is for the intake distribution, not the requirement distribution, and the reference point is the EAR and not the RNI. The details of this approach and further information on other situations, such as when the requirement distribution is asymmetrical, can be found elsewhere (Subcommittee on Criteria for Dietary Evaluation 1986; Beaton 1999; Food and Nutrition Board 2000).

As a final note, Fig. 44.5 has assumed that intake distributions are normal. If these must be transformed, then care needs to be taken to apply the correction factors appropriately. The above comments about the RNI do not apply to energy, because

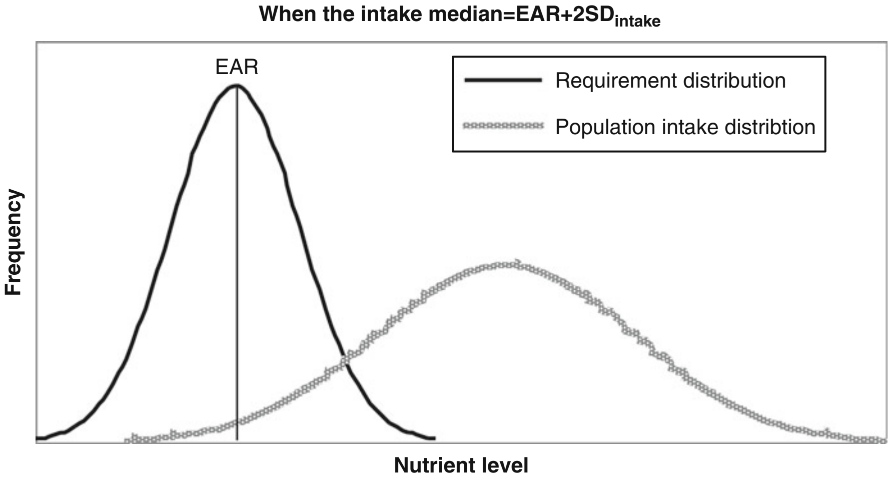

Fig. 44.5 If the mean population intake is 2*SD$_{intake}$ (*SD* = standard deviation) above the Estimated Average Requirement (EAR), then the prevalence of inadequate intakes in the population is 2.5%

the energy recommendations are set at the EAR and not at two SD above the EAR. It is also important to examine how words are used in each country, because the same word may be used to signify different concepts, and to realize that definitions may even vary within a document. Values for the EAR and RNI may vary between countries, either because they have been based on different indicators of nutritional status or on a different selection of literature sources or because they are defined as mg/kg while the mean body weight varies between populations.

44.8.4 Impact of Underreporting of Intake

Because people tend to underreport their intake by most dietary methods (Black et al. 1991), the data collected in a national survey will tend to underestimate total intake. For example, when the criteria of Goldberg et al. (1991) for assessing a 24-h intake were applied to the 1995 Australian survey, 11.9% of men and 20.6% of adult women had energy intakes that were implausible. Compared to the total population surveyed, those with plausible intakes had higher intakes of all nutrients (Table 44.4). Clearly leaving those with implausible intakes in the data can affect the results of the analysis, especially for some of the minerals. Therefore analyses of national surveys that have not excluded these individuals would tend to overestimate the prevalence of low intakes of most nutrients. However, one problem with simply excluding them is that people may underreport some foods differently from others. If energy-containing foods are underreported to a greater extent than low-energy foods such as fruit and vegetables, then excluding the implausible reporters may incorrectly inflate intakes of nutrients such as vitamins A and C and to some extent

Table 44.4 Comparison of median nutrient intakes in the total survey sample and persons with plausible EI/BMR ratios, adults 19 years and older, by sex. 1995 National Nutrition Survey, Australia (ABS & HEALTH 1998)

	Men		Women	
Nutrient	Total	Plausible[a]	Total	Plausible[a]
Energy (kilojoule)	10, 377	10, 997	7, 083	7, 824
Protein (g)	100.1	106.4	69.5	76.3
Total fat (g)	89.8	96.4	61.6	70.3
Dietary fiber (g)	23.8	25.1	18.9	20.5
Vitamin A (ug retinol equivalents)	941	1, 012.9	753.6	833.0
Thiamin (mg)	1.7	1.8	1.2	1.3
Riboflavin (mg)	2.0	2.2	1.6	1.7
Niacin equivalents (mg)	47.1	49.8	32.3	35.1
Folate (mg)	285.3	299.6	216.7	232.6
Vitamin C (mg)	102.9	110.2	85.4	92.2
Calcium (mg)	827.3	891.4	663.1	737.6
Magnesium (mg)	360.3	380.8	266.9	291.1
Iron (mg)	15.2	16.1	11.1	12.2
Zinc (mg)	12.8	13.6	8.7	9.6

[a]Plausible intakes: 24-h intakes with an energy intake/basal metabolic rate ratio of 0.9 or greater are above the lower bound of the 95% confidence interval in a weight-stable individual undertaking light activity (Goldberg et al. 1991)

folate and fiber. A further problem is that equivalent criteria for defining those with implausibly high reports are not available.

44.8.5 Consequences of Within-Person Variability in Other Areas of Public Health Nutrition Practice

As noted above, intraindividual variation in dietary measures is not due to the subjective nature of the measure. The error related to reporting or measurement occurs in addition to the underlying instability of the parameter being measured. Many “objective” measures also vary every time they are measured. Blood pressure is a notable example – it can vary from minute to minute. Even biochemical measures also exhibit within-person variability. Some parameters have a regular variation (e.g., diurnal variation) in addition to random variation. The particular problems with dietary measures occur because the within-person variance is larger, generally much larger, than the between-person variance. However, the observed prevalence can be affected even for parameters where the within-person variance is smaller than the between-person variance. Looker et al. (1990) found that the prevalence of impaired iron status (based on mean corpuscular volume, transferrin saturation, and erythrocyte protoporphyrin) was 10% in a national survey using the single measure data. This was reduced to 4% when corrected for within-person variation.

The within-person variation is why many parameters are measured more than once before a diagnosis and treatment decision can be made in the clinical setting. Irwig et al. (1991) showed that the interpretation of a single measure of cholesterol level in a client depends on knowing the underlying population distribution and that single measures cannot be used to assess whether the client's true underlying average has changed since the previous measurement. These observations can be generalized to other characteristics as well.

Program evaluation is another area where taking a single measure may yield misleading results because of within-person variability and measurement error. People may be eligible to enter a program because their level of a characteristic is below a cut-off. In this case, the mean level of the characteristic in the eligible group will be higher when it is measured again than it was at baseline even if the program has no effect. Similarly, if people are selected because their characteristic is above a cut-off, then the group mean will be lower on the second occasion, even if the program is ineffective. In both cases, the mean value of the second measurement is closer to the mean in the total unselected population than the mean of the first measurement. This effect occurs because of a statistical phenomenon called regression to the mean (Davis 1976; Newell and Simpson 1990; Bland and Altman 1994). If the evaluation uses a randomized control design, then the effects of regression to the mean and other explanations such as seasonal or secular trends occur in both the control and the intervention group. The artefact can thus be avoided by comparing the follow-up level in the intervention group to the follow-up level in the control group instead of comparing the follow-up to the baseline levels in the intervention group only. Because randomized studies are perceived as very complex, it may be tempting to conduct a non-randomized study and using ineligible people (i.e., those whose values did not meet the criterion for eligibility) as a control group, but this will not allow the regression to the mean effect to be detected. Sometimes, a specific subgroup is not selected at the outset, but the total group may be divided up in the analyses and authors may report that those with the most extreme values at baseline benefited most from the intervention. If there is no randomized control arm, this sort of finding is questionable because the results may be simply due to regression to the mean rather than to the intervention (Vickers and Altman 2001).

Whether a national survey provides a useful source of information for studying diet-disease relationships depends on exactly how it is carried out. Even though it may be possible to demonstrate associations, national surveys which assess dietary intake and outcome markers such as blood pressure and hemoglobin levels are cross-sectional surveys, even if the information is collected over a few days. This inevitably limits causal inference. It is not possible to determine the temporal relationship between, e.g., concentration of blood lipids or blood pressure and consumption of fat type or sodium. Sometimes, a population involved in a national survey may be followed up beyond the survey. Even though this converts a cross-sectional survey into a cohort study, the extent of the analysis would depend on the initial measurements obtained. If only a single 24-h recall was obtained, then correlation and regression coefficients will be attenuated (Liu et al. 1978; Sempos et al. 1985) as previously described.

44.9 Conclusions

There are few health outcomes for which nutrition does not play a direct or indirect role in causation and therefore in disease prevention. Worldwide, there is a complex mix of problems of over- and undernutrition, often stratified by education or economic groups (World Health Organisation 2011). Some of these nutrition-related problems are clear and simply require the political will to be dealt with. Others are more complex and the correct way to solve the problem may not be obvious. This is where nutritional epidemiology has to play a critical role. In order to improve and maintain public health, it is important to provide a strong evidence base to guide action. This is particularly the case where there are vested interests that may not want the dietary patterns to change. In order to justify and support such changes, it is essential that the scientific evidence supports policy. The methods of nutritional epidemiology guide that evidence base.

The major concern in nutritional epidemiology is how to define and measure with required accuracy the relevant measure of exposure, free from bias. Because diet and other behaviors are complex and interrelated, it is important, in both the design and interpretation of studies, to understand how this complexity may affect the results of the study. These issues cannot simply be resolved by statistical adjustment, it is essential to have an understanding of the underlying social, psychological, and biological factors.

Because most studies are of limited statistical power, there is a growing tendency to undertake meta-analyses using pooled data. Before data are pooled, it is important to assess whether there are methodological differences between studies. This is more than assessing the heterogeneity using a statistical technique. It is important to investigate whether the differences in dietary assessment methods and ways of presenting data allow such pooling. The range of exposure in the referent category and the way data are subdivided into categories will all affect the prevalence of the exposure and the size of the risk estimate in each study.

Acknowledgments We would like to thank Dorothy Mackerras for her input to the previous chapter on Nutritional Epidemiology of this book. Some sections of this revised text are largely unchanged from the first edition.

45.1 Introduction

45.1.1 Reproductive Epidemiology: Reading Instructions

In writing this chapter, we assumed that the reader is familiar with the basic concepts in epidemiology. Therefore, you will not find any overview of different designs, measure of disease occurrence, standardizations, other ways of adjusting for confounders, or any general discussion on bias, confounding or on measuring effects. If you are not familiar with these topics, you should start by reading other parts of the book or turn to one of the many fine available textbooks.

Our intent is to point out the problems and methods that are of particular interest in reproductive epidemiology, with emphasis on selected topics in this area of research.

We focus upon methodology, and, for the most part, we avoid reporting on any "state-of-the-art" overview on what is known about specific exposures or endpoints. Such reviews are soon outdated and, furthermore, space does not permit them here.

By highlighting some of the aspects that set reproductive epidemiology somewhat apart from other areas of epidemiology, we hope to alert readers to the problems and options that this field presents and to illustrate how important it is to develop a highly critical outlook. Research in reproductive epidemiology, like research in general, is not to prove or confirm anything but rather to question, make critical appraises, and, of course, identify potential causal or preventive factors of reproductive diseases.

We use references to illustrate specific problems of methodological interest. We use more of our own work than could ever be justified on the basis of our modest contribution to the field. Our justification is that these references reflect our source of information for learning about the many problems inherent to reproductive epidemiology. We cannot rule out that they also reflect our inflated egos. Most of the references we have selected present information of methodological relevance. We also provide references to full textbooks in reproductive epidemiology.

We do not in any way claim to provide a complete overview of problems that you should be aware of as a student of reproductive epidemiology. We are not aware of all these problems ourselves: some are yet to be described and some have not yet caught our attention. Even describing all the specific problems that we are aware of would require more space than you, the reader, would like us to have. What we have tried to do is to describe the most important problems as we see them. Our choice is a subjective one, and it reflects our experience and interests.

Reproductive health was defined by the WHO at the Cairo conference in 1994 as

> ... a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity, in all matters relating to the reproductive system and its functions and processes.
>
> Reproductive Health, therefore, implies that people are able to have a satisfying and safe sex life and that they have the capability to reproduce and the freedom to decide if, when, and how often to do so. It also includes sexual health, the purpose of which is the enhancement of life and personal relationships, and not merely counseling and care related to reproductive and sexually transmitted diseases.

We will not cover all the possible topics related to this definition, nor do we intend to provide research methods for studying well-being or even happiness. We will limit our focus to the more traditional domain of epidemiology, namely, to the studies of determinants of diseases directly related to reproduction, as long as these studies can be applied to human populations. Although many diseases will have an effect on procreation through biological, psychological, or social mechanisms, we will restrict ourselves to studies dealing with fecundity, pregnancy, birth, and early markers of child health. Many of the diseases we describe only manifest themselves in the time period of reproduction, such as subfecundity, pre-eclampsia, and, of course, birth outcomes.

We are aware of the hypothesis that many adult chronic diseases may originate in the pre- and perinatal time period. Although we consider this to be one of the most exciting new areas of epidemiology, this aspect will not be dealt with here but in the chapter on ▶Life Course Epidemiology of this handbook.

Our experience mainly stems from research in Europe and the USA, and we do not cover research problems of particular relevance to developing countries. Since reproductive health problems are usually larger in these countries, we are aware that this is a major shortcoming, and our only excuse is our limited experience in this field. We do want to stress, however, that research in developing parts of the world should also be based upon sound methods as the ones we advocate in this chapter. We do not believe in low-quality research anywhere, but we accept that circumstances may set limitations for what can be done.

Many diseases of the reproductive organs, such as cancer or infections, may have an effect on reproduction if the diseases appear before or during reproductive age. In most cases, studying the determinants of these diseases will be similar to studying determinants of other diseases, and, as such, they are not pertinent to the analysis in this chapter.

Our aim is not to provide a cookbook for research in reproductive health but to make readers aware of some of the aspects they should pay attention to. Associations come in many shapes, and they are not always what they pretend to be. “Be careful” is the main (and perhaps the only) message we want to convey, and if you are satisfied with that, you could stop here – if you want to know why you should be careful, please go on reading. We expect you to disagree on several occasions. Remember, you may be right and we may be wrong.

45.1.2 Reproductive Health: Specific Epidemiological Research Problems

Unlike epidemiologists studying cancer and chronic diseases, reproductive epidemiologists deal with an area that has been strongly shaped by evolution. Susceptibility to chronic diseases that do not affect the ability to reproduce would not be selected out in the course of evolution with the same pressure as would susceptibility to conditions that interfere with the ability to reproduce. Selective forces operate before and during pregnancy, even in the highly medicalized industrialized world; keeping this feature in mind when dealing with reproductive epidemiology is important when trying to understand events that occur in pregnancy.

Most epidemiologists deal with identifying determinants of diseases that may operate over time spans of varying length. The induction period may be very short (e.g., is a migraine attack triggered by a given nutritional component?) or may span many years (e.g., does prenatal exposure to smoking affect adult semen quality?) (Ramlau-Hansen et al. 2007). In reproductive health, we study determinants of factors that play a role for successful reproduction. Sometimes this involves studies that span generations, and many studies address couples (or families) rather than individuals. Unlike other fields of epidemiology, the individuals studied in reproductive epidemiology are often not ill in the common meaning of the word. Women who have repeated miscarriages or give birth to dead or severely malformed children are usually healthy themselves, and so are their partners. Women who become severely ill during pregnancy, for instance, with pre-eclampsia, often fully recover after the pregnancy ends, but they have a relatively high risk of experiencing pre-eclampsia again in their next pregnancy (and a somewhat increased risk of developing cardiovascular disease later in life). In general, risk of recurrence is relatively high for most reproductive outcomes. Many reproductive failures have a tendency to repeat themselves, suggesting that at least some of the causes are relatively stable in time.

In many cases, reproductive epidemiology deals with hidden phenomena that may represent serious disorders, which, however, may never come to light if a woman does not become pregnant. Furthermore, many women experience more than one pregnancy in their lifetime so that a pregnancy, rather than an individual, will often be the unit of analysis. All these elements, intrinsic to reproduction, provide interesting design options and challenging methodological problems, and they set reproductive epidemiology somewhat apart from other areas of epidemiology.

In evolutionary terms, successful reproduction means that the parents' genes are transmitted to viable offspring who will, eventually, produce offspring of their own. Part of this process is subject to epidemiological observation. Although the maternal and paternal evolutionary interests are similar as far as gene transmission is concerned, the parents' contributions – and stakes – are different. The mother provides the environment in which the fetus develops and is nourished during pregnancy and, often, also for a period of time after birth (through breastfeeding). A growing body of literature suggests that the intrauterine environment plays an important role for shaping future disease susceptibility in ways we do not fully understand. Fetal growth may not only affect organ size but also organ function in adulthood (Gluckman and Hanson 2005). The role of the uterine environment is therefore of great importance, but it is often difficult to disentangle its effects from those that are genetically mediated by the mother. The interaction between fetal and maternal genes might sometime trigger adverse outcomes, as may be the case for recurrent miscarriages. It should also be kept in mind that pregnancy can be life threatening for the mother: it is estimated that, in Africa, the lifetime risk for a woman to die of pregnancy-related causes is 1 in 16, while, in more developed countries, this figure is 1 in 1,800 or lower (AbouZahr 1998). Situations may thus occur when a pregnancy is interrupted for the sake of the mother's chance of reproducing again. Maternal, paternal, and fetal genes thus have different stakes in any given pregnancy (Haig 1993). Reproductive epidemiology has acquired a powerful tool with the new genetic technologies, and epigenetic changes (changes in gene function that occur without changes in the DNA sequence) in this time period may change gene expression. Epigenetics is a rapidly emerging area of research that may aid in the understanding of the impact of prenatal exposures on later health. These technologies will, hopefully, provide new important clues on the complex events taking place from conception to birth and onwards.

In epidemiological studies, we can generally only obtain data on pregnancies that end in delivery or miscarriage (and usually only on miscarriages of clinically recognized pregnancies, thus missing the early ones). As a consequence, most of the processes leading to events that result in early terminations are hidden or altogether absent from the data we have access to. We thus have to take into consideration what potentials for errors this entails. Access to ultrasound measures will change this in the future.

Especially for women, the time period of reproduction is relatively short and, in most countries, under intensive surveillance. Often, we can only study the causal links that remain after health-care providers have tried to prevent negative outcomes. Data on births are routinely collected in several countries at the national level and following standardized procedures, thus allowing comparisons over time and, in some instances, place. In some countries, data are computerized, facilitating access to researchers. Most countries regularly publish reports that include some indicators of reproductive health.

Reproductive health, at least the part associated with pregnancy and childbirth, covers events that can be frequent and serious, such as infertility, miscarriage, preterm birth, and pre-eclampsia. These are events we would like to prevent rather than treat, and most are willing to recognize that prevention must be based upon good quality research.

Not only do we need to identify determinants of reproductive failures connected to lifestyle, occupation, environment, diet, or medication but also to find out how antenatal care (ANC) can be best organized. Antenatal care is, in many countries, the most expensive part of preventive care within the health-care system, and much more research is still needed, especially in countries where resources are sparse. Much of this documentation has to be time- and place-specific. Evidence on health-care technology cannot just be transferred from one country to another. But many of the findings related to the etiology of given outcomes will apply to most populations.

By making efficient contraceptive methods more widely available, increasing the potential for ending unwanted pregnancies, and, especially, by developing more and more sophisticated methods for treating infertility, we are increasingly interfering with the forces of evolution and, to some extent, also with our ability to study reproductive epidemiology (e.g., how fertility declines with age, or to what extent the causes of infertility, rather than assisted reproductive technology (ART), affect pregnancy outcome). We should make it one of the priorities of reproductive epidemiology to study whether and to what extent ART will affect future generations. Reproduction is, in many ways, a playground for new technologies that are being introduced without much concern for the potential long-term consequences. Children born of ART (including in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI)) are still too young for us to study whether they may suffer any long-term health consequences associated with the mode of their conception, although these individuals are relatively young and we are thus still unable to evaluate properly whether their health has been affected. However, many of the studies that have been performed so far are reassuring. Interventions like ICSI may undermine the very core of the natural selective forces behind reproduction. At present we do not know if ICSI is a safe-assisted reproductive technology (Ludwig and Diedrich 2002), although early reports are reassuring to some extent about ICSI not being associated with more risks than IVF (Hansen et al. 2002; Lie et al. 2005; Steel and Sutcliffe 2009).

In the case of ART, it may turn out that trying to solve health problems for some may introduce health problems for their children. Some of these health problems may never come to the attention of physicians, and the potential consequences of infertility treatment must be brought to light by research. In relation to this and many other technologies, epidemiologists have an important role to play in monitoring disease data over time in the population. Reproductive health should be an important part of any health surveillance system.

It is peculiar to reproduction that, during pregnancy, the mother provides most of the exposures that may influence the future health of the unborn child. The fetus is only partly protected by the placental barrier. Many toxic substances pass this barrier, and the developing fetus will often be less able than the mother to metabolize these substances, especially early in pregnancy. This is, e.g., the case with alcohol, caffeine, and several drugs.

Thus, another peculiar feature of pregnancy is that not just one individual is involved in the process under study but three: the mother, the father (through fetal genes and, possibly, substances carried by semen (Ness and Grainger 2008; Savitz et al. 1994)), and the fetus itself through its continuing interaction with the mother during the pregnancy period. When studying reproductive outcomes, it is thus, in many cases, insufficient to focus only on the mother, although she usually represents the most accessible part.

It is now known that during pregnancy and delivery, there is a two-way traffic of cells between the mother and the fetus and that these cells can persist in the bloodstream for decades (Bianchi et al. 1996). This phenomenon, called "microchimerism," may interfere with the immune system and thus contribute to the etiology of several diseases, especially those of autoimmune origin (Bianchi 2000; Whitacre et al. 1999; Fugazzola et al. 2010). That pregnancy itself, or phenomena related to pregnancy, might have something to do with the etiology of these diseases is suggested by the fact that females are more subject to autoimmune diseases than males, although these differences may also depend on immunological, hormonal, or other factors that are related to sex but not specifically to pregnancy (Whitacre et al. 1999; Whitacre 2001). Changes during pregnancy may have health implications for the mother as well as for the child, and the growing fetus totally depends upon maternal supply of nutrition and oxygen. A growing area of research investigates whether changes in this supply may "reprogram" organ development, with possible long-term health consequences (Barker 1994; Gluckman and Hanson 2005). It is also well known that infections during pregnancy may affect the child. Torch was the acronym given to known fetotoxic agents (T = toxoplasma gondii, r = rubella, c = cytomegalovirus, h = herpes simplex, and o = the unknown agent). If infectious agents, or antibodies to infectious agents, attack the fetal brain, it could lead to neurological or psychiatric diseases that do not become manifest until much later in life.

45.1.3 Pregnancies as Repeated Events

Each pregnancy provides a new set of observations, and, in populations with a high fertility, a woman may be subject to repeated studies of exposures of interest for the outcome of each pregnancy. A pregnancy is a new event that, at the same time, shares many features with the previous pregnancy(ies). Most reproductive failures (such as miscarriages, preterm delivery, and pre-eclampsia) have a tendency to recur, probably because time-stable causes (e.g., genes or part of the maternal environment) are present during all events. However, it is not entirely clear how this aspect should be taken into consideration when analyzing data.

In animal studies, the variance within a litter and between litters is dealt with separately, probably even successfully, in the statistical analysis, but the situation is somewhat different for humans. Human births are usually sequential, except for multifetal pregnancies, which, however, are relatively rare and often not comparable to singleton pregnancies. Methods have been developed to take into account the statistical dependence resulting from women contributing more than one pregnancy (or one baby) (Hoffman et al. 2001; Watier et al. 1997), but these methods may not be able to properly take into account some of the issues specific to multiple pregnancies (Olsen and Andersen 1998). More recently, directed acyclic graphs (DAGs) have been used to illustrate how data from two pregnancies could be analyzed (Howards et al. 2007a; Olsen 2008).

Each new pregnancy has a number of features in common with the previous pregnancy and a number of features that are peculiar to it. In some situations, each new pregnancy is an independent event and should be treated as such, but the contrary argument can be made as well. However, even if the dependency between pregnancies were to be modeled in the analysis, it is not clear whether doing this would produce a different type of bias, because the statistical model will not take selective change in behaviors related to previous pregnancy outcomes into account. Pregnancies are, in many instances, planned as a function of the outcome of a previous pregnancy, and this aspect can hardly be addressed by methods aimed at accounting for the statistical dependency between pregnancies. A miscarriage or a stillbirth may be replaced very shortly with a new pregnancy in order to have the desired child. A surviving child with severe handicaps may delay or stop further childbearing, while parents of a child that dies with the same handicap may attempt a new pregnancy soon. Some women may avoid certain exposures as a result of how previous pregnancy ended. A mother who is a heavy smoker and had a child with a very low birth weight may well give up smoking when she becomes pregnant again, even in situations where smoking was not the only or even the major determinant of the low birth weight. If smoking was not the only cause of low birth weight, she may then become a non-smoking pregnant woman with a high a priori risk of getting a child with a low birth weight. How should this be addressed in the statistical analysis? Or how would we be able to design a proper counterfactual comparison? This type of confounding by the risk that triggers a change in exposure is very difficult to address, and it is a common and often neglected problem. A valid analytical solution may be to study first pregnancies only (Olsen 1994), but this approach is somewhat conservative and leads to loss of information, thus resulting in loss of statistical power. The occurrence of several outcomes changes with parity, in part due to selection (not all women will be able – or want – to have a new pregnancy) and in part, perhaps, due to physiology or changes in the uterine environment brought about by the previous pregnancy(ies). A first pregnancy may modify the uterus in ways that could facilitate the next pregnancy, as suggested by the finding that a long interval between pregnancies is associated with an elevated risk of pre-eclampsia in the next pregnancy (Basso et al. 2001; Skjaerven et al. 2002; Trogstad et al. 2001). Why this is the case is not known, but a pregnancy leads to both physical and endocrine adjustments that may modify risks in a subsequent pregnancy.

When studying the effect of a given determinant on an adverse reproductive outcome, one may be tempted to stratify on (or adjust for) a previous occurrence of that outcome (e.g., miscarriage). Such a temptation should be resisted if the intent is to study etiology, since adjustment for any factor that is caused in part by the exposure under study and is also correlated with the outcome will likely bias the estimate (Weinberg 1993), unless the objective of such a model is predictive and not epidemiological.

The fact that women tend to have more than one pregnancy does not, however, result only in difficulties and traps but provides reproductive epidemiologists with a powerful tool that is unique to this discipline. Many reproductive outcomes tend to recur in different pregnancies of the same woman, and this provides the opportunity to examine whether some putative factors play a role in the etiology of a given event by studying women who had the outcome in question in a pregnancy and estimating whether their recurrence risk changes as a function of a change in a given factor between the two pregnancies (Olsen et al. 1997; Basso 2007). This design, called "the computerized square dance design" (because square dancers continuously change partner) makes it possible to estimate whether the paternal genome plays a role by studying maternal half siblings. It can be applied to pregnancy outcomes as well as disorders occurring in early childhood, such as febrile seizures (Vestergaard et al. 2002). One of the advantages of this approach is that a great deal of confounding is adjusted for by using the woman as her own control. The time between pregnancies may itself play a role in the occurrence of the outcome of interest, and thus the interval between pregnancies may have to be taken into account, especially when studying change of partners, since women who change partner tend to have a much longer interpregnancy interval (Basso et al. 2001; Skjaerven et al. 2002).

45.1.3.1 The Problem of Incomplete Denominators

Ideally, we would like to be able to study the outcome of all conceptions that take place in a given population in a given time period, in order to be able to observe how many end in very early losses, how was the karyotype of the lost fetuses, their sex ratio, etc. Less ideally, we would like to be able to obtain information on all conceptions surviving the first 8 weeks of gestation, because missing them may lead to serious bias in studies examining specific exposures. In many instances, reproductive epidemiologists work with less well-defined cohorts and are thus often the victims of incomplete denominators.

45.1.3.2 Miscarriage

A frequent adverse pregnancy outcome, miscarriage, is to a large extent part of nature's own quality control system (Quenby et al. 2002). Some miscarriages are, however, the result of external exposures and could, in principle, be avoided if their causes were identified. A large number of losses occur in the preclinical phase, before the pregnancy is recognized (Wilcox et al. 1988), while others occur after the pregnancy is recognized. The timing of observation thus becomes of crucial importance and a potential source of bias.

The best approach to study fetal losses would be to start observation before conception (even though a pregnancy can only be recognized after implantation), but this requires access to women who plan their pregnancies and are willing to provide daily urine samples (Wilcox et al. 1988). Pregnancy planners are likely to include more subfecund women (women with a low probability per cycle of conceiving), as women who become pregnant as a result of contraceptive failures have, generally, higher fecundity. Participating women may thus also be at an elevated risk of a number of adverse outcomes, since subfecundity appears to be correlated with several adverse pregnancy outcomes (Henriksen et al. 1997; Draper et al. 1999; Basso and Baird 2003; Basso et al. 2003; Zhu et al. 2006, 2007a). To reduce the proportion of subfecund couples taking part in a study, one could enroll only couples who discontinue contraception in order to have a child or who have been trying for no longer than six cycles. This requires screening of a large number of couples but will lead to a study sample that is likely more representative of the underlying fertility of the population of interest (Baird et al. 1986; Weinberg et al. 1993, 1994a).

Currently, few investigators have attempted to detect pregnancies by using biomarkers (usually hCG, human chorionic gonadotropin). These studies (Wilcox et al. 1988; Bonde et al. 1998a, b) do not tell us how frequent miscarriages really are, but they suggest that at least 30% of conceptions end as miscarriage and that a little more than half of these occur in the preclinical phase.

An exposure that delays miscarriages without increasing their incidence would appear as a risk factor in a study based exclusively upon recognized pregnancies. Such an exposure may move a loss from the preclinical phase to the detectable phase. In contrast, an exposure that advances the time of loss would appear to prevent miscarriages. Such an exposure would produce a low miscarriage rate because miscarriages would tend to occur in the preclinical phase among the exposed. For this reason, the timing of pregnancy diagnosing is important. Women who take a long time to conceive may be more aware of early losses than women who have not waited a long time if the former tend to seek earlier confirmation of pregnancy. This type of bias may be partly responsible for the association between subfecundity and miscarriage (Baird et al. 1993). The use of early pregnancy tests may play a role in analyzing and interpreting data from studies based upon pregnancy planners. Such studies are, however, difficult and expensive to conduct and require a very cooperative study population. If women are recruited at different times during pregnancy, the statistical analysis should account for time of entry to avoid bias (Howards et al. 2007b), especially in circumstances where the exposure may in part determine when women are recruited.

When studying environmental determinants of miscarriage, you may want to exclude the so-called habitual aborters (a term generally applied to women who have miscarried three or more pregnancies). Such women will not provide information related to risk following the exposure (Gladen 1986; Weinberg et al. 1994b). The problem is that these particular women cannot be identified by their history of loss alone and cannot be identified at all if they have no pregnancy history. Stratifying results on pregnancy number can distort associations, since only some of the women with several miscarriages will be habitual aborters. Some miscarriages will be due to chance, while others could be caused by the exposure under study.

45.1.3.3 Measuring Infertility

When we are interested in measuring the biological component of fertility, called fecundity, we are often able to ask pregnant women how long it took them to conceive. Couples who had planned to become pregnant will provide the best-quality information, but difficulties are attached to the fact that “planning” is often not a well-defined concept. Furthermore, some respondents may not have planned a pregnancy but will nonetheless report that the pregnancy was planned when asked. As mentioned before, among planners, there will be a number of subfecund couples, and therefore we should also find a way to study couples who had not planned their pregnancy and those who became pregnant despite using contraception, as their underlying fecundity may differ from that of couples who plan a pregnancy. We would also like to have information on all couples that conceived and had an early pregnancy loss (Jensen et al. 1998) or failed to conceive because they were sterile, and we would also like information on those who gave up trying (Bonde et al. 2006). When studying time to pregnancy in samples of pregnant women, one must be reasonably confident that giving up a pregnancy attempt is completely independent of the putative risk factors under study (Basso et al. 2001), a condition similar to what we encounter when working with censored data in general.

45.1.3.4 Congenital Malformations

Congenital malformations are relatively frequent (2–6%), and they constitute a major cause of infant mortality and morbidity. Having a child with a congenital malformation is also a very stressful event for the involved family, which has led to concerns about the possibility of obtaining comparable information in a case-control study addressing determinants of congenital malformation.

It is now generally accepted that the proportion of congenital malformations at birth is a measure of prevalence. The incidence of congenital malformations is not available for study, given that it requires counting of new events since time of conception. Congenital malformations that occur in utero and end as miscarriages, some as very early miscarriages, are usually not detected. Some exposures may simultaneously increase the incidence of some congenital malformations while at the same time reducing the survival rate of the affected fetuses (or embryos) in utero, thus decreasing the prevalence at birth. Monitoring systems of congenital malformations with no data on miscarriages or terminations due to the diagnosis of a malformation could therefore miss important teratogens and even wrongly conclude that a given factor is protective. Many of the established monitoring systems on possible teratogenic effects of medicines taken during pregnancy are based only on data on prevalence at birth. When dealing with miscarriages and congenital malformations, missing early losses may lead us to biased effects measures. Many of the routine monitoring systems are furthermore of poor quality, partly because only some of the congenital malformations are visible at birth. Some heart defects may, e.g., only produce symptoms – and thus first surface to clinical detection – under extreme physical strain late in life (Knox et al. 1984).

45.1.3.5 Time Matters

If you were a student of mortality, you would know that the question is not *if* people die but *when* they die. Mortality rates (*MR*) reflect this time function, as $1/MR$ is the life expectancy in the same time unit as the rate is measured, given that a number of strong conditions are fulfilled. All estimates of risks come with a time tag. The estimate depends upon the length of time it represents. Time is underlying all occurrence research, even when it is not explicitly mentioned since all events happen in time. If you do not wake up in the morning, it may be because you are dead. You ran out of time.

In reproductive health, time is important from several points of view, not only as the time from exposure to the endpoint of interest. The timing of exposure itself is more important in this area than in most others. Specific windows of vulnerability open and close over the time of gestation; the time of organogenesis and organ development plays a crucial role for congenital malformations and many other outcomes. Not only may malformations of genital organs impair reproduction, but the number of Sertoli cells is at least partly determined in fetal life. Exposures that reduce Sertoli cell production may have implications for sperm production in adult life (Sharpe and Skakkebaek 1993; Wilcox et al. 1995). Organ development is under the influence of hormonal factors that operate at certain time periods. Fetotoxic exposures may have different outcomes as a function of the timing of exposure, and growth-determining factors may only play a role during a time period of rapid fetal growth.

Early losses appear to account for the largest proportion of losses (Wilcox et al. 1988). Although we have very little direct knowledge about the determinants of these early losses, many are likely due to chromosomal abnormalities or other defects. Among clinical losses, there is an excess of congenital abnormalities compared with birth (Shepard et al. 1989). Identifying avoidable losses depends to a great extent on the timing of the exposure which may be difficult to identify, partly because fetal death need not coincide with the expulsion of fetal tissue. Fever could, e.g., appear to be a cause of miscarriage, because fever may be induced by dead fetal tissue. In that case, the association would be from fetal death to fever and not from fever to fetal death (reverse causation). However, Andersen et al. (2002) did not find that routine episodes of fever were associated with miscarriage.

The period at risk for teratogenic actions (usually the second and third months of gestation) is almost over when antenatal care (ANC) begins. All actions taken to reduce, e.g., occupational exposures during pregnancy are usually put into operation too late. Some types of prevention (like the use of folic acid to prevent neural tube defects) need to be started even before the pregnancy is planned. If a given toxicant (such as lead) is stored in the maternal tissue over a long period of time, its mobilization during pregnancy may affect the mother or the embryo many years after the exposure took place (Rothenberg et al. 2002).

It is likely that relevant exposure windows for specific effects are only open during short time periods. Exposure to influenza virus has, e.g., been associated with schizophrenia in the offspring, but only for infections during the second trimester of pregnancy (Mednick et al. 1994). On the other hand, neurotoxic exposures may influence brain development, if they operate at the time of the vulnerable structural changes that take place throughout fetal life and in early childhood (Sun et al. 2009). It is possible that diseases like ADHD (attention deficit and hyperactivity disorder), autism, or Tourette's syndrome have a pre- or perinatal etiology.

The nutritional demand of the fetus is at its maximum in late gestation. Smoking in this period is much more closely associated with low birth weight than smoking early in pregnancy (Royal College of Physicians of London 1977).

The Dutch famine study suggested that the timing of undernutrition during gestation may play an important role for later health outcomes (Susser and Stein 1994). Being exposed to undernutrition in the last trimester was associated with obesity later in life (Ravelli et al. 1976).

Most side effects of drugs taken during pregnancy depend on the timing of drug intake within the gestational period. This is likely true not only for teratogenic effects but also for more subtle outcomes, such as learning disabilities or developmental milestones (Zhu et al. 2009). Drugs are particularly difficult to study as an exposure, because it is difficult to disentangle the effect of the drugs from the effect of the indication for taking the drug in the first place (what is usually termed "confounding by indication") (Olsen et al. 2002). If two or more drugs with the same indication but different active molecules are available and are prescribed to pregnant women independently of the severity of the indication, this may provide useful options for better characterizing the effects related to one specific drug.

The fetal alcohol syndrome (FAS) is characterized by specific facial characteristics, low birth weight, and cognitive impairment. It is likely that these impairments are the result of time-specific exposures and, if so, binge drinking may be of concern (Sun et al. 2009), even binge drinking among low or moderate alcohol drinkers. Still, no studies in humans have shown that binge drinking alone causes cognitive impairments or any other important FAS characteristics, perhaps because all studies have been too small. However, binge drinking has been associated with an increased risk of cleft defects in a recent study (DeRoo et al. 2008). If the exposure window for binge drinking is short, then only a small fraction of binge drinkers will be at risk at any given time, and small studies will thus have limited power to detect an effect. FAS is seen in children of some women, who drink large amounts of alcohol every day. A high daily intake leads to exposure during the time periods of vulnerability, regardless of their duration.

Exposure to mercury, determined on the basis of amounts found in umbilical cord blood at birth, has been associated with impaired cognitive functions (Grandjean et al. 1997). Measurement of mercury in cord blood reflects an average exposure throughout gestation, and, as such, it does not indicate whether certain time periods are more vulnerable than others.

Hormonal factors play a profound role in fetal life. Sexual hormones are, e.g., needed for a fetus to develop a male phenotype. It is furthermore believed that hormonal factors influence the probability of developing some diseases in adult life. For example, it has been suggested that a high intrauterine estrogen level may modify breast cancer risk (Trichopoulos 1990) and reduce the number of Sertoli cells (Sharpe and Skakkebaek 1993), thus resulting in an increased risk of undescended testis, hypospadia and testis cancer, as well as reduced semen production in adulthood. This latter hypothesis is, however, not corroborated by epidemiological findings in general, and it probably has to be modified to fit existing data (Strohsnitter et al. 2001; Storgaard et al. 2006). There is, on the other hand, clear evidence of an association between some of the above diseases. Patients with testis cancer have a higher frequency of undescended testis and apparently a lower fecundity before the cancer is diagnosed (Jacobsen et al. 2000). Macro-epidemiological (ecological) studies furthermore show that the geographical variation in, e.g., testis cancer is often followed by similar geographical variations in low sperm count and a high prevalence of malformations of the male genitalia. The link between testicular cancer and undescended testis is relatively well established, although most studies have been based upon self-report of undescended testis, often reported retrospectively. In many instances, undescended testis descend spontaneously shortly after birth or at puberty. More recent studies based upon recording at birth show a weaker association between testis cancer and undescended testis than that reported in studies based on recall (Stang et al. 2001; Sabroe and Olsen 1998; Trabert et al. 2013). It is possible that only persistent undescended testis correlate with the risk of testicular cancer. It is unclear whether descent through treatment eliminates the risk or whether the risk is caused by the underlying reasons of the displacement itself. If the risk is a function of underlying hormonal disturbances at the time period of organogenesis, treatment is not expected to affect cancer risk.

Single peak exposures to drugs are seen in pregnant women who try to commit suicide by taking an overdose of medicine. In principle, these studies provide unique data for studying the fetotoxic effects of these drugs, since they often bypass confounding by indication (unless the study concerns anti-depressant drugs). Many of these studies, however, have not taken abortions (induced or spontaneous) into consideration and have often been too small to detect teratogenic effects, since such studies must focus upon suicide attempts in specific and short time periods. Furthermore, many women terminate their pregnancy after a suicide attempt because of fear of a fetotoxic effect or because of their inability to cope with a pregnancy. Newborn children available for this type of study are thus few and selected. Most of the findings from these studies have been reassuring, indicating that healthy babies are often born after a single exposure to a high dose of a specific drug (Flint et al. 2002).

Although it is generally accepted that timing of exposure is of crucial importance for most outcomes of pregnancy, many studies rely on information where the timing of exposure is not specified. Many studies make use of retrospective data from pregnancies and exposures that are difficult to recall, as they have taken place years before reporting. Large cohort studies have been started or are being planned in order to provide researchers with prospective data on exposures (Olsen et al. 2001; Birthcohorts.net 2011).

45.2 The Case-Parent Triad Design

There are several design options for studying genetic risk factors. Many of these are described in chapters ▸Modern Epidemiological Study Designs and ▸Statistical Methods in Genetic Epidemiology of this handbook. One of these designs is, however, of particular interest in reproductive epidemiology, namely, the case-parent triad design. The idea is to use parents of affected children to serve as genetic controls. The maternal genome can be very relevant to early outcomes, such as birth defects, and case-control designs that do not study the mother may result in the discovery of apparent genetic effects in the offspring that are really just confounded with maternal genetic effects. Case-control studies may also be confounded by genetic factors when they are applied to populations with a mixture of different ethnic groups. The parents are by definition ethnically matched to the case, and they are furthermore usually motivated to take part in the study. The two non-transmitted parental alleles can be compared to the two transmitted alleles, and since this Mendelian transmission occurs at random, the observed allele structure can be compared with the expected values. If the parents, e.g., both have the allele structure Aa, the children will under Mendelian transmission be AA, Aa, Aa, or aa with equal probabilities, 25% probability of AA and aa, respectively, and 50% of Aa. If cases with such parents differ from this, it may be because these genes are causally linked in the disease.

If the genotype is associated with the disease under study, affected children will have an allele distribution that deviates from expected values according to Mendelian principles. All this may be analyzed using well-known log-linear models (Weinberg et al. 1998). The main limitation in using this design for diseases with an adult onset is that the assumption of non-selective survival of the parents to the time of the study is strong, at least for severe diseases. For diseases with an early onset, the assumption will usually be fulfilled. Using this design to, e.g., study genetic causes of congenital malformations is an attractive option. The parents will be available, motivated, and present in a setting where a saliva or blood sample can easily be taken at any time.

45.3 Infertility and Subfecundity

45.3.1 Measures Used to Describe Fertility

Fertility refers to the reproductive capacity of an individual, although there may be differences in meaning, as explained later in this section, depending on whether the term is used in demography or in clinical settings. The fertility rate is defined as the number of live births a woman has during her reproductive life. A fertility rate of 1.3 means that in a population of 100 women, there will be, on average, 130 liveborn children – not enough to replace their parents if migration in and out of the country is in balance at all age groups. A fertility rate of more than 2.0 usually is needed to keep the population in a steady state (as slightly fewer females than males are born and some will die before they reach the age of reproduction). How much more depends upon the life expectancy and the sex ratio of the newborn children in the population, which generally varies slightly but can be severely altered in countries where a strong preference for a specific sex exists. On average, a woman should produce one girl who survives until the end of her reproduction age in order to keep the population in a steady state, if life expectancy is stable over time.

Fertility is determined by both a biological capacity to reproduce (fecundity) and the desire for a given family size, which is under the influence of social and cultural conditions, broadly defined. Available methods for family planning play, of course, a crucial role and, in many ways, interfere with the epidemiologists' ability to study fertility, as many couples plan their reproduction as a function of many factors, including their professional ambitions and their past reproductive history.

Fertility is a term used by demographers to describe the actual production of live children, whereas infertility is used by the medical profession to describe a reduced biological capacity to reproduce. This dual use of the same terminology is confusing.

We suggest that the term fecundity be used to describe the biological capacity to reproduce and fecundability (the probability of conceiving within a given menstrual cycle) to be a quantitative estimate of fecundity. Unlike Cramer and Goldman (1994), we propose to let the more specific details of the terms be defined in the actual study, in order not to have too many words describing rather similar conditions. Reproduction, at least historically, requires sexual contact, fertilization, implantation, and survival to birth and beyond. Now alternative methods exist.

Most studies use a recognized pregnancy (or birth) as the endpoint, and recognition of pregnancy usually depends upon clinical or biochemical measures. Fecundity could, therefore, depending on the specific study, describe the ability to obtain a biochemically detectable pregnancy (by means of hCG), a clinically recognized pregnancy, or a pregnancy that led to a liveborn child. Fecundity can thus be used to describe the capacity to achieve any of these endpoints, which may be confusing. On the other hand, having a specific term for each of these situations would complicate communication to an even larger extent. We will use the term fecundity to refer to a variety of situations.

Childlessness can be voluntary or involuntary, and the latter may be subject to epidemiological research. Subfecundity (i.e., taking a long time to conceive while having unprotected sexual intercourse) is a frequent problem, and treatment for subfecundity is a rapidly growing sector of many health-care systems. Research that can potentially lead to prevention of subfecundity is therefore receiving increasing attention, and epidemiology plays an important role in this research. Subfecundity is a measure for a couple, defined on the basis of unsuccessful attempts for a given length of time (often set at 6, 12, or 24 months). In many industrialized countries, about 15% of all couples that at least try to become pregnant will experience subfecundity, if this is defined as a waiting time of 12 months or more (Juul et al. 1999). The term infertility usually describes an unsuccessful waiting time of 12 or 24 months. Often the cut-point of 12 months is used in affluent societies and 24 months in countries with limited health-care resources because the term provides access to treatment in some countries.

Sterility is defined as an absent capacity to reproduce – a fecundability of 0. Since most couples' probability of conceiving is very rarely 0, many women will eventually become pregnant if they keep trying. Some of the women who become pregnant after infertility treatment would have become pregnant without receiving the treatment.

Time to Pregnancy (TTP) If a normal fecundability is 0.25, then 3% of couples with normal fecundity will not succeed within 12 months of trying ($(1\text{–}0.25)^{12}$) just because of bad luck. These couples need no treatment but may (and some will) be treated nonetheless, usually with an "excellent prognosis" (25% success rate for each cycle). The remaining 12% who had a TTP of 12 months or more are the proper candidates for treatment. If all couples who wait unsuccessfully for 12 months or more to become pregnant receive treatment, then any treatment will to some degree be successful. Some couples will have normal fecundity, and some will have subnormal fecundity without being sterile. An effective treatment has to demonstrate better performance than chance alone would produce. This is not always easy to measure, as many treatments involve transfer of more than 1 embryo, which will result in higher chances of a live birth than if only one embryo was implanted.

If a couple is defined as subfecund after an unsuccessful waiting time of 24 months, then only about 0.1% of "normal" couples will meet the definition, and those targeted for treatment will include 99.9% of actually subfecund (and sterile) couples. For this reason, less affluent societies do not start infertility treatment until couples have tried for at least 24 months.

Since fecundability is related to the duration of a waiting time to pregnancy (TTP), TTP is a frequently used measure in subfecundity research. The measure was first used by demographers when they examined the time from marriage to the first liveborn child; in this context, TTP is a measure that only has biological relevance in societies where procreation starts with marriage and contraception is not practiced in that time period.

In societies with a higher degree of family planning, TTP (now defined as the number of cycles – often approximated by months – that elapse from the time a couple first starts trying to when they actually conceive a clinically recognized pregnancy) becomes a useful tool in the study of determinants of subfecundity. It has been used in epidemiology since the early 1980s (Rachootin and Olsen 1982, 1983; Olsen et al. 1983; Baird et al. 1986). It appears that women are able to recall with sufficient accuracy how long they took to conceive, even after several years (Joffe et al. 1993, 1995), although there are also indications that accuracy of recall may not be very good (Cooney et al. 2009). Time to pregnancy is easy to use and, perhaps for this very reason, has undoubtedly been used too frequently without proper concern for its shortcomings and pitfalls, which have been described in detail (Baird et al. 1986; Weinberg et al. 1993, 1994a; Basso et al. 2000a; Olsen and Rachootin 2003). When comparing TTP values in different populations, you should take into consideration frequency of sexual intercourse, the desired family size, and the persistence in trying to become pregnant at least for some time. And, as always, you have to take into account the potential confounders of the association of interest.

45.3.2 Design Options in Studies of TTP

The best option to study fecundity would be to follow women from when they first become sexually active, recording contraceptive use, intercourse, pregnancy, etc. However, this is hardly feasible. The next best option is to study TTP in a longitudinal design that starts when couples stop using contraception in order to conceive (starting time). Exposures of interest can then be recorded at the relevant point in time (and independently of the length of TTP). Generally, the starting time (when couples start trying to conceive) is the time when exposures should be recorded, although if prior information on exposures exists, that can be used. Exposures should also be registered for attempts that do not lead to a pregnancy. Studies that rely on exposures recorded at the time of pregnancy rather than the starting time may produce biased results, especially for exposures suspected to cause infertility. For example, if smokers stop smoking after having tried in vain to become pregnant for a certain time period, but they do not quit if they conceive quickly, smoking recorded at the time of conception will correlate with a short waiting time, as if smoking prevented subfecundity. In fact, abundant evidence points towards the opposite assessment: smoking impairs fecundity, at least in women (Rachootin and Olsen 1983; Baird and Wilcox 1985; Bolumar et al. 1996; Alderete et al. 1995). However, other sources of bias may contribute to exaggerating the effect of smoking or other exposures on fecundability. Studies restricted to couples who plan their pregnancy, as they can more reliably report a time to pregnancy, do not include couples with unplanned pregnancies. If an exposure is associated with a higher risk of having an unplanned pregnancy, the most fertile among the exposed will enter the study when they start planning, while those who have conceived by accident (usually the more fertile) will be excluded. This way, the effect of an exposure may be exaggerated in studies restricted to planners (Weinberg et al. 1994a).

The proportion of couples that become pregnant during the first cycle is an estimate of the fecundability rate in the population. The entire TTP distribution will, however, normally be used in the analysis, e.g., in a discrete Cox model. Such a study need not last 12 or 24 months. Even a study with a follow-up time of only one cycle could provide evidence that some exposures have an effect on fecundability. If the estimated effect is a 20% decrease in fecundability, we would expect 30 out of 100 non-exposed women to be pregnant within the first cycle versus 24 out of 100 exposed women. Such a study of pregnancy planners is straightforward to design and to analyze but extremely difficult and expensive to carry out, unless it is based upon couples that are seeking treatment for infertility, like IVF patients (Olsen et al. 2005). Results from infertility patients are, however, hampered by limited generalizability to the population at large, in part because the couples are highly selected, in part because spermatozoa, eggs, and embryos are selected by health personnel according to criteria that may be quite different from those of "natural" selection. A longitudinal study on pregnancy planners may also provide other related endpoints, such as information on early losses or semen quality.

Epidemiologists have looked for less expensive designs than the concurrent follow-up of pregnancy planners. These designs have mainly been population-based cross-sectional studies or designs based upon samples of pregnant women, both of which are prone to a number of problems, although they are less expensive and easier to carry out.

Cross-sectional surveys rest upon the assumption that women recall their TTP with some accuracy, even a long time after the event. In a survey, the selected women will try to record attempts to become pregnant, exposures of relevance – often from the same time period – infertility treatment, and TTP (or time waited in unsuccessful pregnancy attempts). Population studies of this type are relatively inexpensive, and they usually rest on random sampling principles. The main problem is inaccurate recall, especially of exposures at the relevant point in time (the starting time), and the ability to obtain response rates that do not introduce selection bias. Analyzing data may be simple, although TTPs usually have to be recorded in rather broad categories, often referring to months rather than to cycles. Women may be able to recall if they had to wait for at least 6, 12, or more months to become pregnant, but usually they will not be able to remember if they became pregnant after 5, 6, or 7 months of waiting time, when the relevant event took place several years before (although women will probably remember if they became pregnant in the first month of trying). Digit preference also has to be taken into consideration, as clusters of reporting will be seen at specific waiting times (such as 6 or 12 months).

Using pregnant women in data collections has, for obvious reasons, been a convenient design. In most countries, pregnant women are easy to locate and to contact. They are usually more willing to take part in studies than other women, and they are generally able to accurately report their TTP if the pregnancy was planned. Women usually remember when they started planning a pregnancy, and may be able to recall the exposures around the starting time, at least if the planning did not start too long ago. The way questions about planning a pregnancy are asked is important, because the notion of having planned a pregnancy is open to interpretation, and its desirability may increase once a woman is pregnant. The question should be as specific as possible and at the same time formulated in such a manner as to elicit the most honest response.

Since pregnancy is a condition for participation in this type of study, this design will result in the exclusion of sterile couples and is thus unable to reveal an all-or-none exposure effect (i.e., an exposure that either causes sterility or does not delay conception). However, most exposures that we know of are not of this type, and the exposures that reduce fecundability will show a longer TTP in a pregnancy-based study. The qualitative effect measure that comes from a study of this kind is, however, not a measure of fecundability in itself (Olsen and Andersen 1999), although it will correlate with fecundability under a number of conditions. The most important, and often neglected, of these conditions is the persistency in trying to become pregnant. This persistency should not be related to the exposure under study, because, if so, the exposure may falsely appear to increase fecundity (Basso et al. 2000b). The timing when diagnosing a pregnancy also plays a role. If couples wait very long to have a pregnancy verified, then an early loss may count as waiting time. Had women used a sensitive pregnancy test early, the event would have been recognized as a TTP of a given length followed by an early loss. The length of the waiting time may influence the timing of detection, thus potentially producing bias (Baird et al. 1993).

Exposures that cause irregular or long cycles may also interfere with the timing of pregnancy recognition as well as with the woman's ability to report the starting time and the waiting time to pregnancy.

The use of family planning methods should be taken into consideration. Couples who use unsafe contraceptive methods without getting pregnant will, over time, include an increasing fraction of couples with a low fecundability. Couples who know how to time sexual intercourse around the time of ovulation have shorter waiting times than other couples, all other factors being equal. Couples who, in the past, have experienced subfecundity may have since modified their exposures or sexual behavior in a way that may impair our ability to find a proper reference group.

Starr and Levine (1983) have suggested the calculation of a standardized fertility ratio. The underlying idea is to compare the observed fertility measured by liveborn children with the expected fertility for couples of the same age and from the same region. Such a standardized fertility ratio can then be calculated before and after an exposure of interest. If the exposure impairs fecundity, the standardized fertility ratio after the exposure divided by the standardized fertility ratio before the exposure would be less than one, other things being equal. The observed number of liveborn babies before exposure may be close to expected values based upon age and calendar time-specific rates in the population at large, but the exposure may then reduce this observed/expected ratio. Although this method was able to detect the fecundity-reducing effect of dibromochloropropane (DBCP) (Levine et al. 1981), it rests upon strong assumptions, and it only works when examining exposures that have a specific (and known) starting point in time.

In addition to the sources of bias mentioned here, there are numerous other sources of bias in time to pregnancy studies (Weinberg et al. 1994a; Weinberg and Wilcox 2008; Baird et al. 1994). It is not an easy task to develop a monitoring design sensitive enough to pick up subtle changes in fecundity over time (Olsen and Rachootin 2003), which is unfortunate. We would like to detect changes in fecundity that may correlate with widespread environmental pollutants, such as perfluorinated compounds (PFCs), which may be associated with decreased fecundity (Fei et al. 2009).

Only about half or less of those who experience infertility seek medical help (Olsen et al. 1998a, b), making patients of infertility clinics a selected sample of infertile couples. The factors that determine which couples seek treatment should therefore be considered when using infertility patients in epidemiological studies.

If the forces of selection are correlated with the exposure under study, then a case-control study with cases defined by treatment is not a valid option for an analytical study. We expect these forces of selection to treatment to be related to several factors, such as cultural background of the population, age, parity, education, social status, and availability of treatment facilities. Some of these conditions may well correlate with lifestyle factors, dietary factors, infections, or other putative causes of subfecundity.

Given these conditions, the source population has to be defined by the case series. The source population could be defined by all those who would come to the treatment center if they had a similar infertility problem as our cases had in the time period of study. The source population is then defined by all potential cases (and, of course, by the enrolled cases as well). Had we known the source population, we could have sampled controls from this group at the time the cases came to be detected. Candidates for controls selection would then be couples who have planned a pregnancy and would be cases if they had a waiting time of 12 months or longer. We could then compare exposures at starting time, or before, and estimate the relative risk of being infertile as a function of the exposures under study. The problem in this design is that we do not know the source population and it may be impossible, even in principle, to identify it along with its exposure experience. A viable option may be to take advantage of the fact that infertility is a couple phenomenon. Infertility is sometimes caused by exposures that affect females, sometimes males, and sometimes both males and females. If we take an interest in exposures to prenatal tobacco smoking as a cause of "male infertility," for example, we may then compare the frequency of this exposure for males in couples that had a male problem (e.g., poor sperm quality) with the exposure frequency in males from couples where the female was identified as having the problem. Both sets of couples sought help and therefore belong to the source population. Since couples where both members have a fecundity problem belong to both the case and the control group, they do not provide useful information for the question under study and can be excluded. The potential problem in this design is that, often, both individuals in a couple seeking help for infertility have low fecundability, even if a specific problem is only identified in one member of the couple. Also, it is not guaranteed that all possible causes of infertility are investigated in both partners, as several may be present.

Alternative design options for monitoring fecundity have been proposed like using dizygotic twinning rates as a surrogate for fecundity (Tong et al. 1997), but one of the problems is to exclude twins that are a result of infertility treatment.

Studies on semen quality may also be used as a surrogate measure of fecundity. Much of the concern for a declining fecundity stems from studies on semen (Carlsen et al. 1992), although the quality of these comparisons over time of semen studies is questionable at best.

The main problems related to using measures of semen quality in epidemiological studies stem from low participation rates and difficulties with obtaining comparable conditions in the analyses. Several factors have to be taken into account: time since last ejaculation, the conditions related to the ejaculation itself, the time from ejaculation to analysis, the technical conditions for the analysis, the season of sampling (as sperm counts are higher in winter than summer periods in temperate climates), and all other potential confounders. Specific diseases may interfere with sperm production, together with external exposures.

45.4 Twins

Dizygotic twins have been seen for a long time as an indication of high fecundity, given that they require two eggs to be fertilized by two spermatozoa within a short time period. However, only recently have studies shown a direct link between time to pregnancy and twinning (Basso et al. 2004a; Ferrari et al. 2007; Zhu et al. 2007b). The rate of dizygotic twins varies geographically and by ethnicity, and mother's height and body mass index may have an influence (Basso et al. 2004b; Reddy et al. 2005). The "natural" incidence in Caucasian populations is about 1 in 80 births. Monozygotic twin rates are, on the other hand, more stable. For a time, a decline in dizygotic twins in several countries was, by some, interpreted as a decline in fecundity across several populations (James 1982, 1986), although the mechanisms responsible for such putative decline have not been firmly identified, and twinning rates started increasing again. Whether this increase is only the result of an increasing use of Clomid and IVF or whether the natural twinning rate also increased is difficult to determine, as birth records rarely reflect whether a birth was secondary to IVF or Clomid.

Twinning is associated with a higher risk of perinatal morbidity, including congenital malformations, and an increasing number of countries with health care providing IVF cycles to infertile couples are recommending single embryo transfer, to avoid increasing the rate of twinning.

Twins provide a very interesting source of data concerning the nature-nurture discussion in disease occurrence. Twin studies have been the basis for studies that tried to disentangle the effects of genes and those of the environment.

Genetic disorders are expected to have higher correlation (concordance) in monozygotic (MZ) twins than in dizygotic (DZ) twins. MZ twins are genetically identical (although some minor genetic differences have been found to exist and have even been used to identify a genetic cause of a congenital malfunction (Kondo et al. 2002)), and DZ twins share genes like ordinary sisters/brothers. Unlike ordinary siblings, however, DZ twins share the same uterine environment as well as very similar conditions in early childhood. These factors considerably reduce the confounding that would arise by comparing ordinary siblings. Although the twin model is definitely of interest, the design does not allow the quantification of heritability, as was previously believed. MZ twins have the same gene map but need not have the same functional genetic expression. Since females are mosaics where a random X chromosome is inactivated in each cell line, female twins are not functionally genetically identical. Epigenetic characteristics and genetic imprinting may differ between MZ twins (boys and girls). Furthermore, MZ twins' intrauterine conditions may differ, in terms of chorionicity or transfusion syndrome, for example, which results in often large variation in size between babies in a pair. Finally, both twins have to survive to be part of a twin study, and twin mortality is higher than in singletons, most likely from the time of conception, thus resulting in selected pairs of twins being born. It is well documented that a number of pregnancies start as twins, but both fetuses do not always survive, and it has been suggested that the surviving twin is at increased risk of cerebral palsy (Pharoah and Adi 2000).

Because twins are relatively rare and differ from singletons in terms of birth weight, gestational age at birth, mortality, and morbidity risks, they are often not included in epidemiological studies on potential fetotoxic hazards.

Twin pregnancies have been used as a model to study the effect of hormone exposure during pregnancy. The estrogen level is high in twin pregnancies, and twins of different sex also offer unique intrauterine exposure conditions (Storgaard et al. 2002). One can use opposite sex DZ twins to study differences in sex hormone exposures during prenatal life. It is, for example, believed that DZ females that have a twin brother have been exposed prenatally to a higher testosterone level than DZ females that had a twin sister, and some believe that this may affect their fertility (Lummaa et al. 2007), although some evidence suggests no differences (Christensen et al. 1998). It has also been suggested that a high intrauterine exposure to testosterone may increase the risk of autism in childhood (McClure 2003).

45.5 Measuring Adverse Reproductive Outcomes

Estimating the frequency of adverse reproductive outcomes is, in several ways, similar to estimating the frequency of any other disease. Frequencies are measured by means of rates or proportions (and many proportions are, unfortunately, called rates). Incidence measures new events over time, while prevalence describes an existing state at a given point in time.

Rates are used to present reproductive failures as a function of time, e.g., the incidence of cervical cancer in Danish women in 1997 was 11.42 per 100,000 person-years. The cumulative risk is estimated by the proportion of people who contract a specified illness over a given time span. Estimation can be made directly in a population where follow-up is complete: for example, the cumulative risk of stillbirth can be estimated if a sufficiently large number of pregnant women are followed from their 24th week of gestation until they give birth (if 24 weeks is the threshold used to distinguish between miscarriages and fetal deaths). Rates describe occurrence of events per time unit, like new respiratory syncytial virus (RSV) cases per 1,000 observation months in children less than 1 year in a given region and a given time period. Rates thus estimate disease occurrence in populations. Risks indicate estimates of the probability of a given event in a given time period for an average member of the population in question. In a population with complete follow-up, the risk of, e.g., second-trimester miscarriage in 500 pregnant women who are followed until the start of the third trimester would be estimated as 0.02 if 10 of the 500 women experience a miscarriage in these 3 months.

Incidence rates and cumulative risks are based upon data from a population at risk, that is, the population at risk of getting the disease (which excludes individuals who already have the disease when follow-up starts). Time is generally included in the measure. Prevalence proportions are estimated as the number of people with the disease in question at a given point in time divided by all in the population at that time, regardless of their disease status. If 500 women are pregnant in a population of 50,000, the pregnancy prevalence proportion is 0.01 (500/50,000). Since prevalence (P) is a function of incidence (I) and duration (D), the incidence of new pregnancies in a population in steady state would be 500/8, if the average duration of a pregnancy is set at 8 months (to take miscarriages into consideration), that is, 62.5 pregnant women per month in the population of 50,000, or 750 per year.

Measuring adverse outcomes during pregnancy is often complicated by the fact that the exact time of conception is generally unknown. When the pregnancy is planned, the time from when a pregnancy is planned to a recognized pregnancy will be measured with reasonable accuracy. Estimating the rate of miscarriage requires registration of time from conception to the fetal loss in question or to the gestational week at which a fetal loss is defined as a stillbirth. At best, the time of conception may be identified by means of biochemical measures at a very early stage, but, in most cases, a diagnosis of pregnancy is not established until 3 to 4 weeks after conception at the earliest, and then it is retrospectively estimated by means of last menstrual period data (LMP) or – later – by using growth measures based upon ultrasound examination. Observation time for calculating rates of miscarriages, therefore, often starts at different time periods in gestation, and we have to take this delayed entry into consideration in order to obtain meaningful results when we try to, e.g., identify determinants of miscarriage (Baird et al. 1993).

45.5.1 The Measures Used to Describe Mortality

The World Health Organization (WHO) defines live births, fetal deaths, and induced abortions in the following way:

The definition of a *live birth* is the complete expulsion or extraction from the mother of a product of human conception, irrespective of the duration of pregnancy which, after such expulsion or extraction, breathes or shows any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles whether or not the umbilical cord has been cut or the placenta is attached.

Fetal death is defined as death prior to the complete expulsion or extraction from the mother of a product of human conception, fetus and placenta, irrespective of the duration of pregnancy: the death is indicated by the fact that, after such expulsion or extraction, the fetus does not breathe or show any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions; respiration is to be distinguished from fleeting respiratory efforts or gasps.

This definition excludes induced terminations of pregnancy.

Induced termination of pregnancy is defined as the purposeful interruption of an intrauterine pregnancy with the intention other than to produce a liveborn infant and which does not result in a live birth. This definition excludes management of prolonged retention of products of conception following fetal death.

Induced Termination of Pregnancy Rate (Conceptions). This measure uses live births, induced terminations of pregnancy, and fetal deaths in the denominator.

$$\begin{array}{l}\text{Induced termination}\\ \text{of pregnancy rate}\\ \text{(conceptions)}\end{array} = \frac{\begin{array}{l}\text{Number of induced terminations occurring during}\\ \text{a specific time period}\end{array}}{\begin{array}{l}\text{Number of induced terminations} + \text{live births} + \text{reported}\\ \text{fetal deaths during the same time period}\end{array}} * 1{,}000$$

Induced Termination of Pregnancy Rate (Population). This is the probability that women of reproductive age will have an induced termination of pregnancy within a given time period.

$$\begin{array}{l}\text{Induced termination}\\ \text{of pregnancy rate}\\ \text{(population)}\end{array} = \frac{\begin{array}{l}\text{Number of induced terminations occurring during}\\ \text{a specific time period}\end{array}}{\text{Female population aged 15 through 44 years}} * 1{,}000$$

$$\text{Fetal death rate} = \frac{\text{Number of fetal deaths during a specified time period}}{\begin{array}{l}\text{Number of fetal deaths + number of live births during}\\ \text{the same time period}\end{array}} * 1{,}000$$

$$\text{Fetal death ratio} = \frac{\text{Number of fetal deaths during a specified time period}}{\text{Number of live births during the same time period}} * 1{,}000$$

Maternal mortality ratio is the number of deaths attributed to maternal conditions in a given time period divided with a number of live births during the same time period.

WHO recommends including maternal deaths that occur within 42 days of the end of the pregnancy. Some countries use other time periods (i.e., within 1 year).

Although international comparisons are difficult to make because of variable reporting practices, we know that wide differences in maternal mortality exist worldwide (AbouZahr 1998).

The *perinatal mortality ratio* is the number of fetal deaths (>24 weeks of gestation) and deaths during the first 7 days of life divided by the number of stillbirths and liveborn children in the same period. Stillbirths are births of fetuses that show no sign of life after 24 weeks of gestation (or other specified thresholds).

Recent results indicate that this definition should be separated into stillbirths and deaths during the first week of life. Stillbirths should furthermore be divided into death before labor and death during labor. In the past, fetal death and early death after birth often had asphyxia as the common cause. Congenital malformations are now a much more common cause of death around the time of birth (Kramer et al. 2002).

Infant mortality is computed as the number of deaths during the first year of life, divided by the number of live births during the same time period. Instant mortality rates vary between 5‰ and 10% in the poorest countries in the world.

Many of these measures are difficult to record in a comparable way over time and between countries. Live births are well registered in many countries, but that is not the case with stillbirths, in part because the gestational age threshold that separates miscarriages from births differs between countries and in part because stillbirths do not count in population statistics (Gourbin and Masuy-Stroobant 1995).

In some countries, the threshold of 24 weeks is used to distinguish a birth from a miscarriage. Other cut-offs have been 28 or 27 weeks. Some countries use 20 weeks as the threshold. The complicating issue is, however, that birth of a liveborn child is a birth, regardless of the time of delivery or if the child dies shortly after birth. Any researcher with an interest in both live and stillbirths who uses routine registration systems to identify births should make sure that the time at risk for the outcome of interest is comparable (e.g., including in the analysis only babies born from the 28th week onwards, if that is the threshold for defining a stillbirth). It is often very difficult to identify the cause of death for stillbirths (Winbo et al. 1997) or the time of death, which may be of importance in a monitoring system. It has, for example, been suggested that fetal death during labor is a better indicator of the quality of obstetric care than fetal death before labor (Kiely et al. 1985).

45.6 Fetal and Infant Death

When we study mortality, we usually estimate mortality rates, i.e., the number of people who die as a function of the size of the underlying population and the period of time during which this population was under observation. Since mortality rates strongly depend upon age (and sex), we usually calculate age (and sex)-specific mortality rates. The mortality rate for people of 90 years of age will be the number of 90-year-olds who die within a year divided by the number of observation years we have for 90-year-olds in that population. We will count observation time from their 90th birthday until they turn 91, die, or leave the population for other reasons.

In reproductive epidemiology, age is even more important, but the problem is that we now work on two time schedules: one is starting at the time of conception and the other at the time of birth. Age may be counted from either the time of conception (gestational age) or the time from birth (normal age). We expect mortality to be high shortly after conception, and we also expect mortality to be high when the fetus leaves the intrauterine environment. We would prefer to present mortality as a function of observation time in the population at risk from conception, which is difficult for early fetal deaths (miscarriages) because we usually do not know how many have conceived in the source population. We have to start our observation when the pregnancy is diagnosed, and that often varies. Sometimes the pregnancy is first diagnosed by the occurrence of a miscarriage, and sometimes a conception ends in an early loss without the woman ever realizing that she was pregnant. Moreover, bleeding early in pregnancy may cause problems in the attribution of gestational age based on the date of last menstrual period (LMP) (Gjessing et al. 1999).

An additional problem is that the timing of fetal death is often not known and only the time of expulsion is. In early gestation, these two points in time may differ by several days or even weeks (missed abortions), and some dead fetuses may even be absorbed rather than expelled. Later in gestation, we expect a stillbirth to be closer to the time of death. When signs of life disappear, most women in affluent societies will seek medical assistance. The fetal death will be diagnosed and a birth induced.

Some studies on fetal death use survival methods that take delayed entry and gestational age into consideration, or they use the ratio of all miscarriages to births as the endpoint. In any case, caution is called for. If exposures cause very early (preclinical) loss, these need not be detected. Exposures that move miscarriages to the preclinical stage will appear as if they prevented miscarriage, regardless of whether they are based upon rates or cumulative risk.

The time in which a pregnancy is diagnosed depends upon a number of known and unknown factors. It is reasonable to expect a planned pregnancy to be detected earlier than an unplanned one. On average, women with regular menstrual cycles probably become aware of a pregnancy earlier than women with irregular cycles. A woman who has been pregnant before may detect symptoms of a pregnancy earlier than a woman who is pregnant for the first time. Availability and sensitivity of pregnancy tests will also play a role for the starting point of observation.

Assume that we base our study upon a cohort of pregnant women. Assume furthermore that we take an interest in an exposure that, for some reason, correlates with how early the pregnancy is recognized. The exposed women would then enter the cohort at a later (or earlier) gestational age than the unexposed women. Since the risk of miscarriage decreases with gestational age, at least early in pregnancy, their ratio of spontaneous abortions to birth would be lower (or higher) than that of the unexposed group and the results would thus be biased. Comparison of gestational age-specific miscarriage rates should, however, be unbiased – provided that the exposure does not modify the time period from fetal death to expulsion.

If an exposure changes only the timing of pregnancy detection, gestational week-specific ratios of miscarriage remain valid. If the exposure changes the timing of miscarriage around the threshold of when a loss becomes clinically detectable, all the possible measures of miscarriage may be biased.

Studying miscarriage may also be complicated for other reasons. Since the risk varies largely with gestational age, it is important to use valid data for gestational age in the model that is left truncated at the time of entry. Unfortunately, precise data on gestational ages are difficult to obtain, even if ultrasound measures are available. A fetus with a poor survival prognosis may show early growth patterns that deviate from standard values, possibly resulting in biased ultrasound estimates. Furthermore, the exposure of interest may also correlate with the estimate of gestational age (Henriksen et al. 1995), which may make it impossible to obtain unbiased comparisons even when doing the proper statistical analyses. In addition, the start of observation time need not coincide with the time of exposure. If the exposure causes miscarriage after a short time, the susceptible pregnancies may be removed from the study early on (and before they are recruited in a study), leaving only a selected group available for study. This selection could attenuate or even eliminate an effect of the exposure on the risk of miscarriage.

Using a case-control approach to study causes of miscarriage may be prone to bias in some situations. Controls should (using the principles of incidence density sampling, see chapter ▶Case-Control Studies of this handbook) be selected at the time of fetal death (which is often unknown) and not at the time of miscarriage. Furthermore, measurements taken at the time of miscarriage that change over gestational time may be poor indicators of the cause of fetal death, even in situations where they are the cause of death rather than a consequence of it.

Dietary habits (such as coffee consumption during pregnancy) may change when nausea disappears, and since a fetal death would reduce nausea, cases may then have a higher intake of coffee than controls, not because coffee killed the fetus but because nausea and aversion against coffee disappeared when the fetus died. The exposure frequency is then high during the time from death to expulsion but was not so at the time of death. The high coffee intake is thus a consequence of fetal death, not a cause of death, which is an example of reverse causation. Whether coffee consumption during pregnancy is associated with an increased risk of miscarriage continues to yield conflicting findings, even when trying to address the above issue (Weng et al. 2008; Savitz et al. 2008).

At birth, a new time schedule starts. Preterm or very preterm children will start this new clock before their fetal maturation has come to its natural end. Babies born in week 35 will start their extrauterine life 5 weeks before a baby born at term. Diseases that originated in utero with a fixed induction time will have an onset that perhaps should have been counted from conception time rather than the time of birth. Childhood colic may, for example, be a disease that peaks at a given time in childhood counting rather from the time of conception, independently of the time of birth (Sondergaard et al. 2000).

Measures that use births as the denominator rather than the population at risk in the proper time intervals deviate from the principles on which normal age-specific rates usually rest upon. Fetal death rates would, in normal practice, be seen as death within a given gestational time period divided by the observation time for fetuses at that gestational age, just as infant mortality is estimated as death during the first year of life divided by observation time for children less than 1 year of age in that population.

Some researchers estimate the week-specific rate of stillbirth (usually starting at week 20 or later). Conventionally, this has been done by dividing the number of stillbirths at each week by the number of stillbirths + live births in the denominator. This approach will result in the proportion of stillbirths decreasing with increasing gestational week since live births increase with gestational time.

Yudkin et al. (1987) have argued that it is incorrect to use all births at any given week to estimate the rate of week-specific antenatal fetal death rate. Instead, they suggested the so-called “fetuses at risk” approach, where all fetuses at risk of stillbirth are included in the denominator at each week (thus including all as yet unborn fetuses). Following this approach, which is more properly a rate than the conventional method, will yield a completely different impression of the stillbirth risk compared with the conventional method, i.e., the rate of stillbirth will increase at each gestational week, instead of decreasing. Joseph (2004) has proposed to extend this approach to neonatal deaths as well as other conditions. However, using this approach for postnatal events seems problematic, as it assumes that birth has not affected the babies’ risk (Paneth 2008). Furthermore, stillbirths are not at risk of neonatal death. Whether it is more appropriate to use the conventional or the fetuses at risk approach probably depends on the purpose of the analysis.

Rather than using survival principles in studying determinants of miscarriage, many use the ratio of miscarriages to birth, or miscarriages/(induced abortions + miscarriages + births). The latter presents a proportion of miscarriages among all who end their pregnancy with either a birth or an abortion. The first measure will overestimate the cumulative risk of miscarriage, as it does not take induced abortions into consideration (some of which would have ended in a miscarriage). The latter estimate will attenuate the cumulative risk since some of the miscarriages would have contributed to the numerator had they not been terminated. The frequency and the timing of induced abortion thus becomes a source of bias in these studies (Olsen 1984), unless data are analyzed by means of survival techniques. When examining a predictor of miscarriage that is also a strong predictor of induced abortion, such as age, it is particularly important to take terminations of pregnancy into consideration.

The risk that a pregnancy will end as a recognized miscarriage is high, especially if the mother is more than 35 years of age (Nybo Andersen et al. 2000). How high miscarriage rates are from the time of conception is not known because we only have data on conception for very specific in vitro fertilization (IVF) conceptions, which do not represent the general population. Kline et al. (1989) estimated that 50% of all conceptions end as a miscarriage, 40% of pregnancies that could be detected by hCG measures and 10% to 15% among clinically recognized pregnancies. These figures probably do not need much adjustment today, although a new cohort study among pregnancy planners found a slightly lower rate in the preclinical, but detectable, phase of pregnancy of about 25% to 30% (Hjollund et al. 2000), close to what Wilcox found in his study of pregnancy planners (Wilcox et al. 1988). No biological measure is at present able to pick up very early embryonic life (before implantation).

Many miscarried fetuses have chromosomal aberrations, especially among the very early losses (Macklon et al. 2002) as well as other congenital malformations (Shepard et al. 1989). Chromosomal aberrations, or more specific genetic defects, may be used to perform more detailed analyses of cause-specific fetal mortality. If all miscarriages were grouped together, the measure would represent a general mortality endpoint, and, since most exposures are expected to be specific in their causal action, a general mortality measure may in many situations be too imprecise for meaningful research. The problem is, however, that obtaining and genotyping fetal tissue when a miscarriage occurs is neither easy nor inexpensive in an epidemiological study that often includes large numbers of participants.

When studying a specific exposure that is not believed to cause chromosomal aberrations, it would be wise to restrict the outcome to miscarriages without such defects, if possible. Chromosomal analysis may, in some situations, be used to distinguish between consequences of fetal death from causes of the death itself. If, e.g., coffee intake is a result of fetal death rather than the cause of it, one should expect to see coffee equally associated with miscarriage with and without chromosomal aberrations. If coffee drinking is causally related to the fetal death, it will probably operate either via chromosomal aberrations or through another fetotoxic mechanism independently of the chromosomal aberrations. These analytical principles were to some extent used in a study by Cnattingius et al. (2000).

45.6.1 Birth Weight and Mortality

Reducing fetal and early childhood deaths is the goal of many public health programs. The best way to achieve this would be to remove or reduce the frequency of the underlying causes, especially if these causes also lead to long-term health problems for the babies who survive. Still, the main investments in most affluent societies have been spent on improving treatment, an approach due in large part to the fact that we do not know many of these causes or how to eliminate them. In some situations, effective treatment will not only save the life of the fetus but also lead to a better potential for a normal and healthy life. In other situations, treatment may increase the incidence of some conditions, for example, by keeping alive babies (often very preterm) who may be severely impaired.

A number of mortality measures, especially perinatal mortality rates, have been used to monitor how part of the health-care system performs. Perinatal mortality has declined over time in most countries and has reached low values in many industrialized countries and also in some less developed ones.

Often, mortality is presented stratified by birth weight in order to obtain a better monitoring instrument for the quality of treatment. The idea is that advanced treatment would especially show its effect on children born with a low birth weight (who are, generally, also born preterm), as these are the babies with the highest risk of not surviving early extra uterine life. However, birth-weight-specific mortality is fraught with problems and should be used with caution.

Wilcox and Russell (1986) showed that the strongest predictor of perinatal mortality in a population is the proportion of newborns with a birth weight that falls outside the population-specific Gaussian birth weight distribution (the residual). Birth weight usually follows a normal distribution with a small "bump" in the left side tail, mainly made up by small preterm births. The size of the residual (usually reported in percent of the total) is a more consistent predictor of the perinatal mortality for the population than the proportion of newborns with a low birth weight (<2,500 grams), which remains the main indicator used in monitoring systems. If we follow this thinking, the aim should not be that of changing the birth weight distribution for the population but to reduce the residual portion of the distribution, i.e., the proportion falling outside the Gaussian distribution. This translates mainly into preventing preterm birth rather than increasing birth weight. Most reproductive epidemiologists would probably agree on this strategy. The present obesity epidemic in many countries is, e.g., expected to increase birth weight in the coming years but not to decrease perinatal mortality; in fact, we may observe the opposite.

When stratifying mortality rates according to birth weight, a number of so-called paradoxes appear. For example, small babies born to mothers who smoke during pregnancy have lower mortality than small babies with low birth weights born to non-smoking mothers (among the first to comment on this apparent paradox were Yerushalmy (1964), Macmahon et al. (1965), and Comstock and Lundin (1967)). Babies born to smokers have, however, higher mortality at all birth weights beyond a certain point. The same is seen for African Americans compared with

European Americans in the USA (Adams et al. 1991; Wilcox 2001). Babies born at high altitude show a similar phenomenon, although their overall mortality is not elevated (Wilcox 2001). These phenomena of intersecting weight-specific mortality curves could be interpreted as a result of confounding by the underlying causes of impaired fetal growth. Smoking may, for example, be a less harmful determinant of low birth weight, in terms of mortality risk, than other causes that also cause low birth weight and mortality. Basso and Wilcox (2009) have shown how this apparent paradox could have a simple explanation (see below), without any causal link existing between birth weight and mortality. Heterogeneity in the mortality risk of different causes of low birth weight had been hypothesized as a mechanism for intersecting mortality curves by earlier publications (Macmahon et al. 1965; Meyer and Comstock 1972).

The nature of the relation between birth weight and mortality is a subject of debate (Chalmers 1979; Wilcox 2001; Shrimpton 2003; Haig 2003; Basso et al. 2006a; Hernandez-Diaz et al. 2006; Basso and Wilcox 2009). The main evidence for a causal link is limited to the strong association between the two; no direct evidence exists to causally link low birth weight and mortality. Basso et al. (2006a) have shown how, at least in theory, rare factors with a strong effect on both birth weight and mortality can reproduce the weight-specific mortality curve at a given week of gestation, without birth weight having any effect (direct or indirect) on mortality. The model is based on simple assumptions, illustrated in Fig. 45.1. Building on this premise, it can be shown that birth-weight-specific mortality curves will intersect when stratified on a factor, such as smoking, that has a weaker impact on mortality than the hypothesized confounders (Basso and Wilcox 2009), as shown in Fig. 45.2. According to this model, the reason why small babies born to smokers have lower mortality than equally small babies born to non-smokers is that there are worse reasons for being small than smoking (in terms of mortality risk). For a more detailed demonstration, see Basso and Wilcox (2009).

Although this explanation has been formulated assuming no effect of birth weight on mortality, such a strong assumption is not needed. However, for the intersection to occur in the specified manner, the "causal" association between birth weight and mortality would have to be considerably less (if any) than that suggested by the empirical weight-specific mortality curve (Basso and Wilcox 2009).

Stratifying perinatal mortality according to birth weight ranks (or a z-score) for the particular distribution rather than the absolute birth weight (e.g., calculating z separately for smokers and non-smokers) generally eliminates the paradox of crossing mortality curves, suggesting that birth weight in itself may be an inappropriate indicator of mortality risk. For the intersection to be eliminated through the z-score, however, it is necessary that the other factors that affect birth weight and mortality (other than the one being stratified on) be the same in the two groups (in terms of frequency and effect) (Basso and Wilcox 2009).

Birth weight has been widely used because it is available in most countries and generally well measured. Data on gestational age are, on the other hand, less often available, and the quality may be poor. Still, uncritical use of birth weight as an "exposure" or endpoint in reproductive epidemiology is not appropriate.

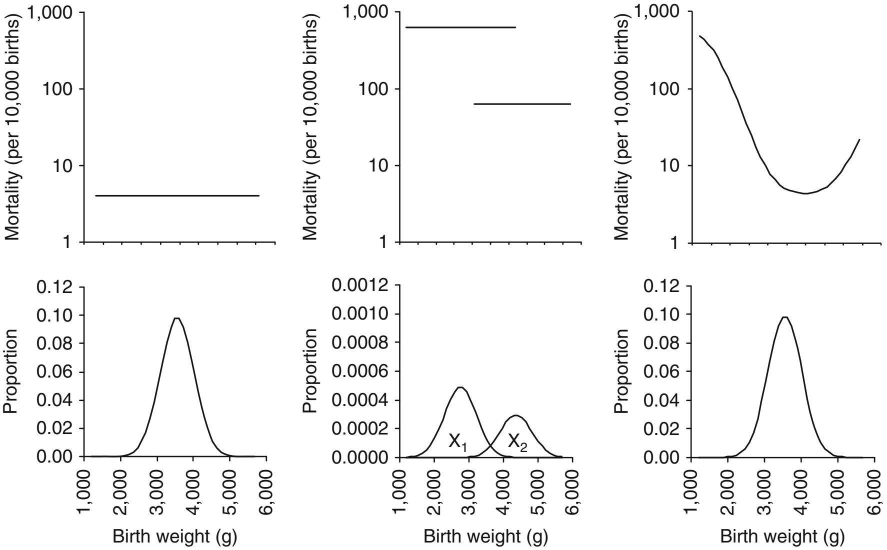

Fig. 45.1 Hypothetical scenario to reproduce the weight-specific neonatal mortality curve in the absence of any effect of birth weight on mortality. Population in figure ideally represents babies born at 40 weeks' gestation (Basso et al. 2006a; Basso and Wilcox 2009. Figure modified from Basso and Wilcox (2009)). *Left*: A population has mean birth weight of 3,500 g (±460) and mortality of 4 per 10,000 births. This distribution represents the birth weight that babies would have if no factor intervenes to modify their growth potential. *Center*: Two conditions, X_1 and X_2, affect 0.5% and 0.3% of babies, respectively. X_1 decreases birth weight by 782 g and increases mortality with an odds ratio (*OR*) of 171. X_2 increases birth weight by 782 g and increases mortality with an *OR* of 16 (note the different proportion scale in the y-axis of the birth weight distribution). *Right*: Resulting mortality curve plotted without stratifying by X_1 and X_2

If a woman is exposed to agents that reduce fetal growth, growth may be reduced proportionally or disproportionally. If mainly fat tissue is reduced, the newborn will have normal length but a reduced birth weight. The ponderal index is a measure that attempts to distinguish between thin and normal body proportions. The index is calculated as the newborn's weight divided by height raised to the third power. Readers, who are familiar with the body mass index (BMI), will know that the ponderal index deviates from BMI only by raising height to the power of 3 rather than to the power of 2. The only reason for this difference is to obtain a more symmetrical distribution of the ponderal index in newborns. How well this index actually reflects body composition among newborn children is, however, not well known, and its ability to predict adverse outcomes is also controversial.

There are other anthropometric measures of interest than birth weight or birth length. Head circumference is one such measure. Abdominal circumference may also be used. Most of these entities are probably measured with less precision, and less systematically, than birth weight, at least in countries that use standard weighing conditions and well-calibrated scales. It is also more difficult to accurately measure the length of a baby or a circumference. It is, e.g., likely that babies born vaginally

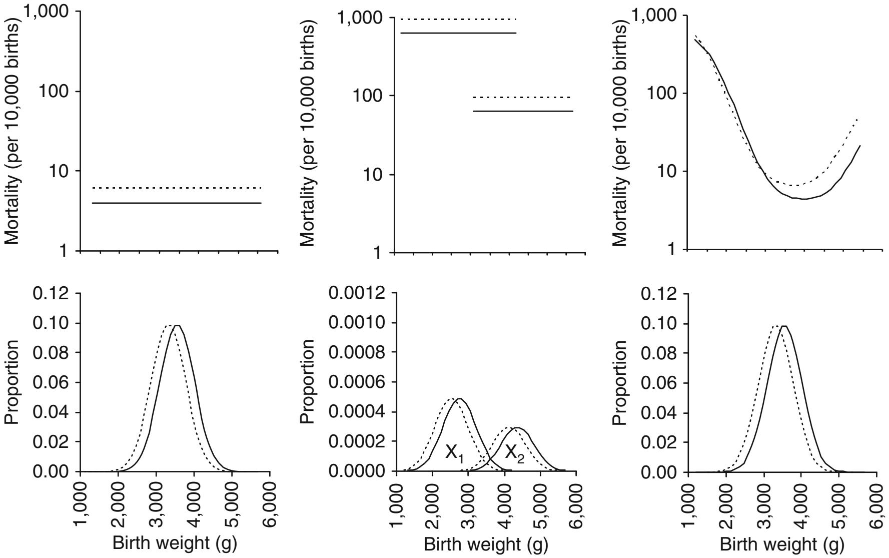

Fig. 45.2 A population of babies exposed to a factor F that decreases birth weight by 230 g (*broken line*) is added to the scenario shown in Fig. 45.1 (Figure modified from Basso and Wilcox (2009)). *Left*: Exposed population has standardized mean birth weight of 3,270 g (±460) and mortality 1.5 times that of non-exposed babies. *Center*: X_1 and X_2 affect 0.5% and 0.3%, respectively, of babies in each population. Effect of X_1 and X_2 on mortality of babies with F is increased with *OR*s of 171 and 16, respectively, (note the different proportion scale in the y-axis of the birth weight distribution). *Right*: Intersecting weight-specific mortality curves, stratified by exposure status

will present a molding of the cranial plates that will modify their head circumference compared to babies born with a caesarean section. Also, it is possible that some of these additional measurements would not be taken, which could result in selection bias if babies are excluded because not all measures were taken. It is also possible that some measures may have a systematically different quality depending on the baby's condition at birth (e.g., healthy babies may appear to be shorter than sick babies because it is more difficult to have them lie flat).

Since birth weight is a function of both pregnancy duration and fetal growth, pregnancy duration is usually taken into consideration when analyzing birth weight. The simplest procedure is to stratify results on preterm and term birth, but this will not fully account for the effect of gestational age on birth weight. Another popular option is to estimate "small for gestational age" (SGA), which implies identifying the, say, 10% (or 2.5%, or 5%) with the lowest birth weight among children born at each gestational week. Since the birth weight distribution is population-specific, an internal reference may be desirable if the size of the study allows for it. There are several disadvantages in using SGA; however, as it does not make use of the entire birth weight distribution, it will identify a number of babies who are constitutionally small but otherwise healthy, and it will consistently miss babies who have suffered from fetal growth disruption but have a birth weight above the designated threshold. Furthermore, at the earliest weeks of gestation, most births will be from complicated pregnancies, thus not representing the distribution of birth weight of all fetuses at that week (including those remaining in utero). This will result in the categorization of SGA defined on the basis of births to underestimate the true proportion of SGA babies when compared to the fetuses still in utero (Hediger et al. 1995; Hutcheon and Platt 2008). It has thus been proposed to use fetal standards, based on ultrasound measurements, although these will have a degree of measurement error (Cohen et al. 2010; Kacem et al. 2013). Babies who are defined as SGA in either manner do, however, have a substantially increased risk of death compared with those above this threshold.

SGA should, furthermore, not be taken as a measure of intrauterine growth restriction (IUGR) since the term SGA is purely descriptive. The use of the term IUGR should be limited to situations where it is known that the fetus is growth restricted. Such a diagnosis requires, at least in principle, a documented deviation from the growth curve for that baby, which may be available if several ultrasound measurements have been taken during pregnancy.

Gestational age, as the strongest predictor of birth weight, should be taken into consideration when continuous birth weight is the outcome. In order to account for the non-linear effect of gestational age on birth weight, gestational age could be modeled including a quadratic term, or with quadratic splines, or as several categories of gestational age as dummy variables (for an introduction to regression models, see chapter ▶Regression Methods for Epidemiological Analysis of this handbook).

The drawback of adjusting birth weight for gestational age one way or the other (or to use SGA measures) is mainly related to the often poor quality of data for gestational age, especially evident at some low gestational ages, where babies that are most likely born at a later gestation (given their birth weight) are instead recorded with a low gestational age (Gjessing et al. 1999; Tentoni et al. 2004; Basso and Wilcox 2010). Birth weight is usually measured more accurately than gestational age, and, by using an endpoint such as small for gestational age (SGA), the quality of the data may be compromised by making use of a composite measure that includes a variable that is imprecise at best and possibly biased (although gestational age is a very important variable). An exposure with no effect on fetal growth that causes irregularities in the menstrual cycle could either show an effect on SGA, if gestational age was based upon LMP data, or be biased if gestational age is measured by ultrasound and the exposure correlates with early fetal growth (Henriksen et al. 1995; Henriksen and Wilcox 1994).

The term “small for gestational age” is somewhat misleading, since it is a purely descriptive population concept: the baby is among the smallest in this particular population. Usually, what we would like to know is if the baby is small because it has suffered a disruption in growth. A baby that has achieved its full genetic growth potential could be an SGA baby just because it is constitutionally small. We expect such a baby to be at low risk for complications and diseases that may be related to impaired fetal growth.

Our interest in birth weight from a health perspective should focus upon a deviation from the genetic growth potential rather than on the absolute birth weight. Unfortunately, we do not know the genetic programming of the fetus, and we often have to rely upon indirect estimates that could lead to severe misclassification. The birth weight of babies previously born to the same mother could be used as a tool for estimating the growth potential of a later baby (Skjaerven et al. 2000; Basso et al. 2005; Pedersen et al. 2007), as the correlation between birth weights of siblings who share the same mother is about 0.5.

Given the fact that birth weight has been used for convenience – too extensively and for too long a period – a group of scientists (Adams et al. 2003) met in June 2002 in Denmark to announce the so-called Sostrup statement (named after the residency where the meeting took place). These statements concluded that:

1. In population studies, "percent low birth weight" (LBW) is a poor research tool for detecting factors or conditions that damage perinatal health.
2. "Percent LBW" is a poor index of population perinatal health.
3. Adjustment for absolute birth weight is rarely justifiable in looking for effects of specific exposures on infant or perinatal mortality.
4. Some exposures or conditions may compromise fetuses without causing preterm delivery or impaired fetal growth.

It is, however, difficult to propose another indicator that is as accurately measured and as easy to obtain, especially if we want such an indicator to be applicable in less affluent countries. The best alternative for a single indicator is probably preterm birth, although that is subject to a substantially higher degree of misclassification, especially when estimated on the basis of the last menstrual date.

45.6.2 Optimal Birth Weight

The concept of "optimal birth weight" has been used in the literature mainly to indicate the birth weight with the lowest perinatal mortality in specific populations. It is, however, unclear whether this birth weight actually is associated with lower mortality because of some biological property or, instead, because it is the category of birth weight associated with the "optimal" combination of factors that affect birth weight and mortality. As Basso and coauthors show (Basso et al. 2006a; Basso and Wilcox 2009), a model that assumes no effect of birth weight will nonetheless result in an "optimal" birth weight slightly above the mean. This happens because the factors that reduce birth weight and increase mortality have a greater impact than those that increase birth weight and mortality, a possibility previously suggested by Haig (2003). Whether or not birth weight is believed to play a role, it is probably legitimate to assume that babies born at the optimal birth weight are the least likely to have suffered from severe fetal growth disruptions, although no interpretation of the causal effect of birth weight on mortality can be currently ascribed to this weight.

Overall, we do not recommend the concept of optimal birth weight to be used broadly, as the optimal birth weight depends on what the birth weight has to "optimize," mortality, immune defenses, cognitive development, etc. In general, it is to be expected that the "optimal birth weight" would be a different birth weight for any given baby and that it would follow an approximately normal distribution at each week of gestation (as represented by the population in the left panel of Fig. 45.1).

The problems related to the concept of "optimal birth weight" without taking into consideration what its determinants are illustrated by the importance of the mother's BMI on birth weight (Nohr et al. 2008). The obesity epidemic will increase birth weights in the population but without reducing morbidity and mortality.

45.7 Gestational Age

A pregnancy starts at conception, but, since the time of conception is usually unknown, the starting point is often taken from the first day of the last menstrual period (LMP), which is usually around 2 weeks prior to conception. Based on this, a pregnancy is expected to last 280 days, or 40 weeks.

In most countries, Naegele's rule is still applied to estimate gestational age when using LMP data. The expected day of birth is calculated starting from the first day of LMP, and then 3 months are subtracted and 1 week is added. This rule, however, works well only for women who remember their menstrual periods and whose periods are regular (and close to 28 days of duration). The Naegele rule also works best in non-leap years at the population level (Basso et al. 2000a). With such easy access to electronic calendars, one would expect to see more electronic devices that simply add 280 days to LMP, taking leap years into account.

In affluent societies, ultrasounds (US) are more and more often used as a way of estimating gestational age, even in normal pregnancies with a certain LMP date. The idea behind the estimate is that certain structures, like the biparietal diameter (BPD), grow linearly and similarly for all babies in early pregnancy.

A given diameter is compared with a growth standard, and the gestational week is based upon the measure read from the standard growth curve – 16 weeks in the example above (cf. Fig. 45.3).

Experience has shown that ultrasound estimates are more precise than LMP measures and, for this reason, are better at predicting the date of delivery. They need not always be better for research, however. If you study exposures that impair early fetal growth, then an ultrasound measure may cause bias. The bias is probably too small to be of relevance in clinical practice, but it may be of concern in research. There may be research projects that are better off with an unbiased estimate with a low precision (like LMP) than with a biased estimate with a high precision. As previously mentioned, however, a substantial proportion of misclassified gestations is present in LMP estimates at pre- and postterm weeks. Thus, their use for research is unadvisable, especially when focusing on the extremes of the distribution of gestational length (Joseph et al. 2007; Basso and Wilcox 2010).

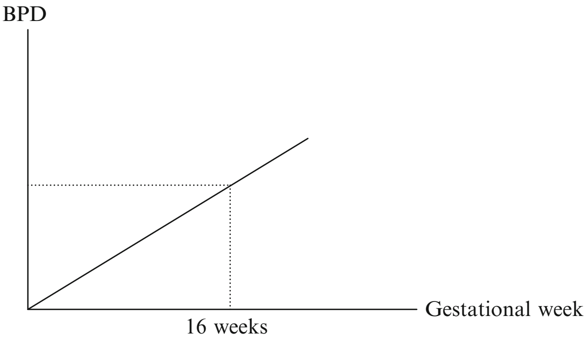

Fig. 45.3 Biparietal diameter (BPD) according to time since conception

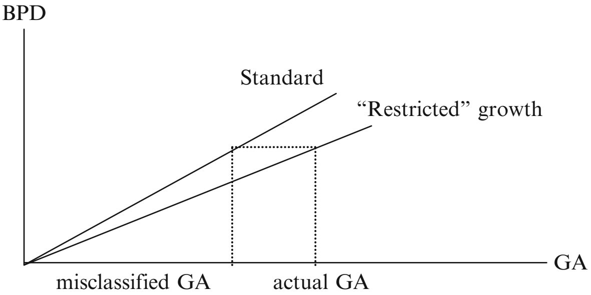

Fig. 45.4 Actual and standard Biparietal diameter (BPD) growth curves. GA = gestational age

As certain exposures, such as smoking, may affect even early fetal growth (Henriksen et al. 1995), use of ultrasound dating could result in babies of smokers to systematically be misclassified as having an earlier gestation than their actual one, given that their growth curve will be lower than the standard (Fig. 45.4). Assume that the difference between the actual and estimated gestational age (GA) is 2 days. If the woman gives birth shortly after 37 weeks of gestation, she would – erroneously – be classified as having given birth preterm.

If an inappropriate standard is used indicating a more rapid growth than for the population, gestational age will then be biased towards a low value, which will lead to a higher frequency of preterm birth. Using an inappropriate standard for the population under study will thus have impact on the estimated proportions of preterm and postterm birth for the population.

Gestational age is counted in days or in completed weeks. Preterm birth is a birth occurring before the woman has reached week 37, while postterm birth is defined as a birth taking place after completion of the 42nd week. "Prematurity" was often used in the past for newborns with a birth weight of less than 2,500 g. This term should generally be avoided, because we do not know if newborns with a birth weight of less than 2,500 g are premature; some will not be. Being premature requires clinical signs of prematurity; it is a clinical diagnosis that should not be used unless clinical data support it. "Preterm" is a more accurate description when having data on gestational age only, and sometimes it will be useful to study very preterm as well. Very preterm has been defined as birth before 34, 33, or 32 weeks

(Berkowitz and Papiernik 1993). Some studies investigate babies born even before 32 weeks. Thus, the definition of “very preterm” is generally study specific. The best definition may depend not only on the hypothesis one wants to examine but also on the available sample size, as very early births are, fortunately, very rare.

The frequency of pre- and postterm births depends upon precision and validity of the estimates of gestational age. If the central tendency of two measures (ultrasound and LMP) are the same, but one is measured with larger measurement errors (like LMP), then the imprecise measure will lead to more pre- and postterm births, provided that the central tendency is the same. In a study of pre- or postterm delivery, it is therefore important that gestational age is at least measured using the same methods in the groups to be compared. If studies are based upon routine registrations of gestational age, it may not be known how it was measured. If the exposure under study correlates with early fetal growth, LMP should be applied. If the exposure correlates with menstrual irregularities, then ultrasound is preferable. In order to detect a given difference in gestational age between two compared groups, a larger sample size is usually needed if gestational age is estimated by LMP compared with ultrasound estimates.

An example of the latter case may occur when studying whether a long waiting time to pregnancy leads to preterm delivery. If only LMP measures are available, one may find that women with irregular or long menstrual periods have a longer TTP, as many subfecund women have irregular cycles. The measure of time to pregnancy itself will be affected by this irregularity, since time to pregnancy, although ideally reflecting the number of cycles that a couple takes to achieve a clinically detectable pregnancy, is often reported in months. In such cases, not only imprecision but also bias can affect the effect measures, and the burden to estimate how much the observed effect can be ascribed to these problems falls on the researcher. If ultrasound measurements are not available, one way to assess whether the association may be due to bias caused by differential misclassification of gestational age could be to use birth weight as a support measure to corroborate the finding. Birth weight is less subject to error than gestational duration, and its accuracy is less, if at all, dependent on correlates of the exposure. However, birth weight is strongly influenced by duration of gestation. Thus, checking whether the association between a given exposure and preterm birth is replicated when using birth weight as the outcome may provide reassurance for the finding – or grounds for rejecting it. If there is no difference in the birth weight distribution according to time to pregnancy before adjustment for gestational age, this suggests that most of, or all, the observed effect is due to differential measurement error of gestational age. If, on the other hand, the birth weight of children born to women with a long time to pregnancy is lower than that of women with a short time to pregnancy, this is supportive of the conclusion that there may be some effect of time to pregnancy on gestational duration (provided that there are no residual confounders that can reduce birth weight that are more common in women with long time to pregnancy): this would be a problem if, for instance, short women – who have lighter babies – also had a longer time to pregnancy than tall women but a gestation of the same duration. A long time to pregnancy appears to have an effect on fetal growth as well as on gestational age (Zhu et al. 2007a; Basso and Baird 2003), and one could thus estimate this by adjusting for gestational age when examining birth weight as a function of time to pregnancy.

Another example of a factor affecting the accuracy of gestational age selectively in exposed and non-exposed women may occur when examining the effect of short interpregnancy intervals (the time between the previous birth and the next conception) on the gestational age of the subsequent pregnancy. Women who have short intervals are likely to have less accurate estimate of gestational age, because cycles resume some time after a pregnancy, and they may be irregular at first. Therefore, women with very short intervals may have systematically inaccurate measures of gestational age. Again, by checking with birth weight, one can try to assess whether there is evidence of this phenomenon. Although short interpregnancy intervals have been associated with both preterm delivery and low birth weight, in a study among Danish women (Basso et al. 1998), only the association with preterm delivery was observed, while the one with low birth weight disappeared entirely after adjustment for preterm delivery.

As previously stated, being born pre- or postterm may have stronger health impacts than deviating from a “normal” birth weight. Using the proportion of preterm births as an indicator of one component of reproductive health in a monitoring program is therefore of interest. In the past, such a measure was based upon LMP data. Now it would often be mainly ultrasound based. From a monitoring point of view, this raises issues related to comparability over time. The standard used to estimate gestational age based upon BPD should be appropriate, and that means both time- and population-specific. It should be a standard for the population it is applied to, and it should be changed over time if fetal growth in the population changes over time. In diverse populations, one standard may not be enough, if growth patterns vary by ethnicity. Many countries face increasing obesity problems, which may influence not only birth weights but also early fetal growth. If so, BPD standards need frequent adjustments for an ultrasound-based monitoring system of preterm births to be unbiased.

No matter how gestational ages are calculated, you will often find implausible gestational ages based upon the newborn children’s birth weight or maturity. Depending on the circumstances, one can attempt to “clean” the data or code such instances are missing. Whichever approach is taken, however, there will be consequences for the analysis. For estimating gestational age at the time of miscarriage, the LMP method is to be recommended in most cases, even if ultrasound was used.

It is well accepted that preterm birth is a heterogeneous condition (Romero et al. 1994, 2006; Klebanoff and Shiono 1995; Klebanoff and Schoendorf 2004; Greenwood et al. 2005; Savitz 2008; McElrath et al. 2008). Although being born early is a strong predictor of morbidity and mortality per se, the various causes of preterm birth likely have an independent effect on mortality risk. Thus, the observed week-specific mortality rates do not represent the pure effect of being born early but are a combination of both components. It is thus theoretically possible that a large portion of mortality among preterm babies is due to the pathologies that cause preterm birth and increase mortality risk (Basso and Wilcox 2010, 2011). Just as in the case of birth weight, remembering that gestational length does not explain the entire gradient of risk from very preterm to postterm can explain what may appear at first to be paradoxes, such as those instances where high-risk babies (e.g., twins, babies with pre-eclampsia) have lower mortality at preterm weeks than babies at lower risk (e.g., singletons, babies without pre-eclampsia). In other words, a twin baby born at 32 weeks is more likely than a singleton to have a more benign reason for being born preterm (as the only problem may have been twinning), whereas a singleton will have to have had another reason, potentially conferring a higher mortality risk (Basso and Wilcox 2010, 2011). Because babies born preterm tend to constitute a pathological group, studies among very preterm births (such as those carried out within perinatal networks) that examine morbidity or mortality as a function of a specific condition (e.g., pre-eclampsia and retinopathy of prematurity, see, e.g., Fortes Filho et al. 2011) cannot be interpreted causally, as babies with the exposure of interest are compared with babies who have other, often non-specified, exposures that can affect the outcome under study (Basso and Wilcox 2011). In general, as long as there are unmeasured causes of preterm birth that strongly affect the outcome, it is not possible to estimate the "pure" mortality (or morbidity) risk due to being born early, nor the causal effect of a given cause of preterm birth on an endpoint (Mann et al. 2011).

The pregnancy period is, in many countries, under intense monitoring by health-care personnel. The effects of any exposure under study reflect only the effect remaining after health-care intervention. This limitation is always true but is especially important to keep in mind when studying pregnancy duration, especially postterm birth. A birth may be induced when the clinicians believe the child is better off outside the uterus, or perhaps just because they believe the child is sufficiently mature to be born, or if the mother's health is at risk if the pregnancy is continued. In any case, a substantial number of pregnancies are not carried to a "natural" end, and these observations are "censored." Since the censoring will, in many cases, be associated with the risk of complications (to the mother or the baby), we cannot study, e.g., the risk associated with postterm birth per se. The only option is to study what remains of risk after health-care intervention. In like manner, one cannot nowadays study determinants of postterm delivery, only determinants for pregnancies that are allowed to continue after 42 weeks of gestation. Although these limitations are self-evident, they are often not mentioned in scientific reports – perhaps because they are self-evident (or are "forgotten"). In any case, the necessary precautionary warnings should be mentioned so that the results are not misleading.

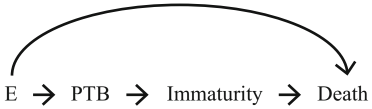
It is well known that many adverse outcomes strongly correlate with preterm birth (PTB) and/or low birth weight (LBW), although these associations may not be causal. These factors are probably the strongest predictors of early postnatal mortality and morbidity. PTB and LBW are, however, not isolated events but have causes that may directly or indirectly cause the reproductive failure of interest. LBW is, for example, strongly correlated with infant mortality, but the current obesity may well reduce the frequency of LBW without reducing mortality.

A failure to distinguish between a confounder and an intermediate may also have serious consequences as illustrated by a few simple directed acyclic graphs (DAGs) (cf. chapter ▸Directed Acyclic Graphs of this handbook).

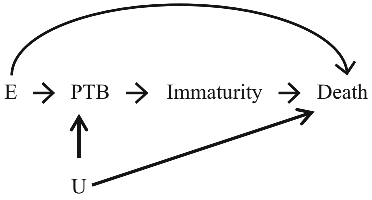
In the following example, an exposure's (E) effect on mortality is mediated by PTB and immaturity:

E → PTB → Immaturity → Death

Adjusting for these factors would block the association you want to study. But there could be a direct link from the exposure (E) to the disease (D) you take an interest in. If so the DAG looks like this:



The direct link from E → Death would show if you adjusted for PTB (or immaturity). Most likely the DAG would be a bit more complicated because there are other factors (U) causing PTB and the DAG could look like this:



If you now adjust for PTB, you will generate a backdoor path E – U – Death. This backdoor path could be closed by controlling for U. However, U usually stands for "unknown" or "unmeasured," leaving this option out.

Simply adjusting for length of gestation in the situation above may yield grossly biased results (Wilcox et al. 2011). Alternatively, assumptions could be made on the frequency and strength of the U's to obtain a range of estimates of the direct effect of E on the outcome, be it neonatal death or another endpoint (VanderWeele and Hernández-Diaz 2011; VanderWeele et al. 2012; MacLehose and Kaufman 2012).

A failure to distinguish between confounders and intermediates has produced many misleading results that need to be corrected. The problem with intermediating factors has been well known for many decades, although this has not prevented misleading analyses. The awareness of collider bias is, however, relatively new and a result of using DAGs in causal research. DAGs have also been helpful in our understanding on how to deal with past pregnancy histories (Howards et al. 2012).

45.8 Congenital Malformations

Congenital malformations have been subject to numerous epidemiological studies and monitoring systems because they are very serious for the affected children, their families, and society in general. Researchers dealing with studies of teratogenic or fetotoxic effects prefer to include a wider range of abnormalities than structural malformations. Some prefer to use the broader term congenital anomalies (CA) that will include genetic disorders and some functional impairment as well. CA will be present in 2% to 7% of all newborn children, depending on the definition and the level of monitoring. Many anomalies will not be diagnosed until childhood or even later, and a number of defects (such as some heart malformations) may go undetected for many years or not ever be diagnosed. The effectiveness of prenatal screening followed by induced abortion of affected fetuses also plays a role for the prevalence of congenital anomalies at birth.

If congenital anomalies are taken to be all structural or functional defects or deviations that are present at birth (whether or not they are detected at the time), the frequency could be defined to cover many more than 7%. Many functional defects may be present at birth in a form that is not yet detectable with the diagnostic tools that we have at present, such as cognitive defects, color blindness, other brain defects, mutations of importance for some cancers, like childhood leukemia, or testis cancer. Fetal organ programming of organ functioning could, in principle, also be seen as a congenital anomaly in the sense that programming may increase susceptibility to many diseases, such as insulin resistance and all the diseases it may lead to. Clearly, using such a broad approach makes congenital abnormalities an impracticable or even impossible endpoint. Most studies and monitoring systems will restrict the endpoint to what is described in official disease classifications, such as Chap. 17 in the International Classification of Diseases (ICD10).

Monitoring systems of congenital malformations have been, and are still being, used in order to detect changes in the prevalence of malformations over time. Many of these systems have their root in the Thalidomide disaster. Thalidomide was released on the market in the 1950s as a sedative and a tranquillizer to treat nausea and insomnia and was considered to be safe even for pregnant women. The drug was regularly used by pregnant women in countries where this drug was approved. The drug was teratogenic, as reported by Lenz and MacBride in 1961 (Diggle 2001). About 40% of the pregnant women who used the drug during organogenesis (mainly in the second and third months of gestation) gave birth to children with malformations. The most common defect was phocomelia, a syndrome where the extremities were severely underdeveloped. The drug is not teratogenic in most experimental animals, and pregnant women are never included in pre-marketing randomized trials. Pregnant women used the drug believing it was safe. It is therefore important to set up programs that fully utilize the information generated by pregnant women when they start using new drugs. At present, we are alarmingly short of such information systems (Olsen et al. 2002).

It is currently hoped, somewhat naïvely, that the monitoring systems will pick up new teratogenic drugs, even at an early phase, and that such an effect will be detected by the reporting of side effects. Most drugs, especially new ones, are, however, only used by few pregnant women, and the person who prescribes the drug is usually not the same as the person who diagnoses a congenital malformation. A monitoring system of congenital malformations would, on the other hand, be of importance for setting up specific studies, because good quality data on congenital malformations are often lacking in routine medical records.

The technology available to detect congenital malformations at an early stage in gestation is continuously improving with the use of ultrasound or biochemical and genetic methods. Clearly, measuring prevalence at birth may become a questionable endpoint if prenatal diagnosis is not used in exactly the same way in the groups to be compared.

Since specific malformations are rare, most studies on determinants of congenital malformations will be based upon large routinely collected data sources covering many thousands, possibly hundreds of thousands, of pregnant women, or by using a case-control approach. The main advantage with the case-control approach is the possibility of collecting valid exposure information concerning the pregnancy (often very early pregnancy) by means of interviews. These data may, however, be difficult or even impossible to obtain for exposures that are hard to recall. The recall easily leads to bias related to a lack in symmetry of the information obtained from a woman who had a child with a severe handicap when compared to the information provided by a woman who had a healthy child. Using another set of patient controls (e.g., another type of congenital malformation than the one under study) may be a possible solution, although it is not without problems. When using patient controls as a surrogate for representative source population samples, the "control" disease should neither be caused nor prevented by the exposure under study, and, since we know so little about the causes of most malformations, this might be a hazardous assumption to make. However, interviewing women who all had a child with congenital malformations should render the quality of information more comparable, thus reducing the potential for bias (Swan et al. 1992). There is indication of a more accurate recall of medicine intake in mothers who had a child with a congenital malformation than in mothers who had a healthy child (Rockenbauer et al. 2001). Furthermore, it has been shown that the way questions on medicine intake are phrased plays an important role (Mitchell et al. 1986).

Using a case-crossover design (Maclure 1991) might be an option to overcome biased reporting (and confounding by personal characteristics). Since only exposures at a given time period may be of relevance for the malformations under study, another time interval during gestation before or after the index exposure may be selected as a reference. The relative prevalence ratio for the case in question can be estimated by dividing mothers who were exposed in the exposure window but not in the reference window and vice versa, given that these windows have the same duration. The rest of the exposure combinations do not provide any information to the study concerning the associations between drug intake and the specific malformations (Kjaer et al. 2007, 2008).

A case-control approach will allow specific diagnostic classification of the cases. By setting up specific diagnostic standards, it is possible to make sure that only the individuals with the malformation in question enter as cases (high specificity), although some with the disease may not meet the criteria (sensitivity <1). As long as specificity is high, however, a relative effect measure will not be biased by a low sensitivity, but the study power will be reduced. The following example illustrates why this is the case.

Imagine that the underlying source population has the following structure:

Exp	Cases	All births
+	2,000	100,000
–	1,000	100,000

$$RP = \frac{2{,}000/100{,}000}{1{,}000/100{,}000} = 2.0$$

Now assume that only half of the time cases will be diagnosed. The display of data would then be:

Exp	Cases	All births
+	1,000	100,000
–	500	100,000

$$RP = \frac{1{,}000/100{,}000}{500/100{,}000} = 2.0$$

The relative prevalence ratio (*RP*) is still 2, simply because there are still twice as many diagnosed children with malformations among the exposed compared with the non-exposed. The low diagnostic sensitivity did not change this. It is easy to design a case-control study to replicate these results. It is just a matter of proper sampling from the source population.

A case-control sampling using all cases and a sample from the base from any of the two above situations would produce an unbiased estimate of the *RP*. A 1:5 case-control sampling would, in the first case, give

Exp	Cases	Controls
+	2,000	7,500
–	1,000	7,500
All	3,000	15,000

$$OR = \frac{2{,}000/1{,}000}{7{,}500/7{,}500} = 2.0$$

and in the second case

Exp	Cases	Controls
+	1,000	3,750
–	500	3,750
All	1,500	7,500

$$OR = \frac{1{,}000/500}{3{,}750/3{,}750} = 2.0$$

The power would be less in the second example, as reflected by a larger variance in the second study (the variance of the odds ratio (OR) is 0.0018 and 0.0035 in the first and second study, respectively).

45.9 Pregnancy Complications

45.9.1 Operational Definition

During pregnancy almost all maternal physiological systems are subjected to major changes. Cardiac output increases by 30–50%, and thus the kidneys have to filter a much higher amount of blood. The space taken up by the enlarging uterus changes the way the lungs and digestive systems work. The major changes are, however, hormonal, and the placenta produces a large amount of hormones that help maintain the pregnancy. The immune system is also affected, as pregnancy is a mildly immunodepressed state. Also, there are indications that pregnancy requires a shift in the type of immune response from Th1 (pro-inflammatory) to Th2 (antibody mediated), modifying the maternal type of immune response as well.

Because of these major changes, there are a number of preexisting diseases (such as diabetes, kidney disease, affections of the thyroid, heart failure, rheumatoid arthritis, and other autoimmune diseases) that may be modified by pregnancy and harm the woman or the fetus. Some autoimmune diseases improve in pregnancy, such as rheumatoid arthritis; others relapse or worsen or present a cluster of onsets immediately following a pregnancy.

Pregnancy complications are defined in the Medical Subject Headings as the co-occurrence of pregnancy and a disease. The disease may have started before conception or after. This definition is rather general and not in line with what most people would think of as being a pregnancy complication. A puerperal depression is considered triggered by the birth and not just a depression that happens to occur shortly after delivery, although it may be difficult to distinguish a depression triggered by birth from a depression that would have occurred in any case. In these paragraphs, we will, therefore, deal with some aspects of complications that are only seen during pregnancy or which are only defined as such during a pregnancy. We will briefly deal with some common pregnancy complications (such as hyperemesis and placenta previa), reserving a particular emphasis to gestational diabetes and pre-eclampsia, the former because it is a clear example of some of the problems facing epidemiologists who deal with pregnancy complications. Pre-eclampsia is a relatively common and serious complication of pregnancy, and it is also one of the most fascinating mysteries of reproduction.

Other chronic diseases pose a risk to the mother and to the fetus. It is likely that most of them will be seen among pregnant women, but with a lower prevalence than in the general population, especially if they are severely debilitating for the woman in her reproductive years. The "healthy pregnancy effect" is analogous to the better known "healthy worker effect" and is due to the fact that a reasonably good health is required to conceive and carry a pregnancy to term. This "effect" need not cause bias if properly addressed in the design of the study. The "healthy pregnancy effect" only underlines the fact that many diseases will be less frequent among parous women if these diseases interfere with actual fertility.

45.9.2 Methodological Challenges

45.9.2.1 Defining a Disease: Choosing a Cut-Point

A general problem in studying pregnancy complications is due to the fact that many such conditions are defined as an extreme of events that occur in the course of a normal pregnancy. Thus, a disease that represents an extreme value of the distribution of a given trait rather than a qualitatively different entity will be more problematic to study. In this case, the distinction between normal and pathological becomes relatively blurred, and very often the challenge faced by clinicians is that of defining a cut-point beyond which a condition is declared a disease (as in obesity, diabetes, hypertension, and pre-eclampsia) and below which the same condition is considered within the norm. It is immediately evident that definitions of this type are susceptible to many problems, as is the case with all diseases defined this way, because any arbitrary threshold will introduce some degree of misclassification, especially since pregnancy is a condition under intensive medical surveillance, which will then make pregnant women a population in which virtually the entirety of its members will be screened for severe diseases one way or the other and, in most cases, more than once in the course of pregnancy. It is well known that even a test with a high specificity will produce a large number of false positives in a population with a low prevalence of a disease, and this leads to women being unnecessarily treated and subjected to the stress of being diagnosed with a disease they may not have. However, missing women with a given disease by moving the cut-point towards more extreme values will result in a low sensitivity that will lead to missing cases with consequences that may be very serious for the mother and the baby. The extent of these problems depends not only on the criteria for defining a disease but also on the approach adopted by the care providers, the access to prenatal care, and the frequency with which pregnant women are monitored. The more frequently women are seen and their blood glucose, blood pressure, or proteinuria are measured, the more likely it will be that they can be wrongly (and rightly) classified as having a given disorder, especially if these measures fluctuate over time. Conversely, women who are not screened often or do not comply with prenatal care may be underdiagnosed in these circumstances, and women who are frequently screened may be overdiagnosed. Factors related to monitoring, such as insurance coverage and distance from antenatal care centers, can thus produce bias, especially – but not only – if risk factors for the disease are also part of the reasons why women comply less with prenatal care (smoking may, in some circumstances, fulfill these criteria). In some cases, modeling the number of ANC visits or other factors affecting the access to ANC (distance, social class, insurance plan when applicable) might provide some information about whether a problem of this type has occurred, but this will not necessarily be sufficient to correct for the bias.

Even if all women comply equally well with prenatal care, problems may arise if the exposures under study correlate to some degree with the probability of being diagnosed, as health-care personnel may differentially screen women according to their risk profiles.

Furthermore, the consensus on the cut-points usually changes in time and is often not even geographically homogeneous at the same point in time. Comparisons over time and between different areas thus become difficult to perform and of questionable value depending on the level of prenatal care and definition of the disorder. Often researchers do not have the crude values of what is actually measured but only the clinical diagnosis, which makes virtually every study susceptible to well-founded criticism because uncertainties and the potential inaccuracy of the diagnosis may well depend on the putative risk factors under study. Random errors will also tend to dilute associations with the number of false positives that will be included in most case series. We are thus left with studying the phenotype that clinicians in a particular region and at a given point in time call a disease, which may not be the best classification from an etiological point of view.

45.9.2.2 Design Strategies

In general, i.e., if the disease prevalence is low, relative effect measures, such as the relative risk or the odds ratio, are more profoundly affected by low specificity than by low sensitivity. A possible strategy when dealing with diseases that have been classified on the basis of a definition determined by exceeding a given cut-point (such as gestational diabetes) is to limit the number of false positives by restricting the study to the more severe cases (which will, most likely, be identified with a lesser degree of error), if the possibility to do so exists. However, this may reduce the power of the study when dealing with disorders that, in general, are quite rare to start with.

Ad hoc studies (made for the specific purpose of investigating a given disease in a defined population) with access to medical records are an important option, which, however, will be more costly than studies based on routine information recorded, for example, in registries and will, once again, raise the issue of how many cases will be available for the study.

In some instances, combining the clinical diagnosis of the disease of interest with a feature that should be concomitantly present if the disease is actually present may increase the quality of the data for the study. For example, placenta previa is a relatively rare pregnancy complication, where the placenta is positioned to partly cover the opening to the birth canal. In early pregnancy, however, the placenta will relatively often appear to be positioned in such a way but will, in many cases, spontaneously reposition itself during the course of pregnancy (Dashe et al. 2002). If a study is based on all diagnoses of placenta previa, including those made in early pregnancy, cases will include a proportion that are not truly cases. If placenta previa persists, on the other hand, the common practice is that of performing a caesarean section to deliver the baby and thus, by including only the women diagnosed with placenta previa who were later delivered by caesarean, one will probably be limiting the analysis to the more severe or, at least, the more persistent cases. This has been done, for example, in studies investigating whether pregnancies with placenta previa presented a higher male to female ratio (Wen et al. 2000; Ananth et al. 2001). Whether this type of approach should be used or not has to be evaluated depending on the specific aim of the study.

The significance of the same symptom may change across the duration of pregnancy, and it may be a cause or a consequence of another condition, also depending on the timing. This is probably the case, for example, of bleeding during pregnancy, which, in the last trimester, is probably a consequence of placenta previa or placental abruption, while it may be an entirely different entity in the first two trimesters (such as threatened abortion). Hyperemesis, severe vomiting in pregnancy, is another example of a "normal" condition becoming pathological when presenting with extreme symptoms. Several studies have investigated fetal outcome among women who had hyperemesis, with conflicting results (Depue et al. 1987; Kallen 1987; Godsey and Newman 1991; Hallak et al. 1996; Gross et al. 1989). Yet, a recent review states that severe vomiting does not have a negative effect on perinatal outcome (Eliakim et al. 2000). However, if the definition of the case series is based on a hospital diagnosis without taking severity into consideration, then the cases may include a number of women with a relatively mild disease that is not really distinct from the "normal" nausea and vomiting of pregnancy. Restricting cases to those where some objective biomarkers, such as severe ketosis or serum electrolyte disturbance, can be measured may then provide a "purer" case series, which might be one of the reasons for the inconsistent findings.

Timing of the disease could also be of relevance, as in two studies investigating the association between hyperemesis and female sex of the baby, it was noted that the association between hyperemesis and having a female baby was evident only for hospitalized cases of hyperemesis occurring in the first trimester of pregnancy (Askling et al. 1999; Basso et al. 2001). Hyperemesis occurs more frequently in women carrying multiple fetuses as well as in women (carrying singletons) who will later be diagnosed with pre-eclampsia (Zhang and Cai 1991). These observations suggest that there might be multiple causal paths leading to hyperemesis and that, in some women, a large placenta (with a high hormone production) may be the cause of the disease, while in others hyperemesis could be a sign of some other pathological process under way. In any event, whenever etiological heterogeneity exists in a process, and signs and symptoms are the same as that of another process (so that they are considered the same disorder), it is always very difficult to disentangle what is being studied. If only a small fraction of the case population represents a different etiological entity, even a moderately strong predictor of the “minority” disease entity will likely appear not to be associated with the mixed entity and will thus be repeatedly missed. If the fraction is large, then a predictor will be called a risk factor for all entities presenting with the same symptoms, and perhaps this uncertainty contributes to some of the failures of epidemiology to encourage changes in people’s habits and in policies. When these conditions occur in pregnancy, it may, in some cases, be possible to discriminate to some extent between different entities by paying particular attention to the timing in which the events occur.

45.9.3 Gestational Diabetes

As many other metabolic functions, the metabolism of carbohydrates is altered in normal pregnancies. The fasting blood glucose level decreases early in pregnancy until the 12th week and usually remains at this lower level until the end of pregnancy. Insulin, by contrast, remains stable during the first and second trimesters but increases during the third. Outside pregnancy, blood glucose returns rapidly to fasting levels after a meal, while, in pregnancy, both glucose and insulin levels reach higher peaks than they would after a similar meal in the non-pregnant state. This higher level is, furthermore, maintained for a longer time. Human placental lactogen (hPL) is the hormone that is believed to be responsible for these changes in metabolism (Haig 1993). In general, pregnancy is often a state of mild insulin resistance, and some women develop gestational diabetes. As an adaptation, insulin production is increased at the same time that the mother is becoming insulin resistant. Within his evolutionary theory about the genetic conflicts of pregnancy, Haig (1993) proposes an interesting hypothesis about why this change may occur. Glucose is an important nutrient for the growing fetus, but it is also important for the mother’s survival that not too many of her resources are depleted by the fetus, which could happen if fetal demands went unopposed: the decline in blood glucose early in pregnancy could thus represent a maternal attempt to limit fetal uptake. In addition, after every meal, there will be a competition between the mother and the fetus over the respective share. The longer it takes the mother to reduce her blood sugar, the higher the share taken by the fetus, hence the insulin resistance, according to Haig. At the beginning of pregnancy, the fetus has limited demands and limited “power,” which is why the mother succeeds in “hiding” her blood glucose. During the third trimester, however, the fetus has very high demands (as this is the time when most fetal weight is gained), and it is strong enough to take the upper hand in the competition with the mother. When seen in the light of how to optimize survival probabilities, this is an attractive hypothesis, although hard to test.

Barker (1995, 1998) has a different hypothesis, suggesting that insulin resistance after birth is a consequence of limited nutrient supply in fetal life. Clearly, however, glucose metabolism is crucial during pregnancy, and a mechanism has evolved that creates a delicate balance between the maternal and fetal needs. Diabetes during pregnancy is a complex problem that requires a very careful management to prevent damages to the fetus and to the mother. Preexisting diabetes is a risk factor for several congenital abnormalities, stillbirth, and macrosomia. Gestational diabetes is not associated with an increased risk of congenital abnormalities (likely because it occurs later in pregnancy), but the risk of stillbirth and macrosomia is present also for this condition (Schmidt et al. 2001; Johnstone et al. 1990). Macrosomia is the most frequent outcome in diabetic mothers, and this can complicate delivery to the point that a caesarean section is required. Women who have had gestational diabetes are at increased risk of having it again in a subsequent pregnancy and are also at a high risk of developing diabetes (Dornhorst and Beard 1993), especially type 2 diabetes (O'Sullivan and Mahan 1964; O'Sullivan 1991), later in life. Gestational diabetes, as well as other types of diabetes, is also a risk factor for pre-eclampsia (Schmidt et al. 2001), another potentially severe pregnancy complication. Obesity is a predisposing factor (with insulin resistance as the underlying condition), as is advanced maternal age or having a family history of diabetes.

The definition of gestational diabetes is problematic and the subject of controversy (Dornhorst and Beard 1993; Martin et al. 1995; Gabbe 1998; Bonomo et al. 1998; Schmidt et al. 2000). The discussion has to do with whether there should be universal screening for all pregnant women or only for those at higher risk. Risk factors for gestational diabetes are advanced maternal age, high body mass index, family history of diabetes, and certain ethnicities. There is no agreement over the "gold standard" test for women who are screened positive. The oral glucose tolerance test is the norm, but the load (the dose of administered glucose) varies geographically. There is also discussion about which cut-off limits should be used, as the prevalence of gestational diabetes would change depending upon the threshold, and the risk would be to either classify too many women who are not diabetic as such or to miss too many women who are diabetic and at risk of adverse pregnancy or health outcome. In a randomized trial among women with gestational diabetes of routine vs. nutritional advice, blood glucose monitoring, and insulin therapy as needed, Crowther et al. (2005) reported a significantly higher rate of perinatal complications (death, bone fracture, shoulder dystocia, and nerve palsy) among women in the routine care group vs. the intervention group.

The distinction between normal and pathological values is arbitrary, which hampers any diagnostic criterion. Often, epidemiologists do not deal with the actual values of glucose level but instead with the clinical diagnosis collected in several hospitals, without guarantee of uniformity in the criteria used for screening and diagnosis. The diagnosis will also depend on whether glucose is measured or not, and, since gestational diabetes is mostly asymptomatic, this is an added complication. Researchers planning studies requiring an accurate diagnosis of gestational diabetes should thus be aware of the medical attitude towards screening in pregnancy in the locations where they plan to collect their data and of the tools and cut-off levels in use as well as of the criteria that govern which women are screened and which are not. At best, studies are based upon follow-up of cohorts that are all subject to testing within the same protocol.

Geographical variations in the definition and incidence as well as changes in definition and screening attitudes over time are also to be taken into consideration when making comparisons between places and periods. Long- and short-term consequences for the baby have been identified, and in some countries, the focus of the diagnosis of gestational diabetes has now shifted from the likelihood of progression to later chronic diabetes in the mother to the outcome of pregnancy, a shift that also has consequences on the diagnostic criteria. Since obesity is associated with a highly increased risk of type 2 diabetes as well as gestational diabetes, a number of women would only be diagnosed during pregnancy, and the two types of diabetes would then be confused. However, since both types of diabetes increase the risk of pregnancy complications (such as pre-eclampsia) and adverse fetal outcome, this may not be a major problem, depending on the specific purpose of the study. When studying pre-eclampsia, for instance, there are situations where it would be advisable to exclude women with preexisting diabetes but not those with gestational diabetes (which shares with pre-eclampsia obesity as a risk factor and, possibly, other predictors), and this may prove difficult to do. If and how much of an impact this could have on the estimates will, once again, depend on the specific situation and will in many cases be hard to evaluate.

45.9.4 Pregnancy-Induced Hypertension and Pre-Eclampsia

45.9.4.1 Definition and Diagnosis

In the first trimester of pregnancy, blood pressure is usually reduced from normal values. In many women, however, blood pressure increases around mid-pregnancy to values above normal. A modest degree of hypertension is thus a rather common condition of pregnancy and has not been consistently associated with unfavorable outcomes.

Pre-eclampsia is, on the other hand, one of the most common and potentially severe complications of pregnancy. In pre-eclampsia, maternal blood pressure can increase dramatically, and the heart, brain, and kidneys may be severely damaged. If the mother survives, the affected organs usually return to normality shortly after delivery, but long-term morbidity can persist, and pre-eclampsia can be fatal. If seizures occur, the disease is called eclampsia (a very rare occurrence in countries with well-functioning health-care systems) and the risk for both the mother and the fetus is then much higher. While eclampsia is a dramatic event that is probably rarely misclassified, pre-eclampsia is, by definition, much more elusive. In most countries, it is currently defined as the concurrent presence of hypertension and proteinuria. Gestational hypertension is defined as either a persistent rise of 25 millimeter mercury in systolic blood pressure during pregnancy compared to pre-pregnant values (if the pre-pregnant values are not known, a systolic blood pressure of 140 mmHg or higher) or as a rise of 15 in diastolic blood pressure (DBP) (or as a DBP above 90). The definitions of gestational hypertension do, however, vary geographically. For the disorder to be called pre-eclampsia, hypertension must be accompanied by a specified level of proteinuria. The degree of severity depends on the values of blood pressure and the amount of protein loss, as well as on additional signs and symptoms, often including edema. Previously, pre-eclampsia was defined by the concomitant presence of two out of three symptoms (hypertension, proteinuria, and edema), but the definition has since changed to be restricted to cases where both hypertension and proteinuria are present at the same time, as edema was too unspecific. The problem with this definition is, however, that a mild state of hypertension is common in pregnancy and, often, the pre-pregnant values are not known. What is termed mild pre-eclampsia may thus, in some cases, be nothing more than a change in values of blood pressure and proteinuria within the norm. Sometimes, changes in these values may be severe enough to qualify for the diagnosis, but they will escape detection. Furthermore, some women become nervous when their blood pressure is taken in a clinical setting and may thus end up being classified as hypertensive due to a temporary and harmless rise in blood pressure ("white coat" hypertension). On the other hand, a number of cases may be missed by applying the definition, either because of ignorance of the baseline pre-pregnancy values or because women do not have their blood pressure measured at the moment of the increase, and, if there are no severe symptoms, the diagnosis will never be made. In severe cases, women become very sick and there is little doubt about the diagnosis, but these cases are the minority.

The reported incidence of pre-eclampsia appears to vary widely across places, from an estimated 2% to approximately 8%. This variation may reflect real variations in susceptibility and determinants across populations, but it almost certainly also depends on the sources of information for the diagnosis as well as on the access to prenatal care and the problems mentioned above.

The only known "cure" for pre-eclampsia is to end the pregnancy, as the placenta appears to be the organ that causes the disease, and pre-eclampsia is therefore the major cause of iatrogenic preterm delivery.

45.9.4.2 Pathophysiology of Pre-Eclampsia

In normal pregnancy, the maternal spiral arteries are modified and penetrate deeply into the decidua (first trophoblastic invasion) and, around the 16th to 18th week, into the myometrium (second trophoblastic invasion). The invasive trophoblast enlarges the vessels from within, and a fibrin substance that renders the vessels flaccid and unresponsive to maternal vasoconstriction replaces the vessels' internal lining. In pre-eclampsia often, but not always, the second trophoblastic invasion does not occur, or occurs only to a very modest degree (Salas 1999; Roberts and Lain 2002), resulting in placental perfusion being severely compromised because the arteries are narrow and with a high resistance, instead of being wide, low-resistance vessels, as they would be if the invasion had proceeded normally.

Haig (1993) expresses the view that hypertension in pregnancy is a fetal adaptive mechanism. Because of the structure of the modified spiral arteries, maternal ability to control the blood flow to the placenta is limited, and the placental site is characterized by low resistance to blood flow. Thus, for any given resistance of the placental unit, a compensatory rise in the maternal peripheral blood pressure will increase the blood flow to the placenta. According to Haig, this may be a sign of a feto-maternal conflict, where the growing fetus is able – by some unknown mechanism – to increase maternal blood pressure and thus increase the placental blood flow. Drug-induced reduction of mean arterial pressure may be associated with a reduction in fetal growth (von Dadelszen et al. 2000).

Pre-eclampsia is not, however, always accompanied by defective placentation and is, most likely, a common syndrome resulting from heterogeneous causes (Ness and Roberts 1996). It is believed that large placental mass (as seen in multiple pregnancies) and endothelial disease (as seen in diabetics) are mechanisms that can also produce placental hypoperfusion and start the cascade of events that leads to pre-eclampsia (Salas 1999).

45.9.4.3 Known Predictors of Pre-Eclampsia

The etiology of pre-eclampsia is mostly unknown, although understanding of the pathophysiology of pre-eclampsia has progressed dramatically in the last few decades. This disorder is one of the most tantalizing mysteries of reproductive epidemiology. The best-known predictors are multifetal pregnancies, nulliparity, obesity, and some maternal disease (such as kidney disease or diabetes), while smoking is protective for reasons unknown, although several hypotheses have been raised to explain this association (Condé-Agudelo et al. 1999). Africans and African Americans appear to be at a higher risk, possibly because susceptibility to pre-eclampsia is related to susceptibility to cardiovascular disease (Roberts and Lain 2002). One study suggested that women giving birth preterm with pre-eclampsia were at a higher risk of later death from cardiovascular disease, while women giving birth at term with pre-eclampsia had no increased risk compared with non-pre-eclamptic women (Irgens et al. 2001). A meta-analysis of studies of cardiovascular *sequelae* in women who have experience pre-eclampsia suggested an elevated risk, which further increased with the severity of pre-eclampsia (McDonald et al. 2008). Whether pre-eclampsia is an early manifestation of a predisposition to cardiovascular disease or, instead, it is a contributing cause is not clear.

Several trials have addressed the association between pre-eclampsia and dietary factors, mostly calcium, magnesium, antioxidants, and fish oil. Unfortunately, no clear answer has emerged from these studies, except for the finding that calcium appears to be protective among women with a very low baseline intake or for women with a very high risk of pre-eclampsia (Villar and Belizan 2000). In general, however, the attempts to prevent pre-eclampsia through dietary supplements or aspirin have been overall disappointing (Sibai 1998; Dekker and Sibai 2001). A Cochrane review in 2006 examined trials where at least 1g daily of calcium was administered to pregnant women, who had a generally low calcium intake, and indicated that calcium reduced the risk of pre-eclampsia as well as the risk of a composite outcome (death or serious morbidity) (Hofmeyr et al. 2006).

It is well accepted that a genetic component to pre-eclampsia exists, since children born of pre-eclamptic pregnancies are themselves at a higher risk of having children born of pregnancies with pre-eclampsia (Esplin et al. 2001; Skjaerven et al. 2005). Also, among males who have a child with a woman different from the one with whom they had previously had a child have almost twice the risk of having their subsequent partner also developing pre-eclampsia, compared to males whose previous partner had not had pre-eclampsia (Lie et al. 1998).

A large number of biomarkers and genetic factors have been explored as predisposing to pre-eclampsia (Broughton Pipkin 1999; Roberts and Cooper 2001). Genetic studies on pre-eclampsia have not consistently revealed a specific genotype associated with pre-eclampsia, although women with pre-eclampsia are more likely to have a heterozygous factor V Leiden mutation and other thrombophiliac mutations (Alfirevic et al. 2002). Not all researchers agree on the role of thrombophiliac mutations (Livingston et al. 2001), however.

Reduced levels of placental growth factors (PIGF) and elevated levels of markers predictive of pre-eclampsia, soluble fms-like tyrosine kinase 1 (sFlt-1), which binds to the placental growth factor (PlGF), predict the subsequent development of pre-eclampsia (Levine et al. 2004). Soluble endoglin, another antiangiogenic protein, acts together with sFlt-1 to induce a pre-eclampsia-like syndrome in pregnant rats, and a study indicated that the risk of pre-eclampsia was greater among women in the highest quartile for both biomarkers, but among those in the highest quartile for either biomarker alone (Levine et al. 2006). Soluble Flt-1 (sFlt-1) causes endothelial dysfunction by antagonizing vascular endothelial growth factor (VEGF) and placental growth factor (PlGF). VEGF maintains endothelial health in several tissues, including the kidney, and, in normal pregnancy, the placenta produces only modest concentrations of VEGF, PlGF, and soluble Flt-1 (Karumanchi et al. 2005). Makris et al. (2007) reported a syndrome analogous to human pre-eclampsia and an increase in circulating sFlt-1 in non-human primates after induction of utero-placental ischemia, suggesting that placental ischemia is sufficient to induce pre-eclampsia as well as elevated sFlt-1 (Karumanchi and Epstein 2007). Interestingly, sFlt-1 levels appear to be lower throughout pregnancy in smokers compared with non-smokers, and smokers also differed from non-smokers between the 10th and 20th week of gestation in levels of PIGF (higher) and soluble endoglins (lower), so the observed protective effect of smoking on pre-eclampsia may occur through some effect of nicotine on angiogenic proteins (Levine et al. 2006).

45.9.4.4 Methodological Challenges in Studies of Pre-Eclampsia

Although pre-eclampsia is probably the most studied among all pregnancy complications and keeps fascinating researchers from many areas of medicine, several difficulties face the investigators, mainly because of the difficulty of accurately identifying cases in sufficient numbers, without incurring selection problems. Research based upon nationwide hospital registries can provide population-based data that may, however, be of limited quality if the only available information is the code according to the International Classification of Diseases. The advantages of these studies are that women are most likely unselected and that the numbers will be large enough to allow studying even relatively rare predictors or outcomes. In some cases, these studies might be the only viable option. If, to improve the quality of the data, researchers restrict their case series to severe pre-eclampsia only, then the numbers will be dramatically reduced, but, possibly, fewer false positives will be included.

On the other hand, studies of the case-control type where medical charts are available would provide a much better case series if proper diagnostic procedures can be applied to document the disease, whereas problems may exist in recruiting a sufficient number of controls retaining a sufficient confidence that self-selection will not bias the study. If the women who accept to enter the study as controls do so according to the exposure under study, this will produce biased estimates to an extent that is often impossible to judge. Since pregnant women are invited to lead a healthy lifestyle for the sake of the baby if not their own, it is likely that some women whose pregnancy went well but whose habits were not "beyond reproach" would be relatively unwilling to take part in a study where such behaviors would be questioned. On the other hand, women who had a negative experience may be less reluctant to be under scrutiny, because they want to know what went wrong. However, problems in studying pre-eclampsia go well beyond the objective difficulties of appropriately defining cases or of finding unselected study populations.

Pre-eclampsia is a cause of preterm delivery, mostly iatrogenic. This fact complicates the interpretation of studies attempting to evaluate whether pre-eclampsia is associated with conditions that are more common in babies that are born preterm, such as cerebral palsy. Some studies have reported that babies of pre-eclamptic pregnancies were protected from cerebral palsy when the risk was examined by gestational week at birth (Gray et al. 1998; Murphy et al. 1995). Is this a protection conferred by pre-eclampsia, or is it an artefact due to the fact that the causes of preterm delivery in pre-eclamptic pregnancies differ from those of other preterm deliveries, where the causal factors may more frequently also be a cause of cerebral palsy? Because babies born preterm for causes other than pre-eclampsia have different pathologies that resulted in their early birth, disentangling the effects of preterm birth from its causes is a major challenge, as is examining the various causal paths leading to preterm birth that may very well be implicated in the diseases "associated" with preterm birth. Also, many cases of pre-eclampsia are delivered by emergency caesarean section, and the delivery complications due to caesarean section are generally different from those arising from vaginal deliveries, as several spontaneous preterm births will be. If complications that can arise from vaginal delivery were associated with cerebral palsy or other health problems (e.g., anoxia), then comparison of babies born of pre-eclamptic pregnancies with babies born of non-pre-eclamptic ones will be problematic.

Another problem has to do with studying pre-eclampsia in connection with other conditions or factors that are associated with preterm delivery. If a given factor causes preterm delivery, it may also appear to protect from pre-eclampsia simply because women with a shortened pregnancy have had less opportunity of developing it, since pre-eclampsia often occurs after the 36th week of gestation, but being pregnant (or just delivered) is a necessary condition for being diagnosed with it. If the date when pre-eclampsia was first diagnosed is known, data may be analyzed through Cox regression or survival methods to overcome this problem (for a general introduction to survival analysis, see chapter ►Survival Analysis of this handbook).

Beyond preterm birth, babies of pre-eclamptic pregnancies are at higher risk of fetal and neonatal death. However, the risk of stillbirth has declined over time, probably due to increased monitoring of pregnancies and earlier obstetric intervention. At least in Norway, however, the risk of neonatal death has increased only slightly among first-born babies of pre-eclamptic pregnancies, despite a marked increase in the rate of babies born before 32 weeks among pre-eclamptic mothers (Basso et al. 2006b). Babies of pre-eclamptic pregnancies are usually smaller on average than babies of normotensive pregnancies, at least if born by 37 weeks, while they are of comparable (or even larger) size thereafter (Xiong et al. 2002).

If an important confounder is systematically omitted when studying a given disease, this will lead to the potential establishment of a wrong conclusion (cf. chapter ▶Confounding and Interaction of this handbook). For example, a widespread hypothesis about the etiology of pre-eclampsia proposes that a maternal immune reaction to paternal antigens could be a cause of the failed trophoblastic invasion. This hypothesis was mainly based on the observation that pre-eclampsia is more frequent in first pregnancies. Among multiparous, women who had changed their partner from the previous pregnancy had an increased risk (Dekker et al. 1998; Dekker 1999; Trupin et al. 1996; Lie et al. 1998; Li and Wi 2000). Also, women with a long period of sexual cohabitation prior to a pregnancy and women using oral contraceptives appeared to be at a lower risk of pre-eclampsia than women with a short cohabitation period or those using barrier contraceptive methods (Robillard et al. 1994; Dekker et al. 1998). This suggested that a prolonged exposure to the partner's sperm may confer a protection that would reduce the risk of pre-eclampsia, thus leading to the notion that "primipaternity" was a risk factor for pre-eclampsia. For some researchers (including the authors of this chapter), however, this hypothesis has lost its plausibility since three studies (two based on the Norwegian Birth Registry (Skjaerven et al. 2002; Trogstad et al. 2001) and one based on a sample from the Danish Birth Registry (Basso et al. 2001)) independently reported that the increased risk of pre-eclampsia with change of partner disappeared if the interval between births was adjusted for. Women who change partner have, on average, a much longer interval between births: if any factor correlated with time has an impact on the risk of pre-eclampsia, then women waiting a longer time will have an increased risk, regardless of whether they change partner. This was found to be true in the abovementioned studies, even after maternal age was controlled for. This finding prompted a further study where time to pregnancy was investigated in association with pre-eclampsia, as a fraction of the women waiting a long time between pregnancies may be subfecund. Time to pregnancy, as previously mentioned, is a proxy for the couple's fecundity and thus a relatively crude marker, since it reflects a multitude of disorders. It is, however, interesting that an association between long time to pregnancy and pre-eclampsia could be observed despite these limitations (Basso et al. 2003), and this evidence may lead to further research for identifying a subgroup of infertile women with a specific disorder that relates to pre-eclampsia.

Pre-eclampsia is most likely the result of an interaction between the maternal and the fetal systems, but its diagnosis relies exclusively on symptoms that are observed in the mother. It is perhaps for this reason that, so far, pre-eclampsia has eluded most attempts to clarify its etiology, despite substantial progress in the understanding of its physiopathology in recent years.

45.10 Delivery Complications

Delivery complications may arise before or during delivery and present a risk for the mother and/or the baby. Some of the risks have to do with the fetus's presentation or its inability to pass through the birth canal. Unlike the other great apes, humans have very difficult deliveries, largely due to the tight fit of the infant's head in the mother's birth canal. This difficulty has to do with the rearrangements of the pelvis in humans to accommodate bipedalism as well as with the disproportionately large head of human infants (Trevathan). Until less than a century ago, obstructed labor was the major cause of fetal and maternal morbidity and mortality. Because of malnutrition, many women had underdeveloped pelvises and the baby's head would remain trapped in the birth canal. Nowadays, fetal or maternal death because of this is a very rare event in industrialized countries but still a major problem in developing countries, where most babies are delivered at home and hospitals are far away and may lack adequate resources. The three major causes of maternal mortality in developing countries are hemorrhage, sepsis, as well as hypertensive disorders, and the first two usually result from delivery complications.

Beyond fetal presentation (and position) and feto-pelvic disproportion, delivery complications also include weak contractions, prolonged labor (of any of the three stages), prolapse of the umbilical cord, perineal or vaginal tears, fetal asphyxia, retention of the placenta, and hemorrhage. Caesarean sections, which account for between 15% and 30% of all births, depending on countries, constitute perhaps the major difficulty when studying delivery complications. Caesarean sections can be planned or acute, and the latter could be started before delivery or during delivery. Emergency caesarean sections, themselves considered a "delivery complication," are triggered by complications arising in the mother or the fetus.

In the case of delivery complications even more than in other cases, researchers have to study what is left after physicians have acted. Therefore, only babies being born vaginally will be at risk of having specific accidents during their descent through the birth canal, accidents that may affect the supply of oxygen to the brain. This would not be a problem if the decision of delivering a woman by caesarean section were independent of any factors that may put the baby at higher risk of encountering such mishaps, but – usually – this is not the case. Since the relative size of the mother and the baby or signs of fetal distress may well trigger the decision of performing a caesarean section, it is likely that babies born vaginally and those born by caesarean section are not completely comparable before delivery, which will complicate any interpretation of findings associated with a given delivery complication. This will also complicate any study trying to evaluate the "effects" of any given intervention during delivery, as it will be difficult to separate the effects of the intervention from the causes that provoked it, which may also be the causes of the outcome of interest. Even restricting to planned caesareans may not be sufficient to solve the problem, as caesareans are planned for a reason, and a likely reason is that a complication is foreseen and a caesarean section may prevent it from occurring. Experience in previous pregnancies will also affect the mode of delivery. A woman who has previously delivered by caesarean section will, in many cases, have one also for her next delivery, especially if the two pregnancies are close in time. Since many events tend to repeat themselves in one woman's reproductive life, it will be hard to decide how to consider such women in a study, especially if the cause for the previous caesarean is not known.

A caesarean section is the preferred choice of delivery mode for an increasing number of women, and immediate risks appear to be few. Only little is, however, known about long-term effects, and recent results suggest that the risk of asthma may be increased (Kero et al. 2002), although recent findings have shown conflicting results.

Obstetric complications have been associated with schizophrenia (Geddes and Lawrie 1995; Verdoux et al. 1997), and hypoxia correlates with cerebral palsy (Blair and Stanley 1993). Anoxia or hypoxia will most likely cause cerebral damage, and it is reasonable to assume a causal link. But it may also be argued that a baby who had brain damage (which will later cause cerebral palsy) prior to birth will be more likely to have a complicated delivery and suffer from anoxia.

In general, if one wishes to study a delivery complication that may, in some cases, lead to a caesarean section (or to induction of delivery), it will be necessary to have information on why the caesarean section was performed. Practice of caesarean section, induction of delivery, instrumental birth, etc., change between geographical areas and in time, and dealing with these variations may prove a daunting and perhaps impossible task. Usually, many elements are used in the decision to treat and intervene, and it may just be impossible to identify all these elements and appropriately control for them in the analysis. Confounding by indication is one of the strongest arguments for evaluating treatments in randomized trials, which, however, will often be difficult to carry out in this context.

Since the practice of inducing birth (also by means other than caesarean section) is now widespread, with criteria for induction that often differ from one hospital to the other, it will always be difficult to study either induction itself or phenomena such as postterm delivery or macrosomia, even when good information about the causes of the induction are present.

If preterm babies are at a higher risk of incurring delivery complications, it may be this latter fact rather than the timing of birth that makes them at higher risk of several diseases. On the other hand, if some babies who are born preterm are born early because of some damage that will later cause the disease and makes them at higher risk of delivery complications, then delivery complications will spuriously appear to cause the disease.

45.11 Fetal Origins of Adult Diseases

Most reproductive epidemiology has been related to the time period from pregnancy planning to the early time period of a new life. Many diseases are now seen as trajectories that start at the time of conception, during pregnancy, or in early childhood. Obviously, studying exposures with an induction and latency time of causation spanning several decades raises severe problems of being able to control for intervening factors. Without longitudinal readings of the occurrence of possible confounding factors that may be affected by the exposure of interest, such studies may yield confounded results.

It is not unexpected (or even questionable) news that exposures during fetal life may have lasting effects. What is new is that prenatal exposures may cause diseases that surface to clinical detection long after birth, perhaps even as late as in the following generations. Fetal programming is the name that has been used to describe what could happen if a stimulus or insult at a critical period of organ development interferes with cell division and thus with the function of the affected organ. Permanent changes of organ function could, in principle, lead to many diseases (Olsen 2000), but best documented are the associations between origins of disproportional fetal growth and cardiovascular diseases, perhaps through insulin resistance (Barker 1994, 1995, 1998).

Although the brain is, to some extent, spared in periods of undernutrition, specific nutritional factors, stress, medicine, etc., may influence brain function. Studying determinants of brain function and brain pathology in fetal life is a high priority research area.

Hormonal factors during fetal life may not only affect the reproductive organs but could also be associated with other diseases, such as mental disorders or cancer of the breast, prostate, and testis. As early as 1990, Trichopoulos suggested that breast cancer might originate in utero. It was suggested that estrogen could play a role, and, since estrogen correlates with fetal growth, it is expected that rapid fetal growth could be associated with a higher risk of breast cancer five or more decades later. The hypothesis has, to some extent, been corroborated (McCormack et al. 2003), but we still lack cohort data of sufficient follow-up time with valid exposure data from the time of conception.

The role of infections during pregnancy is also an area of intense research activity, especially related to mental and neurological disorders (Xiao et al. 2009; Zhu 2009; Mortensen et al. 2007; Sørensen et al. 2009; Sun et al. 2008).

45.12 Sources of Data

As in other areas of epidemiology, data come from different sources: secondary routine data, or ad hoc data based upon self-reported information, information from clinical measures, or information extracted from biological samples – blood, urine, placenta tissue, etc. (Longnecker et al. 2001).

More secondary data are available in reproductive health than in most other epidemiological areas. Most pregnant women and most newborn children are carefully monitored, and data are stored in medical records or even in computerized birth registers that may include not only birth endpoint data but also exposure data such as smoking and medical treatment (Ericson et al. 1999).

The data that usually have to be collected for research are those that describe putative causes of reproductive failures. Many of these exposures have to be collected prospectively, since they are often forgotten or cannot be reconstructed in an unbiased way back in time, once the outcome of the pregnancy is known. This is often true for dietary factors, medical treatments, occupational exposures, etc. Data on infections, occupational exposures, lifestyle factors, dietary factors, etc., cannot be recalled for more than a few weeks or perhaps months, unless they tend to change little over time. Usually, the mother is, not unexpectedly, a better source for data on pregnancy and birth than the father (Coughlin et al. 1998).

For these and other reasons, it seems justified to set up large cohort studies, starting shortly after conception and with the aim of collecting exposure information during pregnancy. It is also necessary to establish cohorts that can be followed over long time periods, the best case scenario being from conception to death, including information on the offspring of the children born into the cohort. These cohorts need to be large to provide sufficient information for rare outcomes, such as congenital abnormalities. Large cohorts of this type were set up in the past, and the best known is probably the National Collaborative Perinatal Project from the USA, started in the late 1950s, where more than 50,000 pregnant women were enrolled. The cohort aimed at studying obstetrical complications and the risk of cerebral palsy and other neurological disorders, although the cohort has served many other research purposes since then.

The Danish National Birth Cohort (DNBC) enrolled 100,000 pregnant women from 1996 to 2002 (Olsen et al. 2001; Statens Serum Institut 2013, www.dnbc.dk) and included data from interviews, registers, and self-administered questionnaires, together with blood from the mother and child stored in a biobank (Statens Serum Institut 2013, www.bsmb.dk). In this cohort, there is an ongoing follow-up of children and parents based upon record linkage. More detailed data are collected when the child reaches 7 and 11 years of age. Similar studies have been done in Norway and China and are being conducted in other countries (Birthcohorts.net 2011).

45.13 Conclusions

In this chapter, we have tried to highlight some of the main features of reproductive epidemiology as we see them. In particular, the fact that reproduction, even in our medicalized world, is a direct result of selective processes, which are still active. In addition, most of the events that we study in this area are what is left after the selection of couples who succeeded in conceiving, and further selection of those conceptions will progress to clinical recognition and, potentially, medical intervention, which may lead to anticipated delivery, termination of pregnancy, or treatment of a disorder. For this reason, denominators are usually unknown. Furthermore, the processes that occur during a pregnancy that ends in a birth are usually also hidden, and therefore we do not really know what has happened to the fetus during the most delicate phases of development.

Any event in reproduction generally concerns two individuals rather than one (three when counting the father). In many instances, pregnancies are voluntary events, and many women have more than one pregnancy, although the decision to have further pregnancies often depends to some extent on the outcome of the previous ones and almost all adverse outcomes have a relatively high recurrence risk. Time is also of crucial importance when dealing with reproductive epidemiology, but its dimension is generally different from the time involved in the development of, say, cancer after exposure to a given mutagenic substance. The types of bias that can occur in this area are, in many cases, peculiar to this discipline, and they have to be taken into consideration.

Genetic and functional genetic studies are playing an increasing role in this field of study. We know now that gene expression is modified by epigenetic changes that provide room for "programming" health later in life (Foley et al. 2009). Although we may not be able to answer the big questions, such as how the entire process of organ development is coordinated, finding answers to less broad questions is of interest. We need to know much more about genetic and gene-environment interaction, as well as epigenetics, not only in the development of congenital malformations and childhood cancers but also for long-term organ programming (for an introduction to genetic epidemiology, see chapter ▶Statistical Methods in Genetic Epidemiology of this handbook). Using information on genetic factors in, e.g., metabolism of environmental exposures, such as alcohol, may even be of help in examining confounding. How much of the association between, e.g., alcohol and reproductive failures is due to confounding cannot be examined in a randomized trial, but the genetic factors that modify alcohol metabolism may follow "Mendelian randomization" and thus provide a design for comparison that bypasses some of the problems associated with the intercorrelation between lifestyle factors (Smith and Ebrahim 2003, 2005).

The peculiarities of reproductive epidemiology offer a number of opportunities to researchers willing to exploit them. We have tried to introduce readers to a number of the features that make this area of epidemiology exciting, vibrating, and fairly unique.

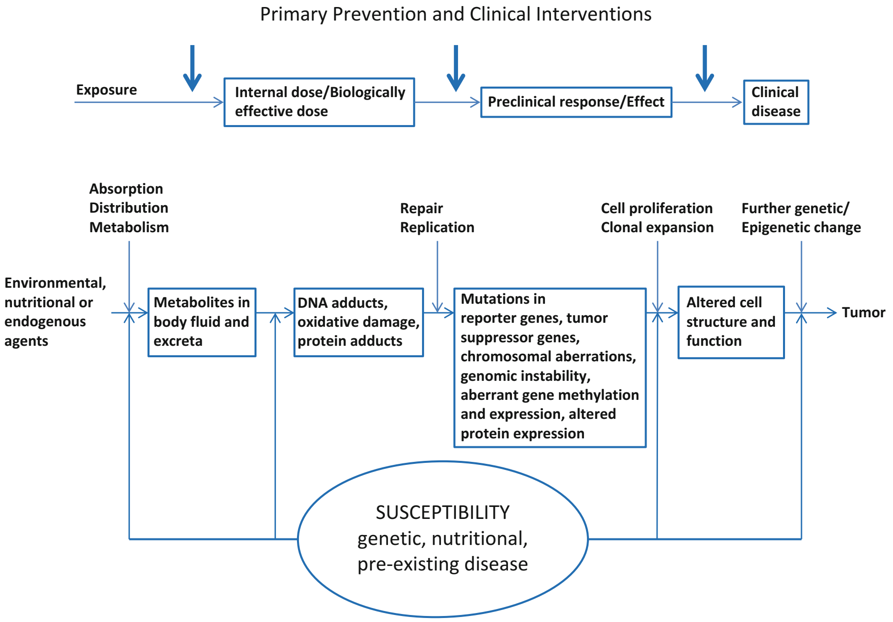
46.1 Introduction

Molecular epidemiology can be defined as the application of the techniques of molecular biology to the study of the epidemiology of disease in human populations. Molecular investigations, as we will see, have several aims and can contribute to the elucidation of disease etiology. In molecular epidemiology, the study of the determinants of disease focuses on causative, protective, or predisposing factors (including infectious agents and a variety of environmental exposures such as chemical or physical agents and lifestyle habits) and host characteristics such as genetic susceptibility. These studies are performed at the molecular level using the techniques of molecular biology.

Markers used in molecular epidemiology are usually divided into the three categories: *markers of exposure, markers of biological effect, and markers of susceptibility* (Vineis and Perera 2007). The underlying concept is that there is *continuity* between exposure to a toxic agent (such as carcinogens), metabolism (activation or deactivation), adduction to proteins or deoxyribonucleic acid (DNA) (i.e., formation of links by active metabolites), DNA alterations (such as mutations or chromosome damage), onset of disease, and finally, progression of disease. These concepts are schematically represented in Fig. 46.1, from Vineis and Perera (2007).



Primary Prevention and Clinical Interventions
Exposure
Internal dose/Biologically effective dose
Preclinical response/Effect
Clinical disease
Absorption
Distribution
Metabolism
Repair
Replication
Cell proliferation
Clonal expansion
Further genetic/
Epigenetic change
Environmental, nutritional or endogenous agents
Metabolites in body fluid and excreta
DNA adducts, oxidative damage, protein adducts
Mutations in reporter genes, tumor suppressor genes, chromosomal aberrations, genomic instability, aberrant gene methylation and expression, altered protein expression
Altered cell structure and function
Tumor
SUSCEPTIBILITY
genetic, nutritional,
pre-existing disease

Fig. 46.1 Updated model for molecular epidemiology – large arrows indicate points for intervention (Adapted after Vineis and Perera (2007))

In contrast to classical epidemiology, molecular and genetic epidemiology enhances the understanding of the pathogenesis of disease by identifying specific molecular pathways and specific molecules and genes that influence the risk of developing disease. For example, genetic markers rather than surrogate information (i.e., positive family history) might more precisely characterize host susceptibility. Molecular epidemiology can also improve the validity of and reduce bias in the assessment of environmental exposures. It can help to evaluate markers at the subclinical level, very early during disease onset. Molecular epidemiology provides tools to ultimately reduce or clarify heterogeneity within a disease, such as the development of breast cancer subtypes (i.e., basal, luminal A, luminal B, normal breast-like, and ERBB2+ (Kapp et al. 2006)). However, most of the expectations stemming from molecular epidemiology need to be carefully verified in well-designed studies.

Not all molecular biology markers are suitable for molecular epidemiology studies as many are extremely labor intensive and/or expensive to use. It is critical to test all laboratory techniques, but even more so those used in molecular epidemiology studies, for their validity, sensitivity and specificity, and variability within and between laboratories before using them in an epidemiological setting. Access to appropriate biological specimens, ethical issues, and costs are also important considerations in molecular epidemiology.

This chapter includes an introduction to the main features of molecular epidemiology and sections addressing biomarkers of exposure and effect, host susceptibility, issues in using biomarkers in epidemiology, common study designs, risk assessment, and the use of biorepositories. The concept of Mendelian randomization will be also introduced describing the use of genetic markers to better address possible bias and confounding in exposure assessment. This chapter is meant to present an overview; the authors refer the reader to the book edited by Wild et al. (2008) for more detailed explanations of the topics discussed here.

Critical issues in molecular epidemiology include those relevant to any epidemiological study but are particularly important in molecular epidemiology: an appropriate study design, careful attention to sources of bias and confounding, and the development of markers that can be applied on a population scale. The study design is particularly important because past research that applied laboratory methods to human populations was often based on “convenience samples” – that is, groups of patients recruited in the most comfortable efficient way without a proper design – that were frequently affected by bias.

Study design is thoroughly covered in several chapters of Part I (Concepts and Designs in Epidemiology) of this handbook. Within this chapter, we will focus on specificities of molecular epidemiology. Important issues associated with epidemiological studies, such as confounding and interaction (see also chapter ▸Confounding and Interaction of this handbook) and measurement error (see also chapter ▸Measurement Error of this handbook), are dealt with in detail in this book.

46.2 Classes of Biomarkers

46.2.1 Biomarkers of Exposure

The International Programme on Chemical Safety (IPCS 1999) defines human exposure as any contact with chemical, physical and biological agents. Molecular epidemiology studies seek to establish causality and biological plausibility for associations between exposure and disease (Wild 2009). Exposure assessment is one aspect of this continuum, and biomarkers of exposure may contribute to this assessment by providing more precise information related to the exposure-disease association. Chapter ▸Exposure Assessment of this handbook gives a thorough explanation of the definition, data, assessment, and the role of measurement error in exposure assessment. The role of exposure assessment in molecular epidemiology is thus only briefly described here.

Molecular epidemiology utilizes biomarkers to refine exposure assessment in the face of the complexity of distinguishing between the contribution of environmental and individual factors to disease etiology (Wild 2009). Validated biomarkers have the potential to provide measurements at the individual level that are relevant to events on, or related to, the causal pathway and information applicable to the biological plausibility of an exposure-disease association. For example, in the field of virology, antibodies have long been used to identify the type of virus that a person has been infected with. Further, the measurement of accumulation of chemical agents or metals in biological tissues like arsenic in hair or mercury in fingernails and toenails provides direct measurements of an exposure at the individual level.

Using sensitive laboratory technologies, biomarkers of exposure can detect low levels of exposure. Although these biomarkers are usually designed to measure exposure to environmental toxicants, they can also identify levels of ingested dietary components, bacterial and viral infections, as well as serve as endpoints in the determination of the success of intervention strategies.

Biomarkers of exposure are classified depending on what they measure, either an internal dose such as serum vitamin D or a biologically effective dose (i.e., a dose that causes DNA damage). Internal dose biomarkers measure the presence of environmental chemicals and their metabolites in human tissues, excretions, and/or exhaled air. Additionally, measurements can be made using dietary biomarkers either as “recovery” biomarkers, such as measurements of sucrose and fructose in 24-hour urine samples to directly assess sugar consumption, or “concentration” biomarkers, such as serum carotenoids, which are related to dietary intake but only indirectly because their levels are the result of complex metabolic processes. Exposure biomarkers can also be applicable in intervention strategies aimed at primary prevention or mechanism-based approaches like chemoprevention, that is, biomarkers can be used as endpoints to measure the success of the intervention. The utility of such biomarkers is limited to the availability of detectable levels of the compound, its metabolites, and/or antibodies and proteins, discussed below.

Although biomarkers of exposure are often described as a separate topic from biomarkers of effect, many actually overlap and can be utilized as both. This overlap can be attributed in part to the fact that the biomarkers provide information related to both endpoints. In addition, the same tissue(s) and/or cells may be used, for example, lymphocytes can be a surrogate for exposure and also a target for the exposures' effect.

46.2.2 Biomarkers of Effect

Biomarkers of effect measure the interaction between an agent and/or its metabolites and target cell(s) or molecule(s); they are defined as "measureable changes in the organism" (IPCS 1999). This definition also includes markers of effect that can indicate a preclinical response not always detectable using conventional clinical diagnostic tools. Early effects within an individual may also be used as informative markers of disease risk. Several molecular-based assays have been developed to identify cellular response(s) stimulated by such exposures. Some of these assays are listed in Table 46.1, and their utility as a marker of both exposure and effect is discussed.

Biomarkers of a biologically effective dose measure the amount of the agent reaching a critical cellular target, such as DNA adducts or the amount of a chemical agent bound to a cellular receptor. Other markers of effect measure the damage that is induced by the agent. For example, in the case of a biologically effective UV dose, UV-induced DNA damage is measured, and the type of damage can be further characterized by the wave length, that is, DNA damage from UVA exposure induces base excision repair, while UVB exposure induces nucleotide excision repair. Biomarkers of DNA damage include mutations, adducts, chromosomal aberrations, micronuclei, DNA strand breaks, and sister chromatid exchanges, among others. Additional examples of biomarkers can be found in Box 46.1 which provides a list of measures used in molecular epidemiology that is organized by biological tissue.

46.3 Biomarker Selection

There are several issues to consider when identifying candidate biomarkers. In the case of molecular epidemiology studies that evaluate biomarkers, the prevalence of the biomarker of interest in the population being studied should be known. The ability of the biomarker to represent the agent of interest and the specificity and sensitivity of the biomarker to detect low levels of exposure are additional factors to take into consideration when selecting appropriate biomarkers of exposure. Additionally, the validity of the biomarker, defined as the lack of systematic measurement error when compared to a standard reference, must be established. Epidemiological studies utilizing biomarkers must take into account that environmental exposures will vary qualitatively and quantitatively over time.

Table 46.1 Examples of laboratory measurements that can be utilized as biomarkers of exposure and effect

Marker	Description	Biomarker of exposure	Biomarker of effect
Measurement of genetic alterations			
DNA damage (Olive and Banath 2006)	Comet assay – lymphocytes are treated and run out on a gel; DNA from the cell “migrates” to form a “tail.” The length of the tail is proportional to the amount of DNA breakage	Measures DNA damage as a result of exposure, without time for repair	Cells are subjected to a damaging agent and allowed time to repair. Then their DNA repair capacity is measured by the length of the comet tail
Chromosome aberrations (CA) (Bonassi and Au 2002)	Detection of altered chromosome formations in blood lymphocytes	CAs are specific to the agent of exposure, allow for the ability to distinguish the type of exposure	Can predict survival of cells with certain CAs, thought to have the ability to predict cancer risk
Micronuclei (MN) (Neri et al. 2003; Bonassi and Au 2002)	Detects micronuclei after the cells have progressed past the first cell cycle, MN contain either chromosomal fragments or whole chromosomes	Useful for biomonitoring studies of exposure, including low-dose environmental exposures	Can distinguish the cause of MN formation: chromosome breakage or aneuploidy
Sister chromatid exchange (SCE) (Albertini et al. 2000)	Formation of SCEs correlates to the effectiveness of recombinational DNA repair and induction of point mutations, gene amplification, and cytotoxicity	Alterations in SCE levels may be correlated to exposure levels	Indicator of DNA damage, can evaluate altered cell viability induced by genetic defects or exogenous exposures

Hypoxanthine phosphoribosyltransferase (HPRT) (Bonassi and Au 2002)	Gene mutation assay, detects somatic mutation in this hemizygous gene in the X chromosome in post-thymic lymphocytes	Used for detection of mutation(s) in exposed populations, can evaluate the mutagenic potential of various compounds (Perera et al. 2002)	Mutation frequency has been found to correlate with the presence of DNA adducts, has also been found to correlate with exposure level (Ammenheuser et al. 2001)
Epigenetic modifications	Changes in the genome that do not involve alterations in the nucleotide sequence can be measured using various techniques	CpG-promoter sequence methylation, histone modification, and chromatin remodeling	Alterations in the balance of methylation are related to gene transcriptional silencing
Glycophorin A (GPA) gene mutations	Detects damage in bone marrow cells, damage is measured as the loss of alleles	Mutant frequency can be correlated to exposure	GPA levels can be correlated to metabolite levels
DNA adducts	Measure of DNA damage	Levels of DNA adducts can be correlated with exposure levels	Unrepaired DNA adduct levels reflect DNA repair capacity
Measurement of other biological alterations			
Transcriptomics	Detection of altered gene expression	Alterations in gene expression vary depending on the type of exposure	Changes in gene expression profiles in response to chronic exposure
Proteomics	High-throughput broad screen of proteins using mass spectrometry	Albumin and hemoglobin adducts: changes in protein structure as a consequence of exposure	Changes in protein expression as a consequence of exposure (i.e., altered growth factors and cytokines)
Metabolomics	Detection of metabolites, defining metabolic profiles to predict onset of disease	Accumulation of metabolites of exposure agents	Changes in the metabolic capacity as a consequence of exposure or disease

Box 46.1. Common biological samples used for biomarker analysis in molecular epidemiological studies, listed according to the source of the material. It should be noted that this list will continually change over time

1. DNA
   - (a) Genomic DNA
     - Single nucleotide polymorphisms (SNPs) (>1% prevalence)
     - Epigenetic modifications (i.e., methylation, histone modification, and chromatin remodeling)
     - Adducts
     - Copy-number variations (CNVs)
   - (b) Tumor DNA
     - Somatic mutations (>1% prevalence)
     - Copy-number variations (CNVs)
   - (c) Mitochondrial DNA
     - Insertions and deletions

2. RNA
   - Viral genotyping
   - Microarray chips for gene expression profiles

3. Whole cells
   - (a) Lymphocytes
     - Incorporation of damaged plasmid (host-cell reactivation assay (HCRA))
     - Comet assay
     - Hypoxanthine phosphoribosyltransferase assay in peripheral T lymphocytes (HPRT) assay
   - (b) Chromosomes
     - Cytogenetic assays to assess mutagen sensitivity (mutagen sensitivity assay (MSA))
     - Chromosome breaks and deletions (chromosomal aberrations CAs)
     - Sister chromatid exchanges (SCEs)
   - (c) Shed cells – for extraction of DNA, RNA, measurement of DNA damage, DNA repair, adducts, micronuclei, and metabolomics in:
     - Exfoliated bladder cells
     - Oral buccal cells
     - Broncholavage
   - (d) Glycophorin A (GPA) gene mutations in erythrocytes

4. Plasma/serum
   - Extraction of tumor and genomic DNA from plasma and serum
   - Measurement of indicators of immune response (antibodies, cytokines, T lymphocytes, etc.)
   - Proteomics – albumin adducts

Metabolomics
Measurement of biochemicals, i.e., vitamin D and folate

5. Red blood cells
   Hemoglobin, hemoglobin adducts, and biochemical content, i.e., folate

6. Urine
   Urinary metabolites – biochemical assays, i.e., cotinine
   Exfoliated bladder cells – for DNA, see above

7. Hair
   Biological accumulation, i.e., arsenic and cotinine

8. Fingernails, toenails
   Biological accumulation, i.e., arsenic, and mercury

Another consideration is that some biomarkers decay over their lifetime, so that the half-life of biomarkers must be considered when choosing an appropriate design for a molecular epidemiological study. Most biomarkers of exposure are transient with a relatively short biologically relevant half-life. In "traditional" epidemiology, a case-control study design is particularly useful when the disease being studied is rare and the exposure hypothesized is frequent and easily identifiable. Studies aimed at investigating cancer and other chronic diseases are usually focused on events that have taken place many years before the disease onset and often involve chronic exposures. In the molecular epidemiology of chronic diseases, the case-control approach is limited if the potential biomarker has a short half-life, that is, it refers to an acute exposure that took place a short time before disease onset. In the case of adducts, those measured in the DNA of lymphocytes have a half-life of months, and those measured in hemoglobin have a half-life of weeks. The value of DNA adducts as biomarkers is discussed in detail below. These issues demonstrate the utility of prospective studies for molecular epidemiological investigations; however, such studies are often limited in the sense that they are based on the use of a "one-time" biological sample that is not necessarily representative of the usual exposure or of changing exposures (thus, introducing misclassification, see chapter ►Misclassification of this handbook).

Biomarker validation encompasses several issues that require consideration when assessing the utility of a biomarker for a molecular epidemiological study. Analytical validity, *c*linical validity, *c*linical utility, and ethical, legal, and social implications and safeguards are often referred to as the *ACCE* evaluation of a biomarker (Vineis and Gallo 2007). The analytical validity component of this evaluation refers to the ability of a test to accurately and reliably measure the marker/genotype of interest which includes its sensitivity and specificity. The ability of a genetic test to detect or predict the phenotype is the focus of the clinical validity or the positive predictive value. The clinical utility component of this evaluation considers the risks and benefits associated with the incorporation of the test into routine clinical practice. Lastly, the ethical, legal, social implications and safeguards are other components that require consideration when evaluating the utility of a biomarker. For a more detailed description of the principles of biomarker validation, the reader is referred to the recent book edited by Vineis and Gallo (2007).

Betsou and colleagues (2009) recommended several types of assessments to evaluate the vulnerability of a biomarker to pre-analytical variation; these assessments can be utilized for determination and evaluation of candidate biomarkers to ensure that association with clinical endpoints is not due to uncontrolled pre-analytical variation. Biospecimen research focuses on artifactual variation as opposed to true variation that may compromise results; if such variation occurs before the laboratory analysis, it is referred to as pre-analytical variation (see the Sect. 46.8 of this chapter). Clearly, if serum is not handled properly, the characteristics can change quickly (e.g., vitamin C is light sensitive). Empirical biospecimen research is recommended to assess the impact of pre-analytical variation on biomarkers. Proteomic markers, for example, are particularly sensitive to the need for consistent handling, or the results are meaningless. Other sources of pre-analytical variation include the time of specimen collection, fasting conditions, the position of the patient during collection, the patient's diet, or other life habits, all of which must be considered when selecting an appropriate biomarker (Betsou et al. 2009).

The selection of an inaccurate biomarker may partly result from publication bias toward false-positive associations. There are likely many biomarkers tested but never published due to poor results. Publication bias may be a result of time-consuming and costly assays, such that manuscripts reporting positive results are more likely to be published than negative findings, although the results may have been obtained by chance due to a small sample size.

46.4 Types of Biomarkers: Examples

Technological advances continue to produce innovative molecular biological techniques. The following section describes some common molecular-based assays used in molecular epidemiological studies. Some of the biomarkers are relatively old and well established; others are novel. The descriptions of the assays below include recent validation efforts and issues to consider when employing these techniques. Table 46.1 contains examples of some of the laboratory methods described in this section.

46.4.1 DNA Adducts

Chemically induced DNA adducts are an indication of the mutagenicity of chemical agents as well as of an elevated cancer risk (Angerer et al. 2007). Studies assessing exposure to air pollution have utilized DNA damage as an endpoint (Vineis and Husgafvel-Pursiainen 2005). In particular, several studies have found an association between external measures of exposure to air pollution and increased levels of DNA adducts, with an apparent leveling off of the dose-response relationship (reviewed in Vineis and Husgafvel-Pursianinen (2005)).

The use of DNA adducts as biomarkers requires consideration of several issues: (i) reproducibility of adduct levels measured with different methods, (ii) correlation between levels of the same type of DNA adduct in normal versus surrogate tissue and/or normal versus tumor tissue, and (iii) correlation between different biomarkers of exposure. Although DNA damage is a reflection of exposure, the resulting detectable damage is influenced by inherent and acquired susceptibilities (Vineis and Husgafvel-Pursianinen 2005; Gyorffy et al. 2008).

As an example, DNA adducts and urinary metabolites have been examined to measure the correlation between polycyclic aromatic hydrocarbons (adduct) and prenatal environmental tobacco smoke (Perera et al. 2007). The study was designed to measure prenatal exposure and its effect on postnatal development.

46.4.2 Epigenetic Markers

Cancer epidemiology has traditionally focused on evaluating exposure to carcinogens by monitoring genomic biomarkers of DNA damage. Recently the focus has shifted to include biomarkers of exposure that represent changes in epigenetic mechanisms. Epigenetic modifications are changes in the genome that do not involve alterations in the nucleotide sequences and that can pass from somatic cells to their daughters. These modifications have been thought to explain the disconnection between genotype and gene expression (Vineis and Perera 2007). In particular, methylation of CpG promoter sequences (CpG sequences are areas in the genome, cytosine-guanine nucleotides separated by a phosphate, that are particularly prone to methylation), histone modification, chromatin remodeling, microRNAs, and receptor binding have been identified in cancer and used as epigenetic biomarkers of exposure and of disease susceptibility (Wild 2009).

DNA methylation is thought to play a role in suppressing gene expression subsequently affecting protein synthesis. Alterations in the balance of intrinsic methylation, such as hypermethylation of promoter regions, are related to gene transcriptional silencing, which in the case of human cancer, is a common mechanism for the inactivation of tumor suppressor genes (Robertson and Wolffe 2000). This example of gene silencing, an epigenetic alteration, demonstrates the relevance of epigenetic changes as biomarkers. Utilizing epigenetic changes as biomarkers of exposure has become a promising tool since some of the epigenetic events are reversible and can provide points of intervention for cancer prevention and therapeutic agents. Conversely, some of the epigenetic components are known to be inherited and in the context of molecular epidemiological investigations could provide an opportunity to evaluate disease susceptibility. Additional research is necessary to determine the mechanism underlying exposure-induced as well as inherent alterations in epigenetic processes which in turn alter cellular function and cancer risk (Wild 2009).

46.4.3 RNA-Based Markers

One example of an important use of RNA-based platforms to investigate a disease is that by Kang et al. (2010) in which they utilized microarray analysis to determine whether gene expression profiling could be used to improve risk classification and outcome prediction in pediatric acute lymphoblastic leukemia patients at high risk for relapse. In this study, a 38-gene expression classifier predictive of relapse-free survival which significantly enhanced outcome prediction and risk classification was identified using post treatment diagnostic samples in blood.

46.4.4 "Omic" Studies

Transcriptomics, proteomics, and metabolomics express recent advances in high-throughput technologies that have the potential to identify previously unobservable responses to exposure, assuming that the exposure of interest is reflected in the body by altered levels of specific mRNA, proteins, or metabolites, respectively. These techniques could reveal additional specific targets for exposure assessment. To mention two examples, a small pilot study evaluating prenatal arsenic exposure (Fry et al. 2007) and another one assessing tobacco smoke exposure (Spira et al. 2004) have both suggested that changes in gene expression, measured by transcriptomic technology, are related to exposure and vary depending on the type of exposure.

Proteomics The analysis of total protein output encoded by the genome is referred to as proteomics. To date, this technology has mainly been utilized to distinguish proteomic profiles between normal, benign, and disease states (Vineis and Perera 2007).

Recently, global proteomic approaches have been developed to investigate environmental exposure and subsequent biological alterations using mass spectrometry (Colquhoun et al. 2009). This high-throughput approach based on a broad screen of proteins can be utilized to identify changes in protein expression in response to exposure. Colquhoun and colleagues (2009) utilized cord blood to characterize the fetal serum proteome of infants exposed in utero to maternal cigarette smoke. In their validation study, they were able to identify candidate biomarkers that were biologically related to fetal chemical exposure where expression levels of these proteins were different from expression levels of unexposed infants. The utility of blood serum and plasma for this approach makes it applicable to large molecular epidemiological studies. Although this proteome-wide approach is still under development and requires further validation, the potential exists for further adaptation of proteomics to the epidemiological analysis of chemical exposures (Colquhoun et al. 2009).

Metabolomics Metabolomics provides a method for defining metabolic profiles of an individual that can be used to predict the onset of common diseases, characterization of certain disease states and metabolic disorders (Vineis and Perera 2007). Specifically, metabolomics is the "systematic study of the unique chemical fingerprints that specific cellular processes leave behind," the study of their small-molecule metabolite profiles using advanced technologies like nuclear magnetic resonance spectroscopy and liquid and gas chromatography (Psychogios et al. 2011; Davis 2005).

Validation of this technology has only been reported in a few published studies, to date. However, it is becoming evident that metabolomics can have broad applications to exposure assessment by investigating metabolites from many different agents.

A review of recent studies utilizing transcriptomics, proteomics, and/or metabolomics can be found in the 2009 review paper by Wild. The initial findings warrant further investigations to validate these technologies as well as to determine the sensitivity and specificity of potential biomarkers of exposure measured.

46.4.5 Cell-Based Assays

The Comet Assay The "Comet" assay was developed in the late 1980s/early 1990s and uses only a few lymphocytes. The lymphocytes have to be frozen at a very low temperature to assure their viability. The lymphocytes are then treated and run out on a gel that is spread on a glass slide. DNA from the cell "migrates" to form a "tail." If DNA is "broken" (i.e., single-strand breaks or double-strand breaks), then the length of the tail is proportional to the amount of breakage (Olive and Banath 2006). This assay is amenable to measurement of DNA single-strand breaks, cross-links, base damage, and apoptotic nuclei. Cells are also subjected to damaging agents, allowed to repair, and then placed on the gel on the glass slides. In these cases, this assay is utilized as a biomarker of effect to measure DNA repair "capacity" by the length of the comet tail (Olive and Banath 2006).

The Comet assay is frequently used in human and animal studies evaluating environmental toxicant-induced and/or experimental DNA damage; the assay first was described as an exposure biomarker. The popularity of this assay exponentially increased when it was shown that – based on its high sensitivity and specificity – this method can also enable researchers to measure increased risks for different health outcomes. Extensive validation efforts have been undertaken to achieve standardization of the method and reliable application of the Comet assay by the European Standards Committee on Oxidative DNA Damage (ESCODD 2002; Collins et al. 2004).

The Mutagen Sensitivity Assay The bleomycin-induced mutagen sensitivity assay (MSA) is an in vitro measure of DNA repair capacity developed by Hsu et al. (1989). This assay is an indirect measure of both DNA damage and DNA repair expressed as chromosome "breaks per cell" (b/c) in short-term cultured lymphocytes. It is a relatively simple test in which a higher number of bleomycin-induced chromatid breaks indicate higher "mutagen sensitivity" and lower DNA repair. For example, if the number of “breaks per cell” is greater than the median of the controls, usually around 0.8, the examined subject is considered “mutagen sensitive” (Hsu et al. 1989). Mutagen sensitivity is regarded as a genetic susceptibility phenotype for various cancers; in this assay, chromosomes in metaphase are evaluated for breakage from a specific mutagen. The response to the mutagen likely involves a number of genes from different DNA repair pathways (Cloos et al. 2006) although the specific genes accounting for the response are still unknown (Caporaso 1999).

The MSA has been used to investigate the etiology of brain cancer (Bondy et al. 1996, 2001; El-Zein et al. 2001) as well as survival with brain cancer (Sigurdson et al. 1998). This assay has also been found to distinguish between individuals with cancer who will develop second malignancies and those who will not (Cloos et al. 1996, 1999, 2000), as well as those with a family history of cancer and those without (Spitz et al. 1994; Ankathil et al. 1999; Berwick et al. 2001; Zhu et al. 2002; Wu et al. 2002; Zheng et al. 2003).

One concern about phenotypic assays, such as the mutagen sensitivity assay, has been the typical wide variation in results that may depend on the timing of the assay (within subject variation), the person performing the assay (between observer variation), and the laboratory where the assay has been performed (interlaboratory variation). However, Erdei et al. (2006) have demonstrated excellent interobserver and interlaboratory correlations. Such studies have not been performed with other functional DNA repair capacity assays.

Micronucleus Assay The micronucleus (MN) assay, as introduced in Table 46.1, which detects MN, extracellular bodies, after the cells have progressed past the first cell cycle, has the ability to distinguish chromosome breaks from aneuploidy (abnormal number of chromosomes) and can detect chromosome loss. Since MN are formed from acentric chromosomal fragments or chromosomes that are not included in either daughter nuclei, they are classified depending on whether they contain chromosomal fragments or whole chromosomes (Albertini et al. 2000). This assay lends itself to molecular epidemiological studies because of the relative ease of scoring, limited costs and personnel requirements, and the precision that scoring larger numbers of cells provides. The MN assay can be performed in peripheral blood lymphocytes, epithelial cells, erythrocytes, alveolar macrophages, and fibroblasts (Neri et al. 2003). Since this assay requires that the cells under investigation survive at least one round of nuclear division, some of the damaged cells are lost before the analysis begins, and the survivability of the damaged cells detected is not known with this assay.

Neri and colleagues (2003) conducted a review of published studies that evaluated the occurrence of MN and the impact of genotoxic exposures on MN frequency in children and adolescents. Their review revealed that this cytogenetic assay is a useful, sensitive tool available for biomonitoring studies of children including those with low-dose exposures to environmental agents. The confounding effects of age, sex, and chronic and infectious diseases on MN levels were evaluated in these studies; the only variable whose influence was irrelevant to MN frequency was sex.

In 1997, the international database collaboration known as the HUman MicroNucleus (HUMN) project was initiated using a network of laboratories to compare various protocols used to determine whether and to what extent variations might affect baseline MN frequencies (Bonassi et al. 2001). The idea was that HUMN provided (i) baseline MN frequency data from various laboratories that can be evaluated for the influence of key variables (e.g., age, sex, and exposures) on MN frequencies, (ii) analysis of variation and reproducibility in laboratory protocols and methods, and (iii) a large database of individual data that permitted a prospective cohort study linking MN frequency data with disease incidence (Bonassi and Au 2002; HUMN: The International Collaborative Project on Micronucleus Frequency in Human Populations 2011).

Chromosome Aberrations Detection of chromosome aberrations is extensively used in molecular epidemiology as a biomarker of chromosomal damage, genome instability, and eventually of cancer risk. The detection of these altered chromosome formations from blood lymphocytes is used as part of the efforts in evaluating exposures to hazardous chemicals or suspected environmentally released and/or toxic compounds. Large prospective studies of cancer-free individuals have been conducted that demonstrate that chromosomal aberrations can predict cancer occurrence among the cohort 15 years later (Olden 1994; Bonassi et al. 2000; Hagmar et al. 2004).

Although very time consuming, the chromosomal aberration (CA) assay is considered one of the best validated biomarkers of early biological effects in population studies. This assay detects chromosomal abnormality at the metaphase stage of the cell cycle. Exposure-induced CAs have been found sometimes to be specific to the agent of exposure. This may allow for the CA assay to distinguish between radiation and chemical exposures. In a few cases, the assay has been able to specify certain chemical exposures. The distinctive CAs induced by various exposures have also permitted results of the assay to predict survival of cells with certain CAs (Bonassi and Au 2002). Fluorescence in situ hybridization and whole chromosome painting, a technique that uses chromosome-specific probes that are labeled with fluorescent dyes and hybridized to chromosomes to detect chromosome rearrangements and region-specific breaks, are two common techniques utilized in studies evaluating CAs (Bonassi and Au 2002).

Based on their review of findings from CA studies, Bonassi and Au (2002) provided four arguments indicating that CAs are predictive of the development of cancer: (i) chromosome rearrangements play an important role in the activation of proto-oncogenes and inactivation of tumor suppressor genes, (ii) congenital disease has been characterized with abnormally high CAs and increased malignancies, (iii) all neoplastic cells have been found to have alterations in the karyotype, some of which are highly specific for particular diagnostic categories, and (iv) carcinogenic chemicals tend to be clastogenic and clastogenicity is known to be associated with known human carcinogens. A review of biomarkers in molecular epidemiology studies with respect to CAs and their role in health risk assessment and prediction of cancer has been given by Bonassi and Au (2002).

Sister Chromatid Exchange During the S phase of the cell cycle, DNA is replicated, and each chromosome is present in a duplicated state with the two genetically identical chromatids joined together at the centromere. These two sister chromatids are readily apparent in late prophase or early metaphase of mitosis. Sister chromatid exchange (SCE) is the process wherein the two sister chromatids break and rejoin with one another, physically switching positions on the chromosome. Because the exchanges occur with exact precision to the DNA sequence, the sister chromatids stay genetically identical. No genetic information is altered during this process, and no mutations can be detected. It is important to note that these exchanges are natural events during cell replication. Usually, each cell can undergo three or four SCEs during each replication cycle. Even though this process is common, it can also be induced by mutagens and xenobiotics that form DNA adducts or that interfere with DNA replication processes and enzymes. The formation of SCEs has been correlated with the effectiveness of recombinational DNA repair and the induction of point mutations, gene amplification, and cytotoxicity.

The measurement and counting of SCEs has been applied in several in vitro genotoxic effects studies (Gu et al. 1981; Beckman and Nordenson 1986; Baldacci et al. 1997; Kasuba et al. 2000; Wagner et al. 2004; Bonina et al. 2008). An increased number of exchanges (15–100/cell) is considered to be an indication of increased cancer risk and genotoxic chemical exposure. Furthermore, in Bloom syndrome, an autosomal recessive disorder with defects in DNA repair by homologous recombination, pediatric patients have more than 160 SCEs per cell and have increased risk for developing cancers. This assay represents an integrated measure of chromosome-instability phenotypes and altered cellular viabilities caused by genetic defects and/or exogenous exposures to genotoxic agents.

Reporter Gene Mutations The HPRT (hypoxanthine phosphoribosyltransferase) gene mutation assay detects somatic mutations of the HPRT hemizygous gene in the X chromosome in post-thymic lymphocytes and is most commonly used for detection of mutation(s) in exposed populations (Bonassi and Au 2002). This cell cloning assay can distinguish between high mutant frequencies arising from clonal expansion of only a few mutated cells versus induction of a large number of mutated cells. Since the assay quantifies mutations in the HPRT gene which is only present on one allele, it is difficult to extrapolate mutant frequencies to genes present on both alleles. The HPRT assay allows for evaluation of the mutagenic potential of various compounds; however, the significance of these observations in terms of risk assessment for somatic mutation related diseases is difficult to evaluate (Bonassi and Au 2002). HPRT mutant frequencies have been utilized as a biomarker of effect in a study of polymer production workers, exposed to 1,3-Butadiene (Ammenheuser et al. 2001). HPRT mutant frequencies were found to be threefold greater in the high-exposure group. In addition, the assay has the utility to evaluate in utero exposures. This was evaluated in cord blood lymphocytes from healthy newborns in which the mutation frequency correlated with the presence of DNA adducts (Perera et al. 2002).

The glycophorin A mutation assay (GPA) detects damage in bone marrow cells. The mechanism of genotoxicity measured with this assay is the loss of alleles, which may explain why this assay is less sensitive than the HPRT assay (Bonassi and Au 2002). Fluorescent-labeled monoclonal antibodies and erythrocyte flow cytometry are used to detect the loss of one of the cell surface glycoproteins associated with the allele(s) of interest (Lee et al. 2002). A dose-dependent increase in the frequency of variants has been detected following exposure to genotoxic agents (Grant and Bigbee 1993). Further, Lee and colleagues (2002) found a significant association between GPA variant levels and urinary metabolite levels in a study of workers from an industrial waste incinerating plant, demonstrating the utility of the GPA as an early marker of biological effects of polycyclic aromatic hydrocarbon exposure.

Acquired Somatic Mutations in Genes There are several examples of studies considering somatic (acquired) gene mutations in relation to cancer. CDKN2A is a cell-cycle gene that is important in many cancers. Mutation of this gene, whether inherited or acquired, has been found in melanoma, lung cancer, among others. For example, p16^{INK4a} belongs to the family of cell-cycle-regulator enzymes called cyclin-dependent kinase inhibitors (CDKI), which bind to “cyclin-CDK” complexes and cause cell-cycle arrest in the G1 phase. p16^{INK4a} exerts its antiproliferative effects by binding to and inhibiting the actions of CDK 4 and 6 cyclin-dependent kinases.

Many studies in cancer have explored the importance of the integrity of this tumor suppressor protein and its activity. The INK4a gene is located at the chromosome locus 9p21, a region that has frequently been detected to undergo hemi- and homozygous deletion in human cancers. Both germline and somatic mutations of INK4a have been detected in familial melanoma and pancreatic adenocarcinoma. Somatic mutations of this gene were identified in Barrett’s esophagus-related adenocarcinomas, transitional cell carcinomas of the bladder, head and neck squamous cell carcinomas, and a variety of other malignancies (Caldas et al. 1994; Liu et al. 1995; Smith-Sørensen and Hovig 1996). Recent investigations have revealed another important molecular pathway of gene inactivation, hypermethylation of the INK4a-promoter region, which may be the predominant mechanism in some tumors (Belinsky et al. 2002). Tobacco smoke exposure can increase methylation levels in the INK4a-promoter region (Soria et al. 2002; Belinsky 2004).

Immunohistochemical staining (IHC) has been developed for p16^{INK4a} protein assessment which is applicable to fixed paraffin-embedded tumor tissues. Like all IHC assays, this technique has the advantage of detecting the p16^{INK4a} status irrespective of the mechanism of gene inactivation. For example, although there is a low frequency of INK4a mutations or allelic deletions in this tumor, nearly 20% of gastric carcinomas demonstrate reduction or loss of p16^{INK4a} expression by IHC, underscoring the importance of epigenetic and environmentally induced mechanisms in downregulating protein expression (Tamura 2006).

p53, another tumor suppressor gene, is expressed in every cell of the human body. It controls the synthesis of proteins that are involved in the regulation of cell division, DNA replication, cell differentiation, and in scheduling cell necrosis (Lutz and Nowakowska-Swirta 2002). p53 is a negative regulator of cell division and will block growth of cells and initiate repair mechanisms in cells with damaged DNA. Congenital defects and/or externally induced damage to this gene have extensive consequences on the maintenance of cellular homeostasis. This gene is of particular interest as it is has been found to be mutated in approximately half of human cancer cases (Lutz and Nowakowska-Swirta 2002).

Several studies investigating the presence of p53 gene mutations in lung cancer and normal tissue among smokers and non-smokers have found a correlation between the frequency of p53 mutations and the daily amount of smoking (reviewed in Vineis and Husgafvel-Pursianinen (2005)). Mutations in the p53 gene have been found to precede clinical symptoms by months to years in hepatic angiosarcoma patients exposed to vinyl chloride (Lutz and Nowakowska-Swirta 2002). In their review of p53, Lutz and Nowakowska-Swirta (2002) suggested that detecting mutations in this gene may serve as a way to identify early phases of carcinogenesis at the cellular level and thus become an early biomarker of health effect.

The finding that p53 mutations and changes in its expression form the basis of cancer processes has prompted molecular epidemiologists to use biomarkers in easily available cellular material or systemic liquids. Mutations in the suppressor gene p53 cause variations of cellular protein p53 concentration because the mutated protein accumulates in cancer tissues due to the loss of its DNA-binding capacity. Higher cellular protein p53 levels are associated with increased protein transfer to the extracellular liquid and to blood. It has been observed that increased blood serum protein p53 concentrations may have a prognostic value in early diagnosis of lung cancer (reviewed in Lutz and Nowakowska-Swirta (2002)). Elevated blood serum protein p53 concentrations have been observed also in patients with mesothelioma many years before the cancer became clinically overt (Hemminki et al. 1996).

46.5 Biomarkers of Susceptibility

Molecular epidemiology includes the identification of genetic and acquired susceptibility (such as DNA repair capacity – Berwick and Vineis 2000). Genetic epidemiology methods are well described in chapter ▸Statistical Methods in Genetic Epidemiology of this handbook. Association studies are the most common genetic epidemiology studies carried out these days. A large number of studies have been conducted on candidate genes on the basis of biochemical hypotheses regarding their involvement in carcinogen metabolism, DNA repair, or cell cycle. We will not address this issue here. Multiple meta-analyses and GWAS analyses (see below) are currently evaluating large numbers of SNPs (see Manolio and Collins (2009) for an overview of methods) and genetic loci that appear to be associated with disease. Although these studies tend to be large, including thousands of cases and thousands of controls, some smaller studies with very well-selected subjects have contributed to the understanding of genetic susceptibility (Klein et al. 2005). For example, in the study by Klein et al. (2005), a genome-wide screen of 96 cases and 50 controls identified an intronic and common variant in the complement factor H gene (CFH) that is clearly important in age-related macular degeneration (odds ratio $(OR) = 7.4$, 95% confidence interval (CI) = (2.9;19)).

46.5.1 Genome-Wide Association Studies (GWAS)

Genome-wide association studies (GWAS) are exploratory studies of genetic variation across the entire human genome designed to identify genetic associations with observable traits or the presence or absence of a certain disease of interest (Pearson and Manolio 2008). The basic premise is that the entire genome can be evaluated for variation and some SNPs will stand out as important risk factors for disease. Individuals with disease are compared to individuals without disease. As the genome is large and the number of SNPs is even larger, thousands of subjects are necessary to appropriately investigate associations. The agnostic approach of GWAS provides an advantage over candidate gene studies and has increased the exploratory potential of genetic analyses.

GWAS employ 500,000 to more than more than 2,500,000 SNP-genotyping platforms that provide cost-effective increases not only in the genetic information gained but also because they allow large populations to be studied. GWAS collect a large number of study participants with a disease or phenotypic trait of interest and a similarly large comparable, disease-free comparison group. The study sample originates usually from ongoing collaborative scientific efforts involving different institutions and even different continents. These studies take advantage of high-throughput genotyping technologies, automated sample collection, DNA isolation methods, and high-quality-control practices. They also employ statistical analyses to identify a relationship between certain SNPs that have passed assay-dependent detection thresholds and the presence of a disease or phenotypic trait. Tremendous laboratory and biostatistical effort has resulted in over hundreds of GWAS so far which no doubt will contribute to the knowledge base of molecular epidemiology around the world (McCarroll and Altshuler 2007). Accurate GWAS also try to replicate their findings in different population samples or in experimental animals, when the biological pathways allow mechanistic modeling or toxicological applications. These studies have also been used to identify SNPs associated with different gene expression patterns and certain phenotypic traits, like height and electrocardiographic QT intervals (Weedon et al. 2007, Arking et al. 2006).

Considering the “common disease, common variant” hypothesis, GWAS rely on SNPs as indicators of allelic variants that represent over 1–5% of each human genome. The National Cancer Institute has provided support for many cancer studies (breast, prostate, and colon) that have applied high-throughput powerful genomic analyses to reveal some of the key genetic factors that affect risk for these cancers. Through genetic characterization, followed by finer and finer mapping and analysis, scientists are able to identify common genetic aspects of the cancers being studied. Usually, genome-wide scanning is performed on an initial group of cases and controls, and then a smaller series of possible SNPs are evaluated as replicates in a second and maybe a third set of cases and controls. This multistaging study design was implemented to reduce the number of false-positive or false-negative findings (Skol et al. 2007). Furthermore, this methodology helps to reduce the genotyping cost of GWAS. Also, with carefully employed quality controls, the repeated genotyping provides the required validation, especially for unknown functional or intronic SNPs.

GWAS are prone to biases. One of the most important is population stratification. Population stratification is an important confounding effect where an underlying population structure contributes to false-positive associations with the disease being studied and occurs when the detected SNPs are also linked with unknown factors reflecting ethnicity or geographical origin of study participants. The large amount of data generated by GWAS is highly susceptible to false-positive associations. Effective statistical techniques have to be applied to reduce the occurrence of false-positives raised by the large number of multiple comparisons.

Another important limitation is that even though current technology used in GWAS captures the majority of common variants, they are determined based upon the concept of linkage disequilibrium or other statistical algorithms validated across the Human Genome International HapMap databases. These approaches build on our understanding that the human genome is organized by blocks of nucleotides called haplotypes. Haplotypes are inherited together; they form a linkage disequilibrium, and some SNPs within a given block define and explain or “tag” within block variability (Zhang et al. 2002). These tagging SNPs became popular in GWAS. Nevertheless, it is possible that some variants are still not captured by the applied genotyping chips although they represent potentially important but unknown susceptibility factors. Furthermore, it is imperative to consider that certain genetic variants might be important only in conjunction with exposures that initiate or modify expression of that gene (Ambrosone 2007). Without accounting for exposures to evaluate cancer or other chronic disease risks, we cannot successfully reveal the intricate patterns of gene-environment and even gene-gene interactions which account for a large proportion of cancer or chronic disease risk. “Next-generation GWAS” probably should incorporate more detailed analyses of common exposures (smoking, air pollutants, dietary patterns and supplements, xenobiotics (like common non-steroidal anti-inflammatory drugs (NSAIDs)), over-the-counter medications, alcohol, recreational drugs, etc.) influential in chronic disease etiology and pathogenesis.

46.5.2 Copy-Number Variation

Another interesting area of research that has emerged from the use of GWAS is the study of copy-number variations (CNVs) across the human and primate genomes (Dumas et al. 2007). Human populations have been found to have extensive polymorphisms not only in nucleotide sequences within genes but also in the form of additions or deletions resulting in variations in the number of copies of chromosomal segments (Hastings et al. 2009). A CNV is a segment of DNA in which the number of copies differs from that in a reference library (Pinto et al. 2007). Copy-number variants are as important as SNPs in determining individual differences between human beings (Kidd et al. 2008). The number of gene segments that differ from one individual to another varies for particular genetic regions due to deletion or duplication of DNA. The gene segments that are affected by the CNV processes can range from larger than 1 kilobase to up to many megabases. CNVs may either be inherited or caused by de novo mutation (Stankiewicz and Lupski 2010) and later many of them have become fixed in humans. Most of the CNVs are stretches of duplicated DNA that are more than 1 kilobase in size and share a sequence similarity that exceeds 90%. They are presented twice or more within the genome. It is thought that CNVs could have serious implications for the functionality of the gene and subsequently contribute to disease susceptibility (Gu and Lupski 2008).

Based on data generated from the Human Genome Project, approximately 12% of the human genome is subject to CNV, which is greater than the variation due to SNPs found to date (Sebat et al. 2004; Hastings et al. 2009). However, 75% of all CNVs detected have a prevalence of less than 3% in human populations. CNVs can arise both meiotically and somatically. Even identical twins can have different CNVs based on somatic events during their lives. More interestingly, tissues and organs from the same individual can vary in copy number, which indicates that probably CNVs are randomly incorporated in the genome. It is possible that genes with a higher frequency of CNVs are directly relevant to the immediate environment of the individual. CNVs are enriched in genes involved in olfaction, immunity, and secreted proteins. One example is the presence and protein amount of salivary amylase (*AMY1*) in diverse human populations (Perry et al. 2007) especially those with high starch consumption. It is believed that genes under recent selection pressure contain higher than average frequencies of non-synonymous mutations and CNVs. However, it is possible that because CNVs are randomly present, their functionality can change over time or in different environments, and their role within the human genome is continuously tested by evolutionary processes.

Copy-number variations require a change in chromosome structure. During cell division, two different single-stranded DNA structures get close to each other and join DNA sequences. Probable molecular events behind the mechanisms for de novo CNVs are fork stalling and template switching, both of which are considered frequent mistakes during genomic replication. Several methods are used to study how the structural change has arisen in humans; however, most of the molecular studies have used bacteria and yeast model organisms.

46.5.3 Mendelian Randomization

Establishing causal relationships between environmental exposures and common diseases is beset with problems of unresolved confounding, reverse causation, and selection bias that may result in spurious associations.

Mendelian randomization (Davey-Smith et al. 2004) is a method of using measured variation in genes of known function to examine the causal effect of a modifiable exposure on disease in non-experimental studies. An important focus of observational epidemiology is the identification of modifiable causes of common diseases that are of public health interest. In order to have firm evidence that a recommended public health intervention will have the desired beneficial effect, the observed association between the particular risk factor and disease must imply that the risk factor actually causes the disease. Well-known successes include the identified causal links between smoking and lung cancer, and between blood pressure and stroke. However, there have also been notable failures when identified exposures were later shown by randomized controlled trials (RCTs) to be non-causal. For instance, it has now been shown that hormone replacement therapy (HRT) will not prevent cardiovascular disease, as was previously thought. HRT may even have other adverse health effects (Rossouw et al. 2002). The reason for such spurious findings in observational epidemiology is most likely to be confounding by social, behavioral, or physiological factors which are difficult to control for and particularly difficult to measure accurately. Moreover, many findings cannot be replicated by RCTs for ethical reasons.

Mendelian randomization is a method that allows one to test for, or in certain cases to estimate, a causal effect from observational data in the presence of confounding factors by using common genetic polymorphisms with well-understood effects on exposure patterns (e.g., propensity to drink alcohol; Davey-Smith et al. 2004) or effects that mimic those produced by modifiable exposures (e.g., raised blood cholesterol; Katan 1986). Importantly, the genotype must only affect the disease status indirectly via its effect on the exposure of interest. Because genotypes are assigned randomly when passed from parents to offspring during meiosis, if we assume that choice of mate is not associated with genotype (panmixia), then the population genotype distribution should be unrelated to the confounders that typically plague observational epidemiology studies. In this regard, Mendelian randomization can be thought of as a "natural" RCT. From a statistical perspective, it is an application of the technique of instrumental variables, with genotype acting as an instrument/proxy for the exposure of interest. As with all genetic epidemiology studies, there are problems associated with the need for large sample sizes, the non-replication of findings, and the lack of relevant functional information on genetic variants (refer to chapter ▸Statistical Methods in Genetic Epidemiology of this handbook for more information on genetic epidemiology). In addition to these problems, genetic findings may be confounded by other genetic variants in linkage disequilibrium with the variant under study or by population stratification. Furthermore, pleiotropy of effect of a genetic variant may result in null associations, as may canalization of genetic effects. If correctly conducted and carefully interpreted, Mendelian randomization studies can provide useful evidence to support or reject causal hypotheses linking environmental exposures to common diseases.

46.6 Methodological Issues in Using Biomarkers

It is widely accepted that environmental exposure measurements in cancer epidemiology require well-developed and validated exposure assessment methodologies (Wild 2009; Vineis and Perera 2007; Gyorffy et al. 2008). Before newly developed high-throughput technologies can be used on a regular basis in exposure or risk assessment, they will require extensive validation.

Rundle (2006) described common methodological limitations in using biomarkers, including the use of target versus surrogate tissues, modifying effects of the disease on DNA adduct levels, the use of inappropriate statistical analyses, and small sample sizes in published data. These problems make it difficult to assess whether lack of an association between the presence of carcinogen-induced DNA adducts and cancer reflects a lack of association between the xenobiotic exposure of interest and cancer or mirrors problems in methodology (Rundle 2006). A focus on measurement of adduct levels in tissues collected years prior to a cancer diagnosis (i.e., in benign biopsy specimens) may resolve some of these uncertainties.

The measurement of DNA-based markers depends on the type and amount of DNA available: genomic DNA (including mitochondrial DNA) or tumor DNA. Amount of DNA available and methods of collection and storage all greatly affect the quality of the assays and thus the appropriate application. Microarray technology was made available to researchers in the late 1980s. The main principle of this technology is based on the Southern blot assay in which DNA fragments containing a specific DNA sequence of interest that serve as a probe to hybridize to a complementary DNA (cDNA), which has been amplified using fluorescent primers. If the cDNA contains the complementary sequence, it will hybridize with the probe, and the fluorescence is measured. The quality of the DNA becomes an issue when considering the area of interest within the DNA sequence as well as the requirements for amplification. This becomes particularly important when designing studies using stored DNA samples in which the quality of the DNA is often not known.

46.7 Risk Assessment

The main goal in molecular epidemiological research is to explore and explain relationships between environmental factors (including diet and behavioral exposures) and health outcomes. The extensive scientific inquiry of molecular epidemiology uses and appreciates the far-reaching framework of risk assessment used in regulatory risk management and policy making (World Health Organization (WHO) 2012; US Environmental Protection Agency (EPA) 1989).

The first phase of risk assessment is *exposure assessment* (for a full description, see chapter ▸Exposure Assessment of this handbook and the specific section in chapter ▸Environmental Epidemiology for general principles of scientific environmental risk assessment in this handbook) based on results of pertinent toxicological and epidemiological studies. This step also involves a description of the chemical or biological agent's behavior and interactions within the human body. Applicable molecular markers developed for this purpose may also be considered in molecular epidemiological studies linking organ-, tissue-, and cellular-level changes to disease development. Animal models are frequently used in this phase of scientific inquiry especially for evaluations of potential toxic exposures. Research then links laboratory and field observations of adverse health effects with exposure to particular agents (e.g., leukemia as a result of benzene exposure).

The second step of risk assessment is to evaluate whether dose-effect and sometimes more accurately dose-response relationships exist by describing and quantifying the relationship between exposure or absorbed dose and related health outcomes. Often this component of the assessment is hindered by the lack of appropriate methods necessary to extrapolate data from high-dose (e.g., occupational exposure settings) to low-dose exposure (e.g., general air pollution exposure conditions) or from animal models to humans (Yassi et al. 2001; Friis 2007).

High-risk groups are important to identify in epidemiology, particularly in relation to environmental health hazards. Fetuses, infants, young children, elderly people, pregnant women, the nutritionally deprived, and people with existing chronic conditions or genetic disorders are often more sensitive to physical, chemical, and biological hazards. Since individuals have varied exposures and susceptibility, the standards for protective measures should be set based on the most vulnerable population groups, that is, public health policies should attempt to provide protective measures to those who are most susceptible.

Risk characterization is important for policy development, bringing together exposure assessment and potential dose-effect associations for estimating the incidence and severity of the potential adverse health effects. It involves exposure characterization, dose estimation, and prediction of lifetime risk, including susceptibility of subgroups. These steps lead to risk management, that is, the development and implementation of regulatory actions aimed to reduce risk and apply effective protective measures for the population at large.

46.8 Biorepositories

As a vital component of biomarker-related molecular epidemiological studies, biorepositories have been established in order to provide tissue and blood samples that are kept together with demographic and clinical data, including information regarding clinical diagnosis and response(s) to therapeutic options. Biorepositories involve collections of blood or tissue for genetic research that can be linked to medical, genealogical, or lifestyle information about a specific population, where the material is gathered using a specific consent process for future undetermined genetic and molecular research (Maschke 2005). Biorepositories lend themselves to the ultimate goal of molecular epidemiological studies which is to identify indicators of disease susceptibility or prognostic markers to reduce disease incidence and mortality. Thus, biorepositories are an invaluable resource for studies of cancer etiology, progression, and development of new biomarkers of precursors of disease (Ambrosone 2006).

Population-based biorepositories consist of specimens from large populations of individuals. Attempts to create such large repositories usually require a coordinated effort at the national level (Maschke 2005; Goodman et al. 2005). This type of repository for tissue, blood compartments, urine, DNA, or other biological material is sometimes initiated for surveillance or as part of genome studies and has the advantage of providing an unbiased sampling frame that is useful for examining genes and protein targets as therapeutic and/or diagnostic tools (Goodman et al. 2005). In the case of cancer research, population-based tissue repositories are ideal for testing new molecular classification schemes for cancer, for validation of new biological markers of malignancy, for prognosis of disease progression, for assessment of therapeutic targets, and for measurement of allele frequencies of cancer-associated genetic polymorphisms in representative samples (Goodman et al. 2005).

The US National Cancer Institute (NCI) created a national program of population-based cancer registries in 1973, the Surveillance, Epidemiology and End Results (SEER) program (National Cancer Institute 2011). SEER collects information on cancer incidence, survival, and prevalence from 26 specific geographical areas within the United States (Seer 2013). Recently, this cancer registry has expanded to include a collection of formalin-fixed, paraffin-embedded tissues from cancer patients at the population level. This repository is unique in the sense that the large-scale collection is performed at the population level and yet these tissues constitute specimens from many different types of one disease, cancer (Goodman et al. 2005). Further, Goodman and colleagues suggest that this type of tissue resource may provide a foundation for molecular epidemiological studies of cancer in the USA.

Another example of a large-scale population-based tissue resource in the USA is the Cooperative Human Tissue Network (CHTN) which was initiated by the Cancer Diagnosis Program of NCI in 1987 as a means of providing basic and applied scientists from academia and industry with access to human cancer tissues. This biorepository was established with the intention of accelerating the advancement of discoveries in cancer diagnosis and treatment. Currently, six institutions throughout the USA are funded to procure and distribute tissues to biomedical researchers throughout the USA and Canada. Materials are obtained from surgical resections, autopsies, and remnant serum/plasma and other biofluids (urine and buffy coat). The CHTN continuously updates a list of requested tissues from regional investigators, and when a tissue request matches a surgical resection, the excess specimen not needed for diagnosis is prepared and preserved according to the specified needs of the investigator (National Cancer Institute 2012). CHTN provides investigators with tissues that can be age-, sex-, and race-matched based on their needs; this allows for robust data collection for molecular epidemiological studies (case-control matching is discussed further in chapter ▶Case-Control Studies of this handbook). Even though this resource is valuable for molecular epidemiology studies, samples will most likely be used to generate hypotheses because classical epidemiological information, for example, exposure data, cannot be obtained through the tissue repositories.

The International Agency for Research on Cancer (IARC 2012) hosts the database and biorepository for the largest study of diet and health ever undertaken, the European Prospective Investigation into Cancer and Nutrition (EPIC project). The EPIC project has recruited over 520,000 participants in ten European countries and was designed to investigate the relationships between diet, nutritional status, lifestyle, and environmental factors and the incidence of cancer and other chronic diseases. Scientists included in the EPIC project are based in 23 centers throughout the ten participating European countries and have utilized the available individual data (dietary, lifestyle), follow-up data (cancer, mortality, and other endpoint data), and biospecimens including plasma, serum, red blood cells, and buffy coats, to conduct investigations that have resulted in over 768 publications up to 2008. The study is jointly coordinated at IARC and Imperial College in London.

The UK Biobank (2012) is another large-scale European effort designed to demonstrate the effect of lifestyle, environment, and genes on the health of 500,000 people aged 40–69 from the United Kingdom. This study is designed to collect blood, urine, standard measurements, and lifestyle information from participants that can be utilized by approved researchers over the next 20–30 years. The overall aim of this study is to help researchers develop new and better ways to prevent, diagnose, and treat chronic illnesses (UK Biobank 2012).

Biorepositories consisting of tissues from subgroups within a population can be for example created as part of collaborations between public clinics/health-care facilities and biotech companies. These studies are defined as convenience studies and can be subject to selection bias (Goodman et al. 2005). Potential problems exist among biorepositories: the type and timing of tissues collected and stored. Tissue is either collected during surgery, treatment, or in the course of a diagnostic procedure or alternatively collected only for the purpose of research (van Veen 2006). Residual tissue can be used in research provided consent is obtained, or the tissues are not linked to any personal identifiers. Use of tissues collected explicitly for research is dependent upon whether appropriate consent was obtained.

Although biorepositories are an excellent resource for molecular epidemiological studies, access to samples and inconsistencies in the quality of the samples or problems with sample integrity can hinder utilization of these resources (Ambrosone 2006). The long-term value of biospecimens is dependent upon proper collection and handling of specimens, accurate collection of appropriate data about the study participant, and specimen quality (Vaught 2006). Despite appropriate collection, processing, and storage of specimens, variations prior to analysis could influence the validity of the results.

The International Society for Biological and Environmental Repositories (ISBER), which was established in 1999, has developed best practice guidelines for biorepositories. The inception of these guidelines has initiated a focused attention on the important aspects of proper biospecimen handling as well as legal and ethical standards and regulations that govern specimen collection (Vaught 2006). The ISBER Biospecimen Working Group has compiled a list of publications that focus on examination and validation of various experimental designs in accordance with biospecimen research (International Society for Biological and Environmental Repositories 2012).

Ethical Issues Collection, analysis, and storage of biospecimens and medical information from individuals entail several legal and ethical requirements. Ideas regarding the regulation of tissue repositories and the existence of laws to enforce this control vary widely at the international level. In particular, issues relating to informed consent, access to research results, the use of archived samples, and the ownership of biological samples as well as intellectual property of discoveries and inventions have been debated. Ideally, an international regulatory framework would be the most appropriate entity to address these issues; however, until its establishment, laws, regulations, and ethics advisory board guidelines at the national level govern the collection, storage, and research use of biological samples (Maschke 2005).

Informed consent provides individuals with information related to the research and the ability to decide whether they are willing to have their samples collected, stored, and studied. Voluntary informed consent is a core ethical principle of human research ethics (Maschke 2005).

Archived biospecimens are ideal for studies evaluating long-term survival; biomarkers of interest can be evaluated to determine whether their presence or absence predicts survival from a specific disease years after the specimen was collected. An area of recent debate is whether the use of archived specimens that were not previously consented for future research is ethically sound (Maschke 2005).

Regarding ownership of biological specimens and intellectual property rights to discoveries and inventions resulting from research with biospecimens, the general consensus in the international and national law has been that there are no property rights on the human body (Maschke 2005). For additional examples of ethical issues arising in epidemiological studies, refer to chapter ►Ethical Aspects of Epidemiological Research of this handbook.

46.9 Conclusions

Conventional epidemiology, based on classical research methods and tools such as interviews and questionnaires, has achieved extremely important goals and contributed tremendously to public health policy and regulatory changes. Even a difficult issue such as the relationship between air pollution and chronic disease has been successfully dealt with by time-series analysis and other methods not based in the laboratory. The added value of molecular techniques coupled with solid and carefully executed epidemiological design can be most appreciated in complex and chronic disease research.

In addition to its positive features, the limitations of molecular epidemiology should also be acknowledged: the complexity and cost of many laboratory methods, with partially unknown levels of measurement error or interlaboratory variability; the scanty knowledge of the sources of bias and confounding; in some circumstances, the lower degree of accuracy (e.g., urinary cotinine compared to questionnaires of smoking history); and the uncertain biological meaning of some markers, as in the case of some types of adducts or some early response markers. The timing of the exposure and the biological measurement often do not reflect the cumulative nature of the exposure which is usually dependent upon the biological pathway (e.g., vitamin D serum levels or arsenic in toenails).

Molecular epidemiology is not distinct from traditional epidemiology, but represents a development that aims at achieving specific scientific goals: (a) a better characterization of exposures, particularly when levels of exposure are very low or different sources of exposure are integrated into a single measure; (b) the study of gene-environment interactions; and (c) the use of markers of early response, in order to overcome the main limitations of chronic disease epidemiology, that is, the relatively low frequency of specific forms of disease and the long latency period between exposure and the onset of disease.

47.1 Introduction

This chapter will begin with providing a brief overview of the history of clinical epidemiology and describe its relation with evidence-based medicine. Clinical epidemiology differs from classical epidemiology in that clinical epidemiology supports other basic medical sciences such as biochemistry, anatomy, and physiology because it facilitates their application in research through formulation of sound clinical research methods and, thus, puts these disciplines into clinical context. Therefore, clinical epidemiology goes beyond clinical trials. We will describe this concept in the following paragraphs (see Sects. 47.1.1–47.1.3). The following sections include case scenarios that facilitate the introduction of the key concepts about developing clinical questions, using diagnostic tests, evaluating therapy, appraising systematic reviews, developing guidelines, and making clinical decisions. By describing clinical epidemiology in this way, the relation to evidence-based health care (which in the authors' view encompasses all fields of medicine and associated clinical sciences) will become clear.

47.1.1 Brief History of Clinical Epidemiology

Sackett provides an astute historical summary of the development of clinical epidemiology in his tribute in memory of Alvan Feinstein (Sackett 2002). Sackett's account gives John Paul credit for introducing the term clinical epidemiology describing it as the "new basic science for preventive medicine" (Paul 1938; Sackett 2002). Feinstein and Sackett made major contributions to the field of clinical epidemiology. Sackett founded, in 1966, the first clinical epidemiology research unit at the University at Buffalo, New York, USA, and in 1967 moved to Hamilton, Canada, to establish a department of clinical epidemiology and biostatistics at McMaster University, which he served as chair from 1968 to 1973. This institution, in part through the International Clinical Epidemiology Network (INCLEN), has trained numerous clinical epidemiologists, some of whom have taken on chair positions themselves. It has grown to host one of the largest graduate programs worldwide in health research methodology with over 180 Master's and PhD students. Today there are departments and units of clinical epidemiology throughout the world, though the development in some jurisdictions has been slower than in others. For example, it was in this millennium that the first department of clinical epidemiology was founded in the German-speaking countries of Europe (Basel, Switzerland, H. Bucher, personal communication), although professorships of clinical epidemiology existed in these countries for some time.

47.1.2 A Definition of Clinical Epidemiology

Although seminal, Paul's simple description of clinical epidemiology was perhaps not sufficient in helping investigators and clinicians understand the principles underlying the term clinical epidemiology. Articles and textbooks have provided further definitions. Feinstein portrayed clinical epidemiology as investigating "the occurrence rates and geographical distribution of disease; the pattern of natural and post-therapeutic events that constitute varying clinical courses in the diverse spectrum of disease; and the clinical appraisal of therapy. The contemplation and investigation of these or allied topics constitute a medical domain that can be called clinical epidemiology" (Feinstein 1968; Sackett et al. 1991). Sackett defined clinical epidemiology as "the application, by a physician who provides direct patient care, of epidemiological and biostatistical methods to the study of diagnostic and therapeutic processes in order to effect an improvement of health" (Sackett and Winkelstein 1967; Sackett 1969, 2002). Fletcher et al. (1996) described clinical epidemiology as the science of making predictions about individual patients by counting clinical events in similar patients, using strong scientific methods for studies of groups of patients to ensure that the predictions are accurate. Weiss (1996) defined clinical epidemiology as the study of variation in the outcome of illness and of the reasons for that variation. Despite the numerous definitions, one might argue that by providing the subheading "A Basic Science for Clinical Medicine" to their textbook "Clinical Epidemiology," Sackett and colleagues provided a pithy definition that not only turned the wheel back to John Paul but widened it to all areas of clinical medicine by replacing *preventive medicine* with *clinical medicine* (Sackett et al. 2000).

Definitions are inevitably limited, and in-depth understanding requires a more comprehensive discussion. We characterize clinical epidemiology by focusing on its purpose: to ensure that clinicians' practice and decision-making is evidence-based. Clinical decision-making requires answering questions about diagnosis, therapy, prevention, and harm, providing estimates of prognosis and obtaining unbiased and precise estimates of intervention effects. Clinical epidemiology supports other basic medical and health sciences such as biochemistry, anatomy, and physiology because it facilitates their application in research through formulation of sound clinical research methods and, thus, puts these disciplines into the health care context. Thus, clinical epidemiology provides the integrative force of medical science and medical practice.

47.1.3 Clinical Epidemiology and Evidence-Based Medicine

When working optimally, clinical epidemiologists communicate results of investigations in ways that clinicians can readily apply in practice. Clinical epidemiology provides the evidence for management decisions resulting in more good than harm. In fact, the methodological principles of clinical epidemiology question the millennia old credo of "primum non nocere." Clinical decision-making demands that the commonplace interpretation as "never do harm" is impossible to adhere to. Every decision in life, including the simplest ones, but particularly health care decisions, comes with downsides. The smallest perceptible downside is the time to consider the decision, but there are also always opportunity costs that result from giving up an alternative action. Clinicians' and patients' action, therefore, require the explicit consideration of both desirable and undesirable consequences and assigning due considerations depending on the magnitude and importance of the consequences. Understanding of health research methodology and its application in clinical epidemiology is critical for these considerations and for weighing benefits and downsides of decisions. One of us, therefore, described the guiding principle for health care decision-making as to ensure that there is, in summary, more benefit than harm; in other words, the credo should be "to do no net harm" ("primum non net nocere") (Schunemann 2011).

Clinicians should use best evidence to consider these consequences for clinical decision-making. Thus, clinical epidemiology and evidence-based practice are closely linked. Clinical epidemiology grounds health care research in the mission to deliver optimal care to individual patients. As it turns out, clinicians optimally applying the best evidence to their patient care must understand the basic concepts of clinical epidemiology (Bhandari et al. 2003). At the same time, while clinical epidemiology grounds the clinical investigators' viewpoint, evidence-based medicine (EBM) provides the framework for application of research findings in clinical practice, including a framework for clinical decision-making. In the next sections of this discussion, we will describe the basics of clinical epidemiology methods and how insights from clinical practice may enlighten clinical epidemiologists in their work from "study to bedside."

47.1.4 The History and Philosophy of Evidence-Based Medicine

When one of us first coined the term evidence-based medicine (EBM) in an informal residency training program document, he described it as "an attitude of enlightened skepticism toward the application of diagnostic, therapeutic, and prognostic technologies in their day-to-day management of patients" (Guyatt 1991, 2002a, b). Through a series of articles published by the evidence-based medicine working group, the term as well as the philosophy of EBM became well known (Evidence-Based-Medicine-Working-Group 1992; Oxman et al. 1993). A Medline search revealed 7 citations including the term "evidence based medicine" in 1993, 3,904 citations in 2002 (when we worked on the first edition for this book), and 7,573 in 2011 (when we worked on the current edition of this book). The history of evidence-based health care has been summarized in a book (Daly 2005). While the Department of Clinical Epidemiology and Biostatistics at McMaster University is widely regarded the home of EBM, EBM became quickly established across the world. For example, Sackett spent several years in the UK to develop the Oxford Centre for Evidence-based Medicine.

EBM evolved out of the efforts of clinicians with research methodology training – that is, clinical epidemiologists – to apply their particular insights and approaches to solving clinical problems. In contrast to the traditional paradigm of clinical practice, EBM acknowledges that intuition, unsystematic clinical experience, and pathophysiologic rationale are important but not sufficient for

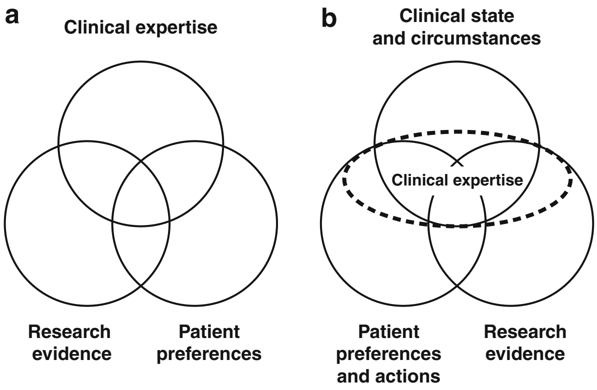

Fig. 47.1 (**a**) and (**b**) Former models of evidence-based decision-making (Reproduced with permission from Haynes et al. (2002a, b))

making the best clinical decisions. Although it acknowledges the importance of clinical experience, EBM postulates that optimal clinical decision-making requires the integration of this experience with the circumstances (setting), patients' values and preferences, and estimates of effects of interventions or diagnostic strategies. In 2002, Haynes and colleagues described a model for making evidence-based clinical decisions (Haynes et al. 2002a, b). That model focuses on evidence as research evidence and requires an integration of other factors to make the best decisions. Since then, the field of practice guideline development has led us to develop an extended model of evidence-based decision-making.

In that model, there was increasing recognition (Fig. 47.1a, b) that clinical expertise is an overarching pillar of supporting best decision-making but that these decisions should be based on the best research evidence. The better recognition of the importance of patients' state and circumstances as well as values and preferences supplemented the original model. However, the emphasis was on research evidence about effects and a clear delineation of what constitutes evidence to support decision-making was missing.

EBM places a lower value on authority than the traditional medical paradigm and explicitly includes patients' and society's values in the clinical decision-making process. Patients or their proxies must always trade the benefits, harm, and costs associated with alternative treatment strategies and in doing so must consider values and preferences.

To achieve the integration of research results in clinical practice, EBM proposes a formal set of rules to help clinicians interpret and apply evidence. Clinical epidemiologists have, by and large, developed these rules, but they have been refined in the two decades of evidence-based medicine. These rules are characterized by a hierarchy of evidence: that is, the confidence in research results is greatest if systematic error (bias) is lowest and decreases if bias is more likely to play a role. However, they have moved from simple, now outdated

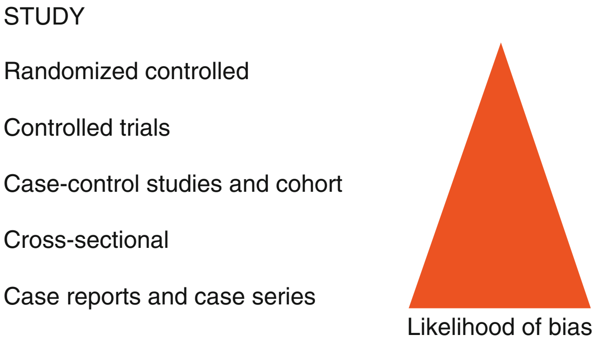

Fig. 47.2 Depicts the hierarchy of quality of evidence. As the research design becomes more rigorous (moving from *bottom* to *top*), the likelihood of bias of individual studies decreases

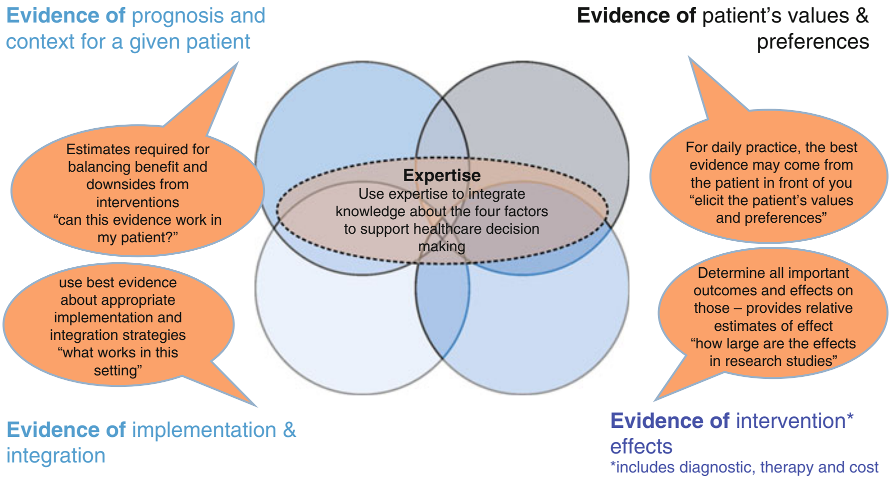
hierarchies as shown in the figure in the prior version of this chapter (Fig. 47.2) to balanced approaches that include considerations about "the evidence about the evidence."

Although randomized and controlled study designs provide the highest quality of evidence from a perspective of single studies, EBM is not a science of randomized controlled trials. Rather, because higher-quality evidence often is not available, EBM acknowledges that a large body of highly relevant evidence comes from observational studies. That is, to answer clinical questions clinicians will often depend on observational studies in their evidence-based practice. Therefore, the practice and application of EBM requires an understanding and critical evaluation of all study designs. Clinical epidemiology provides the necessary toolbox for this evaluation. For example, clinical epidemiologists of the Cochrane Collaboration, an international organization dedicated to making up-to-date and accurate information about the effects of health care readily available worldwide, have provided important insights into the conduct of systematic reviews and meta-analysis that inform clinicians and patients choices. It produces and disseminates systematic reviews of health care interventions and promotes the search for evidence. It can be accessed at www.cochrane.org. The Grading of Recommendations Assessment, Development and Evaluation (GRADE) working group has developed an approach to assessing the quality of a body of evidence for a given question, ideally based on highly credible systematic reviews (Atkins et al. 2004; Guyatt et al. 2008b, 2011a, b; Schünemann et al. 2011c). We will describe this approach in more detail below.

In a further evolved model for evidence-based decision-making, increasing emphasis is placed on the recognition that evidence about the various factors that influence decision-making can come from various sources and that a single patient in the clinical decision-making context provides evidence about her own values which requires integration with other pieces of evidence. Without doubt must the highest demands made toward obtaining any evidence with methods that are least vulnerable to bias. This new model also includes considerations about the best implementation and knowledge integration methods as a critical part of medical decision-making (Fig. 47.3).



Evidence of prognosis and context for a given patient
Evidence of patient's values & preferences
Estimates required for balancing benefit and downsides from interventions "can this evidence work in my patient?"
Expertise
Use expertise to integrate knowledge about the four factors to support healthcare decision making
For daily practice, the best evidence may come from the patient in front of you "elicit the patient's values and preferences"
use best evidence about appropriate implementation and integration strategies "what works in this setting"
Determine all important outcomes and effects on those – provides relative estimates of effect "how large are the effects in research studies"
Evidence of implementation & integration
Evidence of intervention* effects
*includes diagnostic, therapy and cost

Fig. 47.3 Evolved model of evidence-based decision-making

47.2 Case Scenario

Example 47.1.
Imagine you are the attending physician on ward rounds with your team. The senior resident presents the case of a 64-year-old woman who came to the emergency room one early morning with left-sided chest pain lasting for 15 minutes. The pain was severe enough to awaken her. She also had to sit up in her bed because of difficulties with getting her breath. Finally, her symptoms became so severe that she called an ambulance.

You immediately think that this woman has had an acute myocardial infarction. However, other diagnoses such as pulmonary embolism, pneumonia, pericarditis, asthma, and a severe case of gastroesophageal reflux disease also come to mind.

The resident continues with her presentation and tells you that the pain radiated to her left arm and neck and you further hear that she had another episode of similar pain in the ambulance. You feel that this information confirms your early intuition and that it makes a diagnosis of myocardial infarction more likely.

An electrocardiogram (EKG) in the emergency room was unremarkable and cardiac enzymes drawn at arrival to the emergency room were borderline elevated (troponin I, a marker for myocardial injury, was 1.5 microgram per milliliter (μg/ml)). Her chest x-ray was normal.

You now think that the diagnosis might be one of acute coronary syndrome, perhaps unstable angina or a myocardial infarction without EKG changes, and you continue to entertain pulmonary embolism, pneumonia, and pericarditis as alternative – although less likely – diagnosis. The key decision you face is whether to admit the patient to hospital, possibly to a cardiac care unit, or to send her home with provision for subsequent investigation, perhaps an exercise test.

The patient's past medical history includes diabetes mellitus type 2. Her lipid profile is within the limits set by the last available update of the National Cholesterol Education

Program Guidelines (Grundy et al. 2004), and there is no significant family history of cardiovascular disease. She takes an oral hypoglycemic agent and 325 mg of aspirin daily as recommended by her physician. She has had similar chest pain over the past year when vacuuming her home. However, she did not mention these complaints to her physician because the discomfort always resolved after a few minutes of rest. The patient has no history of cough, wheezing, indigestion, heartburn, or changes in her bowel habits. Your own physical examination of the patient following the resident's presentation shows an anxious patient, but there are no abnormal findings on physical examination.

Your team concludes that the probability that the presentation represents acute coronary syndrome is at least 50%. While you are discussing the patient and her further management, a second set of laboratory results shows that the troponin I is elevated at 4.1 μg/l.

At this point, you feel that a myocardial infarction without ST-segment elevation on the EKG (a non-ST-segment elevation myocardial infarction – NSTEMI) is the most likely diagnosis and together with your team you consider further management. This discussion focuses on which antiplatelet agents should be used in this patient.

47.3 Formulating a Clinical Question

Using research evidence to guide clinical practice requires formulating sensible clinical questions (Oxman et al. 1993; Richardson et al. 1995; McKibbon et al. 2002). For most questions, the key components are the patients, the intervention or exposure, comparison interventions (or exposure), and the outcomes (Table 47.1).

The clinical scenario of an older diabetic women presenting with chest pain potentially generates several clinical questions (about her diagnosis, appropriate therapy, prevention of future events, prognosis). We will use some of these questions to demonstrate how clinical epidemiology helps solve clinical problems and can make practice evidence-based.

Table 47.1 Formulating the clinical question

Component	Explanation
Population or patients	Who are the relevant patients?
Interventions or exposures	What are the management strategies clinicians are interested in? For example, diagnostic test, drugs, toxins, nutrients, and surgical procedures.
Comparison (or control) intervention or exposures	What is the comparison, control, or alternative intervention clinicians are interested in? For questions about therapy or harm, there will always be a comparison or control (including doing nothing, placebo, alternative active treatment, or routine care). For questions about diagnosis, there may be a comparison diagnostic strategy (for example, troponin I compared to creatine kinase MB in the diagnosis of myocardial infarction).
Outcome	What are the patient-important outcomes of the therapy, diagnostic test, or exposure clinicians are interested in?

47.4 Diagnosis

Based on the framework for developing a clinical question, we will start with a question about diagnosis:

Population:	In women with chest pain typical for angina pectoris
Intervention/exposure:	What is the test performance of troponin I serum levels?
Outcome:	To predict myocardial infarction and associated adverse outcomes (congestive heart failure, death, serious arrhythmia, or severe ischemic pain) in the next 72 hours

The process of diagnosis is a complex cognitive task. There are different approaches to making a diagnosis, but pattern recognition, which is also known as the gestalt method, and logical reasoning play an important role (Sox et al. 1988; Sackett et al. 1991; Glass 1996). Clinicians always look for clues that help them establish a diagnosis, although with increasing clinical experience this process becomes increasingly subconscious. Some clues make a diagnosis more likely; other clues or the absence of certain clues makes a diagnosis less likely (Ladenheim et al. 1987). In the scenario described at the beginning of this chapter, the first clue was the presence of left-sided chest pain awaking the patient at night. This clue suggested that the patient might suffer from a cardiac problem. The presence of shortness of breath strengthened this suspicion but brought other possible diagnosis into consideration (asthma, pneumonia, and pulmonary embolus).

When clinicians use clues offered by clinical history, symptoms, signs, or test results, they routinely, if often subconsciously, apply probabilities associated with these clues. For example, the presence of chest pain makes a heart attack more likely than no chest pain. Thus, a first step in making a diagnosis is to assign probabilities to the contemplated diagnoses. Clinicians then group the findings into coherent clusters, such as left-sided (location) chest (heart or lungs) pain (symptom). These clusters inform the differential diagnoses. The differential diagnoses in the case scenario included acute myocardial infarction, pulmonary embolism, pneumonia, asthma, or gastroesophageal reflux disease. In the next step of making a diagnosis, the clinician incorporates new information, which lowers or increases the relative likelihood of the differential diagnoses. The process is therefore sequential. The presence of pain radiating to the left arm increased the probability of coronary heart disease and the absence of cough and gastrointestinal symptoms lowered the likelihood of pneumonia and gastrointestinal disease.

47.4.1 Establish the Framework for Bayesian Thinking for Diagnosis

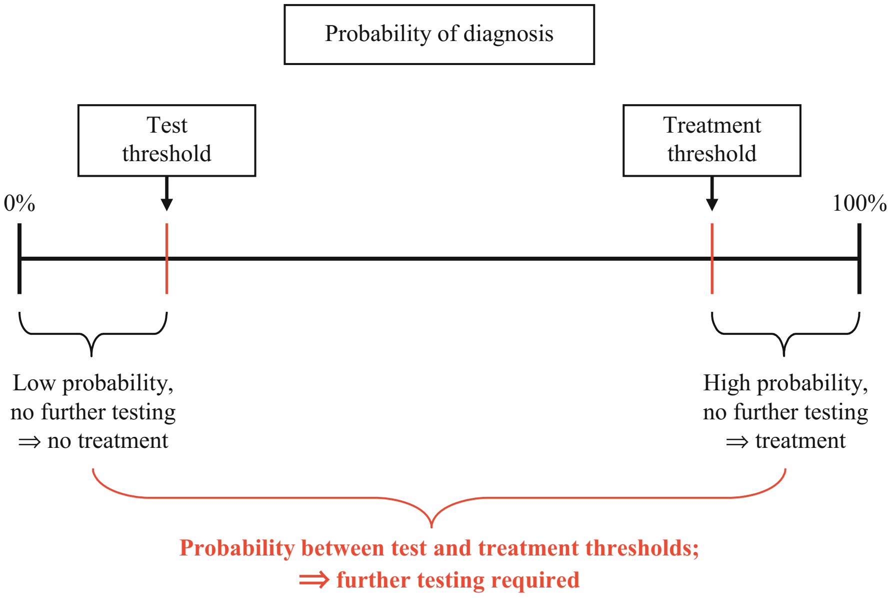
As described above, the process of diagnosis can take place on a subconscious level in which the clinician estimates the associated probabilities and relative likelihoods or it can employ explicit probabilities and relative likelihoods. For some clinical problems, such as diagnosing pulmonary embolism, a clinician's intuition is good. The Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study has shown this (PIOPED-Investigators 1990). Even when intuition is reasonably accurate, use of exact numbers generated by empirical studies can improve clinical decisions (Diamond and Forrester 1979; Diamond et al. 1980, 1981; Dolan et al. 1986). The latter approach of using explicit information is based on epidemiological and biostatistical concepts, but both the intuitive and the explicit approaches are founded in Bayesian theory, because both approaches depend on probabilities that are altered by subsequent information (Ledley and Lusted 1959; Bernardo and Adrian 1994; Berry 1996; Diamond 1999). Using the Bayesian approach in the diagnostic process, the clinician starts with a certain probability (often called the pretest probability) of a disease being present. Then, based on clues from the history, physical exam, or test results, the clinician modifies this probability into another probability (often called the posttest probability).

47.4.2 Choosing the Right Test

The best test would be one that excludes or confirms a diagnosis beyond doubt. Using an ideal test, no patient would have the disease if the test is negative and all patients with a positive test would have the disease. For our example, if troponin I was the perfect test, one could assume that a troponin I level $\geq 2\ \mu g/l$ proves beyond doubt that the patient has an acute myocardial infarction or will suffer a serious clinical event associated with acute coronary syndrome in the next 72 h, and a level $<2\ \mu g/l$ establishes that the patient does not have an acute myocardial infarction and will not suffer a serious event. Unfortunately, most information that clinicians obtain in clinical practice comes with uncertainty, and tests that definitively distinguish between disease and no disease are few and far between.

The typical cut-off value for troponin I in clinical practice is $2.0\ \mu g/l$ (Meier et al. 2002). However, astute clinicians would not dismiss a diagnosis of myocardial infarction in our scenario after the first troponin I level was $<2.0\ \mu g/l$, because both EKG and biomarkers may be what is typically defined as normal even when disease is present. Furthermore, they are aware that the troponin I may be normal early and may rise subsequently. What clinicians expect of a good test is that results change the probability sufficient to confirm or exclude a diagnosis. If a test result moves the probability below a threshold at which the disease is very unlikely and downsides associated with the treatment outweigh any anticipated benefit, then no further testing and no treatment are indicated. We call this probability the test threshold. If, on the other hand, the test result moves the probability of disease above a threshold at which one would not further test because disease is highly probable and one would start treatment, we have found the treatment threshold. This scenario shows how a clinician can estimate the probability of disease and then compare disease probability to these two thresholds (Fig. 47.4).

In a clinical context in which the pretest probability of a particular diagnosis is above the treatment threshold, further confirmatory testing that raises the probability further would not be helpful. On the other end of the scale, for a disease with a pretest probability below the test threshold, further exclusionary testing lowering



Probability of diagnosis
Test threshold
Treatment threshold
0%
100%
Low probability, no further testing ⇒ no treatment
High probability, no further testing ⇒ treatment
Probability between test and treatment thresholds; ⇒ further testing required

Fig. 47.4 Test and treatment thresholds

the probability would not be useful. When the probability is between the test and treatment thresholds, testing will be diagnostically useful. Test results are of greatest value when they shift the probability across either threshold.

What determines our treatment thresholds? If adverse effects of treatment are frequent and severe, clinicians choose a higher treatment threshold. For example, because a diagnosis of pulmonary embolism involves long-term anticoagulation with appreciable bleeding risk, clinicians are very concerned about falsely labeling patients. The invasiveness of the next test will also impact on the threshold. If the next test (such as a computed tomography angiography) does not have important side effects and generates few false-positives, clinicians are ready to choose a high treatment threshold. Clinicians are more reluctant to institute an invasive test associated with risks to the patient, such as a pulmonary angiogram, and this will drive their treatment threshold downward. That is, clinicians are more inclined to accept a risk of a false-positive diagnosis because a higher treatment threshold necessitates putting more patients through the risky test.

Accordingly, the more serious a missed diagnosis, the lower we will set our test threshold. Since a missed diagnosis of a pulmonary embolus could be fatal, clinicians are inclined to set their diagnostic threshold low. At the same time, the risks associated with the next test we are considering have an influence on where to set the test threshold. If the risks are low, clinicians will be comfortable with a very low diagnostic threshold. The higher the risks, the more the threshold rises.

47.4.3 Likelihood Ratios

The center of any diagnostic process is a patient presenting with a constellation of symptoms and signs. Consider two patients with chest pain and shortness of breath in whom the clinician suspects a myocardial infarction without findings suggestive of pneumonia, airflow obstruction, pulmonary embolism or heart failure, or other conditions. One patient is the 64-year-old woman described in the clinical scenario and the other is a 24-year-old man with a history of anxiety disorder. Clinicians would agree that the probabilities of myocardial infarction for these two patients – that is, their pretest probabilities – are very different. In the woman described in the scenario, the probability is high; in the young man, it is low. Consequently, even if both patients had borderline elevated troponin I levels of 1.0 μg/l at presentation, management is likely to differ between the two. An informed clinician might well treat the elderly woman immediately with aspirin, clopidogrel, anticoagulation, and percutaneous coronary interventions but order further investigations in the young man.

One can draw two conclusions from these considerations. First, regardless of the results of the troponin I test, they do not definitively establish whether myocardial infarction is in fact the underlying disease or whether the patient will suffer a serious event associated with an acute coronary syndrome. What they do accomplish is to alter the pretest probability of the condition, yielding a new posttest probability. The direction and magnitude of this change from pretest to posttest probability are determined by the test's properties. The test property of greatest value is the likelihood ratio.

Hill and colleagues (2004) investigated the diagnostic properties of troponin I as an early marker of acute myocardial infarction or acute coronary syndrome with serious sequelae in the next 72 h in patients who did not have definitively diagnostic EKG changes. The investigators found 20 individuals with a serious cardiac outcome by the reference standard and 332 individuals who did not (Table 47.2). For all patients, troponin I tests were classified into four levels: <0.5 μg/l, 0.5 to <2.0 μg/l, 2.0 to <10.0 μg/l, and ≥10.0 μg/l. Several questions arise.

How likely is a substantially elevated (≥10.0 μg/l) troponin I among people who suffered adverse outcomes? Table 47.2 illustrates that 3 of 20 (or approximately 15%) people with adverse outcomes had troponin I levels ≥10.0 μg/l. How often is the same test result, a positive troponin I, found among patients in whom high-risk acute coronary syndrome was suspected but ruled out? The answer is 4 out of 332 (or approximately 1.2%). The ratio of these two likelihoods is the likelihood ratio (LR); for a highly elevated troponin I test, it equals 0.15/0.012 (or 12.5). In other words, a highly elevated troponin I is 12.5 times as likely to occur in a patient with – in contrast to without – an ultimate adverse outcome.

In a similar fashion, one can calculate the likelihood ratios for troponin I values of <0.5 μg/l, 0.5 to <2.0 μg/l, and 2.0 to <10.0 μg/l. This calculation involves answering two questions: First, how likely it is to obtain a given test result (e.g., a troponin I < 0.5 μg/l) among people with the target disorder (myocardial infarction)? Second, how likely it is to obtain the same test result (again, a troponin

Table 47.2 Test properties of early troponin I testing in myocardial infarction or ischemia-associated adverse outcomes

	Myocardial Infarction or other adverse outcomes				
	Present | proportion		**Absent | proportion**		**Likelihood ratio (95% CI)**
Test results					
≥ 10.0 μg/l	3	3/20 = 0.15	4	4/332 = 0.012	12.5 (3.0, 51.9)
2.0 – <10.0 μg/l	2	2/20 = 0.10	5	5/332 = 0.015	6.6 (1.4, 32.1)
0.5 – < 2.0 μg/l	3	3/20 = 0.15	20	20/332 = 0.06	2.5 (0.8, 7.7)
<0.5 μg/l	12	12/20 = 0.60	303	303/332 = 0.910	0.7 (0.5, 0.9)
Total	20		332		

I $< 0.5\,\mu g/l$) among people without the target disorder? For this troponin I test result, the likelihoods are 12/20 (0.60) and 303/332 (0.91), respectively, and their ratio (the likelihood ratio) is 0.7.

Thus, the likelihood ratios indicate by how much a given diagnostic test result will raise or lower the pretest probability of the target disorder. A likelihood ratio of 1 indicates that the posttest probability is identical to the pretest probability. Likelihood ratios above 1.0 increase the probability that the target disorder is present, and the higher the likelihood ratio, the greater is this increase. Likelihood ratios below 1.0 decrease the probability of the target disorder, and the smaller the likelihood ratio, the greater is the decrease in probability and the smaller is its final value.

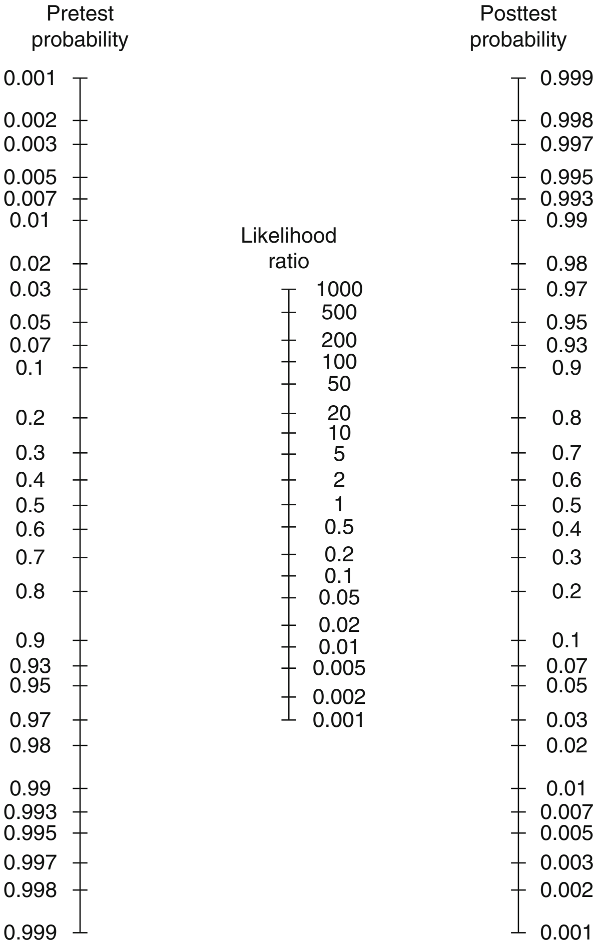
Users of likelihood ratios often ask “What are good likelihood ratios for a test?” The answer is that day-to-day clinical practice lets clinicians gain understanding and their own sense of interpretation and there is a strong dependence on the pretest probability, but one can consider the following as a rough guide:

1. Likelihood ratios of >10 or <0.1 generate large and often conclusive changes from pre- to posttest probability.
2. Likelihood ratios of 5–10 and 0.1–0.2 generate moderate shifts in pre- to posttest probability.
3. Likelihood ratios of 2–5 and 0.5–0.2 generate small (but sometimes important) changes in probability.
4. Likelihood ratios of 1–2 and 0.5–1 alter probability to a small (and rarely important) degree.

How can clinicians use likelihood ratios to move from pretest to posttest probability? Unfortunately, one cannot combine likelihoods directly, such as one can combine probabilities or percentages. Their formal use requires converting pretest probability to odds, multiplying the result by the likelihood ratio, and then converting the posttest odds into a posttest probability. Although this calculation is relatively straightforward for an experienced user, it can be time consuming and, fortunately, there is an easier way.

Figure 47.5 shows a nomogram proposed by Fagan that performs the conversions and allows simple transition from pre- to posttest probability (Fagan 1975). The line

Fig. 47.5 Likelihood ratio (Fagan) nomogram (copyright 1975 Massachusetts Medical Society. All rights reserved) (Reproduced with permission from the Massachusetts Medical Society)



on the left-hand side represents the pretest probability, the middle line represents the likelihood ratio (LR), and the line on the right-hand side depicts the resulting posttest probability. One can obtain the posttest probability by anchoring a straight line at the pretest probability and rotating it until it lines up with the likelihood ratio of the relevant test result.

If we assumed a pretest probability of 50% (see below) for the elderly woman with multiple risk factors and we applied the LR associated with a troponin I of 1.0 μg/l to the nomogram (connecting 0.5 or 50% on the left with an LR of approximately 2.5 on the middle line and extending it through the right line), we would obtain a posttest probability of approximately 70% (or 0.7). If we assumed a pretest probability of 1 in 1,000 or 0.1% for the young man and applied the same LR, the posttest probability remains very low at between 0.2% and 0.3%.

To further explain the application of LRs, let us assume the two patients had troponin levels of 0.3 μg/l. Applying the associated LR (0.7) to the pretest probability of 50% of the elderly woman would result in a posttest probability of approximately 45% (or 0.45). Applying this LR (0.7) to the pretest probability of 0.1% of the young man results in a posttest probability of <0.1%. It becomes evident from these latter two hypothetical examples that the test result has not altered the posttest probabilities to a large extent and further testing is necessary or that the clinician needs to make a decision on the basis of posttest probabilities that are similar to the pretest probabilities. These strategies will differ between the two patients. Most clinicians would remain worried about the elderly women but would safely discharge the young man.

Readers who are interested in the formula for converting pretest probabilities to posttest probabilities will note that it is based on Bayes theorem:

$$\text{posttest odds} = \text{pretest odds} \times \text{likelihood ratio.}$$

Mathematically, we can write this formula as

$$O(D|R) = (O(D) \times P(R|D))/P(R|\bar{D}),$$

where P is the probability of a specific test result R given the status of disease D = disease present, $\bar{D}$ = disease absent, and $O(D)$ is the odds of disease to be calculated as $P(D)/[1 - P(D)]$.

Example 47.1. (Continued)
Returning to our examples, for our elderly female patient with a test result of 1.0 μg/l and pretest odds $= 0.5/(1 - 0.5) = 1$, this formula translates to

$$\text{posttest odds of myocardial infarction} = 1 \times 0.15/0.06 = 2.5.$$

Posttest odds can be converted into posttest probabilities using the following formula:

$$\text{posttest probability} = \text{posttest odds/(posttest odds + 1)} = 2.5/(2.5 + 1) = 71.4\%.$$

This estimate is similar to the estimate on the Fagan Nomogram. In fact, had we been able to use the nomogram as accurately as the calculator we would have obtained identical numbers. This probability moves us into the range of probability where most clinicians would treat patients without further testing because of the morbidity and mortality associated with myocardial infarction.

Example 47.1. (Continued)
For the young male with a troponin of 1.0 μg/l, this formula translates to

$$\text{posttest odds of myocardial infarction} = \text{pretest odds} \times 2.5.$$

We can derive the pretest odds from the pretest probability of 0.1% = 0.001/(1 − 0.001) which is about 0.001.
Thus, it follows that the posttest odds can be calculated as

$$\text{posttest odds} = 0.001 \times 2.5 = 0.0025$$

and the posttest probability as

$$\text{posttest probability} = 0.0025/(0.0025 + 1)$$

which is approximately 0.25%.

Again, the estimate of 0.25% corresponds to the estimate using the Fagan Nomogram but is the exact result of the application of Bayes theorem. Even a troponin I test associated with an LR greater than 1 and commonly considered elevated in the young man does not alter the probability for a myocardial infarction to a great extent.

47.4.4 How to Obtain Pretest Probabilities

We guessed at the pretest probability of the two patients with chest discomfort. How do clinicians obtain valid pretest probabilities? Intuitively, clinicians use their experience based on previous patients with similar presentations. However, the probabilities clinicians and in particular learners assume are prone to bias and error (Richardson 2002; Richardson et al. 2003).

Richardson has suggested that there are two different forms of clinical research that can guide clinicians' estimates of pretest probabilities that need to be distinguished (Richardson 2002). The first type are studies that yield disease probability based on representative patient cohorts with a defined clinical problem that carry out careful diagnostic evaluations and apply explicit diagnostic criteria. Examples include studies on causes of syncope (Soteriades et al. 2002) and cancer in involuntary weight loss (Hernandez et al. 2003). The study by Hill et al. (2004) that provided the estimates for the test properties of troponin I to obtain pretest probabilities could also serve as example. Ideally these prognostic studies are summarized in systematic reviews and evaluated for the confidence that one has in the actual estimate of that pretest probability. The second type of studies is clinical decision rules. These studies assemble cohorts suspected of having the target disorder, apply standard reference tests, and report the frequency of diagnoses in subgroups with identifying clinical features (McGinn et al. 2003). High-quality studies that provide valid estimates of frequency are applicable to our patients and can provide precise estimates of pretest probability. For example, Richardson et al. (2003) estimated in a consecutive patient series that for 78% (95% confidence interval (CI) = (66%, 96%)) of clinical problems evidence of pretest probabilities existed in the literature.

47.4.5 Sensitivity and Specificity

Likelihood ratios help users understand diagnostic tests. However, clinicians use two other descriptive terms for diagnostic tests. It is, therefore, helpful for those with interest in clinical epidemiology to understand these two other terms: sensitivity and specificity.

Table 47.3 Sensitivity and specificity of diagnostic tests ($a + b + c + d = 100\%$)

	Disease or reference standard (proportion)	
	Present (positive)	Absent (negative)
Test results		
Disease present (positive)	True positive (a)	False positive (b)
Disease absent (negative)	False negative (c)	True negative (d)
Sensitivity =	True positive/positive reference standard ***a*/(*a* + *c*)**	
Specificity =		True negative/negative reference standard ***d*/(*b* + *d*)**
Likelihood ratio for positive test (LR+) =	Sensitivity/(1 − Specificity) = $(a/(a+c))/(1-d/(b+d))$	
Likelihood ratio for negative test (LR−) =	(1 − Sensitivity)/Specificity = $(1-(a/(a+c))/(d/(b+d))$	

We could have described the test properties of the study by Hill and colleagues using the concepts of sensitivity and specificity defining normal and abnormal test results. We presented the four different interpretations of troponin I levels, each with the associated likelihood ratios. That classification allowed us to omit the terms normal and abnormal or positive and negative. However, this is not the way most investigators present their result. Investigators also often rely on concepts of sensitivity and specificity.

Sensitivity expresses the proportion of people with the target disorder in whom the test result is positive and specificity expresses the proportion of people without the target disorder in whom a test result is negative. Table 47.3 shows the general concept of sensitivity and specificity in a 2 × 2 table. We could transform the 4 × 2 table described above (Fig. 47.2) into three 2 × 2 tables, depending on what we call positive or negative. Let us assume that only troponin I values $\geq 10.0\,\mu\text{g}/\text{l}$ are positive (or abnormal).

To calculate sensitivity from the data in Table 47.2 for positive troponin I levels, we look at the number of people with proven myocardial infarction ($n = 20$) who were diagnosed as having the target disorder on troponin testing ($n = 3$) showing a sensitivity of 3/20, or approximately 15% ($a/(a + c)$). To calculate specificity, we use the number of people without the target disorder (332) whose troponin test results were classified as normal or $<0.5\,\mu\text{g}/\text{l}$ (303), yielding a specificity of 303/332, or 91% ($d/(b + d)$).

As indicated above, one can easily calculate LRs for different levels of quantitative test results, while sensitivity and specificity require a definition of normal and abnormal that is often arbitrary. In using sensitivity and specificity, one has to either discard important information or recalculate sensitivity and specificity for every cut-point. Therefore, the likelihood ratio is much simpler and much more efficient when tests have more than two possible results, which is very often the case (Guyatt et al. 1990, 1992, 2008a).

47.5 Therapy/Prevention

Example 47.1. (Continued)

Returning to the clinical scenario and having treated the elderly woman with aspirin, clopidogrel, and fondaparinux as well as other relevant medication such as an ACE inhibitor and her other diabetes medication, the team questions whether or not clopidogrel should be continued long term. The fourth-year medical student on the team questions what the evidence related to this treatment is. The resident points you to a study that aimed at maximizing platelet inhibition in patients with acute coronary syndrome, the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial (CURE-Investigators 2001). You remember this study and that it is the only one you are aware of addressing this question in patients with acute coronary syndrome. You know that neurologists and cardiologists in your institution often use two antiplatelet agents to maximize platelet inhibition, but you are aware that this leads to an increased bleeding risk and wonder about the quality of the evidence supporting this conclusion and the magnitude of benefits and downsides. An electronic database search confirms that there is no additional evidence addressing this specific question in a randomized trial in patients with acute coronary syndrome (Keller et al. 2007; Vandvik et al. 2012). The CURE investigators addressed the following question. “In patients with acute coronary syndromes without ST-segment elevation, does early and long-term use of clopidogrel plus aspirin versus aspirin alone prevent cardiovascular events and is the combination safe?” You find that this question would be highly relevant to your patient in whom you want to prevent further cardiovascular events.

You decide to critically appraise this study together with your team. The resident retrieves the article through your library’s online full text journal subscription and you evaluate the article with your team over lunch break.

The concepts of clinical epidemiology help clinicians appraise clinical research. We list the three commonly agreed on steps of critical appraisal for studies on therapy or prevention in Table 47.4 and describe how clinical epidemiology facilitates interpretation and evaluation of clinical research. This form addresses critical appraisal for most clinicians. Other important issues for experienced readers concern the appropriateness of the statistical methods.

The first factor that can influence confidence in research results is systematic error or bias. Bias is directly linked to the design and execution of a study. Therefore, the first step is an appraisal of whether results are valid and to what extent bias is present (Table 47.4 – Are the results valid?). The next step in the evaluation of research is the review of the results. Because clinicians often are unfamiliar with applying the magnitude of effects to patient care and because classical epidemiology applies research results in different contexts using different terminology, clinical epidemiologists can bring quantitative outcome measures closer to the clinician. This helps address the question “How large is the effect of an intervention and how large is the role of random error or chance? (What are the results?)” Finally, clinicians need to know whether the results are applicable to their patients. Therefore, clinicians need to appraise whether the results help with decision-making in individual practice circumstances (How can I apply the results to my patient care?). Clinicians must decide whether their patients are similar to those included in the studies from which they obtain the relevant evidence, but clinical epidemiologists can help them in the decision-making process (see Sect. 47.8).

Table 47.4 Critical appraisal of studies about therapy

Question	Therapy or prevention
Study design and execution – evaluation of bias	I. Are the results of the study valid? 1. Were patients randomized? 2. Was randomization concealed? 3. Were patients analyzed in the groups to which they were randomized? 4. Were patients in the treatment and control groups similar with respect to known prognostic factors? 5. Were patients aware of group allocation? 6. Were clinicians aware of group allocation? 7. Were those who collected the data aware of group allocation? 8. Were outcome assessors aware of group allocation? 9. Were data analysts aware of group allocation? 10. Was follow-up complete?
Results and random error	II. What are the results? 1. How large was the treatment effect? 2. How precise was the estimate of the treatment effect?
Application and uptake	III. How can I apply the results to my patient care? 1. Were the study patients similar to my patients? 2. Were all clinically important outcomes considered? 3. Are the likely treatment benefits worth the potential harms and costs?

Critical appraisal (Table 47.4) of the CURE trial reveals that patients were randomized using a 24-h computerized randomization service to conceal randomization. Control patients received placebos and investigators and outcome assessors were blinded to treatment assignment. While blinding refers to not being aware of treatment allocation when treatment has been assigned, concealment refers to avoiding biased allocation of patients because of prior knowledge of forthcoming treatment allocation. Investigators can achieve concealment through measures such as central (telephone) randomization and sealed envelopes. The more stringent the method for concealment, the less likely are those allocating patients to temper with this important aspect of randomized controlled trials. Fulfilling these validity criteria protects against bias, because systematic reviews suggest that lack of blinding and concealment (see Table 47.4) may lead to systematic overestimation of treatment effects although the effects may differ by clinical specialty only (Moher et al. 1998; Balk et al. 2002).

The CURE investigators achieved a follow-up of greater than 99.9% (only 13 out of 12,562 patients were lost) and analyzed patients in the group they were assigned according to the intention to treat principle. The intention to treat principle refers to analysis of patient outcomes based on which group they were randomized regardless of whether they actually received the planned intervention. This analysis preserves the power of randomization, thus maintaining that important unknown factors that influence outcome are likely equally distributed in each comparison group.

Table 47.5 Measures of association and effect

General 2 × 2 table

	Outcome		Absolute risk of outcome:
	+	−	
Intervention (Y)	a	b	Intervention $= a/(a+b) = Y$
Control (X)	c	d	Control $= c/(c+d) = X$

2 × 2 Table for the example from CURE et al. (CURE-Investigators 2001)

	Combined primary outcome		Absolute risk of outcome:
	+	−	
Clopidogrel	1,035	5,224	Clopidogrel = 1,035/(1,035 + 5,224) = 16.5%
Placebo	1,187	5,116	Placebo = 1,187/(1,187 + 5,116) = 18.8%

Absolute risk reduction (*ARR*)
Definition: The difference in risk between the control group and the intervention group
$ARR = c/(c+d) - a/(a+b) = X - Y$
Example:
$ARR = 1{,}187/(1{,}187 + 5{,}116) - 1{,}035/(1{,}035 + 5{,}224) = 2.3\%$ points

Relative risk or risk ratio (*RR*)
Definition: The ratio of risk in the intervention (Y) to the risk in the control group (X)
$RR = Y/X$
Example:
$RR = (1{,}035/(1{,}035 + 5{,}224))/(1{,}187/(1{,}187 + 5{,}116)) = 0.87$

Relative risk reduction (*RRR*)
Definition: The percent reduction in risk in the intervention compared to the control group
$RRR = 1 - RR = (1 - X/Y) \times 100\%$ or
$RRR = [(X - Y)/X] \times 100\%$
Example:
$RRR = (1 - 0.87) \times 100\% = 13\%$

Number needed to treat (*NNT*) – to benefit (NNT_B) or harm (NNT_H)
Definition: Inverse of the *ARR*
$NNT_B = 1/ARR = 1/(X - Y)$
Example:
$NNT_B = 1/2.3\% = 44$

The evaluation of clinical research results requires an understanding of measures of association or effect. As noted above, clinical epidemiologists often use terms that are different from those of classical epidemiologists (see relative risk reduction and number needed to treat below in this section). Table 47.5 summarizes the measures we will now describe in more detail (cf. chapter ▶Rates, Risks, Measures of Association and Impact of this handbook).

47.5.1 Absolute Risk

The easiest measure of risk to understand in clinical epidemiology is the absolute risk. In the CURE trial, the main outcomes were a composite of death from cardiovascular causes, non-fatal myocardial infarction (MI), or stroke and a composite of death from cardiovascular causes, non-fatal MI, stroke, or refractory ischemia. Safety outcomes included major and minor bleeding. We will focus on the latter composite endpoint. The absolute risk for this combined primary endpoint was 16.5%, and the absolute risk for this outcome in the control group was 18.8% (Table 47.5). As described above, other terminologies for the risk of an adverse outcome in the control group are baseline risk, absolute risk, or control event rate.

47.5.2 Absolute Risk Reduction

One can express treatment effects as the difference between the absolute risks in the experimental and control groups, the absolute risk reduction, or the risk difference (*RD*). This effect measure represents the proportion of patients spared from the unfavorable outcome if they receive the experimental therapy (clopidogrel), rather than the control therapy (placebo). In our example, the absolute risk reduction is $18.8\% - 16.5\% = 2.3\%$ points.

47.5.3 Relative Risk

The relative risk or risk ratio presents the proportion of the baseline risk in the control group that still is present when patients receive the experimental treatment (clopidogrel). The relative risk of the combined outcome after receiving clopidogrel is $1{,}035/(1{,}035 + 5{,}224)$ divided by $1{,}187/(1{,}187 + 5{,}116)$ (the risk in the control group), or 0.87. One could also say the risk of experiencing the combined outcome with clopidogrel and aspirin is approximately 87% of that with aspirin alone.

47.5.4 Relative Risk Reduction

The most commonly reported measure of dichotomous treatment effects is the complement of this relative risk, the relative risk reduction. One can obtain the relative risk reduction easily from the relative risk because it is the proportion of baseline risk that is removed by the experimental therapy and it is equivalent to 1.0 – relative risk. It can be expressed as a percent: $(1 - \text{relative risk}) \times 100\% = (1 - 0.87) \times 100\% = 13\%$ or $100\% - 87\% = 13\%$ for this example. Alternatively, one may obtain the relative risk reduction by dividing the absolute risk reduction by the absolute risk in the control group. Therefore, the result is the same if it is calculated from 2.3% (the absolute risk reduction) divided by 18.8% (the risk in the control group) $= 0.13$ (13%). A relative risk reduction of 13% means that clopidogrel reduced the risk of combined outcome by 13% relative to that occurring among control patients. The greater the relative risk reduction, the more efficacious is the therapy. Investigators may compute the relative risk over a period of time,

Table 47.6 Relation between risks and odds

Risk (%)	Risk (proportion)	Odds
80	0.80	4.0000
60	0.60	1.5000
50	0.50	1.0000
40	0.40	0.6667
33	0.33	0.5000
25	0.25	0.3333
20	0.20	0.2500
10	0.10	0.1111
5	0.05	0.0526
1	0.01	0.0101

as in a survival analysis, and call it a hazard ratio, the weighted relative risk over the entire study (see chapter ▶Survival Analysis of this handbook).

In fact, the CURE investigators calculated the hazard ratio which was slightly more in favor of clopidogrel (0.86). For practical purposes, we use the relative risk for the CURE trial in our example. If we had used the hazard ratio for the calculation of the *RR*, the *RRR* would have been 14%.

47.5.5 Odds Ratio

Instead of evaluating the risk of an event, one can estimate the odds of having an event compared with not having an event. Most individuals are familiar with odds in the context of sporting events, when sport reporters describe the odds of a team or player winning a particular event. When odds are used in the medical sciences, it stands for the proportion of patients with the target outcome divided by the proportion without the target outcome. The odds in the control group of the example trial described are 1,187 of 6,303 divided by 5,116 of 6,303. Because the denominator is the same in both the numerator and the denominator, it is canceled out, leaving the number of patients with the event (1,187) divided by the number of patients without the event (5,116). The odds are 1,187/5,116 or 0.232. To convert from odds to risk, one divides the odds by 1 plus the odds. As the odds of the combined endpoint are 0.232, the risk is $0.232/(1 + 0.232)$, or 0.188 (18.8%), identical to the baseline risk reported in the CURE trial. Table 47.6 presents the link between risk and odds. The greater the risk, the greater is the divergence between the risk and odds. Odds and risk are about equal if the absolute risk is small.

In the CURE trial, the odds of the combined endpoint in the clopidogrel group are 1,035 (those with the outcome) compared with 5,224 (those without the outcome), or $1{,}035/5{,}224 = 0.198$, and the odds of the combined endpoint in the placebo group are 0.232. Therefore, the ratio of these odds is (1,035/5,224)/(1,187/5,116), or 0.854. If one used a terminology parallel to risk (note that epidemiologists call a ratio of risks in most instances a relative risk), one would call the ratio of odds relative odds. The commonly used term, however, is odds ratio (*OR*). The odds ratio has been the most popular measure of association. The reason for the use of the odds ratio is that the odds ratio has a statistical advantage because it essentially is independent of the choice between a comparison of the risks of an event (such as death) and the analogous non-event (such as survival), which is not true of the relative risk.

However, clinicians do not easily understand a ratio of odds. Clinicians would like to be able to substitute the relative risk, because it is more intuitively understandable, for the odds ratio. As shown in Table 47.6, as the risk decreases, the odds and risk come closer together. For low event rates, the odds ratio and relative risk are very close. In fact, if the risk is below 25%, odds and risks are approximately equal and many authors calculate relative odds and then report the results as if they calculated relative risks. One can see from the example that the odds ratio of 0.85 is very similar to the relative risk of 0.87. Clinicians should be aware that if events are frequent in either the control group or experimental group, odds ratios can be a very inaccurate estimate of the relative risk. The *RR* and *OR* also will be more similar when the treatment effect is small (*OR* and relative risk are close to 1.0) than when the treatment effect is large. When considering *RR*, *HR*, and *OR*, the *RR* is always closest to unity; the odds ratio is farthest away; and the *HR* is intermediate (Symons and Moore 2002). These differences can become large when effect sizes increase. When event rates are high and effect sizes are large, there are ways of converting the odds ratio to relative risk. Fortunately, clinicians will need to do this infrequently. One note of caution is that typical case-control studies do not yield relative risks.

47.5.6 The Number Needed to Treat and Natural Frequencies

Having seen that making a distinction between odds ratio and relative risk rarely will be important when evaluating clinical research, because high event rates are rare, one must give much more attention to distinguishing between the odds ratio and relative risk compared with the absolute risk reduction. Let us assume that the absolute risk of experiencing the combined outcome would be twice as high in both groups in the CURE trial. This could have happened if the investigators had conducted a study in patients at greater risk for the endpoint, for example, by restricting the study population to older patients. In the clopidogrel group, the absolute risk would become 33% compared with 37.6% in the control group. Therefore, the absolute risk reduction would increase from 2.3 to 4.6%, whereas the relative risk (and therefore the relative risk reduction) would remain identical at 33% divided by 37.6% = 0.87 (the relative risk reduction remains 13%). Therefore, the increase in the proportion of those experiencing the endpoint in both groups by a factor of 2 leaves the relative risk (and the relative risk reduction) unchanged but increases the absolute risk reduction by a factor of 2.

A 13% reduction in the relative risk of the combined endpoint may not sound very impressive; however, its impact on patient groups and practice may be large.

This notion is shown using the concept of the number needed to treat, the number of patients who must receive an intervention during a specific period to prevent one additional adverse outcome or produce one positive outcome (Laupacis et al. 1988). When discussing the number needed to treat, it is important to specify the treatment, its duration, and the outcome being prevented. The number needed to treat is the inverse of the absolute risk reduction, calculated as 1/absolute risk reduction. Therefore, in the example above with an absolute risk reduction of 4.6%, the number needed to treat to benefit (*NNT* or NNT_B) would be 22 (1/4.6%) and it would be 44 (1/2.3%) in the CURE trial. Finally, imagine young patients with no additional risk factors for adverse outcomes. Such patients may carry a baseline risk of 4% for experiencing the endpoint and, therefore, the number needed to treat could increase to 192 $[1/(0.13 \times 4\%)]$. Given the duration, potential harms and cost of treatment with clopidogrel, and the increased risk for bleeding, it could be reasonable to withhold therapy in that latter patient. The *NNT* should always, to prevent misinterpretation, be provided with the time frame that is required to achieve the effect. Unfortunately, we do not know for certain how best to present risk information to patients (Akl et al. 2011). However, presenting the relative risk reduction alone is more persuasive for making actual or hypothetical medical decisions, because the actual benefit appears larger (Bucher et al. 1994; Edwards and Elwyn 1999; Edwards et al. 1999; Akl et al. 2011). Thus, direct to patient advertising and pharmaceutical industry detailing uses relative risk reduction as measure of effect to persuade clinicians and patients to use drug interventions. However, omitting the presentation of baseline risk or not informing those who receive this information that the baseline risk drives the absolute benefit is misleading (Akl et al. 2011). A recent systematic review also showed that there is no clear evidence that the presentation as *NNT* or *ARR* is superior (Akl et al. 2011). Evidence is mounting although not entirely consistent that natural frequencies, numbers presented per 100 or 1,000 where a 33% absolute risk reduction would be expressed as 33 per 100, are better understood and lead to more correct answers (Akl et al. 2011; Woloshin and Schwartz 2011).

47.5.7 How Clinicians Can Use Confidence Intervals

Until now we presented the results of the CURE trial as if they represented the true effect. The results of any experiment, however, represent only an estimate of the truth. The true effect of treatment actually may be somewhat smaller, or larger, than what researchers found. The confidence interval (CI) tells, within the bounds of plausibility, how much smaller or greater the true effect is likely to be. For each of the measures described, one can use statistical programs to calculate confidence intervals.

The point estimate within the confidence interval and the confidence interval itself help with two questions. First, what is the one value most likely to represent the true difference between treatment and control; and second, given the difference between treatment and control, what is the plausible range of differences within which the true effect might actually lie? The smaller the sample size or the number of events in an experiment, the wider the confidence interval. As the sample size gets very large and the number of events increases, investigators become increasingly certain that the truth is not far from the point estimate and, therefore, the confidence interval is narrower.

One can interpret the 95% confidence interval as "what is the range of values of probabilities within which, 95% of the time, the truth would lie?" If investigators or clinicians would not need to be so certain, one could ask about the range within which the true value would lie 90% of the time. This 90% confidence interval would be somewhat narrower.

How does the confidence interval facilitate interpretation of the results from the CURE trial? As described above, the confidence interval represents the range of values within the truth plausibly lies. Accordingly, one way to use confidence intervals is to look at the boundary of the interval that represents the lowest plausible treatment effect and decide whether the action or recommendation would change compared with when one assumes the point estimate represents the truth. Based on the numbers provided in the CURE trial, one can calculate a confidence interval around the point estimate of the relative risk reduction of 13% ranging from approximately 6 to 21%. Values progressively farther from 13% will be less and less likely. One can conclude that patients receiving clopidogrel are less likely to experience the combined endpoint – but the magnitude of the difference may be either quite small (and not outweigh the increased risk of bleeding) or quite large. This way of understanding the results avoids the yes/no dichotomy of testing a hypothesis. Because the lower limit of the CI is associated with a benefit, certainty about beneficial treatment effects from clopidogrel on the combined endpoint is relatively high. However, toxicity and expense will bear on the final treatment decision.

The chief toxicity of clopidogrel the authors of the CURE trial were concerned about was bleeding. They found that the absolute risk increase (*ARI* – conceptually similar to the absolute risk reduction but indicating an increase in risk from the investigational therapy) for major bleeding was 1% point (an increase from 2.7% in the placebo group to 3.7% in the clopidogrel group). The investigators defined major bleeding as substantially disabling bleeding, intraocular bleeding or the loss of vision, or bleeding necessitating the transfusion of at least 2 units of blood. Similarly to the number needed to treat, we can calculate the number of patients who must receive an intervention during a specific period to cause one additional harmful outcome. The number needed to treat to inflict harm (*NNH* or NNT_H) for major bleeding in the CURE trial is equal to 1/*ARI* or $1/0.01 = 100$. The authors also provided the information for minor bleeding which they defined as hemorrhages that led to interruption of the study medication but did not qualify as major bleeding. The risk for minor bleeding was 5.1% in the clopidogrel group compared to 2.4% in the placebo group. Thus, the *NNH* for minor bleeding was $1/0.027 = 37$. Clinicians should keep in mind that estimates of harm also come with uncertainty and, therefore, authors usually present confidence intervals around these harmful effects.

47.5.8 Use of Composite Endpoints

Investigators often use a composition of endpoints when they compare interventions. For example, the CURE trial investigators used a composite endpoint of death from cardiovascular causes, non-fatal MI, stroke, or refractory ischemia. Safety outcomes included major and minor bleeding with the definitions described in the foregoing paragraph. There are a number of reasons for combining several endpoints. First, investigators may believe that distinguishing between outcomes is unnecessary because the endpoints have the same consequences. For example, many investigators combine the outcome ischemic stroke with hemorrhagic stroke because they believe they may be similarly disabling (Lubsen and Kirwan 2002). Second, investigators may choose composite endpoints to avoid misleading conclusion when an intervention reduced an endpoint (usually less severe) by increasing another endpoint (usually more severe) that precludes patients from suffering the less severe endpoint. For example, surgery for cerebrovascular disease could reduce strokes by directly killing those at highest risk for stroke (those who die at surgery are no longer at risk for strokes) (van Walraven et al. 2002). Thus, the use of stroke alone as the endpoint would be misleading. To avoid an erroneous conclusion, an investigator facing this situation must combine the more and less serious outcomes, creating an endpoint such as “stroke or death.” Third, investigators chose to combine endpoints because of the reduced sample size when event rates increase, as one would expect for a combined endpoint. The latter is probably the reason why the CURE investigators used a combined efficacy endpoint.

Using composite endpoints has a number of implications. The most obvious implication is that if these endpoints have different importance to patient (i.e., patients have different underlying values and preferences for these outcomes), treating them as equally important is an oversimplification.

Using combined endpoints does not always support reaching conclusive results in clinical trials. Freemantle et al. (2003) reported on the use of composite endpoints in 167 trials published between 1997 and 2001 in 9 leading medical journals. The authors found that in 69 of these trials the difference between treatment arms in the CEP was not statistically significant. Investigators sometimes included component endpoints that reduced trial efficiency by diluting the treatment effect. For example, Freemantle and colleagues described that the CAPRICORN (Carvedilol Post-Infarct Survival Control in LV Dysfunction) trial investigated the effects of carvedilol, a ß-blocker, in 1,959 patients with left ventricular dysfunction following myocardial infarction (The CAPRICORN Investigators 2001). Originally, the CAPRICORN investigators identified all-cause mortality as primary outcome in the trial protocol. However, while the study was ongoing, the data and safety monitoring board (whose assignment is to protect the patients in a trial) noted that the overall rate of mortality was lower than that predicted for the power analysis and sample size calculation. The board informed the CAPRICORN steering committee of the trial’s insufficient power to identify the primary endpoint as significant (a preset level of significance α of 0.05). Taking the uncommon measure of altering the primary outcome, the steering committee defined a new composite outcome (all-cause mortality or cardiovascular hospital admissions). The steering committee assigned a critical level of significance of $\alpha = 0.045$ to this new composite outcome that they introduced while the trial was ongoing and reduced the significance level of the original primary outcome to achieve statistical significance to $\alpha = 0.005$. They reduced the level of α of the original primary outcome to penalize their retrospective action, but the board decided that if the p-value for either primary outcome achieved statistical significance at the new critical level, the study would be deemed positive.

At the end of the study, the original primary endpoint (all-cause mortality) achieved a p-value of 0.03 (i.e., substantially larger than the new 0.005 allocated after consultation from the data safety and monitoring board but smaller than the original critical level of significance), but the alternative primary outcome achieved a p-value of 0.30. Thus, the original primary outcome did not reach statistical significance at the new and more stringent level and neither did the new composite outcome. Although 12% of patients died in the carvedilol group, compared with 15% in the placebo group, 23% of patients in the carvedilol group and 22% of patients in the placebo group qualified for the composite outcome on the basis of hospitalizations alone, a result that undermined the relatively small reduction in mortality in the carvedilol group. Thus, CAPRICORN provides a neutral result, although the study would have been modestly statistically significant had the original primary outcome of all-cause mortality been maintained.

Of even more concern, composite endpoints can be misleading when the components vary in importance and the least important endpoints dominate the composite (Montori et al. 2005). The use of composites has become widespread, particularly in cardiovascular trials, and trials in which the least important component dominates the results are frequent (Ferreira-Gonzalez et al. 2007).

In summary, evaluating trials that use composite outcome requires scrutiny in regard to the underlying reasons for combining endpoints and its implications and has impact on medical decision-making (see below in Sect. 47.8). Composite endpoints are credible only when the components are of similar importance and the relative effects of the intervention are similar across components (Guyatt et al. 2008a).

47.6 Systematic Reviews

The patient in our scenario took aspirin at a dose of 325 mg on admission. Aspirin use is associated with gastrointestinal bleeding and the risk for bleeding increases with the aspirin dose used (Weil et al. 1995; García Rodríguez et al. 2001). On the other hand, the beneficial effects of lower doses of aspirin on cardiovascular events likely do not differ from those of higher doses (Antithrombotic Trialists' Collaboration 2002). Taken together, studies comparing higher and lower doses of aspirin show similar effects. However, a clinician would ask the following question: "Which of the available studies should I trust and consider for decision-making?" Even for clinicians trained in critical appraisal, evaluating all available studies would be a time-intensive solution.

Traditionally, clinicians – when they did not invest the time and resources to review individual studies – have relied on review articles by authorities in the field. However, experts may be unsystematic in their approach to summarizing the evidence. Unsystematic approaches to identification and collection of evidence risks biased ascertainment. That is, treatment effects may be underestimated or, more commonly, overestimated, and side effects may be exaggerated or ignored. Even if the evidence has been identified and collected in a systematic fashion, if reviewers are then unsystematic in the way they summarize the collected evidence, they run similar risks of bias. In one study, self-rated expertise was inversely related to the methodological rigor of the review (Oxman and Guyatt 1993). One result of unsystematic approaches may be recommendations advocating harmful treatment; in other cases, there may be a failure to encourage effective therapy. For example, experts supported routine use of lidocaine for patients with acute myocardial infarction when available data suggested the intervention was ineffective and possibly even harmful, and they failed to recommend thrombolytic agents for the treatment of acute myocardial infarction when data showed patient benefit (Antman et al. 1992).

Systematic reviews deal with this problem by explicitly stating inclusion and exclusion criteria for evidence to be considered, conducting a comprehensive search for the evidence, and summarizing the results according to explicit rules that include examining how effects may vary in different patient subgroups. When a systematic review pools data across studies to provide a quantitative estimate of overall treatment effect, we call this summary a meta-analysis (cf. chapter ▶Meta-Analysis in Epidemiology of this handbook). Systematic reviews provide higher-quality evidence when the quality of the primary study design is high and other criteria are fulfilled (see section below on GRADE); they typically provide weaker evidence when study designs are observational in nature or other reasons to lower our confidence in the estimates of effect exist, for example, when sample sizes are small and/or designs are poor. Because judgment is involved in many steps in a systematic review (including specifying inclusion and exclusion criteria, applying these criteria to potentially eligible studies, evaluating the methodological quality of the primary studies, and selecting an approach to data analysis), the results of systematic reviews are not immune to bias, for example, publication bias (Atkins et al. 2004; Schünemann et al. 2011a, b).

Nevertheless, in their rigorous approach to identifying and summarizing data, systematic reviews reduce the likelihood of bias in estimating the causal links between management options and patient outcomes.

Over the past 20 to 25 years, the literature describing the methods used in systematic reviews, including studies that provide an empiric basis for guiding decisions about the methods used in summarizing evidence, has rapidly expanded. Clinical epidemiologists have contributed significantly to this development (Egger et al. 2000).

Table 47.7 demonstrates the process of conducting systematic reviews.

As we described above for answering questions in clinical practice (see also Table 47.1), investigators who conduct a systematic review should begin by formulating a clinical question. This question formulation constitutes the essential specific selection criteria for deciding which studies to include in a review. These criteria define the population, the exposures or interventions, the comparison

Table 47.7 The process of conducting systematic reviews

Define the question

- Specify inclusion and exclusion criteria
  - Population
  - Intervention or exposure (and comparison)
  - Outcome
  - Methodology
- Establish a priori hypotheses to explain heterogeneity
- Consider the content of the Summary of Findings (SoF) Table

Conduct literature search

- Decide on information resources: databases, experts, funding agencies, pharmaceutical companies, hand-searching, personal files, registries, citation lists, or retrieved articles
- Determine restrictions: time frame, unpublished data, language
- Identify titles and abstracts

Apply inclusion and exclusion criteria

- Apply inclusion and exclusion criteria to titles and abstracts
- Obtain full articles for eligible titles and abstracts
- Apply inclusion and exclusion criteria to full articles
- Select final eligible articles
- Assess agreement on study selection

Create data abstraction

- Data abstraction: participants, interventions, comparison interventions, study design
- Results
- Methodological quality
- Assess agreement on validity assessment between data abstractors

Conduct analysis

- Determine method for pooling results
- Pool results (if appropriate)
- Decide on handling of missing data

Assess quality of a body of evidence and present results

- Assess the quality of a body of evidence by outcome with the GRADE approach
- Present data in a Summary of Findings (SoF) Table
- Interpret data

intervention, and the outcomes of interest. When formulating the clinical question, authors of systematic reviews should consider all outcomes that are critical or important for decision-making. A good way to present findings from a systematic review is a *Summary of Findings (SoF) Table* which we will describe below (Schünemann et al. 2011a, b). A systematic review will also restrict the included studies to those that meet minimal methodological standards. For example, systematic reviews that address a question of therapy will often include only randomized controlled trials.

Having evaluated the potential eligibility of titles and abstracts, and obtained the full text of potentially eligible studies, reviewers apply the selection criteria to the complete reports. Having completed the data collection process, they assess the methodological quality of the eligible articles and abstract data from each study. Finally, they summarize the data, including, if appropriate, a quantitative synthesis or meta-analysis. The analysis includes an examination of differences among the included studies, an attempt to explain differences in results (exploring heterogeneity), a summary of the overall results, and an assessment of their precision and validity. Guidelines for assessing the validity of reviews and using the results correspond to this process and are available (Oxman et al. 2002).

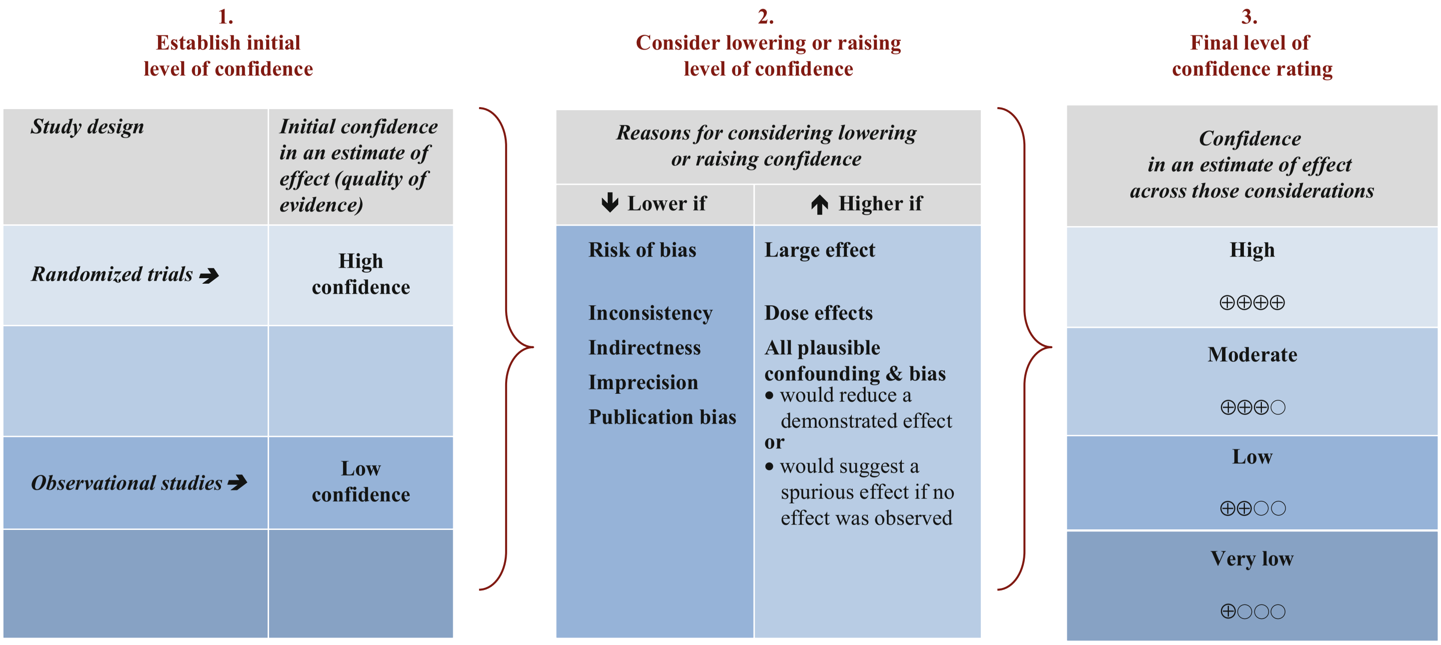
Systematic reviews and other summaries of the evidence should express the confidence users of the review can place in estimates of effect. The GRADE working group has developed an approach to doing this. The next section will focus on this approach and describe a Summary of Findings Table (Guyatt et al. 2011a).

47.7 The GRADE Approach

The GRADE approach assesses the confidence in estimates of effect (i.e., the quality of a body of evidence) for an outcome following a stepwise and transparent process. GRADE classifies the confidence in an estimate of effect into four categories from very low (⊕OOO), low (⊕⊕OO), moderate (⊕⊕⊕O), to high (⊕⊕⊕⊕). The quality of a body of the available best evidence is assessed, beginning with an evaluation of the underlying study design (randomized trials vs. observational studies). This is followed by a detailed assessment of limitations in the design and execution of the studies (risk of bias), imprecision, inconsistency, indirectness, publication bias, magnitude of effect, dose-effect relations, and an assessment of the effect of plausible residual opposing confounding and bias. The overall quality of evidence is determined by the lowest quality of evidence for each of the critical outcomes (Fig. 47.6).

When outcomes point in the same direction (all critical outcomes suggesting benefit), then the overall quality of evidence reflects the quality of the better evidence (e.g., two critical outcomes showing convincing benefit are of low quality and a third of very low quality, the overall quality is not reduced from low to very low). This approach is used by over 70 international organizations, including the World Health Organization (WHO), the National Institute of Health and Clinical Excellence in the UK (NICE), and professional societies such as the American College of Physicians.

One of the outcomes of an assessment following the GRADE approach is a GRADE evidence profile or a Summary of Findings (SoF) Table (for an example, see Fig. 47.7). An SoF Table presents a summary of the key findings from a systematic review in a table, facilitating understandings and identification of key information. There are five sections of the Summary of Findings Table. The first section describes the question the systematic review addresses, including the intervention that was evaluated, to what it was compared and in whom. Next, the table includes information about the desirable and undesirable outcomes that are important to patients and other decision-makers; information for up to seven outcomes can be provided. The third section describes the numerical results for each outcome. In particular, the magnitude of the effect is presented in relative



1.
Establish initial
level of confidence

Study design	*Initial confidence in an estimate of effect (quality of evidence)*
Randomized trials ➔	**High confidence**
Observational studies ➔	**Low confidence**

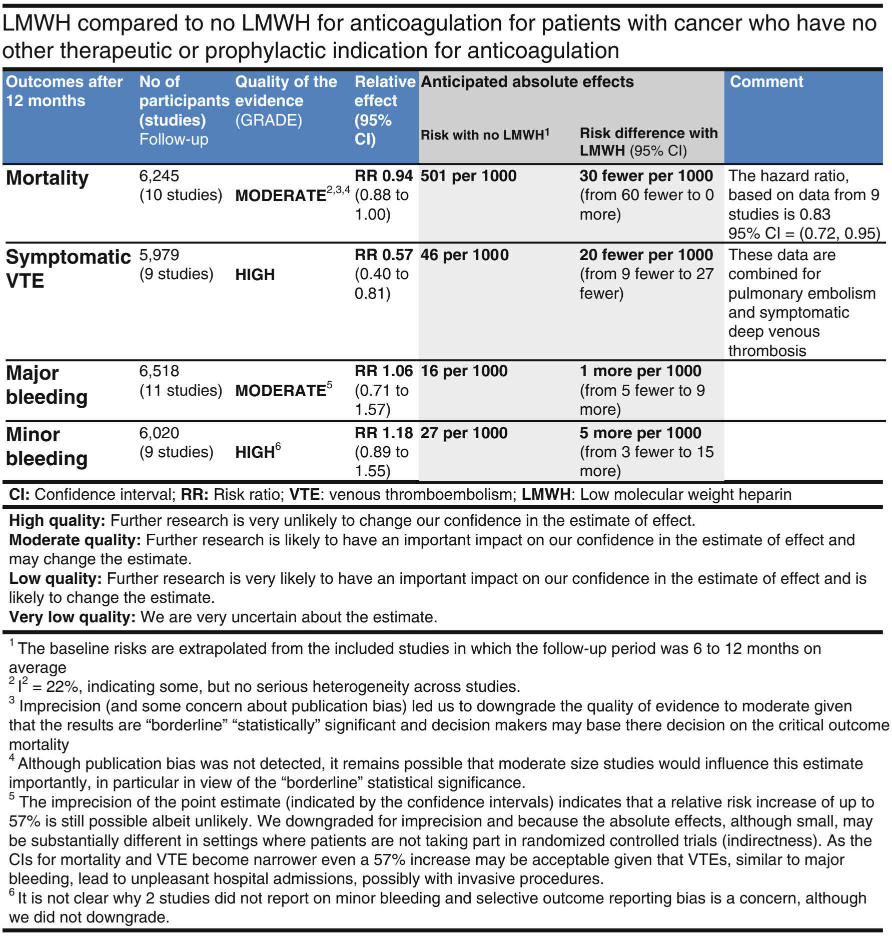
2.
Consider lowering or raising
level of confidence

Reasons for considering lowering or raising confidence	
↓ **Lower if**	↑ **Higher if**
Risk of bias **Inconsistency** **Indirectness** **Imprecision** **Publication bias**	**Large effect** **Dose effects** **All plausible confounding & bias** • would reduce a demonstrated effect **or** • would suggest a spurious effect if no effect was observed

3.
Final level of
confidence rating

Confidence in an estimate of effect across those considerations
High ⊕⊕⊕⊕
Moderate ⊕⊕⊕○
Low ⊕⊕○○
Very low ⊕○○○

Fig. 47.6 GRADE's approach to rating quality of evidence (aka confidence in effect estimates) *For each outcome based on a systematic review and across outcomes (lowest quality across the outcomes critical for decision-making)*



LMWH compared to no LMWH for anticoagulation for patients with cancer who have no other therapeutic or prophylactic indication for anticoagulation

Outcomes after 12 months	No of participants (studies) Follow-up	Quality of the evidence (GRADE)	Relative effect (95% CI)	Anticipated absolute effects		Comment
				Risk with no LMWH[1]	Risk difference with LMWH (95% CI)	
Mortality	6,245 (10 studies)	**MODERATE**[2,3,4]	**RR 0.94** (0.88 to 1.00)	**501 per 1000**	**30 fewer per 1000** (from 60 fewer to 0 more)	The hazard ratio, based on data from 9 studies is 0.83 95% CI = (0.72, 0.95)
Symptomatic VTE	5,979 (9 studies)	**HIGH**	**RR 0.57** (0.40 to 0.81)	**46 per 1000**	**20 fewer per 1000** (from 9 fewer to 27 fewer)	These data are combined for pulmonary embolism and symptomatic deep venous thrombosis
Major bleeding	6,518 (11 studies)	**MODERATE**[5]	**RR 1.06** (0.71 to 1.57)	**16 per 1000**	**1 more per 1000** (from 5 fewer to 9 more)	
Minor bleeding	6,020 (9 studies)	**HIGH**[6]	**RR 1.18** (0.89 to 1.55)	**27 per 1000**	**5 more per 1000** (from 3 fewer to 15 more)	

CI: Confidence interval; **RR:** Risk ratio; **VTE**: venous thromboembolism; **LMWH**: Low molecular weight heparin

High quality: Further research is very unlikely to change our confidence in the estimate of effect.
Moderate quality: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate.
Low quality: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate.
Very low quality: We are very uncertain about the estimate.

[1] The baseline risks are extrapolated from the included studies in which the follow-up period was 6 to 12 months on average
[2] I^2 = 22%, indicating some, but no serious heterogeneity across studies.
[3] Imprecision (and some concern about publication bias) led us to downgrade the quality of evidence to moderate given that the results are "borderline" "statistically" significant and decision makers may base there decision on the critical outcome mortality
[4] Although publication bias was not detected, it remains possible that moderate size studies would influence this estimate importantly, in particular in view of the "borderline" statistical significance.
[5] The imprecision of the point estimate (indicated by the confidence intervals) indicates that a relative risk increase of up to 57% is still possible albeit unlikely. We downgraded for imprecision and because the absolute effects, although small, may be substantially different in settings where patients are not taking part in randomized controlled trials (indirectness). As the CIs for mortality and VTE become narrower even a 57% increase may be acceptable given that VTEs, similar to major bleeding, lead to unpleasant hospital admissions, possibly with invasive procedures.
[6] It is not clear why 2 studies did not report on minor bleeding and selective outcome reporting bias is a concern, although we did not downgrade.

Fig. 47.7 Summary of Findings (SoF) summarizing the key findings of a systematic review (developed with Dr. E. Akl) (Akl and Schunemann 2012)

effects (taken directly from the results of the review) and in absolute effects (calculated based on baseline risks). The number of studies and the participants for which there were data are also described. The fourth section provides the assessment of the quality of evidence using the GRADE approach. Finally, there is a section for footnotes and comments. The footnotes and comments describe the judgments behind the quality of the evidence and additional information about how to interpret the results (e.g., validity of an outcome measure). GRADE evidence profiles and SoF Tables can be produced with the GRADE profiler software (freely available for non-profit purposes through www.guidelinedevelopment.org) (Brozek et al. 2011).

Returning to our example, the question you want to address could be formulated as follows: "In patients with coronary artery disease, does low-dose aspirin (75 mg daily or less) compared with high-dose aspirin (325 mg daily or more) confer similar mortality benefits?" Keep in mind that gastrointestinal side effects are more likely with higher doses of aspirin.

A prudent clinician will look for a systematic review to answer this question. A systematic review by the Antithrombotic Trialists' Collaboration provides useful information to answer this question (Antithrombotic Trialists' Collaboration 2002). The investigators carefully evaluated 448 trials for inclusion and finally performed a meta-analysis of 195 trials of antiplatelet effects in cardiovascular disease. Overall they observed that aspirin markedly reduced the risk of recurrent events in patients with acute myocardial infarction (odds ratio 0.7) and patients with previous myocardial infarction (odds ratio 0.75). They identified three trials in patients at high risk for cardiovascular events that compared doses of aspirin of $\leq$75 mg daily to higher doses. Higher doses of aspirin conferred no additional benefit in preventing cardiovascular events when compared with lower doses. In fact the point estimate indicated a benefit of lower doses of aspirin (relative odds reduction 8%). However, these results were not statistically significant (95% CI ranging from approximately -12% indicating a slight benefit with higher doses to 28% indicating a benefit with lower doses). When the investigators compared the effects of low-dose aspirin versus placebo and higher-dose aspirin versus placebo, the effects were similar. Although the evidence from direct comparisons is limited and the investigators included additional patient populations, such as patients with stroke, the systematic review and meta-analysis of all available trials provides additional indirect evidence for comparable effects of higher- and low-dose aspirin. Most clinicians would judge the biology for the role of aspirin in coronary artery disease and other cardiovascular disease to be sufficiently similar to have confidence in this extrapolation. Combining the available evidence in a properly conducted systematic review helps the clinician to obtain answers that are valid and based on methodological evaluation of the literature. Chapter ▶Meta-Analysis in Epidemiology of this handbook addresses methodological issues related to meta-analysis.

Having explained some of the benefits of systematic reviews, we will explain how systematic reviews can be used to guide patient care. Available guidance on therapeutic or prevention goes beyond systematic reviews, because factors in addition to the quality of the evidence and treatment effects are important to make recommendations about treatment (Freemantle et al. 1999). However, systematic reviews should be conducted in the process of generating evidence-based guidelines that provide treatment recommendations (Institute of Medicine 2011).

47.8 Guidelines

Guidelines are systematically developed statements, based on the best available evidence, that should assist providers and recipients of health care and other stakeholders to make informed decisions. Recommendations (in guidelines) may relate to clinical interventions, public health activities, or government policies

(World Health Organization 2003). The key elements of each synthesis include the scope of the guidelines, the interventions and practices considered, the major recommendations and the strength of the evidence and recommendations, and the underlying values and preferences (Guyatt et al. 2002a; Guyatt et al. 2004b; Schünemann et al. 2004, Schunemann et al. 2006a, b; Institute of Medicine 2011; Qaseem et al. 2012; Shekelle et al. 2012). A list of guidelines maintained by the US Agency for Healthcare Research and Quality is available at the National Guidelines Clearinghouse (U.S. Department of Health and Human Services 2013) and by the Guidelines International Network (GIN).

Organizations such as professional societies or governing boards, government agencies, and academic or private institutions typically develop guidelines by convening expert panels. Usually, guideline developers will define the topic of a guideline before evaluating the evidence for clinical sensible questions. Dialogue among clinicians, patients, and the prospective users of the guideline contributes to its refinement. Although it is possible to develop guidelines that are broad in scope, it requires considerable time and resources. Before engaging in a guideline development process, management of conflict of interests has become a key step. This can occur in many different ways and suggestions have been made by several authors and organizations (Schunemann et al. 2009; Guyatt et al. 2010; Eccles et al. 2012; Norris et al. 2012).

One method of defining and focusing the clinical questions of interest and also identifying the processes for which evidence needs to be collected and assessed is the construction of models or causal pathways (Woolf 1994). The causal pathway is a diagram showing the relation of the population, intervention(s) of interest, and the intermediate, surrogate, or definitive health outcomes (Shekelle et al. 1999). When designing the pathway, guideline developers should describe explicitly which outcomes (benefits and harms) they consider important and the associated values. This process reveals specific questions that the evidence must address and where high-quality evidence is lacking, identifying areas for additional research.

While investigators have not tested alternative approaches to guideline development, one suggestion is to include all groups whose activities would be covered by the guidelines and any others with legitimate reasons for having input (Shekelle et al. 1999). A group size of 6 to 15 individuals with clearly identified roles, including group leader and members, specialist resource, technical support, and administrative support, may be advisable (Shekelle et al. 1999). The group should comprise members proficient in the following areas: literature searching and retrieval, epidemiology, biostatistics, health services research, clinical area of interest (generalists and specialists), group process, writing, and editing.

Over the past few years, several groups have suggested standards for the preparation of clinical practice guidelines (Shiffman et al. 2003; Schünemann et al. 2004; Schunemann et al. 2006a, b; Institute of Medicine 2011; Qaseem et al. 2012). A high-quality clinical practice guideline should consider the following steps which include a systematic review of the literature:

1. Define explicit criteria to search for evidence. Similar to the clinical sensible questions identified above for searching the evidence and conducting systematic reviews, this step should include a clear definition of the population, the

intervention and comparison intervention, and the outcome of interest. The development of a clinical pathway helps in identifying the components of the clinical question and in identifying gaps.

2. Define explicit eligibility criteria for the identified evidence. Guideline development groups should define eligibility criteria for the evidence that they wish to include. Examples include restricting evidence to randomized controlled trials or studies that have used validated instruments for functional outcomes or assessed mortality.
3. Conduct or use comprehensive searches for evidence. A guideline development group should ensure that they conduct a complete evaluation of the evidence. The group may either use a high-quality systematic review developed by others or conduct their own systematic review for each recommendation they make in their guideline.
4. Perform a standard consideration of study quality. If a systematic review is identified that answers the group's clinical question and may suffice for developing the guideline, the group should still consider an evaluation of the individual study quality. Should the group conduct a systematic review or update an existing review, the evaluation of study quality becomes an essential step in conducting a systematic review. Quality evaluation includes looking at the basic study design, the detailed study design and execution, and the directness of evidence. The directness of the evidence refers to reporting of surrogate outcomes, for example, deep venous thrombosis by ultrasonography as risk factor for fatal events, versus outcomes such as mortality.
5. Summarize the evidence. Guideline development groups who use high-quality systematic reviews often will find meta-analysis of studies included in the systematic review. The summaries help in obtaining estimates of intervention effects. It is important to note that summary estimates should be available for all important outcomes, both beneficial and harmful. Ideally the summary estimates also would be available for cost.
6. Acknowledge values and preferences underlying the group's recommendations (Schunemann et al. 2006a, b). Many guideline reports take for granted that guideline developers adequately represent patients' interests. The latter is not necessarily correct and there is a risk that, for example, a specialty society may recommend procedures where the benefits may not outweigh the risks or costs (Woolf et al. 1999). For example, the American Urologic Society and the American Cancer Society recommend prostate cancer screening with prostate-specific antigen (PSA) for men older than 50, while the American College of Preventive Medicine and the US Preventive Services Task Force (USPSTF) do not make this recommendation (Ferrini and Woolf 1998; American Urological Association 2000; USPSTF 2002; Smith et al. 2003). Thus, there should be clear statements about which principles, such as patient autonomy, non-maleficence, or distributive justice, were given priority in guiding decisions about the value of alternative interventions to inform users of the guidelines (Shekelle et al. 1999). Guidelines should report whether it is intended to optimize values for individual patients, reimbursement agencies, or society as a whole. Groups that

ensure representation by experts in research methodology, practicing generalists and specialists, and public representatives are more likely to have considered diverse views in their discussions than groups limited to content area experts.

7. Grade the strength of recommendations. Because clinicians are interested in the strength of a recommendation and the balance of benefits and risks, the next section is devoted to recommendations and the grading of the strength of recommendations. Many organizations use the GRADE approach to doing this.

Recommendations Treatment decisions involve balancing likely benefits against harms and costs. Evidence-based guidelines and treatment recommendations are systematic syntheses of the best available evidence that provide clinicians with guidance for treating average patients in clinical practice. To integrate recommendations with their own clinical judgment, clinicians need to understand the basis for the clinical recommendations that experts offer them. A common systematic approach to grading the strength of treatment recommendations can minimize bias and aid interpretation.

As part of the first American College of Chest Physician (ACCP) Consensus Conference on Antithrombotic Treatment in 1986, Sackett suggested a formal rating scheme, derived from the Canadian Task Force on the Periodic Health Examination, for assessing levels of evidence (Canadian Task Force on the Periodic Health Examinsation 1979; Sackett 1986). During the past 25 years, clinical epidemiologists have lead the evolution of these "rules of evidence" (Cook et al. 1992; Guyatt et al. 1995, 2001, 2011a, b, 2002a, b; Atkins et al. 2004; Brozek et al. 2011), which experts have applied to generate grades of recommendations.

The strength of any recommendation depends on four factors: the trade-off between benefits and downsides and the quality of the body of evidence that leads to estimates of the treatment effect, values and preferences, and resource considerations. The GRADE approach to grading the quality of evidence and strength of recommendations captures the key issues of guideline development. GRADE generates strong or weak (aka conditional) recommendations either in favor or against a management strategy based on evaluation of the four factors that influence the strength of recommendations (Table 47.8).

Examples of recommendations developed with the GRADE approach are now ubiquitous in the medical literature (Schunemann et al. 2007a, b; Brozek et al. 2010; Fiocchi et al. 2010; Falzon et al. 2011; Qaseem et al. 2011; Akl et al. 2012; Bates et al. 2012; Santesso et al. 2012). Many guideline developers use frameworks such as the one shown in Table 47.9 to enhance transparency and record the process and reasons for recommendations (Santesso et al. 2012).

Table 47.8 Reasons and definition of strong and weak recommendations according to GRADE

Strength	Definition
Strong	The guideline panel is confident that the desirable effects of adherence to the recommendation outweigh the undesirable effects
Conditional	The guideline panel concludes that the desirable effects of adherence to a recommendation probably outweigh the undesirable effects

Table 47.9 GRADE approach to moving from evidence to recommendations: enhancing transparency when moving from evidence to recommendations

Question/recommendation:

Population/patients:

Intervention:

Setting (if relevant):

Decision domain	**Explanation**	**Summary of reason for judgment**	**Judgment**
Quality of evidence (QoE) *Is there high or moderate quality evidence?* The higher the quality of evidence, the more likely is a strong recommendation	**Consider** **QoE for benefits:** **QoE for harms:** **QoE for resource use:** • *Key reasons for down- or upgrading?* • *All critical outcomes measured?*		Yes No □ □
Balance of benefits versus harms and burdens *Are you confident that the benefits outweigh the harms and burden or vice versa?* The larger the difference between the benefits and harms and the certainty around that difference, the more likely is a strong recommendation. The smaller the net benefit or net harm and the lower the certainty for that net effect, the more likely is a conditional/weak recommendation	**Baseline risk for benefits, harms and burden:** • *Is the baseline risk similar across subgroups?* • *Should there be separate recommendations for subgroups?* **Relative risk for benefits and harms:** • *Are the relative benefits large?* • *Are the relative harms large?* **Requirement for modeling:** • *Is there a lot of extrapolation and modeling required for these outcomes?* **Average values:** • *What are the average values?* • *Are there differences in the relative value of the critical outcomes?*		Yes No □ □

Values and preferences *Are you confident about the assumed or identified relative values and are they similar across the target population?* The more certainty or similarity in values and preferences, the more likely a strong recommendation	**Perspective taken:** **Perspective taken:** • *Patients or general population/society?* **Source of values:** **Source of variability if any:** **Method for determining values satisfactory for this recommendation:**	Yes ☐ No ☐
Resource implications *Are the resources worth the expected net benefit from following the recommendation?* The lower the cost of an intervention compared to the alternative and other costs related to the decision – that is, the fewer resources consumed – the more likely is a strong recommendation in favor of that intervention	**What are the costs per resource unit?** **Feasibility:** • *Is this intervention generally available?* **Opportunity cost:** • *Is this intervention and its effects worth withdrawing or not allocating resources from other interventions?* **Differences across settings:** • *Is there lots of variability in resource requirements across settings?*	Yes ☐ No ☐
Overall strength of recommendation		
Remarks		
Evidence to recommendation synthesis		

Returning to our clinical scenario and applying the GRADE approach to grading of recommendation, the use of clopidogrel in addition to aspirin generated the following recommendation regarding the dual use of aspirin and clopidogrel over aspirin alone in the last iteration of the ACCP antithrombotic guidelines (Vandvik et al. 2012):

For patients in the first year after an acute coronary syndrome who have not undergone percutaneous coronary intervention, [the guideline panel] recommends dual antiplatelet therapy [. . .] clopidogrel 75 mg daily plus low-dose aspirin 75–100 mg daily over single antiplatelet therapy (strong recommendation, moderate quality evidence).

In the next section, we will describe the importance of health-related quality of life (HRQL) outcomes followed by a section on integrating patient preferences in decision-making and how clinical epidemiology is key in obtaining patients' preferences and values.

47.9 Health-Related Quality of Life Instruments and Their Application in Clinical Studies

Clinical journals have published trials in which HRQL instruments are the primary outcome measures. With the expanding importance of HRQL in evaluating new therapeutic interventions, investigators (and readers) are faced with a large array of instruments. Researchers have proposed different ways of categorizing these instruments, according to the purpose of their use, into instruments designed for screening, providing health profiles, measuring preference, and making clinical decisions (Osoba 1991), or into discriminative and evaluative instruments.

We have also suggested a taxonomy based on the domains of HRQL which an instrument attempts to cover (Guyatt et al. 1989). According to this taxonomy, an HRQL instrument may be categorized, in a broad sense, as generic or specific. *Generic instruments* cover (or at least aim to cover) the complete spectrum of function, disability, and distress of the patient and are applicable to a variety of populations. Within the framework of generic instruments, health profiles and utility measures provide two distinct approaches to measurement of global quality of life. *Specific instruments* are focused on disease or treatment issues specifically relevant to the question at hand.

47.9.1 Generic Instruments

Health profiles are single instruments that measure multiple different aspects of quality of life. They usually provide a scoring system that allows aggregation of the results into a small number of scores and sometimes into a single score (in which case, it may be referred to as an index). As generic measures, their design allows their use in a wide variety of conditions. For example, one health profile, the Sickness Impact Profile (SIP), contains 12 "categories" which can be aggregated into two dimensions and five independent categories and also into a single overall score (Bergner et al. 1981). The SIP has been used in studies of cardiac rehabilitation (Ott et al. 1983), total hip joint arthroplasty (Liang et al. 1985), and treatment of back pain (Deyo et al. 1986). In addition to the SIP, there are a number of other health profiles available: the Nottingham Health Profile (Hunt et al. 1980), the Duke-UNC Health Profile (Parkerson et al. 1981), and the McMaster Health Index Questionnaire (Sackett et al. 1977). Increasingly, a collection of related instruments from the Medical Outcomes Study (Tarlov et al. 1989) has become the most popular and widely used generic instruments. Particularly popular is one version that includes 36 items, the SF-36 (Brook et al. 1979; Ware and Sherbourne 1992; Ware et al. 1995). The SF-36 is available in over 40 languages and normal values for the general population in many countries are available.

While each health profile attempts to measure all important aspects of HRQL, they may slice the HRQL pie quite differently. For example, the McMaster Health Index Questionnaire follows the World Health Organization approach and identifies three dimensions: physical, emotional, and social. The Sickness Impact Profile includes a physical dimension (with categories of ambulation, mobility, body care, and movement), a psychosocial dimension (with categories including social interaction and emotional behavior), and five independent categories including eating, work, home management, sleep and rest, and recreations and pastimes.

General health profiles offer a number of advantages to clinical investigators. Their reproducibility and validity have been established, often in a variety of populations. When using them for discriminative purposes, one can examine and establish areas of dysfunction affecting a particular population. Identification of these areas of dysfunction may guide investigators who are constructing disease-specific instruments to target areas of potentially greatest impact on the quality of life. Health profiles, used as evaluative instruments, allow determination of the effects of an intervention on different aspects of quality of life, without necessitating the use of multiple instruments (and thus saving both the investigator's and the patient's time). Because health profiles are designed for a wide variety of conditions, one can potentially compare the effects on HRQL of different interventions in different diseases. Profiles that provide a single score can be used in a cost-effectiveness analysis, in which the cost of an intervention in dollars is related to its outcome in natural units.

The main limitation of health profiles is that they may not focus adequately on the aspects of quality of life specifically influenced by a particular intervention. This may result in an inability of the instrument to detect a real effect in the area of importance (i.e., lack of responsiveness). In fact, disease-specific instruments offer greater responsiveness compared with generic instruments (Guyatt et al. 1999; Wiebe et al. 2003; Brozek et al. 2009). We will return to this issue when we discuss the alternative approach, specific instruments.

47.9.2 Specific Instruments

An alternative approach to HRQL measurement is to focus on aspects of health status that are specific to the area of primary interest. The rationale for this approach lies in the increased responsiveness that may result from including only those aspects of HRQL that are relevant and important in a particular disease process or even in a particular patient situation. One could also focus an instrument only on the areas that are likely to be affected by a particular drug.

In other situations, the instrument may be specific to the disease (instruments for chronic lung disease, for rheumatoid arthritis, for cardiovascular diseases, for endocrine problems, etc.); specific to a population of patients (instruments designed to measure the HRQL of the frail elderly, who are afflicted with a wide variety of different diseases); specific to a certain function (questionnaires which examine emotional or sexual function); or specific to a given condition or problem (such as pain) which can be caused by a variety of underlying pathologies. Within a single condition, the instrument may differ depending on the intervention. For example, while success of a disease-modifying agent in rheumatoid arthritis should result in improved HRQL by enabling a patient to increase performance of physically stressful activities of daily living, occupational therapy may achieve improved HRQL by encouraging family members to take over activities formerly accomplished with difficulty by the patient. Appropriate disease-specific HRQL outcome measures should reflect this difference.

Specific instruments can be constructed to reflect the "single state" (how tired have you been: very tired, somewhat tired, full of energy) or a "transition" (how has your tiredness been: better, the same, worse) (MacKenzie and Charlson 1986). The same could be said of generic instruments. Specific measures can integrate aspects of morbidity, including events such as recurrent myocardial infarction (Olsson et al. 1986).

The disease-specific instruments may be used for discriminative purposes. They may aid, for example, in evaluating the extent to which a primary symptom (e.g., dyspnea) is related to the magnitude of physiological abnormality (e.g., exercise capacity) (Mahler et al. 1987). Disease-specific instruments can be applied for evaluative purposes to establish the impact of an intervention on a specific area of dysfunction, and hence aid in elucidating the mechanisms of drug action (Jaeschke et al. 1991). Guidelines provide structured approaches for constructing specific measures (Guyatt et al. 1986). Whatever approaches one takes to the construction of disease-specific measures, a number of head-to-head comparisons between generic and specific instruments suggest that the latter approach will fulfill its promise of enhancing an instrument's responsiveness, the ability to detect change in HRQL (Tandon et al. 1989; Tugwell et al. 1990; Chang et al. 1991; Laupacis et al. 1991; Smith et al. 1993; Goldstein et al. 1994).

In addition to the improved responsiveness, specific measures have the advantage of relating closely to areas routinely explored by the physician. For example, a disease-specific measure of quality of life in chronic lung disease focuses on dyspnea during day-to-day activities, fatigue, and areas of emotional dysfunction, including frustration and impatience (Guyatt et al. 1987). Specific measures may therefore appear clinically sensible to the clinician.

The disadvantages of specific measures are that they are (deliberately) not comprehensive and cannot be used to compare across conditions or, at times, even across programs. This suggests that there is no one group of instruments that will achieve all the potential goals of HRQL measurement. Thus, investigators may choose to use multiple instruments. Some of these instruments are preferences or value instruments that can also be used for clinical decision-making described in the next section.

47.10 Integrating Patient Preferences in the Decision-Making Process and Resolution of the Clinical Scenario

In reviewing the data from the CURE trial, you conclude that if the patient before you does not receive clopidogrel as additional therapy, the best estimate of the risk for recurrent myocardial infarction or any of the other endpoints summarized in the composite endpoint in the trial during the next year is 16.5% and, further, that clopidogrel is likely to decrease this risk by approximately 13%, corresponding to absolute risk reductions (*ARR*) of 2.3% points over a 1-year period. As described above, this translates into a number needed to treat (*NNT*) for 1 year to prevent one of the endpoints summarized in the composite endpoint of approximately 44 for treatment with clopidogrel (Table 47.5).

Examining the likelihood of major bleeding, the CURE trial suggests an absolute risk increase of 1.0%. This estimate translates into a *NNH* of 100. In light of your knowledge that the patient before you is intelligent, conscientious, and very concerned about his health, you anticipate a high rate of adherence; in addition, you anticipate that the bleeding risk rate of 1% (or the *NNT* of 100) represents a good estimate for risk of the patient in front of you.

Considering these numbers, you are aware that the treatment decision may depend on the relative value the patient places on avoiding a recurrent myocardial infarction or any of the other endpoints summarized in the composite endpoint in the CURE trial and avoiding a major bleeding including those leading to vision loss. We have pointed out that since there are always advantages and disadvantages to an intervention, evidence alone cannot determine the best course of action. Patients, their proxies, or, if a parental approach to decision-making is desirable, the clinician as decision-maker must always trade the benefits, harm, and costs associated with alternative treatment strategies, and values and preferences always bear on those trade-offs. Findings that assume that the patient's values are similar to one's own, yet this may be incorrect. For example, facing a decision concerning anticoagulation in atrial fibrillation, clinicians are more concerned about bleeding risk, and place less weight on the associated stroke reduction, than patients (Devereaux et al. 2001). Thus, a fundamental principle of EBM is the explicit inclusion of patients and society's values and clinical circumstances in the clinical decision-making process as described before in Fig. 47.1b (Haynes et al. 2002a, b). Clinical epidemiology can help identifying and applying the key issues in the decision-making process.

Considering the model by Haynes et al. (2002a, b) and our updated model, you are now faced with the problem of how to best incorporate the patient's values into the decision. Before resolving the scenario, we will describe different ways to optimize decision-making.

For many – perhaps most – of our clinical decisions, the trade-off is sufficiently clear that clinicians need not concern themselves with variability in patient values. Previously healthy patients will all want antibiotics to treat their pneumonia or their urinary tract infection, anticoagulation to treat their pulmonary embolus, or aspirin to treat their myocardial infarction. Under such circumstances, a brief explanation of the rationale for treatment and the expected benefits and side effects will suffice.

When benefits and risks are balanced more delicately and the best choice may differ across patients, clinicians must attend to the variability in patients' values (such as in a weak recommendation in the GRADE approach to grading recommendations). One fundamental strategy for integrating evidence with preferences involves communicating the benefits and risks to patients, thus permitting them to incorporate their own values and preferences in the decision. One advantage of this approach is that it avoids the vexing problem of measuring patients' values. Unfortunately, the problem of communicating the evidence to patients in a way that allows patients to clearly and unequivocally understand their choices is almost as vexing as the direct measurement of patient values.

A second basic strategy is to ascertain the relative value patients place on the key outcomes associated with the management options. One can then consider the likely outcomes of alternative courses of action and use the patient's values as the basis of trading off benefits and risks. When done in a fully quantitative way, this approach becomes a decision analysis using individual patient preferences (Guyatt et al. 2002a, b). A number of texts provide information on decision analysis and decision analyses are available for a number of topics, such as the prevention of ischemic stroke with warfarin in atrial fibrillation (Petitti 1994; Thomson et al. 2000; Guyatt et al. 2002a, b).

In addition, patients often have preferences not only about the outcomes, but about the decision-making process itself. These preferences can vary, and the patient's desired level of involvement should determine which approach the clinician takes (Strull et al. 1984; Degner et al. 1997; Stiggelbout and Kiebert 1997). Ethicists have characterized the alternative strategies (Emanuel and Emanuel 1992). At one end of the spectrum, the physician acts as a technician, providing the patient with information and taking no active part in the decision-making process. This corresponds to the first strategy for incorporating patient values, presenting patients with the likely benefits, risks, inconvenience, and cost and then letting patients decide. At the opposite extreme, corresponding to the second strategy, ascertaining the patient's values and then making a recommendation in light of the likely advantages and disadvantages of alternative management approaches, the clinician takes a "paternalistic" approach and decides what is best for the patient in light of that patient's preferences.

However, intermediate approaches of shared decision-making are generally more popular than those at either extreme. Shared decision-making uses both of the two fundamental approaches to decision-making presented above: the clinician typically shares the evidence, in some form, with the patient while simultaneously attempting to understand the patient's values. Evidence that more active patient involvement in the process of health care delivery can improve outcomes and reported quality of life – and, possibly, reduce health care expenditures – provides empirical evidence in support of secular trends toward patient autonomy and away from paternalistic approaches (Greenfield et al. 1988; Stewart 1995; Szabo et al. 1997).

Clinicians should temper their enthusiasm for active patient involvement in decision-making with an awareness that many patients prefer paternalistic approaches. For example, the results of a survey of 2,472 patients suffering from chronic disease (hypertension, diabetes, heart failure, myocardial infarction, or depression) completed between 1986 and 1990 supported this approach (Arora and McHorney 2000). In response to the statement: "I prefer to leave decisions about my medical care up to my doctor," 17.1% strongly agreed, 45.5% agreed, 11.1% were uncertain, 22.5% disagreed, and only 4.8% strongly disagreed. In another study of node-negative breast cancer patients considering adjuvant chemotherapy, 84% of 171 women preferred an independent or shared role in decision-making (Whelan et al. 2003). Increasing general levels of education, the advent of the Internet and the resulting access to medical information, and an increasingly litigious and consumerist environment have all contributed to patients wishing to play a more active role in decision-making and may explain a shift in patient preferences for decision-making. Shared decision-making and patient-centeredness have become attractive approaches to resolving the profusion of challenging choices facing patients and clinicians (Charles et al. 1999a, b; Edwards and Elwyn 2001; Guyatt et al. 2004a).

Regardless of the decision-making approach chosen by the patient and clinician, integrating values and preferences and communicating options inject challenges into the process by insisting that clinicians consider quantitative estimates of benefits and risks, rather than just whether a treatment works or whether toxicity occurs. If clinicians leave the decisions to patients, they must effectively communicate the probabilities associated with the alternative outcomes to them. If they opt for taking responsibility for combining patient values with the evidence, they must quantify those values. A vague sense of the patient's preferences cannot fully satisfy the rigor of the optimal decision-making approach.

We will now describe some of the specific strategies associated with two decision-making models: one in which the clinician presents the patient with the likely consequences of alternative management strategies and leaves the choice to the patient, and the other in which the clinician ascertains the patient's values and provides a recommendation.

47.10.1 Patient as Decision-Maker: Decision Aids

If the patient wishes to play the primary role in decision-making, clinicians may use intuitive approaches to communicating concepts of risk and risk reduction that they have developed through clinical experience. They will answer the patient's questions and ultimately act on the patient's decision. Alternatively, if available for a particular decision, clinicians can use a decision aid that presents descriptive and probabilistic information about the disease, treatment options, and potential outcomes in a patient-friendly manner (Levine et al. 1992; Holmes-Rovner et al. 2001; O'Connor 2001; Barry 2002; Akl et al. 2007; Breslin et al. 2008; Mullan et al. 2009; Montori et al. 2011).

A well-constructed decision aid has two advantages. One is that someone has reviewed the literature and produced a rigorous summary of the probabilities. Clinicians who doubt that the summary of probabilities is rigorous can go back to the original literature on which those probabilities are based and determine their accuracy. A second advantage of a well-constructed decision aid is that it will offer a pretested and effective way of communicating the information to patients who may have little background in quantitative decision-making. Most commonly, decision aids use visual props to present the outcome data in terms of the percentage of people with a certain condition who do well without intervention, compared to the percentage who do well with intervention. Decision aids will summarize the data regarding all outcomes of importance to patients.

Theoretically, decision aids present an attractive strategy for ensuring that patient values guide clinical decision-making. What impact do decision aids actually have on clinical practice? Stacey and colleagues conducted a systematic review, finding 86 randomized trials that used decision aids, for example, the decision for or against hormone replacement therapy in women after menopause or decisions related to breast surgery in breast cancer (Stacey et al. 2003, 2011).

The findings of this systematic review suggest that decision aids "increase people's involvement and improve knowledge and realistic perception of outcomes" but the size of the effect varies across studies. Decision aids reduce the choice of interventions such as discretionary surgery and have no apparent adverse effects on health outcomes or satisfaction.

47.10.2 Patient as Provider of Values

The second set of approaches all begin with, at minimum, establishing the relative value the patient places on the target outcomes. Doing so requires that the patient understand the nature of those outcomes. How, for instance, would a patient with atrial fibrillation facing a decision about using oral anticoagulation to prevent strokes imagine living with a stroke, or the experience of having a gastrointestinal bleeding episode as a side effect of the oral anticoagulation? Patients may find

Table 47.10 Sample descriptions of major stroke and gastrointestinal bleed

Major stroke	Bleeding
• You suddenly are dizzy and blackout • You are unable to move one arm and one leg • You cannot swallow or control bladder and bowel • You are unable to understand what is being said • You are unable to talk • You feel no physical pain • You are admitted to hospital • You cannot dress • The nurse feeds you • You cannot walk • After 1 month with physiotherapy, you are able to wiggle your toes and lift your arm off the bed • You remain this way for the rest of your life • Another illness will likely cause your death	• You feel unwell for 2 days then suddenly you vomit blood • You are admitted to hospital • You stop taking warfarin • A doctor puts a tube down your throat to see where you are bleeding from • You receive sedation to ease the discomfort of the test • You do not need an operation • You receive blood transfusions to replace the blood you lost • You stay in hospital 1 week • You feel well at the end of your hospital stay • You need to take pills for the next 6 months to prevent further bleeding • You do not take warfarin any more • After that you are back to normal

a written description of the health states (Table 47.10) useful in the process of describing their preferences (Devereaux et al. 2001).

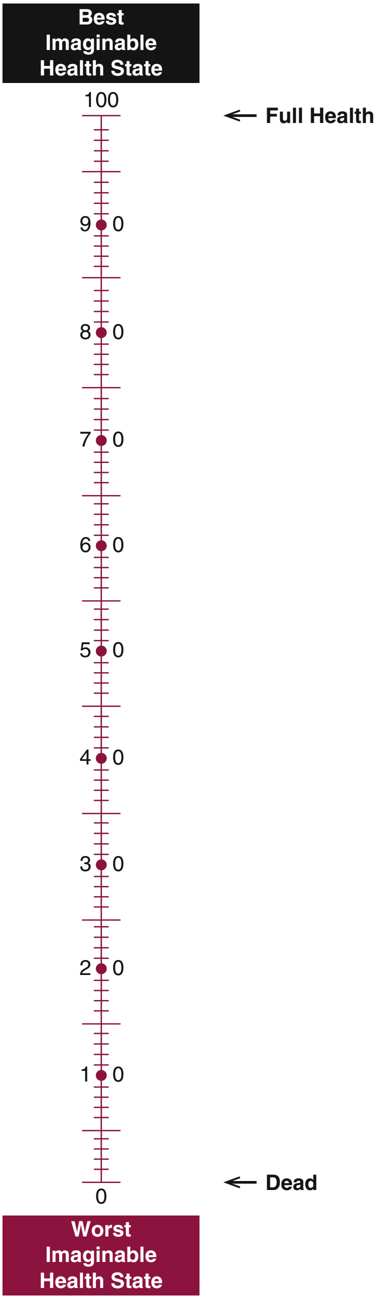
Having made their best effort to ensure that patients understand the outcomes, clinicians can choose from among a number of ways of obtaining their values for those outcomes. They can gain a qualitative sense of their patients' preferences from a discussion without a formal structure. Alternatively, a direct comparison between outcomes may prove useful. For instance, with only two outcomes, the patient can make a direct comparative rating. The question may be as follows: "How much worse would it be to have a stroke versus a gastrointestinal bleeding episode? Would it be equally bad? Twice as bad to have a stroke? Three times as bad?"

Using a somewhat more complex strategy, the clinician can ask the patient to place a mark on a visual analogue scale or "feeling thermometer," in which the extremes are anchored at dead and full health, to represent how the patient feels about the health states in question (Fig. 47.8).

When, as in the case of a gastrointestinal bleeding and a stroke, some health states are temporary and others are permanent, the clinician must ensure that patients incorporate the duration of the health state in their rating.

More sophisticated approaches include the time trade-off and the standard gamble (Torrance 1986). In completing the time trade-off, patients choose between a longer period in a state of impaired health (such as recovery from severe stroke) and a shorter period in a state of full health. With the standard gamble, by contrast, patients are asked to choose between living in a state of impaired health versus taking a gamble in which they may return to full health or die immediately. These latter approaches may come much closer to meeting assumptions that health

Fig. 47.8 The feeling thermometer



economists argue are necessary for accurate ratings of the relative value of health states in the context of choice with uncertain outcomes.

Regardless of the strategy clinicians use to obtain patient values, they must somehow integrate these values with the likely outcomes of the alternative management strategies. Formal decision analysis provides the most rigorous method for making this integration. Practical software for plugging in the patient's values and conducting a patient-specific decision analysis for common clinical problems is being developed, although not yet available for routine use in daily clinical practice. Investigators have shown that, when patients' values are used in individualized decision analyses, their decisions about anticoagulation in atrial fibrillation differ from those suggested by existing guidelines (Protheroe et al. 2000). Whether the decisions would have differed had the patients been provided with the probabilities and asked to choose their preferred management strategy – as with a decision aid – remains unknown.

Even if the tools for individual decision analysis were widely available, application of the approach would depend on the availability of clinicians who could devote time to eliciting patient values. Such a process may be resource intensive, and issues of how much gain there is from the investment, or the intervention's cost-effectiveness, may become very important. Exactly the same considerations apply to the use of decision aids, in which the improvement of knowledge is clear but the impact on anxiety, or on the choices patients actually make, is not as obvious.

Another method of expressing information to patients that incorporates their values is the likelihood of being helped versus harmed (Sackett et al. 2000). Clinicians can apply the likelihood of being helped versus harmed to any clinical decision, and preliminary evidence suggests the approach may be useful on busy clinical services. The clinician begins by calculating the *NNT* and *NNH* for the average patients in a study or studies from which the data about treatment effectiveness and harm come. The clinician then adjusts the average *NNT* and *NNH* for the individual patient according to that patient's likelihood of suffering the target event that treatment is intended to prevent, and the risks it may precipitate, relative to the average patient. Having established the relative likelihood of help versus harm, the clinician explores the patient's values about the severity of adverse events that might be caused by the treatment relative to the severity of the target event that treatment helps prevent. The final adjustment of the likelihood of being helped versus harmed incorporates the patient's values without providing formal help by a decision aid.

47.10.3 Likelihood of Help Versus Harm

For the sake of simplicity, we will assume that the patient in our scenario places a mean value on the composite endpoints cardiovascular disease (defined by the CURE investigators as death from cardiovascular causes, non-fatal MI, stroke, or refractory ischemia), major bleeding (substantially disabling bleeding, intraocular bleeding or the loss of vision, or bleeding necessitating the transfusion of at least 2 units of blood), and minor bleeding (any other bleeding leading to interruption of study medication), respectively. We will ignore other factors bearing on the decision, such as taking an additional pill daily.

During your discussion with the patient about the consequences of further cardiovascular disease and major bleeding, you asked her to use the "feeling thermometer" (see Fig. 47.8) to estimate how she feels about each of the two combined outcomes. We will ignore minor bleeding episodes in this example, because your patient is not concerned at all about the risk and consequences of minor bleeding. However, she places a mean value of suffering additional consequences of cardiovascular disease at 0.2 and of living with a major bleed at 0.7. You use these on your handheld personal digital assistant to calculate her likelihood of being helped or harmed (*LHH*) from clopidogrel therapy versus placebo therapy.

Using the *NNT*s calculated in the scenario, the *LHH* for clopidogrel versus placebo becomes:

$$\begin{aligned} LHH &= (1/NNT):(1/NNH) \\ &= (1/44):(1/100) = 100/44 \\ &= 2.3. \end{aligned}$$

(Note: we could also use (1/absolute risk reduction):(1/absolute risk increase) but this uses decimal fractions and may increase the likelihood of arithmetic errors.)

Therefore, you can tell the patient that clopidogrel is approximately twice as likely to help her as to harm her, when compared with placebo.

Incorporating her values that you elicited, the *LHH* becomes

$$\begin{aligned} LHH &= (1/NNT) \times (1-\mathrm{Uevent}):(1/NNH) \times (1\text{–}\mathrm{Utoxicity}) \\ &= (1/44) \times (1-0.2):(1/100) \times (1-0.7) \\ &= 6.1, \end{aligned}$$

where Uevent is the value of the outcome prevented (composite endpoint of death from cardiovascular causes, non-fatal MI, stroke, or refractory ischemia) and Utoxicity (major bleeding) is the value of the side effect.

You can now inform the patient that clopidogrel is approximately six times as valuable to help her as to harm her. Including additional outcomes would increase the number of terms in the numerator (benefits) or denominator (adverse consequences).

Alternatively, a quicker way of incorporating the patient's values is to ask the patient to rate one event against another. For example, is the adverse effect about as severe as the event the treatment prevents – or ten times as bad or only half as severe? This rating ("*s*") can then be used to adjust the *LHH* as

$$\text{LHH} = (1/\text{NNT}) \times \text{s}:(1/\text{NNH}).$$

Having ascertained the likely outcomes of the alternate courses of action, the clinician must either present patients with the options and outcomes and leave it for them to choose, try to discover the patient's values and having done so suggest a course of action to the patient (the paternalistic approach), or choose the middle course of shared decision-making. The patient's preferred decision-making style will guide the clinician in this regard. However, communicating the nature of the outcomes and their probabilities in a way the patient will understand, or accurately ascertaining the patient's values regarding the outcomes, remains problematic.

The challenges of optimal clinical decision-making should not obscure the realization that clinicians face these challenges in helping patients with every management decision. For each choice, clinicians guide patients with their best estimate of the likely outcomes. They then help patients balance these outcomes in making their ultimate decision. Finding better strategies to carry out these tasks remains a frontier for clinical epidemiology.

47.10.4 Semistructured Conversation and Resolution

Example 47.1. (Continued)

You discuss the option of clopidogrel therapy with your patient who is feeling better now and appears to have a good understanding of the information you are providing. You explain that – based on your assessment and the patients' values and preferences – benefit and harm of clopidogrel are pointing clearly toward more desirable than undesirable consequences: for every 44 patients treated for 1 year in the CURE trial, there was one less occurrence of the combined endpoint. However, for every 100 patients treated with clopidogrel for 1 year, one additional patient suffered a major bleeding episode, and for every 37 patients treated for 1 year, there was one additional minor bleeding episode. You also explain that, because these are only estimates, the true effect might be somewhat smaller or larger for both the benefit and harms. Your patient states she agrees that clopidogrel for the longer terms seems to be a good choice.

Because the decision to take clopidogrel depends to some degree on the patient's values and preferences regarding preventing the combined endpoint versus incurring additional risk of bleeding and you have the results of the calculation of the likelihood of being helped or harmed. You explain that the results of your calculation using the software on your personal digital assistant support her preference for taking clopidogrel. In terms of expense, you are uncertain about the cost of clopidogrel. Because you feel that this question will come up with additional patients and that you had wanted to address it for some time, you call the hospital pharmacist. She informs you that the cost for clopidogrel is approximately $90 per month and that at least one analysis has suggested the drug is not cost-effective (Gaspoz et al. 2002). The patient tells you that she has minimal co-pay for most medications and remains interested in taking the medication. Together, you decide that beginning clopidogrel treatment clearly is in her best interest and you start the patient on a 300 mg loading dose of clopidogrel and continue with 75 mg daily. You also suggest reducing the dose of aspirin as lower doses of aspirin confer similar benefits and doses of 75–325 mg were given in the CURE trial together with clopidogrel. She is reassured by the fact that most patients in her situation choose the same option for therapy.

47.11 Conclusions

We have presented several concepts of clinical epidemiology. Working through the clinical problems has implicitly highlighted some of clinical epidemiology's research challenges. The following makes explicit some of these challenges that clinical epidemiologists and other investigators need to tackle in future research. A number of important areas have been identified and we will list them here briefly. It is not clear what are the best ways to educate clinicians and students in the methodology of clinical epidemiology, and educational researchers will have to focus on this aspect. The Cochrane Collaboration, other organizations, and researchers will further elaborate the methodology of systematic reviews (e.g., of diagnostic studies, observational studies, and health-related quality of life outcomes). Obtaining further information about the most valid and informative ways of presenting statistical information and education of patients and clinicians about these issues is an important task for clinical epidemiologists. Research should also focus on improving the development of clinical practice guidelines and integrating cost information in guidelines and recommendations (Schünemann et al. 2004). Furthermore, research on implementing guidelines into clinical practice is an area of intensive research (e.g., DECIDE 2012). It is clear that studies of guideline implementation should follow the same methodological rigor as other studies, but they are presented with different challenges, such as the need for large cluster randomized clinical trials. We described the integration of preferences and values in medical decision-making as well as bedside decision-making in particular above. Tools that facilitated this difficult task are in development. Health decision aids, in particular electronic decision aids, promise to advance this science. Along with health decision aids, the integration of HRQL information into clinical practice and guidelines presents challenges that investigators need to resolve (Frost et al. 2003). Finally, conducting additional research of integrating electronic health (eHealth) (including multimedia decision aids) into clinical practice presents a fascinating but challenging outlook.

48.1 Introduction

In the last decades we have witnessed a tremendous progress in the medical sciences that has led to the development of a great number of new powerful pharmaceuticals. These new medicines enable us to provide much better medical care, but occasionally they will cause harm and give rise to serious adverse reactions that were unexpected from preclinical studies or premarketing clinical trials. Against this background, pharmacoepidemiology has developed as a scientific discipline at the interface between clinical pharmacology and clinical epidemiology (cf. chapter ►Clinical Epidemiology and Evidence-Based Health Care of this handbook). Pharmacoepidemiology can be defined as the application of epidemiological knowledge, methods, and reasoning to the study of the effects and uses of drugs in human populations (Porta et al. 1997). The application of epidemiological methods – i.e., the use of non-experimental observational techniques – the epidemiological perspective with an emphasis on investigations in large unselected populations and long-term studies, the public health approach, and the philosophy of epidemiology are all extended to the scope of clinical pharmacology, i.e., the study of the effects of pharmaceuticals in humans.

Pharmacoepidemiology investigates both beneficial and adverse drug effects. Its focus and the one that receives the greatest attention is the assessment of the risk of uncommon, at times latent, and often unexpected adverse reactions that present for the first time after a drug has been marketed. The greatest challenge of pharmacoepidemiology is then to quantify the risk of a drug accurately, relative to one or several alternatives.

The study of adverse drug effects poses a number of methodological difficulties that must be addressed by pharmacoepidemiological research designs: First, drug exposure is not a stable phenomenon. Drug prescription habits may change due to the development of new pharmaceuticals, better knowledge on already available medications, or other reasons. Second, drug exposure can be sensitive to a great number of factors that may also be related to the outcome of interest, such as the indication for prescribing potential contraindications for drug use, the natural course of the disease or disease severity and compliance. Third, the risk of an adverse drug reaction (ADR) is often not constant, but it may change over time which may have important implications for the design and interpretation of pharmacoepidemiology studies.

In this chapter, we will first discuss limitations of premarketing clinical trials; we will then describe the characteristics of spontaneous reporting systems which have been implemented by regulatory agencies and the pharmaceutical industry for postmarketing surveillance. Another issue will be the use of multipurpose cohorts and large administrative health-care databases for drug effect studies, which have found widespread application in pharmacoepidemiology. We will further discuss several methodological aspects that are unique to pharmacoepidemiological research, e.g., the phenomenon of “depletion of susceptibles,” which is a form of selection bias, or “confounding by indication,” which is also referred to as “confounding by disease severity” or “channelling bias.” Unmeasured confounding is of particular concern in pharmacoepidemiology studies conducted with large healthcare utilization databases which often do not contain information on all potential confounders. We will discuss instrumental variable analyses as an approach to study drug effects in the situation of unmeasured confounders, if a valid instrument can be found. We will further present the use of propensity scores, as a tool to reduce confounding particularly in studies of intended drug effects, and will discuss newer approaches of studying drug effects, such as the case-crossover, case-time-control, and self-controlled case series designs. Characteristics of drug utilization studies and their units of measurement will also be discussed.

48.2 Limitations of Premarketing Clinical Trials

Prior to marketing, new drugs are subjected to preclinical animal studies followed by three phases of clinical trials in humans. These phases are divisions of convenience in what is a continuous process of acquiring knowledge on the effects of a new drug in humans. In *phase I studies*, humans are exposed to a new drug for the first time. These studies are often conducted in small numbers of healthy volunteers and are intended to explore the tolerability, pharmacokinetic, and pharmacodynamic properties of a new drug in humans. In *phase II studies*, the optimal dose range of the new drug is investigated, and its efficacy and safety are explored in the intended patient population. These studies usually include several hundreds of patients. *Phase III studies* are aimed to prove the efficacy and safety of the new drug under strictly controlled experimental conditions in a larger patient population. They are mostly conducted as randomized controlled clinical trials (RCT) and often include several thousand patients altogether. In spite of the size of phase III studies, these studies have still limited ability to identify rare ADRs, since this would require an even larger number of study participants.

Table 48.1 displays sample size calculations for prospective studies. It shows the number of patients needed to detect a relative risk of a given magnitude in relation to the incidence of the event in the reference group. We can see that for the detection

Table 48.1 Sample sizes for detection of a given drug risk in an RCT or a cohort study (size per study arm)

	Incidence of outcome in the control group			
Relative risk	1/50,000	1/10,000	1/5,000	1/1,000
2.0	1,177,295	235,430	117,697	23,511
2.5	610,446	122,072	61,025	12,187
3	392,427	78,472	39,228	7,832
5	147,157	29,424	14,707	2,934
7.5	78,946	15,783	7,888	1,572
10	53,288	10,652	5,323	1,059

Calculations are based upon a two-sided significance level α of 0.05, a power of 80% ($\beta = 0.2$), and one control subject per exposed subject

Table 48.2 Drug removals from the US market between 1997 and 1998. Number of patients exposed to withdrawn drugs in clinical trials compared to actual use after marketing

Removed drug	Number of patients exposed before marketing[a]	Approximate exposure prior to withdrawals
Terfenadine	5,000	7,500,000
Fenfluramine	340	6,900,000
Dexfenfluramine	1,200	2,300,000
Mibefradil	3,400	600,000
Bromfenac	2,400	2,500,000

[a] Number of patients included in the US premarketing studies

of very rare ADRs with sufficient statistical power, prohibitively large sample sizes in premarketing clinical studies would be needed. It is thus inherent in the drug development process – taking into account the already high cost for development of new pharmaceuticals – that serious rare ADRs will usually only be detected after drug marketing when the drug has been used in large patient populations.

An investigation by the Food and Drug Administration (FDA) into the withdrawal of five pharmaceuticals from the US market between 1997 and 1998 illustrates this point (Friedman et al. 1999). All five drugs were removed from the US market because of the discovery of unexpected serious adverse drug reactions (ADR) in the postmarketing period. The FDA investigated whether this unexpectedly high number of drug removals in only a 12-month period was related to the expedited drug review and approval process that had been implemented. They calculated the number of patients exposed in the clinical trials before marketing and the approximate number of patients exposed before drug withdrawal (Table 48.2). The figures demonstrate that usually huge numbers of patients need to be exposed before sufficient knowledge on a rare ADR has been accumulated. For example, serious hepatotoxic effects of bromfenac occurred in approximately 1 in 20,000 patients who took the drug for longer than 10 days (Friedman et al. 1999). To reliably detect this toxic effect, some 100,000 patients would need to be included in the premarketing clinical studies.

In addition, premarketing clinical studies differ from routine clinical care for a number of other reasons: (1) These studies mostly include a selected study population, defined by strict inclusion and exclusion criteria, which is often not fully representative of subsequent users of the drug. It is well known that premarketing studies tend to under represent the elderly, patients with comorbid conditions, pregnant women, and children. Patients in premarketing trials may even be considered a selected group of patients just because they are willing or able to participate. (2) Premarketing clinical trials are performed at selected sites which are typically better equipped than routine care facilities. They are conducted by specialists in their field, and all participating persons have been specially informed and trained. Surveillance of patients is almost by definition more intensive than in routine clinical treatment, if only one considers the frequency and spectrum of laboratory tests or the assessment of therapeutic and unwanted effects. (3) Treatment regimens in premarketing clinical trials are largely fixed and allow almost no individual treatment variations. In contrast, adjustments are constantly made in routine care, depending on the progress of therapy and on the interaction between doctor and patient. (4) Premarketing clinical trials are usually of short duration. This renders it impossible to detect ADRs that only develop after a long induction period or after cumulative drug intake.

For all these reasons, crucial answers to questions of drug safety cannot be provided even by the most valid and complex phase III study.

48.3 Characteristics of Spontaneous Reporting Systems

48.3.1 Description

In the early 1960s, systems evolved in most Western countries that collected spontaneous reports on ADRs from doctors. Establishment of these spontaneous reporting systems was largely a consequence of the "thalidomide disaster," in which children exposed to the hypnotic thalidomide in utero were born with phocomelia, a congenital deformity of the limbs resulting from prenatal interference of the drug with the development of the fetal limbs (Wiholm et al. 2000). Worldwide, several thousand cases of limb malformations in newborns observed in the 1950s and 1960s were attributed to the use of thalidomide during pregnancy (Lenz 1987). Based on this experience, spontaneous reporting systems were set up to monitor drug safety in the postmarketing period. In these systems, physicians – in some countries also pharmacists, other health-care professionals, or patients – report the suspicion of an ADR to the country's drug regulatory agency or to the pharmaceutical company that is marketing the drug. Drug regulatory agencies exchange the ADR reports with the concerned pharmaceutical companies and vice versa. The reports are locally assessed; the reported adverse event terms are coded using a standardized international terminology, e.g., MedDRA (the Medical Dictionary for Regulatory Activities), and are entered in a computerized database. In December 2011, 103 countries also forwarded their ADR reports to the World Health Organization (WHO) Collaborating Centre for International Drug Monitoring in Uppsala (Uppsala Monitoring Centre 2011). This so-called Vigibase^{TM} set up by the WHO contained already over seven million ADR reports at that time. The ADR reports are subject to further statistical screening to identify possible new risks associated with drugs and are further analyzed by a review team. When there are a number of reports of a suspected new adverse reaction to a particular drug, this may be circulated among program members as a "signal" – a notice of a need for increased awareness of a possible hazard. Through membership in the WHO program, one country can know whether similar ADR reports are being made elsewhere. An ADR report usually contains the patient's demographic information including age and sex; the patient's weight and height; adverse event (AE) information including date and outcome of the event, description of the event, evidence, and existing medical history; information of suspect and concomitant medicine(s), including drug name, dose, application, and indication for use; whether the event abated after drug use was stopped ("dechallenge") and whether the event reappeared after the drug was reintroduced ("rechallenge"); and the reporter's name and address.

Each report is assessed for its causality with drug intake by trained reviewers. Causality assessment is usually based on a set of criteria which includes the time interval between drug administration and the onset of the ADR, the course of the reaction when the drug was stopped, the results of re-administration of the drug, the existence of other causes that could also account for the observed reaction such as patient comorbidity or concomitant drug treatment, the pattern of the adverse effect, and the existence of reliable and specific laboratory test results. Causality assessment is not based on the single case report, but will also take into account other available information on the drug(s). In France, causality assessment criteria have been built into an algorithm (the "official method of causality assessment") that is used throughout the country (Benichou 1994). The French method distinguishes "intrinsic imputability" which takes into account only the single case report information from "extrinsic imputability" which is based on all published data on all drugs. Overall, causality assessment from individual case reports is a complex task and often associated with a high degree of uncertainty, since confounding by concomitant drug therapy or the underlying disease can frequently not be ruled out. Rare exceptions are a positive rechallenge to the drug (which is mostly accidental and involuntary, since this is rarely without risks) or positive results of specific laboratory tests such as the detection of drug-dependent antibodies.

Spontaneous reporting systems have several important advantages. They are relatively inexpensive to operate with respect to staff and basic technical equipment. They have the potential to cover the whole patient population and are not restricted to either hospitalized patients or outpatients. Surveillance starts as soon as a drug is marketed, and monitoring of drug safety continues throughout the whole post-marketing life cycle of a drug. The suspicion of an ADR is, in theory, based on the experience of all treating physicians and pharmacists. Spontaneous ADR reporting systems can provide an alert to very rare, but nevertheless potentially important drug toxicity. Spontaneous reporting systems have identified many new, i.e., previously unrecognized drug hazards, e.g., clozapine-induced granulocytopenia, captopril-induced cough, and amiodarone-induced hepatotoxicity. Further examples can be found in the article by Rawlins et al. (1989).

48.3.2 Limitations

Many of the successes of spontaneous reporting systems have been in the recognition of ADRs occurring shortly after starting therapy. Spontaneous reporting schemes are much less effective in identifying reactions with a long induction period. An example is the oculomucocutaneous syndrome associated with exposure to practolol which was undetected by the yellow card spontaneous reporting scheme in the UK (Venning 1983). For the same reason, spontaneous reporting schemes are not well suited to identify drug-induced cancerogenicity.

ADR reports often do not provide sufficient information to confirm that a drug caused an event. For example, the ADR report may not give enough details on comorbidity or other medications to rule out other possible causes for the event in a remote expert assessment. It may be impossible to exclude confounding by indication, i.e., that the cause for the reported adverse event is rather related to the indication for the drug than to the drug itself. As an example, depression has been reported with the anti-acne medication roaccutane (Wysowski et al. 2001). Depression could, however, also be related to psychological disturbances over severe acne in sensitive teenagers rather than to roaccutane itself.

Recognition of an ADR depends on the level of diagnostic suspicion of the treating physician and may be related to the nature of the adverse event. Some ADRs are more likely to be diagnosed and reported than others because of their known association with drug therapy. For example, acute agranulocytosis is attributable to drug treatment in about 60–70% of cases (Kaufman et al. 1996). It may therefore be more likely to be attributed to drug therapy than a disorder, e.g., acute myocardial infarction, that is usually not related to drug treatment (Faich 1986).

Spontaneous reporting systems suffer from serious underreporting of ADRs and various biases that affect reporting. Even in the UK, a country with a relatively high reporting rate in relation to its population size, rarely more than 10% of serious ADRs are notified to the regulatory agency (Rawlins et al. 1989). In France, a recent comparison of ADR reports with data about drug-induced hospitalizations in three pharmacoepidemiology field studies indicates that only 5% of ADRs leading to hospitalizations are actually reported in the spontaneous reporting system (Begaud et al. 2002). Lack of knowledge how to report an ADR and misconceptions about the type of ADR that should be reported are important reasons contributing to underreporting (Eland et al. 1999). But it also has to be taken into account that spontaneous reporting and published case reports may also lead to numerous false alarms.

Medical or mass media attention can stimulate reporting in a distorted manner and give rise to differential reporting in a dramatic way (Griffin 1986). An example of such “media bias” is that of central nervous side effects following treatment with the benzodiazepine triazolam. After van der Kroef published a case series of these ADRs in 1979 (van der Kroef 1979), these side effects received extensive media coverage on Dutch television. As a consequence, the Netherlands received 999 ADR reports related to triazolam in 1979 out of a total of 1912 annual reports in 1979 overall (Griffin 1986). Reporting can also be affected by the market share of the drug, the quality of the manufacturer’s surveillance system, reporting regulations, and the length of time a drug is on the market (Griffin 1986; Lindquist and Edwards 1993). It has been shown that reporting rates do not remain stable over time, but usually rise until approximately the middle to end of the second year of marketing and then progressively decline over the following years despite steadily increasing prescribing rates. This phenomenon was first described by Weber in the context of a study of nine non-steroidal anti-inflammatory drugs (NSAIDs) in the UK during the late 1970s and early 1980s and has therefore been called the "Weber effect" (Weber 1984). The Weber effect has also been reported from other studies of adverse drug reactions (Haramburu et al. 1992, 1997; Hartnell and Wilson 2004).

48.3.3 Statistical Approaches: Reporting Rates and Disproportionality Measures

An ideal early warning system should not only recognize new hazards but also provide an estimate of their incidence. Spontaneous reporting systems may provide alerts of drug hazards, but they cannot be used to calculate incidence rates of adverse events related to a specific drug. Calculation of an incidence rate requires accurate numerator and denominator information, both of which are not available from the spontaneous reporting systems. First, the extent of underreporting for an individual drug is very difficult to assess and may even differ between drugs of the same pharmacological class. Second, the population exposed to the drug (i.e., the population at risk) is unknown and cannot be determined from drug sales data, since the duration of drug use, the dose regimen, and compliance in individual patients are unknown.

Instead of the calculation of incidence rates, reporting rates (number of AE reports per market share) based on sales data are sometimes computed as an alternative approach (Moore et al. 2003; Pierfitte et al. 2000). Calculation of reporting rates is based on the assumption that the magnitude of underreporting is reasonably similar for similar drugs that share the same indication, country, and period of marketing (Pierfitte et al. 1999). The comparison of ADR reporting rates should therefore be restricted to drugs of the same category used for the same indication. Factors that may bias the comparison of reporting rates include differences in the length of time the drugs are on the market, differences in exposure populations, secular reporting trends, reporting variations, diagnosis and prescription variation, and the publicity of an ADR. Statistical corrections for year of marketing, secular trends of all-drug-all-adverse event reporting, and drug usage have been proposed (Tsong 1995). These adjustments do not, however, cover all possible sources of bias. In particular, do they not erase concerns about differences in the magnitude of underreporting for different drugs: Interpretation of reporting rates should therefore be conducted with an understanding of their limitations. Differences in reporting rates do not establish differences in incidence rates. They may, however, provide alerts of drug hazards to be investigated by more rigorous pharmacoepidemiological study designs.

The proportional reporting ratio (*PRR*) and the reporting odds ratio (*ROR*) have been proposed as measures of disproportionality for signal generation (Evans et al. 2001; Stricker and Tijssen 1992). These measures are based on the observed number of reports of a particular suspected drug-ADR combination compared with an estimate of the expected number based on all other reporting in the same database; the expected number of reports is calculated on the assumption of independence of the drug and the suspected ADR. The ADR databases maintained by the regulatory authorities and the WHO contain a large number of reports suitable for statistical signal generation, e.g., over 7 million reports in the WHO database (Uppsala Monitoring Centre 2011), over 4 million reports in the Adverse Event Reporting System (AERS) database maintained by the FDA (US Food and Drug Administration 2010), and over 600,000 reports in the Yellow Card Scheme of the Medicines and Healthcare Products Regulatory Agency (MHRA) (MHRA Centre NorthWest 2009). The *PRR* or *ROR* involves calculation of the proportions of specified reactions or groups of reactions for drugs of interest where the comparator is all other drugs or other selected drug groups in the database. Whereas the *PRR* is the quotient of $a/(a+c)$ divided by $b/(b+d)$ derived from the reported frequencies of all drug-event pairs in the database arranged in a two-by-two table, the *ROR* is the quotient of a/c divided by b/d (Table 48.3). In practice both measures tend to be similar, since usually $a << (b, c) << d$ (Almenoff et al. 2007).

The *PRR* and *ROR* behave in a similar fashion as the relative risk, i.e., the higher the *PRR* or *ROR*, the greater the strength of the signal. The usual application of these measures is in conjunction with computing the two-by-two table chi-square values for association on 1 degree of freedom. With this approach, large ratios of the disproportionality measures with non-significant chi-square values, which are typically seen with small numbers of suspected drug–ADR combinations and even smaller expected values, are ignored (Almenoff et al. 2007). Signals can then be identified based on the value of the *PRR* or *ROR*, the value of the chi-squared test, and the absolute number of reports. In a proof-of-concept study, Evans et al. (2001) defined a signal as a *PRR* value of at least 2, a value of chi-squared test of at least 4, and a minimum of 3 cases. Using these criteria on the UK Yellow Card Scheme database for 15 newly marketed drugs, they identified 481 potential signals, 339 (70%) of which were recognized ADRs, 62 (13%) were considered to be related to the underlying disease, and 80 (17%) were signals requiring further evaluation. Statistical approaches such as calculation of *PRR*s or *ROR*s are not a substitute for a detailed ADR review, but they may aid in the decision on which series of cases should be investigated next. Similarly, as already mentioned for reporting rates, the *PRR* or *ROR* may be affected by differential ADR reporting related to notoriety, surveillance, and market size effects. A *PRR* or *ROR* above 1 may therefore just indicate a higher reporting of a possible reaction under a drug, but not necessarily a differential occurrence (Moore et al. 2003). Whereas for calculation of the *ROR* cells a, b, c, and d has to contain reports, only reports in cells a and b are required for calculation of the *PRR* (van Puijenbroek et al. 2002). With the *ROR*, different adjustments can be calculated in logistic regression analysis, and interaction terms can be included in the model (van Puijenbroek et al. 2002). A discussion of both measures can be found in Rothman et al. (2004) and Waller et al. (2004).

Table 48.3 Calculation of the proportional reporting ratio (*PRR*) or the reporting odds ratio (*ROR*) (a, b, c, and d are absolute frequencies of the according combination)

	Drug of interest	All other drugs in the database
Event of interest	a	b
All other events	c	d

Other measures of disproportionality have been proposed using Bayesian statistics (Bate et al. 1998; DuMouchel 1999; Szarfman et al. 2002). These more complex statistical approaches are, like the *PRR* or *ROR*, based on a comparison of observed versus expected frequencies of ADRs under a particular drug, but they differ in the way they relate all drug-event combinations in the database to each other. Bayesian approaches account for the uncertainty in the disproportionality ratio when the counts are small. Bayesian statistical methods produce "shrinkage" values of the observed/expected ratio, so that the raw value of the observed/expected ratio is moved toward the null hypothesis value of 1 by an amount that depends on the variability of the disproportionality statistic (DuMouchel 1999). The raw values of the observed/expected ratio are transformed using Bayesian theory to a basic estimate called *EBGM* (Empirical Bayes Geometric Mean of the relative reporting ratio), and a 90% confidence interval (*EB05*, *EB95*) is calculated. In the WHO database, a similar procedure is used which calculates a statistic known as the Information Component (Bate et al. 1998, 2008).

As more data become available, the shrinkage property will gradually diminish in influence. Shrinkage is often negligible when there is a large observed count for a drug-event combination. Shrinkage thus reduces the number of false-positive associations which would be generated for combinations with little observed data where the observed/expected ratio might be unexpectedly high for the very low expected counts of rarely reported drugs and rarely reported ADR terms (Bate et al. 2008).

48.4 Sources of Data in Pharmacoepidemiological Research

A great number of pharmacoepidemiology studies are being conducted as field studies, with data being collected for the specific hypothesis under study. These studies are sometimes conducted in an international setting to increase the number of cases and to provide more timely results (Abenhaim et al. 1996; Anonymous 1986, 1995a; Spitzer et al. 1996). Increasingly, already existing data sources are being used for pharmacoepidemiological research. Existing data sources include multipurpose cohort studies or large health-care utilization databases. Studies utilizing such data can be conducted more quickly and are less expensive than field studies, since the data have already been collected.

48.4.1 Multipurpose Cohorts

Multipurpose cohorts are designed to investigate many different research hypotheses. Their study population usually consists of a subset of a defined population that has not been assembled by a specific exposure, but by other factors. For example, in the US Nurses' Health Studies, study participants were defined by age, female sex, and profession (Nurses' Health Study I: 121,700 female nurses aged 30–55 years at baseline in 1976; Nurses' Health Study II: 116,671 female nurses aged 25–42 years at baseline in 1989). If a multipurpose cohort is used to investigate an association between a specific drug exposure and a disease, its cohort members will usually have sufficient variability in their exposure status for the drug to be investigated: They may currently be exposed or unexposed, they may be exposed to different doses of the drug, they may have been exposed in the past, or they may be exposed in the future. If, in addition, disease occurrence and relevant confounder information has been ascertained, the multipurpose cohort data may be used to investigate a specific pharmacoepidemiological hypothesis. The US Nurses' Health Studies have been extensively used for pharmacoepidemiology research questions. Examples include the association between nonsteroidal anti-inflammatory drugs and risk of Parkinson's disease (Chen et al. 2003); use of estrogens and progestins and risk of breast cancer in postmenopausal women (Colditz et al. 1995); postmenopausal estrogen and progestin use and risk of cardiovascular disease (Grodstein et al. 1996); oral contraceptives and the risk of multiple sclerosis (Hernan et al. 2000); aspirin, other non-steroidal drugs, and risk of ovarian cancer (Fairfield et al. 2002); calcium intake and risk of colon cancer (Wu et al. 2002); and many more associations (Grodstein et al. 1998; Hee and Grodstein 2003; Hernandez-Avila et al. 1990; Weintraub et al. 2002). Other multipurpose cohorts that have been less frequently used for pharmacoepidemiological research include the Health Professionals Follow-Up Study (Chen et al. 2003; Giovannucci et al. 1994; Wu et al. 2002), the National Health and Nutrition Examination Survey I (NHANES) epidemiological follow-up study (Funkhouser and Sharp 1995; Lando et al. 1999), the Framingham cohort study (Abascal et al. 1998; Felson et al. 1991; Kiel et al. 1987; Worzala et al. 2001), and the Rotterdam Study (Beiderbeck-Noll et al. 2003; Feenstra et al. 2002; Schoofs et al. 2003).

48.4.2 Record Linkage Studies

Large health-care utilization databases have emerged as another important data source for pharmacoepidemiology research. In the United States and Canada, administrative health-care utilization databases have been set up for the administration of reimbursement payments to health-care providers in nationally funded health-care systems or managed care organizations. In the Scandinavian countries, data are based on reimbursement data in state-funded health-care systems. These databases offer the advantage that their data can be linked to birth, cancer, and other disease registries as well as to mortality registries based on the pseudonymized unique personal identifier used in these countries (Furu 2008; Furu et al. 2010). In the United Kingdom, the Netherlands (IPCI 2012a), and some other countries, large health-care utilization databases consist of data entered by general practitioners (GP) into their practice computers (Schneeweiss and Avorn 2005; Suissa and Garbe 2007). In Germany, a large population-based database has recently been established based on data from several health insurances (Pigeot and Ahrens 2008) and has meanwhile been applied in several pharmacoepidemiological studies (Amann et al. 2012; Behr et al. 2010; Garbe et al. 2011; Jobski et al. 2011). A brief overview of selected databases is given in Table 48.4. More detailed information on some of these databases can be found in the textbook "Pharmacoepidemiology" by Strom et al. (2012).

Table 48.4 Examples of administrative health databases in the USA, Canada, and Europe

Database	Characteristics	Eligible population	Drug prescriptions and/or dispensations since
Saskatchewan's Health Databases, Saskatchewan, Canada (Saskatchewan Ministry of Health 2010)	Provincial health plan	1 million	1975
RAMQ database, Quebec, Canada (RAMQ 2010)	Provincial health plan	7.6 million[a]	1997
Group Health Cooperative, Washington, USA[b] (Group Health 2012)	Health Maintenance Organizations (HMO)	600,000	1977
Kaiser Permanente, Northern California, USA (Kaiser Permanente 2012a)	HMO	3.2 million	1994 (from all pharmacies)
Kaiser Permanente Northwest Division, USA (Kaiser Permanente 2012b)	HMO	479,000	1986
Tennessee Medicaid database, USA[c] (Tennessee Government 2012)	Health insurance for low-income children, parents, pregnant women, and elderly and disabled adults	1.2 million	1977
New Jersey Medicaid Database, USA (State of New Jersey 2012)	Health insurance for low-income children, parents, pregnant women, and elderly and disabled adults	1.2 million	1980
CPRD (former GPRD), UK (GPRD 2012)	Medical records from primary care	13 million (5.2 million active patient records)	1987 for selective practices, 1991 for the majority
The Health Improvement Network (THIN) database, UK (UCL Research Department of Primary Care and Population Health 2011)	Medical records from primary care	9.1 million (3.4 million active patient records)	1987
QResearch, UK (QResearch 2012b)	Medical records from primary care	13 million (5 million active patient records)	1988
GePaRD (German Pharmacoepidemiological Research Database) (Pigeot and Ahrens 2008)	Reimbursement data from 4 health insurance providers (regional as well as national)	15 million	2004
Integrated Primary Care Information Project (IPCI), Netherlands (IPCI 2012a)	Medical records from primary care	700,000 patients	1994

(continued)

Table 48.4 (continued)

Database	Characteristics	Eligible population	Drug prescriptions and/or dispensations since
PHARMO, Netherlands (PHARMO Institute for Drug Outcomes Research 2012)	Record linkage of pharmacy data with hospital and other data	3.2 million community-dwelling inhabitants of 65 municipal areas in the Netherlands	1998
Pedianet, Italy[d] (Pedianet Project 2012)	Medical records from pediatricians	180,000	2000
Swedish Health and Welfare Statistical Databases (The National Board of Health and Welfare (Socialstyrelsen) 2012a)	Data from the National Health System including prescription data; hospital discharge data; data from birth, cancer, and mortality registries	9.2 million	2005
The National Patient Register (NPR), Sweden (The National Board of Health and Welfare (Socialstyrelsen) 2012b)	Medical records from inpatient care, from 2001 including outpatient care	9.2 million	1987
Norwegian Prescription Database (NorPD) (Furu 2008)	Information on drugs dispensed by prescription from all pharmacies in Norway	4.9 million	2004
STAKES – National Research and Development Centre for Welfare and Health, Finland (Furu et al. 2010)	Statistical and register information on social welfare and health care, diseases, and treatment of diseases	5.3 million	1993
KELA, Finland (KELA – The Social Insurance Institution of Finland 2012)	Data from the Finnish prescription reimbursement register	5.3 million	1994
Danish Registry of Medicinal Product Statistics (The Danish Medicines Agency 2010)	Data from the Danish prescription register	5.5 million	1994
Odense University Pharmacoepidemiological Database (OPED), Denmark (Sturkenboom 2007)	Public institution research registry of dispensing claims data	1.2 million	1990
The Pharmacoepidemiological Prescription Database of North Jutland (PDNJ), Denmark (Sturkenboom 2007)	Public institution research registry of dispensing claims data	1.7 million	1989

[a] Including 3.3 million covered by the Public Prescription Drug Insurance plan

[b] Members from Washington State and Idaho

[c] Tennessee withdrew from the federal Medicaid program on 1/1/94 and implemented TennCare

[d] There was a test period of 3 years. As of August 2007 there were 130 participating family pediatricians

48.4.2.1 Administrative Databases in the USA and Canada

These databases usually consist of patient-level information from two or more separate files which can be linked via a unique patient identifier contained in each file. The unique patient identifier often consists of the social security number of the patient which is "scrambled" to ensure patient confidentiality. Information contained in the different files usually consists of demographic patient information, information on drug dispensations from pharmacies, information on hospitalizations, and information on ambulatory physician visits (Fig. 48.1). Through record linkage, person-based longitudinal files can be created for particular research questions. In some databases, record linkage is possible with cancer registries or birth malformation registries to investigate hypotheses of drug carcinogenicity or teratogenicity. Researchers usually have to submit a study protocol for review by an ethics committee, and they only receive subsets of the files which are extracted to investigate the particular research hypothesis. Fees are charged for the time needed to extract the necessary data from the entire database. All statistical analyses are done on the anonymized data.

Saskatchewan's Health Databases have been used extensively for pharmacoepidemiological studies (Saskatchewan Ministry of Health 2010). These databases will be used to illustrate which information may be expected in an administrative healthcare database (Table 48.5). Health Databases in Saskatchewan are based on the universal health insurance program in this Canadian Province. Differently from the Medicaid program, there is no eligibility distinction based on socioeconomic status. Record linkage is possible with the province's cancer registry. Medical records in hospitals are accessible upon approval from individual district health boards and affiliated facilities. Physician records may also be accessed for specific studies. A wide range of conditions has been validated by hospital chart review, including rheumatoid arthritis (Tennis et al. 1993), hip fractures (Ray et al. 1989), gastrointestinal bleeding (Raiford et al. 1996), and asthma-related conditions (Spitzer et al. 1992).

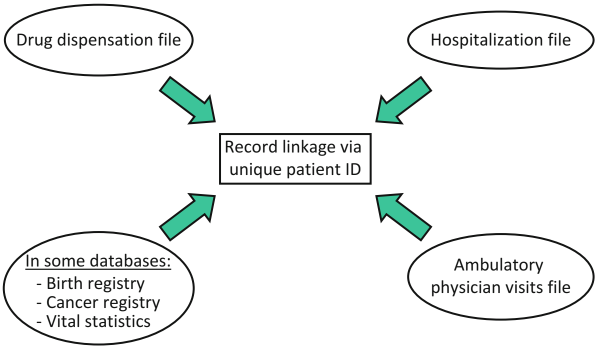

Fig. 48.1 Record linkage in administrative health databases

Table 48.5 Information contained in different files of Health Databases in Saskatchewan (Saskatchewan Ministry of Health 2010)

Population registry	Prescription drug data	Hospital services data	Medical services data
• Name • Health services number (HSN) • Sex • Date of birth • Residence information • Dates of coverage initiation and termination • Reason for coverage termination[g] • Indicator for registered Indian status • Indicator for current social assistance recipients receiving extended health benefits	*Patient information* • HSN • Sex, year of birth • Designation of special status[a] *Drug information* • Pharmacologic-therapeutic classification of drug[b] • Drug identification number[c] • Drug active ingredient number[h] • Generic and brand names • Strength and dosage form • Date dispensed • Quantity dispensed *Provider information* • Prescriber identification number[k] • Dispensing pharmacy identification number *Cost information* • Unit cost of drug materials • Dispensing fee and markup • Consumer share of total cost • Government share of total cost • Total cost	*Patient information* • HSN • Sex, year, and month of birth • Residence *Diagnostic and treatment information* • Most responsible diagnosis • Other diagnoses[d] • Principal procedure • Other procedures[d] • Accident code[i] *Other* • Admission and discharge dates • Length of stay • Admission and separation types • Case mix group • Resource intensity weight • Attending physician • Attending surgeon[e] • Hospital identification number	*Patient information* • HSN • Age, sex • Location of residence • Indicator for registered Indian status *Physician information* • Physician specialty • Referring physician[e] • Physician identification number[f] *Services and diagnostic information* • Date of service • Service code • Type of service • Diagnosis • Location of service[j] • Payment information[l]

[a] e.g., Saskatchewan Assistance Plan recipient

[b] Based on the American Hospital Formulary Service classification system

[c] DIN – assigned by Health Canada

[d] Number potentially available varies depending on the time period

[e] If applicable

[f] Which can be linked with the physician registry for additional information such as physician's age, sex, place and year of graduation, and practice type

[g] e.g., death, left the province

[h] AIN – also assigned by Health Canada

[i] External cause code

[j] e.g., office, inpatient, outpatient, home, other

[k] Which can be linked with the physician registry for additional information such as location of practice and prescriber specialty

[l] e.g., amount paid, date of payment

48.4.2.2 Physician-Based Databases

The former General Practice Research Database (GPRD) is a large physician-based computerized database of anonymized longitudinal patient records from hundreds of general practices in the UK, containing more than 35 million patient years of data. In March 2012, the GPRD became part of the data services provision of the Clinical Practice Research Datalink (CPRD) (Clinical Practice Research Datalink 2012). Currently, information is collected on approximately 3 million patients, equivalent to approximately 5% of the UK population. The database was created in June 1987 as the Value Added Medical Products (VAMP) research databank. VAMP provided practice computers and general practice software to general practitioners (GPs), and in return, GPs consented to undertake data quality training and to contribute anonymized data to a central database for subsequent use in public health research. During the 1990s, VAMP research databank underwent several organizational and management changes. The database was renamed General Practice Research Database (GPRD) in 1994 when it was donated to the UK Department of Health. In 1999, management responsibility for the database was transferred to the UK Medicines Control Agency which became part of the newly created Medicines and Healthcare Products Regulatory Agency (MHRA). The database has been used extensively for pharmacoepidemiology and clinical epidemiology research. A bibliography of studies using GPRD data can be found on the webpage of the CPRD (Clinical Practice Research Datalink 2012). The database includes the following information: demographics, including age and sex of patient (information on race is not collected); medical diagnosis, including comments; all prescriptions; events leading to withdrawal of a drug or treatment; referrals to hospitals; treatment outcomes, including hospital discharge reports where patients are referred to hospital for treatment; and miscellaneous patient information, e.g., smoking status, height, weight, immunizations, and for a growing number of patients also lab results. Recently, the GPRD gained approval to enable record linkage of GPRD data with other UK health-care databases via the patient's NHS (National Health Service) number, sex, date of birth and post code. Specifically, the Hospital Episode Statistics (HES) database records information on all hospitalizations, including data on length of stay, ward types, as well as extensive disease and procedure coding. The linkage between the GPRD and the HES databases applies to approximately half of the practices contributing to the GPRD. Validation studies of the GPRD have shown that the recording of medical data into GPs' computers is almost complete (Garcia Rodriguez and Perez 1998).

Besides the CPRD, other physician-based databases are The Health Improvement Network (THIN) database (The Health Improvement Network 2012) and the QResearch database (QResearch 2012a) in the UK and the IPCI database (IPCI 2012b) in the Netherlands. The MediPlus databases from IMS Health are also physician-based databases which are available in different countries. Depending on the particularities of the respective health-care system, different data are available for research. A description of the German IMS Disease Analyzer–MediPlus database can be found in an article by Dietlein and Schroder-Bernhardi (2002). The IMS databases have not been used extensively for pharmacoepidemiology research. Studies which examine data validity and comprehensiveness are mostly lacking. The German IMS Disease Analyzer–MediPlus database does not contain patient hospitalization data. It also lacks diagnostic or treatment information from all physician specialists, since it is usually based on one panel of doctors only, e.g., on a panel of GPs and internists or gynecologists or urologists. The database derived from the panel of gynecologists would therefore not include information on ambulatory physician contacts in GPs' or internists' offices and vice versa. The German IMS Disease Analyzer–MediPlus database has been used for several drug utilization studies, e.g., on the dosing of cava-cava extracts (Dietlein and Schroder-Bernhardi 2003), whether hospitals influence the prescribing behavior of general practitioners (Schroder-Bernhardi and Dietlein 2002), or how doctors treat Helicobacter pylori infections (Perez et al. 2002). In the UK, the MediPlus database contains similar patient information as the CPRD database.

48.4.3 Advantages and Limitations

Large health-care utilization databases offer several important advantages: (1) They are usually of enormous size, with patient numbers ranging from several hundred thousand to well over several millions. This makes it possible to study rare adverse events of pharmaceuticals in large populations. (2) Medication information is usually more accurate than self-recorded exposure information. Drug histories obtained from patients have limited reliability particularly for drugs that are used only intermittently and not on a regular basis (Kelly et al. 1990). Database information probably represents the most accurate information on drug utilization that can be obtained in elderly patients (Tamblyn et al. 1995). In drug dispensation databases, fairly accurate information can be obtained on drug intake that occurred a long time ago. Exposure information is available also for patients who are deceased or too ill to answer questions, without having to rely on proxy information. There is no potential for recall or interviewer bias which is always of concern with primary data collection. (3) Because the data are collected in an ongoing manner as a by-product of health-care delivery, epidemiological studies can be undertaken in reasonable time and at relatively low cost. The study variables are already available in computerized form and need not be obtained in time-consuming and expensive processes of data collection. (4) Some databases provide population-based data which cover the entire population of a geographical region and are thus fully representative of the population. Database studies do not require an informed patient consent and are therefore less prone to selection bias which may be a consequence of a low response rate in the study population.

Use of computerized databases for pharmacoepidemiology research is, however, not undisputed (Shapiro 1989), and there are a number of important limitations. A major concern is related to the validity of the diagnostic information contained in the database. In administrative health databases, diseases are primarily coded for billing and not for research purposes. There is no incentive for the health-care provider to use specific codes, e.g., "duodenal ulcer with bleeding" instead of "upper gastrointestinal bleeding otherwise not specified." Diseases are often coded according to the International Classification of Diseases (ICD-9 or ICD-10 coding schemes), and many different ICD-codes may be compatible with the same disease process. A combination of several diagnostic codes into a single "broader" code may therefore be necessary (Garbe et al. 1997, 1998a). Strom and Carson (1990) have described this problem by stating that researchers using diagnostic codes in a computerized database must be "lumpers" rather than "splitters."

The validity of diagnostic coding also depends on the ability of a diagnostic code to rather selectively represent the condition in question and therefore varies with the condition. Strom conducted a validation study of ICD-9 coding of Stevens–Johnson Syndrome in the COMPASS Medicaid database in the US (Strom et al. 1991). Records of 3.8 million patients in five US states were searched for ICD-9-CM code 695.1 which codes for Stevens–Johnson syndrome, but also for several other, less serious conditions. In an expert medical record review, only 14.8% of patients with ICD-9-CM code 695.1 whose medical records could be reviewed were judged to have Stevens–Johnson syndrome. Thus, studies of Stevens–Johnson syndrome in databases with ICD-9 coding cannot be conducted without additional validation of the diagnosis. Whenever possible, validity of disease coding should be quantified for each condition studied.

Validation studies usually use the paper medical or pharmacy record as the "gold standard." Access to patient charts for validation purposes is often obtained via the scrambled social security (patient identification) number. All personal identifying information is removed before copies of the charts are made available. The validation study by Strom also illustrates another problem: Only 51% of the medical records that were sought for in the study could actually be obtained (Strom et al. 1991). The authors state several reasons why they did not obtain access to the medical records: refusal of hospitals (30%), transcription errors (27%), translation of ID number not possible (17%), no location of medical record possible (22%), and other reasons (4%).

Administrative databases usually contain information on large numbers of patients; however, the amount of information per patient is limited: (1) Information about disease severity and many important risk factors that physicians use to make prescribing decisions is mostly lacking, and it may not be possible to exclude confounding by disease severity (Schneeweiss and Avorn 2005). In some instances, it is possible to construct an index of disease severity based on the patient's pharmacotherapy (Spitzer et al. 1992). (2) Relevant other confounder information for the association under study may not be contained in the database, creating a potential for bias. For example, most administrative databases do not contain information on smoking or alcohol use (Friedman et al. 2000) or age at menopause and reproductive history in women. (3) Administrative databases usually do not contain data on laboratory values or clinical measurements, although, in some databases, linkage with laboratory files has now become possible. (4) If relevant confounder information is missing and additional data collection required, it will make a study considerably more expensive and time-consuming, thereby diminishing some of the advantages connected with database research. It has to be decided on a case-by-case basis whether the information contained in a database is sufficient for the investigation of an association of interest and how much time and cost would be incurred if additional data have to be collected.

Although the medication information in databases is one of their major strengths, it also has some limitations: Information on drugs bought over the counter (OTC) and not prescribed by a physician is not available in the database; the patient's compliance with the prescription is unknown; in-hospital medication is usually not contained in the database; the prescribed daily dose is not documented in most databases, and the average daily dose has to be calculated instead based on the duration of drug use and the quantity of drug prescribed; the prescription file does not contain the indication for drug prescribing; however, in many instances, this information may be deduced from diagnostic coding in the ambulatory physician file; medication data will be truncated, if the database does not exist long enough or the database only includes elderly subjects. Truncation will limit the study of cumulative drug toxicity. Confounding by previous drug use may be avoided if a prior period of follow-up in the database is defined and the risk is only investigated in new users of the drug (Garbe et al. 1998b); many of the newest and/or most expensive drugs may not be available for study, if they are not included on the drug formulary.

Other important issues include whether the population contained in a database is representative of the source population and stable over time. For example, Saskatchewan Health Databases, which cover the population of the whole province of Saskatchewan, consist of a representative and fairly stable database population (Downey et al. 2003). In contrast, Medicaid databases in the USA are not representative of the US population, since they only include social welfare recipients and thereby over represent children, females, and non-whites in comparison with the total US population (Strom and Carson 1990). The skewness of Medicaid databases may not compromise the internal validity of a pharmacoepidemiology study conducted with these databases, but it may be a serious threat to its external validity, particularly when the data are being used for drug utilization research. In Medicaid Databases, turnover of the database population is high due to changing eligibility for Medicaid. Over a 5-year time period, only 35% of Michigan and 38% of Tennessee Medicaid enrollees were still in the system, with loss of eligibility being greatest in children and young adults (Ray and Griffin 1989). High patient turnover may also make it difficult to locate patient files for validation studies as has been reported in the study by Strom et al. (1991). Data from health maintenance databases are also not fully representative of the US population. Members of these organizations tend to be less frequently black or poor and have higher educational achievements. Turnover in membership at HMOs is usually less than in Medicaid databases (Friedman et al. 2000; Saunders et al. 2000).

48.5 Methodological Approaches for Pharmacoepidemiology Studies

The strategies employed to verify hypotheses on drug risks or benefits are similar to those used in other fields of epidemiology. The case-control design is the design of choice for the investigation of rare drug risks, particularly if multiple countries are necessary to attain sufficient power, while the cohort approach is preferably used to assess the risk of more frequent events or if more than one outcome has to be considered simultaneously. The special nature of drug exposure and the availability of existing databases in pharmacoepidemiology have given rise to specific challenges and preferred solutions to estimate risk and benefit.

48.5.1 Case-Control Studies

Field studies that employ a case-control design (cf. chapter ▸Case-Control Studies of this handbook) are not common in the evaluation of the risks and benefits of prescribed drugs. Drugs available over the counter without prescription are not recorded systematically in computerized databases and can therefore not be studied with linked databases. Thus studies of drugs such as analgesics, vitamin supplements, and anorexiants can only be studied by directly obtaining exposure information from subjects. With this design, cases with the outcome under study are identified from a given population, usually in hospitals or specialized clinics since they mostly involve serious outcomes. The approach to select the controls varies across studies. The International Agranulocytosis and Aplastic Anemia Study (IAAAS) that evaluated the effect of different analgesics on the risks of agranulocytosis and aplastic anemia used hospital-based controls (Anonymous 1986). The International Primary Pulmonary Hypertension Study (IPPHS) of the risk of primary pulmonary hypertension associated with anorexiant agents used patients treated by the same physician as the source of controls (Abenhaim et al. 1996). The Yale Hemorrhagic Stroke Study assessing the risk of diet and cough/cold remedies containing phenylpropanolamine used population-based controls identified by random-digit dialing (Viscoli et al. 2001) (see also chapter ▸Epidemiological Field Work in Population-Based Studies of this handbook). Finally, the transnational study on oral contraceptive risks used both hospital and population-based controls (Spitzer et al. 1996). Such field studies that collect information from patients, physicians, or medical charts are the exception because of the resources, expense, and time required to complete the study.

Case-control studies using existing health databases are much more common. Besides the usual concerns with case-control studies in general, some are specific to studies conducted from databases. For example, the General Practice Research Database (GPRD) was used to evaluate the impact of inhaled corticosteroids on the risk of hip fracture (Hubbard et al. 2002). The entire GPRD was used to identify 16,341 cases of hip fracture and a random sample of 29,889 subjects selected as controls. This design is attractive because of its efficiency in using only a sample of subjects to estimate an effect for an entire population. Such an approach, however, can be deceiving for specific diseases such as asthma because of the illusion of large sample sizes. Indeed, all cases of hip fracture selected within a population such as the GPRD suggest a very large sample size for the study, along with the very large number of controls. However, in assessing the effect of inhaled corticosteroids, a drug pertinent exclusively to the population of asthma or chronic obstructive pulmonary disease (COPD) patients, a large proportion of the cases and the controls are in fact irrelevant to the question at hand. Thus, for example, for the GPRD case-control study of hip fracture risk, only 878 of the 16,341 cases and 1,335 of the 29,889 controls were subjects with asthma or COPD (Hubbard et al. 2002). With its 16,341 cases and 29,889 controls, the study appears at first more powerful than the Quebec study, based on 3,326 cases of hip fracture and 66,237 controls selected from the asthma/COPD population (Suissa et al. 2004). In fact, the inference on the effect of inhaled corticosteroids is actually based on many fewer subjects than believed. This point is particularly relevant for studies that find no significantly increased risk since, despite appearances, conclusions are based on fewer numbers of cases and controls with respiratory disease and thus lower power than expected. Furthermore, the estimate of effect may be biased if the outcome of interest, in this instance fractures, is also associated with the disease itself (asthma or COPD) and not only with the medications used to treat these conditions. In this case, the bias due to the association with the disease can only be eliminated by restricting the analyses to the population of patients who have the disease (Suissa et al. 2004).

Another issue in such database case-control studies is the manner by which controls are selected and particularly the index date for controls. In the GPRD study of the impact of inhaled corticosteroids on the risk of hip fracture, controls were matched to cases on age, sex, general practice, and date of entry into the database (Hubbard et al. 2002). While the index date from which exposure was assessed was the fracture date for the cases, the index date for the controls was the same date as the matched case. To allocate such a date, one must be assured that the control is at risk on that date. Indeed, there could be control subjects with the same age, sex, general practice, and date of entry, but who are dead or not in the practice at the time of the matched case's fracture. These will be necessarily currently "unexposed," which could bias upward the rate ratio.

48.5.2 Cohort Studies

Observational database studies that use a cohort design (cf. chapter ▶Cohort Studies of this handbook) differ primarily with respect to their definition of cohort entry or time zero. The Saskatchewan asthma cohorts have defined asthma as well as its onset by the dispensing of medications used to treat the condition, without the use of diagnostic codes from physicians (Blais et al. 1998b; Suissa et al. 2002). Patients were considered to have asthma as of the first time they received three prescriptions for an asthma medication, including bronchodilators, inhaled steroids, and other asthma drugs, on at least two different dates within a 1-year period. The date of the third prescription defined the onset and diagnosis of asthma, and patients were then followed from that point on for the occurrence of asthma outcomes. Such a definition is not entirely accurate for two reasons: Subjects with asthma may be hospitalized at their initial presentation, and medications for asthma are used for other conditions such as COPD. In an attempt to exclude patients with COPD, age criteria were used, including only patients to the age of 44 and also excluding oral corticosteroids as one of the defining drugs for asthma.

Alternatively, cohort entry may be defined by calendar time. For example, a cohort formed from a health maintenance organization in eastern Massachusetts defined cohort entry as October 1, 1991 (Adams et al. 2002; Donahue et al. 1997). This cohort of 16,941 asthma patients was followed from this date or registration in the insurance plan to September 30, 1994. Such calendar time-based definitions of cohort entry will inherently define cohorts with patients who have varying durations of disease at time zero (cohort entry). Such a "prevalent" cohort, to be distinguished from an "incident" cohort defined by patients with new onset of asthma, can be subject to serious biases when evaluating the association between drug use and asthma outcomes. Indeed, if the risk of the asthma outcome and of being dispensed the drug under study are both associated with the duration of asthma, such prevalent cohorts will produce biased estimates of this association unless the duration of the condition can somehow be adjusted for. A source of selection bias for such prevalent cohorts is that the treatment itself may change because of prior events that are not included in the period of observation. For example, if a patient was hospitalized for asthma in the past and, as a result, was prescribed inhaled corticosteroids, such a patient may be at increased risk of a further hospitalization and of being dispensed inhaled corticosteroids subsequently. For such studies to be valid, information on the history of asthma prior to cohort entry, which includes the duration of the disease and prior outcomes such as asthma hospitalizations as well as prior drug exposures, are required for the purpose of adjustment or for testing for effect modification. A frequent problem with computerized database studies is that these historical data on the duration and history of the disease before cohort entry are rarely available.

The third type of cohort defines cohort entry by a specific clinical event, such as hospitalization, emergency room visit, or a physician visit. Here again, these cohorts can be incident or prevalent if these cohort-defining events are either the first one ever or rather the first to occur after a certain date. An example of this approach is a study from the Saskatchewan databases of asthma patients, with entry defined by the first time they received three prescriptions for an asthma medication within a 1-year period, after a 2-year span with no asthma medications. The study cohort consisted of all subjects hospitalized for asthma for the first time after cohort entry and followed until readmission. The use of inhaled corticosteroids subsequent to the first hospitalization was evaluated with respect to the rate of readmission (Blais et al. 1998a). A similar cohort definition was used with the Ontario database, although this cohort was based on elderly COPD patients and the COPD hospitalization defining cohort entry was not necessarily the first one to occur in their disease (Sin and Tu 2001a).

48.5.3 Nested Case-Control Studies

The complexity in data analysis is greater in the field of database studies because of the technical challenges presented by their large size. Indeed, the asthma cohort formed from the health maintenance organization in eastern Massachusetts included 742 asthma hospitalizations occurring during the 3 year follow-up period (Donahue et al. 1997). With over 16,000 patients in the cohort, an analysis based on the Cox proportional hazards model with time-dependent exposure (cf. chapter ▸Survival Analysis of this handbook) would require 742 risk sets (all patients in the cohort on the day of hospitalization), each containing approximately 16,000 observations with information on exposure and confounding factors measured at the point in time when the case occurred. Such an analysis would therefore require to generate close to 12 million observations (742 × 16,000), each with dozens of variables. Another example is the cohort study that included over 22,000 elderly patients hospitalized for COPD in Ontario, Canada, of whom around 8,000 either died or were re-admitted for COPD (Sin and Tu 2001a). A proper time-dependent analysis could include up to 140 million observations, creating a serious technical challenge in statistical computing. As a result of this complexity, the temptation to analyze these cohorts with exposures that are assumed not to change over time is attractive but, as described below, can cause severe immortal time bias (see Sect. 48.6.1).

Rather than analyzing such cohort studies with proper but complex time-dependent techniques, methods based on sampling can produce practically the same results at greater efficiency. The nested case-control design (cf. chapter ▸Modern Epidemiological Study Designs of this handbook), nested within the cohort, is precisely such an approach (Essebag et al. 2003; Suissa 2000). It is based on using data on all the cases with the study outcome that occurs during cohort follow-up. These represent the case series. A random sample of person-moments, namely, time points during the subjects' follow-up is then selected from all person-moments in the cohort to provide the control group for the nested case-control approach. For the cases, the index date, on which the timing of the exposure to the drug of interest is based, is simply the time at which the outcome occurred. For controls, the index date is the random person-moment(s) selected for that subject during follow-up, or the same point in time of the corresponding case (Suissa 2000). Because of the highly variable nature of drug exposure over time, it is important that person-moments are selected properly from all person-moments of follow-up for all members of the cohort. Thus, a subject may be selected more than once at different moments of their follow-up, and particularly person-moments preceding the index date of a case are valid control person-moments. For practical reasons and to conform to the Cox proportional hazards model, person-moments are usually selected from the risk set of each case. This approach involves identifying, for each case, all subjects who are at risk of the event at the time that the case occurred (the risk set) and controls are selected from this risk set (incidence density sampling, cf. chapters ▸Case-Control Studies and ▸Modern Epidemiological Study Designs of this handbook). Part of the simplicity of this approach is that all subjects in a risk set are allocated the same index date as the set-defining case.

The advantage of this approach is the direct relationship between the Cox proportional hazard model with time-dependent exposure and the conditional logistic regression analysis (cf. chapter ▸Regression Methods for Epidemiological Analysis of this handbook) that is used to analyze such nested case-control data. Thus, instead of using exposure data on all members of the risk set, as the Cox model would require, data on only a few subjects (usually 4 or 10 controls per case) are sufficient to provide a very efficient estimator of the rate ratio. Such ease of data analysis with the large size databases that are used in pharmacoepidemiology is crucial. As an example, with the asthma cohort study of Donahue, if 10 controls per case were used for each of the 742 cases, the analysis would be based on 7,420 observations instead of the 12 million observations necessary with the Cox model analysis.

In studying the effectiveness of drug treatment, one of the major problems is confounding by indication. The nested case-control approach becomes more useful, as it allows cases and controls to be matched on several measures of disease severity. Thus, the effect of a drug can be isolated, independently of the effects of the severity markers. Such a matched nested case-control study was used to evaluate the effectiveness of inhaled corticosteroids on asthma death (Suissa et al. 2000a). In that study, cases were identified from a cohort of over 30,000 asthma patients, from which 66 died of asthma. The Cox analysis would have required almost two million observations to be processed. For each case, however, the only members of the risk sets that were identified as controls were those with the same disease severity characteristics as the case, namely, prior hospitalization for asthma, oral corticosteroid use, number of canisters of beta-agonists, use of theophylline, and nebulized beta-agonists. Thus, cases and controls were similar on all these severity markers, except with respect to inhaled corticosteroids. As a result, the effect of inhaled corticosteroids could be assessed independently of these potential confounding factors.

48.5.4 Case-Crossover Design

Pharmacoepidemiology is frequently faced with the assessment of the risk of rare acute adverse events resulting from transient drug effects. Although the case-control approach can be used, the acuteness of the adverse event and the length of the drug's effect, as well as difficulties in determining the timing of drug exposure, induce uncertainty about the proper selection of controls. Moreover, confounding by indication may often be a problematic issue in such a design. In this situation, within-subject approaches have been proposed, including the case-crossover design and its extension the case-time-control design which was devised to counter time trend biases. The principle is that, when studying transient drug effects and acute outcome events, the best representatives of the source population that produced the cases are the cases themselves (cf. chapter ▸Modern Epidemiological Study Designs of this handbook).

To carry out a case-crossover study, three critical points must be considered. First, the study must necessarily be dealing with an acute adverse event which is alleged to be the result of a transient drug effect. Thus, drugs with regular patterns of use which vary only minimally between and within individuals are not easily amenable to this design. Nor are latent adverse events which only occur long after exposure. Second, since a transient effect is under study, the effect period (or time window of effect) must be precisely determined. An incorrect specification of this time window can have important repercussions on the risk estimate. Third, one must obtain reliable data on the usual pattern of drug exposure for each case, over a sufficiently long period of time.

The case-crossover study is simply a crossover study in the cases only. The subjects alternate at varying frequencies between exposure and non-exposure to the drug of interest, until the adverse event occurs, which happens for all subjects in the study, since all are cases by definition. With respect to the timing of the adverse event, each case is investigated to determine whether exposure occurred within the predetermined effect period. In the VACCIMUS study of Hepatitis B vaccination and the risk of a multiple sclerosis relapse, spontaneous reports indicated that such an effect could occur within 2 months of the vaccination (Confavreux et al. 2001). Thus, the case-crossover design used as the risk period the 2-month period prior to the onset of the relapse and any vaccination in this period to determine exposure status. To obtain control exposure, data on the average drug use pattern are necessary to determine the typical probability of exposure to the time window of effect. This is done by obtaining data for a sufficiently stable period of time prior to time of the event occurrence and its exposure period. For the VACCIMUS study, there were four control periods consisting of the four 2-month periods prior to the 2-month risk period. The estimation of the odds ratio is based on any appropriate technique for matched data (4 controls per case), such as conditional logistic regression.

This design has been used in pharmacoepidemiology (Barbone et al. 1998; Confavreux et al. 2001; Etienney et al. 2003; Fagot et al. 2001; Ki et al. 2003; Neutel et al. 2002; Sturkenboom et al. 1995).

48.5.5 Case-Time-Control Design

One of the limitations of the case-crossover design, particularly in the context of drug exposures, is that the exposure pattern may have changed over time and particularly between the control and risk periods. For example, a rapid increase in vaccination rates over time during the span of the case ascertainment for the VACCIMUS study, particularly if this span had been short, would have biased the estimate of the odds ratio. Indeed, this estimate would also include the effect of the natural time trend in exposure. If control subjects are available, the case-time-control design can be used to separate the time effect from the drug effect (Suissa 1995). In simple terms, the time effect is estimated from the case-crossover odds ratio of exposure among the control subjects. The net effect of exposure on event occurrence is then computed by dividing the combined time and drug effect estimated from the case-crossover odds ratio of exposure among the case subjects by the time effect (cf. chapter ▶Modern Epidemiological Study Designs of this handbook).

The approach is illustrated with data from the Saskatchewan Asthma Epidemiologic Project, a study conducted to investigate the risks associated with the use of inhaled ß-agonists in the treatment of asthma. Using databases from Saskatchewan, Canada, a cohort of 12,301 asthmatics was followed during 1980–1987. All 129 cases of fatal or near-fatal asthma and 655 controls were selected. The amount of ß-agonist used in the year prior to the index date, namely, high (more than 12 canisters per year) compared with low (12 or less canisters), was found to be associated to the adverse event. Of the 129 cases, 93 (72%) were high users of ß-agonists, compared with 241 (37%) of the 655 controls. The resulting crude odds ratio for high ß-agonist use is 4.4 (95% confidence interval (CI): 2.9–6.7). Adjustment for all available markers of severity, such as oral corticosteroids and prior asthma hospitalizations as confounding factors, lowers the odds ratio to 3.1 (95% CI: 1.8–5.4), the "best" estimate one can derive from these case-control data using conventional tools (Spitzer et al. 1992).

The use of inhaled ß-agonists, however, is known to increase with asthma severity which also increases the risk of fatal or near-fatal asthma. It is therefore not possible to separate the effects of the drug to the risk from that of disease severity, so that a within-subject design may be preferable. To apply the case-time-control design, exposure to ß-agonists was obtained for the 1-year current period and the 1-year reference period. Among the 129 cases, 29 were currently high users of ß-agonists and were low users in the reference period, while 9 cases were currently low users of ß-agonists and were high users previously. The case-crossover estimate of the odds ratio (*OR*) is thus 29/9 ($OR = 3.2$; 95% CI: 1.5–6.8). However, the high use of ß-agonists may have increased naturally over time, so that the control subjects were used to estimate this effect. Among the 655 controls, 65 were currently high users of ß-agonists and were low users in the reference period, while 25 were currently low users of ß-agonists and were high users previously, for an odds ratio of the time trend of 65/25 ($OR = 2.6$; 95% CI: 1.6–4.1). The case-time-control odds ratio, using these discordant pair frequencies for a paired-matched analysis, is given by $(29/9)/(65/25) = 1.2$ (95% CI: 0.5–3.0). This estimate, which excludes the effect of unmeasured confounding by disease severity, indicates a minimal risk for these drugs (Spitzer et al. 1992).

The case-time-control approach provides a useful complement to the case-crossover design when the probability of drug exposure is not stable over time, particularly between the control and risk periods (Donnan and Wang 2001; Hernandez-Diaz et al. 2003). However, its validity is subject to several assumptions, including the homogeneity of the odds ratio across subjects (Greenland 1996; Suissa 1998). This approach has been applied more frequently in pharmacoepidemiology recently (Corrao et al. 2005; Hernandez-Diaz et al. 2003; Kjaer et al. 2007; Nicholas et al. 2012; Park-Wyllie et al. 2009; Risselada et al. 2011; Schneider et al. 2005; Wang et al. 2012; Zambon et al. 2009).

48.5.6 Self-Controlled Case Series Method

The self-controlled case series (SCCS) method was first introduced in 1995 to study associations between vaccines and acute adverse events (Farrington 1995; Farrington et al. 1995). It gained broader attention when application of the method did not confirm the widely debated association between mumps, measles and rubella vaccines, and autism (Taylor et al. 1999). It has since been used more widely in vaccine, but also non-vaccine safety studies (Hubbard et al. 2003; Weldeselassie et al. 2011). The method was originally developed for the study of transient exposures with acute outcomes using only cases, i.e., subjects who had developed the outcome of interest (Whitaker et al. 2006), but the method was later extended also to non-acute outcomes, e.g., autism. The SCCS method estimates the relative incidence of the outcome of interest in a predefined postexposure risk period, compared to other times, which constitute the control period.

First, an overall study time window, usually defined by age or calendar time boundaries, is chosen in a way that the chance that individuals experience both risk and control periods is maximized. Then, individuals with the outcome of interest (cases) within this study time window are identified. For each case, the observation period – i.e., the time spent within the study time window – is determined. In a next step, the exposure histories of the cases are ascertained. The exposure dates of each case are used to define one or more risk periods, during which individuals are hypothesized to be at increased risk of the outcome of interest after the exposure. All other time within an individual's observation period that does not fall within a risk period is included in that individual's control period. To take account of only sampling cases, the likelihood is conditional on an event having occurred during the observation period. Having conditioned on the event in the observation period, and having fixed the risk and control intervals that each individual has progressed through, the only quantity that remains undetermined is the interval – i.e., the risk period or control period – in which that individual's event actually occurred. Since only this information contributes to the estimation of the exposure effect, an individual with zero events, i.e., with no information on when events occurred, does not contribute to the estimation and needs not be sampled. The relative incidence, i.e., the incidence in a risk period relative to the control period, is estimated by fitting a conditional Poisson regression model. Since inference is within individuals, the method implicitly adjusts for all confounders that remain fixed over the observation period, such as genetic or socioeconomic factors. Time-varying confounding factors, such as age, can be accounted for by subdividing each individual's observation period into age categories, which are modeled explicitly. The tutorial by Whitaker provides full practical details and worked examples (Whitaker et al. 2006). The SCCS method relies on three key assumptions: These are (1) events arise in a non-homogeneous Poisson process, (2) the occurrence of an event must not alter the probability of subsequent exposure, and (3) the occurrence of the event of interest must not censor or affect the observation period (Whitaker et al. 2009).

48.6 Some Methodological Challenges

48.6.1 Valid Drug Exposure Information and Relevant Exposure Risk Window

Accurate and complete exposure information is a prerequisite for both drug utilization and drug risk studies in pharmacoepidemiology. Data on drug exposures can be ascertained from different sources including exposures ascertained from self-report, medical records, electronic prescription data, or pharmacy dispensation data. Self-reported exposure data have in theory the advantage that drugs used many years previously can be ascertained, whereas this may not be the case in medical records or claims databases when a person's data do not go back long enough in the database or the database itself has not sufficient follow-up. Medications provided by self-report are more likely to reflect actual drug consumption than medications ascertained in databases, where information on patient compliance is lacking (West 1997). Collection of self-reported exposures in standardized interviews is, however, very expensive, time-consuming, and may be subject to interviewer bias. Moreover, recall inaccuracies will lead to exposure misclassification which is particularly of concern in studies of past drug exposures. Only few studies have investigated this issue and shown recall of past drug exposures to be influenced by the type of drug and the frequency of its administration (Behr et al. 2012; van den Brandt et al. 1991; West et al. 1995). A study which compared self-reported use of non-steroidal anti-inflammatory drugs (NSAIDs) and non-contraceptive estrogens against pharmacy dispensation data found that of those with only a single NSAID dispensation, 41% were able to recall *any* NSAID use compared with 85% for those with multiple NSAID dispensations, but only 30% recalled the NSAID name and only 15% the dose. For non-contraceptive estrogens, recall was higher with 78% of users recalling the name, but only 26% recalling the name and dose (West et al. 1995).

Drug exposure information ascertained from medical records has equally been shown to be less complete than that of pharmacy dispensation data (West et al. 1994). Even when a drug is suspected to cause an adverse drug reaction which led to hospitalization, it may not be entered in the inpatient medical record. Strom et al. found that for 128 hospitalized cases of Stevens–Johnson syndrome, only 50% of the 234 prescriptions for drugs suspected of causing the syndrome had been entered in the medical record when compared to the computerized Medicaid pharmacy claims files (Strom et al. 1991).

Since claims databases do not rely on physician's prescription documentation nor on patient recall, the drug exposure data from these databases are usually regarded as most complete. Completeness may, however, depend on the type of drug: If the medication of interest is rather inexpensive to purchase out-of-pocket compared to a person's drug insurance co-payment, this might decrease completeness and increase the potential for exposure misclassification. If OTC drug use or drugs administered during hospitalization are of relevance, medical record abstraction will often be necessary to obtain these types of drug exposures, since they are usually not contained in the databases. Medical records databases contain only the entry of the drug prescription, but it is unknown if the prescription was filled at a pharmacy. For this reason, they are more prone to misclassification of exposure than claims databases due to primary non-compliance, i.e., patients not filling the prescribed medication in a pharmacy. This issue has been investigated in several studies, with primary non-compliance ranging from 1.6% to 22% depending on the study and on the type of drug (Ekedahl and Mansson 2004; Esposito et al. 2008; Kennedy et al. 2008; Kirking et al. 2006).

Whereas information on the prescribed daily dose and the duration of each prescription is usually not contained in claims databases, this can be calculated in medical record databases based on the number of tablets to be taken per day

(Andersohn et al. 2009; Schade et al. 2007). This information is, however, entered in so many different ways in the medical record databases that it is tedious to extract and therefore underused. As a consequence, some medical record database studies did not calculate the duration of each prescription, but assigned fixed time windows for each prescription (Azoulay et al. 2010; Opatrny et al. 2008) or estimated the duration of exposure by the number of prescriptions written (Bodmer et al. 2012; Brauchli et al. 2011; Meier et al. 2010).

The correct definition of the relevant exposure to a medical drug for the outcome of interest (referred to as the exposure risk window) is a great challenge in all pharmacoepidemiology studies. For example, if an adverse outcome is known to occur only immediately after initial use of a drug and the exposure definition includes all of the patient's time on a drug in the analysis, a significant amount of non-relevant exposure time could be included and could produce biased risk estimates (van Staa et al. 1994). Information from other sources, e.g., data from spontaneous reporting systems or published case reports, can increase the likelihood of focusing on relevant periods of exposure. Sensitivity analyses might provide further insight into the relevant exposure risk window.

For drugs presenting an immediate hazard after initial use, an incident or new user cohort design has been recommended (Ray 2003). When defining new users, investigators have to define look-back periods to ensure that prevalent users are not incorrectly classified as new users, e.g., patients who were already using the drug of interest when they entered the database.

48.6.2 Immortal Time Bias in Cohort Studies

A challenge of cohort studies is in their data analysis. Since drug therapy, the exposure of interest, often changes over time, data analysis must take this variability into account. However, such variability in exposure over time is not simple to incorporate in the analysis. Due to the complexity of such analyses, several of the studies mentioned above employed a time-fixed definition of exposure, by invoking the principle of intention-to-treat analysis. This principle, borrowed from randomized controlled trials, is based on the premise that subjects are exposed to the drug under study immediately at the start of follow-up. This information is unknown in database studies.

To emulate randomized controlled studies in the context of cohort studies, some authors have looked forward after cohort entry for the first prescription of the drug under study. In this way, a subject who was dispensed a prescription for such drug was considered exposed and a subject who did not was considered unexposed. Different time periods of exposure assessment were used. For instance, in the context of COPD, a prescription for inhaled corticosteroids during the period of 90 days after cohort entry was used to define exposure (Sin and Tu 2001b). In other studies, periods of 1 and 3 years were used to consider subjects exposed to inhaled corticosteroids in assessing their impact on mortality (Sin and Man 2002;

Sin and Tu 2001a). This approach, however, leads to immortal time bias, a major source of distortion in the rate ratio estimate (Suissa 2003).

Immortal time bias arises from the introduction of immortal time in defining exposure by looking forward after cohort entry. Indeed, if exposed subjects were classified as such because they were observed to have been dispensed their first prescription for an inhaled corticosteroid 80 days after cohort entry, they necessarily had to be alive on day 80. Therefore, this 80-day period is immortal. While some exposed subjects will have very short immortal time periods (a day or two), others can have very long immortal periods. On the other hand, unexposed subjects do not have any immortal time, and in particular the subjects who die soon after cohort entry, with too little time to receive the drug under study. Therefore, the exposed subjects will have a major survival advantage over their unexposed counterparts because they are guaranteed to survive at least until their drug was dispensed.

This generation of immortal time in exposed subjects, but not in the unexposed subjects, causes an underestimation of the rate of the outcome among the exposed subjects. This underestimation results from the fact that the outcome rate in the exposed is actually composed of two rates. The first is the true rate, based on the person-time cumulated after the date of drug dispensing that defines exposure (post-*Rx*), while the second is that based on the person-time cumulated from cohort entry until the date of drug dispensing that defines exposure (pre-*Rx*). The first rate will therefore be computed by dividing all outcome events in that group by the first rate person-time, while the second rate will by definition divide zero events by the second rate person-time. For example, the rate in the exposed

$$\text{rate} = \text{deaths}/\text{total person-years}$$

consists in fact of two rates:

$$\text{rate pre-}Rx = 0/\text{person-years pre-}Rx$$

and

$$\text{rate post-}Rx = \text{deaths}/\text{person-years post-}Rx.$$

The zero component of the rate will necessarily bring down the exposed rate. Since there is no such phenomenon in the unexposed group, the computation of the rate ratio will systematically produce a value lower than the true value because of the underestimation of the exposed rate. In particular, if the drug under study is altogether unrelated to the outcome, so that the true rate ratio is 1, this approach will produce rate ratios lower than 1, thus creating an appearance of effectiveness for the drug.

The immortal time in exposed subjects also causes an overestimation of the rate of the outcome among the unexposed subjects. This is because the zero component of the rate in the exposed group should in fact be classified in the unexposed group. Indeed, subjects are in fact unexposed to the drug under study between cohort entries until the date of drug dispensing that defines exposure. They only start to be exposed after the drug is dispensed. Thus, the zero rate should in fact be combined with the unexposed rate.

Immortal time bias is thus the result of simplistic yet improper exposure definitions and analyses that cause serious misclassification of exposure and outcome events. This situation is created by using an emulation of the randomized controlled trial to simplify the analysis of complex time-varying drug exposure data. However, such studies do not lend themselves to such simple paradigms. Instead, time-dependent methods for analyzing risks, such as the Cox proportional hazard models with time-dependent exposures or nested case-control designs, must be used to account for complex changes in drug exposure and confounders over time (Levesque et al. 2010; Samet 2003; Suissa 2003, 2004, 2007, 2008).

48.6.3 Confounding by Indication and Unmeasured Confounding

The indication for which a medication is given may act as a confounder in observational studies, particularly when assessing the effectiveness of a drug (Horwitz and Feinstein 1981; Slone et al. 1979; Strom et al. 1983). Such confounding by indication will be present if the indication for the prescription of the medication under study is also a determinant of the outcome of interest. Generally, a drug is more likely to be prescribed to a patient with more severe disease who, in turn, is more likely to incur an adverse outcome of the disease. Thus, patients prescribed the drug under study will have higher rates of outcome than the subjects not prescribed the drug. Such an appearance of lack of effectiveness could simply be a reflection of the effect of indication, in this case disease severity.

Confounding by indication is often difficult to control, primarily because the precise reason for prescribing is rarely measured. This may preclude the study of drug effectiveness with observational designs (Miettinen 1983). Yet, a clinical trial to answer this question would require the follow-up of thousands of patients over a long time, which may simply be unfeasible. Observational studies become the tool of choice as long as validity of the study is not compromised by intractable confounding by indication (Miettinen 1983). If such an observational study produces lower rates of outcome for the drug under study, one may conclude on the one hand that these medications are effective. On the other hand, if users of the drug are found to be at equal or increased risk of the outcome relative to non-users, it would not be possible to conclude on the absence of a protective effect of these medications.

This problem of confounding by indication is compounded with the use of computerized databases, because of their lack of information on important confounders (Shapiro 1989). The absence of information on drug indication precludes the control of confounding by adjustment in the analysis. Thus, control for confounding by indication must be tackled at the design level. One approach is to restrict the study to a group of patients homogeneous with respect to disease severity. For example, in a study of the effectiveness of inhaled corticosteroids in asthma, Blais et al. (1998a) identified a point in time at which users and non-users of inhaled corticosteroids would have a similar level of asthma severity. The study was thus restricted to patients who had just been hospitalized for asthma, with the discharge date taken as time zero, which would greatly reduce heterogeneity in disease severity. The rate of a readmission for asthma was then assessed according to the use of inhaled corticosteroids after this initial hospitalization.

Another approach is to compare two medications prescribed for the same indication (Strom et al. 1983, 1984). In this case, relative effectiveness as opposed to absolute effectiveness will be evaluated. An example of this approach was also used in a study of the effectiveness of early use of inhaled corticosteroids in asthma. Blais et al. (1998b) identified a cohort of newly treated asthma patients and compared regular users of inhaled corticosteroids with regular users of either antiallergic agents or theophylline and matched for the duration of asthma at the initiation of therapy.

In addition to disease severity, genetic factors can determine individual susceptibility to both dose-dependent and dose-independent ADRs.

More recently, instrumental variable (IV) methods have been proposed as a possible solution to confounding by indication or otherwise unmeasured confounding in comparative effectiveness and drug safety studies, provided a suitable instrument can be identified (Brookhart et al. 2006a, 2010; Rassen et al. 2009a, b). The idea is that the causal effect of exposure on outcome can be captured by using the relationship between the exposure and another variable, the IV (Martens et al. 2006).

For an IV to provide unbiased treatment effects even in the presence of unmeasured confounders, three important assumptions have to be fulfilled: (i) The IV should be correlated to the exposure under study, (ii) the relationship between the IV and the exposure should not be confounded by other variables, and (iii) the IV should influence the outcome neither directly nor indirectly by its relationship with other variables and should be associated with the outcome only by its association with the exposure. As such, an IV can be thought of as an observed variable that is associated with variation in the exposure similar to randomized assignment. If these assumptions are met, IV analyses can provide unbiased treatment estimates even in the presence of unmeasured confounding. If both the instrument and the exposure are dichotomous, the classic IV estimator, also called the Wald estimator, is given by

$$\beta_{\mathrm{IV}} = \frac{E[Y|Z=1] - E[Y|Z=0]}{E[X|Z=1] - E[X|Z=0]}$$

where X is the treatment, Y is the outcome, Z is the instrument, and β is a measure of the effect of X on Y. The numerator of this estimator is comparable to the intention-to-treat (ITT) estimate of an RCT measured as a risk difference with the randomization providing Z. The denominator presents the difference in treatment rates between levels of Z. In an RCT, this would refer to the compliance in the different treatment arms. In the case of perfect compliance, i.e., when Z perfectly predicts X, then $E[X|Z=1] - E[X|Z=0] = 1$, the IV estimator will be identical to the ITT estimator (Brookhart et al. 2010).

It is, however, not possible to empirically verify assumptions (ii) and (iii) regarding the instrument making it difficult in practice to find a suitable one (Hernan and Robins 2006). In pharmacoepidemiology studies, where the instrument needs to be unrelated to patient characteristics, physician prescribing preference has been used in several studies (Brookhart et al. 2006b; Schneeweiss et al. 2007, 2008; Wang et al. 2005, 2007), but this instrument may actually have violated assumptions (ii) and (iii) leading to bias (Hernan and Robins 2006). In the case of a weak instrument, i.e., when the instrument is only weakly related to the exposure under study, this would actually increase the bias (Hernan and Robins 2006; Martens et al. 2006). It has also been pointed out that the standard IV methodology deals only poorly with time-varying exposures which are most frequently the case in pharmacoepidemiology studies (Hernan and Robins 2006).

If a valid instrument cannot be identified, sensitivity analyses may provide further insight into the impact of residual or unmeasured confounding. Basic sensitivity analyses are conducted to assess how strong and how imbalanced a confounder would have to be between the exposures of interest to explain the observed effect. A review of sensitivity analysis and adjustment for unmeasured confounders with external data in pharmacoepidemiology studies is provided by Schneeweiss (2006).

48.6.4 Depletion of Susceptibles

In general, the risk of an ADR associated with drug use does not remain constant over time, and can change in different ways from the start of its use. The risk may increase with cumulative drug exposure (e.g., the risk of cardiomyopathy associated with cumulative anthracycline exposure or the risk of cataract associated with continued glucocorticoid use), but it may also decrease after an initial period of sharp increased risk. Therefore, in using a case-control study that evaluates the effect of current use of a drug, past history of use of a drug or a class of drugs must be accounted for as it may modify the risk of an ADR associated with current use of the drug.

A decreasing risk after an initial period of increased risk is probably more important than cumulative drug toxicity and may, at the population level, lead to a phenomenon which has been described as “depletion of susceptibles”: Patients who remain on the drug are those who can tolerate it, while those who are susceptible to adverse drug reactions will stop the drug and thereby select themselves out of the exposed cohort (Moride and Abenhaim 1994). Such a pattern has been demonstrated for the gastrointestinal toxicity of non-steroidal anti-inflammatory drugs (NSAIDS). It has been shown that the risk of upper gastrointestinal bleeding (UGIB) was highest after the third NSAID prescription and thereafter decreasing (Carson et al. 1987). Moride and Abenhaim (1994) empirically showed a depletion of susceptibles effect in a hospital-based case-control study of NSAIDS and the risk of UGIB. They investigated the risk of UGIB associated with recent NSAID use stratified by past or no past NSAID use. The risk of UGIB was significantly greater for those patients who used NSAIDS for the first time in 3 years ($OR = 22.7$) than for those who had used these drugs before ($OR = 3.0$) (Moride and Abenhaim 1994).

The enormous importance of accounting for changes in drug risk over time in the design and/or analysis of pharmacoepidemiology studies was highlighted in the debate about the risk of venous thromboembolism (VTE) associated with second-or third-generation oral contraceptives (OC). Several pharmacoepidemiology studies published in 1995/1996 reported an increased risk of VTE among users of newer OC preparations compared with those of older OC preparations (Anonymous 1995b; Bloemenkamp et al. 1995; Jick et al. 1995; Spitzer et al. 1996). Additional analyses suggested that the magnitude of the risk estimates for individual OC was closely linked with the time of market introduction of the respective OC, with increasing risk for the newer preparations (Lewis et al. 1996). Since a larger proportion of users of older OC preparations were long-term users compared with those using newer OC, a depletion of susceptibles effect was postulated to be active within these studies. It was hypothesized that individuals with good tolerance were preferentially long term users of older OC preparations, whereas groups with shorter duration of use might be more frequently using the newer OC preparations and thereby constitute a different subpopulation.

The phenomenon of depletion of susceptibles can lead, if not accounted for properly, to a comparison of OC medications with different years of entry into the market and result in an overestimation of the risk associated with the most recently introduced medications. To properly account for depletion of susceptibles, the approach to statistical analysis must take account of the duration and patterns of OC use and of course have the available data to do so. In this example, the pattern and duration of OC use are not confounders, but effect modifiers of the risk of VTE associated with recent OC use. OC pattern and duration can therefore not be simply "adjusted for" in the statistical analysis, but a stratified analysis has to be conducted which compares the risk of VTE for the different OC preparations for the different durations and patterns of use. When the analysis was restricted to the same pattern of OC use, distinguishing between first time users, repeaters, and switchers, the risk of VTE as a function of the duration of oral contraceptive use was essentially the same for second-and third-generation pills relative to never users (Suissa et al. 1997, 2000b).

48.6.5 Use of Propensity Scores in Pharmacoepidemiology

In a randomized trial, randomization of study subjects to different treatment regimens aims to assure the absence of systematic differences between the patients in terms of measured and unmeasured confounders. In observational studies, direct comparisons of the outcomes of treated and untreated patients may be misleading because of systematic differences between those patients who have and have not received treatment. The propensity score has been proposed as a method of adjusting for covariate imbalances in an observational study and has recently been proposed also for pharmacoepidemiology research (Perkins et al. 2000;

Wang and Donnan 2001; Wang et al. 2001). The propensity score $\pi(X)\!:= Pr(\text{exposed}|\ X)$ is defined as the conditional probability of receiving a particular treatment (i.e., being exposed) given the set of observed covariates X. The propensity score thus represents a summary of the covariates X that are associated with treatment allocation in the form of a single variable.

The propensity score approach is a two-stage approach. At the first stage, the propensity score is estimated for each study subject based on the values of the observed covariates. The most commonly used approach is to obtain the propensity score estimates in a logistic regression model, where treatment allocation is used as the dependent (response) variable and observed potential confounders X are used as explanatory variables: $\log(\frac{\pi(X)}{1-\pi(X)}) = X \cdot \beta$, where the regression coefficients β are estimated by maximum likelihood.

Having obtained the estimated propensity score, it can be used by a number of approaches at the second stage: Study subjects may be matched or stratified based on their propensity scores or the propensity scores may be adjusted for in a regression model (Wang and Donnan 2001).

Many published applications use stratification by the propensity score. A common approach is to stratify by quintiles of the distribution of the estimated propensity scores and to test the balance of each confounder between the treatment groups in each stratum (Wang and Donnan 2001). Having patients with similar propensity scores in each stratum, it may be assumed that the covariate distributions in the two treatment groups are equally similar within each stratum, so that the treatment assignment within the strata can be functionally regarded as random. If unbalanced confounders are still found, the propensity score model may be re-estimated with modifications until balance is achieved.

Stratification by the propensity score cannot control confounder effects within a single stratum. The somewhat arbitrary choice of five strata can be viewed as a compromise between reduction of bias and robustness of the results: An increasing number of strata will reduce the bias in the stratification estimate, but it will at the same time decrease the robustness of the results when the sample size of the smaller arm in a stratum becomes too small. Control of bias through use of propensity scores is based on the following assumptions:

- All subjects must have some non-zero probability of receiving each treatment (referred to as the "strongly ignorable assumption"). This ensures independence of treatment assignment and response variable within propensity score strata.
- Treatment assignment depends solely on the observed covariates, i.e., *all* confounders are included in the propensity score model.

If *all* confounders were not ascertained or confounder measurement was associated with bias, the use of propensity scores will not eliminate bias. In fact, the study will be subject to the same bias as an observational study that did not measure all confounders and could only incompletely adjust for known confounders. The use of propensity scores may, however, help to detect incomparability between treatment groups (i.e., lack of overlap in covariate values) that may remain undetected in a standard regression model. It also provides an additional tool to assess the performance of the traditional regression model (Wang and Donnan 2001).

Propensity scores have more often been used in cohort studies of drug effectiveness (Mojtabai and Zivin 2003; Schroder et al. 2003; Seeger et al. 2003; Young-Xu 2003), but they have also been applied to studies of drug safety (MacDonald et al. 2003). Nevertheless, the use of propensity scores may be a particular challenge in the common situation in pharmacoepidemiology of time-dependent exposures and covariates. Moreover, with the very large sizes of databases used in pharmacoepidemiology, the need to reduce the number of covariates to a single score is not crucial, and thus, the advantage of propensity scores compared to including the confounders directly in the model of data analysis becomes less evident. Recently, the use of propensity scores has been extended to semiautomated covariate selection called high-dimensional (HD) propensity score to identify surrogates for unobserved confounder information (Rassen et al. 2011; Schneeweiss et al. 2009; Schneeweiss and Rassen 2011).

48.7 Drug Utilization Studies

Drug utilization studies are an important tool in improving rational drug use and providing data for cost/benefit considerations. Drug utilization has been defined as the “prescribing, dispensing, administering, and ingesting of drugs” (Serradell et al. 1991). This definition implies that several steps are involved in drug utilization and that, consequently, in each of these steps, problems in drug use can arise. The World Health Organization defines drug utilization in a broader sense as the “marketing, distribution, prescription and use of drugs in a society, with special emphasis on the resulting medical, social and economic consequences” (World Health Organization 1977), thereby including also the effects of drug use on the population. Apart from examining drug use, goals of drug utilization studies include the identification of problems of drug utilization with respect to their importance, causes, and consequences; the establishment of a scientific basis for decisions on problem solving; and the assessment of the effects of actions taken. Some examples for studies that illustrate these goals are the following: What are the prevalence, pattern, and risk factors of use for benzodiazepines in Italy? What is the quality of NSAID prescribing in Croatia and Sweden (Vlahovic-Palcevski et al. 2002)? Are labeled contraindications to the use of cisapride adhered to (Weatherby et al. 2001)? What is the impact of safety alerts on the prescribing of a drug (de la Porte et al. 2002; Weatherby et al. 2001)? After a drug has been withdrawn from the market, in which way does drug utilization of related drugs change (Glessner and Heller 2002)? What are characteristics of physicians and practices that make early use of new prescription drugs (Tamblyn et al. 2003)?

Drug utilization studies can be qualitative and quantitative. *Quantitative* drug utilization studies are conducted for a number of purposes: to ascertain the quantities of drugs consumed in a specific period and in a specific geographical area, to investigate the development of drug utilization over time, to compare and contrast the use of a drug between different geographical areas, to identify possible over- or underutilization of drugs, to determine trends in drug use according to population demographics, to estimate the prevalence of illness based on the consumption of drugs utilized in its treatment, and to compare the prevalence of an illness in different areas.

The main aim of *qualitative* drug utilization studies is to determine the appropriateness of drug prescribing. They require the a priori establishment of quality indicators against which drug utilization is compared. National or international expert panels are sometimes used to help defining quality indicators in a consensus process (McLeod et al. 1997). Quality indicators may be based on the following parameters: the medical necessity for drug treatment; adherence to labeling with respect to labeled indications, contraindications, or interactions; duration and dose of treatment; use of fixed drug combinations when only one of its components would be justified; availability of treatment alternatives which are more effective or less hazardous; availability of an equivalent less costly drug on the market; etc. In North America, these studies are known as drug utilization review (DUR) studies. DUR studies are aimed at detecting and quantifying problems of drug prescribing. They should be distinguished from DUR programs which are interventions in the form of an authorized, structured, and ongoing system to improve the quality of drug prescribing (Lee and Bergman 2000). In contrast to DUR studies which provide only minimal feedback to the involved prescribers and are not interventional by their design, DUR programs include efforts to correct inappropriate patterns of drug use and include a mechanism for measuring the effectiveness of corrective actions taken to normalize undesirable patterns of drug use (Hennessy and Strom 2000).

For quantitative and qualitative studies, it would be ideal to have a count of the number of patients who either ingest a drug of interest during a certain time frame or who use a drug inappropriately in relation to all patients who received the drug during a given time frame. The available data are often only approximations of the number of patients and may be based on cost or unit cost, weight, number of prescriptions written or dispensed, and number of tablets, capsules, doses, etc., sold (Lee and Bergman 2000). Drug cost data have a number of limitations, since the price of a drug is not the same within and across countries. Drug pricing may be affected by different drug distribution channels, the quantities of drugs purchased, exchange rate fluctuations, different import duties, and regulatory policies that affect pricing (Serradell et al. 1991). Studies based on the overall weight of a drug sold are similarly limited, since tablet sizes vary which makes it difficult to translate weight even into the number of tablets sold (Lee and Bergman 2000). The number of prescriptions written or dispensed for a particular drug product is a measure that is frequently used in drug utilization studies. However, the number of prescriptions for different patients in a given time interval varies and also the supply of drugs prescribed. To estimate the number of patients, one must divide by the average number of prescriptions per patient. The number of tablets, capsules, etc., sold is often used in conjunction with the defined daily dose (DDD) measurement unit for drug use.

The DDD is the assumed average maintenance dose per day for a drug used for its main indication in adults. Use of the DDD underlies two basic assumptions: that patients are compliant and that the doses used for the major indication are

Table 48.6 The structure of the ATC coding system for metformin

A	Alimentary tract and metabolism (first level, anatomical main group)
A10	Drugs used in diabetes (second level, therapeutic subgroup)
A10B	Oral blood glucose-lowering drugs (third level, pharmacological subgroup)
A10B A	Biguanides (fourth level, chemical subgroup)
A10B A02	Metformin (fifth level, chemical substance)

the average maintenance doses (Serradell et al. 1991). The DDD dosing levels are assigned per ATC fifth level by the WHO Collaborating Centre for Drug Statistics Methodology in Norway based on recommendations in the medical literature. The DDD provides a fixed unit of measurement independent of the price and formulation of a drug. It can be used to examine changes in drug consumption over time and permits international comparisons. The DDD is a technical unit of measurement and does not necessarily reflect the recommended or prescribed daily dose (PDD). Doses for individual patients and patient groups will often differ from the DDD based on individual patient characteristics such as age, weight, and pharmacokinetic considerations. DDDs may be used to obtain crude estimates of the number of persons exposed to a particular drug or class of drugs and are sometimes used as denominator data for crude estimation of ADR rates (Kromann-Andersen and Pedersen 1988; Leone et al. 2003). This use of the DDD methodology is rather limited in drugs with more than one indication, particularly when the drug dose differs for each indication. It is also limited when the duration of drug treatment varies greatly between patients. The DDD does not take into account pediatric use of a drug. DDDs are not established for topical preparations, sera, vaccines, antineoplastic agents, allergen extracts, general and local anesthetics, and contrast media.

The defined daily dose (DDD) is usually used in conjunction with the Anatomical Therapeutic Chemical (ATC) coding system. Coding for the ATC system at the WHO Collaborating Centre for Drug Statistics Methodology in Norway is based on requests from users including manufacturers, regulatory agencies, and researchers. In the ATC system, drugs are classified in groups at five hierarchical levels. The drugs are divided into 14 main groups (first level), with one pharmacological/therapeutic subgroup (second level). The third and fourth levels are pharmacological/therapeutic and chemical subgroups, and the fifth level is the chemical substance. Table 48.6 illustrates the structure of the ATC coding system using metformin as an example. In the ATC system, all plain metformin preparations are thus given the code A10B A02.

Coverage of the ATC system is not comprehensive: Complementary and traditional medicinal products are generally not included in the ATC system; ATC codes for fixed combination drugs are assigned only to a limited extent; some drugs may not be included in the system since no request for coding has been received by the WHO Collaborating Centre; a medicinal product that is used for two or more equally important indications will usually be given only one code based on its main indication which is decided from the available literature. On the other hand, a medicinal product can have more than one ATC code if it is available in two or more strengths or formulations with clearly different therapeutic uses.

Use of computerized databases has greatly facilitated drug utilization research. Databases can be distinguished into those which include both drug and diagnostic data (examples have been given in Sect. 48.4) and into those which include only drug data (e.g., Denmark's Odense Pharmacoepidemiologic Database, Denmark's Pharmacoepidemiologic Prescription Database of the County of North Jutland, Spain's Drug Data Bank, Sweden's County of Jämtland Project). Some more databases used in drug utilization research and a description of these databases can be found in the references (Lee and Bergman 2000; Serradell et al. 1991).

Interpretation of drug utilization data needs appropriate care. Observed geographical or time differences in drug utilization may be caused by many factors different from prescribing behavior, e.g., differences in the age and sex distribution, different patterns of morbidity, change in diagnostic criteria, and differences in the access to health care. If used appropriately, drug utilization research provides a powerful scientific tool to identify factors that influence drug prescribing and to develop strategies to modify prescribing behavior. Further research is needed to determine which characteristics of inappropriate prescribing are susceptible to modification and what are the most efficient intervention strategies.

48.8 Conclusions and Prospects

Pharmacoepidemiology is still a relatively young scientific discipline. Over the last 20–30 years, there has been enormous progress in the improvement of its methods and development of new approaches to studies of drug safety and effectiveness. Pharmacoepidemiology has taken advantage of the rapidly expanding methods in epidemiology and has developed sophisticated methods to cope with problems that are specific to the field. New statistical approaches have been developed for signal generation based on data from the spontaneous reporting systems. Large computerized health-care utilization databases are now widely used for research into beneficial and harmful drug effects, their use being facilitated by the development of more and more powerful computer technologies. With the experience gained through the use of these data and a careful understanding of the underlying health-care systems in which the data were generated, computerized databases provide a highly useful data source for pharmacoepidemiology studies. Despite the often enormous size of these databases, statistical power may be lacking for rare exposures or rare outcomes within a single database. In Europe and North America, there are several initiatives to combine data from multiple databases for pharmacoepidemiology studies. The European Medicines Agency has coordinated the European Network of Centres for Pharmacoepidemiology and Pharmacovigilance (ENCEPP) since 2006 to strengthen post-authorization safety surveillance of medicinal products in Europe by facilitating the conduct of multicenter post-authorization safety studies across different European countries. In the USA, the Sentinel Initiative has been launched by the Food and Drug Administration in May 2008 to proactively monitor the safety of drugs, biologics, and medical devices and to provide a database for the rapid investigation of medicinal product safety issues. The Sentinel Initiative was set up with the goal to access data from 100 million patients from several data sources by July 2012. In Canada, the Canadian Network for Observational Drug Effect Studies (cNODES) was launched in October 2011 consisting of 60 researchers at universities across Canada who will draw data from existing databases representing about 27 million people. Combining data from multiple sources brings exciting new challenges for pharmacoepidemiologists with respect to issues of data privacy, coordination of research projects, governance and organizational issues, as well as methodological issues such as the combination and analysis of data with different data structure and data availability, the harmonization of terminologies when the data are coded according to different coding systems, and different approaches to finally synthesize the data. In Europe, experience on these issues is already gained in some multi-country database studies such as SOS (Safety of Non-steroidal Anti-Inflammatory Drugs), ARITMO (Arrhythmogenic Potential of Drugs), SAFEGUARD (Safety Evaluation of Adverse Reactions in Diabetes), and some other projects, some of which are part of the Innovative Medicines Initiative. In the USA, experience comes from the Mini-Sentinel pilot program which includes 25 participating institutions. In Canada, first experiences with the network are being obtained within a study on the renal safety of statins.

Regarding methods, there has been a progressive refinement of case-control and cohort studies, and efficient sampling strategies within a cohort are now often employed. The case-crossover and case-time-control designs are being used for the study of acute transient drug effects to eliminate control selection bias and confounding by indication or other factors. Propensity scores are increasingly used as a method to minimize confounding in the study of intended drug effects. High-dimensional propensity score methods have been proposed to improve confounder control by adjusting for surrogates of unmeasured confounders. Instrumental variable analyses provide another approach to unmeasured confounding, if a valid instrument can be found. Some databases, e.g., the UK CPRD, meanwhile offer initial randomization of patients with electronic follow-up of randomized patients in the database (“randomize into database epidemiology”). Drug utilization review programs are now required in all US hospitals and have been implemented voluntarily in many other health-care programs which will lead to further refinement of drug utilization research. A great challenge ahead is linkage of pharmacoepidemiology studies with the latest techniques of genetics, biochemistry, immunology, and molecular biology. The CPRD has over 300 practices with access to over 2 million patients that are willing to collect blood or other samples suitable for genetic research. It is of particular interest to understand why individuals respond differently to drug therapy, both in terms of beneficial and adverse effects. Investigation of the genetic makeup of study patients on a population level will be greatly facilitated through the enormous progress in pharmacogenomics and molecular biology. New study designs may emerge as a consequence of these developments. It remains to be explored to which extent database studies may be used to include molecular genetic or immunologic investigations.

49.1 Introduction

The earliest reports of exercise as a recognized means of health promotion go back to ancient China approximately 2500 BC, where Hua T'o, a Chinese surgeon, encouraged exercises based on the movement of animals. Medical practice in ancient Greece incorporated exercise for the protection and rehabilitation of health through the physicians Hippocrates (460–370 BC) and Galen (129–199 BC). From the sixteenth through the nineteenth century, physical activity was introduced as an important part of hygiene in Western medicine largely by physicians and pharmacologists (MacAuley 1994; U.S. Department of Health and Human Services 1998). The beginnings of modern physical activity epidemiology as a research field can be traced back to the late 1940s, when the British epidemiologist Jeremy Morris uncovered the link between physical exercise and the prevention of heart attacks (Paffenbarger et al. 2001). Finally, the seminal publication of the report of the U.S. Surgeon General, Physical Activity and Health released in 1996, provided public health guidelines and policy and posted important research questions for the future (U.S. Department of Health and Human Services 1996).

Physical activity epidemiology is the study of the distribution and the determinants of physical activity behaviors (Caspersen 1989). It investigates the association of physical activity with disease and other health outcomes and seeks to identify biological, psychosocial, genetic, and environmental factors that influence physical activity. The knowledge obtained from physical activity epidemiology is applied to intervention programs for the prevention and therapy of diseases and for the promotion of health, including population surveillance and evaluation of exercise programs. A major underlying issue in physical activity epidemiology is the development and application of reliable and valid measures of physical activity.

To date, a vast accumulation of epidemiological studies has revealed that moderate exercise prevents chronic illnesses such as cardiovascular disease (CVD), type 2 diabetes, and certain forms of cancer (U.S. Department of Health and Human Services 1998) and that it reduces all-cause mortality (Kesaniemi et al. 2001). Although the benefits of regular, moderate-intensity activity for these and other health outcomes have been widely accepted, precisely quantifying the levels of physical activity is a difficult task. Measurement of physical activity not merely aims to attain accurate assessments of energy expenditure (EE) but also strives to capture dimensions of physical activity including type, duration, frequency, and intensity. The choice of an appropriate assessment method is of major concern as inadequate or crude measurements of physical activity are likely to result in misleading data and may have inappropriate consequences. Two types of methods for measurement of physical activity can be distinguished: (1) objective methods including activity monitors such as pedometers and accelerometers, heart rate monitoring, doubly labeled water (DLW), indirect calorimetry, and direct observation and (2) subjective methods including questionnaires, recalls, diaries, and logs (Vanhees et al. 2005).

The aim of the current chapter is to focus on methods for the measurement of physical activity rather than discuss health outcomes in relation to physical activity, which are described elsewhere (Dishman et al. 2004).

We will begin this chapter with a description of conceptual definitions and the multidimensional aspects of physical activity. Next, we will present domains of physical activity research and physical activity recommendations. Methods and monitoring devices for measuring physical activity that are commonly used in epidemiological studies will be reviewed. We will further address study designs that are commonly used in physical activity research. Another issue will be methodological considerations of studies on physical activity and disease. Finally, we will review areas of potential future development in physical activity epidemiology.

49.2 Definition of Physical Activity

The terms *physical activity*, *physical exercise*, and *physical fitness* have been defined in different ways and have frequently been used interchangeably in physical activity epidemiology. However, a standardized terminology and a clear distinction between these variables are important for the measurement of their associations and interactions with different health outcomes. Physical activity is considered any bodily movement produced by the contraction of skeletal muscle that increases energy expenditure (Caspersen et al. 1985). Physical exercise solely represents a subtype of physical activity undertaken in leisure time that intends to maintain or improve physical fitness (Pate et al. 1995). Physical fitness is distinct from physical activity in that it does not represent a behavior but rather portrays the capacity to attain a certain performance standard or trait (Caspersen et al. 1985; Livingstone et al. 2003). Recently, sedentary behavior has emerged as an additional potential health determinant and has thus become a distinct dimension in physical activity epidemiology.

49.2.1 Physical Activity

Physical activity comprises different types and components including frequency, intensity, and duration which are illustrated in Fig. 49.1. In contrast to physical fitness which describes a physiological construct, physical activity corresponds to a health-related behavior with intra-individual day-to-day variability. Common units of time used to assess physical activity are per day or per week.

Whether the term physical activity comprises all activities or comprises only defined activities in specific domains (occupational, household, transportation, or recreational) depends on the purpose of the individual study. Occupational activity is defined as any work-related activity such as walking, lifting, carpentry work, hauling, pushing, shoveling, and packing boxes normally within the time frame of an 8-hour workday. In contrast, housework, yard work, physically active child care, and

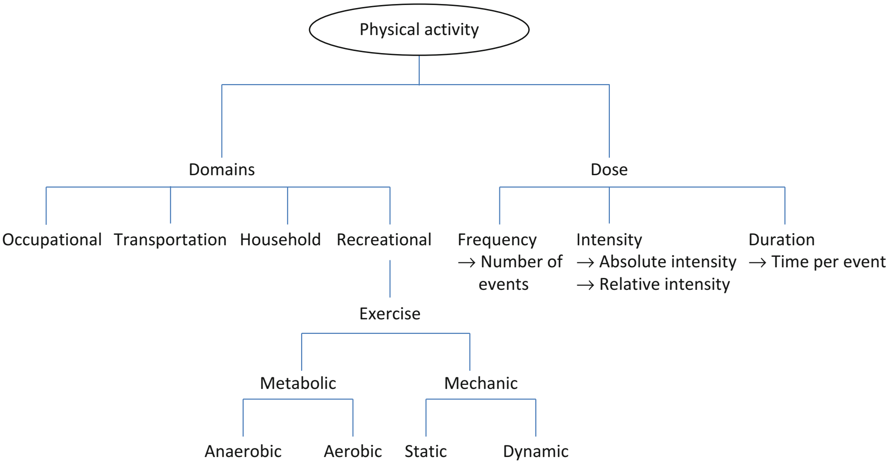

Fig. 49.1 Components of physical activity

chores are covered by the term household activity. Transportation activity includes walking or bicycling for the purposes of going somewhere. Finally, recreational physical activity can be subcategorized into exercise training, competitive sports, and recreation that are undertaken during leisure or discretionary time by personal choice (Courneya et al. 2000).

49.2.2 Physical Exercise

Physical exercise (exercise training) is defined as "a subset of physical activity that is planned, structured, and repetitive and has as a final or an intermediate objective the improvement or maintenance of physical fitness" (Caspersen et al. 1985). It describes a form of leisure-time physical activity involving repetitive bodily movement that is performed to improve or maintain physical fitness. Physical exercise can be categorized according to its mechanical (static or dynamic) or metabolic (aerobic or anaerobic) characteristics. Depending on the muscle contraction that makes the limbs move, the term mechanical differentiates between (1) isometric (same length) or static exercise if there is no movement of the limb and (2) isotonic (same tension) or dynamic exercise if there is movement of the limb (Haskell and Kiernan 2000).

The classification pertaining to the metabolic characteristics of physical exercise encompasses the availability of oxygen (aerobic) or the non-availability of oxygen (anaerobic) for muscle contraction depending on the intensity of exercise performed. Aerobic exercise involves large muscle groups in dynamic activities leading to increases in heart rate and energy expenditure (Haskell and Kiernan 2000). Examples of aerobic exercise include walking, hiking, skating, jogging, cycling, rowing, stair climbing, dancing, and swimming. Anaerobic exercise is performed at a very high-intensity level, and thus, energy is provided by glycolysis and stored phosphocreatine (Howley 2001). Resistance training such as weight lifting is anaerobic exercise that is performed to increase muscular size, strength, and endurance (Hu 2008). Several activities may involve both static and dynamic contractions as well as aerobic and anaerobic metabolism (U.S. Department of Health and Human Services 1998).

Sometimes classification of an activity as exercise may be unclear. For example, using a bicycle solely as transportation to work is not exercise, but bicycling with the idea of reducing body weight is exercise. Hence, it has been suggested that the term *exercise training* is used when activity is performed for the exclusive purpose of enhancing physical fitness (Haskell and Kiernan 2000).

49.2.3 Physical Fitness

Physical fitness is defined as "a set of attributes that people have or achieve that relates to their ability to perform physical activity" and is therefore often used as a surrogate marker for physical activity (Caspersen et al. 1985). Indeed, physical fitness has been shown to be more strongly related to various health outcomes than physical activity (Blair et al. 2001). Its primary modifiable determinant is habitual physical activity, and fitness can thus represent a valuable surrogate marker for physical activity. Several other factors may influence cardiorespiratory fitness including sex, age, health status, and genetic components (Sui et al. 2007).

Observations from the HERITAGE Family study revealed that the heritability of maximal oxygen uptake ($VO_{2\,max}$) among sedentary adults can reach 50%, although that value is potentially inflated by non-genetic factors (Bouchard et al. 1998). Furthermore, maternal influence has been shown to account for nearly 30% of familial transmission. Bouchard et al. (1999) investigated whether individual differences in responses of $VO_{2\,max}$ to a standardized training program are characterized by familial aggregation (Bouchard et al. 1999). In their study, the maximal heritability estimate of the $VO_{2\,max}$ response to exercise training reached 47%, with maternal heritability reaching 28%.

As the attributes related to physical fitness differ in their importance for athletic performance versus their relevance to health, physical fitness has been classified into performance-related fitness and health-related fitness (Pate et al. 1995) (Fig. 49.2). Performance-related fitness is usually linked to attributes such as power, balance, and reaction time. Health-related fitness includes cardiorespiratory fitness, also termed aerobic fitness or endurance, and body composition, muscular fitness, and flexibility (U.S. Department of Health and Human Services 1998). Cardiorespiratory fitness represents the major component of physical fitness, and quantitative data on the relationships between physical fitness and health are mostly based on cardiorespiratory fitness and body composition (Garber et al. 2011). Cardiorespiratory fitness refers to the ability of the circulatory and respiratory systems to supply oxygen to the working muscles during heavy dynamic exercise. During physical exertion, oxygen uptake (VO_2) increases directly proportional to the rate of work. The $VO_{2\,max}$ that can be utilized by the body during extensive

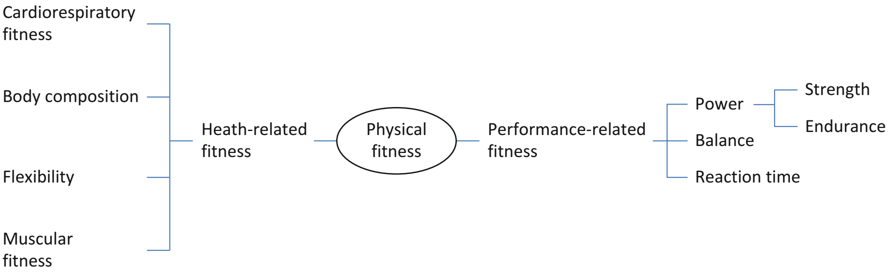

Fig. 49.2 Components of physical fitness

physical effort represents the most accurate measure of cardiorespiratory fitness (U.S. Department of Health and Human Services 1998). Physical fitness assessment has the disadvantage that it is not feasible in large studies compared to physical activity measures by questionnaires.

49.2.4 Sedentary Behavior

In the past decade, interest in sedentary behavior as an independent health risk factor has emerged. According to the definition by Patel et al. (2008), sedentary behavior refers to activities with low levels of energy expenditure in the range of 1.0 to 1.5 metabolic equivalent tasks (METs) (Patel et al. 2008). That definition corresponds to activities such as sleeping, sitting, lying down, watching TV, and other forms of screen-based entertainment (Patel et al. 2008). Among sedentary behaviors, TV viewing has been the most commonly studied.

It is apparent that sedentary behavior is not merely the absence of physical activity (Tudor-Locke and Myers 2001; Healy et al. 2008). In epidemiological studies, the correlation between sedentary behavior and physical activity has tended to be minimal (Hu et al. 2003). Moreover, time spent in sedentary behaviors was found to have correlates distinct from those associated with physical activity (Leatherdale and Wong 2008). Moreover, sedentary behavior may easily coexist with physical activity (Owen et al. 2010). However, misconceptions about the definition and the measurement of sedentary behavior exist. Thus, more research on the assessment of sedentary behavior and its potential health outcomes is needed.

49.3 Dimensions of Physical Activity

49.3.1 Energy Expenditure of Physical Activity

Energy expenditure reflects the energy cost or intensity due to physical activity and it comprises a complex series of biochemical processes and physiological adaptations that result in the transfer of metabolic energy to perform skeletal

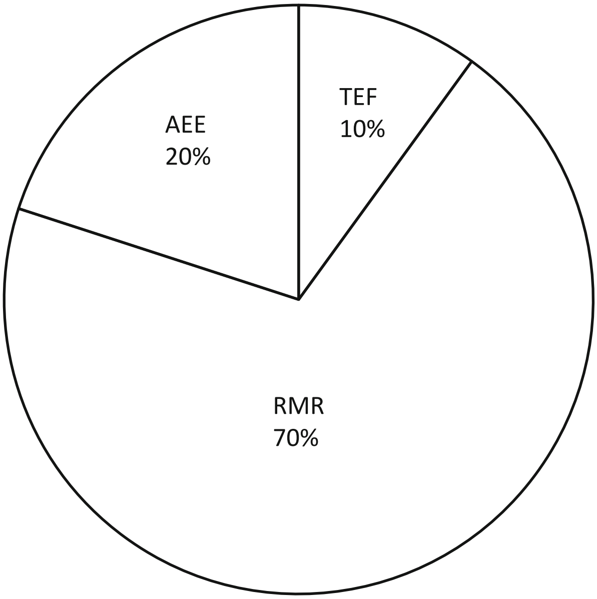

Fig. 49.3 Distribution of major components of total energy expenditure; *AEE* activity energy expenditure, *TEF* thermic effect of food, *RMR* resting metabolic rate

muscle contraction (Lamonte and Ainsworth 2001; Lee et al. 2009). Several factors may influence energy expenditure, such as age, body size, body weight, and fitness level (Lamonte and Ainsworth 2001). Typically, total energy expenditure (TEE) is divided into three components: (1) resting metabolic rate (RMR) as the main component (approximately 70% of TEE), (2) thermic effect of food (TEF, approximately 10% of TEE), and (3) activity energy expenditure due to physical activity or muscular activity (AEE, typically 20% of TEE), which represents the most variable component of TEE (Fig. 49.3).

The rate at which the body uses energy is expressed as the metabolic rate. It can be estimated by indirect calorimetry that measures oxygen uptake and carbon dioxide production to obtain energy expenditure. Oxygen uptake can be translated to kcal (kilocalories) using a constant of 5 kilocalories per liter (kcal$\cdot$L^{-1}), and to kJ (kilojoules) using a constant of 4.19 kilojoules per kilocalories (kJ$\cdot$kcal^{-1}) (U.S. Department of Health and Human Services 1998). The resting metabolic rate is the minimal rate of energy that is necessary for maintenance of basic bodily functions. It is measured following an overnight fast and 8 h of sleep (Howley 2001). To quantify energy expenditure during exercise, the metabolic rate at rest is defined as 1 MET, which has an oxygen uptake of approximately 3.5 milliliter per kilograms per minute (mL$\cdot$kg$^{-1}\cdot$min^{-1}) (U.S. Department of Health and Human Services 1998). Thus, an activity of 7 METs represents an activity that requires seven times the resting metabolic rate. The net energy cost of an activity can be obtained by subtracting 1 MET (RMR) from the gross energy cost (TEE) (Howley 2001).

49.3.2 Dose of Physical Activity: Frequency, Duration, and Intensity

The dose or volume of the energy expended during physical activity represents the product of three components, including the frequency and duration of the activity and the intensity with which the activity is performed (Fig. 49.1). For certain health-related questions, the volume of all-encompassing energy expended may be appropriate. However, in terms of dose-response relationships, the term "physical activity" should be used according to its specific components. For example, in the 1990s interest emerged in whether moderate-intensity activity is sufficient for the promotion of health and in whether vigorous-intensity activity provides further benefit (Pate et al. 1995). This can be considered analogously to the term "diet" in nutritional epidemiology: diet is an overarching term comprising many nutrients and foods. In terms of research questions related to health outcomes, such as cancer or heart disease, one may not only look at diet in its entirety but also at individual dietary factors, such as *trans*-fatty acids or vegetables and fruits consumed (Lee et al. 2009).

In particular, *frequency (how often)* measures the number of physical activity events during a specific time period, for example, per day, per week, or per month (Livingstone et al. 2003). *Duration (for how long)* describes the amount of time spent participating in a physical activity event and is typically expressed in hours or minutes. *Intensity (how hard a person works to perform the activity)* refers to the level of effort required to perform a specific activity. It is expressed in various ways depending on the domain (e.g., recreational activity or occupational activity) and on the time frame within which the activity is performed (i.e., 20 to 60 min for a workout vs. 8 h for a workday).

The *absolute intensity* of physical activity describes the actual rate of energy expenditure. It is commonly expressed in kcal or kJ per minute, oxygen uptake ($\mathrm{L{\cdot}min^{-1}}$), oxygen uptake relative to body mass ($\mathrm{mL{\cdot}kg^{-1}{\cdot}min^{-1}}$), or METs. Alternatively, to the MET definition of 3.5 $\mathrm{mL{\cdot}kg^{-1}{\cdot}min^{-1}}$, 1 MET is also equivalent to an energy expenditure of 1 $\mathrm{kcal{\cdot}kg^{-1}}$ body weight per hour (U.S. Department of Health and Human Services 1998; Howley 2001). Physical activity is often expressed as MET-time/week (MET-hours/week or MET-minutes/week). That variable is created by multiplying the energy cost in MET for each activity by the amount of time (in minutes or hours) spent performing that specific activity during a given week (Lee et al. 2009). Ainsworth et al. (2011) recently provided an updated compendium of MET values that refers to different types of physical activities (Ainsworth et al. 2011). To facilitate research regarding dose-response relationships, activities are grouped into light-intensity activities (1.6 to 2.9 METs) (Patel et al. 2008; Tudor-Locke et al. 2009), moderate-intensity activities (3.0 to 5.9 METs), and vigorous-intensity activities (≥6 METs) (Table 49.1) (Ainsworth et al. 2011).

Relative intensity refers to "the relative percentage of maximal aerobic power that is maintained during exercise" (Fletcher et al. 2001). Persons vary in their fitness status and may respond differently to an exercise performance with a predetermined absolute intensity. To account for such variation, relative intensity has been related to some maximal degree of physiological response. Relative intensity can be

Table 49.1 Classification of physical activity intensity according to Ainsworth et al. (2011)

Classification	Metabolic equivalent tasks (METs)	Examples
Sedentary behavior	1.0–1.5	TV viewing, playing video games
Light intensity	1.6–2.9	Fishing, golf, washing dishes, food shopping
Moderate intensity	3.0–5.9	Easy swimming, yard work, bowling, surfing, yoga
Vigorous intensity	≥6.0	Jogging, tennis, skiing, running, aerobics

expressed as percentage of $VO_{2\,max}$, percentage of oxygen uptake reserve ($\%VO_{2R}$), percentage of heart rate reserve (%HRR), percentage of maximum heart rate ($\%HR_{max}$), or Borg Rating of Perceived Exertion (RPE) (Howley 2001). Borg (1998) developed the RPE which is based on a scale from 6 to 20 to describe a person's perception of exertion during exercise (Borg 1998). In adults, an RPE of 12 to 13 represents moderate intensity of physical activity, which corresponds to 40% to 60% of $VO_{2\,max}$ (Fletcher et al. 2001).

49.4 Descriptive Epidemiology of Physical Activity

The descriptive epidemiology of physical activity helps identify public health priorities and research needs, and it often serves as a basis for the development of national policies and provides guidance to physical activity programs (Lee et al. 2009; Hallal et al. 2012). Information about physical activity behavior in populations is typically gathered using physical activity surveillance systems, which have become a necessary tool in public health. Data on the distribution of physical activity in representative population samples are generally derived from national governmental surveillance systems. The World Health Organization (WHO) regularly provides data on physical activity of representative samples at the global population level (World Health Organization 2012a). While public health surveillance systems that track physical activity prevalence have increased nationwide, only few are well established and monitor physical activity trends on a regular, long-term basis (Hallal et al. 2012).

The current section provides information on the prevalence of physical activity among adults, adolescents, and children. It also describes time trends of habitual physical activity in those populations.

49.4.1 Prevalence and Trends in Physical Activity Among Adults

The Behavioral Risk Factor Surveillance System (BRFSS), the National Health and Nutrition Examination Survey (NHANES), and the National Health Interview Survey (NHIS) are well-established surveillance systems that provide data on

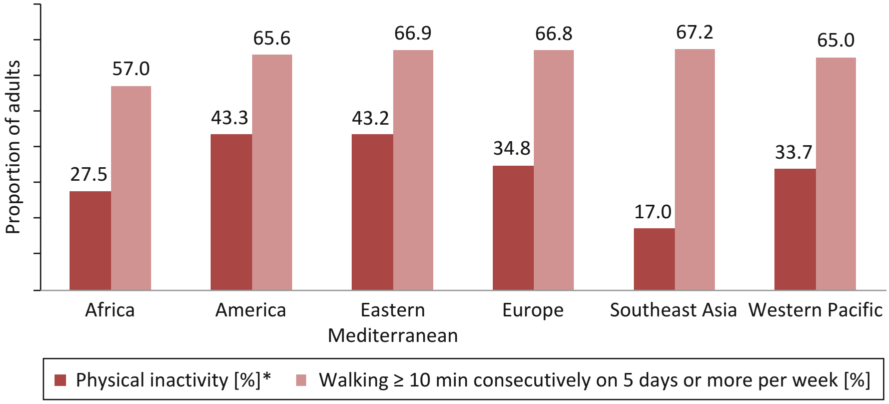

Fig. 49.4 Physical inactivity and walking behavior in individuals aged ≥15 years by World Health Organization region (Hallal et al. 2012); *Physical inactivity was defined as not meeting any of the following criteria: 30 min of moderate-intensity physical activity on at least 5 days every week, 20 min of vigorous intensity physical activity on at least 3 days every week, or an equivalent combination achieving 600 MET-minutes per week

physical activity behavior of the U.S. population (Centers for Disease Control and Prevention 2012). The most recent data from the BRFSS from 2009 reveal that 50.6% of U.S. adults engage in at least 20 min of vigorous physical activity on 3 or more days per week or in at least 30 min of moderate physical activity on 5 days or more per week. Moreover, 75.8% of U.S. adults affirmed the question "During the past month, did you participate in any physical activities?" (Centers for Disease Control and Prevention 2009).

Recently, the Lancet Physical Activity Series Working Group published current data on the prevalence and trends in global physical activity using data from the WHO global health observatory data repository (Hallal et al. 2012). The analysis included self-reported estimates of physical activity from persons aged 15 years or more across 122 countries. Physical inactivity was assessed using the International Physical Activity Questionnaire (IPAQ 2012) and the Global Physical Activity Questionnaire (GPAQ) and was defined as not reaching any of the following criteria: 30 min of moderate-intensity physical activity on at least 5 days per week, 20 min of physical activity of vigorous intensity on at least 3 days per week, or a combination of moderate- and vigorous-intensity physical activity up to 600 MET-min per week. The results show that 31.1% of adults worldwide are physically inactive. The frequency of physical inactivity varies considerably among the different WHO regions: 43.3% of persons are inactive in America, 43.2% in the Eastern Mediterranean, 34.8% in Europe, 33.7% in the Western Pacific, 27.5% in Africa, and 17.0% in Southeast Asia (Fig. 49.4). Estimates across countries vary by sex but in general, women are more inactive (33.9%) than men (27.9%). Also, physical inactivity increases with age (Hallal et al. 2012). On a worldwide basis, 64.1% of adults participate in walking for at least 10 min on 5 or more days per week, with only modest variation between WHO regions (Fig. 49.4). The prevalence of walking differs only weakly between men and women or between age groups. Worldwide, 31.4% of adults report engaging in vigorous-intensity physical activity on 3 or more days per week, with substantial differences between WHO regions. For example, only 25.4% of adults in Europe and 24.6% in America perform vigorous physical activity on at least 3 days per week, compared to 43.2% of adults in the Eastern Mediterranean and Southeast Asian regions. Men are more likely to engage in vigorous-intensity physical activity than women, and physical activity participation decreases with age (Hallal et al. 2012).

Temporal trends of physical activity data show a decline in overall physical activity participation in the past decades and that trend is stronger in industrialized than non-industrialized countries (Brownson et al. 2005; Hallal et al. 2012). Occupational and transportation physical activity have been continuously decreasing, while recreational physical activity has been concurrently increasing over time (Brownson et al. 2005; Knuth and Hallal 2009; Church et al. 2011). For example, Borodulin et al. (2008) examined 30-year time trends in recreational, occupational, and transportation physical activity from 1972 to 2002 across birth cohorts in Finnish adults. They used data from the FINRISK Study, which monitors levels of chronic disease risk factors in Finland. Between 1972 and 2002, the prevalence of recreational physical activity increased from 49% to 67% in women and from 66% to 77% in men, whereas the prevalence of occupational physical activity declined from 47% to 25% in women and from 60% to 38% in men. Moreover, transportation physical activity decreased from 34% to 22% in women and from 30% to 10% in men (Borodulin et al. 2008). Increasing industrialization and emerging technologies along with less physically demanding jobs have led to people becoming more sedentary in their daily routines. Although data are sparse, it has been documented that in parallel with declines in adult physical activity levels, sedentary time has increased, which is attributable to increased television watching and computer use (Brownson et al. 2005; Proper et al. 2011).

Recently, Bauman et al. (2011) reported on sedentary time among adults aged 18 to 65 years from 20 countries. The median sitting time was 300 min (interquartile range, 180 to 480 min) per day. Adults aged 18 to 39 years were more likely to fall into the highest quintile of sitting than adults aged 40 to 65 years (Bauman et al. 2011). Objectively measured physical activity and sedentary behavior data obtained from participants of the Australian Diabetes, Obesity, and Lifestyle (AusDiab) study revealed that on average, adults spent more than half of their daily time in sedentary behaviors, with only 5.8 h per day spent in light-intensity activity and 0.6 h per day spent in moderate to vigorous activity (Healy et al. 2007) (Fig. 49.5). The trend toward an increase in sedentary time and a decline in physical activity might continue to unfold throughout future decades. Ng and Popkin (2012) calculated predictions for physical activity levels in five countries for the years 2020 and 2030, assuming that trends will remain linear. According to that report, in the U.S. in 2009, total physical activity levels were 160 MET h per week and are forecasted to decrease to approximately 142 MET h per week by 2020. Great Britain, China, and Brazil are predicted to achieve that level by the year 2030, whereas in India, total physical activity levels are expected to decline less rapidly (Ng and Popkin 2012).

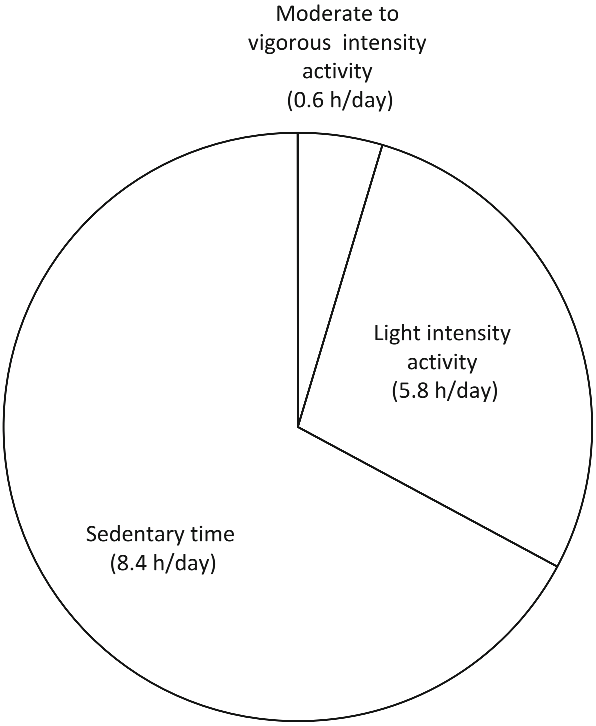

Fig. 49.5 Distributions of sedentary time, physical activity of light intensity, and physical activity of moderate to vigorous intensity in Australian adults (Healy et al. 2007)

49.4.2 Prevalence and Trends in Physical Activity Among Children and Young Persons

Physical activity of children and young persons encompasses sports, games, play, recreation, transportation, physical education, or planned exercise, in family, school, and community settings (World Health Organization 2011). Compared to adults, physical activity patterns in children are sporadic, and continued periods of moderate or vigorous physical activity are infrequent (Armstrong and Welsman 2006). Representative data on physical activity in youth can be derived from the Global School-based Student Health Survey (GSHS) and the Health Behavior in School-aged Children (HBSC) Survey. The Youth Risk Behavior Surveillance System (YRBSS) provides comprehensive data on physical activity prevalence in U.S. youth. The survey is conducted biennially and represents data from 9th to 12th grade students (usually aged 15 to 18 years) in schools throughout the U.S. (Centers for Disease Control and Prevention 2011). The most recent national overview of physical activity from the YRBSS concludes that 13.8% of students do not engage in “at least 60 minutes of any kind of physical activity that increased their heart rate and made them breathe hard some of the time on at least one day during the seven days before the survey." On average, 28.7% of students reported being physically active for at least 60 min on all 7 days (Centers for Disease Control and Prevention 2011). Current data from the GSHS and HBSC included 105 countries worldwide and revealed that 80.3% of 13- to 15-year-olds fail to achieve 60 min of physical activity per day (Hallal et al. 2012).

Data are consistent in that physical activity levels of both sexes are high during childhood and decline thereafter through teenage time. Also, differences exist in physical activity habits among girls and boys. Nader et al. (2008) examined patterns of moderate to vigorous activity among young persons who were followed from ages 9 to 15 years and observed that physical activity levels decreased significantly during that age period (Nader et al. 2008). At the age of 9 years, children engaged in 3 h of moderate- to vigorous-intensity physical activity per day on both weekends and weekdays. By the age of 15, adolescents participated in moderate to vigorous activity for only 49 min per weekday and 35 min per weekend day (Nader et al. 2008).

In a review of habitual physical activity data of European children and adolescents, Adams (2006) stressed the difference in physical activity patterns between sexes, with boys being more engaged in vigorous activity than girls (Adams 2006). Also, the Lancet Physical Activity Series Working Group found girls to be less physically active than boys. The group reported that 80% or more of boys in approximately half of the 105 countries investigated and 80% of girls in 95% of the countries did not reach the recommended 60 min per day of physical activity (Hallal et al. 2012).

As mentioned above, time trends toward lower physical activity levels have been observed in the adult population, and this is also true for children and adolescents. In an analysis of trends in physical activity levels in adolescents according to sex, age, and race, the weighted percentage of adolescents defined as being active was higher in school grades 9 and 10 at all years compared to school grades 11 and 12. A decline in physical activity was observed among all adolescents of school grades 9 and 10 in 2003 compared to 1993. When change in physical activity levels according to sex and year was considered, a downward trend was observed only in boys and only in school grades 9 and 10 (Adams 2006). Recently, a study characterized temporal trends in free time and organized physical activity participation of U.S. youth across different age groups during a 5-year period (Wall et al. 2011). The prevalence of free-time physical activity participation declined linearly from ages 9 to 17 years in both sexes. Organized physical activity declined after the age of 14 years in both sexes. Free-time physical activity participation was lower in girls compared to boys between the ages of 12 and 16 years (Wall et al. 2011). Guthold et al. (2010) used data from the GSHS to analyze sedentary behavior in youth from 32 countries. They demonstrated that in more than half of the countries examined, one third or more of students spend 3 h or more per day in sedentary behaviors. Figures 49.6 and 49.7 illustrate comparisons of weekday time spent in sedentary behavior and moderate- to vigorous-intensity physical activity in 9- and 15-year-olds from four European countries (Nilsson et al. 2009). Across all four countries,

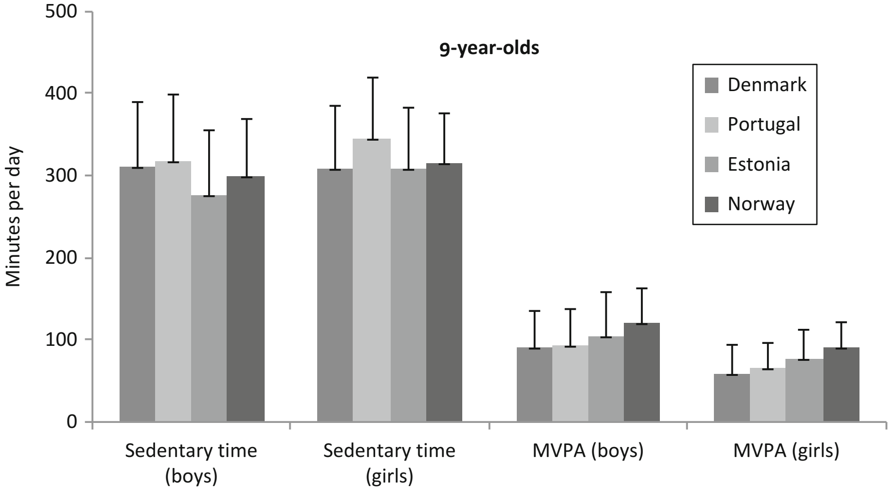

Fig. 49.6 Sedentary time and physical activity levels of moderate to vigorous intensity (MVPA) on an average weekday among 9-year-olds according to sex and country (Nilsson et al. 2009)

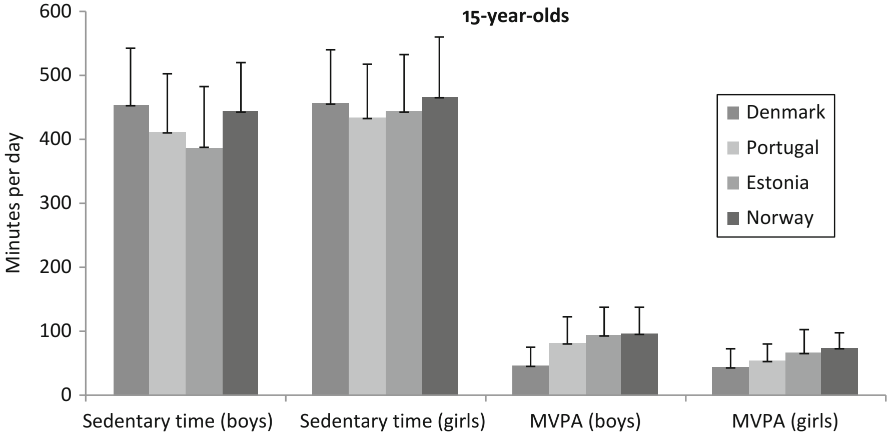

Fig. 49.7 Sedentary time and physical activity levels of moderate to vigorous intensity (MVPA) on an average weekday among 15-year-olds according to sex and country (Nilsson et al. 2009)

15-year-old adolescents spent more time in sedentary behavior than 9-year-old children. In both age groups, boys were more likely to engage in moderate to vigorous activity than girls (Nilsson et al. 2009). Current data from the YRSS revealed that 31.3% of U.S. students played video or computer games or used computers outside school time for 3 or more hours per day on an average school day. A similar amount of students (32.4%) reported watching television 3 or more hours per day on an average school day (Centers for Disease Control and Prevention 2011). Those data underpin the rise in sedentary activities along with an increased time spent in television watching and computer use, a trend that is more pronounced in teens than in children.

49.5 Domains of Physical Research

Physical activity epidemiology includes a number of interrelated research areas, each of which has specific issues and challenges. While research within these specific domains is frequently conducted independently by individual research groups, the body of evidence generated in each research group impacts upon the other research areas. The following section provides a summary of the different domains of research in physical activity epidemiology.

49.5.1 Surveillance Research

Physical activity surveillance research focuses on detecting trends and patterns in physical activity in the population (Hallal et al. 2012). Examples of surveillance research include the development of valid and reliable methods to monitor physical activity patterns in national surveys and the improvement of techniques for documenting long-term physical activity patterns in the population as a whole and among population subgroups, such as children, adolescents, or people with disabilities. This research provides the data needed to prioritize public health activities, identify research needs, allocate funding, inform policy to promote the public's health, direct physical activity promotion efforts, and identify appropriate behavioral intervention targets aimed at increasing physical activity levels in the population. Physical activity measures for this area of research depend almost entirely on self-reports or interviewer-administered assessments because they can be applied to large groups of the population at low cost. A critical issue in physical activity surveillance research is the need for high accuracy and precision of the assessment instruments because small inconsistencies in the wording of questions can translate into considerable variation in estimates of the prevalence of physical activity. Such heterogeneity would make it challenging to track physical activity patterns over time or to compare prevalence estimates of physical activity across subgroups of the population. Surveillance research also encompasses the area of correlates research, which studies the determinants of physical activity through the identification and multilevel modeling of personal, social, economic, and environmental determinants of physical activity (Trost et al. 2002). Physical activity correlates research identifies mediators that can be used to inform physical activity intervention research.

49.5.2 Health Outcomes Research

Health outcomes research is aimed at exploring the associations between physical activity and health (Adami et al. 2010). Examples of this type of research include investigating the association of physical activity with heart disease, diabetes, cancer, bone loss, or quality of life or studying the health benefits of physical activity in specific subgroups of the population, such as racial and ethnic minorities, the elderly, or people with disabilities. Physical activity assessments for this research area vary depending on the particular research question but are primarily based on self-reported questionnaires due to the large sample sizes typically needed. Self-reported instruments usually provide a simple ranking of physical activity levels based on job titles or time spent in recreational activities. Despite their imperfect nature, self-reported measures of physical activity have been successfully employed in numerous large epidemiological studies and have provided evidence of important health benefits of physical activity. Lack of precision may lead to underestimation of the health effects of physical activity. Although simple classifications have been adequate to uncover strong associations between physical activity and disease risk in the past, more refined physical activity assessments will be needed in the future to uncover more complex relations of physical activity with risk of disease, such as the delineation of the relation of specific dimensions of physical activity (e.g., duration, frequency, intensity) to disease risk.

49.5.3 Physical Activity Intervention Research

Physical activity intervention research is aimed at creating and evaluating programs designed to promote physical activity. Focus is often placed on population subgroups that have been found in surveillance research to be at increased risk for sedentary behavior, such as lower socioeconomic populations or children and adolescents (Heath et al. 2012). The principal goal in designing an appropriate intervention program is to organize and prioritize the numerous factors that are known to impact upon physical activity and to integrate them in an intervention program. The effectiveness of physical activity interventions is greater when established behavioral theory is taken into consideration in designing the intervention. The targets of physical activity interventions have evolved considerably over the past several decades as physical activity recommendations and principles of behavioral modification have developed. Because early physical activity guidelines emphasized vigorous forms of physical activity for health promotion, initial intervention programs were directed at structured exercise and cardiorespiratory fitness. By comparison, current physical activity recommendations focus on moderate-intensity activity and on avoidance of sedentary behavior as means of promoting health. Thus, current interventions are aimed at facilitating the development of individualized lifestyle physical activity programs that enable people to accumulate the recommended dose of moderate-intensity physical activity over the day. Because an individual's behavior is strongly determined by the social, economic, and physical environment, physical activity interventions often target multiple domains and levels of influence with the rationale of enhancing the probability of behavior modification (Kahn et al. 2002).

49.5.4 Mechanistic Physical Activity Research

Mechanistic or basic research on physical activity involves any research discipline that aims at elucidating the etiological pathways by which physical activity influences the human organism, including the biological mechanisms through which physical activity impacts upon health. Results from basic research are often used as the basis for formulating research hypotheses in health outcomes research and physical activity intervention research. One illustration of the interrelationship between mechanistic physical activity research and health outcomes research is provided by the link between the health benefits related to regular physical activity. Numerous epidemiological studies have found that an increased level of physical activity decreases the risks of certain types of cancer, such as colon cancer (Wolin et al. 2009). Basic science research investigating potential biological mechanisms suggests that high levels of physical activity may reduce colon cancer risk through reductions of adipose tissue, insulin resistance, chronic low-grade inflammation, or oxidative stress (Quadrilatero and Hoffman-Goetz 2003). The advancement of knowledge in the area of health outcomes research is closely related to continuous progress in basic science research.

49.6 Physical Activity Recommendations

Starting in the 1960s, recommendations for physical activity participation based on scientific data were disseminated by health and fitness organizations for the purpose of promoting health. In addition, several organizations and government agencies drew upon physical activity recommendations designed to address specific health issues such as the attainment of weight control, cardiorespiratory and muscular fitness, and cancer prevention (Garber et al. 2011). A detailed review of various physical activity guidelines is beyond the scope of this chapter. However, we will provide a brief summary of the main landmarks in the development of recommendations for the promotion of physical activity.

In 1965 and 1972, the President's Council on Physical Fitness and the American Heart Association (AHA) released the first guidelines for physical activity programs and exercise prescription as means of improving physical activity performance and promoting health (U.S. Department of Health and Human Services 1998). In 1975, the American College of Sports Medicine (ACSM) issued the guidelines entitled "Graded Exercise Testing and Prescription" followed by the release of "The Quantity and Quality of Exercise for Developing and Maintaining Fitness in Healthy Adults" in 1978. Those recommendations focused on cardiorespiratory fitness and body composition, endorsing exercise training of 3 to 5 days per week with durations of 15 to 60 min per training session and an exercise intensity of 50% to 85% of VO_{2R} and the use of large muscle groups. In 1990, the ACSM updated its position statement, aiming at muscular strength, endurance, and flexibility of the major muscle groups that can be reached by a training program including resistance training and flexibility exercises (U.S. Department of Health and Human Services 1998).

Once it became evident that activities of moderate intensity provide health benefits independently of cardiorespiratory fitness, in 1995 the ACSM and the Centers for Disease Control and Prevention (CDC) coincidently published physical activity guidelines recommending that "every adult should accumulate 30 or more minutes of moderate intensity on most, preferably all, days of the week" (Pate et al. 1995). In addition to the ACSM/CDC (1995), the Institute of Medicine (IOM) of the National Academy of Sciences, the Office of the U.S. Surgeon General (OSG), and the U.S. Department of Health and Human Services (HHS)/Department of Agriculture concertedly advocated that engaging in moderate activity for at least 30 min on most days of the week might produce health benefits (OSG 1996; ACSM/CDC 1995; Pate et al. 1995; U.S. Department of Health and Human Services 1996; U.S. Department of Health and Human Services and U.S. Department of Agriculture 2000; Institute of Medicine of the National Academy 2002).

In order to respond to the population's increasing engagement in cardiorespiratory fitness and resistance training programs and frequent queries for exercise prescription, in 1998 the ACSM provided guidelines for the development and maintenance of cardiorespiratory fitness, body composition, muscular strength and endurance, and flexibility in healthy adults (Pollock et al. 1998).

In 2002, the IOM Committee on Dietary Reference Intake published a report that included the recommendation of 60 min of daily physical activity to prevent unhealthful weight gain (Institute of Medicine of the National Academy 2002). In 2003, the International Association for the Study of Obesity (IASO) addressed the continuously increasing obesity problem by advocating 40 to 50 min of physical activity per day for the prevention of obesity and 60 to 90 min per day for the prevention of weight regain in formerly obese persons (Saris et al. 2003).

In accordance with the 1995 ACSM/CDC physical activity guidelines, a large body of evidence supported the recommendation of lifestyle activities as health-enhancing physical activity (HEPA) (Oja et al. 2010). The term HEPA refers to the recommendation of a minimal volume of physical activity for the prevention of various diseases and premature death and for the enhancement of health (Pate et al. 1995; Bucksch and Schlicht 2006). It does not only include recreational physical activity but also incorporates occupational and household activities that can represent planned or unplanned activities that fit best into everyday life (Dunn et al. 1998). Bucksch and Schlicht (2006) reviewed the epidemiological evidence on the HEPA recommendation. They specifically addressed the questions of whether the accumulation of 30 min of moderate-intensity physical activity per day is sufficient and whether the health-enhancing effect is independent of the domain of physical activity (transportation, recreation, and household) and dimension (frequency, duration, and intensity) of physical activity. They concluded that moderate physical activity of 30 min per day, independent of the domain, provides increased health benefits in sedentary men and women (Bucksch and Schlicht 2006). The HEPA Europe, a collaborative project initiated in 2005, aims to improve health through physical activity among all persons in the WHO European region by supporting and strengthening efforts to increase physical activity participation and by improving the conditions for healthy lifestyles. This includes the development and dissemination of effective strategies, programs, and other examples of good practice for the promotion of HEPA and seeks to facilitate and support multi-sectoral approaches to the promotion of HEPA (World Health Organization 2005).

In 2007, the ACSM and AHA jointly published an updated physical activity recommendation. This update still recommends 30 min of moderate-intensity activity participation but specifies that physical activity be performed for "at least five days per week" rather than "at most, preferably, all days." Physical activity participation may be performed in an accumulation of 10-min bouts (Haskell et al. 2007). The guideline also included an additional statement that 20 min of vigorous intensity on 3 days per week might substitute the 30 min of moderate-intensity physical activity on at least 5 days per week. The recommendation also states that a combination of vigorous- and moderate-intensity activities may produce health benefits.

Also, in 2007 the ACSM issued a separate recommendation for older people aged 65 years or older and for persons aged 50 to 64 years with clinically significant chronic conditions and/or functional limitations (Nelson et al. 2007), which was subsequently updated in 2009 (Chodzko-Zajko et al. 2009).

The *2008 Activity Guidelines for Americans* published by the HHS encourage physical activity participation for health promotion by stating that "physical activity is better than non-activity and adults who participate in any amount of physical activity gain some health benefits" (U.S. Department of Health and Human Services 2008).

The most recent ACSM recommendations are based on the 1998 ACSM guidelines and were released in 2011 with the purpose of promoting physical fitness and health among adults. The 2011 ACSM guideline recommends that most adults should (Garber et al. 2011):

- Perform moderate-intensity cardiorespiratory exercise training for at least 30 min per day on 5 or more days per week or cardiorespiratory exercise training of vigorous intensity for at least 20 min per day on 3 or more days per week ($\geq$75 min per week) or a combination of moderate- and vigorous-intensity exercise.
- Engage in resistance exercise for each of the major muscle groups on 2 to 3 days per week and perform neuromotor exercise (coordination, balance, and agility).
- Do flexibility exercises for each of the major muscle groups (a total of 60 seconds per exercise) on 2 or more days per week.

The exercise training should be modified according to usual physical activity habits, physical function, health status, and exercise responses of the individual (Garber et al. 2011). Moreover, the recommendations include reducing the total time spent in sedentary behaviors and incorporating frequent, short bouts of standing and physical activity between periods of sedentary engagement.

In 2010, the WHO released their "Global Recommendations on Physical Activity for Health" specifically for adults, older persons, and children for the primary prevention of non-communicable diseases. In particular, those recommendations intend to improve cardiorespiratory and muscular fitness, bone health space and cardiovascular and metabolic health markers and reduce symptoms of anxiety and depression. The WHO guidelines give the following recommendations (World Health Organization 2011):

- Children and young persons aged 6 to 17 years should engage in at least 60 min of moderate- to vigorous-intensity physical activity per day, most of which should be aerobic. At least three times per week vigorous-intensity activities should be performed to strengthen muscle and bone.
- Adults aged 18 to 64 years should spend at least 150 min (300 min for additional health benefits) in moderate-intensity aerobic physical activity over the week, or engage in at least 75 min (150 min for additional health benefits) of vigorous-intensity activity over the week, or should combine moderate and vigorous-intensity activities in an equivalent manner. Aerobic physical activity should be performed in bouts lasting for at least 10 min, and muscle-strengthening activities should involve major muscle groups and should be performed on 2 or more days of the week.
- Adults aged 65 years or older should perform physical activity as described for adults aged 18 to 64 years. Persons with poor mobility should engage in physical activity to enhance balance and to prevent falls on 3 or more days per week.

Although muscular injury is uncommon at the recommended level of 150 min per week of moderate-intensity activity, the WHO recommends starting with a moderate physical activity program and gradually increasing to higher physical activity levels (World Health Organization 2011).

A number of countries such as Australia (Australian Government Department of Health and Ageing 2010), Canada (Canadian Society for Exercise Physiology 2012), and the European Union (EU) Member States (European Commission 2008) have national physical activity recommendations. By mid-2013, the EU Expert Group on Sport, Health and Participation will issue guidelines designed to improve "ways to promote health-enhancing physical activity and participation in grassroots sport, and to identify respective measures" (European Commission 2012).

Several studies have investigated adherence to physical activity recommendations in relation to risk of total mortality. The 1990 ACSM and 1995 ACSM/CDC recommended levels of vigorous and moderate physical activity were investigated in relation to the risk of mortality in a sample of men and women from Germany. A significant inverse association was found between moderate activity at recommended levels and risk of mortality in women but not men. By comparison, an inverse association with mortality was seen at recommended levels of vigorous activity in men, but not women (Bucksch 2005). Leitzmann et al. (2007) examined the effect of engaging in physical activity according to the physical activity guidelines of the ACSM/CDC (1995) and OSG (1996) on all-cause mortality in a large U.S. cohort study (Leitzmann et al. 2007). Following the physical activity guidelines of 30 min of moderate activity on most days of the week or engaging in 20 min of vigorous exercise three or more times per week was associated with 27% and 32% reductions in all-cause mortality, respectively (Leitzmann et al. 2007). Schoenborn and Stommel (2011) studied mortality risk associated with adherence to the 2008 Physical Activity Guidelines for Americans. They concluded that meeting the recommendations was associated with a reduced risk of all-cause mortality among U.S. adults, particularly in those with chronic conditions, with odds ratios (OR) ranging from 0.65 to 0.75 (Schoenborn and Stommel 2011).

49.7 Measurement of Physical Activity

Physical activity is a complex, multidimensional exposure that is difficult to measure accurately among free-living individuals. Several physical activity assessment methods exist, each coupled with specific strengths and limitations. Two main types of methods for measurement of physical activity can be distinguished: subjective methods (e.g., questionnaires, diaries, recalls, and logs) and objective methods (e.g., activity monitors, heart rate monitors, DLW, and indirect calorimetry). Subjective methods provide the poorest validity among physical activity assessment methods. Because of their high accuracy, DLW and indirect calorimetry methods have frequently been considered validation criterion methods for other types of physical activity assessments (Fig. 49.8). Different assessment methods measure distinct dimensions of physical activity. As mentioned above, physical activity represents a behavior, whereas energy expenditure mirrors the energy costs of physical activity behavior. Motion sensors such as accelerometers and pedometers measure physical activity which can be converted to energy expenditure by equations, whereas DLW and indirect calorimetry directly assess energy expenditure. Lamonte and Ainsworth (2001) stated that energy expenditure may be a better predictor of health-related outcomes than the specific type of physical activity that results in the expended energy. Therefore, researchers often convert outputs of physical activity

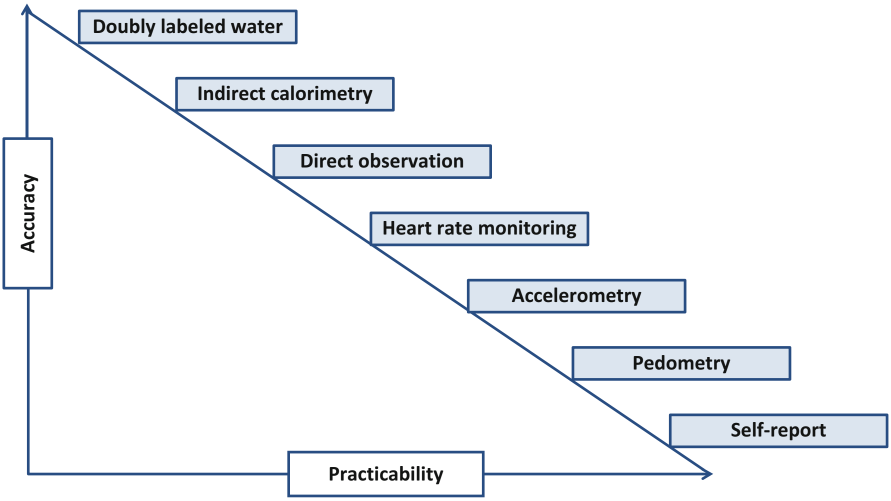

Fig. 49.8 Practicability versus accuracy of different physical activity assessment methods (modified from Mueller et al. (2010))

measurements to units of energy expenditure (Lamonte and Ainsworth 2001). For example, Manson et al. (1999) reported that the association between physical activity and coronary events was similar for both light- to moderate-intensity physical activity and vigorous-intensity exercise when total energy expended was comparable.

While the method for assessment of physical activity should fit the research question, the choice of method will usually represent a trade-off between accuracy and feasibility (U.S. Department of Health and Human Services 1998). The research instruments used must be evaluated not only for their efficacy to assess an individual's physical activity but also for their applicability in large-scale epidemiological settings (U.S. Department of Health and Human Services 1998). Physical activity assessment methods vary in that they are appropriate for specific age groups of the population. For example, direct observation is an assessment method that usually intends to monitor children's physical activity behavior in various settings including school, home, parks, and recreation areas.

Before measuring physical activity in a study, measurement instruments should be tested for reliability and validity in a population which is similar to the one that will be examined. Validity describes how well the instrument assesses the exposure it intends to measure, and reliability assures that the method of measurement delivers the same results if reported under the same circumstances. Both validity and reliability represent quality criteria for measurement instruments.

The following section reviews different methods used for the measurement of physical activity and provides information on their use in different population subgroups (e.g., children, adults, and older persons). Strengths and limitations of the different methods of physical activity assessment will be discussed. An evaluation of instruments for physical activity assessment according to specific attributes is illustrated in Table 49.2.

49.7.1 Subjective Physical Activity Assessment Methods

Subjective methods, also termed self-reported methods, are the most convenient way to collect physical activity data on a large number of individuals. They are most practical for assessing physical activity in large epidemiological studies (Caspersen 1989). Self-reports include questionnaires, recall surveys, diaries, and logs. They have in common that they are inexpensive, relatively easy to administer, and highly acceptable for study participants (LaPorte et al. 1985; Caspersen 1989). However, subjective measurements suffer from poor validity, as outlined below (Vanhees et al. 2005).

49.7.1.1 Self-Reported Physical Activity Questionnaires

Physical activity questionnaires (PAQs) represent self-reported instruments for measuring physical activity that are widely used in epidemiological settings. These instruments can be interview-based or self-administered and usually query physical activity over the past day, week and month but also over a year or even over the

Table 49.2 Evaluation of physical activity assessment instruments according to specific attributes

	Costs	Acceptance by participants	Accuracy	Ease of administration	Measurement of dimensions	Induction of change in PA behavior	Suitable for children (<10 years of age)	Feasible in large-scale free-living populations
Subjective methods								
Self-reported PAQ	++	++	0	++	+	+	–	++
Recall	+	+	0	+	+	+	0	+
Diary	++	0	0	+	++	0	–	0
Log	++	0	0	+	+	0	0	0
Objective methods								
Pedometry	++	++	+	+	–	+	++	+

DLW	–	–	++	+	–	+	++	–
Indirect calorimetry	–	–	++	+	–	0	++	–

– poor, 0 acceptable, + good, ++ very good lifetime. PAQs allow the assessment of different components of physical activity, including type, frequency, intensity, and duration in household, occupation, recreation, and transportation. As occupations have become less physically demanding in industrialized countries over the past decades, PAQs have focused on recreational activities above other domains (Lee et al. 2009). To understand the impact of environmental influences on all domains of physical activity, questionnaires have begun to consider physical activity in other domains including transportation, occupation, and household activities (Brownson and Boehmer 2004). While in earlier studies questionnaires queried job titles only (Lee et al. 2009), recent occupational PAQs inquire about physical activity patterns in greater detail including the frequency, duration, and intensity of activity performed by individuals at work (Friberg et al. 2006; Friedenreich et al. 2007; Lee et al. 2009). Questionnaires differ in their type, complexity, and time frame for which physical activity is assessed (Lee et al. 2009). PAQs may be less accurate in assessing activities of light to moderate intensity compared to activities of vigorous intensity (Warren et al. 2010). This may be explained by the fact that low-intensity activities, such as walking, that occur throughout the day are more difficult to assess than structured and planned exercise of vigorous intensity, such as jogging and swimming (Bassett et al. 2000).

The IPAQ was developed in 1996 by Booth and colleagues, and it represents an established population surveillance tool for physical activity assessment to compare physical activities across countries. The IPAQ has been translated into 22 different languages, including Arabic, Croatian, Danish, Dutch (Belgian), English, Estonian, French, German, Icelandic, Korean, Lithuanian, Malaysian, Norwegian, Persian-Farsi, Polish, Spanish (Argentina), Spanish (Columbia), Spanish (U.S.), Swedish, Taiwanese, Turkish, and Vietnamese (International Physical Activity Questionnaire 2012; https://sites.google.com/site/theipaq/questionnaires). It encompasses a set of four questionnaires including a long version (five activity domains asked independently) and a short version (four generic items) for use by either telephone- or self-reported methods (Craig et al. 2003). The GPAQ was developed by the WHO as a physical activity surveillance tool mainly for use in developing countries. It collects information on physical activity engagement at work, travel, and in recreation (World Health Organization 2012b). The European Prospective Investigation into Cancer Study-Norfolk cohort (EPIC-Norfolk), a large population-based cohort study, designed the EPIC Physical Activity Questionnaire 2 (EPAQ2) which measures activity in different domains of life in order to assess energy expenditure (Wareham et al. 2002). The Baecke Questionnaire represents a short assessment tool aimed at estimating physical activity in disease-free populations over the past year (Baecke et al. 1982).

PAQs are principally tailored to assess moderate- to high-intensity physical activity among healthy young to middle-aged adults, but not other age groups, such as the elderly and children. Children's activity is characterized by short bouts of activity rather than more continuous periods of activity (Pate 1993; Sirard and Pate 2001). Also, cognitive immaturity in children or cognitive degeneration in the elderly makes the application of commonly used self-reported questionnaires difficult in those populations. To overcome this obstacle, specific questionnaires for children and elderly people have been designed. They can be self-reported if feasible or proxy-reported by parents or relatives. Examples of PAQs in children are the self-reported and proxy-reported Children's Leisure and Activities Study Survey (CLASS) questionnaires for 10- to 12-year-olds and 5- to 6-year-olds that intend to assess the type, frequency, and intensity of physical activity over a typical week (Telford et al. 2004). Questions such as "Do you usually bounce on a trampoline," "play with pets," or "play indoors with pets?" are asked. The "Motorik-Modul" (MoMo), as part of the German Health Interview and Examination Survey for Children and Adolescents (KiGGS), explores potential associations between motor fitness, physical activity, and health in cross-sectional and longitudinal investigations. Physical activity is assessed by a questionnaire that contains 51 items about the intensity, frequency, and duration of physical activity in everyday life, during recreation time, at school, and in sports clubs. Moreover, a test profile that consists of 11 items is used to determine cardiorespiratory fitness, strength, coordination, and mobility (Opper et al. 2007).

The Yale Physical Activity Survey, the Physical Activity Survey for the Elderly, and the Zutphen Physical Activity Questionnaire have been specifically designed for the elderly (Washburn 2000). In 1991, the Baecke Questionnaire was slightly modified (Modified Baecke Questionnaire) by Voorrips and coworkers to capture habitual physical activity in older populations (Voorrips et al. 1991).

Information attained from PAQs is frequently converted into estimates of energy expenditure (i.e., kcal, kJ, or METs) or some other summary measure that can be used to categorize or rank persons by their physical activity level. Activity codes and MET intensities can be obtained from a physical activity compendium created by Ainsworth and colleagues (Ainsworth et al. 2011). A compendium designed to quantify children's and adolescent's activity levels is also available (Ridley et al. 2008).

However, most PAQs do not accurately estimate energy expenditure (Macfarlane et al. 2006; Neilson et al. 2008). A vast number of criterion-related validity studies and tests of the reliability of PAQs have been conducted. Neilson et al. (2008) evaluated the validity of PAQs for estimation of AAE, using DLW as a criterion method. Only 5 out of 19 PAQs revealed correlation coefficients >0.60 (Neilson et al. 2008). The long and short versions of the IPAQ were validated against accelerometer data in 14 centers across 12 different countries (Craig et al. 2003). The IPAQ questionnaires produced data with a reasonable reliability (Spearman's correlation coefficient $r = 0.8$). The criterion validity provided a Spearman's correlation coefficient of 0.30 (median of the pooled data). These values were comparable to the reliability and criterion validity correlations achieved from the evaluation of seven other self-reported PAQs (Sallis and Saelens 2000).

Boon et al. (2010) assessed the validity of the New Zealand physical activity questionnaire long form (NZPAQ-LF) and the IPAQ-long form (IPAQ-LF) against the accelerometry method. Both the NZPAQ-LF and the IPAQ-LF were only modestly correlated with accelerometer data with respect to moderate physical activity (Spearman's correlation coefficient $r = 0.19–0.30$) and total physical activity (Spearman's correlation coefficient $r = 0.30–0.32$) (Boon et al. 2010). Moreover, the validity of PAQs may vary with obesity status. Norman et al. (2001) evaluated a self-administered PAQ against 7-day activity records in a group of middle-aged and elderly men. They found significantly lower Spearman's correlation coefficients in obese men compared to normal-weight men (Spearman's correlation coefficients $r = 0.39$ vs. $r = 0.73$) (Norman et al. 2001).

An advantage of PAQs is that physical activity levels can be assessed across different domains. Moreover, they are inexpensive and of low burden for study participants and investigators compared to other self-reported instruments such as physical activity diaries or logs. PAQs can easily be administered under free-living conditions to most individuals in the population at a large-scale level. However, activity information obtained by self-reports is subject to recall and social desirability that may influence the validity and/or precision in physical activity measurement. Specifically, validity appears to be poor for low-intensity physical activities (Warren et al. 2010). There is ongoing research regarding the development of more advanced techniques in self-reported approaches, such as Internet-based assessment methods (Schatzkin et al. 2009; cf. Chap. ▶Internet-Based Epidemiology of the handbook). Electronic and internet-based questionnaires may increase standardization in assessment procedures, they are cost and time saving, they are resistant to coding errors, and they allow for an immediate calculation and storage of the data (Warren et al. 2010). Incorporating video guides or spoken instructions rather than paper-based instructions may be of advantage to individuals with poor literacy (Ridley et al. 2001). Researchers using a questionnaire must be aware of the primary outcome of the questionnaire (e.g., the dimensions and domains of activity the questionnaire is designed to measure) and ensure that the questionnaire fits with the research question. Box 49.1 provides a list of questions they may be considered before conducting a study.

Box 49.1. Possible considerations before using a questionnaire in a physical activity study (Adapted from Warren et al. (2010))

1. Does the questionnaire fit the research question?
2. Does the questionnaire adequately address the population under investigation?
3. What is the time frame for which physical activity is assessed (e.g., past week, month, year)?
4. What types of physical activity does the questionnaire capture?
5. Which dimensions of physical activity does the questionnaire include?
6. How will the questionnaire be administered (self-administered or interviewer-administered)?
7. Does the questionnaire enable to clearly follow the instructions for unmistakably responding to the questions, or in interview-based assessments, are the interviewers well trained?
8. Have tests for reliability been undertaken?

9. Has the questionnaire been validated against objective physical assessment instruments?
10. How will the data be stored and analyzed, and how will outliers and missing values be treated?

49.7.1.2 Retrospective Quantitative History

The retrospective quantitative history represents the most complex form of recall surveys and provides details on past physical activity details typically over 1 year (Caspersen 1989; U.S. Department of Health and Human Services 1996) or even a lifetime (Lee et al. 2009). These surveys are interviewer-based or self-administered. Recall of historical activity is useful to determine the relationship between physical activity and chronic disease that have a long developmental period, such as osteoporosis or cancer (Winters-Hart et al. 2004; Lee et al. 2009) and to establish physical activity and health outcome relationships in studies where long-term or lifetime patterns of physical activity play an important role (Bowles et al. 2004).

Winters-Hart et al. (2004) tested the validity of physical activity data derived from a historical physical activity questionnaire (HPAQ) by comparison with actual PAQ data collected at four points in time over a 17-year period in postmenopausal women. Specifically, in the year 2000, participants recalled their physical activity participation from the years 1982, 1985, 1995, and 1999. At each of the points in time studied, significant correlations in the range of 0.39 to 0.62 between the HPAQ data and the data from the actual PAQ were found, with the highest Spearman's correlation coefficients reached at the most recent points in time (Winters-Hart et al. 2004). In the Medical Research Council Ely Study, Besson et al. (2010) validated an HPAQ against objectively measured physical activity from the same time periods up to 15 years ago (Besson et al. 2010). In their study, physical activity data were obtained using calibrated heart rate monitoring during two periods (between 1994 and 1996 and between 2000 and 2002) and an HPAQ administered to assess physical activity from the age of 20 years to the current age. For both time periods, modest correlations between HPAQ-derived and objectively assessed total AEE and vigorous physical activity were found (Spearman's correlation coefficients $r = 0.44$ and 0.40, respectively) (Besson et al. 2010).

Although the HPAQ provides a comprehensive amount of data, it has the disadvantage of representing a considerable burden to the participant to recall physical activity over a long period of time. Moreover, this method is related to a sizeable administrative burden (Lee et al. 2009; U.S. Department of Health and Human Services 1998).

49.7.1.3 Physical Activity Recall Instruments

Physical activity recall instruments attempt to query a wide range of activities over a defined time frame ranging from 1 week to a lifetime. Either they ascertain precise details about physical activity including type, frequency, and duration or they assess usual or typical participation in physical activities (LaPorte et al. 1985;

Blair et al. 1991). The participant is typically asked to recall past activities, during an interview, in person or by phone. The Stanford 7-Day Recall (7-DR) and the Adolescent Physical Activity Recall Questionnaire (APARQ) provide examples of recall questionnaires that collect information on physical activity over the past 7 days (Sallis et al. 1985; Booth et al. 2002). In short-term physical activity recalls, unannounced telephone-administered interviews are performed, and the participant is asked to recall the amount of time spent during the past 24 h or longer (up to 1 month) in physical activities in occupation, household, and recreation (Hu 2008). Because of daily and weekly variation in physical activity, a number of recalls (at least two) may be necessary to assess long-term physical activity patterns.

Richardson et al. (2001) assessed the reliability and validity of the Stanford 7-DR within the Survey of Activity, Fitness, and Exercise (SAFE) study by comparing the 7-DR with physical activity records, accelerometer readings, $VO_{2\,max}$, and percent body fat. Study participants performed 14 recalls over a 12-month period, one recall approximately every 26 days. The validity of the 7-DR was measured at study visits 10 and 11. In terms of reliability, the authors reported age-adjusted sex-specific Spearman partial correlation coefficients of $r = 0.60$ and $r = 0.36$ for men and women, respectively. 7-DR and physical activity record measures were significantly correlated in men (Spearman partial correlation coefficients $r = 0.58$ at visit 10 and $r = 0.66$ at visit 11), whereas in women, a weaker relationship was observed (Spearman partial correlation coefficients $r = 0.32$ at visit 10 and $r = 0.33$ at visit 11). Comparisons of the 7-DR with $VO_{2\,max}$ and percent body fat showed less consistent correlations with $VO_{2\,max}$, but more consistent relationships for percent body fat in women than men. Data from the 7-DR were significantly related to accelerometer data in men (Spearman partial correlation coefficient $r = 0.54$ at visit 10 and $r = 0.45$ at visit 11) but not women (Spearman partial correlation coefficient $r = 0.20$ at visit 10 and $r = 0.06$ at visit 11) (Richardson et al. 2001).

Because of its retrospective nature, recall methods generally do not influence the individual's activity behavior, and they tend to be less burdensome to the participant and the investigator compared to diaries or logs. However, they require memory of past activities which may lead to recall errors (Baranowski 1985; U.S. Department of Health and Human Services 1998). Additional limitations of the method include the time and costs for training the interviewers. Also, recall questionnaires require an individual's cooperation to remember physical activity participation. Moreover, recall questionnaires are less suitable to assess physical activity in children and the elderly.

49.7.1.4 Physical Activity Diaries

Physical activity diaries (also known as physical activity records) usually represent paper and pen-based instruments. The study participants record all their activities as they typically occur during a 24-h period which is usually broken down into 15-min time intervals. The participant can choose specific activities from a predefined list, but space is provided for other activities. Reported activities are then processed using coding schemes which classify each activity by its MET value and thus allow estimating intensity of physical activity. Physical activity diaries are commonly limited to time spans of 1 to 3 days (Caspersen 1989).

When compared to the indirect calorimetry method, physical activity diaries have demonstrated acceptable accuracy in the measurement of daily energy expenditure (Warren et al. 2010).

Advantages of physical activity diaries are that they provide detailed and comprehensive information about the physical activities undertaken, including bouts and patterns of physical activity performed during a day across all domains. The method is cheap to administer and it does not rely on recall or memory (LaPorte et al. 1985; Caspersen 1989). A disadvantage is that it is cumbersome for participants to keep the diary as it requires a detailed recording of the individual's physical activity which is a time-consuming and tiresome task demanding good cooperation and compliance of the participant. Also, the need to record physical activity may lead to a change in an individual's activity behavior, also known as a reactivity effect (Matthews 2002). Physical activity diaries consume a considerable amount of time, and they impose complex data processing on the investigator (e.g., decoding the activity entries) (LaPorte et al. 1985; Haskell and Kiernan 2000). Physical activity diaries represent the most suitable subjective method to estimate energy expenditure in epidemiological studies. However, the recording and analysis process is time-consuming and inconvenient for both the study participant and the investigator. Thus, this method is often used as a reference method for the validation of self-reported PAQs. For example, the validity of the PAQ used in the Nurses' Health Study was assessed by comparison with 4 past-week physical activity recalls and four 7-day physical activity diaries, administered every 3 months (Wolf et al. 1994).

49.7.1.5 Physical Activity Logs

In contrast to physical activity diaries, where bouts of activity are recorded, in physical activity logs, the participant records broad categories of activities (inactive, sitting; light, moderate, vigorous, and very vigorous activity), usually in a structured form (Bouchard et al. 1983). Similar to physical activity diaries, logs provide a considerable amount of physical activity information, albeit not as detailed as diaries. Macfarlane et al. (2006) compared six physical activity measurement methods (triaxial/uniaxial accelerometers, pedometer, heart rate monitoring, physical activity log, and PAQ) and found weak to modest correlations between the physical activity log and other physical activity measurement methods. Specifically, correlations with a triaxial accelerometer (Tritrac) yielded correlation coefficients of $r = 0.23$ for light activity, $r = 0.32$ for moderate activity, and $r = 0.22$ for vigorous activity (Macfarlane et al. 2006). Schmidt et al. (2003) reported that logs were kept more accurately in leaner women compared to those who were overweight.

Advantages of physical activity logs are that they provide detailed data on physical activity patterns of individuals. Furthermore, physical activity logs are less time-consuming for the researcher to process than activity diaries, making them particularly useful for validation studies. They are not subject to bias due to the cognitive demands of the recall process. However, limitations of physical activity logs are the potential for loss of information for activities not represented on the list (e.g., spontaneous activity). Also, logs require some degree of literacy of the participant, and the recording process may produce changes in activity behavior. As with diaries, the recording and data process of logs can be inconvenient for the participant and investigators, and the recording process may produce changes in activity behavior (U.S. Department of Health and Human Services 1998).

49.7.2 Objective Physical Activity Assessment Methods

An alternative to self-reported physical activity assessment methods is the direct measurement of physical activity through mechanical tools, electronic instruments, direct observation, or physiological measurements. These approaches eliminate the obstacles of limitations in recall and self-reporting, and instruments directly provide an accurate assessment of energy expenditure. However, some of these methods are themselves limited by a high burden on the participant and by high costs, or they are restricted to use in laboratory settings only. Therefore, these measurement tools have predominantly been used in small-scale studies (U.S. Department of Health and Human Services 1998). DLW and indirect calorimetry are frequently used as reference methods in validation studies of subjective physical activity assessment.

49.7.2.1 Pedometry

Pedometers are motion sensors usually worn at the waist which respond to vertical hip accelerations during paces (Bassett et al. 1996). Pedometry output data are usually step counts. Three basic mechanisms of pedometers have been described: a spring-suspended lever arm with metal-on-metal contact, a magnetic reed proximity switch, and a piezoelectric sensor (Crouter et al. 2003; Schneider et al. 2003). As pedometers provide data on steps taken only, they only measure walking activity, but do not capture other activities such as swimming, cycling, weight lifting, or sedentary pursuits. They may underestimate steps from slower gait speeds (i.e., 0.9 meter per second) or steps with irregular gait patterns (Berlin et al. 2006). Furthermore, they do not allow an evaluation of physical activity patterns as they do not provide information relating to activity type, duration, or intensity.

Pedometers are inexpensive and light-weight portable devices that deliver reliable estimates of physical activity for use in research and clinical settings where walking is the main type of activity. They are easy to administer, which makes them a practical tool in the assessment of physical activity in large groups of almost any age. Pedometers also have the potential to promote behavior change and have therefore been used in intervention settings, for example, in the "10,000 Steps Rockhampton Project" (Queensland, Australia) (About 10,000 Steps Project 2012; http://www.10000steps.org.au). Pedometer-derived output data have been classified by Tudor-Locke and Bassett (2004) as follows: 5,000 steps/day (sedentary behavior), 5,000 to 7,499 steps/day (low activity), 7,500 to 9,999 steps/day (somewhat active), 10,000 to 12,499 steps/day (active), and 12,500 steps/day (highly active).

To reduce assessment variability and to capture lower step counts on weekends versus weekdays, pedometers should be worn for 1 week, and the average number of steps per day should be calculated from this period (Berlin et al. 2006).

Wide variation exists between pedometer models, and their costs are proportional to their accuracy. Tudor-Locke et al. (2002) reviewed the validity of pedometers compared to accelerometers, direct observation, energy expenditure, and self-report. They rated pedometry as a valid physical activity assessment method when compared with various accelerometers ($r = 0.86$) and summarized that pedometers are correlated with energy expenditure estimates from heart rate monitoring in the range of $r = 0.46–0.88$ and from indirect calorimetry in the range of $r = 0.49–0.81$ (Tudor-Locke et al. 2002).

In children, the accuracy of a pedometer was compared to accelerometer measures and direct observation. Correlations between the pedometer and the accelerometer were $r = 0.50$ during classroom activity and $r = 0.98$ during recreational activity (Kilanowski et al. 1999). Enhanced accuracy was reported for faster walking speeds compared to slower walking and running speeds (Crouter et al. 2003).

49.7.2.2 Accelerometry

Accelerometry is the most commonly used objective method to determine physical activity intensities and estimates of energy expenditure in free-living populations. Acceleration is measured by small monitor sensoring devices usually attached to the hip or lower back, but they can be also worn on the wrist, thigh, or ankle. Acceleration produced by the movement of a body segment or limb parts is measured in one (longitudinal body axis, usually vertical), two (vertical and mediolateral or vertical and anterior-posterior), or three (vertical, anterior-posterior, and mediolateral) directions (Chen and Bassett 2005), depending on the device. A piezoelectric accelerometer converts a physical force into an electric signal through the deformation of a piezoelectric element by a seismic mass, which changes the charge of the sensor causing a voltage signal that is proportional to the acceleration (Chen and Bassett 2005). The Actigraph (formerly known as the Manufacturing Technology Incorporated (MTI) and the Computer Science Applications, Inc. (CSA)) has been one of the most widely used uniaxial accelerometry device in epidemiological studies. Recent available devices are the AMP-331 (biaxial) and the Actical (multiaxial) (Crouter et al. 2006a). The use of multiple accelerometers only marginally improved the estimation of energy expenditure compared to estimates from a single accelerometer (Trost et al. 2005). However, multiaxial accelerometers are more sensitive to light-intensity activities, and they provide more valid measurements of static upper-body movement in activities such as cycling and rowing (Steele et al. 2003). The Intelligent Device for Energy Expenditure and Physical Activity (IDEEA) represents an accelerometer-based system that uses piezoelectric sensors attached to the chest, feet, and thighs (Zhang et al. 2003). Compared to commonly used accelerometers, the IDEEA uniquely enables to differentiate types of activity such as sedentary behavior (e.g., sitting, lying, or standing) and active paces (e.g., walking, cycling) and thus provides reliable estimation of energy expenditure in free-living populations (Kwon et al. 2010).

The principal output of accelerometers is counts, which are derived from the force and frequency of vertical displacement. Accelerometer counts are sampled over a preset sampling period or epoch (Ward et al. 2005). Several studies have used 1-min epochs to collect accelerometer data. However, short and frequent bouts of children may inadequately be captured using a 1-min epoch and consequently may lead to an underestimation of moderate to vigorous physical activity (Ward et al. 2005).

The conversion of physical activity counts into other measures of activity is termed value calibration (Warren et al. 2010; Bassett et al. 2012). An important methodological issue is how to translate the accelerometer signals and counts into biologically meaningful data. Usually, single linear regression equations are used to relate count values to units of energy expenditure (Crouter et al. 2006b). These estimated energy expenditure values may depend on the accuracy of the prediction equations derived from various calibration studies in laboratory or field settings, which may differ between population groups, such as children and the elderly (Hu 2008). Additionally, these regression equations allow establishing cut-points for classification of physical activity into different activity intensities, including light, moderate, and vigorous intensities (Crouter et al. 2006b).

The range of published cut-points for sedentary activities varies from <100 to <800 counts per min. For moderate-intensity activities, the range varies from 1,900 to 8,200 counts per min (Warren et al. 2010). Thus, the time spent at different intensity levels will differ considerably according to the adopted threshold. This may impact upon results regarding the relationship between physical activity intensity and health outcomes.

A comparison of calibration studies of accelerometers is difficult because of the different populations, protocols, and criterion measures used (van Cauwenberghe et al. 2011). A study by van Cauwenberghe et al. (2011) evaluated differences in physical activity cut-points by comparison of four different cut-points in a population of children (Sirard et al. 2005; Pate et al. 2006; Evenson et al. 2008; van Cauwenberghe et al. 2011). The cut-points for sedentary behavior from Pate et al. and Evenson et al. were considerably lower than the cut-points defined in the Sirard et al. (2005) study and the van Cauwenberghe et al. study. The cut-points for moderate to vigorous physical activity of the van Cauwenberghe et al. study and the Evenson et al. study were comparable, and the cut-points of Pate et al. were lower (Table 49.3). Higher moderate to vigorous activity cut-points have been established by Sirard et al. compared to the cut-points of the other studies (Table 49.3). van Cauwenberghe et al. (2011) speculated that the differences in cut-points among the studies may be primarily ascribed to limited compliance by study participants to the study protocol rather than variation in the actual activities included in the protocol itself. Figure 49.9 shows the time in moderate to vigorous physical activity according to different cut-points used in selected studies.

When using the Pate et al. cut-points for moderate to vigorous physical activity, 91% of children meet the daily moderate to vigorous physical activity recommendation, whereas none of these children meet the recommended moderate to vigorous physical activity levels according to the cut-point of Sirard et al. (Fig. 49.10). Whether the substantial differences in cut-points among these studies are of biological relevance remains to be clarified in further investigations (van Cauwenberghe et al. 2011).

Table 49.3 Physical activity intensity cut-points for preschoolers (Adapted from van Cauwenberghe et al. (2011))

	Moderate to vigorous activity	Vigorous activity
Pate et al. (2006)	420–841	≥842
Sirard et al. 2005	891–1,254	≥1,255
Evenson et al. 2008	574–1,002	≥1,003
van Cauwenberghe et al. 2011	585–880	≥881

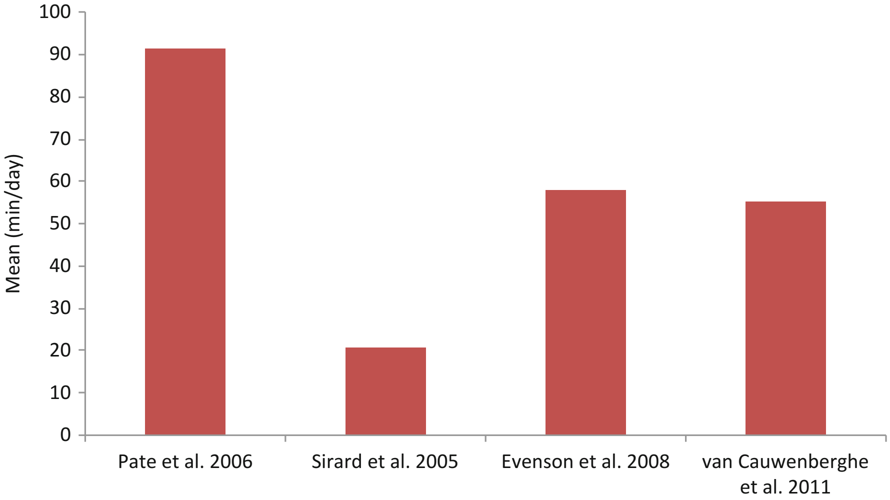

Fig. 49.9 Differences in predicted time spent in physical activity of moderate to vigorous intensity according to different cut-points used (van Cauwenberghe et al. 2011)

As accelerometers are typically worn on the waist, lower-extremity or trunk acceleration such as walking, running, and stair climbing is well captured, whereas upper-extremity movements or seated activities are inaccurately assessed (Crouter et al. 2006b). Welk et al. (2000) have shown that accelerometry underestimates the energy expenditure of household activities (Fig. 49.11) whereas it provides reasonable energy expenditure estimations of activities such as walking and jogging (Welk et al. 2000) (Fig. 49.12). Moreover, Brage et al. (2003) reported that CSA accelerometer outputs increase linearly with speed in the walking range but not in the running range, probably due to relatively constant vertical acceleration in running. Several regression equations are available that relate activity counts to energy expenditure. However, no single regression equation can accurately estimate energy expenditure across the entire range of physical activity. Crouter et al. (2006b) developed a model for the Actigraph accelerometer, which integrates a walk/run regression equation and an equation for intermittent lifestyle activities.

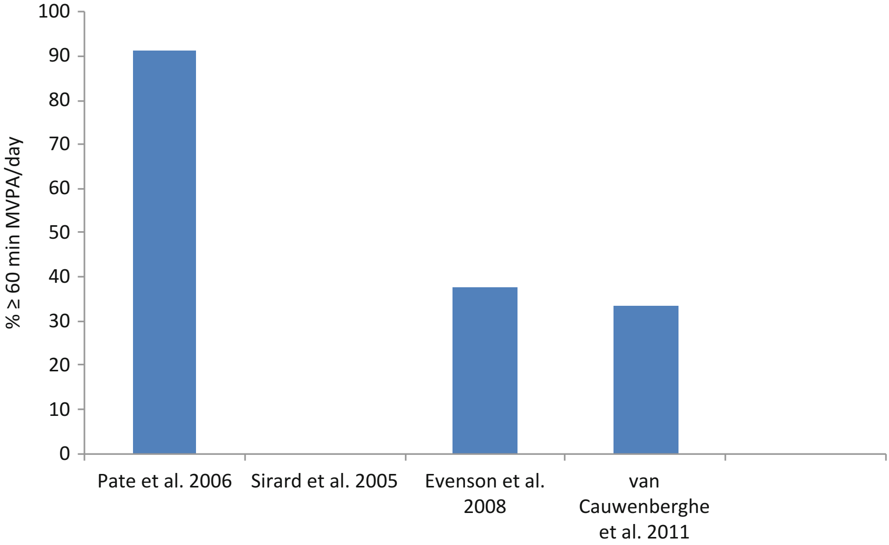

Fig. 49.10 Proportion of children and youth complying with the physical activity recommendations (≥60 min moderate to vigorous physical activity (MVPA) per day) according to different cut-point used (van Cauwenberghe et al. 2011)

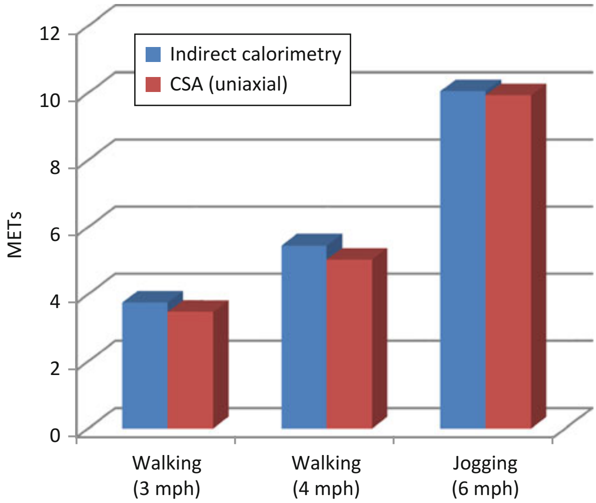

Fig. 49.12 Prediction of energy expenditure of walking and jogging by a CSA accelerometer as compared with indirect calorimetry (mph = miles per hour) (Welk et al. 2000)

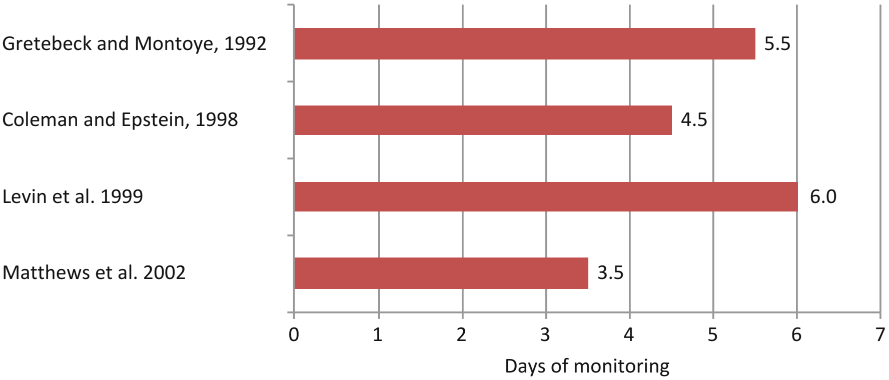

Fig. 49.13 Number of days suggested to reliably assess physical activity using an accelerometer in adults (Adapted from Trost et al. (2005))

The reliability and validity of accelerometers have been thoroughly studied. Bassett et al. (2000) assessed the validity of three accelerometers and one pedometer for estimating energy expenditure during moderate physical activity intensity against energy expenditure measured by a portable indirect calorimeter, with correlation coefficients ranging from 0.33 to 0.62.

Trost et al. (2005) summarized available research regarding the number of days required to wear an accelerometer to achieve reliable estimates of habitual physical activity. The authors suggested that adults wear an accelerometer for 3 to 5 days (Fig. 49.13). In children, the recommendations of monitoring time range from 4 to 9 days, making it difficult to draw a definitive conclusion on the precise number of days needed (Fig. 49.14). Trost et al. (2005) suggested that a 7-day monitoring period may be a reasonably sensitive period for children. An advantage

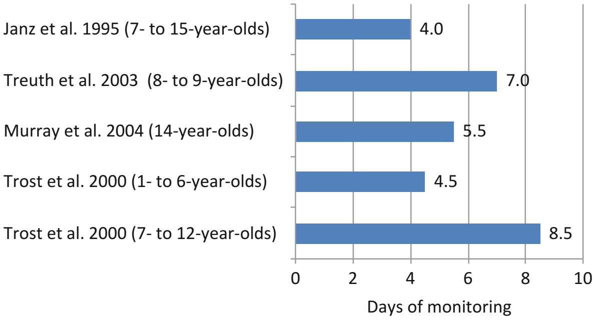

Fig. 49.14 Numbers of days suggested to reliably assess physical activity using an accelerometer in children (Adapted from Trost et al. (2005))

of accelerometers is that they provide a relatively detailed measurement of activity patterns. Moreover, their ease of administration makes them a feasible assessment tool for individuals across all age groups. The amount of data produced from accelerometers requires some skill to process and read into energy expenditure output. There is no standardization regarding the use of energy prediction equations and cutoff points for different activity intensities which vary depending on the types of calibration activities and the setting in which the calibration was performed. Imprecise estimation of energy expenditure may not necessarily be the product of imprecise motion detection but rather caused by limitations in the accuracy of the regression equations used to predict activity-related energy expenditure (Welk et al. 2000). Financial costs may prohibit the use of accelerometers for assessment of physical activity in large samples, unless accelerometer devices become less costly. Moreover, the development of accelerometers with multiple sensors may allow more detailed assessments of physical activity patterns in the future.

49.7.2.3 Heart Rate Monitoring

Heart rate monitoring represents a measure of a direct physiological response to physical activity and can be used to differentiate between activity intensities (Sirard and Pate 2001). Heart rate monitoring devices commonly comprise a chest strap and a wristwatch-type receiver for transmission of data.

Heart rate (HR) increases linearly and proportionately with the volume of oxygen consumed (VO_2) by contracting skeletal muscles in the range of moderate to vigorous physical activity. However, during light-intensity physical activity, linearity is poor since HR is influenced by several factors, such as heart rate, body temperature, muscle mass, caffeine intake, stress, type of exercise, and medication use (e.g., beta-blockers) (Acheson et al. 1980; Janz 2002; Lee et al. 2009).

Heart rate monitoring uses prediction equations that enable the evaluation of energy expenditure of physical activity in free-living populations (Vanhees et al. 2005). In order to reduce interindividual error in the prediction of energy expenditure, calibration curves on the relationship between HR and VO_2 of each individual of the study are constructed. In these calibration studies, HR and VO_2 are determined under resting conditions (lying, sitting, or standing) and during different levels of exercise (e.g., bicycle ergometry) in a laboratory setting. During field conditions,

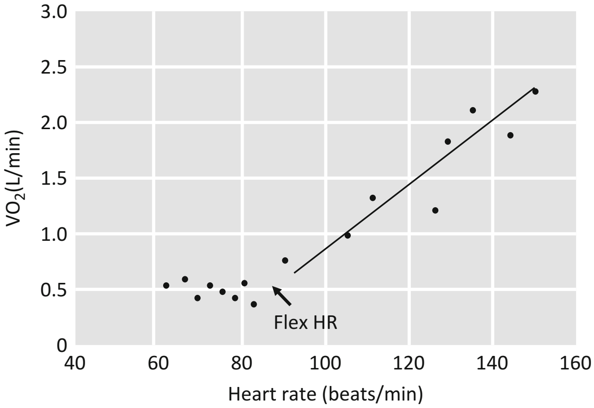

Fig. 49.15 Relation of heart rate to oxygen consumption using the flex heart rate method (Adapted from Janz (2002))

these calibration curves are then used to estimate VO_2 and energy expenditure from heart rate (Janz 2002). One potential limitation of the HR monitoring method is that it requires individual calibration.

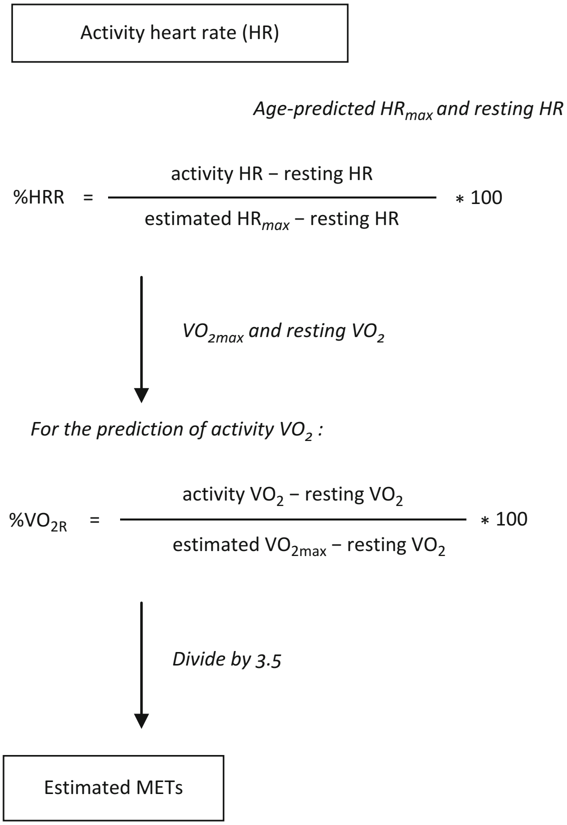
The flex heart rate (flex HR) method represents an approach for estimation of energy expenditure from heart rate (Fig. 49.15). Flex HR is determined by measuring HR and VO_2 at rest and during exercise followed by the determination of the flex HR (Wareham et al. 1997). The flex HR is empirically determined as the mean of the highest resting value and the lowest exercise value. For HR values falling below the flex HR, energy expenditure is assumed to be equal to resting energy expenditure. For HR values above the flex HR, energy expenditure is predicted from individual HR-VO_2 calibration curves.

Energy expenditure can also be derived using the %HRR method. One approach described by Strath et al. (2000) is based on the assumption that %HRR and $\%VO_{2R}$ are approximately equal, which allows the prediction of EE through activity HR and physiological relationships. Figure 49.16 shows how energy expenditure can be calculated from HR data using this method. HR is measured under laboratory conditions. For determination of HR_{max} and $VO_{2\,max}$, prediction equations can be used. For a more precise assessment, direct measurements are required. The HR values are transformed into %HRR values using the following equation:

$$\%HRR = [activityHR - restingHR)/(estimatedHR_{max} - restingHR)] \cdot 100\%.$$

Assuming that %HRR is equal to $\%VO_{2R}$, the relative intensity of the activity can be determined. Absolute VO_2 can be calculated using $\%VO_2$ for each activity by utilizing the equation

$$\%VO_{2R} = [activityVO_2 - restingVO_2)/(estimatedVO_{2\,max} - restingVO_2)] \cdot 100\%.$$



Activity heart rate (HR)
Age-predicted HR_{max} and resting HR
$\%HRR = \frac{\text{activity HR} - \text{resting HR}}{\text{estimated HR}_{max} - \text{resting HR}} * 100$
VO_{2max} and resting VO_2
For the prediction of activity VO_2 :
$\%VO_{2R} = \frac{\text{activity VO}_2 - \text{resting VO}_2}{\text{estimated VO}_{2max} - \text{resting VO}_2} * 100$
Divide by 3.5
Estimated METs

Fig. 49.16 Calculation of energy expenditure (metabolic equivalent tasks) using age-predicted percent heart rate reserve (%HRR) and estimated percent VO_2 reserve (%VO_{2R}), assuming that %HRR = VO_{2R} (modified from Strath et al. (2000))

The flex heart rate and %HRR methods have been validated by comparison with both whole-body indirect calorimetry and DLW. Validation studies have demonstrated a moderate to high degree of accuracy of both methods (Spurr et al. 1988; Livingstone et al. 1990, 1992; Strath et al. 2000). However, the reliability and validity of heart rate monitoring for measuring low-intensity physical activity are lower because of the non-linearity of the heart rate and $VO_{2\,max}$ relation during resting and light activity (Janz 2002).

Currently available heart rate monitors represent an easy and quick method for data collection, and they have a large data storage capacity (Hu 2008; Warren et al. 2010). They pose relatively low burden on the participant, although compared to accelerometers it may be more burdensome for individuals to wear chest belts. Heart rate monitoring measures physical activity of moderate to vigorous intensity well, and it shows a strong association with energy expenditure (Janz 2002).

49.7.2.4 Combination of Heart Rate Monitoring and Accelerometry

Recently, the combination of heart rate monitoring and accelerometry has been introduced for a more accurate assessment of physical activity with the idea that this method compensates for the limitations of each of its component methods. As described earlier, heart rate monitoring is less precise at low physical activity intensity levels. However, it provides reasonable accuracy at high-intensity activities. In contrast, accelerometry is more accurate at low-intensity physical activity levels and is less accurate at high-intensity levels. Moreover, physical activities such as cycling, carrying weights, and upper-body activities are not precisely assessed by accelerometers. However, they are well captured by heart rate monitoring (Brage et al. 2005; Strath et al. 2005). The measurement error from the two methods is not meaningfully correlated with one another (Brage et al. 2004).

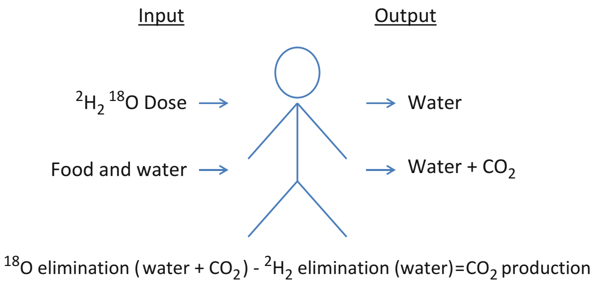
Heart rate monitoring and accelerometry have been applied simultaneously using two separate devices. The Actiheart sensor was the first sensor that combined both methods in one device (Brage et al. 2005). Barreira et al. (2009) validated the Actiheart against an AEI Moxus metabolic cart for light, moderate, and vigorous physical activity intensities and obtained Pearson's correlation coefficient of 0.79, 0.72, and 0.80, respectively (Barreira et al. 2009). Moreover, Brage et al. (2005) examined the reliability and validity of the Actiheart sensor and concluded that the Actiheart is reliable and valid. More validation and reliability studies of combined methods are required.

49.7.2.5 Direct Observation

Direct observational procedures of free-living physical activity behaviors can provide detailed and objective information on physical activity patterns, including activity type, intensity, and duration. They also allow researchers to record factors that are related to physical activity behavior, such as behavioral determinants and environmental conditions (Trost 2007). With a growing interest in the influences of the social and physical environment on activity behavior in young people, the use of this method has increased (Trost 2007).

Direct observation has commonly been used in children as a reference method to assess physical activity. Usually, an investigator will observe a child using a specific observation system and will enter a rating of the child's physical activity level into a computer or coding form (Warren et al. 2010).

One example of an established observation system includes the System for Observing Fitness Instruction Time (SOFIT) that is based on a five category scale (lying, sitting, standing, walking, very active) and uses momentary time sampling at 10 seconds observe/record intervals (McKenzie et al. 1991). This observational system allows studying influences on diet and physical activity in children in a variety of settings. The recently developed System for Observing Play and Recreation in Communities (SOPARC) evaluates physical activity types and levels and related information in boys and girls and people attending community-based settings, such as parks and recreation areas (Brown et al. 2006).



Input
Output
$^2H_2\,^{18}O$ Dose
Food and water
Water
Water + CO_2
^{18}O elimination (water + CO_2) - $^2H_2$ elimination (water)=CO_2 production

Fig. 49.17 Principle of the doubly labeled water method

The validity of the SOFIT was examined in fifth graders using a CALTRAC accelerometer ($r = 0.74$) (Sharma et al. 2011) and in elementary and middle school children using heart rate monitoring ($r = 0.80–0.91$) (Rowe et al. 1997). Interobserver reliability ratings of the SOFIT were >90% for estimates of energy expenditure, total energy expenditure, and time spent in moderate to vigorous activity (McKenzie et al. 2000).

The main strength of the direct observation method is that it provides broad information about physical activity behavior and related factors. However, direct observation does not allow assessment of activity intensity or energy expenditure. Direct observation can only be undertaken in controlled settings or small samples, and it requires considerable time and well-trained observers. In addition, the presence of an observer may lead to a reactivity effect, that is, to a change in habitual behavior (Trost 2007; Warren et al. 2010).

49.7.2.6 Doubly Labeled Water

DLW represents a method by which orally administered doses of the stable isotope tracers ^2H and ^{18}O are used to calculate TEE through carbon dioxide (CO_2) production in the human body. The study participant drinks a defined amount of water labeled with ^2H and ^{18}O and provides urine samples for the next 2 weeks. The ^2H will be eliminated from the body as water, whereas the ^{18}O will be eliminated from the body as water and CO_2 (Fig. 49.17). The difference between the elimination rates is proportional to CO_2 production. The CO_2 production rate is converted to energy expenditure using additional information on the respiratory quotient of food ingested (Starling 2002).

DLW is often considered the gold standard among physical activity assessment tools, and it has been widely used as a criterion method to validate other methods of assessment of physical activity, such as questionnaires, diaries, logs, and accelerometers. The method has been used in adults, children, and infants.

Validation studies of the DLW method against respiratory gas exchange suggest that the DLW method overestimates daily energy expenditure by 4% to 8% as compared with respiratory gas exchange (Schoeller and Webb 1984; Schoeller et al. 1986).

Strengths of the DLW method are that it precisely measures energy expenditure in adults and children in free-living conditions, and it also does not induce any change in physical activity behavior. However, one limitation of this method is that the production and analysis of the isotopes ^{2}H and ^{18}O are expensive and therefore not suitable for large-scale studies. Also, the DLW method does not provide information on specific activities performed. Furthermore, it does not allow distinguishing between RMR, AEE, and TEF. The combined DLW and indirect calorimetry application can overcome this limitation and may provide a robust measure of physical activity energy expenditure (Vanhees et al. 2005; Lee et al. 2009).

49.7.2.7 Indirect Calorimetry

Indirect calorimetry represents a physical activity measurement method that allows an estimation of energy expenditure. This method is based on measurements of oxygen uptake and carbon dioxide production with which energy expenditure can be established by equations (Starling 2002). The individual wears a canopy in the laboratory or a mask under field conditions for more extended measurement times, the investigation is performed in a metabolic chamber. The principle of this method is that controlled room air with known concentrations of O_2 and CO_2 is introduced to the plastic canopy or metabolic chamber and concentrations of O_2 and CO_2 are measured as the air leaves the system (Weir 1949; Vanhees et al. 2005). Energy expenditure can be calculated by entering the volumes of oxygen consumed and CO_2 produced into Weir's equation for calculating resting energy expenditure (REE) (Weir 1949):

$$\mathrm{REE} = [\mathrm{VO}_2(3.94) + \mathrm{VCO}_2(1.11)]\ 1{,}440\,\mathrm{min/day}.$$

Like DLW, indirect calorimetry is relatively expensive and burdensome for the participant and is therefore not feasible for large samples in epidemiological studies. Because of its high accuracy, indirect calorimetry is a widely used criterion measure for validating other physical assessment methods (Vanhees et al. 2005; Hu 2008). New portable devices for measuring RMR may provide an enhanced application of this method in the future (Nieman et al. 2005).

49.7.3 New Technologies in Physical Activity Assessment

Computers, other electronic media, and the internet represent advanced tools that are increasingly used to assess physical activity. Recently, mobile phones, smart phones, Geographic Positioning System/Geographic Information System (GPS/GIS) technology, and speech recognition have been introduced to physical activity promotion in free-living settings. Mobile phones and smart phones represent convenient devices to collect data on a large scale. Some mobile phones include integrated pedometers to monitor physical activity, although limited battery life still represents a disadvantage of these devices. Recently, speech recognition and text classification have been incorporated into physical activity assessment instruments. In speech recognition, recorded physical activity is transmitted into text via electronic circuits. Text classification allows documents to be assigned to predetermined categories according to a specific topic or function. Emerging technologies, such as GPS and GIS, represent tools that enable an accurate tracking of the interaction between people's physical activity and the surrounding environment, such as the route and temporal pattern of a walk or other movement (President's Council on Physical Fitness and Sports 2008). Recently, cell phone-based and other electronic-based diaries have been introduced (Zhu et al. 2006; Sternfeld and Dugan 2011). Zhu et al. (2006) developed an E-diary system by using voice recognition and text classification technology. Participants are reminded by a signal from a watch to record their past physical activity. They talk into a small digital recorder and record their physical activity during the past hour. The recorded voice is then converted to a text form and assigned to an activity category (e.g., "I walked the dog for 15 minutes" is classified into the category "walking") with a validity of 87% (Zhu et al. 2006).

49.7.4 Selection of a Physical Activity Assessment Method

The choice of an appropriate physical activity assessment method usually represents a trade-off between validity and feasibility but should primarily be motivated by the research question (Warren et al. 2010). Considerations that additionally impact on the selection of the method include the population studied, costs, participant burden, the capacity to perform the appropriate data handling and analysis, and experience in the assessment of physical activity (Warren et al. 2010). The study design and the physical activity outcome indented to be measured, which are central to the research question, may narrow the choice of potential physical activity assessment instruments. For example, if a ranking of individuals according to levels of activity for assessing associations in an observational study is required, one may choose between self-reported and accelerometry methods. Both methods provide physical activity outcome data and can be used at the population level, but the accelerometry method is usually restricted to a smaller sample size than the self-reported method. If information only on walking is required, then pedometry might be an appropriate method. The combination of two methods might compensate for the limitations of each method. Figure 49.18 shows available tools to be chosen to assess physical activity with reference to specific study designs.

Particular considerations are necessary when conducting studies in specific populations. For example, children's physical activity patterns consisting of short and frequent bouts and cognitive immaturation make it more challenging to select an appropriate assessment method. Direct observation is regarded as an accurate measurement tool to assess children's physical activity behavior. However, its limiting factors (costs, time, and data processing) may question the suitability of this method in certain situations. For children less than 10 years of age, a proxy report (e.g., by parents) may be the method of choice, although the limited validity of proxy reports should be kept in mind (Dollman et al. 2009). Previous day recalls may be appropriate for 10- to 11-year-olds, and activity diaries may be used in adolescents (Warren et al. 2010). Some researchers suggest using accelerometers or

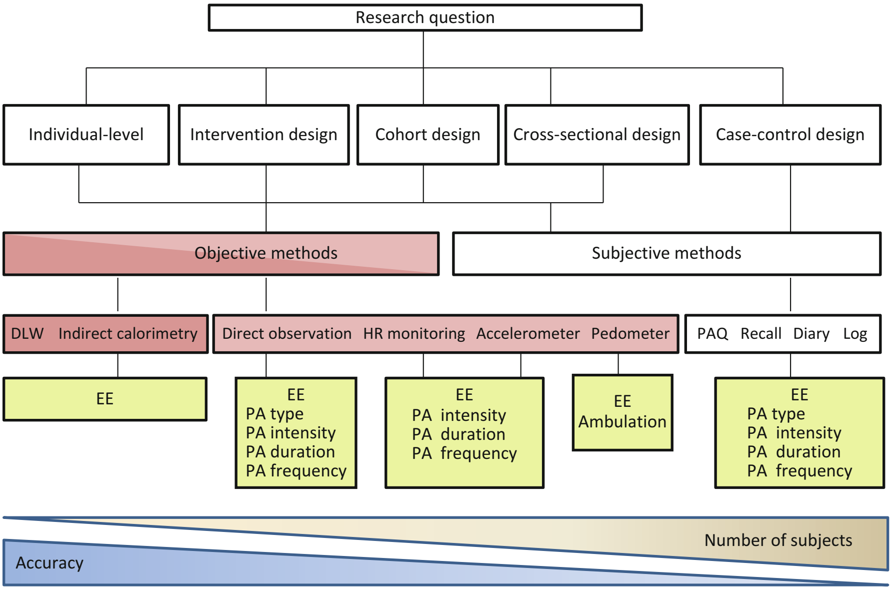


Fig. 49.18 Physical activity assessment methods according to different study designs; *DLW* doubly labeled water, *EE* energy expenditure, *PAQ* physical activity questionnaire, *PA* physical activity, *HR* heart rate (modified from Dollman et al. (2009) and Mueller et al. (2010))

a combination of accelerometers with self-reported methods for accurate assessment of children's physical activity patterns (Harris et al. 2009). To date, there is no unified concept regarding the optimal instrument to assess physical activity in youth.

Assessment of physical activity in the elderly may differ from that among young to middle-aged adults because the main activity in the elderly comprises walking and sedentary behavior. Motion sensors have been suggested as an appropriate tool, but they do not provide detail on physical activity type. Memory of past physical activity is also a concern in older people. Here, a combined approach of objective and self-report measures may allow a more accurate characterization of physical activity behavior (Harris et al. 2009).

49.8 Epidemiological Study Designs in Physical Activity Research

Epidemiological research of physical activity encompasses various study designs, including experimental studies such as randomized controlled trials (RCTs) and observational studies such as cohort studies, case-control studies, and cross-sectional studies. RCTs are generally considered the gold standard of study designs as they are most likely to yield unbiased results (Victora et al. 2004). Due to issues related to compliance, sample size, costs, and ethical considerations, the RCT design has rarely been used in physical activity epidemiological research (Caspersen 1989; Lee et al. 2009). By comparison, observational data from cohort and case-control studies are the main sources of evidence on the relationship between physical activity and risk of diseases (McTiernan 2011). This section describes the main study designs used in physical activity epidemiology including their strengths and limitations.

49.8.1 Cross-Sectional Studies of Physical Activity

The cross-sectional study design is used to examine correlations between engagement in physical activity and risk factors of diseases within populations at a certain point in time. Results from those studies may generate hypotheses and may identify potential mediators that can be targeted in intervention studies (Sallis et al. 2000; Bauman et al. 2002). Cross-sectional survey data are used by governments and institutions to provide descriptive statistics of physical activity at the population level (Garber et al. 2011). A cross-sectional study has the advantage over other studies that it is relatively easy and inexpensive to conduct by using routinely collected data (Mann 2003). However, the cross-sectional study design does not allow establishing temporal relationships between levels of physical activity and disease outcomes, as both variables are typically measured simultaneously, and thus, causality cannot be inferred from cross-sectional physical activity data. Moreover, linking changes of physical activity over time to disease outcomes may be crucial in establishing physical activity and disease relations. The NHANES was initially designed as a cross-sectional study, and it subsequently developed into a follow-up study when participants of the first survey were reexamined 10 years later. It provides both subjectively assessed physical activity by self-reported questionnaires and objectively measured physical activity via the accelerometry method. As mentioned above, NHANES also serves as a well-established surveillance system to provide nationwide descriptive data on physical activity and other health and risk factors of the US population (Centers for Disease Control and Prevention 2012).

49.8.2 Case-Control Studies of Physical Activity

Case-control studies have frequently been conducted to explore associations of physical activity with chronic diseases. For example, considerable evidence from case-control studies exists for an inverse association between physical activity and cancers of the colon, breast, and prostate (Colditz et al. 1997; Friedenreich 2001).

Cases with disease and control individuals who do not have that disease and represent the population that gave rise to the cases are asked to recall their past physical activity participation (Caspersen 1989). Compared with their control counterparts, cases may differentially recall or report their usual levels of physical activity (Caspersen 1989). Such potential differences in recall or reporting can lead to a biased estimate of the true relation of physical activity to the health outcome. A further methodological concern of case-control studies is selection bias.

For example, controls that are willing to participate in a case-control study are frequently more health conscious than subjects who decline to participate. Such health consciousness may be linked to increased physical activity among controls who choose to participate compared to subjects who decline to take part in a study, leading to potential selection bias.

The case-control study design in physical activity is best illustrated by an example. From 1995 to 1997, a population-based case-control study of 1,233 incident breast cancer cases and 1,237 controls was conducted in Alberta, Canada, that investigated the effect of lifetime physical activity patterns on breast cancer risk (Friedenreich et al. 2001). Lifetime physical activity was assessed by interviewer-administered questionnaires. No association between physical activity and breast cancer was found for premenopausal women. For postmenopausal women in the highest versus the lowest quartile of lifetime total physical activity, the adjusted odds ratio (*OR*) was 0.70 (95% confidence interval (CI) = 0.52, 0.94) and the strongest risk reductions were observed for household and occupational physical activity. The authors discussed the possibility of selection bias because of the modest response proportion among the controls (56.5%). Misclassification of physical activity through recall bias may also have been an issue in this study since respondents were asked to report detailed lifetime physical activity patterns retrospectively, and the detail of such reporting may have differed between cases and controls (Friedenreich et al. 2001). A classic retrospective case-control study design only allows ascertainment of physical activity behavior patterns using subjective methods such as PAQs or other recall instruments. Alternatively, one might conduct a nested case-control study by drawing cases and controls from a cohort study where objective measurements have been performed at baseline. This also overcomes the problem of selection bias.

49.8.3 Prospective Cohort Studies of Physical Activity

Observational studies of physical activity provide most of the evidence-based data available that support a beneficial effect of physical activity on the risks of morbidity and mortality (Garber et al. 2011). Particularly, data from prospective cohort studies revealed that increased physical activity participation may reduce the risk of CVD, cancer, and type 2 diabetes (Chomistek et al. 2012). Many studies have addressed the dose-response relationship of physical activity on different health outcomes for which a cohort study provides a superior study design than an RCT. Given a limited number of predetermined intervention arms, an RCT might not be able to capture the variety of physical activity behaviors including intensity, frequency, and duration in a real-life setting (Lee et al. 2009).

In cohort studies, participants are classified according to their physical activity status and are followed over time until the occurrence of disease. The possibility of recall bias is reduced as physical activity habits are assessed before the occurrence of the outcome (Hu 2008). However, this approach also faces methodological obstacles (U.S. Department of Health and Human Services 1998). Cohort studies of chronic conditions such as coronary events or cancer are expensive, as they require large sample sizes and long follow-up periods, and they also may be affected by selection bias when individuals are lost to follow-up. Furthermore, cohort studies are prone to reverse causation which can occur when a severe disease causes a reduction in physical activity levels rather than vice versa, which may lead to spurious results (Rockhill et al. 2001).

In prospective cohort studies, the most common methods used to query physical activity patterns are subjective methods, such as PAQs, or recall methods, but objective methods such as accelerometers have also been used.

The Nurses' Health Study represents an example of a prospective cohort study design including 121,701 female registered nurses aged 30 to 55 years who in 1976 returned a mailed questionnaire about their medical history and lifestyle. Since study enrollment, information about their medical history and lifestyle has been assessed biennially by self-administered follow-up questionnaires. In 1980, women were asked about their recreational physical activity habits, including the average number of hours spent each week during the previous year on activities such as heavy gardening, vigorous sport, running, walking or striding, bicycling, or heavy housework. In the 1982 questionnaire, the question was slightly modified ("For how many hours per week, on average, do you engage in activity strenuous enough to build up a sweat?"). In later years (from 1986 onwards), the physical activity questionnaires inquired about more detailed physical activity patterns. The Nurses' Health Study provides the possibility to perform long-term follow-up, including repeated measurement of physical activity which enables observation of changes of physical activity patterns over the life course. The study has investigated a large number of physical activity and health outcome relations, such as CVD, hip fractures, various cancers, and type 2 diabetes (Lee et al. 2009). Other prospective cohort studies that have addressed physical activity research questions include the National Institutes of Health (NIH)-AARP Diet and Health Study (Leitzmann et al. 2007), the American Cancer Society Cancer Prevention Study (Patel et al. 2008), the California Teachers Study (Mai et al. 2007), the Whitehall Studies (Sabia et al. 2012), and numerous other studies.

49.8.4 Randomized Controlled Trials of Physical Activity

While observational studies of physical activity primarily consider physical activity behavior as an exposure, RCTs have mostly focused on exercise. The RCT study design supports investigations on effects of exercise training on physical fitness and biomarkers of chronic disease or other intermediate factors (Garber et al. 2011). Thus, RCTs allow an unraveling of biological mechanisms to gain insight into etiological pathways linking physical activity to diseases which cannot be captured by observational studies. Compared to observational studies, findings on physical activity-related health effects resulting from RCTs are less likely to be confounded. For example, body mass index (BMI) is considered a major factor that influences physical activity and health outcome associations, and RCTs may only be minimally fraught with confounding by BMI. However, RCTs may not always be feasible to investigate CVD, cancer, or mortality as those endpoints require large sample sizes and/or long follow-up periods. Besides financial and ethical constraints, high dropout rates raise the possibility of selection bias, and non-adherence of the participants to the study protocol represents a potential concern (Caspersen 1989).

The multilateral nature of physical activity behavior includes various types and components, such as duration, intensity, and frequency, which may not be adequately captured in an RCT with only a limited number of intervention arms. As shown by the short time window in which a large number of findings in physical activity research have been produced in the past years, ongoing RCTs may not be able to follow the dynamic feature of physical activity research as their finite protocol does not allow the flexibility needed to tackle emerging issues and new research questions (Lee et al. 2009).

49.9 Methodological Considerations of Studies on Physical Activity and Disease

Each physical activity assessment method is characterized by specific strengths and limitations, and there is no single comprehensive measurement approach that can rule out all potential challenges. Methodological considerations include the precise assessment of physical activity, control for potential confounding, detection and reporting of effect modification, and a reasonable interpretation of the relationship between physical activity and disease outcome (Courneya and Friedenreich 2011). This section reviews methodological considerations that need to be taken into account when conducting studies and analyzing data on physical activity in relation to disease outcomes.

49.9.1 Measurement of Exposure

Discrepancies between studies examining the association between physical activity and a specific health outcome may arise from misconception and misclassification of the term physical activity. This may lead to inconsistency in physical activity assessment and in heterogeneity of the results. Also, systematic error in measurement of physical activity or covariates may lead to underestimation or overestimation of the association with a disease outcome (Schatzkin et al. 2009). In particular, estimating energy expenditure from self-reported PAQs is vulnerable to measurement error. For example, overreporting of the level of physical activity may lead to an overestimation of the true effect of physical activity on disease outcome. Compared to self-reported physical activity assessment, a stronger relationship between objectively measured physical fitness and all-cause mortality has been observed (Lee et al. 2011). Combining subjective and objective measures of physical activity may alleviate the limitations in estimation of energy expenditure by subjective measures alone.

Physical activity is an exposure variable that does not comprise a single factor, but rather includes a cluster of components, including intensity, frequency, and duration of recreational, occupational, transportation, and household physical activity (Caspersen et al. 1985). A greater reduction in breast cancer risk has been observed with vigorous compared to moderate-intensity activity (Friedenreich and Cust 2008). Also, a breast cancer risk gradient according to physical activity domain has been reported, with the greatest risk reduction in breast cancer observed for recreational activity (20% risk reduction), followed by walking/cycling for transportation (14% risk reduction), household (14% risk reduction), and occupational activity (13% risk reduction) (Friedenreich and Cust 2008). Thus, it is important to distinguish between physical activity components and domains when exploring the effect of physical activity on different health outcomes of interest.

Physical activity intensity has been categorized into levels of light, moderate, and vigorous intensity by using MET values as cut-points. MET values vary between age groups, and they also differ between obese and non-obese persons (Garber et al. 2011). Furthermore, the capacity for $VO_{2\,\max}$ varies by fitness status. Thus, when using intensity categories, one should bear in mind that MET values for lean persons might not be appropriate for the elderly or for obese persons. For example, 3 METs might represent light-intensity activity for a young and fit person but moderate or vigorous intensity for an older person.

Most studies linking physical activity to subsequent health outcomes have used baseline physical activity as an exposure. Repeated measurements of physical activity in prospective cohort studies may reduce misclassification of physical activity that arises from intraperson variation (Hu 2008). For example, the Nurses' Health Study found a stronger association between physical activity and the risk of cholecystectomy in a 10-year follow-up when using the cumulative average physical activity generated over subsequent follow-up periods than by using baseline physical activity measurement or the most recent assessment (Leitzmann et al. 1999). Moreover, repeated measurements allow teasing out different patterns and changes of physical activity over time which cannot be captured by a single measurement. It has been proposed that physical activity performed during different time periods in life, such as early, mid-, or later life, is important for reduction in risk of some cancers (Friedenreich and Cust 2008). These observations suggest that inconsistent findings in epidemiological studies of physical activity may be ascribed to differences in the time periods for which physical activity was assessed.

Studies of physical activity and disease or mortality frequently include analyses of dose-effect associations. Indeed, dose-effect relations with physical activity have been reported for a large number of diseases (Kesaniemi et al. 2001). Notwithstanding, misclassification of physical activity level may potentially occur when assigning divergent cut-points for dose-response analyses of continuous measures of physical activity (Lamonte and Ainsworth 2001). For example, a spurious result might occur when cut-points are chosen that maximize the desired effect of physical activity on a disease outcome rather than cut-points that are based on physiological threshold values.

Measurement error correction methods can be used to correct for both random and systematic errors but have rarely been used in epidemiological studies of physical activity. One study examined the effect of measurement error in estimating questionnaire-based physical activity by using data from a subsample of participants who completed four 7-day diaries of physical activity over a 1-year period (Leitzmann et al. 1999). That study reported a relative risk of cholecystectomy of 0.85 (95% CI = 0.80–0.90) associated with each 25-MET per week increase in physical activity that was reduced to 0.58 (95% CI = 0.43–0.77) after adjustment for errors in measuring physical activity.

49.9.2 Confounding

Observational studies of physical activity that do not adequately control for potential confounding factors may yield bias associations between physical activity levels and health outcome. Age, BMI, dietary and alcohol intake, smoking habits, and other health behaviors have been proposed to affect the association of physical activity with disease outcomes (Friedenreich 2001). Statistical adjustment for such potential confounding factors is necessary to evaluate the independent effect of physical activity on disease outcome. For example, inconsistent findings on the relationship between physical activity levels and risk of lung cancer have been documented. One study observed an inverse association between levels of physical activity and lung cancer risk which progressively became attenuated with increasing control for smoking intensity (Leitzmann et al. 2009). Moreover, physical activity was inversely related to lung cancer among current and former smokers but was unrelated to lung cancer risk among never smokers. Because smoking is associated with both levels of physical activity and lung cancer risk and is imperfectly measured, the authors assumed residual confounding by smoking as an alternative explanation for the apparently protective effect of physical activity on lung cancer risk among smokers. They argued that if there was a causal relationship between physical activity and lung cancer, an inverse association would be observed among both smokers and non-smokers. In studies of physical activity, confounding may also occur within different components of physical activity, each of which contributes to the volume of energy expended. For example, a relationship between a specific intensity of physical activity and the risk of disease may be due to an increased volume of the energy expended rather than to the intensity of the activity itself (Lee et al. 2009). In addition to adjustment for the volume of energy expended, adjustments should be made for the intensities of the other activities performed. For example, persons who engage in sports (vigorous intensity) may also more likely walk or use a bicycle for transportation (moderate intensity), the latter of which may constitute a confounding effect in an analysis of the effect of sports activities (Lee et al. 2009).

49.9.3 Effect Modification

Effect modification or interaction occurs when a third factor modifies the effect of physical activity on a health outcome. In physical activity studies, effect modification has been less studied, and little is known about dietary and other lifestyle factors modifying physical activity and disease relations (Slattery and Potter 2002). Sometimes, effects of physical activity vary among subgroups, depending on the characteristics of the population and other factors. One should bear in mind that interactions may also give rise to significant associations by chance (Willett 1998). Low sample size frequently poses a limitation for detecting effect modification and performing subgroup analyses. However, an understanding of modifying effects of physical activity can be useful to identify and explain differences in associations between physical activity and disease outcomes. Moreover, knowledge of modifying effects of specific factors on physical activity and disease associations may provide a better understanding of potentially relevant biological mechanisms (Slattery and Potter 2002).

For example, Patel et al. (2008) examined the role of BMI as a potential effect modifier of the relation of physical activity to endometrial cancer risk among women aged 50 to 74 years (Patel et al. 2008). They observed that increased physical activity was related to a decreased endometrial cancer risk and that BMI significantly modified that association. Specifically, an inverse relationship between physical activity and endometrial cancer risk was seen only among overweight or obese women (relative risk (RR) = 0.59; 95% CI = 0.42–0.83) but not in normal-weight women (RR = 1.01; 95% CI = 0.69–1.48) (Patel et al. 2008). Such data help increase our knowledge regarding the etiological pathways that potentially link increased physical activity with decreased endometrial cancer risk. Specifically, unopposed estrogen is a major determinant of endometrial cancer, and physical activity may decrease estrogen levels in postmenopausal women by reducing peripheral adipose tissue, which is the main source of estrogen production in postmenopausal women. Moreover, physical activity may affect endometrial cancer risk by reducing hyperinsulinemia, even in the absence of weight loss (Kaaks et al. 2002; Patel et al. 2008).

49.9.4 Mediation

A mediator is a variable that is affected by the exposure and lies on the causal pathway between exposure and disease outcome. In studies of physical activity and risks of cardiovascular disease (CVD) or diabetes, the variables blood pressure, high-density lipoprotein (HDL) cholesterol, and inflammatory markers have been suggested as intermediates on the causal pathway (Kesaniemi et al. 2001; Pischon et al. 2003). The Honolulu Heart Program investigated the association between physical activity and the incidence of coronary heart disease (CHD) and mortality during a 23-year follow-up in a cohort of 8,006 middle-aged men of Japanese ancestry (Rodriguez et al. 1994). They found a reduction in CHD morbidity and mortality with increased physical activity when adjusting for age only. When additionally including other risk factors for CHD in the multivariate model, such as hypertension, BMI, serum cholesterol, and diabetes, the physical activity effect estimate was attenuated and was no longer statistically significant, suggesting that those CVD risk factors may mediate the effect of physical activity on CHD. Controlling for intermediate variables that are on the causal pathway of disease can lead to statistical overcontrol and underestimation of the true effect of physical activity on disease outcome.

Sallis et al. (2000) identified several important correlates of physical activity, including social, psychological, demographic, biological, and physical environment factors. In future controlled trials of physical activity and disease outcomes, such correlates of physical activity may be used as mediating or moderating variables and may contribute to the identification of biological mechanisms (Bauman et al. 2002).

49.9.5 Reverse Causation

Epidemiological studies investigating the association of physical activity with a disease outcome are potentially prone to reverse causation. For example, an undiagnosed preclinical disease may cause a decline in physical activity, leading to a spurious relationship between physical activity behavior and the outcome. Rockhill et al. (2001) examined the association between recreational physical activity and mortality in middle-aged and older women in the Nurses' Health Study. They found a stronger inverse association between physical activity and respiratory death and death from other causes (e.g., dementia, chronic obstructive pulmonary disease, or cirrhosis of the liver) than deaths from cancer, CVD, and diabetes. The authors reasoned that part of physical activity and mortality relationship may be spurious and ascribed to reverse causation because women who died from respiratory disease or dementia were more likely to report major activity limitations before death than women who died from cancer or CVD (Rockhill et al. 2001). Analytical approaches to avoid reverse causation are as follows: (1) exclusion of individuals with chronic diseases such as cancer or CVD before or at study baseline, who may have become physically inactive because of health problems; stratification by the presence or absence of chronic diseases at baseline might also be possible; (2) control for potential confounding variables; if repeated measures are done, controlling for updated variables or changes in variables during follow-up is desirable and (3) ceasing the updating of physical activity data when an individual is diagnosed with chronic conditions such as CVD or cancer; also, conducting sensitivity analysis by excluding those with early deaths after diagnosis of disease (e.g., patients with CVD or cancer who died during the early years of follow-up) (Rockhill et al. 2001; Hu 2008).

49.9.6 Intra-Individual Variation: Day-to-Day and Seasonal Variability in Physical Activity Behavior

Physical activity levels among free-living humans vary from day to day and may depend on season, population characteristics, the physical activity component measured, and the days sampled (Matthews et al. 2001a; Ridley et al. 2009). Matthews et al. (2001a) examined sources of variance in physical activity levels

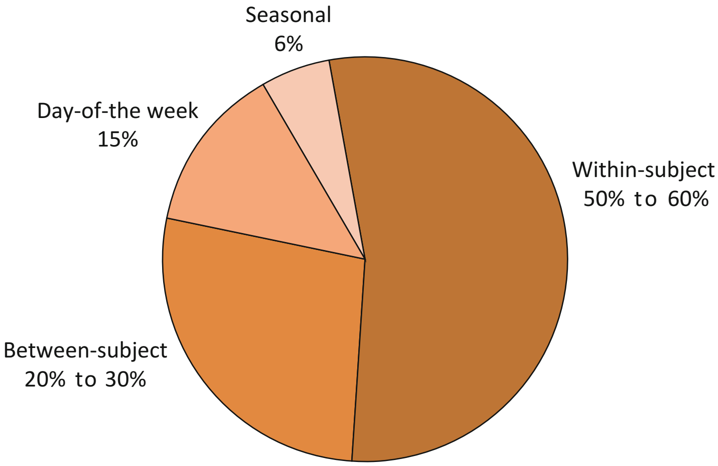

Fig. 49.19 Sources of day-to-day variation in total physical activity (Matthews et al. 2001a)

among adults in the Seasonal Variation of Blood Cholesterol (SEASON) study. The greatest source of variance in total activity was within-subject variance (50% to 60%), followed by between-subject variance (20% to 30%), day-of-the-week variance (15%), and seasonal effects (6%) (Matthews et al. 2001a) (Fig. 49.19).

Seasonal variation in physical activity is related to temperature, precipitation, and daylight (Matthews et al. 2001b; Merrill et al. 2005). In several studies, higher physical activity participation was observed in summer months than in winter months (Matthews et al. 2001b; Merchant et al. 2007). McCormack et al. (2010) investigated seasonal variability of different types and intensities of physical activity in adults and found that compared with winter, participation in walking for recreation was increased in the summer, autumn, and spring and that walking for transportation was increased in autumn. Moderate physical activity was also more likely in the summer. In addition, they observed age- and sex-dependent variation in vigorous physical activity participation (McCormack et al. 2010). Seasonal variability in physical activity patterns has also been shown to vary by BMI and type of physical activity. Matthews et al. (2001b) reported a smaller increase in summer recreational activity in obese or sedentary women compared to lean and active women. Sedentary men and women showed less seasonal variation in recreational activity than men and women who engaged in exercise and sports (Matthews et al. 2001b).

Nilsson et al. (2009) studied 9-year-old children and 15-year-old adolescents in four European countries (Denmark, Portugal, Estonia, and Norway) and found between- and within-day differences in overall physical activity levels, time spent in moderate to vigorous activity, and sedentary pursuits, which differed by sex, age, and geographical location. Specifically, engagement in 60 minutes of moderate- to vigorous-intensity activity and time spent in sedentary behaviors tended to be higher during weekdays than weekend days. Moreover, school-time and leisure-time activities varied between countries (Nilsson et al. 2009). Figure 49.20 shows

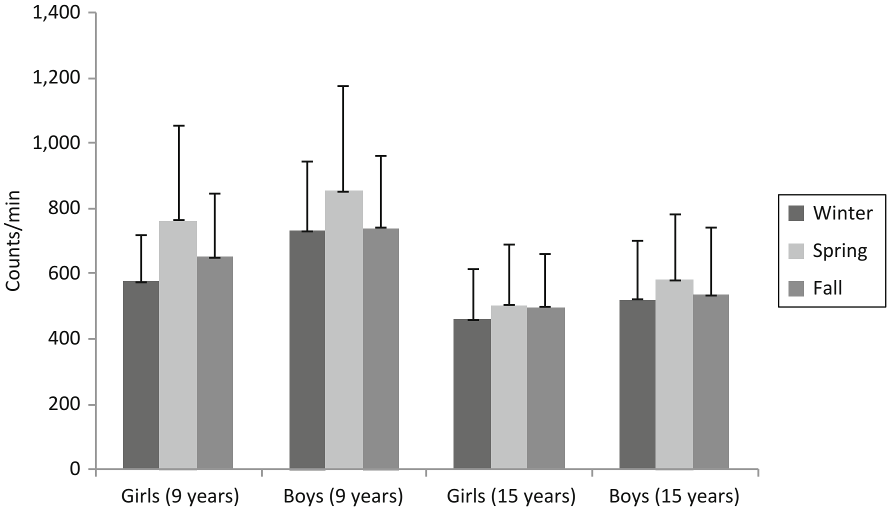

Fig. 49.20 Physical activity levels among children and youth stratified by age, sex, and season (Kolle et al. 2009)

physical activity patterns among 9- and 15-year-olds in Norway, which is a climatically diverse country (Kolle et al. 2009). Nine-year-old children showed significantly higher physical activity levels in the spring than in the winter or fall. By comparison, no differences in physical activity were observed among the 15-year-olds (Fig. 49.20) (Kolle et al. 2009).

Those data emphasize the importance of taking day-to-day variation in physical activity into account because errors may result from intra-individual variability in physical activity. Before conducting a study, an assessment of the number of days required to reliably characterize physical activity behaviors is required. An understanding of the nature of the variability in physical activity pattern in the population under study is necessary for an adequate design and analysis of the study and an appropriate interpretation of physical activity results (Matthews et al. 2001a). Measurement of physical activity at a single point in time is insufficient to capture variation in physical activity patterns. Physical activity assessment over 1 year captures seasonal variability in a population (Matthews et al. 2001a). Paying attention to day-to-day variation in physical activity behavior of individuals including seasonal variability may be important when designing intervention programs.

49.9.7 Causal Inference

The most widely cited epidemiological criteria of causality are those of Sir Austin Bradford Hill (1897–1991), who was the first to define nine criteria for judging whether an association between an exposure and an outcome is causal: consistency, strength, specificity, dose-response relationship, temporality, biological plausibility, coherence, and experiment (Hill 1965). Susser (1991) and the 1964 Surgeon General's Report (1964) used similar criteria to consider causal relationships, and all those criteria have temporality, strength, consistency, and specificity in common (Susser 1991; Department of Health, Education and Welfare 1964; Parascandola et al. 2006). However, these criteria and their implementation in scientific causality judgment have been widely debated. Hill's criterion of consistency encompasses the replication of findings involving different persons, places, circumstances, and time (Hill 1965). Given the multidimensionality and complexity of physical activity research, consistency might not entirely allow judging the causality of an association. From a logical perspective, a strong association between physical activity and a disease outcome might be more likely to suggest causality than a weak or modest association (Hoefler 2005). However, even weak physical activity associations might have biological meaning. In general, associations with disease outcomes are weaker with physical activity than they are with clinical parameters. Nevertheless, physical activity may represent a causal component of disease development. Causation of most diseases relies on the combination of multiple factors, such as dietary, lifestyle, genetic, psychological, and environmental factors, and the causal effect may be the sum of several small effects. Rothman and Greenland (2005) stated that strength does not represent a biological mechanism and may depend on the occurrence of other causes. In physical activity research, the strength of a physical activity effect on the occurrence of a disease may change over time as the prevalence of the determinants of physical activity changes even though the causal mechanisms leading to disease might remain unchanged. Temporality has been the most accepted criterion, assuming that a putative cause precedes the effect. In studies of physical activity in relation to disease incidence, it might be difficult to establish the temporal sequence between physical activity and the disease. For example, temporal sequence can be blurred when the disease has a long induction period (Rothman and Greenland 2005). In physical activity-disease relations in particular, it can be challenging to establish a temporal sequence as physical activity and physical condition are tightly linked, and disease occurrence may lead to reduced physical activity before diagnosis was made. Finally, it was Hill himself who stated: "none of my nine viewpoints can bring indisputable evidence for or against the cause and effect hypothesis and none can be required as a sine qua non" (Hill 1965).

49.10 Areas of Potential Future Development in Physical Activity Epidemiology

In recent years, a rapidly growing body of promising approaches has been achieved in physical activity research including approaches for disease prevention and the development of more advanced devices for physical activity assessment. Physical activity guidelines and intervention programs for the promotion of physical activity are based on the most updated research knowledge in physical activity epidemiology. There are still several unresolved questions that need to be addressed in future research to enhance our knowledge in this field and to incorporate that knowledge into effective physical activity intervention programs. To broaden our understanding of physical activity epidemiology, enhanced research on physical fitness and sedentary behavior is desirable, the latter of which is only beginning to accumulate available data. Moreover, we need to expand research on already existing approaches, such as the health-enhancing benefits of physical activity engagement, but we must also follow new promising theories and concepts. There is a strong research imperative of developing more sophisticated devices for physical activity assessment that allow moving away from subjective to objective physical activity measurements. Moreover, to establish appropriate and effective intervention programs, more emphasis should be placed on the exploration of determinants of physical activity, biological mechanisms linking physical activity to disease etiology, and physical activity behavior in population subgroups. This chapter summarizes areas of potential future research in physical activity epidemiology.

49.10.1 Improvements in Physical Activity Questionnaires

Despite their limited validity, PAQs are crucial in physical activity epidemiology as they represent an inexpensive and quickly administered tool to assess physical activity in large sample sizes at a relatively low participant burden. Compared to objective physical activity assessment instruments such as accelerometers, PAQs offer an advantage by providing a comprehensive measure of physical activity according to its types and components. Specifically, PAQs enable assessments of incline walking, water-based activities, and upper-body movements, such as rowing, activities that are not fully captured by uniaxial and triaxial accelerometers. Moreover, when comparing PAQs and accelerometers, PAQs better distinguish between closely related types of physical activities, such as light dancing and walking. Although considerable advances have been made in the area of questionnaire-based physical activity assessment during the past decades, future improvements in PAQs are needed (Matthews et al. 2012). Given the quantitatively significant contribution of light and moderate-intensity activities to overall energy expenditure and the potential gains in health provided by such activities, the methods used for precisely assessing the individual components of light and moderate activities should be given particular attention. For example, the cumulative effect of moderate-intensity activities, such as walking, may encompass a greater energetic impact on energy expenditure than the cumulative effect of short bursts of high-intensity sports activities (Westerterp 2001). In addition, more information is needed regarding which activities or combinations of activities performed in free-living individuals best meet the current physical activity recommendations. For example, it is currently not known whether leisure-time purposeful walking for 30 min a day on 5 days of the week better characterizes the aspect of physical activity that is relevant for disease prevention than the cumulative weekly amount of casual walking and stair climbing performed during housework, while shopping, and at the workplace.

49.10.2 Increased Use of Objective Physical Activity Assessments

Only a small number of available epidemiological investigations have used objective measures of physical activity, such as pedometers or accelerometers, to assess the association between physical activity and disease. However, objective devices show vast potential to provide more valid and reproducible assessments of physical activity levels than questionnaire-based measurements (Warren et al. 2010). They bear the limitation that activity from a previous time in life cannot be measured. As equipment costs continue to fall, these devices could reach widespread application in epidemiological research and population surveillance. New technologies, such as mobile phones, smart phones, interactive voice response, and interactive video games, also hold promise to become valuable tools for public health promotion of physical activity and delivery of physical activity interventions (van den Berg et al. 2007).

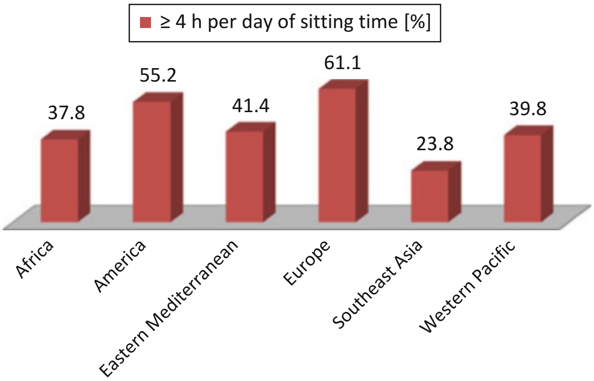
49.10.3 Measurement of Physical Fitness

Little is known about the impact of physical fitness on disease prevention. The sparse data available suggest that fitness is inversely related to risk of heart disease, cancer, and mortality (Blair et al. 1989). Some evidence indicates that physical fitness may be a more important determinant of health outcomes than physical activity, although this may be due to the imprecision in measuring physical activity as compared with the ability of assessing physical fitness. For example, in a study among men with type 2 diabetes, physically inactive men had a 1.7-fold (95% CI = 1.2–2.3) greater risk of all-cause mortality than physically active men, but the low-fitness group had a 2.1-fold (95% CI = 1.5–2.9) higher risk of all-cause mortality compared to fit men (Wei et al. 2000). In another study, a comparison of physical activity and cardiorespiratory fitness in relation to all-cause mortality revealed a stronger association of cardiorespiratory fitness than physical activity with all-cause mortality (Lee et al. 2011). Physical fitness represents an objective and reproducible measure that reflects recent physical activity habits and is not subject to recall bias and is also less likely prone to misclassification, behavior reactivity, and daily variation than physical activity. Thus, physical fitness may represent a superior measure or may provide additional information to studies on the relationships of physical activity to disease outcomes.

49.10.4 Assessment of Sedentary Behavior

From a societal and individual health-care perspective, being sedentary is currently perceived as the norm. Recently, it has been shown that 41.5% of adults worldwide spend 4 or more hours per day in sitting pursuits. As shown in Fig. 49.21, the time spent in sedentary behaviors varies considerably between WHO regions (Hallal et al. 2012). Sedentary behavior enhances the risk of heart disease, stroke, diabetes,

Fig. 49.21 Proportion (%) of individuals aged ≥15 years engaging in sedentary behavior by World Health Organization region (Hallal et al. 2012)



and cancer by 20% to 30% and decreases life span by up to 5 years (Wen et al. 2011). Thus, sedentary behavior places an enormous public health burden on society through burgeoning health-care costs and loss of productivity. Hu et al. (2003) examined the association between various sedentary behaviors and the risk of obesity and type 2 diabetes in women (Hu et al. 2003). For each 2 hour per day increase in time spent watching television, the risk of obesity was increased by 23% (95% CI = 17%–30%), and the risk of diabetes was increased by 14% (95% CI = 5%–23%). Sitting at work or standing was also associated with an increased risk of obesity and diabetes, albeit to a lesser extent than television watching (Hu et al. 2003). Gierach et al. (2009) observed an increased risk of endometrial cancer in women who sat 7 and more hours per day versus those who sat less than 3 h per day (*OR* = 1.56; 95% CI = 1.22–1.99).

Katzmarzyk and Lee (2012) evaluated the impact of sitting and television viewing on life expectancy in the U.S. population. Their analyses revealed that life expectancy in the U.S. population would be prolonged by 2 years if adults reduced their sitting time to less than 3 h per day and by 1.38 years if they reduced their television watching to less than 2 h per day. Thus, public health research and practical efforts to decrease sedentary behavior and to better understand the potentially adverse effects of sedentary behavior on disease risk are a priority (Thorp et al. 2011).

Sedentary behavior and physical activity have to be considered as two distinct concepts that may affect health independently. For instance, in high-income countries, persons are becoming more sedentary during their working time but are increasing their physical activity participation during recreation time. More research investigating the effect of this increasingly widespread physical activity pattern on health outcomes is needed.

49.10.5 Assessment of Physical Activity over the Life Course

An important area of future development in physical activity epidemiology is born from the need for increased knowledge of physical activity over the life course in relation to the maintenance of health and the prevention of disease.

It is unclear whether the potential for chronic disease risk reduction associated with increased physical activity is independent of the timing of physical activity or whether physical activity that is performed during potentially susceptible life stages is the relevant time period of potential risk reduction. For example, one study of timing of physical activity in relation to postmenopausal breast cancer risk among women aged 50 to 70 years of age found that increased levels of physical activity performed during the past 10 years were associated with decreased risk of postmenopausal breast cancer. By comparison, physical activity performed during the ages of 15 to 18, 19 to 29, and 35 to 39 years showed no relation to postmenopausal breast cancer reduction (Peters et al. 2009). Those data support the hypothesis that individual phases of hormonal change have distinct biological consequences that may differentially impact upon the association between physical activity and some types of cancers. There may also be distinct effects of physical activity levels at various stages during normal cell growth to diagnosed cancer. For example, Giovannucci et al. (1998) found no association between physical activity and total prostate cancer but reported a significant reduction in risk for metastatic prostate cancer comparing the highest with the lowest physical activity levels.

Similarly, physical activity relations may apply to further disease entities, such as heart disease and diabetes. For example, Wannamethee et al. (1998) investigated changes in physical activity in relation to the incidence of heart disease in older men. The men reported their physical activity participation once in 1978–1980 (Q1) and again 12 to 14 years later in 1992 (Q92). Those who were sedentary at the first point in time and who began participation in at least light activity by Q92 had a significant lower all-cause mortality risk than those who remained sedentary (*RR* = 0.55; 95% CI = 0.36–0.84). Moreover, change to a more active behavior improved both cardiovascular mortality (*RR* = 0.66; 95% CI = 0.35–1.23) and non-cardiovascular mortality (*RR* = 0.48; 95% CI = 0.27–0.85) (Wannamethee et al. 1998).

Thus, to tease out time-specific effects, more lifetime physical activity studies and investigations of changes of physical activity from sedentary behavior to more active behavior across different levels of physical activity are needed. Ideally, a comprehensive assessment of physical activity in a cohort study includes the measurement of levels of physical activity at various points in time. Moreover, RCTs and experimental studies are necessary to investigate the mechanisms by which physical activity timing influences disease risk.

49.10.6 Physical Activity in Tertiary Prevention of Disease

For some diseases such as cancer, the majority of physical activity research has been conducted on the primary prevention of disease, and less epidemiological evidence is available on the role of physical activity in tertiary prevention. For example, only a few studies have addressed the association between physical activity and mortality among survivors of cancers, such as prostate cancer, ovarian cancer, and colorectal cancer (Ballard-Barbash et al. 2012). Survivors of cancer or cardiovascular events have a higher risk of recurrence of disease and mortality (Chen et al. 2011; Roger et al. 2012). Moreover, it was reported that exercise may improve quality of life, cancer-related fatigue, and physical functioning in cancer survivors (Schmitz et al. 2010).

Survivors of cancer or a cardiac event may be more likely motivated to change their lifestyle along with enhanced physical activity participation than the general population. Thus, more physical activity research in survivors of chronic diseases is needed to guide physical activity recommendations on the secondary and tertiary prevention of diseases.

49.10.7 Assessment of Determinants of Physical Activity

The determinants and correlates of physical activity are complex, and they involve numerous factors, including age, sex, income, geographical location, transportation environment, and social and psychological factors such as self-efficacy and aesthetics. Identifying evidence-based personal and environmental determinants of physical activity represents an important step in designing appropriate intervention programs leading to changes in physical activity behavior (Trost et al. 2002). Future research requires enhanced assessments of determinants of physical activity in both high-income and low-income groups that incorporate cultural and country-level factors. Specifically, an increased knowledge of psychosocial, environmental, and economic determinants of transportation and recreational activity in low and middle income groups is needed to facilitate contextually tailored intervention programs aimed at thwarting the rapid development of a sedentary lifestyle brought about by increased urbanization, motorized commuting, and passive entertainment. Studying potential differences in physical activity determinants between low- and high-income groups might also help identify appropriate targets for intervention. For example, socioeconomic status may be inversely associated with total physical activity in low-income countries where transportation and occupational activity are the predominant domains of activity. By comparison, total physical activity may be positively associated with social class in high-income countries where recreational activity predominates.

49.10.8 Study of Physical Activity Levels in Population Subgroups

Considerable disparities exist in levels of physical activity in population subgroups. For example, Levine (2011) reported the greatest sedentariness being in the poorest countries. The author suggested several reasons for this observation, including violence that prevents from engaging in outdoor activities in poor regions, less availability of parks and sports facilities to people living in poor counties, and limited affordability of gym memberships and/or exercise equipment for persons who live in poverty. In future research, more attention should be paid to subgroups of individuals living in countries of low and middle income, socially disadvantaged individuals, ethnic/racial minorities, and persons with disabilities. Moreover, in light of the obesity epidemic, more attention should be paid to obese persons who are at risk for low levels of physical activity. Emphasis should be placed on research to clarify from which physical activity interventions these population subgroups will benefit most. This represents an important step in devising personalized disease prevention strategies. Individuals of these subgroups are more frequently exposed to social and/or environmental barriers to physical activity and may have fewer possibilities to overcome such obstacles than other population groups. Strategies need to be developed to reach these subgroups and to facilitate their access to intervention programs, for example, by mobilizing social networks (Marcus et al. 2006). When tailoring physical activity programs for weight loss and weight control in overweight and obese persons, we should bear in mind that being overweight and having sedentary habits is a barrier to becoming physically active (Sherwood and Jeffery 2000). To achieve weight loss, engagement in a higher amount of physical activity is required which might be difficult for such persons to perform. Moreover, overweight or obese individuals may additionally be burdened by physiological, behavioral, and psychological risk factors (Sherwood and Jeffery 2000). In addition, creation of a supportive environment to facilitate physical activity participation, including neighborhoods, parks, and recreation facilities, is imperative to create effective interventions for the promotion of physical activity. Thus, physical activity epidemiologists and public health professionals need to develop physical activity programs and policy initiatives to enhance physical activity opportunities in the entire population, with particular attention paid to efforts aimed at meeting the needs of population subgroups with limited access to physical activity.

49.10.9 Creation of Strategic Partnerships to Influence Physical Environments

Although an enhanced placement of physical activity within the area of public health appears to be important, a larger potential to increase levels of physical activity in the population might be changing the physical environment (Brownson et al. 2001). This is best accomplished through the creation of strategic alliances with sectors beyond public health. Thus, partnerships between policy makers and public health, behavioral, economic, and social scientists, specifically in the areas of transport and urban planning, should be developed. A systems-based approach incorporating qualitative and quantitative physical activity research with policy analysis is required to evaluate the multifaceted conditions that determine population levels of physical activity. Such data are needed to create the basis for building physical environments in which the opportunity to engage in a physically active lifestyle is easy, convenient, affordable, and safe. Cross-sectoral efforts that promote individual and population-level physical activity as a co-benefit are already in place, such as the creation of green spaces, pedestrian and bicycle systems, integrated transportation networks, traffic restriction, and taxation of petrol.

49.10.10 Examination of Biological Mechanisms Linking Physical Activity to Health

Given evidence of a protective effect of physical activity on disease risk and the potential existence of numerous biological mechanisms linking increased physical activity to decreased risk of disease, little is known about the exact biological pathways through which physical activity influences biological processes leading to protection from disease and improvements in prognosis (McTiernan 2008). Yet a thorough understanding of the biological mechanisms is pivotal to developing specific molecular targets for disease prevention and survival. In addition, the relation of the different components of physical activity to biological pathways remains to be defined. For example, it is not known whether a reduction in low-grade systemic chronic inflammation is best achieved by low-intensity activities such as walking or if vigorous activities such as jogging are required. The sparse data available suggest the existence of a "J"-shaped relationship between physical activity and chronic inflammation based on the commonly observed increase in the frequency of upper respiratory tract infections among elite endurance athletes during periods of intensive training (Walsh et al. 2011).

49.10.11 Expansion of Lifestyle Physical Activity Intervention Programs

Based on research studies and public health guidelines (Epstein et al. 1990; Blair 1993; U.S. Department of Health and Human Services 1996), Dunn et al. (1998) coined the term lifestyle physical activity as "…the daily accumulation of at least 30 minutes of self-selected activities, which includes all leisure, occupational, or household activities that are at least moderate to vigorous in their intensity and could be planned or unplanned activities that are part of everyday life." Thus, a lifestyle physical activity approach does not solely target persons who are interested in doing exercise training and sports, but also facilitates entry for a wider population, including sedentary individuals, to become more physically active thereby providing the potential for increased physical activity to improve health (Haskell 1994). Moreover, as time and access are the most frequently reported barriers to physical activity, the lifestyle activity approach may overcome these obstacles.

Most lifestyle activity interventions focus on approaches to behavior change in individuals and populations. Interventions are typically delivered by face-to-face contacts, telephone and mail, computer-mediated or web-based programs, or a combination of these components (Artinian et al. 2010). Further approaches include modifications of the environment, such as putting up signs to increase stair climbing (Dunn et al. 1998).

Although effective strategies regarding lifestyle activity interventions have been reported in the past (Dunn et al. 1998), there are still issues regarding the promotion of lifestyle activity interventions that need to be targeted in future research. Those include the development of lifestyle intervention programs in different population groups to determine which intervention is best effective for which group. Furthermore, new technologies such as text messaging and social networking for promotion of lifestyle activity should be taken into account (Artinian et al. 2010). Follow-ups of intervention programs are necessary to explore their efficacy with regards to long-term lifestyle activity maintenance (Dunn et al. 1998). Additionally, both behavioral interventions and environmental manipulations need to be tested for their cost-effectiveness. Lifestyle physical activity intervention strategies that are effective under real-life conditions are of major importance, and an understanding of how to embed these strategies in health practice along with organizational and policy issues is an important concern that requires consideration (Artinian et al. 2010).

49.10.12 Evaluation of Vigorous Activity to Promote Body Leanness

While the 1995 ACSM/CDC physical activity recommendation posits the promotion of moderate physical activity (Pate et al. 1995), the 2007 and 2011 ACSM guidelines additionally include recommendations on vigorous-intensity activities for muscle strength and bone health (Haskell et al. 2007; Garber et al. 2011). It has been shown that vigorous physical activity exerts beneficial effects on overall and visceral fat, and bone mass (Kohrt et al. 2004; Friedenreich et al. 2011). Recently, a new theory has emerged which hypothesizes that vigorous physical activity promotes the differentiation of immature stem cells into lean tissue cells rather than into fat cells through mechanical stimulation (Luu et al. 2009). In mice, it was found that low-magnitude mechanical signals promote bone development while inhibiting the development of fat mass. Moreover, in 15- to 20-year-old women with osteopenia, similar observations have been made with mechanical stimulation, which led to an increased bone mass and reduced visceral fat in the lumbar area (Luu et al. 2009). Further research on vigorous activity is needed in support of this theory, which may represent a basis to simultaneously prevent obesity and osteoporosis.

49.11 Conclusions

Physical activity epidemiology represents a young scientific discipline which has emerged over the past decades. It represents a research area concerned with understanding the associations between physical activity and morbidity and mortality, and its interrelations with other health factors. The goal of physical activity epidemiology is to apply that knowledge to intervention programs and to inform recommendations for the prevention and control of diseases and the promotion of health.

There is mounting evidence for benefits of physical activity on mortality, CVD, various types of cancer, type 2 diabetes, and other diseases. However, the recent descriptive epidemiology of physical activity has revealed a decline in overall physical activity participation along with a steady increase in sedentary behavior among populations of industrialized countries. Physical activity research describes a dynamic process continuously building new knowledge about the effect of physical activity on health of which the best evidence provides the basis for physical activity recommendations and intervention programs. For the past two decades, there has been consensus among several governmental bodies and organizations on the recommendation of engaging in at least 30 minutes of moderate physical activity on most days of the week for beneficial health. Engagement in vigorous-intensity activity and resistance training for major muscle groups several times during the week are also elements of the current recommendations. The lifestyle physical activity approach describes a promising strategy to overcome time and access barriers to physical activity and to reach a wider population including sedentary individuals.

Strong research designs should provide the optimal basis for guidelines and effective physical activity intervention programs. Physical activity is a complex and multifaceted human behavior with large day-to-day variability, and its accurate quantification remains a challenge in physical activity research. Before conducting analyses of physical activity, a number of issues need to be considered including considerations regarding methodological aspects (e.g., study design, confounding, reverse causation), the nature of physical activity assessment (e.g., subjective or objective measures), dimensions of physical activity (e.g., intensity, duration, frequency), and population characteristics (e.g., age, sex, geographical location). The selection of a specific study design depends on the research question, and it represents a balance between the needs for accuracy and feasibility. Observational epidemiological studies allow an assessment of physical activity patterns under free-living conditions on a large scale. Information on potential biological mechanisms linking physical activity to diverse disease outcomes is best derived from RCTs and laboratory experiments.

Physical activities of light to moderate intensity, which are often performed as part of daily routine activities and reflect the nature of physical activity among children and the elderly, are more difficult to measure and cannot easily be captured by standard physical activity measurement methods. Physical activity questionnaires allow the assessment of movement in free-living conditions in large samples, albeit at the expense of accuracy. Objectively measured physical activity by accelerometers provides more accurate measurements yet can be limited by cost implications in large-scale investigations and does not provide retrospective physical activity information. DLW and indirect calorimetry represent the most accurate instruments for assessment of energy expended, but they are limited to controlled laboratory settings and to small numbers of individuals and thus solely serve as criterion methods.

Methodological considerations, including appropriate control for confounding, and causality issues are important in epidemiological studies to infer meaningful associations between physical activity levels and health outcomes. Repeated measurements of physical activity during follow-up reduce measurement errors and allow detecting sensitive time frames in disease development in relation to physical activity exposure.

Although considerable progress in physical activity research has been made in recent years, many unresolved questions in physical activity epidemiology require further attention. Besides the development of more sophisticated devices of physical activity measurement, moving from laboratory settings to large-scale studies of physical activity on disease outcomes across all ages under free-living conditions is needed. Furthermore, analyses of those at risk for low engagement in physical activity, such as people with disabilities, obese individuals, ethnic/racial minorities, or socially disadvantaged persons, are encouraged to establish personalized disease prevention strategies. Little is known about biomarkers and etiological pathways through which physical activity affects health outcomes. Thus, improving our understanding of determinants of physical activity and identifying biological mechanisms may help devise intervention strategies for the prevention of diseases and premature mortality. Moreover, enhanced research on physical fitness is required, which may provide additional information about the health effects of physical activity. Our public health goal is moving from sedentariness to a more active population. Thus, in addition to physical activity pursuits, more attention should be paid to time spent in sedentary behaviors in relation to health effects. Finally, while continuing the efforts to build the evidence basis on health effects of physical activity and sedentary behaviors, building a bridge between physical activity research and policy makers and scientists of related research fields is warranted to facilitate behavior modification and environmental change for the promotion of increased physical activity.

50.1 Introduction

Radiation epidemiology aims at investigating the health effects of radiation exposure due to different types of radiation. It is one of the best established specialized fields of epidemiology. The discovery of ionizing radiation in 1895 led to a wealth of subsequent scientific studies on physical, biological, and clinical radiation effects. Medical scientists and epidemiologists have continued to show intense interest in exploring health effects of radiation exposure in environmental, medical, military, and occupational settings, and the large studies of radiation-exposed populations belong to the milestones of international epidemiological research.

Under the label of radiation epidemiology, research on different types of radiation and their health effects is being conducted. The effects of radiation can roughly be categorized to be either ionizing or non-ionizing. Non-ionizing radiation includes electric and magnetic fields and ultraviolet radiation. Ionizing radiation, the topic of this chapter, probably belongs to the best studied human carcinogens, comparable only to tobacco smoke. Both observational epidemiology and experimental research have provided conclusive evidence on the carcinogenicity of ionizing radiation (IARC 2000). However, other effects of ionizing radiation are also well understood and technologically utilized, perhaps most notably the cell-killing properties of ionizing radiation in cancer therapy.

In radiation epidemiology, one large study continues to be a cornerstone for risk estimation and a benchmark for other studies in the field: the Life Span cohort Study (LSS) of the atomic bomb survivors in Hiroshima and Nagasaki in 1945. The study is continuously being updated and now covers a follow-up period of more than 50 years (Ozasa et al. 2012). The influence of this one study sets the field apart from other areas of epidemiology where no such reference exists. Beyond the LSS, an ever-increasing number of epidemiological studies with improved exposure assessment and study methodology contribute to the current knowledge about health effects of ionizing radiation.

Developments in radiation epidemiology have not only been important for an improvement in the understanding of health effects and the subsequent adaptation of radiation protection standards but also for methodological advances in the planning, conduct, and analysis of epidemiological studies. Hence, radiation epidemiology is both an important contributor to the historical scientific development of epidemiology and to ongoing research, methods development, and risk communication. This chapter gives an overview of radiation sources and exposures and then focuses on exposure assessment and examples of studies in the field. The importance of radiation epidemiology for radiation protection as well as current developments in research and open questions are highlighted.

50.2 Sources of Radiation Exposure

There are various natural and man-made sources of ionizing radiation, and virtually all of these sources have been studied with regard to their health effects for humans. A major part of population exposure to ionizing radiation comes from natural sources. Natural radiation exposure is composed of internal and external components.

Via inhaled air and nutrition, human beings have always been exposed to natural radioactive substances. The inhalation of radon gas generally is the largest natural source of radiation contributing to the exposure of the general population. Radon (radon-222) has a half-life of 3.8 days and is the most stable isotope in the radium and uranium decay chain. Radon exposure originates from rocks and soils and varies geographically depending on the local content of radionuclides like uranium and thorium. Indoor exposure to radon gas depends on radionuclide concentrations in soil, shielding and isolation, as well as on building materials (WHO 2009).

Furthermore, radioactive isotopes in food and water lead to internal radiation exposure. Exposures from eating and drinking water are due in part to the uranium and thorium series. Radioactive carbon (carbon-14) is present in all organic matter, accumulates in the food chain, and contributes to the internal background dose from ionizing radiation.

Terrestrial radiation originates from natural radioactive substances which exist in the soils and rock layers of the earth's crust. Rocks and soils are also important raw materials for building materials such as bricks and concrete. Hence, the radionuclides contained in these materials also contribute to external radiation exposure of residents in buildings.

Cosmic rays are radiation that travels through interstellar space. Known sources of this radiation are, among others, the sun and supernovae (exploding stars). The earth's magnetic field provides some protection from cosmic radiation. On the earth's surface, cosmic rays lead to effective doses of around 0.3 millisievert (mSv) per year (for explanation of dose quantities, see Sect. 50.3). The exposure increases with increasing altitude, notably during air travel (Bartlett 2004).

The per capita effective annual dose from all natural radiation sources combined is estimated to be around 2.4 mSv (UNSCEAR 2008). Of this amount, about 1.1 mSv per year comes from radon and its decay products. However, the individual exposure to natural radiation varies considerably due to large differences in environmental concentrations and in population habits (Hendry et al. 2009).

In addition to natural sources, man-made sources contribute to the individual annual dose with an estimated worldwide average of about 0.6 mSv. In many developed countries, these doses are much higher. In Germany, for example, average doses from man-made sources amount to about 2.0 mSv per year. Medical uses of radiation are largely determined by the degree of development of the respective health-care system and contribute the greater part of these exposures, while occupational sources, nuclear power generation, and fallout from nuclear weapons tests generally make comparatively minor contributions. As an example, Fig. 50.1 shows the relative contribution of different radiation sources in Germany (Federal Office for Radiation Protection 2012).

In the field of diagnostic radiology, a rapid increase of computed tomography (CT) use was observed in many countries during the past 20–30 years. The estimated annual number of CT examinations in the United States rose approximately

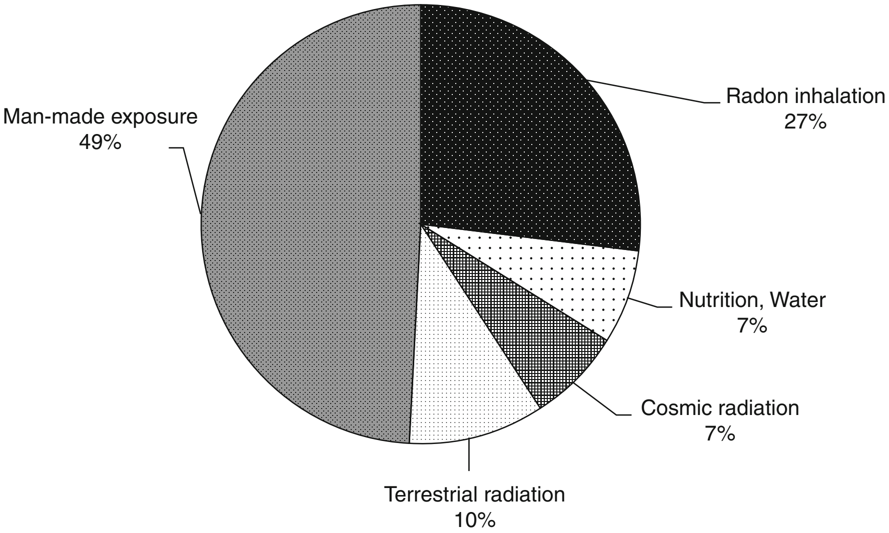

Fig. 50.1 Sources of ionizing radiation in Germany (proportion of total effective dose in %)

Table 50.1 Average effective dose levels from medical procedures compared to the doses of atomic bomb survivors

Medical procedure	Effective dose in mSv[a]
Chest X-ray	0.01
Dental X-ray	0.01
Mammography	0.2
CT chest	10
CT abdomen and pelvis	15
Radiotherapy (average dose to target organ)	30,000–70,000
Atomic bomb survivors (mean dose)	∼200

[a] *mSv* millisievert, generally equal to *mGy* milligray in the examples given here; see Sect. 50.3 for dose quantities

sevenfold from 2.8 million in 1981 to 20 million in 1995 (Brenner et al. 2001). The CT radiation doses are relatively high compared to most conventional X-ray examinations. Thus, CT is a major contributor to the collective diagnostic dose of the population in developed countries. CT doses are of particular concern in pediatric radiological imaging. Compared to adults, children are at higher risk for developing cancer caused by ionizing radiation mainly due to an increased radiosensitivity and a longer life span after exposure (Brenner et al. 2001). To date, ionizing radiation is the only established environmental risk factor for childhood leukemia (Greaves 2006; Lightfoot and Roman 2004).

Table 50.1 shows the effective dose levels from medical procedures in relation to the mean dose of atomic bomb survivors. Note that doses vary considerably depending on technical and patient characteristics.

Therapeutic uses of ionizing radiation differ from diagnostic radiology procedures both in purpose and in the employed doses. Radiotherapy is an important treatment option for many malignant diseases. In most cases, patients receive high doses of radiation in the order of 40–60 gray (Gy) to the target region. Studies of patients treated with radiation provide important information about the carcinogenicity of radiation, on the effects of different radiation types, and on the role of sex, age, or genetic susceptibility (National Research Council 2006). Large cohorts of radiation-treated patients who have been followed for long periods are available and allow the assessment of the risk of a second primary cancer. An example is the British Childhood Cancer Survivor Study (Reulen et al. 2011) (see also Sect. 50.5).

Ionizing radiation was also used for the treatment of certain benign diseases, for example, benign breast diseases, peptic ulcer, and benign thyroid diseases; there are very restricted uses for ionizing radiation in this context nowadays. Even among children, radiotherapy was used to treat diseases such as fungal scalp infections (tinea capitis), enlarged thymus gland, or benign head and neck diseases. In a US cohort of 601 women treated with radiotherapy for acute postpartum mastitis (APM) between 1940 and 1957, the average dose to the breasts was 3.8 Gy. In comparison to non-irradiated control groups, a more than threefold relative risk (RR) for breast cancer of the irradiated breasts was found (Shore et al. 1986).

Occupational exposures account for only about 2% of the man-made exposure overall (National Research Council 2006). However, for specific groups of occupationally exposed workers, these exposures can be substantial. Persons with occupations involving the medical use of radiation were among the first groups where adverse health effects could be demonstrated (March 1944). Other groups include uranium miners, such as the large group of mine workers in the former German Democratic Republic who were highly exposed to radioactive radon (Walsh et al. 2010). Employees in the nuclear power production are exposed to low protracted doses of radiation (Cardis et al. 2005).

Nuclear weapons testing was (with few exceptions) conducted between 1945 and 1980. These tests led to worldwide dispersion of radioactive material in the atmosphere (nuclear fallout) and subsequent radiation exposure. The worldwide average annual effective dose reached a peak of 110 microsievert (μSv) per person in 1963 and has since decreased to about 5 μSv/year. Furthermore, several accidents have led to releases of radioactivity to the environment, among them the Kyshtym accident in 1957 (Russia), the Windscale accident in 1957 (UK), the Accident at Three Mile Island in 1979 (USA), the Chernobyl accident in 1986 (Ukraine) (UNSCEAR 2008), and the Fukushima accident in 2011 (Japan). Children and adolescents exposed to radioactive iodine from the Chernobyl plant showed a dose-related increase in thyroid cancer occurrence (Cardis and Hatch 2011).

In 1945, at the time of the detonation of the atomic bombs, about 500,000 people lived in Hiroshima and Nagasaki. About 200,000 died immediately due to superficial burns, acute radiation syndrome, or injuries. In 1950, the National Census of A-Bomb-Survivors registered about 280,000 victims affected by the bombings. Japanese and American scientists recruited a cohort of 120,000 persons from among the survivors and set up what is now known as the Life Span Study (LSS). This cohort study has become the principal basis for estimating radiation risk of cancer and other diseases because it comprises a wide range of radiation exposures and a relatively accurate dosimetry with estimated radiation doses to numerous organs and tissues (National Research Council 2006) (see also Sects. 50.3 and 50.5).

50.3 Radiation Exposure: Doses and Measurement

50.3.1 Basic Principles of Radiation Physics

Radiation is energy or, equivalently, matter that travels through space and time. It can be roughly categorized into particle radiation and electromagnetic waves – both of which will be described in more detail below. Along its way, radiation can physically interact with the irradiated matter. Depending on the energy content of the radiation, it may either be of the *ionizing* or of the *non-ionizing* variety. The former possesses an energy content larger than the electronic binding energy, therefore possibly altering the electronic configuration of atoms and molecules. The ionization process leads to the emission of a shell electron from the Coulomb field of the atomic nucleus and leaves behind charged atomic or molecular ions.

Ionizing radiation can be many different physical entities, that is, charged energetic particles (e.g., protons, muons, pions, alpha particles, or heavier clusters), neutrons, or high energy, that is, short-wavelength electromagnetic radiation. With non-ionizing radiation, one usually refers to comparatively low-energy, long-wavelength electromagnetic radiation.

Because the chemical bonding pattern between atoms or molecules is determined by their electronic structures, ionization processes can break chemical bonds. Damage of the organic molecule deoxyribonucleic acid (DNA) by ionizing radiation can eventually lead to the development of cancer in the affected individual.

There are stable and instable atomic nuclei. The latter are also called *radioactive nuclei* or *radionuclides*, for which their exact time of decay cannot be predicted as radioactive decay is a stochastic process that, in almost all cases, cannot be influenced from the outside. This is reflected by the concept of *half-life*, which is the time span in which the activity of a specific radioactive substance decreases to 50% of its initial value. The half-life $T_{1/2}$, the mean lifetime τ, and the so-called decay constant λ, which pertain to the probability of a radioactive nucleus to change its state within a given time interval, are related via

$$T_{1/2} = \ln(2/\lambda) = \tau \ln 2.$$

The SI unit (French: Système international d'unités, international system of units) for the activity of a radioactive substance, that is, the number of radioactive transformations per time, is the reciprocal second (s^{-1}) called *becquerel* (Bq). An obsolete, historical unit for the activity is the *curie* (Ci).

If a radioactive atomic nucleus decays in order to attain an energetically more favorable configuration, energy is emitted, in many cases, in the form of *alpha*, *beta*, or *gamma* radiation.

Alpha particles are simply the doubly positively charged atomic nuclei of the element helium, so they consist of two protons and two neutrons. They are predominantly produced by heavier instable nuclei. Two prominent examples of alpha-emitting radionuclides in the context of epidemiology are the isotopes of radium (Martland and Humphries 1929) and radon (Grosche et al. 2006).

Beta radiation consists of elementary particles of negatively charged electrons (β^- radiation) or positively charged positrons (β^+ radiation).

Gamma decay is the emission of nuclear excitation energy in the form of electromagnetic radiation. Here, the mass number, that is, the nucleus' total number of neutrons and protons, remains unchanged, while the energy and actual mass of the nucleus decreases. A prominent example is the gamma decay of the metastable state of barium-137 to that isotope's ground state following the beta-decay of cesium-137 to metastable barium-137. Cesium-137 is a radiologically relevant radionuclide, for example, in nuclear accidents like those in Chernobyl or Fukushima. Hence, the respective emission of 662 kiloelectronvolt (keV) gamma radiation by metastable barium-137 is routinely used for the physical detection of cesium-137 using gamma spectrometry.

Gamma radiation can be regarded both as electromagnetic waves or as another type of elementary particles (photons). In that, it is only distinguishable from other types of electromagnetic radiation, for example, visible light, by its energy content or, equivalently, its (short) wavelength which enables ionization of atoms or molecules. This does not only include gamma radiation from radioactive decay but also the X-rays well known from medical applications and also short-wavelength parts of the ultraviolet spectrum (ultraviolet light does not derive its particular skin cancerogenicity from this fact, though). All other electromagnetic radiation, including the infrared, visible, and radio wave parts of the electromagnetic spectrum, belong to the non-ionizing radiation.

Ionizing radiation can be categorized by the way it causes the ionization of the irradiated target. Charged particles like alpha particles, beta particles, or protons belong to the directly ionizing radiation because these particles are mainly responsible for the ionization of the target. Indirectly ionizing radiation includes the uncharged photons and neutrons that produce charged secondary particles, which are *mainly* responsible for the ionization of the target matter. This does not mean, though, that indirectly ionizing radiation like neutron radiation is less dangerous than directly ionizing radiation (see *relative biological effectiveness* in the following section).

The shielding of ionizing radiation heavily depends on the exact type of radiation. Alpha particles, on the one hand, are typically stopped in air after a few centimeters, depending on their energy, and can be effectively shielded by a sheet of paper. Hence, they derive their radiological relevance mainly from situations where they have been incorporated through ingestion or inhalation. Beta particles, on the other hand, can travel some meters in air but are usually stopped by just a few millimeters of aluminum. For the shielding of photons, thick layers of lead or other absorbers with high atomic numbers are necessary. The situation is again different for neutrons, where substances like paraffin or water are most suitable for moderation or shielding because they are facilitating neutron-proton scattering (Grupen 2010).

Humans cannot sense ionizing radiation. For the purpose of surveillance and exposure limitation as well as for exposure assessment in epidemiological and other studies, devices to measure radiation are needed. The most simple gas-filled radiation detector is the ionization chamber, which, in principle, already allows some spectroscopic analyses. The fiber or pen dosimeter is a common ionization chamber for radiation protection and personal dose measurement. Proportional and Geiger-Müller counters are based on similar physical principles as the ionization chamber but, depending on their respective design, can be used as robust measurement devices for contaminations or ambient doses. In thermoluminescence dosimeters, used, for example, in the form of film badge dosimeters, the blackening of a photographic film is employed as a measure for the received radiation dose. Radiation measurement of environmental samples is nowadays often conducted using (liquid) scintillation counters or semiconductor detectors allowing high-resolution spectroscopy for the differentiation of the various radionuclides.

50.3.2 Dose Quantities and Dosimetry

Since radiation effects on humans are ultimately based on the absorption of radiation energy in tissue, the *energy dose D* can be regarded as a fundamental physical dose quantity. It is the absorbed energy per mass of the absorbing material. It has the unit *gray* (Gy), derived from the SI units for energy (joule, J) and mass (kilograms, kg):

$$1 \text{ Gy} = 1 \text{ J kg}^{-1}.$$

Other physical dose quantities are the *ion dose* and the *kerma*. The ion dose is the produced electrical charge per air mass in an air volume irradiated with ionizing radiation. It has the unit coulomb per kilogram (C kg^{-1}).

The word “kerma” is an acronym for “kinetic energy released per unit mass” (Grupen 2010) and refers to the ratio of the kinetic energy transferred to charged secondary particles from indirect ionizing radiation and the mass of the irradiated volume. The kerma also has the unit Gy.

The described physical dose quantities do not accurately describe the relative biological effectiveness of the various types of radiation. Alpha radiation, for example, belongs to the *densely ionizing radiation*. Its high ionization density entails less effective biological repair mechanisms. Alpha radiation thus has a higher biological effectiveness than, for example, the *sparsely ionizing* electrons, as the response or reaction of a biological system to these different types of radiation differs substantially. Hence, in radiation protection, special dose quantities are used

Table 50.2 List of radiation weighting factors (ICRP 2007)

Type of radiation	w_R
Photons	1
Electrons and muons	1
Protons and charged pions	2
Neutrons	5–20
Alpha particles, fission fragments, heavy nuclei	20

that are derived from the energy dose, but cannot be regarded as physical dose quantities. To differentiate these dose quantities from the energy dose, the unit *sievert* (Sv) with the same relation to SI units is being used:

$$1 \text{ Sv} = 1 \text{ J kg}^{-1}.$$

Thus, Gy and Sv are the same in terms of SI units, but Gy relates simply to an energy dose, whereas Sv includes a measure of biological reaction to the respective type of radiation not included in Gy. Further biological aspects of cell, tissue, and organ response to radiation need to be taken into account when aiming to assess radiation effects on the body.

With the development of a comprehensive system of radiation protection, this became important in the context of efforts to better quantify the risk of stochastic (cancer and genetic) effects. These efforts included the estimation of cancer risks for a number of organs and the concept of a weighted whole-body dose as summary value. Weights were based on the organ-specific cancer risk. The main idea was to create a single value with which different types of radiation and different distributions of radiation in the body could be compared. This resulted in the effective dose concept, details of which are explained in the following section.

Energy dose D and the specific radiation type can be linked via the equivalent dose H_R which is calculated from the energy dose D using

$$H_R = w_R \cdot D$$

with the radiation weighting factor w_R for the radiation type R. By means of this factor, the different relative biological effectiveness of the various radiation types can be accounted for (Table 50.2).

For the radiation weighting factor of neutrons, an energy-dependent set of equations is used (ICRP 2007). The typical range of neutron radiation weighting factors is about 5–20, depending on the energy range of neutrons which can vary substantially.

The organ dose H_T relates to an irradiated organ or tissue type T. It is calculated from the energy dose D_T over organ or tissue type T using

$$H_T = w_R \cdot D_T.$$

Table 50.3 List of tissue weighting factors (ICRP 2007)

Organ/tissue	w_T
Gonads	0.08
Red bone marrow	0.12
Colon	0.12
Lungs	0.12
Stomach	0.12
Bladder	0.04
Breasts	0.12
Liver	0.04
Esophagus	0.04
Thyroid	0.04
Skin	0.01
Bone surfaces	0.01
Salivary glands	0.01
Brain	0.01
Other	0.12

The effective dose E combines the (radiation weighted) organ doses with tissue weighting factors w_T, whose purpose is to represent the different radiation sensitivities of the organs (Table 50.3):

$$E = \sum_T w_T \cdot H_T .$$

The tissue weighting factors aim to take into account the different biological and physiological conditions and functionalities of the various organs, resulting in different susceptibilities for radiation-related detriment. As can be seen from Table 50.3, red bone marrow is estimated to be about three times as sensitive to radiation as, for example, the liver. Hence, the concept of the effective dose allows the calculation of weighted whole-body doses, which serve as a somewhat abstract measure (the effective dose cannot be directly measured) for the whole-body radiation-related detriment.

50.3.3 Assessment of Radiation Exposure in Epidemiological Studies

The validity and informative value of studies in radiation epidemiology depends on the accuracy of the dose assessment. As the type of radiation to be expected is usually known from the physical properties of the radiation source, appropriate dosimetric approaches can be selected purposefully. Various possibilities for quantifying the radiation exposure exist: direct measurement or (indirect) estimation of personal doses, personal- or population-based dose estimation or modeling based on environmental measurements, job-exposure matrices, or dosimetry systems (often developed in the context of large-scale epidemiological studies) combining different approaches.

Certainly, the most straightforward way to assess the radiation exposure of persons included in an epidemiological study is to measure it directly. Using personal dosimeters, one can compile individual person doses, thereby attaining relatively accurate values, which are mostly limited by the uncertainties associated with the physical measurement technique. Obviously, such direct measurements are rarely available as they generally pertain to controlled situations where the exposed persons have been given dosimeters to begin with, for instance nuclear industry workers (Vrijheid et al. 2007). Even then, as, for example, in the international study of nuclear industry workers (Thierry-Chef et al. 2007), changes over time and comparability of measurements from different facilities and countries pose challenges and need to be studied in detail.

Medical radiation exposure, be it for therapeutic or diagnostic purposes for patients or as occupational exposure of personnel, is an important topic of epidemiological research (Boice 1981; Hall and Brenner 2008). In the case of medical personnel, direct measurement of personal doses is certainly desirable and sometimes also possible (Häusler et al. 2009). Yet, epidemiologists often have to resort to more indirect dose surrogates as, for example, in the historical reconstruction of doses received by US radiological technologists included in a large cohort study (Simon et al. 2006). In this study, personal dose measurements available for some cohort members were combined with various, partly time-dependent circumstantial information like work histories, radiation protection practices, and other work conditions, based on measurements, literature data, or assumptions, to yield, after the application of a Monte Carlo simulation approach, individual, probabilistic personal dose estimates.

In the context of epidemiological studies, dose estimation of medical radiation exposures may, as a minimum, include the number of, for example, diagnostic X-ray or computed tomography examinations. If examination parameters are known, dose estimation may be conducted, possibly extended by individual organ dose estimates.

Ongoing research, especially in the area of computed tomography, aims at more detailed and precise dose estimates, including organ doses, based on a thorough analysis of various examination parameters, for example, technical parameters of the computed tomography system or physiological parameters of the patient. The development of several computer codes is ongoing to automate such increasingly complex dose assessments (Stamm and Nagel 2002; Kim et al. 2011).

Epidemiological studies dealing with uncontrolled situations, most prominently nuclear accidents, are another example where personal dosimetry is usually not available. In such situations, one usually has to rely on radioecological measurements of radioactivity in environmental samples, be it soils, locally produced food, or other potentially contaminated material. Following the Chernobyl accident in 1986, extensive measurements of the radionuclide cesium-137 in the environment were conducted (Drozdovitch et al. 2007). Another relevant radionuclide from the Chernobyl fallout was iodine-131, which is very important in the context of studies on Chernobyl-related thyroid cancer. The beta emitter iodine-131 only has a half-life of about 8 days and could not be measured directly anymore in studies conducted years later. A way to alleviate this problem is to make use of a so-called *retrospective dosimetry* technique, where the long-lived fission product iodine-129 with a half-life of almost 16 million years is measured instead. Based on the knowledge of several parameters, among them the ratio of the two iodine isotopes in the Chernobyl fallout and the results of pre-Chernobyl environmental measurements of iodine-129, one can derive thyroid doses due to iodine-131 from current iodine-129 activity measurements in the environment (Michel et al. 2005).

Environmental measurements of radioactivity have also been used in other epidemiological studies, possibly most prominently in the analysis of lung cancer associated with the radioactive noble gas radon (Darby et al. 2005). Here, the measured activity concentration (in becquerel per cubicmeter) of radon in the air of residential homes was used as a replacement for an actual dose quantity.

In the context of occupational radon exposure among miners, one often also encounters the term *working level month* (WLM) as a dose substitute. A working level (WL) is any combination of the radionuclide radon-222 and its decay products in 1 liter of air that emits a potential alpha radiation energy of $1.3 \cdot 10^5$ megaelectronvolt (MeV). This is equivalent to a radon-222 activity concentration in equilibrium with its decay products of $3.7\,\text{kBq m}^{-3}$. One WLM is then the radon exposure of a worker during 1 month of work (170 hours) at 1 WL.

One example of the extensive use of the dosimetric concept of the WLM has been the cohort study of German male uranium miners of the Soviet-German incorporated company Wismut. To assess the radiation exposure in this cohort study, a job-exposure matrix (JEM) was used. The use of JEMs is a common approach in occupational epidemiological studies (see chapters ▸Exposure Assessment and ▸Occupational Epidemiology of this handbook). The Wismut-JEM incorporates information from historical and concurrent measurements of radon gas and radon progeny as well as information on working conditions and mine architecture, to provide, in the end, exposure data for the years 1946–1989 for more than 900 different types of jobs, various mines, and workplaces (Grosche et al. 2006). Since the individually available information on the jobs being done, including times of absence, was mostly well documented, individual exposure could be estimated even for early periods.

In the context of the Life Span cohort Study (LSS), an individual dosimetry system for cohort members within 10 kilometers of the explosions was devised. Over the decades, a succession of dosimetry systems has been developed, the earliest dating back to the 1950s and consisting of just gamma and neutron "air doses" depending on the distance from the explosion and with simple corrections for shielding (Cullings et al. 2006). The recent DS02 dosimetry system, however, is much more sophisticated as will be described briefly below.

The goal of the dosimetry system was the reconstruction of the radiation dose consisting of gamma and neutron exposure for every cohort member. The whereabouts relative to the explosion were derived from personal questionnaire-based interviews. Certain model assumptions had to be made, including physical details of the different atomic bombs in Nagasaki and Hiroshima, iso-contours of the air density, as well as human phantoms. The organ doses were calculated by complex Monte Carlo simulations aiming to describe the transport of radiation from the explosion epicenter to the target organs.

The experimental verification of the methodology included Nagasaki-type test explosions at the Nevada test site with reconstructed Japanese houses to evaluate shielding conditions. These experiments were even continued after the test ban treaty in the early 1960s by installing neutron and cobalt-60 sources on a tower 465 m high (Rühm 2003). Furthermore, samples of building materials and minerals were taken in Nagasaki and Hiroshima to retrospectively evaluate the neutron and gamma radiation by means of the accelerator mass spectrometry detection of neutron activation products or beta or gamma spectrometry and the thermoluminescence technique, respectively. Such extensive efforts are not possible in all radiation epidemiology studies, but experiences obtained in the Life Span Study have been important for many subsequent investigations.

Another important range of studies pertains to the Mayak nuclear facility located near Chelyabinsk in Russia. This facility began operations in 1948 to produce plutonium for the Soviet nuclear weapons program. Substantial exposure to external radiation and to internally deposited plutonium for both workers and the general public occurred mainly in the 1940s and 1950s. Three cohorts were formed: the cohort of Mayak nuclear workers, which were exposed externally at work to neutron and gamma radiation as well as internally due to plutonium inhalation; the cohort of Techa river residents, who were exposed internally due to ingestion of cesium-137 and strontium-90 as well as externally due to deposited radioactive material; the Techa river offspring cohort, with an exposure pattern similar to that of the Techa river cohort. As in the LSS, the retrospective dose assessment in the Mayak study consisted of several complementary approaches. External exposure could partly be monitored with individual film badge dosimeters (Vasilenko et al. 2007). For all cohorts, electron spin resonance spectrometry and strontium-90 beta spectrometry measurements of teeth enamel were conducted to determine absorbed doses. Furthermore, whole-body counting measurements were conducted for all cohorts. Similar to the LSS, thermoluminescence measurements of ceramic building materials helped to estimate external exposures. Biokinetic modeling approaches, partly in combination with urine monitoring data, were employed to cover strontium-90 and plutonium metabolism effects, that is, the distribution and retention of these radionuclides in different parts of the body, as well as to provide lung dosimetry.

Biodosimetry involves the use of biomarkers to assess exposure to ionizing radiation. The radiobiological investigation of cellular effects, in particular induced chromosomal aberrations, has contributed substantially to the understanding of radiation as a toxic agent and cancerogen (National Research Council 2006). Unstable aberrations such as dicentric and ring chromosomes are useful to assess rather recent exposures, whereas stable aberrations including insertions and translocations can provide information about exposures over longer time periods. However, the validity of stable chromosomal aberrations as a retrospective biomarker of radiation exposure is still under debate and investigation. The lower limit of sensitivity of most available techniques is currently above typical low level exposures of many populations under study. New molecular biomarkers have been developed in recent years, but their validity and usefulness for radiation epidemiology is not yet established (Pinto et al. 2010).

In summary, many different ways of measuring, modeling, or estimating radiation doses in epidemiological studies are employed depending on the specific circumstances of the respective studies. Compared to the common indirect exposure assessment in epidemiological studies, it is an outstanding feature of studies with direct measurements of radiation doses that exposure can be assessed with a comparatively high accuracy. Nevertheless, uncertainty in exposure assessment remains an important problem in radiation epidemiology. Improved exposure assessment combined with statistical approaches will help to further quantify and reduce dosimetric and other uncertainties in the future.

50.4 Analysis of Radiation Epidemiology Data

Biological and epidemiological aspects of carcinogenesis of ionizing radiation have been studied extensively for more than 100 years. Today, the main aim of the statistical analysis of new epidemiological studies is not to provide estimates of cancer risk in exposed versus those of non-exposed persons but to quantify the risk as a function of dose and dose rate of high-LET (linear energy transfer) and low-LET radiation and to investigate modifying effects on the dose-response curve such as age at exposure, sex, ethnic group, and lifestyle factors. It is also known that the relationship between risk (or incidence) and dose varies for different types of cancer, and distinctions between different types of radiation are necessary (see Sect. 50.3.1). It has been postulated, for example, by Upton (1977) that the process of carcinogenesis is a combination of initiation (at low to medium dose, e.g., by a mutation) and the survival of the cells; at high doses, the cell is killed by radiation and cannot develop into cancer. As individual doses are available or estimates can be provided by adequate dosimetry in many exposure situations, complex modeling has a long tradition in radiation epidemiology. For X-rays, gamma rays, and electrons, the dose-incidence curve $I(D)$ can in general be described as follows:

$$I(D) = (\lambda_0 + \alpha D + \beta D^2)\exp(-\gamma D + \delta D^2),$$

where λ_0 is the incidence of non-exposed persons (which may depend on further factors such as age and sex). Here, α, β, γ, δ are constant coefficients and D is the dose. More sophisticated expressions include dependency of the parameters $(\alpha - \delta)$ on modifying factors. It has been noted that the radiation-induced excess may be approximated by a constant percentage of the natural age-specific incidence at the time of radiation exposure (relative risk model) or by a constant number of additional cases (absolute risk model).

While in other fields of epidemiology the relative risk (*RR*) is used more frequently to quantify risk, the additional effect of radiation has traditionally been in the focus of analyses in radiation epidemiology. This led to the use of "excess absolute risks" (*EAR*) and "excess relative risks" (*ERR*) to better communicate the risk associated with radiation exposure of populations.

The *EAR* is the difference between the absolute risk of exposed persons and the absolute risk among unexposed persons that is

$$EAR(d, a, e) = \lambda(d, a, e) - \lambda_0(a, e),$$

where $\lambda(d, a, e)$ is the risk (or incidence) of persons with dose $= d$, attained age $= a$, and age at exposure $= e$ and $\lambda_0(a, e)$ is the corresponding baseline rate ($d = 0$).

The excess relative risk (*ERR*) is just the relative risk -1 or

$$ERR(d, a, e) = [\lambda(d, a, e)/\lambda_0(a, e)] - 1.$$

Of course, more complex forms for the risk $\lambda(d,a,e,x)$ can be used, and the risk can be treated as a more complex function of dose (e.g., including a quadratic term) or including further covariates (x). Standard mathematical methods can be used to estimate the parameters in the model and were already used to analyze the data from the Japanese atomic bomb survivors (see Sect. 50.5.4) prior to the extensive use of relative risk models in other epidemiological areas.

In addition to their application for the analyses of data from the atomic bomb survivors, models as described above have been used in studies of the nuclear industry workers, medically exposed persons, and many other cohort and case-control studies in the past. More recently, a new family of models – so-called mechanistic models (Jacob and Jacob 2004; Eidemüller et al. 2010) – was introduced, and several large data sets were reanalyzed with these models. Results from the traditional (now called empirical models) and the mechanistic models are now combined to estimate individual risks to develop cancer and will be used for radiation protection purposes. Mechanistic models include separate parameters for the initiation and promotion steps in cancer development. However, as many processes leading to the different types of cancer are not well understood so far, these models can only include selected aspects of the carcinogenic process.

A major issue in the analysis of radiation epidemiology data is the estimation of risks in the low dose range, that is, below 100 or 200 milligray (mGy). This dose range is of particular interest since most occupational and population exposures occur at low and protracted doses, that is, doses spread over long periods of time. This range is also of great importance for radiation protection.

The shape of the dose-effect curve for solid cancer at lower doses is assumed to be linear without a threshold dose, the so-called linear non-threshold (LNT) hypothesis. This hypothesis includes linear extrapolation from effects of moderate to high doses of ionizing radiation down into the low level range. In this dose range, direct effect estimates often are less precise, such that the actual shape of the curve is frequently driven by estimates at higher doses (see Fig. 50.2, Sect. 50.5.4).

In addition, biological and other considerations suggest that the curve could well take another form in the low dose range; however, statistical testing indicates that other, for example, non-linear or threshold models do not describe the data for solid cancer significantly better than the linear model (Preston et al. 2007). As the nature of the exposure and many other issues related to the study of atomic bomb survivors are unique, direct assessments of radiation risks from low and protracted exposures have been performed in many different study populations in order to arrive at an empirically well-founded risk assessment for ionizing radiation at low and protracted doses.

When comparing data across studies, transferring risk estimates from one population to another is a major issue. This has been of particular concern with regard to the data of the atomic bomb survivors. For example, the Japanese population is known to have markedly higher stomach cancer risks than US Americans; conversely, US American women have much higher breast cancer risks than Asian women. Different baseline rates of disease in populations obviously influence the number of excess cases induced by radiation. The validity of transferring the risk estimated in one population to estimate the disease burden associated with radiation exposure in a different population remains an issue of further investigations (UNSCEAR 2000).

50.5 Selected Radiation Epidemiology Studies

The effects of ionizing radiation have been studied in many different exposure situations, each posing specific challenges to the planning, conduct, analysis, and interpretation of the study. This section presents selected epidemiological studies as examples of the various exposure situations and the populations studied in radiation epidemiology.

50.5.1 Occupational Radiation Studies

There is a long history of radiation studies in occupational settings. Among the early radiation epidemiology studies, the investigation of radium-dial painters has received widespread attention. Women employed in the US radium-dial industry before 1930 used their lips to make fine points on their paint brushes. This habit resulted in the ingestion of large amounts of radium-226. Radium was deposited in the bones with the consequence of excess bone sarcomas many years later (Stebbings et al. 1984).

Many other occupational studies, mainly with a focus on cancer have been conducted since. Some broad categories of occupational groups are presented in Table 50.4, and respective studies will be discussed below:

50.5.1.1 Airline Crew

Airline crew (and others traveling in aircraft) are exposed to increased levels of cosmic radiation. Commercial pilots and flight crews flying about 1,000 h per

Table 50.4 Overview of occupational groups and their exposure situation

Occupational group	Main exposure	Specification
Airline crew	Cosmic radiation	External exposure
Uranium miners	Radon (^{222}Rn)	Internal exposures
Medical staff	X-rays	External exposure
Nuclear industry workers	Gamma radiation	External exposure
Workers in nuclear weapon industries (e.g., Mayak)	Gamma radiation Plutonium (^{239}Pu)	External exposure Internal exposures
Chernobyl accident workers	Gamma radiation Iodine (^{131}I)	External exposure Internal exposure

year receive annual doses of 1–6 mSv, depending on flight routes and several other factors. Cosmic radiation includes a substantial neutron component, and thus aircrew is one of the few populations exposed to neutron radiation. Since about 1980, numerous mortality and incidence studies among aircrew have been conducted. One of the largest is the pooled European cohort study of airline crew with data from nine European countries. Radiation exposure was crudely estimated based on flight routes and other occupational data. Low cancer and cardiovascular mortality was found, but there also were several cancer sites with risk elevations, such as malignant melanoma of the skin among pilots and male cabin crew and, although less prominently, breast cancer mortality among female cabin crew (Standardized Mortality Ratio, *SMR*: 1.11, 95% confidence interval: 0.82–1.48) (Blettner et al. 2003; Zeeb et al. 2003). Studies of cancer incidence yielded slightly higher breast cancer risk elevations (Sigurdson and Ron 2004). Possible selection effects and problems in confounder control, among others, complicate the evaluation of radiation effects in this occupational group, but the overall impact of cosmic ionizing radiation on cancer incidence and mortality appears to be small (Hammer et al. 2009a).

50.5.1.2 Underground Hard-Rock Miners

Underground hard-rock miners such as uranium, iron, tin, and gold miners are exposed to alpha particles emitted from radon decay products. This results in considerable doses to lung tissue when the particles attach to dust and remain in the lung (Boice and Lubin 1997). A pooled analysis of 11 cohorts of underground miners in which radon exposure was estimated for individual workers included 65,000 men accruing nearly 1.2 million person years of observation and over 2,700 deaths from lung cancer. The excess relative risk of lung cancer was approximately directly proportional to the cumulative exposure to radon, that is, there was a linear exposure-disease relationship (Lubin et al. 1995). A major issue in radon and lung cancer studies is the fact that tobacco smoke is the leading cause of lung cancer. Hence, it is important to determine the overall risk arising from the combined exposure to tobacco smoke and radon. In the pooled miner analysis, the excess relative risk per WLM (*ERR* WLM^{-1}) coefficient for never-smoking miners was three times the *ERR* WLM^{-1} coefficient for ever-smoking miners. About 40% of all lung cancer deaths were attributed to radon-progeny exposure, 70% in never-smokers, and 40% in smokers (Lubin et al. 1995; Wakeford 2009).

Extensive uranium extraction took place from 1946 until 1990 at the Wismut mining company in the former German Democratic Republic. About 59,000 male former employees of this company form the largest single uranium miner cohort worldwide. The cohort has been followed up for mortality since the beginning of 1946 to the end of 2003 with a total of 3,016 lung cancer deaths and two million person years. There was a twofold increase in the mortality for lung cancer, and the *ERR* WLM^{-1} coefficient for lung cancer was estimated as 0.0019 (95% confidence interval (CI): 0.0016–0.0022) (Walsh et al. 2010). This is somewhat lower than the earlier estimates from the pooled study mentioned above.

50.5.1.3 Medical Workers

Within a few years after the discovery of X-rays in 1895, there were reports of dermatitis, ulceration, skin cancer, sarcomas, other serious radiation-induced injuries, and deaths in radiologists (Frieben 1902; Hesse 1911). An association between employment as a radiologist and increased risk of acute myeloid leukemia was confirmed in a 1944 report (March 1944), a year before the atomic bombings in Japan.

The results of 100 years of observation on British radiologists (Berrington et al. 2001) showed an excess of cancer mortality of about 40% for radiologists who had been working for more than 40 years compared with other medical practitioners. This was considered as a probable long-term effect of radiation exposure in those who first registered before 1954. There was no evidence of an increase in cancer mortality among radiologists who first registered after 1954. Most likely, the occupational radiation exposures of those employed in more recent years have been lower due to improved radiation protection.

Another example of a medical worker study is the investigation of cancer incidence and mortality among over 90,000 US radiological technologists (77% of whom were women) who were certified for at least 2 years between 1926 and 1982. Regarding the incidence of cancer diseases, female technologists had an elevated risk for all solid tumors including breast cancer. Both female and male technologists showed elevated risks for melanoma and thyroid cancer (Sigurdson et al. 2003), and among workers employed in early years, there was evidence for increased leukemia mortality (Linet et al. 2005).

50.5.1.4 Nuclear Industry Workers

Nuclear industry workers form a very suitable study population to assess effects of low and protracted radiation exposure, as worldwide several hundred thousand employees with detailed personnel and radiation dose records are available for studies (Wakeford 2005, 2009). The *United Nations Scientific Committee on the Effects of Atomic Radiation* (UNSCEAR 2010) defines low doses as those of 100 mGy or less and low dose rates as 0.1 mGy per minute or less (averaged over 1 h) for external X-rays and gamma radiation. The predicted low dose excess radiation-related risk of cancer is small. On the other hand, low and protracted doses are relevant for most persons exposed in an occupational context as well as for the overall population.

The International Agency for Research on Cancer (IARC) coordinated the largest nuclear industry worker study to date (Cardis et al. 2005, 2007). This multinational retrospective cohort study conducted in 15 countries included approximately 400,000 predominantly male workers who had been employed for at least 1 year and who were monitored for external photon radiation using personal dosimeters. The mean cumulative individual dose was 19.4 mSv with 90% of workers having a dose lower than 50 mSv.

For mortality from all cancers excluding leukemia, the excess relative risk was 0.97 Sv^{-1} and was significantly different from zero (95% CI: 0.14–1.97). The *ERR* for mortality from lung cancer was significantly increased with 1.86 Sv^{-1} (95% CI: 0.26–4.01). Since the observed risk of mortality from all cancers excluding leukemia was twice as high as the risk estimate for solid cancer mortality observed in the LSS, the results were intensively discussed.

This study is a revealing example for the application of sensitivity analyses in epidemiological studies which can help to identify, albeit post hoc, specific data constellations, design issues, or, at times, systematic errors. In the 15-country study, the Canadian data have a surprisingly large influence on the *ERR* coefficient for all cancers other than leukemia, even though there are just over 200 Canadian cancer deaths (4% of the total number of cancer deaths). Exclusion of the Canadian cohort from the study reduced the estimate by 40% and changed it from statistically significant to statistically non-significant. Among the Canadian cohort, a specific subgroup of 3,088 workers employed before 1965 was the only group of workers with a radiation-associated increase in risk of solid cancer mortality, and this group had a strong impact on the study findings. A reanalysis showed that these workers had incomplete dose information. A potentially significant gap in reporting zero doses was discovered and introduced substantial distortion of the dose-effect relationships (Ashmore et al. 2010).

Concerning leukemia (excluding chronic lymphocytic (CLL) leukemia which is often considered not to be induced by radiation), the *ERR* per dose unit was 1.93 Sv^{-1} (95% CI: <0–8.47), indicative of an excess radiation-related risk of mortality from leukemia. Given observations from the Mayak Worker Studies (see next section), where the increased leukemia risk was concentrated in the period 3–5 years after the dose was received (Wakeford 2009; Shilnikova et al. 2003), temporal patterns of leukemia risk might be different after low dose protracted exposures compared to higher cumulative doses.

In some countries, worker registries provide an excellent basis for epidemiological studies. For example, in the latest follow-up of 174,541 persons from the UK National Registry for Radiation Workers, an increased risk for leukemia mortality and incidence was observed. Consistent with other studies, the leukemia subtype showing the strongest evidence of an association with radiation is chronic myeloid leukemia (Muirhead et al. 2009). Nuclear workers continue to be studied, and results from additional cohorts will be available in the future.

50.5.1.5 The Mayak Nuclear Weapon Worker Studies

In addition to exposure to external sources of ionizing radiation, some nuclear industry workers inhale or ingest radioactive material, leading to a more complex exposure situation that also affects comparability with other groups. In particular, workers in nuclear weapon industries are exposed to uranium, plutonium, and tritium. The example of Mayak workers has been described in Sect. 50.3. External radiation exposures of these workers far exceeded the doses of other nuclear worker cohorts. Among workers hired before 1959, the mean cumulative external dose was 1.2 Gy, which is more than an order of magnitude above the mean exposure in the 15-country study (see Box 50.1).

There were also substantial internal exposures for plutonium. The mean lung dose was 0.21 Gy, the mean liver dose was 0.28 Gy, and the mean bone surface dose was 1.0 Gy (Vasilenko et al. 2007).

Sokolnikov et al. (2008) published findings for solid cancers from the cohort of 17,740 Mayak workers first employed during 1948–1972. A total of 13,816 workers were potentially exposed to plutonium. Some of the main results are shown in Table 50.5.

The higher ERR coefficients for females, notably for lung cancer and liver cancers, might be due to higher background risks in males as a result of higher tobacco and alcohol consumption. The increased leukemia risk was concentrated in the period 3–5 years after the exposure (Shilnikova et al. 2003). So far, there was no indication of any significant effect of plutonium exposure upon leukemia mortality.

Other examples of occupational groups exposed to plutonium are workers in the Manhattan Project (Los Alamos, USA, 1944–1945; the Manhattan Project was a program that produced the first atomic bomb during the World War II and was initiated by the USA with participation from the UK and Canada), workers at the Rocky Flats nuclear weapon production facility (Colorado, USA, 1952–1979), the Hanford nuclear facility with the world's first plutonium production reactor (Washington, USA, 1944–1978), or the Sellafield plutonium workers (UK, 1947–1975).

50.5.1.6 Chernobyl Cleanup Workers

After the accident at the Chernobyl nuclear power plant in April 1986, so-called liquidators participated in the cleanup of the reactor, sarcophagus construction, decontamination, and other recovery operations. About 240,000 persons worked at

Box 50.1. Comparison of mean cumulative external dose in two important occupational studies

Nuclear energy workers in the 15-country study: 19.4 mGy
Mayak workers hired before 1959: 1,200 mGy

Table 50.5 Risk estimates for different cancer sites derived from the cohort study of Mayak nuclear facility workers (Sokolnikov et al. 2003, 2008)

Cancer	*ERR* coefficients for external dose (adjusted for internal dose)	*ERR* coefficients for tissue-specific doses for the internal exposure to plutonium, adjusted for external dose
Lung cancer	0.19 Gy^{-1}(95% CI: 0.05–0.39)	Males: 7.1 Gy^{-1} (95% CI: 4.9–10) Females: 15.0 Gy^{-1} (95% CI: 7.6–29)
Liver cancer	0.21 Gy^{-1} (95% CI: <0–1.0)	Males: 2.6 Gy^{-1} (95% CI: 0.7–6.0) Females: 29.0 Gy^{-1} (95% CI: 9.8–95.0)
Bone cancer	0.35 Gy^{-1} (95% CI: <0–4.4)	Males: 0.76 Gy^{-1} (95% CI: <0–5.2) Females: 3.4 Gy^{-1} (95% CI: 0.4–20.0)
Leukemia (excl. CLL)	3–5 years since dose received: 6.9 Gy^{-1} (90% CI: 2.9–15) >5 years since dose received: 0.5 Gy^{-1} (90% CI: 0.1–1.1)	

the site during 1986–1987 when exposures were the highest. Sent to the reactor site usually for a period of about 2 weeks, these cleanup workers were exposed primarily to external gamma radiation. Estimates from the national Chernobyl registry data in Ukraine, Belarus, and the Russian Federation indicated a mean dose from external radiation of 144 mGy in 1986, 90 mGy in 1987, and 36 mGy in 1988–1989. The mean effective dose for cleanup workers is estimated to have been around 100 mSv. Furthermore, Chernobyl workers received substantial thyroid doses from intake of radioactive iodine (Wakeford 2009; Romanenko et al. 2008).

In the USSR, a comprehensive registration and active follow-up system was set up for the persons most affected by the Chernobyl accident. However, incompleteness of data, the lack of verification and quality control, and selection bias pose problems. In Russia and the Ukraine, no centralized cancer registration system was in place at the time of the accident, whereas in Belarus a computerized National Cancer Registry existed since 1970. The dosimetric information available for cleanup workers is derived from personal dosimeters, group dosimetry, and measurements at various points where liquidators worked (National Research Council 2006).

Ivanov et al. (2008) conducted a cohort study of 103,427 Chernobyl emergency workers with a follow-up from 1986 to 2003. A total of 22,408 persons were engaged in the early recovery operations in April–July 1986. They received the highest external doses (mean dose: 168 mGy), while the mean dose for those emergency workers employed in 1988–1990 was 33 mGy. A total of 87 cases of thyroid cancers were observed with a statistically significant overall *SIR* of 3.47 (95% CI: 2.80–4.25). The highest *SIR* was found for the emergency workers involved in the recovery operations from April to July 1986. In this group, 34 cases of thyroid cancers occurred, and the *SIR* value was 6.62 (95% CI: 4.63–9.09). Further work is ongoing, and epidemiological data from Chernobyl related studies will continue to enhance the knowledge about radiation-associated disease risks for many years to come.

50.5.2 Environmental Radiation Studies

Not all epidemiological study designs are equally informative for the estimation of radiation risk in humans. Ecological studies do neither include individual exposure estimates nor individual confounder information. In ecological studies, aggregated population estimates or distance-based exposure proxies are used in order to define the likelihood for exposure. Thoroughly conducted case-control or cohort studies overcome these disadvantages. For this reason, this section focuses on selected examples of current case-control or cohort studies that exemplify research approaches in given situations of public health relevance. Comprehensive overviews of epidemiological studies on environmental radiation are given, for example, by the National Academy of Sciences Advisory Committee on the Biological Effects of Ionizing Radiation (National Research Council 2006) and by UNSCEAR in its regular reports.

50.5.2.1 Populations Exposed to Fallout from the Chernobyl Accident

The explosion at the Chernobyl plant in 1986 released substantial quantities of radionuclides into the atmosphere, resulting in the contamination of a large geographical area. Initially, exposures of the population were principally due to radioisotopes of iodine-131 and subsequently cesium-137 from both external exposure and the consumption of contaminated milk and other foods.

Numerous studies have shown an association between radiation exposure from Chernobyl and an increase in the incidence of thyroid cancer in Belarus, Ukraine, and Russia (National Research Council 2006). Iodine deficiency seems to be an important modifier of the risk of radiation-induced thyroid cancer. Some regions contaminated by the Chernobyl accident are areas of mild to moderate iodine deficiency which enhances the risk of thyroid cancer following irradiation. Furthermore, exposure at younger ages is associated with the greatest risk for thyroid cancer. Three case-control studies on thyroid cancer in children and young adults exposed to the Chernobyl accident have shown that exposure at younger ages is associated with the greatest risk for thyroid cancer (UNSCEAR 2008), while rates of childhood leukemia seemed unchanged after Chernobyl.

50.5.2.2 Techa River Populations

The exposure of persons living near the Techa River in Russia consisted of a mixture of radionuclides, mainly strontium-90 and cesium-137. Approximately 30,000 persons living near the Techa River, among them many children and adolescents at the time of exposure, have been followed in a cohort for about 5 decades. Individualized stomach and red bone marrow doses have been estimated for each cohort member. For example, the average stomach dose for cohort members is estimated to be around 0.03–0.04 Gy, with maximum organ doses of about 0.5 Gy. Significantly elevated risks of leukemia and solid cancer mortality have been demonstrated in this study (Krestinina et al. 2007; Eidemüller et al. 2010).

50.5.2.3 Leukemia in Children Living in the Vicinity of Nuclear Power Plants

Leukemia is the most common malignancy in childhood (Parkin et al. 1988). The causes of most leukemias are still unknown. However, high doses of ionizing radiation are an established risk factor for childhood leukemia (Lightfoot and Roman 2004). Regarding low and protracted doses, there has been a long-standing debate whether or not the emission of ionizing radiation during routine operation of nuclear plants increases the risk of leukemia in children living near the plants.

Numerous studies on this issue have been conducted in Europe and the USA, usually employing ecological designs where cancer rates are compared between regions of decreasing vicinity to nuclear power plant sites. A population-based case-control study was conducted in Germany where cases were children younger than 5 years (diseased between 1980 and 2003) registered with leukemia at the German Childhood Cancer Registry (GCCR) (Kaatsch et al. 2008). Population-based controls were matched (1:3) for date of birth, age at diagnosis, sex, and nuclear power plant area (at the date of diagnosis) of the corresponding case. Residential proximity to the nearest nuclear power plant was determined for each subject individually. The study included 593 leukemia cases and 1,766 matched controls. The main result was a negative trend for distance, indicating that cases lived closer to nuclear power plants than the randomly selected controls. A categorical analysis showed a statistically significant odds ratio of 2.19 (lower 95% confidence limit (CL): 1.51) for residential proximity <5 km compared to residence outside this area. A French case-control study of acute leukemia reported similar findings (Sermage-Faure et al. 2012), whereas in a nationwide Swiss cohort study, no excess leukemia risk among children living near nuclear power plants was seen (Spycher et al. 2011). As the radiation exposure near a nuclear power plant in routine operation is very small compared to exposure of the general public from other sources (e.g., terrestrial or medical radiation), other causes beyond radiation exposure have to be considered.

50.5.3 Medical Radiation Studies

Diagnostic radiation techniques include X-ray radiography, fluoroscopies, CT, or interventional radiology. As indicated earlier, medical radiation increasingly contributes to the overall population radiation exposure. Advances in radiation protection help to lower the doses per individual examination; however, since radiological imaging is continuously becoming more widely available and informative with regard to the detection of abnormalities, the balance of benefits and risks requires continuous evaluation. Furthermore, the radiation exposure of patients could be part of their treatment. Usually, therapeutically exposed persons are not typical for the general population, for example, with respect to age (e.g., cancer patients). In addition, exposed individuals have medical conditions that influence the trade-off between the benefits and the risks of using radiation. Nevertheless, the detailed study of potential adverse effects of medical usage of radiation is essential to further gain insight on the benefit-risk balance and to assure appropriate radiation protection of patients. Such studies also provide opportunities to understand radiation exposure effects in specific groups and ages. Some case-control and cohort studies highlighting the respective epidemiological approaches are presented below.

50.5.3.1 The British Childhood Cancer Survivors

Children and young adults treated for cancer nowadays have a very good survival prospect but may face late effects of their treatment. The British Childhood Cancer Survivor Study is a population-based cohort of 17,981 individuals diagnosed with childhood cancer (1940–1991) and surviving for at least 5 years, followed up through December 2006. The greatest excess risk associated with subsequent primary neoplasms at age above 40 years was found for patients with primary digestive and genitourinary neoplasms (Hawkins et al. 1987; Reulen et al. 2011). A joint analysis of the British and French cohorts (de Vathaire et al. 1989) indicated that the risk for developing a second cancer in the 25 years after diagnosis of the first cancer was 12% (Tucker et al. 1991).

Numerous studies of second cancer following radiotherapy in adults have focused on patients with a favorable long-term prognosis (e.g., cervical cancer, breast cancer, testicular cancer, thyroid cancer, or Hodgkin's lymphoma). It should be noted that chemotherapy or hormonal therapy used in the treatment of cancer patients is an important confounder in investigations of the relationship between radiation therapy and second primary cancer. Concerning benign diseases, several cohorts of children and adults treated with ionizing radiation have been followed up over long periods (Kleinerman 2006).

50.5.3.2 The Oxford Survey of Childhood Cancers

Exposures to children including intrauterine exposures during pregnancy are of particular concern in this respect. An association between childhood leukemia and an abdominal X-ray examination of the pregnant mother was first reported in the 1950s (Steward et al. 1956, 1958). It was obtained from a large case-control study conducted in the United Kingdom in which the mothers of children who died from cancer and mothers of control children were asked about their child's history of radiographic examinations in utero and after birth. In 1981, the Oxford Survey of Childhood Cancers (OSCC) included 15,276 case-control pairs. For the calendar period 1953–1981, the overall excess risk of childhood cancer associated with maternal exposure to abdominal radiography during pregnancy in the Oxford survey was approximately 40% (odds ratio (OR) = 1.39, 95% CI: 1.30–1.49) (Gilman et al. 1989).

In contrast to these findings, no statistically increased leukemia risks were seen among children exposed in utero in Hiroshima and Nagasaki, but the numbers were very small. There are numerous arguments against and in favor of the validity of the OSCC findings (Doll and Wakeford 1997; National Research Council 2006). Based on an evaluation of all available evidence, Wakeford and Little (2003) concluded that doses to the fetus in utero of the order of 10 mGy can already lead to increases in the risk of childhood cancer.

50.5.3.3 Other Studies on Diagnostic Radiology

Postnatal medical diagnostic exposures to children have also been studied extensively, albeit with inconsistent results. Recently, the RICC study (Radiation-Induced Childhood Cancer Study) focused on the postnatal exposure of children (<15 years) to X-ray examinations and the risk of childhood cancer. The cohort included 92,957 children who had been examined with diagnostic X-rays in a large German hospital during 1976–2003, and individual dose estimations for all radiological examinations performed in this hospital were available. Newly diagnosed cancers occurring between 1980 and 2006 were determined through record linkage to the German Childhood Cancer Registry. The median radiation dose was very low (0.007 mSv). Eighty-seven incident cases were found in the cohort. The SIR for all cancers was 0.99 (95% CI: 0.79–1.22). No trend in the incidence of total cancer, leukemia, or solid tumors with increasing radiation dose was observed in the SIR analysis or in the multivariate Poisson regression. This result was in contrast to several earlier studies, but the RICC risk estimates had wide confidence intervals and were compatible with a broad range of risks (Hammer et al. 2009b).

During the past 20 years, a rapid increase of pediatric computed tomography (CT) use could be observed in many countries. The CT radiation doses are relatively high compared to those from most conventional X-ray examinations. An international cohort study in 11 European countries, coordinated by the IARC, studies the health consequences of ionizing radiation exposure from CT in childhood and adolescence. This *EPI-CT Study* will eventually include about one million children. The enrolment period began in 1984 with a follow-up until about 2010. Cohort data from the UK were published in 2012 and indicate a risk increase for childhood leukemia associated with ionizing radiation from CT comparable to that estimated from the LSS data. For brain tumors, a markedly larger risk increase was found in this study (Pearce et al. 2012).

Most diagnostic medical radiation is, however, applied to adult patients. An example for a study of relatively high diagnostic exposures is the investigation of patients monitored during their pneumothorax treatment with repeated fluoroscopic examinations (see Table 50.3) (Howe and McLaughlin 1996). In modern medicine, CT examinations as well as interventional radiology procedures are among the interventions leading to relatively high organ doses. The attributable lifetime cancer mortality for a 45-year-old adult undergoing multiple full-body CT scans has been estimated to be around 2% (Brenner and Elliston 2004). Similarly, the use of radionuclides in nuclear medicine – both for diagnostic and therapeutic purposes – has been investigated with regard to health risks. These studies generally point to small risk increases. For example, in the UK, annually less than 20 solid cancers and 12 cases of leukemia are estimated to be due to nuclear medicine procedures, as against a total of about 313,000 cancers diagnosed annually in the country (Parkin and Darby 2011).

50.5.4 Atomic Bomb Survivor Studies

The Life Span Study (LSS) of survivors of the atomic bombings in Hiroshima and Nagasaki as the key study of radiation epidemiology has been mentioned in several earlier sections. The LSS is a representative cohort of all ages and both sexes, with little selection bias concerning socioeconomic factors, diseases or occupations, and a follow-up since 1950. The LSS comprises a wide range of radiation exposures and a relatively accurate dosimetry that has undergone constant improvements over time. The exposure is a whole-body exposure, which allows the assessment of risks for specific cancer sites (National Research Council 2006). What has to be noted, however, is the fact that the studies of atomic bomb survivors only provide evidence for risks following a single acute exposure. Whether acute and protracted exposures lead to similar effects in humans is not well understood, and there is an ongoing controversy whether doses from acute and chronic exposures should be treated differently (Jacob et al. 2009).

The LSS cohort is comprised of 120,321 people who were identified at the time of the 1950 census. Cohort members include three major groups of registered Hiroshima and Nagasaki residents: (1) about 54,000 atomic bomb survivors who stayed within 2.5 km of the hypocenter at the time of the bombings; (2) about 40,000 atomic bomb survivors who stayed between 2.5 and 10 km of the hypocenter at the time of the bombings; and (3) about 27,000 people who resided in the cities at the time of the census but did not stay there at the time of the bombings (Preston et al. 2007). Vital status is updated in 3-year cycles through the Japanese family registration system. Death certificates provide data on the cause of death. Since 1990, data from Hiroshima and Nagasaki tumor registries were linked to the LSS cohort, which allows the evaluation of cancer incidence. The Adult Health Study (AHS) is a cohort which includes a 20% subsample of the LSS. AHS subjects were invited to participate in biennial comprehensive health examinations. The AHS thus complements the LSS and provides more detailed health endpoints based on clinical data (National Research Council 2006).

The LSS provides risk estimates for solid cancers as well as for hematological cancers. Mortality and incidence data are available from reliable registration sources, and due to the size and duration of follow-up of the cohort and the variability of doses, the precision of risk estimates from the LSS is relatively high for many outcomes.

In terms of solid cancer incidence and mortality, risk increases have been found for numerous individual cancer types and for solid cancer overall, and the dose-response curve generally follows a linear pattern (see Fig. 50.2). Latency periods of 10 years or more have been observed for most solid cancers, and the highest risks were seen for those exposed when they were young. The most recent overall risk estimates indicate an incidence increase of 0.35 Gy^{-1} (90% CI: 0.28–0.43) for men and 0.58 Gy^{-1}(90% CI: 0.43–0.69) for women, assuming an age of 30 years at exposure and an attained age of 70 years (Preston et al. 2007). The excess mortality risk is in a very similar order (0.47 Gy^{-1} for both sexes combined) (Preston et al. 2003). For leukemia mortality, an average excess relative risk of 4.04 at 1 Sv has been found in the LSS (Preston et al. 2004), and the proportion of leukemia deaths in the cohort attributable to the radiation (around 50%) is much larger than the comparable proportion for solid cancers.

The LSS is also an important source of information on the radiation-related incidence or mortality risk from diseases other than cancer. Cardiovascular diseases

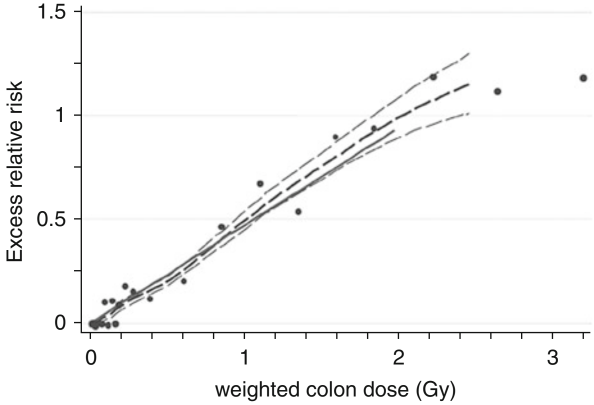

Fig. 50.2 LSS solid cancer incidence, excess relative risk by radiation dose, 1958–1998. The *thick solid line* is the fitted linear sex-averaged excess relative risk (ERR) dose response at age 70 after exposure at age 30. The *thick dashed line* is a non-parametric smoothed estimate of the dose category specific risks, and the *thin dashed lines* are one standard error above and below this smoothed estimate (From Preston et al. 2007 with permission)

have been consistently associated with ionizing radiation, although risks per dose seem to be about 1/4 of the comparable cancer risks. In the LSS, a 0.14 Gy^{-1} increase for heart disease mortality (95% CI: 0.06–0.23) and a somewhat lower risk increase of 0.09 Gy^{-1} for mortality from cerebrovascular disease were estimated (Shimizu et al. 2010). A number of other cohort studies indicate risk increases in a similar order. What remains somewhat unclear is the question of risk increases below doses of about 500 mGy, since the available results are inconsistent, and there are many confounding factors rendering the valid assessment of this question difficult. This is especially so when good confounder information, for example, on smoking or other cardiovascular risk factors possibly associated with radiation exposures, is missing, which is the case in the majority of studies with information on cardiovascular risks.

Beyond cardiovascular diseases, digestive and respiratory diseases (Preston et al. 2003) and eye lens cataract (Ainsbury et al. 2009) have been found to be associated with radiation exposure. Presently, there is substantial research interest in these non-cancer outcomes. For the development of cataract, for example, the previously assumed threshold dose of about 2 Gy is now considered too high, and there may be no threshold dose at all.

50.6 Radiation Epidemiology and Radiation Protection

Soon after the discovery of X-rays in 1895, it became evident that there was an urgent need to implement radiation protection rules to avoid adverse effects for exposed persons. As early as 1896, the importance of distance to the radiation source, the influence of duration of exposure, and the consideration for skin protection with Vaseline for the most exposed areas were discussed. Since then, radiation protection was continuously improved by technical means and by developing and updating protection standards. Changes were driven by new data on the biological effects of ionizing radiation, by large epidemiological studies, as well as by public concern (ICRP, International Commission on Radiological Protection 2009).

At the conferences of the American Roentgen Ray Society in 1924 and the International Congress of Radiology (ICR) in 1925, radiation hazard and protection was a major issue. First formal standards for protecting humans were proposed by the US Advisory Committee on X-Ray and Radium Protection in 1934. The limits were proposed mainly following observations of serious health effects in radium-dial painters.

At the second meeting of the ICR in 1928 in Sweden, the International Commission on Radiological Protection (ICRP, at this time IXRPC) was founded as a registered charity and as an independent non-governmental organization. Since then, the ICRP has played a central role in radiation protection, including evaluation of scientific studies, proposing methods of measuring ionizing radiation and units to compare different types of radiation, proposing dose limits, and discussing concepts and philosophy of protection.

In 1949, the concepts of “absorbed dose” and “dose equivalent” were introduced, and from 1950 onward, results from the LSS became available as well as extensive data from animal experiments. Based on these scientific foundations, the ICRP continued to recommend dose limits for a wide range of populations and exposures. Over the years, the limits have been lowered considerably: for example, the annual limit of the occupational effective dose was 150 mSv in 1950 and stands at 20 mSv in 2011 (100 mSv averaged over 5 years, with doses not exceeding 50 mSv in any single year).

Internationally, the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) was established by the General Assembly of the UN in 1955 amidst growing concerns about effects of radiation. UNSCEAR assesses and reports levels and effects of exposure to ionizing radiation worldwide. Regularly, all relevant epidemiological evidence is summarized and evaluated. The committee’s publications form the basis for evaluation of radiation risk and the development of radiation protection policies, notably by the ICRP (UNSCEAR 2010).

In the 1960s, it became clear that the genetic effect had probably been overestimated in some of the older studies but that cancer mortality and incidence risk increases were now apparent, namely, among atomic bomb survivors. These observations resulted in substantial changes in the discussion on radiation risks and protection. The focus was now on exposure to low doses of ionizing radiation as there was no suggestion of the existence of a threshold for late health effects, notably for cancer.

In practical terms, the ICRP also proposed a philosophy of protection by defining the three principles of justification, optimization of protection, and dose limitation which was confirmed recently (ICRP 2007) (see Box 50.2). These principles as well as other guidance from the ICRP have been adopted by national radiation protection authorities worldwide.

Box 50.2. Principles of radiation protection

Justification: the benefits of using radiation must outweigh the negative aspects.
Optimization: radiation exposure must be kept as low as reasonable achievable (ALARA principle).
Limitation: doses to individuals must not exceed the recommended dose limits.

Radiation protection covers exposures resulting not only from the operation of radiation sources ("planned exposure situations") but also from emergency exposure situations, for instance resulting from nuclear accidents, and a range of other situations such as those involving exposure to natural radiation sources ("existing exposure situations") (Wrixon 2008). Data from epidemiology continue to be an important scientific basis for all radiation protection efforts.

50.7 Conclusions

Radiation epidemiology has developed over many years to become an area where both exposure assessment and analytical epidemiological methods have reached a considerable level of maturity. Radiation protection standards thus have a firm foundation in epidemiology, with studies on a large variety of populations and exposure situations. Nevertheless, open questions remain. These questions refer particularly to the dose levels relevant for the general public, namely, the doses below about 100 mSv, where the statistical power of studies becomes low and the potential for biased results increases. Such low doses are often delivered at low dose rates as well, and there is some controversy whether high dose rates (e.g., from acute accidental exposures) or low dose rates lead to similar risk increases. Multidisciplinary approaches combining experimental radiobiology and radiation epidemiology as well as other disciplines are seen as an option to better understand and quantify risks at low doses.

In terms of exposure assessment, the retrospective quantification of ionizing radiation exposures continues to be challenging. New or extended cohorts and other studies will probably benefit from improving documentation and the growing availability of electronic records of exposures over time, for example, in occupational and medical settings. The investigation of cancer risks from diagnostic CT exposures is an example of such an approach and also highlights the fact that medical exposures are of major relevance for the overall population dose and thus for radiation epidemiology and radiation protection. Biological markers of radiation exposure will play a role in studies where biological material is available, but reliable and stable biomarkers especially for the low dose range are needed.

Another group of radiation effects, the so-called non-targeted effects of radiation, as opposed to the effects directly induced by the energy deposition of radiation in cells, has been a major research issue in experimental radiation biology during recent years, with little evidence from human epidemiological studies so far (UNSCEAR 2006, Annex C). Genomic instability refers to an increased rate of genomic alterations induced by ionizing radiation, which may lead to effects in later cell generations. A related concept is the so-called bystander effect describing effects in cells that are not directly hit by radiation. The relevance of these non-targeted effects for radiation epidemiology and radiation risk assessment remains inconclusive at present. Interdisciplinary research efforts focusing, inter alia, on genetic and epigenetic aspects of radiation risk are under way and will possibly challenge established concepts in the field (Averbeck 2010).

In terms of outcomes, radiation epidemiology has focused on cancer as a late effect of exposure to ionizing radiation in the past, while other health consequences received less attention. This is now changing, with increased research efforts on cardiovascular diseases, lens opacities, and cognitive development as outcomes of interest in radiation epidemiology. Some of these issues can be studied in established cohorts, whereas specific groups such as interventional radiologists or cardiologists may be included in new cohorts, for example, to assess cataract risks.

Recent events such as the Fukushima nuclear accident underline the need for ongoing research efforts as the basis for risk assessment and communication with the public and others. Despite the comparatively large body of evidence, health effects of ionizing radiation are often misrepresented or misunderstood. Radiation epidemiology supports radiation risk assessment with increasingly detailed and methodologically advanced scientific information. As radiation risks are dreaded by the public, a particular challenge remains in the approaches to translate concepts and results of radiation epidemiology into information suitable for risk communication in public health.

51.1 Introduction

51.1.1 Specifics of Infectious Disease Epidemiology

Most textbooks dealing with the epidemiology of infectious diseases address the epidemiological features (also named biology) of specific infectious diseases. In this chapter, the focus is placed on the concepts and methods more specific to the general epidemiological study of infectious diseases. At a later stage, implementation of these methods must be adapted to the specific infectious disease under consideration. Then, detailed knowledge of the disease biology is of capital importance.

Epidemiologists focus their study on population groups (or "herds") rather than on individuals. In addition, infectious disease epidemiology also considers the interaction between individuals within the population group. For non-infectious diseases, each case and his/her risk factors are personal and independent from the neighbor (your neighbor's risk factors for heart disease have no influence on your risk factors). On the contrary, for infectious disease, the interaction between cases and contacts is of prime importance; this special feature of infectious disease epidemiology is discussed in the section transmission and basic concepts important to infectious diseases.

Although not entirely specific of infectious disease epidemiology, some characteristics are more often found in this field of study; for example, infectious disease epidemiology is:

- The closest to "shoe leather" epidemiology, meaning going into the community, talking to patients, contacts, practitioners, observing the environment (living conditions, activities, food preparation, water supply, etc.)
- Direct understanding and "closeness" to data
- Small-scale investigations
- Immediate results
- Easy understanding of etiology

51.1.2 The Global Burden of Infectious Diseases

Infectious diseases are a major cause of human suffering in terms of both morbidity and mortality throughout human history. The spread of infectious diseases was influenced by various steps in human civilization. For example, parasitic and zoonotic diseases have become more common after domestication of animals, airborne viral and bacterial infections after large settlements and urbanization. Throughout the ages, humanity suffered from large pandemics such as plague, smallpox, cholera, and influenza but also from the more silent killers of chronic infectious diseases such as tuberculosis and syphilis.

Morbidity due to infectious diseases is very common in spite of the progress accomplished in recent decades. According to the World Health Organization's (WHO) annual estimates, there are globally 300–500 million cases of malaria, 333 million cases of sexually transmitted diseases (syphilis, gonorrhea, chlamydia,

Table 51.1 Top ten causes of death worldwide (WHO 2008)

	Deaths in millions per year	% of all deaths
Ischemic heart disease	7.25	12.8
Stroke and other cerebrovascular disease	6.15	10.8
Lower respiratory infections	3.46	6.1
Chronic obstructive pulmonary disease	3.28	5.8
Diarrheal diseases	2.46	4.3
HIV/AIDS	1.78	3.1
Trachea, bronchus, lung cancers	1.39	2.4
Tuberculosis	1.34	2.4
Diabetes mellitus	1.26	2.2
Road traffic accidents	1.21	2.1

and trichomonas), 33 million cases of HIV/AIDS, 14 million people infected with tuberculosis, and 3–5 million cases of cholera (WHO 2010).

Even though infectious diseases are much more common in the non-industrialized world, the prevalence of infection is still very high for some infectious diseases in the industrialized world. Annually, approximately 48 million episodes of diarrhea are leading to 128,000 hospitalizations, and 3,000 deaths due to diarrheal illnesses are occurring in the United States (Centers for Disease Control and Prevention (CDC) 2011; Mounts et al. 1999). Every year, influenza virus circulates widely, infecting from 10% to 40% of the world population. Based on CDC estimates, there were 59 million infected during the 2009/2010 H1N1 pandemic (CDC 2011). Furthermore, serological surveys found that by young adulthood, the prevalence of antibodies was 80% against herpes simplex virus type 1, 15–20% against type 2, 95% against human herpes virus, 63% against *Hepatitis A*, 2% against *Hepatitis C*, 0.5% against *Hepatitis B*, and 50% against *Chlamydia pneumoniae* (American Academy of Pediatrics 2006; Mandell et al. 2000).

Not surprisingly, there is also a large imbalance in mortality rates due to infectious diseases between non-industrialized and industrialized countries. Globally, every third death is due from an infectious disease. In 1990, estimated 17 million deaths were due to communicable diseases, along with malnutrition and maternal and perinatal diseases with about 95% of these deaths occurring in the poorest parts of the world, mainly India and sub-Saharan continent (University of California 2011). According to the WHO, the most common causes of infectious disease deaths were lower respiratory infections (3.46 million), diarrheal diseases (2.46 million), HIV/AIDS (1.78 million), tuberculosis (1.34), malaria (1.1 million), and measles (900,000) (WHO 2008) (see Table 51.1).

51.1.3 The Importance of Infectious Disease Epidemiology for Prevention

It is often said that "Epidemiology is the basic science of preventive medicine." To prevent diseases, it is important to understand the causative agents, risk factors, and circumstances that lead to a specific disease. This is even more important for infectious disease prevention, since simple interventions may break the chain of transmission. Preventing cardiovascular diseases or cancer is much more difficult because it usually requires multiple long-term interventions requiring lifestyle changes and behavior modification, which are difficult to achieve.

In 1900, the American Commission of Yellow Fever, headed by Walter Reed, was sent to Cuba. The commission showed that the infective agent was transmitted by the mosquito *Aedes aegypti*. This information was used by the then Surgeon General of the US Army, William Gorgas, to clean up the 200-year-old focus of yellow fever in Havana by using mosquito proofing or oiling of the larval habitat, dusting houses with pyrethrum powder, and isolating suspects under a mosquito net. This rapidly reduced the number of cases in Havana from 310 in 1900 to 18 in 1902 (Goodwin and Gordon Smith 1996).

A complete understanding of the causative agent and transmission is always useful but not absolutely necessary. The most famous example is that of John Snow who was able to link cholera transmission to water contamination during the London cholera epidemic of 1854 by comparing the deaths from those households served by the Southwark and Vauxhall Company versus those served by another water company. John Snow further confirmed his hypothesis by the experiment of removing the Broad Street pump handle (Wills 1996a).

51.1.4 The Changing Picture of Infectious Disease Epidemiology

Over the past three decades, more than 40 new pathogens have been identified, some of them with global importance: *Bartonella henselae*, *Borrelia burgdorferi*, *Campylobacter*, *Cryptosporidium*, *Cyclospora*, *ebola virus*, *Escherichia coli* 0157:H7, *Ehrlichia*, *hantaan virus*, *Helicobacter*, *hendra virus*, *Hepatitis C* and *E*, *HIV*, *HTLV-I* and *II*, *human herpes virus 6* and *8*, *human metapneumovirus*, *Legionella*, new variant Creutzfeldt-Jakob disease agent, *nipah virus*, *norovirus*, *Parvovirus B19*, *rotavirus*, severe acute respiratory syndrome (SARS), etc.

While there are specific causative agents for infectious diseases, these agents may undergo some changes over time. The last major outbreak of pneumonic plague (*Yersinia pestis*) in the world occurred in Manchuria in 1921. This scourge, which had decimated humans for centuries, is no longer a major threat. The plague bacillus cannot survive long outside its animal host (humans, rodents, fleas) because it lost the ability to complete the Krebs cycle on its own. While it can only survive in its hosts, the plague bacillus also destroys its hosts rapidly. As long as susceptible hosts were abundant, plague did prosper. When environmental conditions became less favorable (lesser opportunities to sustain the host to host cycles), less virulent strains had a selective advantage (Wills 1996b).

51.1.4.1 Changes in Etiological Agent

The influenza virus is the best example of an agent able to undergo changes leading to renewed ability to infect populations that had been already infected and immune. The influenza virus is a single-stranded RNA virus with a lipophilic envelope. Two important glycoproteins from the envelope are the hemagglutinin (HA) and neuraminidase (NA). The HA protein is able to agglutinate red blood cells (hence its name). This protein is important as it is a major antigen for eliciting neutralizing antibodies. *Antigenic drift* is a minor change in surface antigens that result from point mutations in a gene segment. Antigenic drift may result in epidemics, since incomplete protection remains from past exposures to similar viruses. *Antigenic shift* is a major change in one or both surface antigens (H and/or N) that occurs at varying intervals. Antigenic shifts are probably due to genetic recombination (an exchange of a gene segment) between influenza type A viruses, usually those that affect humans and birds. An antigenic shift may result in a worldwide pandemic if the virus can be efficiently transmitted from person to person.

51.1.4.2 Changes in Populations at Risk

In the past three decades throughout the world, there has been a shift toward an increase in the population of individuals at high risk for infectious diseases. In industrialized nations, the increase in longevity leads to higher proportion of the elderly population who are more prone to acquiring infectious diseases and developing life-threatening complications. For example, a West Nile virus (WNV) infection is usually asymptomatic or causes a mild illness (West Nile fever); rarely does it cause a severe neuroinvasive disease. In the 2002 epidemic of West Nile virus in Louisiana, the incidence of neuroinvasive disease increased progressively from 0.3 per 100,000 in the 0 to 14 age group to 9 per 100,000 in the 60- to 75-year-old age group and jumped to 32 per 100,000 in the age group 75 and older. Mortality rates showed the same pattern, a gradual increase to 0.7 per 100,000 in the 60 to 75 age group with a sudden jump to 11 per 100,000 for the oldest age group of 75 and older (Balsamo et al. 2003).

Improvement in health care in industrialized nations has caused an increase in the number of immune-deficient individuals, be it cancer survivors, transplant patients, or people on immunosuppressive drugs for long-term autoimmune diseases. Some of the conditions that may increase susceptibility to infectious diseases are cancers, particularly patients on chemo- or radiotherapy, leukemia, lymphoma, Hodgkin's disease, immune suppression (HIV infection), long-term steroid use, liver disease, hemochromatosis, diabetes, alcoholism, chronic kidney disease, and dialysis patients. For example, persons with liver disease are 80 times more likely to develop *Vibrio vulnificus* infections than are persons without liver disease. Some of these infections may be severe, leading to death.

In developing countries, a major shift in population susceptibility is associated with the high prevalence of immune deficiencies due to HIV infections and AIDS. In Botswana, which has a high prevalence of HIV (sentinel surveillance revealed HIV seroprevalence rates of 36% among women presenting for routine antenatal care), tuberculosis rates increased from 202 per 100,000 in 1989 to 537 per 100,000 in 1999 (Lockman et al. 2001), while before the HIV/AIDS epidemics, rates above 100 were very rare.

Changes in lifestyles have increased opportunities for the transmission of infectious disease agents in populations previously at low risk. Intravascular drug injections have increased the transmission of agents present in blood and body fluids (e.g., HIV, Hepatitis B and C). Consumption of raw fish, shellfish, and ethnic food expanded the area of distribution of some parasitic diseases. Air travel allows people to be infected in a country and be halfway around the globe before becoming contagious.

By the same token, insects and other vectors have become opportunistic global travelers. *Aedes albopictus*, the Asian tiger mosquito, which is the vector for dengue, eastern equine encephalitis, and other viruses, was thus imported in 1985 to Houston, Texas, inside Japanese tires. Subsequently, it has invaded 26 US states.

51.1.4.3 Changes in Knowledge About Transmission of Disease Agents

With the advent of nucleic acid tests, it has become possible to detect the presence of infectious disease agents in the air and environmental surfaces. For example, the use of air samplers and polymerase chain reaction analysis has shown that *Bordetella pertussis* DNA can be found in the air surrounding patients with *B. pertussis* infection, providing further evidence of airborne spread (Aintablian et al. 1998) and thus leading to reevaluate the precautions to be taken. However, the presence of nucleic acids in an environmental medium does not automatically mean that transmission will occur. Further studies are necessary to determine the significance of such findings.

51.1.4.4 Bioterrorism Adds a New Dimension

Infectious disease agents, when used in bioterrorism events, have often been reengineered to have different physical properties and are used in quantities not usually experienced in natural events. There is little experience and knowledge about the human body's response to large doses of an infectious agent inhaled in aerosol particles that are able to be inhaled deep into lung alveolae. The probably best examples are the 2001 anthrax attacks in the United States. One week after the September 11 attacks, letters containing anthrax spores were mailed to several news media offices and two US Senators, killing a total of 5 persons and infecting 17 others. During the course of these anthrax letter events, there was considerable discussion about incubation period, recommended duration of prophylaxis, and minimum infectious dose for aerosolized and reengineered anthrax spores. The lack of knowledge base has led to confusion in recommendations being made.

51.2 New Approaches

Although the basics of infectious disease epidemiology have not changed and the discipline remains strongly anchored on some basic principles, technological developments such as improved laboratory methods and enhanced use of informatics (such as advanced mapping tools, web-based reporting systems, and statistical analytical software) have greatly expanded the field of infectious disease epidemiology.

51.2.1 Improved Laboratory Methods

Molecular techniques are being used more and more as a means to analyze epidemiological relationships between microorganisms. Hence, the term molecular epidemiology refers to epidemiological research studies made at the molecular level (see also chapter ▸Molecular Epidemiology of this handbook).

The main microbial techniques use target plasmids and chromosomes, more specifically, plasmid fingerprinting and plasmid restriction endonuclease (REA) digestion, chromosomal analysis including pulse field gel electrophoresis (PFGE), restriction fragment length polymorphism (RFLP), multi-locus sequence type (MLST), and spa typing to name a few of these techniques. Polymerase chain reaction (PCR) is used to amplify the quantity of genomic material present in the specimen. Real-time PCR detection of infectious agents is now possible in a few hours. These techniques are becoming more widely used, even in public health laboratories for routine investigations. For more detailed information on these molecular techniques, please read a book on molecular biology.

Applications of molecular epidemiology methods have completely changed the knowledge about infectious disease transmission for many microorganisms. The main application is within outbreak investigations. Being able to characterize the nucleic acid of the microorganisms permits an understanding of how the different cases relate to each other.

Molecular epidemiology methods have clarified the controversy about the origin of tuberculosis cases: Is it an endogenous (reactivation) or exogenous (re-infection) origin? On the one hand, endogenous origin postulates that *Mycobacterium tuberculosis* can remain alive in the human host for a lifetime and can start multiplying and producing lesions. On the other hand, exogenous origin theory postulates that re-infection plays a role in the development of tuberculosis. The immunity provided by the initial infection is not strong enough to prevent another exposure to *Mycobacterium tuberculosis*, and a new infection leads to disease. In countries with low tuberculosis transmission, for example, the Netherlands, most strains have unique RFLP fingerprints. Each infection is unique, and there are hardly any clusters of infections resulting from a common source. Most cases are the result of reactivation. This is in contrast with areas of high endemicity where long chains of transmission can be identified with few RFLP fingerprinting patterns (Alland et al. 1994). In some areas, up to 50% of tuberculosis cases are the result of re-infection.

Numerous new immunoassays have been developed. They depend on an antigen-antibody reaction, either using a test antibody to detect an antigen in the patient's specimen or using a test antigen to detect an antibody in the patient's specimen.

An indicator system is used to show that the reaction has taken place and to quantify the amount of patient antigen or antibody. The indicator can be a radioactive molecule (radioimmunoassay [RIA]), a fluorescent molecule (fluorescent immunoassay [FIA]), a molecule with an attached enzyme that catalyzes a color reaction (enzyme-linked immunoassay [ELISA or EIA]), or a particle coated with antigen or antibody that produces an agglutination (latex particle agglutination [LA]).

The reaction can be a simple antigen/antibody reaction or a "sandwich" immunoassay where the antigen is "captured" and a second "read out" antibody attaches to the captured antigen. The antibody used may be polyclonal (i.e., a mixing of immunoglobulin molecules secreted against a specific antigen, each recognizing a different epitope) or monoclonal (i.e., immunoglobulin molecules of single-epitope specificity that are secreted by a clone of B cells). It may be directed against an antigen on an epitope (i.e., a particular site within a macromolecule to which a specific antibody binds).

51.2.2 Mapping as an Epidemiological Tool

Plotting diseases on a map is one of the very basic methods epidemiologists do routinely. As early as 1854, John Snow, suspecting water as a cause of a cholera outbreak, plotted the cases of cholera in the districts of Golden Square, St. James, and Berwick in London. The cases seemed to be centered around the Broad Street pump and less dense around other pumps. The map supplemented by other observations led to the experiment of removing the handle on the Broad Street pump and subsequent confirmation of his hypothesis (Frost 1936).

Geographic Information Systems (GIS) have been a very useful tool in infectious disease research. GIS are software programs allowing for integration of a data bank with spatial information. The mapping component includes physical layout of the land, towns, buildings, roads, administrative boundaries, zip codes, etc. Data may be linked to specific locations in the physical maps or to specific aggregates. A GIS system includes tools for spatial analysis. Climate, vegetation, and other data may be obtained through remote sensing and combined with epidemiological data to predict vector occurrence.

However, these tools should be used with caution. They can be useful to generate hypotheses and identify possible associations between risk of disease and environmental exposures. Because of potential bias, mapping should never be considered as more than an initial step in the investigation of an association. "The bright color palettes tend to silence a statistical conscience about fortuitous differences in the raw data" (Boelaert et al. 1998). See chapter ▶Geographical Epidemiology of this handbook.

51.2.3 Computer Reporting and Software Progress

Web-based reporting, use of computer programs, and developments of sophisticated reporting and analytical software have revolutionized epidemiological data collection and analysis. These tools have provided the ability to collect large amounts of data and handle large databases. However, this has not been without risks. It remains crucial to understand the intricacies of data collected to avoid misinterpretation. For example, one should be aware that diseases and syndromes are initially coded by a person who may not be very software proficient, using shortcuts and otherwise could enter data of poor quality.

51.3 Basic Concepts

Too often one sees epidemiologists and statisticians preparing questionnaires, carrying out surveys, gathering surveillance information, processing data, and producing reports, tables, charts, and graphs in a routine fashion. Epidemiology describes the distribution of health outcomes and determinants for a purpose. It is important to question the goals and objectives of all epidemiological activities and tailor these activities to meet these objectives.

The description of disease patterns includes analysis of demographic, geographical, social, seasonal, and other risk factors.

Age groups to be used differ depending on the disease; for example, diseases affecting young children should have numerous age groups among children; sexually transmitted diseases require detailed age groups in late adolescence and early adulthood. Younger age groups may be lumped together for diseases affecting mainly the elderly. Gender categorization, while important for sexually transmitted diseases and other diseases with a large gender gap (such as tuberculosis), may not be important for numerous other diseases.

Geographical distribution is important to describe diseases linked to environmental conditions but may not be so useful for other diseases.

51.3.1 Biology or Natural History of Infectious Diseases: The Intersection of Biology, Microbiology, Climatology, Ecology, and Epidemiology

The natural history of an infectious disease is the way in which the disease is transmitted, how it develops over time from the earliest stage of its prepathogenesis phase to its termination as recovery, disability or death in the human population, in the absence of treatment or prevention.

Epidemiologists dealing with an infectious disease issue are best served by taking the time to study the natural history or biology of that specific infectious disease. Facts to be studied are the nature of the infectious agent (parasite, bacteria, fungus, virus, or prion), the natural hosts, mode of entry into the host and exit from the host, distribution in the host tissues, incubation period, signs and symptoms of illness, natural reservoir in animals or environment, resistance to environmental factors, and geographical distribution of the agent and of human illness (which may be slightly different).

51.3.2 Infectious, Communicable, Contagious, Transmissible Diseases

An infectious disease is a disease due to a specific infectious agent or its toxic products that arises through transmission of that agent or its products from an infected person, animal, or reservoir to a susceptible host, either directly or indirectly through an intermediate plant or animal host, vector, or the inanimate environment (Porta et al. 2008).

Infectious diseases are caused by an infectious agent (helminth, protozoa, fungus, bacteria, virus, or prion, sometimes referred to as microorganisms, although helminths are really not microorganisms).

This definition is apparently simple but may get more complicated:

- The infectious agent does not need to be present all the time. The infectious agent may trigger a pathological process that will continue on its own, even after the agent is gone.
- Other factors may be necessary to trigger the disease; the infectious agent alone cannot cause the disease. The infectious agent may be necessary but not sufficient for the infectious disease. Most agents causing opportunistic infections in AIDS patients cannot cause any disease in normal individuals. They can only cause disease if the host is severely immune-compromised.

The term *communicable disease* is specific to those diseases that can be transmitted from an infected individual to another one directly or indirectly. It is sometimes used interchangeably for infectious diseases (Porta et al. 2008). Sometimes communicable diseases are defined as a subset of infectious diseases that can spread from person to person.

The term *transmissible or contagious disease* is often synonymous to communicable disease.

51.3.3 From Exposure to Disease

The infectious process may be broken down into the following steps. If the infectious disease agent does not gain a foothold, the person was only *exposed* and the infectious disease process ends. If the disease agent gains a foothold but no reaction is occurring, the person will be *colonized* but not infected. An infection occurs when the disease agent attaches itself to the epithelium and begins to multiply. The infectious disease agent will release cytotoxins which will damage the cells and injure the tissue which leads to the dissemination through the human body. Even after dissemination, humans might not show any signs and symptoms and are therefore considered *asymptomatic* or show clinical signs and symptoms and are then considered *symptomatic*.

Exposed means that a person is placed in a situation where effective transmission of an infectious agent could occur. Being exposed does not always mean that transmission did occur. For example, being in the same room as an infectious tuberculous patient is being exposed since tuberculosis is transmitted by droplet nuclei. However, being in the same room with a person with HIV does not meet the criteria for exposure because conditions are not met for transmission to occur.

Exposure definition relies on information that may not be all known:

- Being in the same room with a tuberculous patient means being exposed if the patient is infectious (pulmonary tuberculosis with positive sputum). If the patient is not infectious, then exposure does not occur.
- Sharing a meal that resulted in a food poisoning outbreak is being exposed. If we know that only the potato salad was contaminated, then only those who ate the potato salad were exposed.

Infection: The entry and development or multiplication of an infectious agent in the body of humans or animals. Infection is not synonymous with disease. Disease implies some signs and symptoms or some negative impact on the health status of the individual.

Colonization: Porta et al. (2008) define in the Dictionary of Epidemiology infection and colonization as the same concept. However, in hospital-acquired infection control programs (often abbreviated as "infection control"), a distinction is made between colonization and infection: Colonization is the presence of a microorganism in or on a host with growth and multiplication but *without* any overt clinical expression or immune reaction in the host at the time the microorganism is collected (Brachman 1998). In contrast, infection entails some reaction from the host, either only on an immunological level or on an immunological and clinical level.

A *carrier* is an individual that harbors a specific microorganism in the absence of discernible clinical disease and serves as a potential source of infection. A carrier may be an individual who is colonized, incubating the disease, infected and asymptomatic, or convalescent from acute disease. The period of the carrier status may be short or lengthy. The portal of exit may be urine, genital secretions, feces, and respiratory, or the carrier may not excrete the agent (agent is circulating in the bloodstream).

Clinical infection: Clinical infection may result in signs and symptoms. Some of these may be less obvious or very minor. At the end of the spectrum is the individual with no sign, no symptoms who has an *asymptomatic infection or subclinical infection*. Asymptomatic infection does not mean that "all is quiet." It may cover some very active processes as in the asymptomatic phase of HIV infection, tuberculosis infection, or Hepatitis B carrier state.

51.3.4 Case, Index Case, Primary Case, and Secondary Case

A *case* is an operational definition. It denotes usually a person with a specific infectious disease.

A *surveillance case definition* is not a clinical diagnosis, both have very different purposes. A surveillance case definition is usually very precise and fairly restrictive so as to eliminate subjectivity, as much as possible. It uses a fixed set of indicators to classify disease status regardless of differences between individuals. In contrast to that, a clinical diagnosis' purpose is to ensure best treatment options to the patient and the diagnostic procedures may therefore vary between individuals.

A *diagnosis* is an expression of the clinical judgment of the physician that leads to the therapeutic decisions to be taken.

An *index case* is the earliest documented case of a disease that is included in an epidemiological study or the very first case of an infectious disease that was identified in an outbreak.

A *primary case* is the first individual (case) who brought the infection in the group of population studied. The primary case is not always the index case. The index case may have triggered an investigation, and in the course of the investigation, the primary (or original) case is identified.

A *secondary case* is a case that was infected from the primary case and consequently occurred at a later date. There may be tertiary cases and so on. Usually one does not define cases further than secondary cases. If cases are somewhat synchronized, one may speak of *generations* or waves of cases.

51.3.5 Source, Reservoir, Vehicle, and Vector

A *reservoir* is any person, animal, plant, or environmental medium (soil, water) in which the microorganism normally lives and multiplies, on which it depends primarily for survival, and where it reproduces itself in such a manner that it can be transmitted to the susceptible host. Consider the following examples: Humans are the only reservoir for *Mycobacterium tuberculosis*, measles, chickenpox and smallpox. Numerous animal species are reservoirs for *Salmonella*; rodents are reservoirs for plague. Surface water and water systems are reservoirs for *Legionella*. Soils and the gut of some animals (horses) are reservoirs for tetanus bacteria (*Clostridium tetani*).

A *source of infection* is the actual person, animal, or object from which the infection was acquired.

A *source of contamination* is the person, animal, or object from which environmental media are contaminated. For example, the cook is the source of contamination of the potato salad.

A *vehicle* is an inanimate object which serves to communicate disease, for example, a glass of water containing microbes or a dirty rag.

A *vector* is a live organism that serves to communicate disease. Best known examples are *Anopheles* mosquitoes and malaria as well as *Ixodes* ticks and Lyme disease.

51.3.6 Transmission and Chain of Infection

When describing transmission, one should consider the source of the infectious agent and the portal of entry in the human.

51.3.6.1 The Source of Infectious Material

There are very different sources from where the potential infectious material is coming from. It might be blood splashed on a medical employee during a procedure or a person coming in contact with someone else's blood after a motor vehicle accident. It might be internal body fluids (such as cerebrospinal, pericardial, pleural, peritoneal, synovial, and amniotic fluids), and most of these exposures would occur in the medical setting. For genital fluids (vaginal, prostatic secretions, semen), sexual contact is the main mode of transmission through mucous membranes. Furthermore, transmission of Hepatitis B virus (HBV) and herpes simplex virus (HSV) to the newborn can occur during delivery as the newborns are exposed to vaginal secretions. Both internal and genital fluids can contain blood-borne pathogens (such as HIV, Hepatitis B virus, Hepatitis C virus (HCV), and cytomegalovirus (CMV)). Both secretions (saliva, nasal discharge, sweat, tears, breast milk) and excretions can be infectious. Urine might be contaminated with schistosoma eggs or leptospira bacteria, and feces can contain numerous enteropathogens. Persons can be infected via sexual contact of mucosal membranes (nasal, oropharyngeal, rectal, genital). Contact with contaminated tissue can occur in transfer of human or animal tissue: blood transfusion, blood components (factor VIII), organ transplants, or tissue grafts. Some hormones and proteins may be extracted from the tissue but still carry the infectious microorganisms, for instance, prions of Creutzfeldt-Jakob disease (CJD) in human growth hormone extract. The rabies virus is normally transmitted through animal bites, but also human bites could potentially (however never documented) infect the bite victim with Hepatitis B or C virus. Last but not least, environmental materials such as food, water, air, or even contaminated dust play a major role in the transmission of infectious diseases.

51.3.6.2 The Portal of Entry into Humans

Infectious disease agents can enter the human body through very different paths. They can be inhaled with the air (the respiratory system). Eating contaminated food and drinking contaminated water (gastrointestinal system) can infect persons and of course through sexual activities. Transplacental or intrauterine transmission will pose a risk for the fetuses. Persons also can be infected with viruses, bacteria, rickettsia, and parasites through arthropod bites such as mosquito or tick bites.

51.3.7 Classification of Transmission

51.3.7.1 Droplet Transmission

There are many infectious diseases which are transmitted by droplets (see Box 51.1). Droplets are generated in the upper respiratory tract during talking, singing, spitting, sneezing, and coughing. They are also produced during suctioning, sputum induction, bronchoscopy, and other respiratory procedures. The droplets produced vary in size from 1 to 100 micron (μm). Droplets will fall to the floor; the speed of fall is related to droplet size (see Table 51.2).

Box 51.1. Infections transmitted by droplets

Haemophilus influenzae, *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Corynebacterium diphtheriae*, *Yersinia pestis* (pneumonic plague), *Bordetella pertussis*, *Mycoplasma pneumoniae*, *Streptococcus group* A (pharyngitis, pneumonia, scarlet fever), adenovirus, influenza, mumps virus, parvovirus 19, and rubella virus

Table 51.2 Droplet falling rates

A droplet of (μm)	Will fall in	
100	10 seconds	Droplets above 5 μm are trapped in the nose and upper respiratory tract and usually do not make it to the bronchi
40	1 minute	
20	4 min	
10	20 min	
5–10	30–45 min	May reach the lower respiratory tract
≤5	Droplet nuclei	May be inhaled into the alveoli

Droplet transmission occurs by direct hit when these droplets are propelled from the infected host to the recipient's mouth, nasal mucosa, or conjunctivae. As a rule of thumb, this method of transmission is common within 3 feet of the infected patient. Inhalation of a droplet occurs also while it floats; however, this occurs only during a short period of time since the droplet is falling to the floor. Contact with surfaces contaminated with droplets is the main mode of transmission for rhinoviruses and respiratory syncytial viruses (RSV). Concentrations of rhinoviruses are much higher on the hands than in aerosols. Droplets are created by aerosolization of infectious material: The success of such aerosols reaching susceptible individuals depends on the environmental conditions: humidity, temperature of the air, air currents, and distances of the host. The use of suction devices, catheters in intensive care units (ICU), and blood products in hemodialysis may produce some aerosols containing infectious particles.

In nature, soil particles contaminated with rodent urine have been aerosolized and thought to be responsible for the transmission of hantaviruses. *Legionella* are frequently present in waters (surface waters, hot water systems, and condensation from air conditioning or ventilation systems). When water is sprayed (cooling towers, showers, and cool mist over produce), aerosols containing *Legionella* are generated.

The degree of infectivity depends on the microorganism concentration in the droplets emitted. This varies from one virus to another, from one strain to another. The infecting dose is variable. For some viruses, it may be quite small: seven virions for adenoviruses. Experiments made with influenza virus showed that for similar viral titer in lung tissue, some strains will have very high titer in bronchial secretions while others will not (Schulman 1970).

51.3.7.2 Airborne Transmission

Droplet nuclei or dust particles are responsible for this mode of transmission. Droplet nuclei are small droplets less than 5 μm in diameter. They result from evaporation of larger droplets or from direct formation of smaller droplets (particularly during coughing or during aerosol generating medical procedures). The transmission may occur over a long distance from the source patient.

Tuberculosis (TB) is one of the most important diseases transmitted by airborne means (see Box 51.2). Active pulmonary tuberculosis cases with acid-fast bacilli (AFB) on sputum smear are the cases that are infectious. Tuberculosis is almost exclusively transmitted by droplet nuclei (small particle of 1–5 μm) that contain *Mycobacterium tuberculosis*. The droplet nuclei must reach the pulmonary alveoli to start an infection. Large droplets are swallowed or get stuck in the trachea and bronchus; from there they are brushed back up and swallowed. The rare TB bacilli reaching the stomach are inactivated there. The role of droplet nuclei in the transmission of tuberculosis was demonstrated in several studies. In 1956, Riley and colleagues showed that air coming from rooms occupied by TB patients could infect guinea pigs (Riley et al. 1956). Coughing is the major producer of droplet nuclei. Speaking and singing also produce droplet nuclei, but these do not last very long (see Table 51.3).

Pulmonary tuberculosis cases may have up to 10,000,000 TB bacilli/milliliter (ml) of sputum. A typical sputum smear is about a hundredth of one ml (0.01 ml) and is covering about a 10,000 high power field (magnification ×100 for the oil immersion lens and ×10 for the eye piece). The probability of finding an acid-fast bacillus depends on the concentration of AFB in the sputum, and the number of microscopy fields examined (Toman 2004) (see Table 51.4). In a study carried out among

Box 51.2. Infections transmitted by droplet nuclei

- Tuberculosis (*Mycobacterium tuberculosis*)
- Measles (*Morbilli virus*)
- Chickenpox and shingles (*Varicella zoster* including disseminated zoster)

Table 51.3 Droplet production with coughing and singing

One good cough	⇒ 465 droplet nuclei
30 min after	228 are still airborne (49%)
Counting from 1 to 100	⇒ 1,764 droplet nuclei
30 min later	106 are still airborne (6%)

Table 51.4 Number of AFB per smear and number of immersion fields to be screened

No. of bacilli/ml/sputum	No. of AFB/smear	No. of immersion fields/AFB
10,000	100	100
100,000	1,000	10
1,000,000	10,000	1

Table 51.5 Proportion of infected contacts after index case coughed

Index cases coughed	Proportion of infected contacts (%)
>48 coughs/night	44
<12 coughs/night	27

Box 51.3. Infections transmitted by contact

- Gastrointestinal, respiratory, skin, wound infections
- Colonization with multidrug-resistant bacteria
- Enteric infections, enteroviral infections in infants
- Respiratory syncytial virus (RSV), parainfluenza
- Infectious skin infections: herpes simplex virus (HSV), impetigo, cellulitis, scabies, staphylococcal furunculosis
- Viral hemorrhagic conjunctivitis, viral fevers
- Some respiratory infections, bronchiolitis in infants, children
- Abscess, draining wound

contacts of smear-positive pulmonary cases, Loudon and colleagues showed that the more the index case coughs, the more infected individuals are to be observed among the close contacts (Loudon et al. 1969) (see Table 51.5).

51.3.7.3 Direct and Indirect Contact Transmission

Direct contact transmission results from a direct body surface to body surface contact and physical transfer of microorganisms. Direct contact occurs when shaking hands, taking pulse, turning a patient over, and having sexual intercourse.

Different viruses and bacteria can be transmitted by contact (see Box 51.3). Indirect contact transmission involves contact with the intermediate of an object. Indirect contact occurs through a contaminated dressing, instrument, or glove as well as door handles and keyboards.

51.3.7.4 Gastrointestinal Transmission: Fecal-Oral Route

Transmission by the fecal-oral route is the second most important mode of transmission after the respiratory tract for several infectious disease agents (see Box 51.4). The fecal-oral route refers to the mode of transmission of microorganisms excreted

Box 51.4. Infections transmitted by gastrointestinal transmission: fecal-oral route

- Typhoid fever
- *Shigella* spp.
- Cholera (*Vibrio cholerae*)
- Polio
- Coxsackie virus, echovirus, reovirus
- Norovirus
- Rotavirus
- Hepatitis A, Hepatitis E

by the feces and transmitted to the oral portal of entry through contaminated food, water, milk, drinks, hands, and flies.

The site of entry may be the oropharynx for some microorganisms or the intestinal tract for most viruses. *Surviving through the upper GI tract is essential*. Viruses with envelopes do not survive exposure to hydrochloric acid in the stomach, bile acids in the duodenum, salts and enzymes of the gut. Small enteroviruses without envelope (norovirus, rotavirus, polio, and coxsackie viruses) are able to resist. Hepatitis A and E are also transmitted by the fecal-oral route. For adenoviruses and reoviruses, this route is of minor importance.

Some of these pathogens are essentially found in humans (*Shigella*), while others may survive or multiply in the environment for long periods of time (*Vibrio cholerae*, poliomyelitis virus). This mode of transmission is more amenable to control measures than the respiratory route. Good personal hygiene (mostly proper hand washing), purification of drinking water, pasteurization of milk and dairy products, and sanitary preparation of food are all highly effective prevention measurements for these types of infectious diseases.

51.3.7.5 Gastrointestinal Transmission: Animal Host and Contaminated Food Products

Salmonellas infect a wide variety of domestic animals, birds, and other wildlife. Foods derived from salmonella-infected animal (eggs, dairy products, meat) are the major source of infection if improperly prepared. Salmonella is less often transmitted by water or direct contact. Other microorganisms such as Campylobacter, Yersinia, and Listeria are also transmitted through contaminated food products (see Box 51.5).

Food poisoning overlaps both classes of gastrointestinal transmission. Food poisoning may result:

- From consumption of food from an infected animal or undercooked eggs, for example, chicken and eggs with *Salmonella* or *Listeria* in unpasteurized milk

Box 51.5. Infections transmitted by gastrointestinal (GI) transmission: animal host and contaminated food products

- Salmonella
- Campylobacter
- Yersinia
- Listeria

- From consumption of food contaminated in the environment, for example, *Vibrio vulnificus* or *Vibrio cholerae* in raw oysters or undercooked seafood
- From food contaminated during preparation from an infected food item, for example, potato salad contaminated with *Salmonella* from raw chicken because the uncooked chicken and the salad ingredients were cut on the same cutting board
- From food contaminated by a human source, for example, typhoid fever carrier

51.3.7.6 Skin or Mucous Membrane Transmission

Transmission through the skin is the third most common mode of transmission of infection. Penetration through the intact skin is unlikely. Break in the skin barrier may result from needle injection, cut during a surgical procedure, accidental cut, crushing injury, and bite (rabies).

Transmission of blood-borne pathogens (Hepatitis B and C viruses (HBV, HCV) and HIV) does not occur if the blood was splashed exclusively on intact skin. Penetration through the skin is necessary. In the case of HIV, it takes injury with a hollow bore needle or other sharp object (lancet, glass, and scalpel) with blood to cause an infection. Solid needles do not carry sufficient quantities of blood to cause an infection. The viral titer is the best predictor of risk of infection. After percutaneous exposure to blood from infected patients, the risk of infection in the recipient is 30% for HBV (eAntigen positive), 3% for HCV, and 0.3% for HIV. This follows the ranking of viral titers.

Mucosal membranes allow penetration by blood-borne pathogens. Data from 21 studies worldwide on mucosal membrane exposure to HIV showed only one conversion in a total of 1,107 health-care workers (HCWs). The proportion of conversion was 0.09% (1/1,107).

Some parasites are able to penetrate actively through the intact skin: hookworm larvae and schistosoma cercariae.

51.3.7.7 Sexual Transmission (Mucous Membrane Transmission)

The genital tract is a special case for transmission through the mucosal membranes. The bacteria and viruses listed are present in the genital fluids and on the mucosal membranes (see Box 51.6). They may be transmitted to the mucosal membranes of the partner during sexual acts: Membranes involved may be the vagina, penile urethra, anus and rectum, or oropharynx. Some of microorganisms such as *Shigella* spp. and *Campylobacter* spp. are primarily considered to be transmitted to the gastrointestinal (GI) tract. However, due to transmission when the rectum is involved in sexual activities, they are also listed as sexually transmitted disease (STD) agents.

The presence of lesions on the recipient partner seems to predispose to acquisition of infection, particularly for HIV.

51.3.7.8 Perinatal Transmission (Mucous Membrane Transmission)

These infections (see Box 51.7) occur when the newborn goes through the birth canal, from the cervix or vagina to the newborn.

Box 51.6. Sexual transmissions (mucous membrane transmission)

- *Neisseria gonorrhoeae*, *Chlamydia trachomatis*
- *Treponema pallidum* (syphilis)
- *Hemophilus ducreyi*
- *Mycoplasma hominis*, *Ureaplasma urealyticum*
- *Calymmatobacterium granulomatis*
- *Shigella* spp., *Campylobacter* spp.
- Group B streptococci
- Bacterial vaginosis-associated bacteria
- Herpes simplex virus (HSV) 1 and 2
- Cytomegalovirus (CMV) or herpes virus 5
- Hepatitis B virus (HBV)
- Human papilloma virus
- Molluscum contagiosum virus
- HIV (human immunodeficiency virus) 1 and 2
- *Trichomonas vaginalis*
- *Entamoeba histolytica*, *Giardia lamblia*
- *Phthirus pubis*
- *Sarcoptes scabiei*

Box 51.7. Perinatal transmission (mucous membrane transmission)

- *Neisseria gonorrhoeae*
- *Chlamydia trachomatis*
- HBV
- HSV

Box 51.8. Transplacental transmission or vertical transmission

- *Treponema pallidum* (syphilis)
- *Toxoplasma gondii*
- CMV, HBV
- HIV
- HSV
- Rubella, varicella

51.3.7.9 Transplacental Transmission or Vertical Transmission

The microorganisms in this case are present in the blood of the mother and are able to go through the placenta to infect the fetus (see Box 51.8). In some cases, it is difficult to differentiate between perinatal or transplacental transmission, since both modes of transmission are known to occur.

51.3.7.10 Urinary Transmission

Although some bacteria (typhoid fever, leptospirosis) and viruses (CMV, measles) may be excreted in the urine, the role of urine is a minor one in the transmission of diseases. In urinary schistosomiasis, the adult worms live in the venous plexus around the urinary bladder. They lay their eggs in the lining of the bladder. The eggs are excreted in the urine. If they reach water, they hatch into larvae which look for a suitable intermediate host (freshwater mollusk).

51.3.7.11 Arthropod-Borne Transmission

Mosquitoes, flies, fleas, true bugs, ticks, and lice may transmit various microorganisms by two mechanisms (see Table 51.6):

1. Passive transmission: the insect acts as a live syringe. It picks up microorganisms from blood or superficial lesions and passes them on to another human. There is no incubation time, no multiplication of microorganisms while carried by the arthropod. This mode of transmission is not specific; a wide variety of microorganisms may be transmitted, but the transmission is not very efficient.
2. Active transmission involves multiplication of the microorganisms in the arthropod. This applies only to some microorganisms with a definite set of arthropods. This mode of transmission may be very effective: The microorganisms may be multiplied a thousand to a million times. This mode requires a period of multiplication in the arthropod.

51.3.7.12 Common Vehicle Transmission

The microorganisms have contaminated the "common vehicle" and are persisting over a long period of time in/on the common vehicle. The common vehicle can

Table 51.6 Arthropod-borne diseases

Disease (infectious agent)	Vector/intermediate host
Bacteria	
Plague (*Yersinia pestis*)	Fleas
Borrelia	
Lyme disease (*Borrelia burgdorferi*)	*Ixodes* ticks
Relapsing fever (*Borrelia recurrentis*)	*Ornithodoros* ticks
Rickettsia	
Epidemic typhus (*Rickettsia prowazekii*)	Lice, Pediculus humanus
Murine typhus (*Rickettsia typhi*)	Fleas
Scrub typhus (*Rickettsia tsutsugamushi*)	Larval mites
Rickettsialpox (*Rickettsia akari*)	Mouse mite
Rocky Mountain spotted fever (*Rickettsia rickettsii*)	*Dermacentor, Amblyomma* ticks
Trench fever (*Rickettsia quintana*)	Lice
Virus	
Dengue	*Aedes aegypti*
Flaviviridae	Mosquitoes
St. Louis encephalitis	*Culex* mosquitoes
Japanese encephalitis	*Culex* mosquitoes
Tick-borne encephalitis	*Ixodes* ticks
Powassan	*Dermacentor* ticks
Togaviridae: Alphavirus	
Eastern equine encephalitis	Mosquitoes
Western equine encephalitis	Mosquitoes
Venezuelan equine encephalitis	Mosquitoes
Bunyaviridae	
California encephalitis, La Crosse	Mosquitoes
Crimean-Congo hemorrhagic fever	Ticks
Kyasanur forest hemorrhagic fever	Ticks
Yellow fever	*Aedes* mosquitoes
Protozoa	
Malaria (*Plasmodium* sp.)	*Anopheles* mosquitoes
Chagas disease (*Trypanosoma cruzi*)	*Triatoma* sp. (bugs)
Sleeping sickness (*Trypanosoma gambiense*)	*Glossina* sp. (tsetse flies)
Leishmaniasis (*Leishmania* sp.)	*Phlebotomus* (sandflies)
Helminths	
Bancroft's filariasis (*Wuchereria bancrofti*)	*Culex*, *Aedes*, and *Anopheles* mosquitoes
Malayan filariasis (*Brugia malayi*)	*Culex*, *Aedes*, and *Anopheles* mosquitoes
Mansonella ozzardi	*Culicoides*, *Simulium*
Acanthocheilonema perstans	Gnats, *Culicoides*
Onchocerciasis (*Onchocerca volvulus*)	Black gnats, *Simulium*
Loiasis (*Loa loa*)	Mango flies, *Chrysops*

be food, water (either drinking the water or swimming in the water), soil (tetanus bacteria), medications, medical devices, or equipment.

51.3.8 Different Roles in Transmission: Indicator, Maintenance, and Amplifier

For some infectious diseases, different segments of the population play different roles. The best example for that is foot-and-mouth disease (FMD), a viral disease which rarely affects humans. Cloven-hoofed animals (such as cattle, goats, sheep, and pigs) are susceptible to FMD. FMD viruses are transmitted by air from one infected animal to another. Pigs are considered to be the amplifier host because they may exhale up to 1 million viral particles/ml of air. Sheep are an important reservoir of the virus and are considered maintenance hosts. They are usually asymptomatic when infected with foot-and-mouth disease. When these sheep mix with cattle, the cattle develop severe clinical signs and are therefore easily detected (*indicator host*).

51.3.9 Incubation Period, Latent Period, and Serial Interval

51.3.9.1 Incubation Period

The incubation period is the time interval between the invasion by a microorganism and the first signs or symptoms of disease (onset of disease). The concept of incubation period relies on the assumption that the disease is not asymptomatic and that the onset is clearly identifiable. For asymptomatic cases or carriers, incubation periods are irrelevant. For some infections, a person may get exposed to the agent, become colonized, and sometime in the future become a case. If this happens, incubation is also irrelevant. Incubation periods are only useful if infection is followed by disease within a certain period of time. Incubation periods are useful tools when carrying out infectious disease investigations. A person usually can tell when the first symptoms of a specific disease appeared. From that date, subtracting the incubation period, epidemiologists may estimate the date of infection (within a certain interval). It is also important for follow-up on potential contacts to the primary case that the primary case might have been already infectious before exhibiting any clinical signs and symptoms (see Fig. 51.1). In many instances, a person may be infectious toward the end of the incubation period but before the appearance of the first symptoms. The incubation period varies according to numerous factors:

- Portal of entry: The closer the portal of entry to the site of disease, the shorter the incubation period.
- Type of infection (local or systemic): Diseases caused by local multiplication of a microorganism have short incubation periods. Those that require systemic dissemination and secondary localization have longer incubation periods.
- Pathogenesis: Diseases due to a preformed toxin have very short incubation periods. Diseases due to direct involvement of epithelial surfaces have short incubation periods, for example, streptococcal sore throat, bacterial pneumonias,

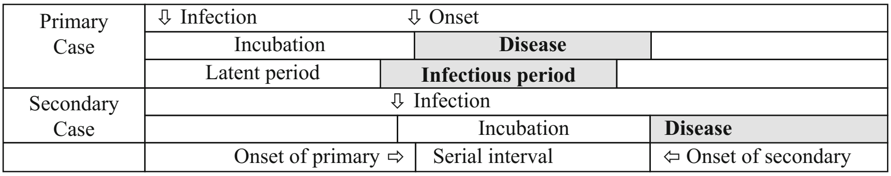

Fig. 51.1 Incubation, latent period, and serial interval

shigellosis, cholera, and gonorrhea. In contrast, *Mycoplasma pneumoniae*, diphtheria, and pertussis as well as diseases like syphilis, brucellosis, and typhoid fever have long incubation periods (2–3 weeks).

- Immune status of the host: It is important that the notion of incubation is relative. HIV provides a good example. Infection of an individual with HIV is followed by a flu-like syndrome. It includes fever, headache, miscellaneous aches (neck and back), malaise, lymphadenopathy, and rash. The incubation period for this primary syndrome is 2 weeks to 2 months. The patient then enters into a remission period with no clinical signs. However, during this period, the HIV multiplies at variable rates, destroying CD4+ lymphocytes which are generated as fast as they are destroyed. The latent remission ends when the patient's organism is no longer able to produce CD4+ lymphocytes in sufficient quantities. Immune defenses fail rapidly and opportunistic infections develop. This phase is considered as the AIDS (acquired immune deficiency syndrome) disease. The incubation period for AIDS diseases ranges from 2 to 10 years, with less than 10% having an incubation period greater than 10 years.

In rabies, the incubation period depends on the length of time it takes the virus to progress along the neurons to reach the brain. Once the brain is reached, the disease becomes manifest. The incubation may be as short as 9 days if the bite was in the face or as long as 1 or 2 months if the bite occurred in the leg. The longest incubation period known for rabies virus is 9 years.

The incubation period is useful for tracing the source of infection and contact, determine the period of surveillance, allow for prophylaxis to become effective (diseases with a long incubation period may be prevented by immunization if administered early), identification of point source or propagated epidemics.

Incubation period in a vector is the time interval between entry of the microorganism in the vector and the time the vector becomes infective. This is also called the extrinsic incubation in contrast to the intrinsic incubation period in humans.

51.3.9.2 Latent Period

The latent period of infection is the length of time between infection and the beginning of the infectious period. It is also a period during which no symptoms occur, an asymptomatic window in the disease (latent period of syphilis, of HIV infection).

51.3.9.3 Serial Interval

A serial interval for diseases spread from person to person is the time between successive generations of cases, that is, the time between appearances of symptoms in successive generations. If a person is infectious before onset of symptoms, the serial interval may be lower than the incubation period.

51.3.9.4 Infectious (Infectivity) or Communicability Period

The infectious (infectivity) period is the length of time a person may transmit a microorganism. There are several patterns for infectious periods:

- Short period at the end of the incubation period and at the beginning of the disease (measles, chickenpox)
- Short period and a few individuals become chronic carriers (Hepatitis B)
- Throughout the disease (open cases of active pulmonary tuberculosis, malaria).

Measuring infectivity is difficult. It is seldom the result of well-controlled studies. It is often the interpretation of observational studies on the occurrence of secondary cases. Factors such as amount of infectious agents put out by the source, closeness, length of contact, and susceptibility of the target contacts have to be considered. In recent times, nucleic acid testing has been used to find remnants of infectious disease agents in human or environmental materials, but their significance to transmission is difficult to interpret.

51.3.10 Distribution Pattern in the Population

For a better understanding of the distribution of infectious diseases in populations, the below terms have to be defined: Epidemiologists define *sporadic* cases as the occurrence of single illnesses in irregular or random instances. *Endemic* defines the occurrence of cases of an illness with a constant frequency. Depending on the intensity of the occurrence, the terms holoendemic, hyperendemic, or hypoendemic are used. *Epidemic is defined as the* occurrence in a community of cases of an illness with a frequency clearly in excess of normal expectancy. If this occurrence of an epidemic occurs worldwide or affects numerous countries, epidemiologists consider it a pandemic. The most recent pandemic was declared in June 2009, when the WHO declared a pandemic of novel influenza A (H1N1). At the time, more than 70 countries had reported cases of novel influenza A (H1N1) infection, and there were ongoing community level outbreaks of novel H1N1 in multiple parts of the world. An *outbreak* is defined as two or more related cases with the identical infectious disease agent suggesting the possibility of a common source or transmission between these cases. It also could be defined as a very limited epidemic; however, the word "epidemic" is usually avoided when the number of cases is relatively small so as not to scare the public. *Elimination of disease* is the reduction to zero of the disease incidence in a defined geographical area (e.g., neonatal tetanus) compared to the *elimination of infections* which is defined as the reduction to zero of incidence of infection in a defined geographical area (e.g., measles, poliomyelitis).

Table 51.7 Infectious dose and attack rates

Dose (no. of organisms)	Attack rate (%)
Experimental human salmonellosis	
125,000	17
695,000	33
1,700,000	67
(McCullough and Eisele 1951)	
Typhoid fever	
1,000	0
100,000	28
10,000,000	50
100,000,000	89
1,000,000,000	95
(Hornick et al. 1970)	

If there is a permanent reduction to zero in the worldwide incidence, the disease is considered *eradicated*, such as smallpox was in 1980.

51.3.11 Infectious Dose

The dose of pathogens received by the exposed individual is an important aspect of infectivity. There is also a close correlation between dose and type of contact. A closer, more direct type of contact delivers a higher dose.

It is rarely possible to have an exact measure of the infecting dose. In the past, experiments have been carried out with human volunteers. In one experiment, *Salmonella bareilly* was given to several groups of six volunteers (McCullough and Eisele 1951). A case was defined as one experiencing clinical diarrhea with *S. bareilly* isolated from the stools. Some of the cases excreted *Salmonella* for 1 day, some for 2 days. The corresponding attack rates, that is, percentage of volunteers experiencing a clinical diarrhea, are displayed in Table 51.7. The attack rate depends heavily on the working case definition.

From this type of data, one may calculate an infectious dose 50 (ID50) = the dose of pathogenic microorganism that will cause disease in 50% of the susceptible exposed. In some outbreaks, particularly foodborne outbreaks where contaminated food is saved, it may be possible to estimate the infectious dose. The dose may also be important in determining the severity of disease. To give an example, 1,000 *Vibrio cholerae* bacteria produce asymptomatic infections, 10,000 to 1 million bacteria produce simple diarrhea in 60%, and at least 1 million bacteria produce severe diarrhea with dehydration in 25–50% of volunteers.

51.3.12 Environmental Factors

There are several factors which influence the spread of microorganisms in the environment. The spread of infectious diseases depends on:

1. The stability of the microorganism in the physical environment required for its transmission including resistance to desiccation, high or low temperature, and ultraviolet light
2. The amount of microorganisms in the vehicle of transmission
3. The virulence and infectivity of the microorganisms
4. The availability of the proper vector or medium for the transmission

Environmental characteristics play a role on different levels:

1. Survival of the virus in the environment
2. Influence on the route of transmission
3. Influence on the behavior of the host

A warm environment enhances the transmission of microorganisms transmitted by water. In tropical and temperate areas, summer increases contacts between humans and surface water. Summer brings more people outside, particularly in the evening, and increases contacts between humans and mosquitoes and other arthropod vectors.

In the cooler seasons in temperate climates, in the rainy season in tropical climates, people tend to stay and congregate indoors promoting transmission by airborne or droplet mechanisms. Long stays in the hot and dry environment indoors impair the protective mechanisms of human mucous membranes and may facilitate the attachment of viruses onto the upper respiratory mucous membranes. The incidence of upper respiratory infections is as high in the middle of winter in the temperate climates as in the middle of the monsoon or rainy season in the tropical climates.

51.3.13 Host Factors

51.3.13.1 Extrinsic Host Factors

Exposure to infectious disease agents depends on both intrinsic (internal) and extrinsic (external) host factors. Extrinsic host factors are the method of transmission of the microorganism as well as the host behavior. Exposure to microorganisms which are transmitted by droplet or airborne modes is very common. Anyone who is out in the public is likely to be exposed to these microorganisms. Microorganisms which are transmitted by vectors result usually from special occupations or special settings (hobbies or leisure activities). For example, persons who love to be outdoors (camping, hiking, or working on fields or in the forest) are more likely to be bitten by ticks or mosquitoes and therefore more likely to develop one of the zoonotic diseases which are transmitted by these arthropods. Exposure to sexually transmitted microorganisms depends entirely on the sexual activities, number of sex partners, and/or lifestyle of the hosts and the carriers of these diseases.

51.3.13.2 Intrinsic Host Factors

The transmission of infectious diseases is also regulated by intrinsic factors that influence the host response. It depends on how many microorganisms are transmitted (dose), how virulent the strain is, and how the microorganisms enter the human body. The person's age at time of infection is important, too. In general, the probability of clinical disease increases with age (e.g., polio, Hepatitis). Preexisting level of immunity to the disease, the nutritional status of the host, as well as any preexisting disease will influence a successful transmission as well. Individuals with impaired immune response (HIV, patients on immunosuppressive therapy for cancer or transplant) have a higher risk of developing severe disease. Also personal habits or lifestyle factors such as smoking, drinking alcohol, drug abuse, or exercise can influence the host response. Smoking depresses the ciliary function of the bronchial tree and increases susceptibility to infections (e.g., tuberculosis). Alcohol consumption increases the risk for chronic Hepatitis infections. Also psychological factors such as motivation and attitude toward disease can contribute to the transmission of infectious disease agents.

51.4 Occurrence of Infectious Diseases

Especially in outbreak situations, epidemiologists investigate the occurrence of disease by asking the following questions:

- When did the disease occur (time)?
- Where do the cases come from (place)?
- Who got infected with the disease (person)?

51.4.1 Time

51.4.1.1 Epidemic Curve

An epidemic curve is the standard graphic representation of cases occurring over time. It is a histogram with number of cases plotted along the vertical axis and time along the horizontal axis. The time unit may be in hours (rapid outbreak such as foodborne outbreaks due to a toxi-infection), days, or weeks. It is important to have a good time unit applied; if the time unit is too short or too long, one does not get a visual picture of the outbreak dynamics.

The examples in Figs. 51.2 and 51.3 show the epidemic of a Saint Louis encephalitis (SLE) outbreak that occurred in Louisiana in September to October 2001. Figure 51.2 uses days as a time unit, and Fig. 51.3 uses weeks. Figure 51.3 provides a better understanding of the outbreak.

An epidemic curve may provide some clues about the nature of the outbreak. A point source outbreak is relatively contracted in time, while a continuous source outbreak is more stretched out. In the beginning of an outbreak which is due to person-to-person transmission, one may see the successive generations.

51.4.1.2 Seasonal and Annual Variations

Seasonal variations are important for some infectious diseases, particularly those which are heavily influenced by the environment such as water, food, and arthropod

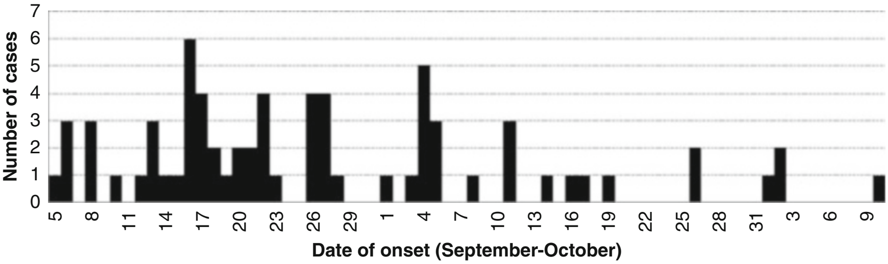

Fig. 51.2 Saint Louis encephalitis (SLE) outbreak, Monroe, Louisiana, September–October 2001, epidemic curve by day of onset

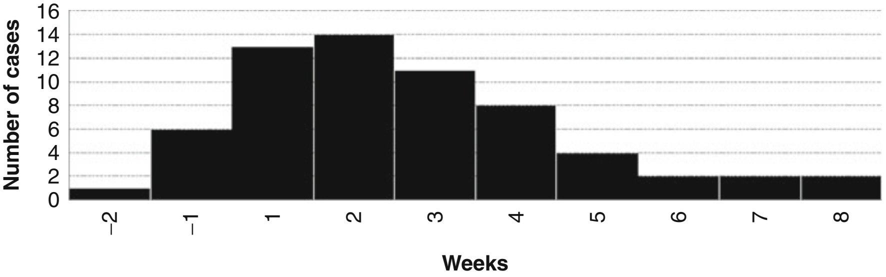

Fig. 51.3 Saint Louis encephalitis (SLE) outbreak, Monroe, Louisiana, September–October 2001, epidemic curve by week of onset. Week 1 = notification of SLE cases. Some cases actually had onset before notification (hence week −1 and week −2)

vectors. These are more prevalent during the warmer months of the year. Respiratory infections on the other hand are more prevalent during the winter in temperate areas or the rainy season in tropical areas.

Annual variations are thought to be mostly the result of accumulation of immune people after epidemics of an infectious disease. Once the proportion of the immune population has reached a certain threshold, there are very few susceptible individuals. In the absence of large epidemics, the pool of susceptible builds up back again, and herd immunity is down again. Then the circumstances are right for another epidemic. These cyclical patterns vary, every other year for measles before the advent of the vaccine, every 3–4 years for pertussis.

51.4.2 Place

Mapping cases is a very common tool used in infectious disease epidemiology. The map may range from a facility to a city, county, province, or country. Maps may be spot maps or rates in boundaries. Mapping may also provide some clues as to the etiology and evolution of an outbreak.

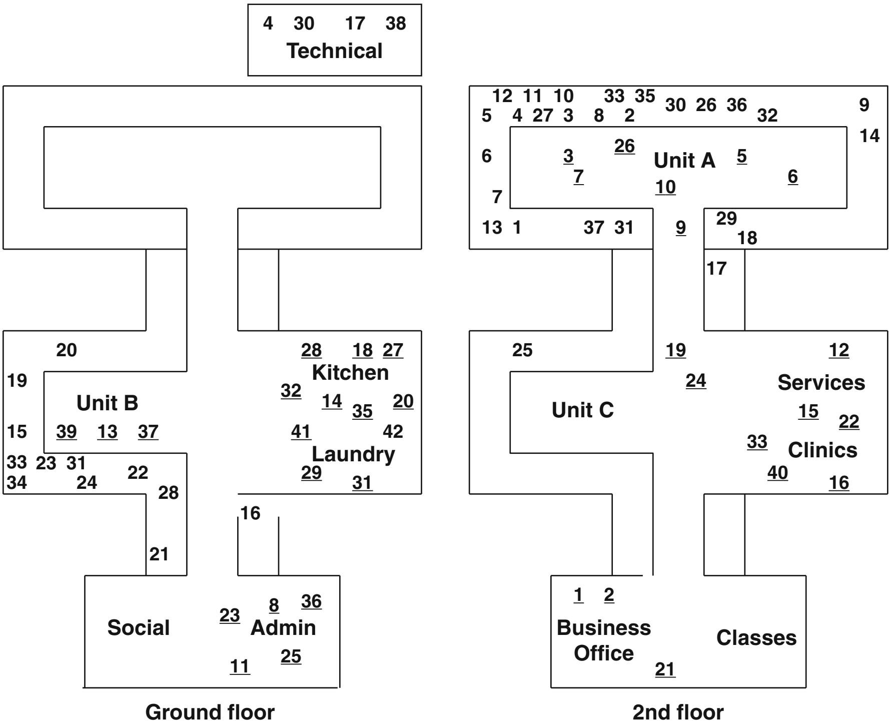

Fig. 51.4 Norovirus outbreak, nursing home, New Orleans 2005

Figure 51.4 shows a map of a nursing home outbreak that occurred in New Orleans in April 2005. Cases are plotted according to their location and are numbered in sequence as they were diagnosed. Cases among employees are underlined compared to cases among patients which are not underlined. The outbreak started with two unattached employees (as indicated as numbers 1 and 2 in Fig. 51.4); they infected an employee in A Unit (number 3). This was followed by a large outbreak in the Unit A. Then an employee in the Unit B was infected and soon after the outbreak was continuing in Unit A but also spreading in Unit B while it also spread among unattached employees. The Unit C was mostly vacant, so there were few cases.

The floor map is accompanied by an epidemic curve showing the cases by their location (A = patients in Unit A, a = employee in Unit A, similarly for unit B and C, and e for employee not attached to a specific unit) (Fig. 51.5).

51.4.3 Host Immunity

The immune status of individuals plays a major role in their susceptibility to infectious agents.

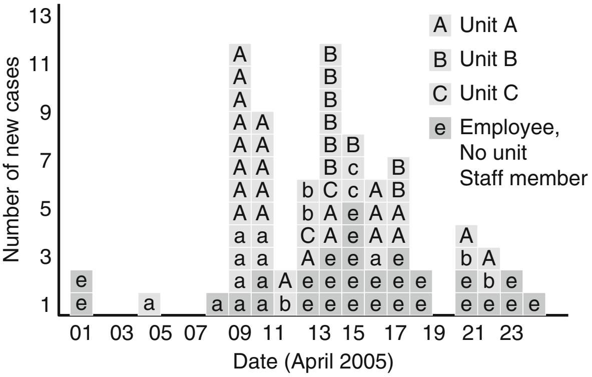

Fig. 51.5 Epidemic curve of a Norovirus outbreak in a nursing home, New Orleans, April 2005

51.4.3.1 Specific Immunity

After acquiring an infectious disease, the immune system reaction may (or may not) lead to protection against another attack of the disease. This so-called refractory period is the time period where no other infection of this disease can occur. It may last from a few days up to lifetime depending on the infectious agent. For some infections such as gonorrhea and *Chlamydia*, there is hardly any protection. A person may become re-infected soon after being cured of the previous infection. For some diseases such as syphilis, a person may not be super-infected while being already infected (immunity of premonition). Once treated, the immunity disappears. For others, the immunity may last for years or even a lifetime (measles, chickenpox). Lifetime immunity may be boosted by repeated contacts with the infectious agents. Immunity may have been acquired following an overt clinical bout of disease or following an unapparent infection. Eighty percent of children in the USA are immune to cytomegalovirus (CMV) infection, and the majority have had a completely asymptomatic infection.

The herd immunity is the immunity of the group. It is related to the sum of immune individuals over the total population. If a high proportion of a population is immune to a disease, one speaks of herd immunity. Above a certain threshold, the incidence of infections may decline. For example, invasive pneumococcal disease decreased dramatically after the pneumococcal conjugate vaccine (PCV7) for young children was introduced in 2000 in the USA. The modeled incidence of pneumococcal disease covered by this vaccine decreased by 76.6% in the unvaccinated population if the three-dose vaccination was completed in children before 15 months of age based on an estimated vaccine coverage between 38.1% and 54% in this population (Haber et al. 2007).

51.4.3.2 Immunocompetence

Immunocompetence is the ability of the immune system to respond to foreign substance and provide adequate protection. Humans with normally functioning immune systems are protected against a wide variety of infectious agents.

Immunocompetence is not fully developed in newborns and is weakened by age or by numerous chronic, acute diseases or medical treatments. Deep depression of the immune system is called immune deficiency. Infection by the HIV virus leads to a profound acquired immune-deficiency syndrome (AIDS). The spread of an infection may be very different depending on the prevalence and distribution of immune-deficient individuals. For example, levels of tuberculosis disease reach the highest incidence in countries with high prevalence of HIV infection.

51.4.4 Contacts: Patterns, Networks, and Structures

Contacts (the persons who are the recipients of the infectious agent) and contact patterns are important in infectious disease epidemiology. Contact may be defined as the type of interaction (or situation) between a person acting as a source of an infectious agent and a person susceptible when the interaction may lead to transmission of the infectious agent.

51.4.4.1 Contact and Interaction

The types of contact vary widely with the type of transmission. Direct contact occurs when the infected host and the susceptible recipient have their skin or mucous membranes touching, for example, by shaking hands, kissing, or having sexual intercourse. Indirect contact occurs when the transmission between both persons involve an inanimate object (fomite) or a mechanical vector (e.g., fly).

When exposure occurs through the air, droplets or droplet nuclei are the vehicles of the infectious agent. The circumstances of the "contact" require a precise definition. For example, a contact of an infectious pertussis case is a person who (1) had face-to-face interaction at less than 3 ft for at least 10–15 min or (2) shared confined space for 1 hour or (3) had a child in a crib located 3–6 ft away or (4) had direct contact with oral, nasal, or respiratory secretions or (5) had shared food, drink, or eating utensils or (6) kissed or (7) was in a medical setting during examination of mouth, throat, intubation, or cardiopulmonary resuscitation (CPR). This type of very detailed definitions is useful to determine the persons at risk of infection and place them under surveillance or prophylaxis.

51.4.4.2 Contact Patterns: Sociograms

Sociograms were developed to analyze choices or preferences within a group. They can diagram the structure and patterns of group interactions. A sociogram consists of nodes (people) and links (contact meeting the definition of a possible transmission).

The nodes on a sociogram who have many choices are called stars. Those with few or no choices are called isolates. Individuals who choose each other are known to have made a mutual choice. One-way choice refers to individuals who choose someone, but the choice is not reciprocated. Cliques are groups of three or more people within a larger group who all choose each other (mutual choice).

The following is an example of a sociogram for sexual contact patterns in a hypothetical high school (Fig. 51.6). Squares represent males, circles females, and

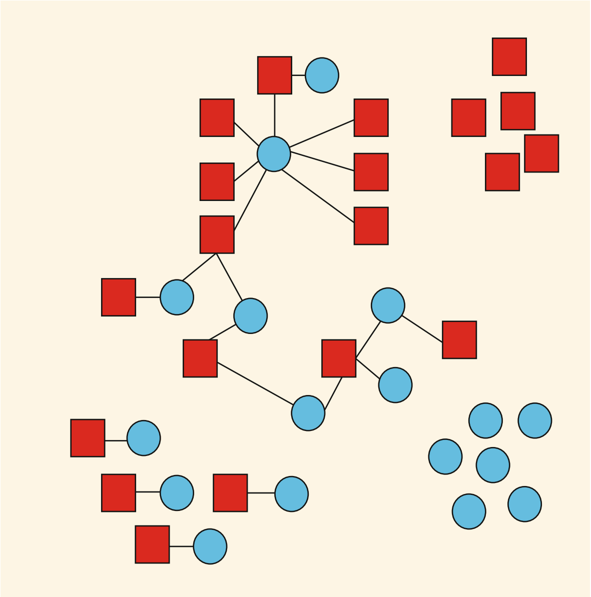

Fig. 51.6 Example of a sociogram depicting sexual relations in a hypothetical high school. Square = male, circle = female

links sexual relations. There are celibate males and females, isolated pairs and a large network of individuals having sexual relations, some with a single partner, and some with multiple partners. Such sociograms may be useful to describe and understand an outbreak, but it may also be useful to describe contact patterns in the absence of any specific disease. It would then help understand what would happen if an outbreak would occur in the population.

51.4.5 Risk Measures

Incidence rate (cumulative incidence), incidence density, and prevalence are commonly used (see chapter ▸Rates, Risks, Measures of Association and Impact of this handbook). The numerator may be the number of cases or the number of persons with serological evidence of past infections for example. Depending on the circumstances, the denominator may be the entire population or the number of persons exposed. All rates used in epidemiology are also used in epidemiology of infectious diseases. However, attack rate and case fatality rates are especially common to infectious disease epidemiology.

51.4.5.1 Attack Rate

The *attack rate* is the proportion of those exposed to microorganisms that develop the disease. Attack rates are frequently used in infectious disease epidemiology. They are heavily influenced on the used definition of exposure and disease. If a segment of the population is immune (previous natural infection or immunization), it will not be susceptible to the disease, and therefore, the attack rate will be underestimated. Attack rate is a misnomer. The attack rate is a cumulative incidence of cases that occurred during an outbreak.

51.4.5.2 Case Fatality Rate

The case fatality rate is the proportion of people who will die of a certain disease over those who have the disease. Since it is a rate, a time period has to be specified. It is different from the mortality rate which is the proportion of the entire population which dies from a certain disease during a definite period of time (usually 1 year).

51.4.5.3 Reproductive Rate

The reproductive rate is the average number of cases that will result from an index case. The reproductive rate depends on the:

- Probability of transmission in a contact between infected and susceptible
- Frequency of contacts in the population
- Duration of infection
- Proportion already immune in the population

51.4.6 Study Designs

Although any design is used in infectious disease epidemiology studies, the most common designs are descriptive and case-control studies (see previous sections in this handbook).

Case reports are detailed descriptions of single cases with exposure, clinical, treatment, and other relevant information. Description of single cases exposed under unusual circumstances may have profound consequences on the prevention of infectious diseases (case of HIV transmitted by a dentist, cases of rabies transmitted by unspecified contact with bats, case of West Nile virus infection transmitted by transfusion or transplantation).

Case series are descriptions of a cluster of cases with detailed exposure, clinical and outcome data without controls. Such case series description has led to the identification of AIDS (cluster of Kaposi's sarcoma and of *Pneumocystis carinii* among homosexual men) and Lyme disease (*Borrelia burgdorferi*) (cluster of arthritis in children in Lyme, Connecticut).

Case-control and *cohort studies,* even though important for infectious disease epidemiology, are not discussed here since the methodology is described in detail in earlier chapters (e.g., see chapters ▶Cohort Studies, ▶Case-Control Studies, ▶Modern Epidemiological Study Designs, ▶Epidemiological Field Work in Population-Based Studies, and ▶Exposure Assessment of this handbook).

51.5 Surveillance Issues

Surveillance is the continuous scrutiny of all aspects of occurrence and spread of a disease that are pertinent to effective control (Porta et al. 2008; see also chapter ▶Emergency and Disaster Health Surveillance of this handbook).

The basic activity in surveillance is to identify new cases. Surveillance, both active and passive, is the systematic collection of data pertaining to the occurrence of specific diseases, the analysis and interpretation of these data, and the dissemination of consolidated and processed information to contributors to the program and other interested persons (CDC 2001b). Surveillance has multiple purposes. It provides quantitative data on the magnitude of an illness, documents the distribution throughout the population and the geography leading to information on the natural history of the disease, allows detecting outbreaks, monitors changes in illness patterns, and evaluates the effects of control measures.

51.5.1 Passive Surveillance

In a *passive surveillance system*, the surveillance agency has devised and put a system in place. After the placement, the recipient waits for the provider of care to report. *Passive case detection* has been used for mortality and morbidity data for decades throughout the world. Many countries have an epidemiology section in the health department that is charged with centralizing the data in a national disease surveillance system collecting mortality and morbidity data.

In theory, a passive surveillance system provides a thorough coverage through space and time and gives a thorough representation of the situation. Practically, compliance with reporting is often irregular and incomplete. In fact, the main flaws in passive case detection are incomplete reporting and inconsistencies in case definitions.

The main advantages are the low cost of such a program and the sustained collection of data over decades. The purpose is to produce routine descriptive data on communicable diseases, generate hypotheses, and prompt more elaborate epidemiological studies designed to evaluate prevention activities.

Some conditions must be met to maximize compliance with reporting:

1. Make reporting easy: provide easy to consult lists of reportable diseases, provide prestamped cards for reporting, and provide telephone or fax reporting facilities.
2. Do not require extensive information: name, age, sex, residence, and diagnosis. Some diseases may include data on exposure, symptoms, method of diagnosis, etc.
3. Maintain confidentiality and assure reporters that confidentiality will be respected.
4. Convince reporters that reporting is essential: provide feedback; show how the data are used for better prevention.

Case definitions are important to ensure that data are consistent over time and multiple jurisdictions. On a global basis as well as for pandemics (e.g., the novel H1N1 flu pandemic in 2009), this data consistency is achieved by adhering to WHO case definitions for the respective infectious disease. In the USA, case definitions are regularly updated and published by the Centers for Disease Control and Prevention (CDC) in the Morbidity and Mortality Weekly Report (MMWR) (CDC 1997).

Table 51.8 Hepatitis A case reporting by physicians' specialty and by active/passive sample category, Kentucky, 1983 (Hinds et al. 1985)

	Active sample[a]			Passive sample[b]		
Specialty	*N*	Cases	Rate[c]	*N*	Cases	Rate[c]
General practice/family practice	71	4	5.6	73	2	2.7
Pediatrics	74	7	9.5	71	3	4.2
Internal medicine	71	3	4.2	72	0	0.0
All[d]	216	14	6.5	216	5	2.3

[a] Samples were obtained through weekly phone calls to health-care providers (HCPs)
[b] Samples were sent to the health department without prior phone calls to HCPs
[c] Cases per 100 physicians
[d] Active sample/passive sample rate ratio, adjusted for specialty = 2.8 (95% CI: 1.1–7.2)

Confidentiality of data is essential, particularly for those reporting health-care providers who are subject to very strict confidentiality laws. Any suspicion of failure of maintaining secure data would rapidly ruin a passive surveillance program.

51.5.2 Active Surveillance

In an *active surveillance system*, the recipient will actually take some action to identify the cases. In an active surveillance program, the public health agency organizes a system by searching for cases or maintaining a periodic contact with providers. Regular contacting boosts the compliance of the providers. Providers are health agencies, but also as in passive case detection, there may be day-care centers, schools, long-term care facilities, summer camps, resorts, and even the public involved in reporting diseases to the public health agency.

51.5.2.1 Active Surveillance Through Interaction with Providers

The agency takes the step to contact the health providers (all of them or a carefully selected sample) and requests reports from them at regular intervals. Thus, no reports are missing.

Active surveillance has several advantages:

- It allows the collection of more information. A provider sees that the recipient agency is more committed to surveillance and is therefore more willing to invest more time her/himself.
- It allows direct communication and opportunities to clarify definitions or any other problems that may have arisen.

Active surveillance provides much better and more uniform data than passive case detection (Table 51.8). Active case detection is much more expensive; however, for certain diseases such as Hepatitis A virus (HAV), the benefit normally outweighs the cost. Based on 9 HAV cases and 38 contacts, the total costs for active

Table 51.9 Costs and benefits of a 22-week active surveillance program for Hepatitis A, Kentucky 1983 (Hinds et al. 1985)

Costs		Benefits	
Activity	Dollar estimate	Activity	Dollar estimate
Central office surveillance		Medical costs averted[b]	$5,273
Personnel	$3,764	Indirect costs averted[b]	$8,748
Telephone	$535		
Local health offices[a]			
Contact tracing			
Personnel	$647		
Telephone	$149		
Travel	$31		
Contact prophylaxis			
Personnel	469		
Immune Serum Globulin (ISG)	21		
Total	$5,616		$14,021

[a] Costs of tracing and prophylaxis of 38 additional active surveillance-associated Hepatitis A contacts

[b] Based on 7 Hepatitis A cases prevented among 38 contacts of 9 additional Hepatitis A cases identified by active surveillance. Indirect costs are primarily due to productivity losses

surveillance were estimated to be $5,616; however, the benefits (medical and indirect costs) of 7 HAV cases prevented in among the 38 contacts were $14,021 (Table 51.9).

51.5.2.2 Active Surveillance Through Active Case Detection

Active surveillance systems are usually designed when a passive system is deemed insufficient to accomplish the goals of disease monitoring. This type of surveillance is reserved for special programs, usually when it is important to identify every single case of a disease. Active surveillance is implemented in the final phases of an eradication program. Best examples are the smallpox and poliomyelitis eradication programs and African guinea worm eradication program in some selected countries. Active surveillance is also the best approach in epidemic or outbreak investigations to elicit all cases.

In the smallpox eradication program, survey agents visited providers, asked about suspected cases, and actually investigated each suspected case. In the global polio eradication program which was launched in 1988, all cases of acute flaccid paralysis were investigated.

Thanks to the distribution of water filters, education about the transmission of the parasite, as well as enhanced active surveillance for guinea worm (*Dracunculus medinensis*) there are only five African countries left where dracunculiasis is still endemic. The disease might be eliminated by 2015 which would make guinea worm the first parasite to be eradicated.

51.5.3 Syndromic Surveillance

With increasing concerns about infectious disease outbreaks caused by bioterrorism or emerging infectious agents, it became important to detect health events (illnesses) before final diagnosis or laboratory confirmation. The assumption is that early detection will lead to better prevention. Timeliness and validity of the information are the two most important factors in a successful syndromic surveillance system.

In a syndromic surveillance system, the data collected is not about diagnoses but about indicators of the early stages of an outbreak. Requests for laboratory tests may be part of a syndromic surveillance system, while results of lab tests that may take hours or days would be considered in a passive surveillance system. Other examples of data that may be used are syndromes elaborated from the chief complaints from emergency department records, clinical impressions on ambulance worksheet, prescription filled, retail drug and product purchases, and school or work absenteeism (Buehler et al. 2004).

Framework for evaluating public health surveillance systems for early detection of electronic reporting of data is instrumental in obtaining a rapid transfer of data which is essential for early detection. Statistical tools for pattern recognition and aberration detection are necessary to identify subtle outbreak patterns.

51.5.4 Case Register

A case register is a complete list of all the cases of a particular disease in a definite area over a certain time period. Registers are used to collect data on infections over long periods of time. Registers should be population based, detailed, and complete. A register will show an unduplicated count of cases. They are especially useful for long-term diseases, diseases that may relapse or recur, and diseases for which the same cases will consult several providers and therefore would be reported on more than one occasion.

Case registers contain identifiers, locating information, disease, treatment, outcome, and follow-up information as well as contact management information. They are an excellent source of information for epidemiological studies. In disease control, case registers are indispensable tools for follow-up of chronic infectious diseases such as tuberculosis and leprosy.

The contents and quality of a case register determine its usefulness. It should contain:

- Patient identifiers with names (all names), age, sex, place and date of birth, and complete address with directions on how to reach the patient
- Name and address of a “stable” relative that knows the patient’s whereabouts
- Diagnosis information with disease classification and brief clinical description (short categories are better than detailed descriptions)
- Degree of infectiousness (bacteriological, serological results)
- Circumstances of detection

- Initial treatment and response with specific dose, notes on compliance, side effects, and clinical response
- Follow-up information with clinical response, treatment regimen, compliance, and side effects
- Locating information (for some diseases, contact information is also useful)

Updating a register is a difficult task. It requires cooperation from numerous persons. Care must be taken to maintain the quality of data. It is important to only request pertinent information for program evaluation or information that would remind users to collect data or to perform an exam. For example, if compliance is often a neglected issue, include a question on compliance. Further details concerning the use of registries in general are given in chapter ▶Use of Health Registers of this handbook.

51.5.5 Sentinel Disease Surveillance

For sentinel disease surveillance, only a sample of health providers is used. The sample is selected according to the objectives of the surveillance program. Providers most likely to serve the population affected by the infection are selected; for example, child health clinics and pediatricians should be selected for surveillance of childhood diseases. A sentinel system allows cost reduction and is combined with active surveillance.

A typical surveillance program for influenza infections includes a selected number of general practitioners who are called every week to obtain the number of cases with influenza-like Illness (ILI) presented to them (Fig. 51.7). This

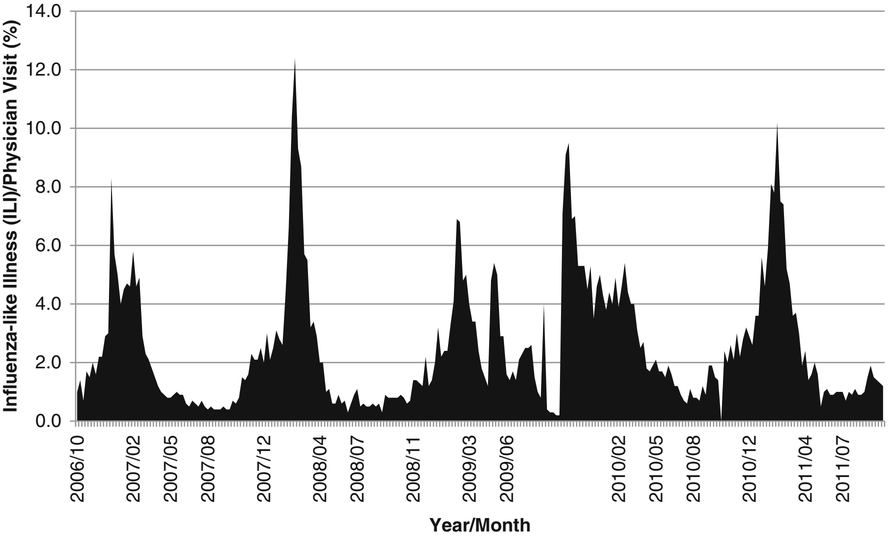

Fig. 51.7 Influenza sentinel surveillance, Louisiana 2006–2011

program may include the collection of samples for viral cultures or other diagnostic techniques. Such a level of surveillance would be impossible to maintain on the national level.

51.5.6 Evaluation of a Surveillance System

Surveillance systems are evaluated on the following considerations (CDC 2001b):

- *Usefulness*: Some surveillance systems are routine programs that collect data and publish results; however, it appears that they have no useful purpose – no conclusions are reached, no recommendations are made. A successful surveillance system would provide information used for preventive purposes.
- *Sensitivity* or the ability to identify every single case of disease is particularly important for outbreak investigations and eradication programs.
- *Predictive value positive* (PVP) is the proportion of reported cases that actually have the health-related event under surveillance. Low PVP values mean that non-cases might be investigated, outbreaks may be exaggerated, or pseudo-outbreaks may even be investigated. Misclassification of cases may corrupt the etiological investigations and lead to erroneous conclusions. Unnecessary interventions and undue concern in the population under surveillance may result.
- *Representativeness* ensures that the occurrence and distribution of cases accurately represent the real situation in the population.
- *Simplicity* is essential to gain acceptance, particularly when relying on outside sources for reporting.
- *Flexibility* is necessary to adapt to changes in epidemiological patterns, laboratory methodology, operating conditions, funding, or reporting sources.
- *Data quality* is evaluated by the data completeness (blank or unknown variable values) and validity of data recorded (see also chapter ▸Quality Control and Good Epidemiological Practice of this handbook).
- *Acceptability* is shown in the participation of providers in the system.
- *Timeliness* is more important in surveillance of epidemics.
- *Stability* refers to the reliability (i.e., the ability to collect, manage, and provide data properly without failure) and availability (the ability to be operational when it is needed) of the public health surveillance system.

51.5.7 Elements of a Surveillance System

The major elements of a surveillance system as summarized by the WHO are mortality registration, morbidity reporting, epidemic reporting, laboratory investigations, individual case investigations, epidemic field investigations, surveys, animal reservoir and vector distribution studies, biologicals and drug utilization, and knowledge of the population and the environment. Traditional surveillance methods rely on counting deaths and cases of diseases. However, these data represent only a small part of the global picture of infectious disease problems.

51.5.7.1 Mortality Registration

Mortality registration was one of the first elements of surveillance implemented. The earliest quantitative data available on infectious disease is about mortality. The evolution of tuberculosis in the USA, for example, can only be traced through its mortality. Mortality data are influenced by the occurrence of disease but also by the availability and efficacy of treatment. Thus, mortality cannot always be used to evaluate the trend of disease occurrence.

51.5.7.2 Morbidity Reporting

Reporting of infectious diseases is one of the most common requirements around the world. A list of notifiable diseases is established on a national or regional level. The numbers of conditions vary; it ranges usually from 40 to 60 conditions. In general, a law requires that health facility staff, particularly physicians and laboratories, report these conditions with guaranteed confidentiality. It is also useful to have other non-health-related entities report suspected communicable diseases such as day-care centers, schools, restaurants, long-term care facilities, summer camps, and resorts. Regulations on mandatory reporting are often difficult to enforce. Voluntary compliance by the institution's personnel is necessary. Reporting may be done in writing, by phone, or electronically in the most advanced system. Since most infectious diseases are confirmed by a laboratory test, reporting by the laboratory may be more reliable. The advantage of laboratory reporting is the ability to computerize the reporting system. Computer programs may be set up to automatically report a defined set of tests and results.

For some infectious diseases, only clinical diagnoses are made. These syndromes may be the consequences of a large number of different microorganisms for which laboratory confirmation is impractical.

When public or physician attention is directed at a specific disease, reporting may be biased. When there is an epidemic or when the press focuses on a particular disease, patients are more prone to look for medical care and physicians are more likely to report. Reporting rates were evaluated in several studies. In the USA, studies show report rates of 10% for viral Hepatitis, 32% for *Hemophilus influenzae*, 50% for meningococcal meningitis, and 62% for shigellosis.

51.5.7.3 Morbidity Case Definition

It is important to have a standardized set of definitions available to providers. Without standardized definitions, a surveillance system may be counting different entities from one provider to another. The variability may be such that the epidemiological information obtained is meaningless.

Most case definitions in infectious disease epidemiology are based on *laboratory tests*; however, some clinical syndromes such as toxic shock syndrome do not have confirmatory laboratory tests. Most case definitions include a brief *clinical description* useful to differentiate active disease from colonization or asymptomatic infection. Some diseases are diagnosed based on epidemiological data. As a result, many case definitions for childhood vaccine preventable diseases and foodborne diseases include epidemiological criteria (e.g., exposure to probable or confirmed cases of disease or to a point source of infection). In some instances, the anatomic site of infection may be important; for example, respiratory diphtheria is notifiable, whereas cutaneous diphtheria is not (CDC 1997).

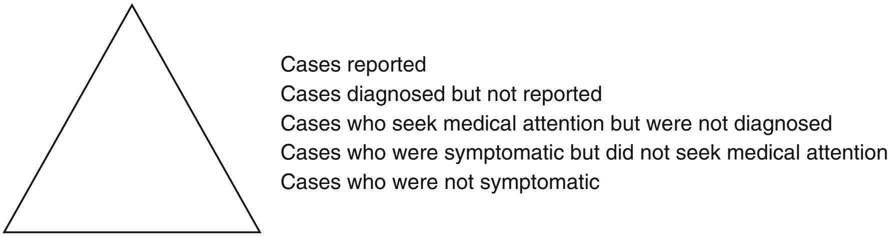
Cases are classified as a confirmed case, a probable, or a suspected case. An epidemiologically linked case is a case in which (1) the patient has had contact with one or more persons who either have/had the disease or have been exposed to a point source of infection (including confirmed cases) and (2) transmission of the agent by the usual modes is plausible. A case may be considered epidemiologically linked to a laboratory-confirmed case if at least one case in the chain of transmission is laboratory confirmed. Probable cases have specified laboratory results that are consistent with the diagnosis yet do not meet the criteria for laboratory confirmation. Suspected cases are usually cases missing some important information in order to be classified as a probable or confirmed case.

Case definitions are not diagnoses. The usefulness of public health surveillance data depends on its uniformity, simplicity, and timeliness. Case definitions establish uniform criteria for disease reporting and should not be used as the sole criteria for establishing clinical diagnoses, determining the standard of care necessary for a particular patient, setting guidelines for quality assurance, or providing standards for reimbursement. Use of additional clinical, epidemiological, and laboratory data may enable a physician to diagnose a disease even though the formal surveillance case definition may not be met.

51.5.7.4 Data for Which Stage of Disease Should Be Collected? The Morbidity Iceberg

Surveillance programs collect data on the overt cases diagnosed by the health-care system. However, these cases may not be the most important links in the chain of transmission. Cases reported are only the tip of the iceberg (see Fig. 51.8). They may not at all be representative of the true endemicity of an infectious disease.

There is a continuous process leading to an infectious disease: exposed, colonized, incubating, sick, clinical form, convalescing, and cured. Even among those who have overt disease, there are several disease stages that may not be included in a surveillance system:



Cases reported
Cases diagnosed but not reported
Cases who seek medical attention but were not diagnosed
Cases who were symptomatic but did not seek medical attention
Cases who were not symptomatic

Fig. 51.8 The iceberg concept

- Some have symptoms but do not seek medical attention.
- Some do get medical attention but do not get diagnosed or get misdiagnosed.
- Some get diagnosed but do not get reported.

Infectious disease cases play different roles in the epidemiology of an infectious disease; some individuals are the indicators (most symptomatic), some are the reservoir of microorganisms (usually asymptomatic, not very sick), some are amplifiers (responsible for most of the transmission), and some are the victims (those who develop severe long-term complications). Depending on the specific disease and the purpose of the surveillance program, different disease stages should be reported. For example:

- In a program to prevent rabies in humans exposed to a suspect rabid animal (usually a bite) needs to be reported. At the stage where the case is a suspect, prevention will no longer be effective.
- For bioterrorism events, reporting of suspects is of paramount importance to minimize consequences. Waiting for confirmation causes too long of a delay. In the time necessary to confirm cases, opportunities to prevent coinfections may be lost, and secondary cases may already be incubating, depending on the transmissibility of the disease.
- Surveillance for West Nile viral infections best rests on the reporting of neuroinvasive disease. Case reports of neuroinvasive diseases are a better indicator than West Nile infection or West Nile fever cases that are often benign, go undiagnosed, and are reported haphazardly.
- For gonorrhea, young males are the indicators because of the intensity of symptoms. Young females are the main reservoir because of the high proportion of asymptomatic infections. Females of reproductive age are the victims because of pelvic invasive disease (PID) and sterility.
- A surveillance program for Hepatitis B that only would include symptomatic cases of Hepatitis B could be misleading. A country with high transmission of Hepatitis B from mother to children would have a large proportion of infected newborns becoming asymptomatic carriers and a major source of infection during their lifetime. Typically in countries with poor reporting of symptomatic Hepatitis, the reporting of acute cases of Hepatitis B would be extremely low in spite of high endemicity which would result in high rates of chronic Hepatitis and hepatic carcinoma.

51.5.7.5 Individual Cases or Aggregate Data?

Most morbidity reporting collects data about individual cases. Reporting of individual cases includes demographic and risk factor data which are analyzed for descriptive epidemiology and for implementation of preventive actions. For example, any investigation leading to contact identification and prophylaxis requires a start from individual cases.

However, identification of individuals may be unnecessary and aggregate data sufficient for some specific epidemiological purposes. Monitoring an influenza epidemic, for example, can be done with aggregate data. Obtaining individual case information would be impractical since it would be too time consuming to collect detailed demographics on such a large number of cases. Aggregate data from sentinel sites consists of a number of influenza-like illnesses by age group and the total number of consultants or the total number of "participants" to be used as denominators. Such data is useful to identify trends and determine the extent of the epidemic and geographical distribution.

Collection of aggregate data of the proportion of school children by age group and sex is a useful predictive tool to identify urinary schistosomiasis endemic areas (Lengeler et al. 2000) without having to collect data on individual school children.

51.5.7.6 Investigations of Cases, Outbreaks, Epidemics, and Surveys

Epidemics of severe diseases are almost always reported. This is not the case for epidemics of milder diseases such as rashes or diarrheal diseases. Many countries do not want to report an outbreak of disease that would cast a negative light on the countries. For example, many countries that are tourism dependent do not report cholera or plague cases. Some countries did not report AIDS cases for a long time.

Case investigations are usually not undertaken for individual cases unless the disease is of major importance such as hemorrhagic fever, polio, rabies, yellow fever, any disease that has been eradicated, and any disease that is usually not endemic in the area.

Outbreaks or changes in the distribution pattern of infectious diseases should be investigated, and these investigations should be compiled in a comprehensive system to detect trends. While the total number of infectious diseases may remain the same, changes may occur in the distribution of cases from sporadic to focal outbreaks. For example, the distribution of WNV cases in Louisiana shifted from mostly focal outbreaks in the first year (2002) the West Nile virus arrived in the state to mostly sporadic cases the following years (2003–2004) (Fig. 51.9).

Surveys are a very commonly used tool in public health, particularly in developing countries where routine surveillance is often inadequate (see chapter ▶Epidemiology in Developing Countries of this handbook). Survey data needs to be part of a comprehensive surveillance database. One will acquire a better picture from one or a series of well-constructed surveys than from poorly collected surveillance data. Surveys are used in control programs designed to control major endemic diseases: spleen and parasite surveys for malaria, parasite in urine and stools for schistosomiasis, clinical surveys for leprosy or guinea worm disease, and skin test surveys for tuberculosis.

51.5.7.7 Surveillance of Microbial Strains

Surveillance of microbial strains is designed to monitor, through active laboratory-based surveillance, the bacterial and viral strains isolated. Examples of these systems are:

- In the USA, the *PulseNet program* is a network of public health laboratories that performs DNA fingerprinting of bacteria causing foodborne illnesses (Swaminathan et al. 2001). Molecular subtyping methods must be standardized to allow comparisons of strains and the building of a meaningful data bank.

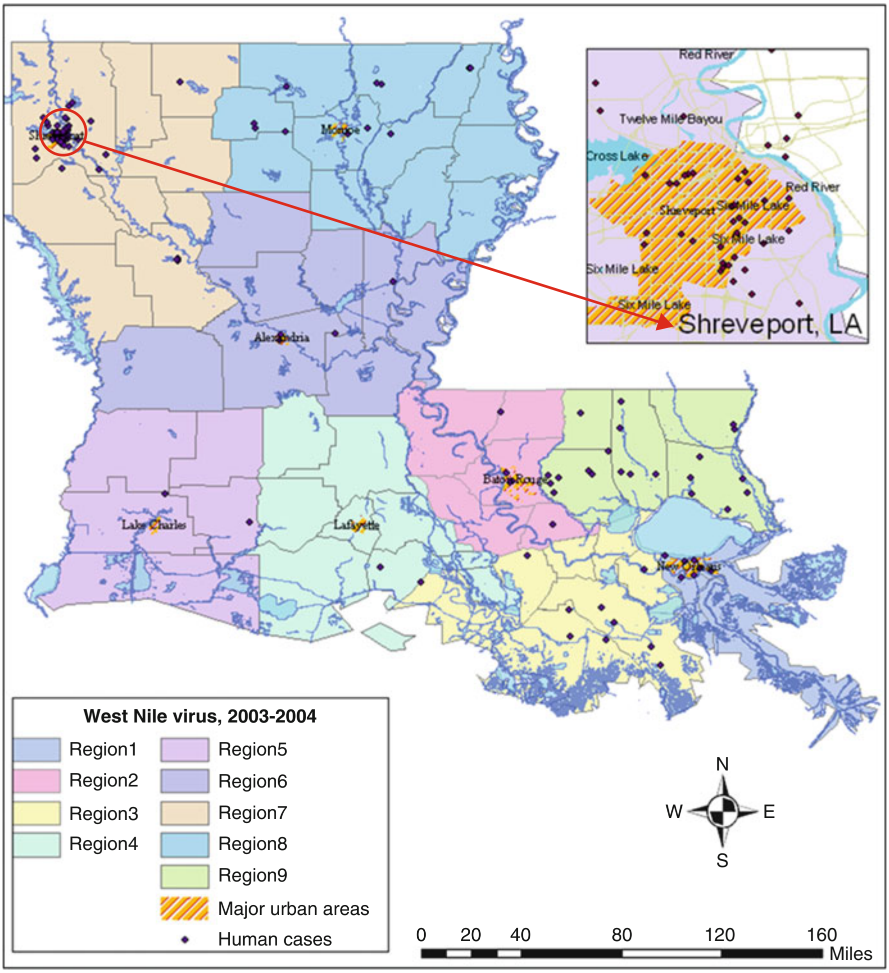


Fig. 51.9 Human West Nile neuroinvasive disease cases in Louisiana, 2003–2004

The method used in PulseNet is pulse field gel electrophoresis (PFGE). The use of standardized subtyping methods has allowed isolates to be compared from different parts of the country, enabling recognition of nationwide outbreaks attributable to a common source of infection, particularly those in which cases are geographically separated.

- The US *National Antimicrobial Resistance Monitoring System* (NARMS) for enteric bacteria is a collaboration between CDC, participating state and local health departments, and the US Food and Drug Administration (FDA) to monitor antimicrobial resistance among foodborne enteric bacteria isolated from humans. NARMS data are also used to provide platforms for additional studies including field investigations and molecular characterization of resistance determinants and to guide efforts to mitigate antimicrobial resistance (CDC 2006).

- Monitoring of antimicrobial resistance is routinely done by requiring laboratories to either submit all or a sample of their bacterial isolates.

51.5.7.8 Surveillance of Animal Diseases

Surveillance for zoonotic diseases should start at the animal level, thus providing early warning for impending increases of diseases in the animal population.

- Rabies surveillance aims at identifying the main species of animals infected in an area, the incidence of disease in the wild animals, and the prevalence of infection in the asymptomatic reservoir (bats). This information will guide preventive decisions made when human exposures do occur.
- Malaria control entomologic activities must be guided by surveillance of *Anopheles* mosquito populations, their biting activities, and *Plasmodium* infection rates in the *Anopheles* mosquitoes.
- Infection rates in wild birds, infection in sentinel chickens, and horse encephalitis are all part of West Nile encephalitis surveillance. These methods provide an early warning system for human infections.
- The worldwide surveillance for influenza is the best example of the usefulness of monitoring animals prior to spread of infection in the human population. Influenza surveillance programs aim to rapidly obtain new circulating strains to make timely recommendations about the composition of the next vaccine. The worldwide surveillance priority is given to the establishment of regular surveillance and investigation of outbreaks of influenza in the most densely populated cities in key locations, particularly in tropical or other regions where urban markets provide opportunities for contacts between humans and live animals (Snacken et al. 1999).

51.5.7.9 Rationale of Selecting Diseases for Surveillance Purposes

The rationale for selecting infectious diseases and an appropriate surveillance method is based on the goal of the preventive program. Table 51.10 shows a few examples of different surveillance methods based on the disease and the objectives of the surveillance.

51.6 Outbreak Investigations

Outbreaks of acute infectious diseases are common, and investigations of these outbreaks are an important task for public health professionals, especially epidemiologists. In 2001, a total of 1,238 foodborne outbreaks with 25,035 cases involved were reported in the USA (CDC 2004) with norovirus being the most common confirmed etiological agent associated with these outbreaks (see Table 51.11).

Table 51.10 Examples of different surveillance methods based on the disease and the objectives of the surveillance system

Disease	Objectives	Surveillance method
Anthrax	Limit bioterrorism event	Active or passive syndromic surveillance
Antibiotic resistance	Description	Active laboratory reporting of antibiograms
Aseptic meningitis	Sentinel event for West Nile Identification of outbreak	Passive surveillance by health-care providers
Gonorrhea	Description of epidemic Treatment of cases	Passive case detection by health-care practitioners Systematic screening of young females (family planning, prenatal, student health services, etc.)
Hepatitis B	Description of endemicity	Survey of representative groups
Hepatitis B	Prevention of perinatal transmission	Screening of pregnant women
Influenza	Quantify endemicity	Sentinel surveillance with aggregate data from physicians’ offices, emergency departments, nursing homes, and schools
Poliomyelitis	Identification of residual cases before complete eradication	Active surveillance of acute flaccid paralysis
Rabies	Prevent human cases	Passive reporting of exposure to potentially rabid animals
Methicillin-resistant *Staphylococcus aureus* (MRSA)	Provide information for management of suspected staphylococcal infections	Active laboratory surveillance of aggregate data on proportion of staphylococci resistant to methicillin
Vancomycin-resistant *Staphylococcus aureus* (VRSA)	Identification of an emerging infection	Laboratory submission of specimens
Tuberculosis	Description of endemicity Case management	Case register
West Nile	Early warning for public and mosquito control	Passive reporting of dead birds by the public, passive reporting of encephalitic horses, sentinel chicken serology, survey of wildlife by serological methods
West Nile	Description of endemicity	Passive and active case finding of neuro-invasive disease

Table 51.11 Confirmed etiological agents of foodborne outbreaks in the USA in 2001

Etiology	Number of outbreaks
Bacillus cereus	5
Brucella spp.	1
Campylobacter spp.	16
Clostridium botulinum	3
Clostridium perfringens	30
Enterohemorrhagic *Escherichia coli*	4
Enterohemorrhagic *Escherichia coli* O157:H7	16
Enterotoxigenic *Escherichia coli*	2
Listeria monocytogenes	1
Salmonella spp.	112
Shigella spp.	15
Staphylococcus aureus	23
Vibrio spp.	4
Yersinia enterocolitica	3
Total bacteria	**235**
Ciguatera	23
Histamine	10
Other chemical	1
Scombroid	18
Total chemical	**52**
Cyclospora cayetanensis	2
Giardia lamblia	1
Trichinella spp.	2
Total parasitic	**5**
Hepatitis A	6
Norovirus	150
Total viral	**156**

Source: CDC Foodborne Outbreak Response and Surveillance Unit (2004)

Outbreaks or epidemics are defined as the number of disease cases above what is normally expected in the area for a given time period. Depending on the disease, it is not always known if the case numbers are really higher than expected and some outbreak investigations can reveal that the reported case numbers did not actually increase. The nature of a disease outbreak depends on a variety of circumstances, most importantly the suspected etiological agent involved, the disease severity or case fatality rate, population groups affected, media pressure, political inference, and investigative progress. There are certain common steps for outbreak investigations as shown in Table 51.12. However, the chronology and priorities assigned to each phase of the investigation have to be decided individually, based on the circumstances of the suspected outbreak and information available at the time.

For example, in 2002, 21 outbreaks of acute gastroenteritis on cruise ships with travel destinations outside the USA were reported to the CDC (CDC 2002). In only

Table 51.12 Fourteen steps in outbreak investigations

#	Step
1	"Outbreak" detected based on initial report or analysis of surveillance data
2	Collect basic numbers and biological specimens
3	Investigate or not?
4	Think prevention first
5	Get information on the disease or condition
6	Sometimes numbers do not count
7	Is the increase real or artificial?
8	Verify the diagnosis
9	Prepare a case definition
10	Put the information in a database
11	Find additional cases
12	Basic descriptive epidemiology (time, place, and person)
13	Hypothesis testing and measures of association
14	Final report and communications

5 of these outbreaks, about 1,400 persons, with an average 280 cases per cruise, had symptoms of viral acute gastroenteritis. Norovirus outbreaks begin usually as a food- or waterborne disease but often continue because of the easy person-to-person transmission in a closed environment and low infectious dose (100 viral particles can be infectious) (CDC 2001a).

51.6.1 Basic Steps in Outbreak Investigations

51.6.1.1 The Initial Report

The original report can originate from very different sources. Examples are:

- A physician is calling the local or state health department about an increase of number of patients seen and diagnosed with a specific disease.
- A high number of patients with similar signs and symptoms are showing up in the emergency room.
- A school principal or day-care owner is reporting a high number of absent students.
- A nursing home health-care professional is seeing a lot of residents with gastrointestinal illnesses.
- A person is complaining to the health department that she/he got sick after eating at a certain restaurant.

Another way to detect an increase of cases is if the surveillance system of reportable infectious diseases reveals an unusually high number of people with the same diagnosis over a certain time period at different health-care facilities.

Outbreaks of benign diseases like self-limited diarrhea are often not detected because people are not seeking medical attention and therefore medical services are not aware of them. Furthermore, early stages of a disease outbreak are often undetected because single cases are diagnosed sporadically. It is not until a certain threshold is passed that it becomes clear that these cases are related to each other through a common exposure or secondary transmission.

Depending on the infectious disease agent, there can be a sharp or a gradual increase of number of cases. It is sometimes difficult to differentiate between sporadic cases and the early phase of an outbreak. In the 2001 St. Louis encephalitis (SLE) outbreak in Louisiana, the number of SLE cases increased from 9 to 18 between weeks 1 and 2, and then the numbers gradually decreased over the next 9 weeks to a total of 63 cases (Jones et al. 2002).

51.6.1.2 Basic Information

After the initial report is received, it is important to collect and document basic information: Contact information of persons affected, a good and thorough event description, names and diagnosis of hospitalized persons (and depending on the presumptive diagnosis their underlying conditions and travel history), laboratory test results, and other useful information to get a complete picture and to confirm the initial story of the suspected outbreak. It also might be necessary to collect more biological specimens such as food items and stool samples for further laboratory testing.

51.6.1.3 Decision to Investigate

On the one hand, based on the collected information, the decision to investigate must be made. It may not be worthwhile to start an investigation if there are only a few people who fully recovered after a couple of episodes of a self-limited, benign diarrhea. Other reasons not to investigate might be that this type of outbreak occurs regularly every summer or that it is only an increase in number of reported cases which are not related to each other.
