
32.4.4 Octahedral Superfine Structure

The octahedral RES has many more local hills and valleys and corresponding types of semiclassical paths than are found on the rigid asymmetric top RES. The tunneling between multiple paths produces an octahedral superfine structure that is more complicated than the asymmetric top doublets. Still, the same symmetry correlations and tunneling mechanics may be used.

First, the octahedral symmetry must be correlated with the local symmetry of the paths on the hills and in the valleys. The hill paths have a C_4 symmetry while the valley paths have a local C_3 symmetry. This is seen most clearly for the low-K paths near the separatrix which are less circular. The C_3 and C_4 correlations are given in Fig. 32.6 with a sketch of the corresponding molecular rotation for each type of path.

To find the octahedral species associated with a $K_3 = 30$ path in a C_3 valley one notes that 30 is 0 modulo 3. Hence the desired species are found in the 0_3 column of the C_3 correlation table: (A_1, A_2, T_1, T_2). This is what appears (not necessarily in that order) in the lower left corner of Fig. 32.4. Similarly, the species (A_2, E, T_2) for a $K_4 = 30$ path on top of a C_4 hill are found in the 2_4 column of the C_4 correlation table since 30 is 2 modulo 4; these appear on the other side of Fig. 32.4. Clusters (T_1, T_2) for $K_4 = 29$ and (A_1, E, T_1) for $K_4 = 28$ are found in a similar manner.

A multiple path tunneling calculation analogous to the one for rigid rotors can be applied to approximate octahedral superfine splittings. Consider the cluster (A_1, E, T_1) for $K_4 = 28$, for example. Six C_4-symmetric paths located on octahedral vertices on opposite sides of the x-, y-, and z-axes may be labeled $\{|x\rangle, |\bar{x}\rangle, |y\rangle, |\bar{y}\rangle, |z\rangle, |\bar{z}\rangle\}$. A tunneling matrix between the six paths follows:

$$\langle H \rangle_{K_4=28} = \begin{pmatrix} H & 0 & S & S & S & S \\ 0 & H & S & S & S & S \\ S & S & H & 0 & S & S \\ S & S & 0 & H & S & S \\ S & S & S & S & H & 0 \\ S & S & S & S & 0 & H \end{pmatrix} \begin{matrix} |x\rangle \\ |\bar{x}\rangle \\ |y\rangle \\ |\bar{y}\rangle \\ |z\rangle \\ |\bar{z}\rangle \end{matrix} ,$$

(32.18)

where the tunneling amplitude between nearest neighbor octahedral vertices is S, but is assumed to be zero between antipodal vertices. The eigenvectors and eigenvalues for this matrix are given in the Table 32.5.

This predicts that the triplet (T_1) level should fall between the singlet (A_1) and the doublet (E) levels and the singlet-triplet spacing $(4S)$ should be twice the split-
Fig. 32.6 Tables of correlations between 0 symmetry species and the cyclic axial symmetry species (K_p means K mod p) of subgroups C_3, C_2 and C_4

ting ($-2S$) between the triplet and doublet. This $2 : 1$ ratio is observed in the (E, T_1, A_1) and (A_2, T_2, E) clusters which can be resolved and also in numerical calculation [32.18–21].

The tunneling amplitudes can be calculated by a separatrix path integral analogous to the asymmetric top formula (32.13) [32.10, 11]. As shown in Fig. 32.4, the tunneling rates or superfine splittings near the separatrix are $\sim 1\,\mathrm{MHz}$, which is only slightly slower than the classical precessional frequency. But as K approaches J on the hilltops, the tunneling rate slows down to a few Hz.

$\sqrt{2}\,\vert T_1, 1\rangle =$	1	-1	0	0	0	0	$E^{T_1} = H$
$\sqrt{2}\,\vert T_1, 2\rangle =$	0	0	1	-1	0	0	
$\sqrt{2}\,\vert T_1, 3\rangle =$	0	0	0	0	1	-1	

32.5 High Resolution Rovibrational Structure

A display of spectral hierarchy for higher and higher resolution is shown in Fig. 32.7 for the $630\,\mathrm{cm}^{-1}$ or $16\,\mu\mathrm{m}$ bands of CF_4. This will serve to summarize the possible rovibrational spectral structures and place them in a larger context. The ν_4 resonance in part (a) corresponds to a dipole active $n_4 = 0 \rightarrow 1$ vibrational

transition, and is just one of many vibrational structures to study. The $P(54)$ sideband resonance in part (b) corresponds to a $(J = 54) \rightarrow (J-1)$ rotational transition, and is just one of hundreds of rotational structures to study within the ν_4 bands.

Each band is something like a Russian doll; it contains structure within structure within structure down to the resolution of few tens of Hz. Examples of rotational fine and superfine structures described in Sect. 32.4 are shown in Fig. 32.7c, d, but even more resolution is needed to see the hyperfine structure in Fig. 32.7e. Such extremely high resolution has been reached with a CO_2 saturation absorption spectrometer [32.27, 28]. The $10\,\mu m$ bands of SF_6 and SiF_4 have been studied in this manner, the latter being similar to CF_4 [32.26].

32.5.1 Tetrahedral Nuclear Hyperfine Structure

High resolution spectral studies of SiF_4 showed unanticipated effects involving the four fluorine nuclear spin and magnetic moments and their associated hyperfine states. First, the Pauli principle restricts the nuclear spin multiplicity associated with each of the rotational symmetry species in much the same way that atomic $L - S$ coupled states ^{2S+1}L have certain spin multiplicities $(2S + 1)$ allowed for a given orbital L species involving two or more equivalent electrons. Second, since superfine splittings can easily be tiny, different spin species can end up close enough that hyperfine interactions, however small, can cause strongly resonant mixing of the normally inviolate species. Finally, a pure and simple form of spontaneous symmetry breaking is observed in which otherwise equivalent nuclei fall into different subsets due to quantum rotor dynamics.

Connecting nuclear spin to rotational species is done by correlating the full permutation symmetry (S_n for XY_n molecules) with the full molecular rotation and parity symmetry [$O(3)_{LAB} \otimes T_{dBODY}$ for CF_4 molecules or $O(3)_{LAB} \otimes O_{hBODY}$ and for SF_6]. For four spin-$1/2$ nuclei, the Pauli principle allows a spin of $I = 2$ and a spin multiplicity of five $(2I + 1 = 5)$ for (J^+, A_2) or (J^-, A_1) species, but excludes (J^-, A_2) or (J^+, A_1) species altogether. The Pauli allowed spin for (J^+, T_1) or (J^-, T_2) species is $I = 1$ with a multiplicity of three, but there are no allowed (J^+, T_2) or (J^-, T_1) species. Finally, both (J^+, E) and (J^-, E) belong to singlet spin $I = 0$ and are singlet partners to an inversion doublet. (None of the other species can have both $+$ and $-$ parity.)

The E inversion doublet is analogous to the doublet in NH_3 which is responsible for the ammonia maser.

However, NH_3-type inversion is not feasible in CF_4 or SiF_4, and so the splitting of the E doublet in these molecules is due to hyperfine resonance [32.9, 16, 23].

The Pauli analysis gives the number of hyperfine lines that each species would exhibit if it were isolated and resolved, as shown in the center of Fig. 32.7e. The rotational singlets A_1 and A_2 have five lines each, the rotational triplets T_1 and T_2 are spin triplets, and the rotational doublet E is a spin singlet but an inversion doublet. If the hyperfine structure of a given species A_1, A_2, T_1, T_2, or E is not resolved, then their line heights are proportional to their total spin weights of 5, 5, 3, 3, and 2, respectively.

If the unresolved species are clustered, then the total spin weights of each add to give a characteristic cluster line height. The line heights of the C_4 clusters (T_1, T_2), (A_2, T_2, E), (T_1, T_2), (E, T_1, A_1) are 6, 10, 6, 10, respectively. The line heights of the C_3 clusters (A_1, T_1, T_2, A_2), (T_1, E, T_2), (T_1, E, T_2) are 16, 8, 8, respectively. This is roughly what is seen in the $P(54)$ spectrum in Fig. 32.7c.

32.5.2 Superhyperfine Structure and Spontaneous Symmetry Breaking

The superfine cluster splittings ($2S$, $4S$, etc.) are proportional to the J-precessional tunneling or 'tumbling' rates between equivalent C_3 or C_4 symmetry axes, and they decrease with increasing K_3 or K_4. At some point, the superfine splittings decrease to less than the hyperfine splittings which are actually increasing with K. The resulting collision of superfine and hyperfine structure has been called superhyperfine structure or Case 2 clusters. The following is a rough sketch of the phenomenology of this very complex effect, using the results of *Pfister* [32.26].

As long as the tunneling rates are $> 1\,MHz$, the nuclear spins will tend to average over spherical top motion. The spins couple into states of good total nuclear spin I, which in turn couple weakly with the overall angular momentum and with well defined rovibrational species A_1, A_2, T_1, T_2, or E as described above. The resulting coupling is called Case 1, and is analogous to LS coupling in atoms.

Stick figures for two examples of spectra observed by *Pfister* [32.26] are shown in Fig. 32.8a and b. The first Case 1 cluster, shown in (a), is a C_4 type (0_4) cluster (A_1, T_1, E), which was solved in Table 32.6. The other Case 1 cluster, shown in (b), is a C_3 type $(\pm 1_3)$ cluster (T_1, E, T_2) (recall the C_3 correlations in Fig. 32.3). They are

similar to the corresponding sketches in Fig. 32.7e. One notable difference is that the inversion doublet shows little or no splitting in the (A_1, T_1, E) cluster, but does split in the (T_1, E, T_2) cluster.

When the tunneling rates fall below 10 or 20 kHz, the angular momentum can remain near a particular C_3 or C_4 symmetry axis for a time longer than the nuclear spin precession rates. Spin precession rates and the corresponding hyperfine splittings are ≈ 50 kHz, and increase with K. Hence, there is plenty of time for each of the nuclear spins to align or anti-align with the C_3 or C_4 symmetry axes of rotation. This is called Case 2 coupling, and the resulting spectrum resembles that of an NMR scan of the nuclei, but here the magnetic field is provided by the molecule's own body frame rotation.

If SiF$_4$ rotates uniformly about one C_4 symmetry axis, then all four F nuclei occupy equivalent positions at the same average distance from the rotation axis and experience the same local magnetic fields. The molecule can be thought of as a paired diatomic F$_2$–F$_2$ rotor with each one symmetrized or antisymmetrized so as to make the whole state symmetric. Table 32.6 shows the spin-$^1/_2$ base states arranged horizontally according to the total projection I_z of nuclear spins on the C_4 axis. Horizontal arrays ($\uparrow\downarrow$) of spins denote symmetric states, while vertical arrays ($\updownarrow$) denote antisymmetric spin states.

The hyperfine energy is approximately proportional to the projection I_z. The resulting spectrum

Table 32.6 Spin $-\frac{1}{2}$ basis states for SiF$_4$ rotating about a C_4 symmetry axis

$I_z = 2$	$I_z = 1$	$I_z = 0$	$I_z = -1$	$I_z = -2$
		$\left(\begin{smallmatrix}\uparrow & \uparrow \\ \downarrow & \downarrow\end{smallmatrix}\right)$		
		$\lvert\uparrow\downarrow\ \uparrow\downarrow\rangle$		
	$\lvert\uparrow\downarrow\ \uparrow\uparrow\rangle$	$\lvert\downarrow\downarrow\ \uparrow\uparrow\rangle$	$\lvert\downarrow\downarrow\ \uparrow\downarrow\rangle$	
$\lvert\uparrow\uparrow\ \uparrow\uparrow\rangle$	$\lvert\uparrow\uparrow\ \uparrow\downarrow\rangle$	$\lvert\uparrow\uparrow\ \downarrow\downarrow\rangle$	$\lvert\uparrow\downarrow\ \downarrow\downarrow\rangle$	$\lvert\downarrow\downarrow\ \downarrow\downarrow\rangle$

is (1, 2, 4, 2, 1)-degenerate pyramid of equally spaced lines as shown in Fig. 32.8c. Four spin-1/2 states without symmetry restrictions would give the standard binomial (1, 4, 6, 4, 1)-degeneracy seen in NMR spectra.

If the molecule settles upon C_3 symmetry axes of rotation, the situation is markedly different. The four nuclei no longer occupy equivalent positions. One nucleus sits on the rotation axis, while the other three nuclei occupy equivalent off-axis positions. The off-axis nuclei experience a different local magnetic field than the single on-axis nucleus (Fig. 32.8d). From the spectrum, it appears that the spin-up to spin-down energy difference is much greater for the lone on-axis nucleus than for the three equatorial nuclei, whose spin states form the energy quartet $\{\lvert\uparrow\uparrow\uparrow\rangle, \lvert\uparrow\uparrow\downarrow\rangle, \lvert\uparrow\downarrow\downarrow\rangle, \lvert\downarrow\downarrow\downarrow\rangle\}$. The on-axis nucleus has an energy doublet with a large splitting, so that the four nuclei together give a doublet of quartets as shown in the figure.

If the off-axis nuclei had experienced the greatest splitting, then the spectrum would have been a quartet of doublets instead of a doublet of quartets. Something like this does occur in the SF$_6$ superhyperfine structure, which shows a quintet of triplets for a Case-2 C_4-symmetry cluster. For either one of these molecules, it is remarkable how different the rovibrational 'chemical shifts' can become for equivalent symmetry sites. The result is a microscopic example of spontaneous symmetry breaking.

32.5.3 Extreme Molecular Symmetry Effects

The most common high symmetry molecules belong to either the tetrahedral T_d or cubic-octahedral O groups. Until the recent discovery of fullerenes and the structure of virus coats, the occurrence of molecular point groups of icosahedral symmetry was thought to be rare or nonexistent in nature [32.24, 25].

For an extreme example of symmetry breaking effects, consider the Buckminsterfullerene or Buckyball molecule C$_{60}$ which has the highest possible molecular point symmetry Y_h. A semiclassical approach to rota-

tional symmetry and dynamics is useful here since the rotational quantum constant is so small for the fullerenes (for C_{60} $2B = 0.0056 \, \text{cm}^{-1}$ or 168 MHz) [32.29–31].

Since there are two isotopes ^{12}C (nuclear spin 0) and ^{13}C (nuclear spin 1/2) it is possible to have a Bose-symmetric molecule ($^{12}C_{60}$), or Fermi-symmetric molecule ($^{13}C_{60}$), or many broken-symmetry combinations ($^{12}C_x\,^{13}C_{60-x}$). The most likely combination is $^{12}C_{59}\,^{13}C$, which has no rotational symmetry at all, only one reflection plane. This may be the most extreme example of molecular isotopic symmetry breaking; it goes from the highest possible symmetry Y_h to one of the lowest, C_h.

The Fermi-symmetric molecule $^{13}C_{60}$ has ten times as many rotating spin-1/2 nuclei as SF_6, and 2^{10} times as many hyperfine states, or about 1.15×10^{18} spin states distributed among 10 symmetry species [32.32]. In contrast, the Bose-symmetric molecule $^{12}C_{60}$ has only one spin symmetry species allowed by the Bose exclusion principle: A_{1g}. It provides an even more extreme example of Bose exclusion than the $Os^{16}O_4$ molecule. In all, 119 of the 120 Y_h rovibrational symmetry states are Bose-excluded, giving $^{12}C_{60}$ an extraordinarily sparse rotational structure. However, it only takes the addition of a single neutron to make $^{12}C_{59}\,^{13}C$. Then all the excluded rovibrational states must return!

32.6 Composite Rotors and Multiple RES

So far, the discussion has focused on Hamiltonians and RES involving functions of even mulipolarity, i. e., constant ($k = 0$), quadrupole ($k = 2$), hexadecapole ($k = 4$), while ignoring odd functions, i. e., dipole ($k = 1$), octupole ($k = 3$), for reasons of time-reversal symmetry. However, for composite "rotor-rotors" any mulitpolarity is possible, and the dipole is of primary utility.

A composite rotor is one composed of two or more objects with more or less independent angular momenta. This could be a molecule with attached methyl (CH_3) "gyro" or "pinwheel" sub-rotors, a system of considerable biological interest. It could be a molecule with a vibration or "phonon" excitation that couples strongly to rotation. Also, any nuclear or electronic spin with significant coupling may be regarded as an elementary sub-rotor. The classical analogy is a spacecraft with gyros on board.

A rotor–rotor Hamiltonian has the general interaction form

$$H_{\text{rotor } R+S} = H_{\text{rotor}_R} + H_{\text{rotor}_S} + V_{RS} \, . \tag{32.19}$$

A useful approximation assumes that rotor S, the "gyro", is fastened to the frame of rotor R, so that the interaction V_{RS} becomes a constraint, does no work, and is thus assumed to be zero. An asymmetric top with body-fixed spin has the Hamiltonian

$$H_{R+S(\text{Body-fixed})} = A R_x^2 + B R_y^2 + C R_z^2 + H_{\text{rotor}_S} + (\sim 0) \, , \tag{32.20a}$$

which is a modified version of (32.1). The total angular momentum of the system is a conserved vector $\boldsymbol{J} = \boldsymbol{R} + \boldsymbol{S}$ in the lab-frame and a conserved magnitude $|\boldsymbol{J}|$ in the rotor-R body frame. So we use $\boldsymbol{R} = \boldsymbol{J} - \boldsymbol{S}$ in place of $\boldsymbol{R}$:

$$\begin{aligned} H_{R,S(\text{fixed})} &= A\,(J_x - S_x)^2 + B\,(J_y - S_y)^2 \\ &\quad + C\,(J_z - S_z)^2 + H_{\text{rotor}_S} \\ &= A J_x^2 + B J_y^2 + C J_z^2 - 2A J_x S_x \\ &\quad - 2B J_y S_y - 2C J_z S_z + H'_{\text{rotor}_S} \, . \end{aligned} \tag{32.20b}$$

The gyro spin components S_a are first treated as constant classical parameters S_a:

$$\begin{aligned} H_{R,S(\text{fixed})} &= \text{const. } 1 - 2A S_x J_x - 2B S_y J_y - 2C S_z J_z \\ &\quad + A J_x^2 + B J_y^2 + C J_z^2 \\ &= M_0 T_0^0 + \sum_d D_d T_d^1 + \sum_q Q_q T_q^2 \, . \end{aligned} \tag{32.20c}$$

This is a simple Hamiltonian multipole tensor operator expansion having here just a monopole T_0^0 term, three dipole T_d^1 terms, and two quadrupole T_q^2 terms. Figure 32.9 shows these three tensor terms, where each graph is a radial plot of a spherical harmonic function $Y_q^k(\phi, \Phi)$ representing a tensor operator T_q^k. The tensor components are

$$T_0^0 = \frac{J_x^2 + J_y^2 + J_z^2}{3} \tag{32.21a}$$

$$T_x^1 = J_x = \frac{T_{+1}^1 + T_{-1}^1}{\sqrt{2}}$$

$$T_y^1 = J_y = \frac{T_{+1}^1 - T_{-1}^1}{i\sqrt{2}}$$

$$T_z^1 = J_z = T_0^1 \tag{32.21b}$$
Fig. 32.9a–c The six lowest order RES components needed to describe rigid gyro-motors

$$T^2_{zz} = \frac{2J^2_z - J^2_x - J^2_y}{2} = T^2_0$$

$$T^2_{x^2-y^2} = J^2_x - J^2_y = \frac{2\left(T^2_2 - T^2_{-2}\right)}{\sqrt{6}} \qquad (32.21c)$$

The constant coefficients or moments indicate the strength of each multipole symmetry:

$$M_0 = A + B + C + 3H'_{\text{rotor}_S} \qquad (32.22a)$$

$$D_x = -2AS_x ,$$

$$D_y = -2BS_y ,$$

$$D_z = -2CS_z \qquad (32.22b)$$

$$Q_{zz} = (2C - A - B)/6$$

$$Q_{x^2-y^2} = (A - B)/2 \qquad (32.22c)$$

The scalar monopole RES (a) is a sphere, the vector dipole RES (b) are bi-spheres pointing along Cartesian axes, and the RES (c) resemble quadrupole antenna patterns. Also, Fig. 32.9a–c plot the six s, p, and d Bohr–Schrödinger orbitals that are analogs for the six octahedral J-tunneling states listed in Table 32.5.

The asymmetric and symmetric rotor Hamiltonians (32.1) and (32.1) are combinations of a monopole (32.21a), which by itself makes a spherical rotor, and varying amounts of the two quadrupole

terms (32.21c) to give the rigid rotor RES pictured in Figs. 32.1 and Fig. 32.2. The Q coefficients in (32.22c) are both zero for a spherical top ($A = B = C$), but only one is zero for a symmetric top ($A = B$).

Combining the monopole (32.21a) with the dipole terms (32.21b) gives the gyro-rotor Hamiltonian (32.20b) for a spherical rotor ($A = B = C$):

$$H = \text{const} + BJ^2 - g\mu S \cdot J , \qquad (32.23)$$

where $-g\mu = 2A = 2B = 2C$. This Hamiltonian resembles a dipole potential $-m \cdot B$ for a magnetic moment $m = gJ$ that precesses clockwise around a lab-fixed magnetic field $B = \mu S$. (The PE is least for J along S.)

The Hamiltonian (32.23) is a simple example of Coriolis rotational energy. It is least for J along S, where $|R| = |J - S|$ and the rotor kinetic energy BR^2 are least. (Magnitudes $|J|$ and $|S|$ are constant here.) The spherical rotor-gyro RES in Fig. 32.10 has a minimum along the body-axis $+S$ and a maximum along $-S$, where BR^2 is greatest.

As is the case for the rigid solid rotors in Figs. 32.1 and Fig. 32.2, the RES topography lines determine the precession J-paths in the body frame, wherein gyro-S is fixed, as shown in Fig. 32.10. The left-hand rule gives the sense of the J-precession in the body S-frame, i.e., all J precess counterclockwise relative to the "low" on the $+S$-axis, or clockwise relative to the "high" on the $-S$-axis. In the lab, S precesses in a clockwise manner around a fixed J.
Fig. 32.10 The spherical gyro-rotor RES is a cardioid of revolution around gyro spin S

Gyro-RES differ from solid rotor RES, which have two opposite "highs" and/or two opposite "lows" separated by saddle fixed points where the precessional flow direction reverses, as seen in Fig. 32.2. The gyro-RES in Fig. 32.10 has no saddle fixed points, and thus has only one "high" and one direction of flow with the same harmonic precession frequency for all J-vectors between the high $+S$ and low $-S$-axes. This is because the spectrum of the gyro-rotor Hamiltonian (32.23) is harmonic, or linear, in the K:

$$\left\langle{}^J_K \middle| H \middle| {}^J_K\right\rangle = \text{const.} + BJ(J+1) - 2BK . \quad (32.24)$$

In contrast, even the symmetric rigid rotor spectrum (32.4) is quadratic in K. Other rotors shown in Figs. 32.2 and Fig. 32.4 have levels that have an even more nonlinear spacing.

32.6.1 3D–Rotor and 2D–Oscillator Analogy

Linear levels are usually associated with harmonic oscillators not rotors, but the gyro-rotor's linear spectrum highlights a 160-year-old analogy between the motions of 3D rotors and 2D vibrations [32.33–45]. Stokes [32.35] first described 2D electric vibration or optical polarization, by a 3D vector that became known as the Stokes vector S, and later as the "spin" S. The Stokes spin was based on Hamilton's quaternions q_μ [32.33,34]. The Pauli spinors $\sigma_\mu = iq_\mu$ [32.36] were defined, 83 years later, as components of a general 2D Hermitian matrix H. Spinors square to the unit matrix $(\sigma_\mu^2 = \mathbf{1} = \sigma_0)$, while quaternions square to $-\mathbf{1}$. The 3D Hamiltonian is

$$H = \begin{pmatrix} A & B - iC \\ B + iC & D \end{pmatrix}$$
$$= \frac{A+D}{2}\sigma_0 + \frac{A-D}{2}\sigma_A + B\sigma_B + C\sigma_C , \quad (32.25)$$

where

$$\sigma_0 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} , \quad \sigma_A = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} ,$$
$$\sigma_B = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} , \quad \sigma_C = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} .$$

The 3D-component labels $\frac{A-D}{2}$ (Asymmetric-diagonal), B (Bilateral-balanced), and C (Circular-Coriolis) are ABC mnemonics for Pauli's z, x, and y, respectively. The 2D operator H has a $\mathbf{1} + S \cdot J$ form of

the Coriolis coupling Hamiltonian (32.23):

$$H = S_0\mathbf{1} + S_A J_A + S_B J_B + S_C J_C$$
$$= S_0 J_0 + S \cdot J , \quad (32.26)$$

where

$$J_0 = \mathbf{1} , \quad J_A = \frac{\sigma_A}{2} , \quad J_B = \frac{\sigma_B}{2} , \quad J_C = \frac{\sigma_C}{2} ,$$

and

$$S_0 = (A + D)/2 , \quad S_A = (A - D) , \quad S_B = 2B ,$$
$$S_C = 2C .$$

The elementary 2D-oscillator ladder operators $a^\dagger$, and a make the 2D-3D theory more powerful. This is known as the Jordan–Schwinger map [32.37–39] between 2D oscillation and 3D rotation. In terms of the ladder operators

$$J_0 = N = a_1^\dagger a_1 + a_2^\dagger a_2 , \quad J_A = \frac{1}{2}\left(a_1^\dagger a_1 - a_2^\dagger a_2\right) ,$$
$$J_B = \frac{1}{2}\left(a_1^\dagger a_2 + a_2^\dagger a_1\right) , \quad J_C = \frac{-i}{2}\left(a_1^\dagger a_2 - a_2^\dagger a_1\right) . \quad (32.27)$$

where

$$a_1^\dagger a_1 = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} , \quad a_1^\dagger a_2 = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} ,$$
$$a_2^\dagger a_1 = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} , \quad a_2^\dagger a_2 = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} .$$

The $a^\dagger a$-algebra gives Schwinger's 3D angular momentum raising and lowering operators $J_+ = J_B + iJ_C = a_1^\dagger a_2$ and $J_- = J_B - iJ_C = a_2^\dagger a_1$, where in two dimensions 1 and 2 are spin-up $(+\hbar/2)$ and spin-down $(-\hbar/2)$, instead of the x-and y-polarized states envisioned by Stokes.

The angular 3D ladder operation is replaced by a simpler 2D oscillator operation:

$$J_+ |n_1 n_2\rangle = a_1{}^\dagger a_2 |n_1 n_2\rangle =$$
$$\sqrt{n_1 + 1}\sqrt{n_2} |n_1 + 1, n_2 - 1\rangle ,$$
$$J_- |n_1 n_2\rangle = a_2^\dagger a_1 |n_1 n_2\rangle =$$
$$\sqrt{n_1}\sqrt{n_2 + 1} |n_1 - 1, n_2 + 1\rangle . \quad (32.28)$$

The 2D oscillator states are labeled by the total number $N = (n_1 + n_2)$ of quanta and the net quantum population $\Delta N = (n_1 - n_2)$. The 3D angular momentum states $\left|{}^J_K\right\rangle$ are labeled by the total momentum $J = N/2 = (n_1 + n_2)/2$ and the z-component

$K = \Delta N/2 = (n_1 - -n_2)/2$, just half (or $\eta/2$) of N and ΔN.

$$|n_1, n_2\rangle = \frac{\left(a_1^\dagger\right)^{n_1}\left(a_2^\dagger\right)^{n_2}}{\sqrt{n_1! n_2!}} |0, 0\rangle =$$

$$\left|{}^J_K\right\rangle = \frac{\left(a_1^\dagger\right)^{J+K}\left(a_2^\dagger\right)^{J-K}}{\sqrt{(J+K)!\,(J-K)!}} |0, 0\rangle \ , \qquad (32.29)$$

where

$$n_1 = J + K \ , \quad n_2 = J - K \ .$$

From this *Schwinger* [32.38] rederived the Wigner matrices $D^J_{MK}(\alpha\beta\gamma)$, which appear in (32.5) and (32.6), and the Wigner–Eckart or Clebsch–Gordan matrix values. This helps clarify the approximation of these values by (J, K)−cone levels around RES hills or valleys [recall (32.10) and (32.11)], since

$$\left\langle {}^{J'}_K \left| T^k_0 \right| {}^J_K \right\rangle = C^{kJJ}_{0KK} \langle J \|k\| J\rangle \sim D^J_{JK}\left(\Theta^J_K\right) \ .$$

32.6.2 Gyro–Rotors and 2D–Local Mode Analogy

The 2D–3D analogy provides insight into spin [32.40–42] and rovibrational dynamics [32.40–45], as well as having computational value. Consider extending a single 2D-oscillator-rotor analogy in the Stokes model to a model of two 1D oscillators with coordinates $x_1 = x$ and $x_2 = y$.

Identical side-by-side oscillators have bilateral B-symmetry. The Hamiltonian H_B commutes with the matrices σ_B (+45° mirror reflection of axes $\pm x \leftrightarrows \pm y$) and $-\sigma_B$ (−45° mirror reflection of axes $\mp x \leftrightarrows \pm y$), both of which switch oscillators. A first-order bilateral Hamiltonian is $H_B = 2B\sigma_B$. This is analogous to a gyro rotor T^1_x with S along the B-axis, as shown in Fig. 32.11a. (The added unit operator T^0_0 shifts levels, but does not affect eigenstates.)

The eigenstates of H_B are the symmetric and antisymmetric normal modes that belong to the fixed points on the S-vector or $\pm B$-axes of the 3D Stokes space. If instead, the S-vector lies on the A-axis, the Hamiltonian is an asymmetric diagonal $H_A = 2A\sigma_A$ matrix. From (32.25) we see that the operator σ_A reflects y into $-y$ but leaves x alone, so that the eigenvectors of H_A are localized on the x-oscillator or the y-oscillator, but not on both. Such motions are local modes, but they are not modes of H_B since it does not commute with H_A.

If the vector J is on the $+A$-axis (local x-mode), the Hamiltonian H_B rotates J to the $-C$-axis, then to the $-A$-axis (local y-mode), then to the $+C$-axis, and then back to the $+A$-axis. This J-path is the equator of Fig. 32.11a. The $\pm C$-axes label circular polarization with right and left chirality, respectively. Twice during a B-beat, J passes the $\pm C$-axes, where one vibrator's phase is 90° ahead and resonantly pumping

a) Spherical gyro-rotor or normal $\pm$ B-modes

c) Symmetric gyro-rotor or local $\pm$ A-mode normal −B-mode

Symmetric normal mode becomes unstable

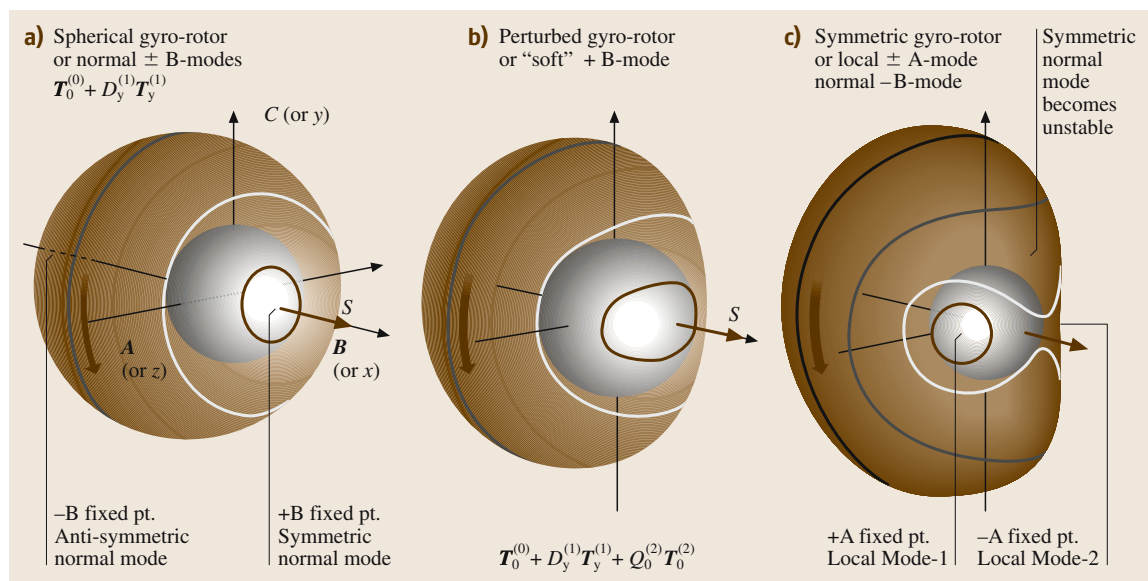
+A fixed pt. Local Mode-1   −A fixed pt. Local Mode-2


Fig. 32.11a–c A spherical gyro-rotor becomes a symmetric gyro-rotor by adding T^2_0

the other. Such bilateral beat and resonant transfer is disrupted by adding anharmonic T_0^2 or $T_{\pm 2}^2$ terms to the B-symmetry terms T_x^1 and T_0^0. Adding T_0^2 causes B-circles in Fig. 32.11(a) to distort near the B-axis, as shown in Fig. 32.11b–c.

In molecular rotation theory, the T_0^2 and T_0^0 terms comprise the initial unperturbed Hamiltonian (32.3) of a symmetric top, while the gyro terms T_q^1 are viewed as perturbations in (32.20), due to an "on-board" gyro rotor. For vibration theory, the T_q^1 terms make up a normal-mode Hamiltonian, and the T_0^2 term is viewed as an anharmonic perturbation.

The effect of T_0^2, seen in Fig. 32.11c, is to replace the stable fixed point $+B$ (representing the (+)-normal mode) by a saddle point as B bifurcates (splits) into a pair of fixed points that head toward the $\pm A$-axes. So one normal mode dies and begets two stable local modes, wherein one mass may keep its energy, and not lose it to the other through the usual B-beating process. (The A-modes become anharmonically detuned.)

Pairs of classical modes, each localized on different sides of the RES in Fig. 32.11, are analogous to the asymmetric top $\pm K$-precession pairs in Fig. 32.2 with degenerate energy in a classical RES picture. The quantum-tunneling Hamiltonian (32.15) splits each trajectory pair into a superfine doublet with $(\pm)$-eigenstates sharing both RES paths, as seen in Table 32.1. The quantum gyro-spin doublets also share $\pm J$ components both up and down the A-axis, as seen in Fig. 32.11c.

32.6.3 Multiple Gyro–Rotor RES and Eigensurfaces

While simple quantum rotors delocalize J to multiple RES paths, a gyro-rotor J may delocalize to multiple paths and surfaces. Gyro-rotor RES vary with S, and if S is a quantum spin, the possibility arises for a distribution over multiple RES [32.46, 47]. A simple quantum theory of S allows both $+S$ and $-S$ at once. The RES for each is plotted one on top of the other, as in Fig. 32.12a, while component RES are shown in Fig. 32.12b for $+S$ and in Fig. 32.12c for $-S$. An energy sphere is shown intersecting an RES pair for an asymmetric gyro-rotor. If the spin S is set to zero, the pair of RES collapses into a rigid asymmetric top RES, shown in Fig. 32.2, having angular inversion (time-reversal $J \rightarrow -J$) and D_{2h} reflection symmetry. The composite RES in Fig. 32.12a has inversion symmetry, but lacks reflection symmetry. Its parts in Fig. 32.12b and c have neither inversion nor reflection symmetry if gyro-spins $\pm S$ are off-axis.

The gyro-rotor Hamiltonian (32.20) allows tunneling or mixing of multiple RES. A two-state spin$-1/2$ gyro-spin model has a $2 \otimes 2$ Hamiltonian matrix and two base-RES:

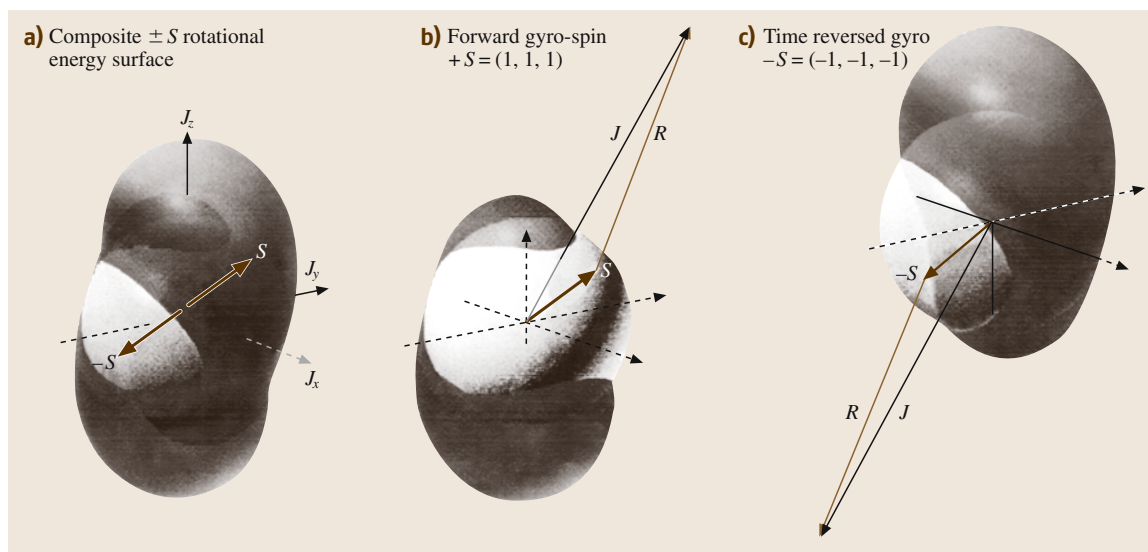
$$H_{\text{gyro}} = M_0 J \cdot J + D_x S_x J_x + D_y S_y J_y + D_z S_z J_z$$
$$+ Q_{xx} J_x^2 + Q_{yy} J_y^2 + Q_{zz} J_z^2 \qquad (32.30)$$


Fig. 32.12a–c Asymmetric gyro-rotor RES (classical body-fixed-spin case); **(a)** Composite $\pm S$; **(b)** Forward spin $\pm S$; **(c)** Reversed spin $-S$

As in (32.7), $\boldsymbol{J}$ is approximated by classical vector components in the body frame:

$$\begin{aligned}
\bigl(J_x = |J| \sin\beta\cos\gamma \,, \quad J_y = |J|\sin\beta\sin\gamma \,, \\
J_z = |J|\cos\beta\bigr) \,.
\end{aligned} \tag{32.31a}$$

But the gyro-spin S uses its quantum representation $\boldsymbol{S} = |S|\boldsymbol{\sigma}/2 = \sqrt{3}\boldsymbol{\sigma}/2$ from (32.25):

$$\begin{aligned}
\bigl\langle H_{\text{gyro}} \bigr\rangle &= M_0 J^2 + Q_{xx} J_x^2 + Q_{yy} J_y^2 + Q_{zz} J_z^2 \\
&\quad + D_x |S|\, \sigma_x J_x + D_y |S|\, \sigma_y J_y + D_z |S|\, \sigma_z J_z \\
&= \begin{pmatrix} h(J) + D_z |S|\, J_z & |S|\bigl(D_x J_x - \mathrm{i} D_y J_y\bigr) \\ |S|\bigl(D_x J_x + \mathrm{i} D_y J_y\bigr) & h(J) - D_z |S|\, J_z \end{pmatrix} \\
&= \begin{pmatrix} h(J) + d_z \cos\beta & \bigl(d_x \cos\gamma - \mathrm{i} d_y \sin\gamma\bigr) \\ & \times \sin\beta \\ \bigl(d_x \cos\gamma + \mathrm{i} d_y \sin\gamma\bigr) & h(J) - d_z \cos\beta \\ \times \sin\beta & \end{pmatrix} \,,
\end{aligned} \tag{32.31b}$$

where

$$h(J) = M_0 J^2 + Q_{xx} J_x^2 + Q_{yy} J_y^2 + Q_{zz} J_z^2$$

and

$$d_\mu = D_\mu |S||J| \,. \tag{32.31c}$$

The dynamics generated by Hamiltonian approximations such as (32.31b) are analogous to other semiclassical approximations, such as the Maxwell–Bloch model of an atom in a cavity. Their solutions are very complicated and often chaotic. The classical variable ($\boldsymbol{J}$ in this case) follows phase contours on a changing RES that depends on the instantaneous expectation values of the quantum variables ($\boldsymbol{S}$ in this case), which in turn vary according to the instantaneous classical variables.

In spite of this complexity, semiclassical spectra may be approximated using RES pairs obtained from eigenvalues of a $2\otimes 2$ matrix such as (32.31b) for each classical angular orientation ($\beta\gamma$) of the J-vector in the body frame [32.46, 47]. The results are pairs of surfaces roughly like those in Fig. 32.12a, but without the intersection lines. The Wigner non-crossing effect prevents degeneracy, except at isolated points.

Near-crossing RES are the rotational equivalent of near-crossing vibrational-potential energy surfaces (VES) described in treatments of *Jahn–Teller* effects [32.48, 49]. The classical, semiclassical, and quantum theory for such loosely-bound or fluxional systems is still inits infancy, but is potentially a very rich source of new effects.

33. Radiative Transition Probabilities

This chapter summarizes the theory of radiative transition probabilities or intensities for rotationally-resolved (high-resolution) molecular spectra. A combined treatment of diatomic, linear, symmetric-top, and asymmetric-top molecules is based on angular momentum relations. Generality and symmetry relations are emphasized. The *energy-intensity* model is founded in a rotating-frame basis-set expansion of the wave functions, Hamiltonians, and transition operators. The intensities of the various rotational branches are calculated from a small number of transition-moment matrix elements, whose relative values can be assumed from the supposed nature of the transition, or inferred by fitting experimental intensities.

33.1 Overview

33.1.1 Intensity versus Line-Position Spectroscopy

The fact that atoms and molecules absorb and emit radiation with propensities that vary with wavelength is the origin of the field called spectroscopy. The relatively sharp intensity maxima are interpreted as corresponding to transitions between discrete states or energy levels. The frequencies or energies of these transitions are used as the primary source of information about the internal structure of the atom or molecule. Line positions can be measured with very high precision (1 ppm or better). Excellent calibration standards have been developed. The quality of these experimental data has attracted extensive analytical and theoretical effort. Sophisticated parametrized models have been developed in which the smallest shifts from the expected line positions can be used to identify perturbations or other subtle effects.

For molecules, knowledge of the strengths of these transitions is far less well developed. One reason is that quantitative experimental data on rotationally-resolved absorption cross sections and emission intensities are much rarer and the experiments themselves are much more difficult to calibrate. Few measurements claim a precision better than 1% and agreement within 10% of measurements in different laboratories is typically viewed as good. This situation is undesirable because most applications of molecular spectroscopy are in fact measurements of intensity. In many cases the strengths of absorptions or emissions are used to infer gas composition, temperature, time evolution, or other environmental conditions. In other examples the actual absorption and emission is the primary interest. Among the most important of these are atmospheric absorption of solar radiation and the greenhouse effect.

33.2 Molecular Wave Functions in the Rotating Frame

33.2.1 Symmetries of the Exact Wave Function

The exact total wave function for any isolated molecule with well-defined energy and total angular momentum can be expressed in a basis-set expansion over configurations with well-defined internal quantum numbers,

$$\Phi_{\text{exact}} \tag{33.1}$$
$$= \Phi_{\text{trans}} \sum_{\alpha\beta\gamma\delta\epsilon} C_{\alpha\beta\gamma\delta\epsilon} \, \Phi_{\text{rot}}^{\alpha} \, \Phi_{\text{vib}}^{\beta} \, \Phi_{\text{elec}}^{\gamma} \, \Phi_{\text{espin}}^{\delta} \, \Phi_{\text{nspin}}^{\epsilon} \cdot$$

In principle, the coefficients $C_{\alpha\beta\gamma\delta\epsilon}$ can be found only by diagonalizing the exact Hamiltonian. In practice one attempts to find a sufficiently good approximation, containing only a few terms, with coefficients chosen by diagonalizing an approximate or model Hamiltonian. This is the basis of the energy–intensity model developed in Sect. 33.3. As discussed by *Longuet-Higgins* [33.1] and *Bunker* [33.2], there are only six true symmetries of the exact Hamiltonian of an isolated molecule:

1. translation of the center of mass;
2. permutation of electrons;
3. permutation of identical nuclei;
4. time reversal or momentum reversal;
5. inversion of all particles through the center of mass;
6. rotation about space-fixed axes.

Of these, only the symmetries numbered 5 and 6 give quantum numbers (parity and the total angular momentum F) that are both rigorous and useful spectroscopic labels of the states of the molecule. The other symmetries are convenient for simplifying the description of the molecular wave function, for the evaluation of relations between matrix elements, and for classification of molecular states according to approximate symmetries.

The first symmetry, translation of the center of mass, allows the choice of a coordinate system referenced to the center of mass, and suppression of the portion of the wave function describing motion through space (as long as the molecule does not dissociate).

Symmetry number 2, exchange of electrons, does not directly provide any labels or quantum numbers, since the Fermi–Dirac statistics of electrons require that all wave functions must be antisymmetric. However, it provides considerable information about the probable electronic states since it controls whether molecular orbitals can be doubly or only singly occupied. For most (low-Z) molecules, each state will have a nearly well-defined value of electron spin: singlet or triplet for example. Admixture of other spin values usually can be treated as a perturbation. These points will be elaborated in Sects. 33.4.4 and 33.7.4.

Permutation of identical nuclei, symmetry number 3, also gives an identical quantum number to all the states of the molecule (± 1 depending on the character of the permutation and on whether nuclei with integral or half-integral spin are being permuted). It supplies little direct information about the energy separations between the states of the molecule. On the other hand, many molecules have identical nuclei in geometrically or dynamically equivalent positions. The existence of spatial symmetry, for nonplanar molecules, is really the same thing as permutational symmetry. Consequently, nuclear permutation, combined with inversion (symmetry number 5), is the basis for naming the states according to the approximate spatial symmetry group of the molecular frame and vibrational motion. These concepts will be explored in Sect. 33.4.3.

Symmetry number 4, time reversal, is both subtle and simple. In the absence of external magnetic fields the Hamiltonian for a molecule will contain only even combinations of angular momentum operators, e.g., $F_{\alpha}F_{\beta}$, $F_{\alpha}L_{\beta}$, or $F_{\alpha}S_{\beta}$. Thus changing the signs of all the angular momenta should result in an equivalent wave function. This will require that matrix elements retain

the same absolute value when the angular quantum numbers are reversed, leading in general to complex conjugation [33.3].

Spatial inversion, symmetry number 5, is always an allowed operation for any molecule, even if it appears to lack internal inversion symmetry. This operation can be considered as a symmetry of the spherically-symmetric laboratory in which the molecule resides. If the molecule is linear, triatomic, rigid with a plane of symmetry, or is nonrigid with accessible vibrational or tunneling modes that correspond to plane reflections, inversion symmetry divides the states of the molecule into two classes, called parities. Perturbations can occur only between states of the same parity. For optical transitions, the change in parity of the states must match the parity of the operator. Otherwise, reflection of the molecule in a plane will interchange inconvertible optical isomers. Such optical isomers are energetically degenerate, so in all cases, inversion through the center of mass remains a valid symmetry of the rotating molecule. However, the separation of the states into two kinds does not provide any selection rules. The two parity classes are perfectly degenerate, thus there is always an allowed level with the correct parity either for perturbations or for optical transitions.

33.2.2 Rotation Matrices

The final symmetry, rotation about the center of mass, restricts the discussion to states with well-defined laboratory angular momentum, and to re-expression of the exact wave function by changing variables from *laboratory* coordinates to *body-fixed* or internal coordinates, and introducing the Euler angles relating these two coordinate systems,

$$\Phi_{\text{exact}}^{F,M_F}(\text{lab}) = \sum_{K_F} \Phi_{\text{rot}}^{F,M_F K_F}(\text{Euler angles})$$
$$\times \Phi_{\text{vesn}}^{(F,K_F)}(\text{internal, spins}) . \quad (33.2)$$

Here F is the total angular momentum of the molecule, including vibrational, mechanical-rotation, electron-orbital, electron-spin, and nuclear-spin contributions. M_F and K_F are the projections of F in the laboratory and body-fixed frames, respectively. In the majority of cases, the magnitude of nuclear hyperfine interactions is sufficiently small that its influence can be ignored when analyzing wave functions and computing energies. Thus the quantum numbers J, M_J, and K_J, or just J, M, and K can be used.

Explanation is postponed of how the body-fixed frame is to be selected, but for any choice, the wave function for rotation of the entire molecule can be expressed using a rotation matrix [33.4, 5]

$$\Phi_{\text{rot}}^{F,M_F K_F}(\text{Euler angles})$$
$$= \left(\frac{(2F+1)}{8\pi^2}\right)^{1/2} D_{M_F K_F}^{*F}(\phi, \theta, \chi) . \quad (33.3)$$

For diatomics, *Zare* [33.5] suggests multiplying by $(2\pi)^{1/2}$ and setting $\chi = 0$. The internal wave function for the vibrational, electronic, electron-spin, and nuclear-spin degrees of freedom [thus the label (vesn)] can be thought of as the partial summation

$$\Phi_{\text{vesn}}^{(F,K_F)}(\text{internal, spins})$$
$$= \sum_{\beta\gamma\delta\epsilon} C_{(FK_F)\beta\gamma\delta\epsilon} \Phi_{\text{vib}}^{\beta} \Phi_{\text{elec}}^{\gamma} \Phi_{\text{espin}}^{\delta} \Phi_{\text{nspin}}^{\epsilon} , \quad (33.4)$$

expressed in the internal or rotated coordinate system. Note that the FK_F designation is only a parametric label. The rotational wave function has been absorbed into the rotation matrix.

33.2.3 Transformation of Ordinary Objects into the Rotating Frame

The assumption of rotational symmetry allows re-expression of matrix elements between total wave functions as a sum of matrix elements between internal wave functions. For example, the tensor operator $T^{(L)}$ belonging to the L representation of the rotation group, can be written in the rotating frame as [33.5–8]

$$T_p^{(L)}(\text{lab}) = \sum_q D_{pq}^{*L}(\phi\theta\chi) T_q^{(L)}(\text{body}) , \quad (33.5)$$

and can be used to evaluate matrix elements that might represent radiative transitions:

$$\langle \psi^{F',M_F''+p} | T_p^{(L)}(\text{lab}) | \Phi^{F'',M_F''} \rangle$$
$$= \left(\frac{(2F''+1)}{(2F'+1)}\right)^{1/2} \langle F''M_F'', Lp | F'M_F''+p \rangle$$
$$\times \sum_{qK_F''} \langle F''K_F'', Lq | F'K_F''+q \rangle$$
$$\times \langle \psi_{\text{vesn}}^{(F',K_F''+q)} | T_q^{(L)}(\text{body}) | \Phi_{\text{vesn}}^{(F'',K_F'')} \rangle , \quad (33.6)$$

where $\langle F''M_F'', Lp | F'M_F''+p \rangle$ and $\langle F''K_F'', Lq | F'K_F'' +q \rangle$ are Clebsch–Gordan coefficients that vanish if $|F' - F''| > L$, $|M_F'' + p| > F'$, or $|K_F'' + q| > F'$.

This transformation forms the basis for the derivation of rotational branch strengths (Sect. 33.7.2) and for the description of electron motions that are weakly coupled to the molecular frame (Sect. 33.7.4).

33.3 The Energy–Intensity Model

33.3.1 States, Levels, and Components

The previous section introduced the concept of representing the wave function of a molecule as a product of five simpler wave functions:

$$\psi \approx \psi_{\text{elec}} \psi_{\text{vib}} \psi_{\text{rot}} \psi_{\text{espin}} \psi_{\text{nspin}} . \tag{33.7}$$

This construction yields a similar separation of the Hamiltonian,

$$H \approx H_{\text{elec}} + H_{\text{vib}} + H_{\text{rot–fs}} + H_{\text{hf}} , \tag{33.8}$$

and representations of the energies as sums of contributions,

$$E \approx T_{\text{e}} + G_{\text{v}} + F_{\text{c}}(J) , \tag{33.9}$$

and absorption or emission transition strengths as products,

$$I \approx I_{\text{elec}} I_{\text{vib}} I_{\text{rot–fs}} I_{\text{hf}} . \tag{33.10}$$

Whatever theoretical arguments might favor such a separation, the real impetus is the empirical observation that most molecular absorption and emission spectra exhibit recognizable patterns arising from the dissimilar magnitudes of the energies associated with these five degrees of freedom. Separation of the wave function and the Hamiltonian into these four or five contributions facilitates the assignment of molecular spectra, in addition to suggesting models with parameters that can be adjusted to quantitatively represent the observed spectra.

Most states of molecules are dominated by a single set of electronic and vibrational quantum numbers. Electronic states are often well separated. With each electronic state is associated a potential energy surface, the energy at the minimum being labeled T_{e}. Motion of nuclei within this potential generates various levels corresponding to different vibrational quantum numbers, following regular patterns or progressions in energy, summarized by a small number of parameters called vibrational frequencies. The quantity G_{v} represents the energy of the the vibrational level above the potential minimum. For each vibrational level, a progression of rotational levels is expected. For linear molecules in electronic states without electronic angular momentum (i. e., $^1\Sigma$ states) the rotational energies are also reproduced by a few rotational constants.

For more complicated molecules and electronic states, i. e., most cases, there are multiple energetically distinct levels with the same value of J (in addition to the $2J + 1$ orientational degeneracy of each level). These multiple levels all share the same nominal quantum numbers (additional analysis may subdivide them into parity or permutational symmetry types). These sublevels are called "components" with energies expressed by the notation $F_{\text{c}}(J)$. The quantity N_{c}, the number of components expected, reflects the assignment of the nature of the vibronic state. For linear molecules there is a limited number of components corresponding to the various orientations of electron spin and orbital angular momentum. For example, a $^2\Pi$ electronic state will have four components for each value of J (except for $J = 1/2$, where there are only two components). For nonlinear molecules the number of components increases with J, proportional to $2J + 1$, corresponding to various possible projections of the total angular momentum onto the tumbling molecular frame.

The conclusion of this analysis is that a basis set be chosen, over which a model rotational and fine-structure Hamiltonian can be expressed. The wave functions then become vectors of numbers. A priori, only the form of the matrix elements and their dependence on J and body–frame projection (K or Ω) are known. Little is known in advance about how strong the interactions are in any given molecule. Thus one tends to write the Hamiltonian with parameters that are to be determined by fitting the observed energy levels.

Similarly, the choice of the basis sets for the upper and lower states specifies the overall form of the matrix of transition moments between the basis functions. The transition can be chosen to be of a simple standard form, for example, parallel or perpendicular, with only one unknown parameter representing the overall strength of the transition. Alternatively, the transition matrix elements can be considered to be independently adjustable, within the symmetry restrictions that are required (time reversal) or assumed (spatial symmetry).

33.3.2 The Basis Set and Matrix Hamiltonian

For linear molecules it is convenient to choose a basis set labeled by the projections of orbital and spin angular momenta in the body–frame coordinate system, represented symbolically by

$$|\Lambda\Sigma; JM\Omega\rangle = \left(\frac{(2J+1)}{8\pi^2}\right)^{1/2} D_{M\Omega}^{*J}|\Lambda\Sigma\rangle,$$

(33.11)

where $\Omega = \Lambda + \Sigma$. This is called the Hund's case (a) basis set, which is an accurate representation in a single term if the body–frame angular momenta are nearly conserved. This is true if the spin-orbit interaction is larger than the separation between rotational levels. Under all circumstances, this basis set facilitates construction of the matrix Hamiltonian and representation of sources of transition probability [33.9].

One parametrization for the spin–rotation Hamiltonian is provided by *Brown* et al. [33.10–12]:

$$\begin{aligned}
\boldsymbol{H}_{\text{spin–rot}} \\
= T_e + G_v + B_v \boldsymbol{N}^2 - D_v \boldsymbol{N}^4 \\
+ \frac{1}{2}\left[A_v + A_{D_v}\boldsymbol{N}^2, L_z S_z\right]_+ \\
+ \left(\gamma_v + \gamma_{D_v}\boldsymbol{N}^2\right)\boldsymbol{N}\cdot\boldsymbol{S} \\
+ \frac{1}{3}\left[\lambda_v + \lambda_{D_v}\boldsymbol{N}^2, 3S_z^2 - \boldsymbol{S}^2\right]_+ \\
+ \eta_v L_z S_z\left[S_z^2 - \frac{1}{5}\left(3\boldsymbol{S}^2 - 1\right)\right] \\
- \frac{1}{4}\left[o_v + o_{D_v}\boldsymbol{N}^2, \Lambda_+^2 S_-^2 + \Lambda_-^2 S_+^2\right]_+ \\
+ \frac{1}{4}\left[p_v + p_{D_v}\boldsymbol{N}^2, \Lambda_+^2 S_- N_- + \Lambda_-^2 S_+ N_+\right]_+ \\
+ \frac{1}{4}\left[q_v + q_{D_v}\boldsymbol{N}^2, \Lambda_+^2 N_-^2 + \Lambda_-^2 N_+^2\right]_+,
\end{aligned}$$

(33.12)

where $[x, y]_+$ is the anticommutator $(xy + yx)$, and $\boldsymbol{N} = \boldsymbol{J} - \boldsymbol{S}$. *Zare* et al. [33.13] provide an alternative parametrization, with different interpretations of the *spectroscopic constants* $(B, D, A, \gamma, \lambda,$ etc.) because they multiply different symbolic operators. One significant difference is that *Zare* et al. use the "mechanical angular momentum" $\boldsymbol{R} = \boldsymbol{J} - \boldsymbol{L} - \boldsymbol{S}$ as the expansion operator, rather than $\boldsymbol{N}$, which might be called the "spinless angular momentum." These differences mean that care must be taken in attempting to construct simulated spectra from published constants. In spite of much discussion in the literature, there is little theoretical foundation for

preferring one parametrization over another, as long as the observed levels are accurately fit. In a number of cases naive assumptions about the origin of certain types of interactions have been overturned. For example, the spin–spin interaction, represented by the constant λ, is often dominated by level shifts due to off-diagonal spin-orbit perturbations [33.14].

For polyatomic molecules, a suitable basis set for expansion can be chosen to have a similar form [33.8, 15, 16]

$$|l\Lambda\Sigma; JMK\rangle = \left(\frac{(2J+1)}{8\pi^2}\right)^{1/2} D_{MK}^{*J}|l\Lambda\Sigma\rangle,$$

(33.13)

where Λ and Σ represent the projections of the electron- orbital (L) and spin (S) angular momenta, and l represents the projection of the vibrational angular momentum (p for degenerate vibrational modes). This is the symmetric top basis set. Generalizing the work of *Watson* [33.17, 18], the parametrized Hamiltonian might be written in a form such as

$$\begin{aligned}
\boldsymbol{H}_{\text{rot}} = \sum h_{\zeta\eta\theta l}^{\alpha\beta\gamma\delta\epsilon}\Bigg\{ \left(\boldsymbol{J}^2\right)^\alpha \left(J_z\right)^{2\beta}\left(J_+^{2\gamma} + J_-^{2\gamma}\right) \\
\times (\boldsymbol{J}\cdot\boldsymbol{p})^\delta (\boldsymbol{J}\cdot\boldsymbol{L})^\epsilon (\boldsymbol{J}\cdot\boldsymbol{S})^\zeta \\
\times (\boldsymbol{p}\cdot\boldsymbol{L})^\eta (\boldsymbol{p}\cdot\boldsymbol{S})^\theta (\boldsymbol{L}\cdot\boldsymbol{S})^l \Bigg\},
\end{aligned}$$

(33.14)

where the {} indicates that an appropriately symmetric combination be constructed with anticommutators.

For both linear and nonlinear molecules, it is convenient to use the Wang transformation [33.19] to combine basis functions with opposite sense of rotation: for diatomics

$$\frac{1}{\sqrt{2}}\left[||\Lambda|, \Sigma; J, M, \Omega\rangle \pm |-|\Lambda|, -\Sigma; J, M, -\Omega\rangle\right];$$

(33.15)

and for polyatomics

$$\begin{aligned}
\frac{1}{\sqrt{2}}\big[|l, \Lambda, \Sigma; J, M, K\rangle \\
\pm |-l, -\Lambda, -\Sigma; J, M, -K\rangle\big].
\end{aligned}$$

(33.16)

For diatomic molecules, these combinations can be assigned the parity $\pm(-1)^{J+S+s}$, where $s = 1$ for Σ^- states, and 0 otherwise [33.13, 20]. For symmetric top molecules, each term is to be accompanied by the appropriate hidden nuclear-spin basis function [33.8, 21].

For asymmetric top molecules, the Wang transformation divides the basis functions into four symmetry

classes $E^\pm$ and $O^\pm$ according to the combining sign and whether K is even or odd. The eigenstates are often labeled by two projection quantum numbers called K_{-1} and K_1. Assuming that $A \geq B \geq C$, the asymmetry parameter

$$\kappa = \frac{(2B - A - C)}{(A - C)} \tag{33.17}$$

ranges from -1 for a prolate symmetric top $(B = C)$ to 1 for an oblate symmetric top $(B = A)$. A, B, and C are the rotational constants, or reciprocals of the moments of inertia, about the three principal top axes. Each asymmetric top level can be correlated with specific symmetric top levels (i.e., K-values) in the two limits. The prolate limiting K-value is called K_{-1} and the oblate limit is called K_1 (i.e., $\kappa = \pm 1$). Note that the symmetric-top principal axes rotate by 90° during this correlation. The eigenstates are given additional symmetry names (ee,eo,oe,oo) according to whether K_{-1} and K_1 are even or odd. *Papousek* and *Aliev* [33.18] discuss the relations between the ($E^\pm$, $O^\pm$) and (ee,eo,oe,oo) labeling schemes.

33.3.3 Fitting Experimental Energies

Having chosen a basis set and model Hamiltonian for both the upper and lower levels, the observed transition energies can be used to infer the numerical values of the constants that best fit the spectrum. The following quotation provides a good description of the process:

> *The calculational procedure logically divides into three steps: (1) The matrix elements of the upper and lower state Hamiltonians are calculated for each J value using initial values of the adjustable molecular constants; (2) both Hamiltonians are numerically diagonalized and the resulting sets of eigenvalues are used to construct a set of calculated line positions; and (3) from a least-squares fit of the calculated to the observed line positions, an improved set of molecular constants is generated. This nonlinear least-squares procedure is repeated until a satisfactory set of molecular constants is obtained.*

This quotation is taken from the article by *Zare* et al. [33.13] in which they describe the basis for the LINFIT computer program, one of the first to accomplish direct extraction of constants from diatomic spectral line positions based on numerically diagonalized Hamiltonians.

33.3.4 The Transition Moment Matrix

Diagonalization of the model Hamiltonians for the upper and lower states yields vector wave functions that can be used for calculating matrix elements, especially those needed to evaluate radiative transition probabilities. The wave functions for diatomic molecules have the form

$$\psi'_{J'M'c'} = \sum_{\Lambda'\Sigma'} b^{J'c'}_{\Lambda'\Sigma'} |\Lambda'\Sigma'; J'M'\Omega'\rangle' ,$$

$$\Phi''_{J''M''c''} = \sum_{\Lambda''\Sigma''} a^{J''c''}_{\Lambda''\Sigma''} |\Lambda''\Sigma''; J''M''\Omega''\rangle'' . \tag{33.18}$$

Section 33.2.3 expresses matrix elements of laboratory-frame operators in terms of matrix elements in the rotating body-fixed frame. Terms of the form

$$\mu_{K'K''} = \langle \psi^{(J'K')} | T_q^{(L)}(\text{body}) | \Phi^{(J''K'')} \rangle \theta(-q) \tag{33.19}$$

need to be evaluated. These terms are multiplied by zero if $K' \neq K'' + q$. In the diatomic basis set these become

$$\mu_{\Lambda'\Sigma'\Lambda''\Sigma''} = {}'\langle \Lambda'\Sigma' | T_q^{(L)}(\text{body}) | \Lambda''\Sigma'' \rangle'' \theta(-q) , \tag{33.20}$$

where $\theta(-q)$ is a phase factor described in Sect. 33.7.2. Only a few of these matrix elements are independent and nonzero. For electric dipole transitions ($L = 1$), time-reversal and inversion-symmetry can be used to establish the relation

$$\mu_{-\Omega'-\Omega''} = \eta(-1)^{\Omega'-\Omega''} \mu_{\Omega'\Omega''} . \tag{33.21}$$

The sign of $\eta = \pm 1$ is determined by the overall character of the electronic transition, and is related to the classification of levels into e- and f-parity types and to the determination of which components are involved in the rotational branches (P, Q, and R). These concepts are elaborated in Sect. 33.4.

33.3.5 Fitting Experimental Intensities

For allowed transitions in linear molecules and symmetric tops, only one independent parameter is normally expected in the transition moment matrix. Thus no additional information is available from fitting the experimental rotational branch strengths (assuming the energy–intensity model is adequate). In diatomic molecules, the intensities of different vibrational bands can be used to infer the internuclear-distance dependence of the electronic transition moment (for example, see *Luque* and *Crosley* [33.22]).

For forbidden transitions and allowed transitions in asymmetric tops, more than one independent parameter is expected. The intensity of a single given rotational line can be expressed in the form

$$I^{\text{line}} = \left| \sum_{K'K''} \mu_{K'K''} Z_{K'K''}(\text{line}) \right|^2 , \qquad (33.22)$$

33.4 Selection Rules

33.4.1 Symmetry Types

Selection rules are guidelines for identifying which transitions are expected to be strong and which are expected to be weak. These rules are based on classifying rovibronic levels into labeled symmetry types. Some symmetry distinctions are effectively exact: such as total angular momentum F, or laboratory-inversion parity. Others are approximate, derived from estimates that certain matrix elements are expected to be much larger than others. The most important of these are based on electron spin (for light molecules) and geometrical point-group symmetry (for relatively rigid polyatomics). In actual fact, no transition is completely forbidden. The multipole nature of electromagnetic radiation (electric-dipole, magnetic-dipole, electric-quadrupole, etc.) implies that any change in angular momentum or parity is possible in principle. Practical interest emphasizes identification of the origin of the strongest source of transition probability, and estimation of the strengths of the weak transitions relative to the stronger ones. The result is a collection of *propensity rules* using *selection rules* as tools of estimation.

Basis functions for expansion of the wave functions for the upper and lower states were chosen in Sect. 33.3.2. The first step in the symmetry classification of rovibronic levels consists of identifying various linear combinations of basis functions that block-diagonalize the exact or approximate Hamiltonians. Symmetry-type names are then assigned to these linear combinations based on the value of F or J and knowledge of the symmetry properties of the underlying vibrational and electronic states. Thus each eigenfunction or rovibronic level consists of an expansion over only one of the kinds of linear combination, and the level can be assigned a specific symmetry type.

Similarly, the basis-set expansion leads to a matrix representation of the possible transitions. Spin- and spatial-symmetry arguments establish relationships be-

where $Z_{K'K''}(\text{line})$ can be calculated in advance from the energies (wave functions) and quantum numbers alone, using the formulas in Sect. 33.7.2. Nonlinear least-squares fitting can be used to derive the best intensity parameters [33.23–26], analysis of which can help characterize the nature of the transition, and identify the sources of transition probability.

tween these transition matrix elements, and provide estimates of which are much smaller than the others. Each combination of upper- and lower-state symmetry types results in a specific pattern of rotational branches. The most important patterns are ΔJ even (Q-branches) or odd (P- and R-branches), and intensity alternation for consecutive values of J (nuclear spin statistics).

33.4.2 Rotational Branches and Parity

The symmetry of time or momentum reversal implies that changing the signs of all the angular momenta should result in an equivalent wave function. For example, the phase convention

$$\Phi_{\text{vesn}}^{(F,-K_F)}(\text{internal, spins})$$
$$= (-1)^{-F+K_F} \Phi_{\text{vesn}}^{*(F,K_F)}(\text{internal}, -\text{spins}) \quad (33.23)$$

can be chosen to establish that the relative phases of matrix elements of the Hamiltonian can be taken as

$$\left\langle D_{M_F-K_F'}^{*F} \Phi_{\text{vesn}}^{(F,-K_F')} \middle| H \middle| D_{M_F-K_F''}^{*F} \Phi_{\text{vesn}}^{(F,-K_F'')} \right\rangle$$
$$= \left\langle D_{M_FK_F'}^{*F} \Phi_{\text{vesn}}^{(F,K_F')} \middle| H \middle| D_{M_FK_F''}^{*F} \Phi_{\text{vesn}}^{(F,K_F'')} \right\rangle^* . \quad (33.24)$$

The formula for matrix elements of optical transition operators can also be reanalyzed,

$$\left\langle \psi^{F',M_F''+p} \middle| T_p^{(L)}(\text{lab}) \middle| \Phi^{F'',M_F''} \right\rangle \qquad (33.25)$$
$$= \left[\frac{(2F''+1)}{(2F'+1)} \right]^{1/2} \left\langle F''M_F'', Lp \middle| F'M_F''+p \right\rangle$$
$$\times \frac{1}{2} \sum_{qK''} \left\langle F''K_F'', Lq \middle| F'K_F''+q \right\rangle$$
$$\times \left\{ \left\langle \psi_{\text{vesn}}^{(F',K_F''+q)} \middle| T_q^{(L)}(\text{body}) \middle| \Phi_{\text{vesn}}^{(F'',K_F'')} \right\rangle \right.$$
$$+ (-1)^{F'+L-F''}$$
$$\times \left. \left\langle \psi_{\text{vesn}}^{(F',-K_F''-q)} \middle| T_{-q}^{(L)}(\text{body}) \middle| \Phi_{\text{vesn}}^{(F'',-K_F'')} \right\rangle \right\} ,$$

to establish that all contributions are purely real or purely imaginary [33.27]. Since such transition matrix elements will be used as absolute squares, they can be treated as if they were purely real.

Parity classification of molecular states according to inversion through the center of mass is important for establishing which transitions are electric-dipole allowed and which states can perturb each other. As discussed by *Larsson* [33.4], such classification is not without subtlety and opportunity for confusion. Inversion of the laboratory spatial coordinates (i_{sp}, also called E^* [33.2]) is equivalent to a reflection σ of the molecule-fixed electronic and nuclear coordinates in an arbitrary plane followed by rotation of the molecular frame by $180°$ about an axis through the origin and perpendicular to the reflection plane (if F is half-integral special care must be taken about the sense of rotation). It follows that

$$
\begin{aligned}
i_{sp}&\Phi_{exact}^{F,M_F}(lab) \\
&= E^*\Phi_{exact}^{F,M_F}(lab) \\
&= \eta(-1)^{F-\gamma}\Phi_{exact}^{F,M_F}(lab) \\
&= \left[\frac{(2F+1)}{8\pi^2}\right]^{1/2} \\
&\quad \times \sum_{K_F}(-1)^{F-K_F}D_{M_F-K_F}^{*F}\sigma_{xz}\Phi_{vesn}^{(F,K_F)}
\end{aligned}
\tag{33.26}
$$

and

$$
\sigma_{xz}\Phi_{vesn}^{(F,K_F)} = \eta(-1)^{K_F-\gamma}\Phi_{vesn}^{(F,-K_F)}\,,
\tag{33.27}
$$

where $\gamma = 0$ or $1/2$ for integral or half-integral F, respectively, and η is the parity label for the state, having values of ± 1. In linear molecules, levels with $\eta = +1$ are called e-levels while those with $\eta = -1$ are called f-levels [33.28, 29].

Inversion symmetry can be combined with time reversal to establish that all matrix elements of the Hamiltonian can be taken to be real [33.27]. The wave function can also be expressed in the form of the Wang transformation [33.19], uniting the $\pm K_F$ components,

$$
\begin{aligned}
\Phi_{exact}^{F,M_F}&(lab) \\
&= \left(\frac{(2F+1)}{8\pi^2}\right)^{1/2}\sum_{K_F\geq 0}\left[D_{M_F K_F}^{*F}\Phi_{vesn}^{(F,K_F)}\right. \\
&\quad \left. + \eta(-1)^{-K_F+\gamma}D_{M_F-K_F}^{*F}\sigma_{xz}\Phi_{vesn}^{(F,K_F)}\right] \\
&\quad \times \left[2(1+\delta_{K_F 0})\right]^{-1/2}\,.
\end{aligned}
\tag{33.28}
$$

If the molecule is rigid and has a plane of symmetry, or is nonrigid with accessible vibrational or tunneling modes that correspond to plane reflections, in-

version symmetry divides the states of the molecule into two classes, according to the sign of η. Perturbations can occur only for $\Delta F = 0$ and $\eta'\eta'' = +1$. For optical transitions, the change in parity of the states must match the parity of the operator. Odd operators (e.g., electric-dipole) require $\eta'\eta''(-1)^{\Delta F} = -1$. Even operators (e.g., magnetic-dipole and electric-quadrupole) require $\eta'\eta''(-1)^{\Delta F} = +1$.

33.4.3 Nuclear Spin, Spatial Symmetry, and Statistics

For most molecules, the coupling of nuclear spin with the electron-spin, electron-orbital, and frame-rotational angular momenta is sufficiently weak that treatment of the energetics of hyperfine interactions can be postponed. The first-order effect of nuclear spin is that rovibronic wave functions for molecules containing identical nuclei must be combined with appropriate nuclear spin wave functions in order to obtain the necessary Fermi–Dirac or Bose–Einstein nuclear permutation symmetry. For many molecules, there exist combinations of nuclear permutations that correspond to combinations of frame rotations, laboratory inversions, and feasible vibrational motions (the rotational wave function makes a contribution because renumbering the nuclei requires a reanalysis of the Euler angles). For rigid molecules, these permutations (possibly including inversion) can be used to generate the point symmetry group of the molecule. For fluxional molecules, with multiple energetically equivalent nuclear configurations, a rather large "molecular symmetry group" can result, one that may not correspond to any ordinary point group [33.1, 2].

In the discussion immediately following, consider the case of N occurrences of one kind of nucleus, the others being unique (e.g., PD_3). The treatment can easily be extended to the case of multiple kinds of identical nuclei (e.g., C_2H_6). The exact wave function can be rearranged into a sum over products of the form

$$
\Phi_{exact} = \sum_{a,b}\Phi_{rves}^{(a)}\Phi_{nspin}^{(b)}\,,
\tag{33.29}
$$

where $\Phi_{rves}^{(a)}$ is a rovibronic wave function belonging to the $\Gamma(a)$ representation of the symmetric group S_N of permutations over N objects, and $\Phi_{nspin}^{(b)}$ is a nuclear spin wave function, belonging to the $\Gamma(b)$ representation of S_N. In order to obtain the correct permutation symmetries for the overall wave function, the only terms that can appear in this sum are those for which the direct product $\Gamma(a)\otimes\Gamma(b)$ contains the symmetric or antisymmetric representation, for bosons or fermions, respectively.

Assumption of negligible hyperfine interactions allows evaluation of matrix elements of the form

$$
\begin{aligned}
&\left\langle \Phi_{\text{rves}}^{(c)} \Phi_{\text{nspin}}^{(d)} \middle| H \middle| \Phi_{\text{rves}}^{(a)} \Phi_{\text{nspin}}^{(b)} \right\rangle \\
&= \left\langle \Phi_{\text{rves}}^{(c)} \middle| H \middle| \Phi_{\text{rves}}^{(a)} \right\rangle \left\langle \Phi_{\text{nspin}}^{(d)} \middle| \Phi_{\text{nspin}}^{(b)} \right\rangle ,
\end{aligned} \tag{33.30}
$$

which vanishes unless $\Gamma(a) = \Gamma(c)$ and $\Gamma(b) = \Gamma(d)$. Thus the nearly-exact wave function can be written as a sum over products where the rovibronic and nuclear-spin factors correspond to basis functions from single known representations:

$$
\Phi_{\text{exact}} \approx \sum_{a,b} \Phi_{\text{rves}}^{(a)} \Phi_{\text{nspin}}^{(b)} , \tag{33.31}
$$

with $\Gamma(a) = \Gamma_{\text{rves}}$ and $\Gamma(b) = \Gamma_{\text{nspin}}$. This divides the states of the molecule into a number of noninteracting symmetry classes, labeled by the representations of the symmetric group. In the absence of hyperfine interactions, optical transitions are possible only within a certain symmetry class.

Thus the existence of spatial or dynamical symmetry implies that each rovibronic wave function transforms according to a particular representation of a subgroup of the permutation-inversion group (called CNPI by *Bunker* [33.2]). Each representation includes only specific values of nuclear spin, corresponding to the permutational properties of the nuclear spin wave functions. The most important effect of this analysis is to assign statistical weights or relative intensities to the different symmetry types. For example, the symmetry group for NH_3 is D_{3h} (including umbrella inversion), with representations A_1', A_2', A_1'', A_2'', E', and E''. The A_1' and A_1'' representations must be combined with the (nonexistent) antisymmetric spin function, yielding a statistical weight of 0. Similarly, A_2' and A_2'' combine with the symmetric $I = 3/2$ spin function, with a statistical weight of 4 (i.e., $2I + 1$). E' and E'' combine with the nonsymmetric $I = 1/2$ spin functions, with a statistical weight of 2. This material is discussed from various viewpoints in numerous articles and text books, of which only a few can be cited here [33.1, 2, 8, 18, 21, 30–36]. See Chapt. 32 for additional details and examples.

Although this analysis appears rather complicated, the selection rules that result are actually the same, at least in simple cases, as the ones that are derivable from simpler ideas. For example, for a $^1\Sigma_g^+$ lower state, even J levels are permutation symmetric and have parity $+1$, while odd J levels are permutation antisymmetric and have parity -1. For a $^1\Sigma_u^+$ upper state, even J levels are permutation antisymmetric and

have parity $+1$, while odd J levels are permutation symmetric and have parity -1. Both the parity selection rule and permutation-symmetry selection rule independently require that $\Delta J = \pm 1$ for electric-dipole transitions. Similarly, that the permanent dipole moment of a symmetric-top molecule must lie along the body-fixed axis replicates the $\Delta K = 0$ selection rule for pure-rotation transitions provided by permutational symmetry arguments. This means that when simulating absorption and emission spectra, the nuclear-spin wave function can usually be ignored. The intensity alternation imposed by spin-statistics can be represented by multiplying each wave function by the appropriate factor, for example, 0 or $[(2I + 1)/(2i + 1)^N]^{1/2}$, where I is the total nuclear spin, and i is the spin of one of the N equivalent nuclei.

Group theory remains vital for understanding the relative strengths of vibrational transitions in polyatomics (see *Cotton* [33.37], for example, and Sect. 33.6.2) and becomes very interesting as interaction between vibration and rotation increases. For the purposes of this discussion, the most important issue is identification of which transition-moment matrix elements $\mu_{K'K''}$ vanish and which are related by symmetry.

33.4.4 Electron Orbital and Spin Angular Momenta

For all molecules, the strongest transitions tend to be those that conserve electron spin. The zero-order transition-moment matrix is diagonal both in total spin and in spin-projection onto the body–frame axis. In the $|\Lambda\Sigma\rangle$ basis set for linear molecules this is expressed by

$$
\mu_{\Lambda'\Sigma'\Lambda''\Sigma''} = \mu_{\Lambda'\Lambda''}\delta_{\Sigma'\Sigma''} . \tag{33.32}
$$

The transition-moment tensor operator $T_q^{(L)}(\text{body})$ can connect basis functions that differ in Λ by at most L. Allowed electric-dipole transitions thus satisfy

$$
\mu_{\Lambda'\Lambda''} = 0, \quad \text{for } |\Lambda' - \Lambda''| > 1 . \tag{33.33}
$$

In the usual case that the upper and lower states each consist of only a single value of $|\Lambda|$, there is only one independent, nonzero, matrix element $\mu_{|\Lambda'|,|\Lambda''|}$ with

$$
\mu_{-|\Lambda'|,-|\Lambda''|} = \eta(-1)^{|\Lambda'|-|\Lambda''|}\mu_{|\Lambda'|,|\Lambda''|} . \tag{33.34}
$$

See Sect. 33.8 for a discussion of spin-forbidden and orbitally-forbidden transitions. Similar arguments and phase relationships can be developed for polyatomic molecules with nonzero electron spin or degenerate vibrational or electronic states.

33.5 Absorption Cross Sections and Radiative Lifetimes

33.5.1 Radiation Relations

Among the most important radiation relations is the connection between the absorption cross section and the rate of spontaneous emission. *Einstein* [33.38] introduced his *A* and *B* coefficients to describe the rates of absorption and emission of radiation of a collection of two-level atoms or molecules in equilibrium with a radiation field at the same temperature. The discussion here follows that of *Condon* and *Shortley* [33.39], *Penner* [33.40], *Thorne* [33.41], and *Steinfeld* [33.42] (with corrections). Also see Chapts. 10, 17, and 68 of this Handbook. The number of absorption events per unit volume per unit time is written as

$$N_l B_{lu} \rho(\nu) .$$ (33.35)

While the rate of emission is

$$N_u B_{ul} \rho(\nu) + N_u A_{ul} .$$ (33.36)

In thermal equilibrium, the radiative energy density is given by the Planck blackbody law

$$\rho(\nu) = \left(\frac{8\pi h \nu^3}{c^3} \right) \left(e^{h\nu/kT} - 1 \right)^{-1} ,$$ (33.37)

and the ground and excited state densities satisfy a Boltzmann relationship,

$$\frac{N_u}{N_l} = \left(\frac{g_u}{g_l} \right) e^{-h\nu/kT} ,$$ (33.38)

where g_u and g_l are the degeneracies of the upper and lower states. The requirement that the rates of absorption and emission must be equal leads to the relations

$$A_{ul} = \left(\frac{8\pi h \nu^3}{c^3} \right) B_{ul} = \left(\frac{8\pi h \nu^3}{c^3} \right) \left(\frac{g_l}{g_u} \right) B_{lu} .$$ (33.39)

Numerical values of the *B* coefficients can be derived from the optical absorption cross section, and thus

$$A_{ul} = \left(\frac{8\pi \nu^2}{c^2} \right) \left(\frac{g_l}{g_u} \right) \int \sigma_{\mathrm{abs}}(\nu) \, d\nu$$

$$= \left(\frac{8\pi \nu^2}{c^2} \right) \int \sigma_{\mathrm{se}}(\nu) \, d\nu .$$ (33.40)

Finally, the expression for the absorption oscillator strength is

$$f_{\mathrm{abs}} = (4\pi\epsilon_0) \left(\frac{mc^3}{8\pi^2 \nu^2 e^2} \right) \left(\frac{g_u}{g_l} \right) A_{ul}$$

$$= (4\pi\epsilon_0) \left(\frac{mc}{\pi e^2} \right) \int \sigma_{\mathrm{abs}}(\nu) \, d\nu .$$ (33.41)

The emission oscillator strength is simply related to that for absorption: $f_{\mathrm{em}} = -(g_l/g_u) f_{\mathrm{abs}}$. The oscillator strength offers considerable advantages as a means of reporting and comparing the strengths of radiative transitions. It is dimensionless, obeys the simple sum rule (for electric-dipole transitions)

$$\sum_u f_{ul} = \text{number of electrons} ,$$ (33.42)

and is directly derivable from an experimental absorption cross section even before the assignment of the upper level has been determined (i.e., before its degeneracy is known).

33.5.2 Transition Moments

In many cases, the intention is to construct model quantum mechanical wave functions for the two states involved in the transition under study. In addition, ab initio electronic wave functions and matrix elements may be available (see Chapt. 31). Quantum mechanics suggests the following expression for the Einstein *A* coefficient (see Sect. 11.5.1):

$$A_{ul} = \left(\frac{64\pi^4 \nu^3}{3hc^3} \right) \left(\frac{1}{4\pi\epsilon_0} \right) \left(\frac{1}{g_u} \right)$$

$$\times \sum_{u', l'', p} \left| \langle \psi'_{u'} | e r_p | \psi''_{l''} \rangle \right|^2 .$$ (33.43)

The summation is over all three optical polarization directions p (i.e., r_p runs over x, y, and z in the lab frame), all degenerate components l'' of the lower state (i.e., g_l of them), and all degenerate components u' of the upper state (i.e., g_u of them). This triple sum is also called the *line strength* S_{ul}. Division by the upper-level degeneracy corrects for the fact that the transitions should be averaged rather than summed over the initial levels.

In practice, choosing the appropriate degeneracy to divide by is a question of some ambiguity. For atoms, it is sufficient to understand how the individual matrix elements and the line strength were calculated. For example, *Bethe* and *Salpeter* [33.43] use a degeneracy of $(2L + 1)$ for Schrödinger wave functions for the hydrogen atom, and $(2J + 1)$ for Dirac wave functions.

For molecules with internal angular momentum, i.e., everything other than $^1\Sigma$ states of linear molecules, the situation is much more complicated. For electric-dipole allowed transitions in light molecules, ab initio transition moments are calculated in a body-fixed coordinate system, ignoring spin, and not summed over anything.

For diatomic molecules, following the work of *Whiting* et al. [33.44, 45], the transition probability from a single upper-state component ($J'c'$) to a single lower-state component ($J''c''$) is written as

$$A_{J'c'J''c''} = \left(\frac{64\pi^4\nu^3}{3hc^3}\right)\left(\frac{1}{4\pi\epsilon_0}\right)$$
$$\times \left(\frac{1}{2J'+1}\right) q_{v'v''}|R_e|^2 S_{J'J''}^{c'c''} . \quad (33.44)$$

In this formula $q_{v'v''}|R_e|^2$ represents the rotationless contribution to the transition moment, symbolically represented as a product of a vibrational overlap ($q_{v'v''}$, i.e., a Franck–Condon factor) and an electronic-only component $|R_e|^2$ (Sect. 33.6.1). All of the rotational complexity is absorbed into the rotational-branch strength factor $S_{J'J''}^{c'c''}$ (Sects. 33.7.2 and 33.7.3). The issue to be addressed here is how to divide numerical factors between $|R_e|^2$ and $S_{J'J''}^{c'c''}$. One approach is to construct an estimate for the rotationless transition probability

$$A_{v'v''} = \left(\frac{1}{N_c'}\right) \sum_{c'J''c''} A_{J'c'J''c''} , \quad (33.45)$$

where N_c' is the number of internal spin-orbit components of the upper state. *Whiting* et al. suggest that $S_{J'J''}^{c'c''}$

be normalized such that for spin-allowed transitions

$$\sum_{c'J''c''} S_{J'J''}^{c'c''} = (2 - \delta_{0,\Lambda'}\delta_{0,\Lambda''})(2S+1)(2J'+1) .$$
$$(33.46)$$

The first factor is 1 for $\Sigma - \Sigma$ transitions, and 2 for all others. The final factor is replaced by $(2J''+1)$ if the sum is over J' instead of J''. For spin-forbidden transitions the following is a plausible extension of this sum rule,

$$\sum_{c'J''c''} S_{J'J''}^{c'c''} = \max(N_c', N_c'')(2J'+1) . \quad (33.47)$$

Section 33.7.3 provides a corresponding sum rule for polyatomic molecules. This normalization yields

$$A_{v'v''} = \left(\frac{64\pi^4\nu^3}{3hc^3}\right)\left(\frac{1}{4\pi\epsilon_0}\right)$$
$$\times \left(\frac{\max(N_c', N_c'')}{N_c'}\right) q_{v'v''}|R_e|^2 \quad (33.48)$$

and for spin-allowed transitions, the simple spin-free expressions for the electronic transition moments:

$$|R_e|^2 = |\langle\Lambda|ez|\Lambda\rangle|^2 \quad (33.49)$$

for parallel transitions and

$$|R_e|^2 = \left|\langle\Lambda+1|e\frac{1}{\sqrt{2}}(x+iy)|\Lambda\rangle\right|^2 \quad (33.50)$$

for perpendicular transitions.

33.6 Vibrational Band Strengths

33.6.1 Franck–Condon Factors

The Born–Oppenheimer separation of electron and nuclear motion suggests that during an optical transition between different electronic states the nuclei should change neither their position nor momentum. This concept was developed from semiclassical arguments by *Franck* [33.46] and justified quantum mechanically by *Condon* [33.47]. Following *Herzberg* [33.48] and *Steinfeld* [33.42] the vibronic transition moment can be written as

$$\mu_{v'v''} = \langle\psi_e'\psi_{v'}'|\mu|\psi_e''\psi_{v''}''\rangle ,$$
$$= \int dR \, \psi_{v'}^{*\prime}(R)\psi_{v''}''(R)$$
$$\times \int dr \, \psi_e^{*\prime}(r, R)\psi_e''(r, R)\mu(r, R) ,$$
$$= \int dR \, \psi_{v'}^{*\prime}(R)\psi_{v''}''(R)\mu(R) . \quad (33.51)$$

If the R-dependence of $\mu(R)$ is sufficiently weak, it can be factored out to obtain

$$\mu_{v'v''} = R_e \int dR \, \psi_{v'}^{*\prime}(R)\psi_{v''}''(R) , \quad (33.52)$$

where R_e is called the electronic transition moment. The transition probability is proportional to the square of the above, which is usually written as

$$I \approx q_{v'v''}R_e^2 , \quad (33.53)$$

where

$$q_{v'v''} = \left|\int dR \, \psi_{v'}^{*\prime}(R)\psi_{v''}''(R)\right|^2 , \quad (33.54)$$

the square of the overlap between initial and final vibrational wave functions, is called the Franck–Condon factor.

The Franck–Condon factors satisfy the sum rule

$$\sum_{v'} q_{v'v''} = \sum_{v''} q_{v'v''} = 1 \quad (33.55)$$

provided the summations include the continuum vibrational wave functions above the dissociation limits. The Franck–Condon approach also can be used to calculate intensities and cross sections for bound–free [33.49] and free–free [33.50] emission and absorption.

In some cases the variation of $\mu(R)$ is significant. Calculation of the effect on the intensities can usually be handled by the *r-centroid* method in which the expression

$$\bar{r}_{v'v''} = \frac{\langle \psi'_{v'} | R | \psi''_{v''} \rangle}{\langle \psi'_{v'} | \psi''_{v''} \rangle} \tag{33.56}$$

is used to calculate an effective internuclear distance for the transition. The transition strength is then proportional to $q_{v'v'}|\mu(\bar{r}_{v'v''})|^2$. An advantage of this formulation is that the vibrational overlaps can be calculated from energy information only, before the transition moment function is known and before the transition strengths are investigated experimentally. The quantitative accuracy of the *r*-centroid method for transition moments that are not linear in the internuclear distance, has been addressed by a considerable literature, which has been summarized by *McCallum* [33.51].

A second complication arises from the fact that the vibrational wave functions themselves depend parametrically on the rotational angular momentum. Calculation of rotationally-dependent Franck–Condon factors is described by *Dwivedi* et al. [33.52] who also discuss the *r*-centroid method.

33.6.2 Vibrational Transitions

Vibrational transitions derive their strength from the variation of the "permanent" dipole moment of the molecule as a function of geometry or internuclear coordinates. As described by several authors [33.31, 32, 34, 53] one can expand the dipole moment as a power series in the internal-Cartesian or normal-mode coordinates

$$M_{xyz}(Q) = M^0_{xyz} + \sum_i \left(\frac{\partial M_{xyz}}{\partial Q_i} \right) Q_i + \cdots \tag{33.57}$$

and calculate intensities from a formula like

$$I \approx \left| \langle \psi_{v'_1} \psi_{v'_2} \cdots | M(Q) | \psi_{v''_1} \psi_{v''_2} \cdots \rangle \right|^2 . \tag{33.58}$$

For homonuclear diatomic molecules, the dipole moment vanishes identically, so there is no rovibrational spectrum. The dipole moment for heteronuclear diatomics is often close to linear in the internuclear distance. The harmonic oscillator model suggests that transitions with $\Delta v = \pm 1$ are the strongest, with intensities approximated by

$$I_{v+1,v} \approx \left| \frac{dM}{dR} \right|^2 (v+1) . \tag{33.59}$$

Overtone bands, i.e., with $|\Delta v| > 1$, are observed, as dramatically illustrated by the $\Delta v = 4, 5$ emissions from the OH radical observed from the Earth's night sky [33.54].

For polyatomic molecules, overtone and combination bands are often quite strong. The presence or absence of which is used to establish the symmetries of the vibrational modes. In general, it is difficult to construct quantitative vibrational intensity formulas with only a few parameters that can be inferred experimentally.

33.7 Rotational Branch Strengths

33.7.1 Branch Structure and Transition Type

The overall rotational structure of a molecular transition is determined by the relative values and phases of the body–frame transition-moment matrix elements, the relative values and phases of coefficients in the expansion of the upper-state and lower-state component wave functions over the angular-momentum-projection basis functions, the energy separations between the components, and the relative values and phases of the vector-coupling coefficients. In simple cases, each lower component might be connected to only a single upper component [Hund's case (b) or symmetric tops],

or $\Delta J = \pm 1$ (*P*- and *R*-branches) may dominate over $\Delta J = 0$ (*Q*-branches).

For diatomic molecules, symmetry arguments are used to divide the components into the two parity classes e and f. For electric dipole transitions, the selection rules from Sect. 33.4.2 imply that

$$\begin{aligned} (N'_e N''_e + N'_f N''_f) && P\text{- and } R\text{-branches} \\ (N'_e N''_f + N'_f N''_e) && Q\text{-branches} \end{aligned} \tag{33.60}$$

are expected, where N_e and N_f indicate the number of components of each parity class (N_e and N_f differ by no more than one). Rotational branches are labeled with

the notation $^{\Delta R}\Delta J_{c'c''}$, using symbols P for -1, Q for 0, and R for $+1$. ΔR indicates the "apparent" change in mechanical rotational angular momentum (i. e., energy) [see Hund's case (b) in Sect. 33.7.4] and ΔJ indicates the "actual" change (i. e., quantum mechanical). The labels $c'c''$ indicate the components involved. Thus a $^P Q_{21}$ branch is expected to be "red shaded" ($\Delta R = -1$) with $\Delta J = 0$ involving the second component of the upper state and the first (lowest) component of the lower state. The notation $^P Q_{21}(J)$ [or sometimes $^P Q_{21}(R = N)$ for Σ lower states] identifies an individual rotational line and specifies the rotational quantum number of the lower state involved in the transition. If the upper- and lower-state component numbers are the same, one of them may be dropped. Thus P_{22} is sometimes written as P_2.

For symmetric top molecules, the rotational branches are labeled ΔJ_K (e.g., P_1). For asymmetric tops, the branches are labeled by $\Delta J_{\Delta K_{-1},\Delta K_1}$, where K_{-1} and K_1 are the prolate- and oblate-limit angular momenta projections (described in Sect. 33.3.2).

The transition dipole moment commonly lies parallel or perpendicular to the body–frame axis. In the former case, $\mu_{K'K''}$ vanishes for $K' \neq K''$, and in the latter for $K' = K''$. Thus parallel bands correspond to $\Delta K = 0$ transitions, while perpendicular bands have $\Delta K = \pm 1$. As enforced by the vector-coupling coefficients or Hönl–London factors described below, for low values of K (e.g., diatomics), $\Delta K = 0$ implies strong $\Delta J = \pm 1$ (P and R) branches and weak $\Delta J = 0$ (Q) branches. On the other hand, $\Delta K = \pm 1$ leads to Q-branches that are approximately twice as strong as either the P- or R-branches.

33.7.2 Hönl–London Factors

The matrix model Hamiltonians for the upper and lower states have been diagonalized, yielding the wave functions

$$\psi_{c'}^{J'M'} = \sum_{K'} b_{J'c'}^{K'} \left(\frac{(2J'+1)}{8\pi^2}\right)^{1/2}$$
$$\times D_{M'K'}^{*J'}(\text{lab})\chi_{K'}(\text{body}) \qquad (33.61)$$

and

$$\Phi_{c''}^{J''M''} = \sum_{K''} a_{J''c''}^{K''} \left(\frac{(2J''+1)}{8\pi^2}\right)^{1/2}$$
$$\times D_{M''K''}^{*J''}(\text{lab})\xi_{K''}(\text{body}) \,. \qquad (33.62)$$

In these expressions, the designations K' and K'' are slightly symbolic. They represent the body–frame projection of the total angular momentum and also a running index over basis functions. For complicated cases, more than one basis function can have a given value of K.

Following Sect. 33.2.3, the rotational branch strength is then written as

$$S_{J'J''}^{c'c''}$$
$$= \sum_{pM'M''} \left|\left\langle \psi_{c'}^{J'M'} \middle| T_p^{(L)}(\text{lab}) \middle| \Phi_{c''}^{J''M''} \right\rangle\right|^2$$
$$= (2J''+1) \left| \sum_{q'K'K''} b_{J'c'}^{*K'} a_{J''c''}^{K''} \left\langle \chi_{K'} \middle| T_q^{(L)}(\text{body}) \middle| \xi_{K''} \right\rangle \right.$$
$$\left. \times \left\langle J''K'', Lq \middle| J'K' \right\rangle \right|^2 \qquad (33.63)$$

or

$$S_{J'J''}^{c'c''} = \left| \sum_{K'K''} b_{J'c'}^{*K'} a_{J''c''}^{K''} \mu_{K'K''} \zeta\left(J',K',J'',K''\right) \right|^2 \,, \qquad (33.64)$$

where

$$\mu_{K'K''} = \left\langle \chi_{K'} \middle| T_q^{(L)}(\text{body}) \middle| \xi_{K''} \right\rangle \theta\left(K'' - K'\right) \quad (33.65)$$

is the body–frame transition-moment matrix introduced in Sect. 33.3.4, with relative values that are hypothesized based on interpretation of the nature of the transition, calculated from ab initio wave functions, or inferred by fitting the observed rotational branch strengths. The Clebsch–Gordan expression

$$\zeta\left(J',K',J'',K''\right)$$
$$= \left(2J''+1\right)^{1/2}\left\langle J''K'', LK'-K'' \middle| J'K' \right\rangle$$
$$\times \theta\left(K''-K'\right)\theta\left(J'-J''\right) \qquad (33.66)$$

represents the transformation of the radiation field from the laboratory-frame to the body–frame, also related to the "direction cosines" used by many authors. The additional phase factors

$$\theta(k) = \text{sgn}(k) = \begin{cases} +1 & k \geq 0 \\ -1 & k < 0 \end{cases} \qquad (33.67)$$

have been included here to make the signs and symmetry relations of $\mu_{K'K''}$ and $\zeta\left(J',K',J'',K''\right)$ agree with those already in use [33.9, 44, 55, 56]. They are related to the choice of the leading signs when T_+ and T_- are expressed as $\pm(T_x + iT_y)$ and $\pm(T_x - iT_y)$. Their inclusion has no effect for spin-allowed transitions with only

one source of transition probability, e.g., purely parallel or perpendicular.

In the usual case of electric-dipole (or magnetic-dipole) radiation (i.e., $L = 1$), ζ^2 is the well-known Hönl–London factor [33.57]. $\zeta(J', K', J'', K'')$ is a real, signed quantity: negative for $\Delta J \Delta K > 0$; or $\Delta J = \Delta K = 0$ and $K < 0$; otherwise positive [33.9].

Setting $L = 2$ provides intensity formulas for electric-quadrupole [33.58], *Raman* [33.59], and two-photon [33.60, 61] transitions. Additional Rayleigh-like terms can appear for $K' = K'' \neq 0$. *Halpern* et al. [33.61] also give formulas for three-photon transitions in diatomics, expressed in terms of Clebsch–Gordan coefficients with $L = 3$ and $L = 1$ (for $|\Delta\Omega| \leq 1$).

33.7.3 Sum Rules

The orthonormality relations for component eigenvectors

$$\sum_{c'} b^{*K'}_{J'c'} b^{K}_{J'c'} = \delta_{K', K} \,, \tag{33.68}$$

$$\sum_{c''} a^{*K''}_{J''c''} a^{K}_{J''c''} = \delta_{K'', K} \tag{33.69}$$

can be used to construct the sum rule

$$\sum_{c'c''} S^{c'c''}_{J'J''} = \sum_{K'K''} \left| \mu_{K'K''} \zeta(J', K', J'', K'') \right|^2 \,. \tag{33.70}$$

Finally, the orthonormality relations of the Clebsch–Gordan coefficients result in

$$\sum_{J'c'c''} S^{c'c''}_{J'J''} = (2J'' + 1) \sum_{K'K''} \left| \mu_{K'K''} \right|^2 \,, \tag{33.71}$$

$$\sum_{J''c'c''} S^{c'c''}_{J'J''} = (2J' + 1) \sum_{K'K''} \left| \mu_{K'K''} \right|^2 \,. \tag{33.72}$$

As discussed in Sect. 33.5.2, it is convenient to have the $\mu_{K'K''}$ matrix elements consist of numbers that represent the nature of the transition but not its strength, the latter being expressed by the "vibrational" ($q_{v'v''}$) and "electronic" (R_e) contributions. Following Sect. 33.5.2, for diatomic molecules, the "orientational" part $\mu_{K'K''}$ is taken to have a fixed sum rule

$$\sum_{K'K''} |\mu_{K'K''}|^2 = \max(N'_c, N''_c) \,, \tag{33.73}$$

where N'_c is the number of components (K' values, or basis functions) for the upper state, and N''_c is the number of components in the lower state. For polyatomic molecules, the sum rule can be written as

$$(2J + 1)^2 (\mu_a^2 + \mu_b^2 + \mu_c^2) \max(N'_c, N''_c) \,, \tag{33.74}$$

where

$$\mu_a^2 + \mu_b^2 + \mu_c^2 = |\mu_+|^2 + |\mu_-|^2 + |\mu_0|^2 = 1 \tag{33.75}$$

and N'_c and N''_c are the numbers of spin-electronic-vibrational components in the upper and lower states, respectively. Also see *Whiting* et al. [33.44, 45] and *Brown* et al. [33.7].

33.7.4 Hund's Cases

In diatomic molecules, several limiting cases are useful as short-hand or first-approximation concepts for classification of energy levels and rotational branch strengths. These are called the Hund's cases [33.62–64]. They are distinguished by the extent to which the electron orbital and spin angular momenta are rigidly attached to the tumbling molecular frame, i.e., whether Λ, Σ, and S are good quantum numbers. Hund's cases are discussed in many journal articles and in every textbook dealing with the rotational structure of diatomic spectra. An appealing recent description is provided by *Nikitin* and *Zare* [33.65].

In most works, the emphasis has been on finding a favorable zero-order approximation for perturbation expansion of energy levels. The advance of precision measurement of transition energies and the availability of sophisticated parametrical matrix models and fast computers on which to realize them, has reduced the importance of Hund's cases for actual computations. In particular, the need to derive and implement numerous explicit energy and intensity formulas leads to unfortunate transcription errors. Nevertheless, they remain of value for qualitative and pedagogical understanding, especially for estimates of the relative intensities of rotational branches.

Hund's case (a) describes the situation in which Λ and Σ are separately well-defined. This is a common case in which the separation between electronic states, i.e., different values of $|\Lambda|$, is larger than the spin-orbit interaction, which in turn, is larger than the separation between rotational levels. At low J, there are $(2S + 1)$ pairs of nearly-degenerate energy levels separated from each other by the spin orbit constant: $E \approx A\Lambda\Sigma +$

$BJ(J+1)$. The wave functions are of the form

$$\psi_{\Omega\pm}^{JM} = \frac{1}{\sqrt{2}}\left(\frac{(2J+1)}{8\pi^2}\right)^{1/2}$$
$$\times\left[D_{M\Lambda+\Sigma}^{*J}|\Lambda,\Sigma\rangle \pm D_{M-\Lambda-\Sigma}^{*J}|-\Lambda,-\Sigma\rangle\right]$$
$$= \frac{1}{\sqrt{2}}[|\Lambda,\Sigma;J,M,\Omega\rangle$$
$$\pm|-\Lambda,-\Sigma;J,M,-\Omega\rangle], \qquad (33.76)$$

with only two nonzero expansion coefficients a_{Jc}^K. If both the upper and lower states are well described by Hund's case (a), then each lower component is optically connected only to the upper components with the same value of $|\Sigma|$. Then

$$S_{J'J''}^{\Omega'\Omega''} = (2J''+1)\left|\langle J''\Omega'',1\Omega'-\Omega|J'\Omega'\rangle\right|^2, \qquad (33.77)$$

with $\Omega'' = \Lambda'' + \Sigma$ and $\Omega' = \Lambda' + \Sigma$.

Hund's case (b) indicates that Λ is well-defined, but spin-orbit coupling is weak. The components correspond to well-defined values of $N = J - S$, ranging from $|J-S|$ to $(J+S)$, with energies approximated by $E \approx BN(N+1)$, and wave functions of the form

$$\psi_{N\pm}^{JM} = \sum_\Sigma (-1)^{S+\Sigma}\langle J-\Omega,S\Sigma|N-\Lambda\rangle$$
$$\times\frac{1}{\sqrt{2}}[|\Lambda,\Sigma;J,M,\Omega\rangle$$
$$\pm|-\Lambda,-\Sigma;J,M,-\Omega\rangle]. \qquad (33.78)$$

This equation is derivable from Mizushima's equation (2-3-26) [33.14] and Zare's equations (2.8), (2.26), and (3.105) [33.5], using the lab-to-body transformation

$$|SM_S\rangle(\text{lab}) = \sum_\Sigma D_{M_S\Sigma}^{*S}(\phi\theta\chi)|S\Sigma\rangle(\text{body}). \qquad (33.79)$$

It disagrees with Judd's problem 9.1 [33.66] by a phase factor $(-1)^{J+2S+\Sigma-N}$ but agrees with Mizushima's expansion of a $^3\Pi$ state [33.14, p. 287] if the Clebsch–Gordan coefficients are taken from *Condon* and *Shortley* [33.39, p. 76].

If both the upper and lower states are well described by Hund's case (b), these wave functions can be substituted into the general rotational-branch strength equations above. Following *Edmonds* [33.67, (6.2.8) and (6.2.13), and Table 5] yields the square of a product of Clebsch–Gordan and Racah coefficients

$$S_{J'J''}^{N'N''} = (2J''+1)(2J'+1)(2N''+1)$$
$$\times\left|\langle N''\Lambda'',1\Lambda'-\Lambda''|N'\Lambda'\rangle\right.$$
$$\times\left. W(N',J'',N'',J';S,1)\right|^2. \qquad (33.80)$$

The Clebsch–Gordan coefficient enforces the case (b) selection rule $\Delta N = 0,\pm1$, while the Racah coefficient provides the $\Delta J = \Delta N$ propensity rule, which becomes more precise as N increases. A similar propensity rule, $\Delta F = \Delta J$, is common for transitions between hyperfine components (see also *Femenias* [33.68]).

Hund's case (c) corresponds to the situation in which spin-orbit coupling is so strong that each level described by the projection Ω actually consists of multiple values of $|\Lambda|$ (e.g., mixing of Σ and Π states) or multiple values of S (e.g., mixing of singlet and triplet spins). This limiting case is formally similar to Hund's case (a), but no assumptions can be made about the relative magnitudes of transition-moment matrix elements $\mu_{\Omega'\Omega''}$. Any of which can be nonzero for $|\Delta\Omega| \leq 1$, for example

$$S_{J'J''}^{\Omega'_+\Omega''_\pm} = \frac{1}{4}\left|\mu_{\Omega'\Omega''}\zeta(J',\Omega',J'',\Omega'')\right.$$
$$\pm\mu_{\Omega'-\Omega''}\zeta(J',\Omega',J'',-\Omega'')$$
$$+\mu_{-\Omega'\Omega''}\zeta(J',-\Omega',J'',\Omega'')$$
$$\pm\left.\mu_{-\Omega'-\Omega''}\zeta(J',-\Omega',J'',-\Omega'')\right|^2. \qquad (33.81)$$

The symmetry (sign) relations between $\mu_{\Omega'\Omega''}\zeta(J',\Omega',J'',\Omega'')$ and $\mu_{-\Omega'-\Omega''}\zeta(J',-\Omega',J'',-\Omega'')$ determine whether this transition occurs only for $\Delta J = \pm1$ (P- and R-branches) or only for $\Delta J = 0$ (Q-branches).

The interest and complexity of Hund's case (c) were exemplified by a seminal work by *Kopp* and *Hougen* [33.69], who considered $\Omega' = 1/2$, $\Omega'' = 1/2$ transitions, under the assumption that both states could consist of arbitrary mixtures of $^2\Sigma_{1/2}$ and $^2\Pi_{1/2}$ character. Each of the six rotational branches shows constructive or destructive interference of parallel ($\Delta\Omega = 0$) and perpendicular ($\Delta\Omega = \pm1$) contributions. Hund's case (c) also describes spin-orbit mixing collisions [33.70] or dissociation to specific spin-orbit limits [33.71–73].

Hund's case (d) arises in the investigation of Rydberg series [33.74], in which the separation between Σ and Π from the same orbital configuration approach each other as the principal quantum number (n) increases. Spin-orbit coupling between these projections also diminishes. The eigenfunction components correspond to well-defined values of $R = J - L$, ranging from $|J-L|$ to $(J+L)$, with energies approximated by $E \approx BR(R+1)$, and wave functions of the

form

$$\psi_{RL}^{JM} = \sum_{\Lambda} (-1)^{L+\Lambda} \langle J-\Lambda, L\Lambda | R0 \rangle | L\Lambda; JM\Lambda \rangle \; . \tag{33.82}$$

Carroll [33.74] used intensity formulas provided by *Kovacs* [33.58] to analyze, by spectral simulation, the 4p–15p $\left({}^1\Sigma_u^+ \text{ and } {}^1\Pi_u\right)$ Rydberg states of N_2 excited from the ground $X^1\Sigma_g^+$. Three strong Q-form branches survive, corresponding to $R' = J''$, two arising from $\Pi \leftarrow \Sigma$ and one from $\Sigma \leftarrow \Sigma$ case (a) branches. The remaining O-form ($R' = J'' - 2$) and S-form ($R' = J'' + 2$) branches fade rapidly as n increases. With the phase conventions used here, this situation corresponds to body–frame transition matrix elements satisfying

$$\mu_{00} = \mu_{-10} = -\mu_{10} \; . \tag{33.83}$$

In the opposite case, corresponding to a parity change of the parent-ion core [33.73], two of the Q-form branches are extinguished, while one Q-form, one O-form, and one S-form branch remain. The transition matrix elements would satisfy

$$\mu_{00} = 0 \; , \quad \mu_{-10} = \mu_{10} \; . \tag{33.84}$$

Hund's case (d) polyatomics are also known [33.8].

Hund's case (e) would correspond to a situation in which L and S are strongly coupled to each other, but neither is strongly coupled to the internuclear axis. No examples are known for bound states of molecules.

33.7.5 Symmetric Tops

For transitions between nondegenerate vibronic states, the transition moment must lie along the principal top axis, leading to the selection rule $\Delta K = 0$. Otherwise, Hougen's convenient quantum number [33.33] $G = \Lambda + l - K$, provides the selection rule $\Delta G = 0, \pm n$ (for an

n-fold major symmetry axis) (Sects. Section 33.3.2, Section 33.4.3, and Chapt. 32). Transitions with $\Delta G = \pm n$ are much weaker than those with $\Delta G = 0$ and are not calculable from a simple formula. Branch intensities can be calculated with the Hönl–London formulas of Sect. 33.7.2.

33.7.6 Asymmetric Tops

In general, no assumptions can be made about the orientation of the transition moment. The vector representations (μ_x, μ_y, μ_z), (μ_a, μ_b, μ_c), and $(\mu_0, \mu_{+1}, \mu_{-1})$ can have any combination of independent nonzero values. It is common that one of the (μ_a, μ_b, μ_c) values is significantly larger than the others, especially for planar molecules with a two-fold symmetry axis. In this case one obtains a type A, B, or C band, if μ_a, μ_b, μ_c dominates, respectively [33.31, 75]. The tradition of analytic calculation of line strengths from explicit representations of wave functions and transition moments leads to formulas of considerable complexity, with somewhat restrictive assumptions [33.35, 36, 76]. In the more general notation of Sect. 33.7.2, the rotational line strength can be written as

$$S_{J'J''}^{\tau'\tau''} = \left| \sum_{K'K''} b_{J'\tau'}^{*K'} a_{J''\tau''}^{K''} \left(\mu_0 \delta_{K'K''} + \mu_+ \delta_{K'K''+1} \right. \right.$$
$$\left. \left. + \mu_- \delta_{K'K''-1} \right) \zeta \left(J', K', J'', K'' \right) \right|^2 \; , \tag{33.85}$$

where

$$\mu_0 = \mu_c \; , \quad |\mu_+| = |\mu_-| \; ,$$
$$|\mu_+|^2 + |\mu_-|^2 = \mu_a^2 + \mu_b^2 \; . \tag{33.86}$$

Papousek and *Aliev* [33.18] and *Zare* [33.5] follow the present formulation, but with somewhat less generality with respect to wave function expansion coefficients or transition moment components.

33.8 Forbidden Transitions

33.8.1 Spin–Changing Transitions

The formalism presented above permits simulation of any allowed transition or forbidden transitions mediated by spin-orbit or spin-spin perturbations, or any perturbation that is diagonal in Ω. For spin-allowed transitions, the transition moment matrix is taken to be

diagonal in and independent of the spin projection, so that

$$\mu_{\Lambda'\Sigma'\Lambda''\Sigma''} = \mu_{\Lambda'\Lambda''} \delta_{\Sigma'\Sigma''} \; . \tag{33.87}$$

For forbidden transitions, or complicated Hund's case (c) mixings, the transition moment matrix elements can be considered as independent variable parameters,

limited only by the symmetry constraint

$$\mu_{-\Omega'-\Omega''} = \eta(-1)^{\Omega'-\Omega''} \mu_{\Omega'\Omega''} , \qquad (33.88)$$

and the fact that terms with $|\Delta\Omega| > 1$ will be multiplied by zero. Alternatively, a specific set of candidate perturbers can be selected, and the Λ- and Σ-dependence of their contributions to the transition-moment matrix evaluated explicitly. For example, first-order spin-orbit mixing would lead to terms of the form

$$
\mu_{\Lambda'\Sigma'\Lambda''\Sigma''}^{S'S''}
$$
$$
= \sum_{\Lambda} \left[\mu_{\Lambda'\Sigma'\Lambda\Sigma'}^{S'S'} \frac{\langle S'\Lambda\Sigma' | H_{SO} | S''\Lambda''\Sigma'' \rangle}{\Delta E''} \right.
$$
$$
\left. + \left(\frac{\langle S'\Lambda'\Sigma' | H_{SO} | S''\Lambda\Sigma' \rangle}{\Delta E'} \right) \mu_{\Lambda\Sigma''\Lambda''\Sigma''}^{S''S''} \right] .
$$
$$(33.89)$$

However, care must be taken in reducing these matrix elements using the Wigner–Eckart theorem, for example, following *Lefebvre-Brion* and *Field* [33.55], in order to satisfy the $\Delta\Omega = 0$ requirement for matrix elements of the rotationless Hamiltonian.

33.8.2 Orbitally–Forbidden Transitions

Even if the upper and lower states share the same value of electron spin, the transition may still be forbidden. The change in orbital angular momentum may be too large, $|\Delta\Lambda| > 1$, or a change in reflection parity, $\Sigma^- \to \Sigma^+$, may cause the zero-order transition matrix elements to vanish. Spin-orbit mixing with other $^{2S+1}\Lambda$ states, as described above, is usually the largest source of transition probability. In addition, terms in the Hamiltonian of the form $\boldsymbol{J} \cdot \boldsymbol{L}$ lead to contributions to the transition strength that increase with J, and that may mix-in higher values of Ω than were present in

the zero-order $\Lambda\Sigma$ basis set for the upper and lower states. This situation can be represented by generalizing the formula from Sect. 33.7.2, following *Huestis* et al. [33.23],

$$
S_{J'J''}^{c'c''} = \left| \sum_{K'K''} b_{J'c'}^{*K'} a_{J''c''}^{K''} \right.
$$
$$
\left. \times \sum_{i=-1}^{1} \mu_{K'K''}^{(i)} \zeta^{(i)}\left(J', K', J'', K''\right) \right|^2 ,
$$
$$(33.90)$$

where $\mu_{K'K''}^{(0)}$ is the rotationless contribution ($\mu_{K'K''}$ from Sect. 33.7.2) and $\mu_{K'K''}^{(\pm 1)}$ are the new rotation-assisted terms. The new reflection-symmetry rule is

$$
\mu_{-K'-K''}^{(i)} = \eta(-1)^{K'-K''+i} \mu_{K'K''}^{(-i)} . \qquad (33.91)
$$

The revised square-root Hönl–London factors are

$$
\zeta^{(0)}\left(J', K', J'', K''\right) = \zeta\left(J', K', J'', K''\right) \qquad (33.92)
$$

(from Sect. 33.7.2) and

$$
\zeta^{(\pm 1)}\left(J', K', J'', K''\right)
$$
$$
= \frac{1}{2}\left\{ \left[J'(J'+1) - K'(K'\mp 1) \right]^{1/2} \right.
$$
$$
\times \zeta\left(J', K'\mp 1, J'', K''\right)
$$
$$
+ \left[J''(J''+1) - K''(K''\pm 1) \right]^{1/2}
$$
$$
\left. \times \zeta\left(J', K', J'', K''\pm 1\right) \right\} . \qquad (33.93)
$$

As in Sect. 33.7.2 the symbols K' and K'' represent $\Lambda'\Sigma'$ and $\Lambda''\Sigma''$ when used as labels, and Ω' and Ω'' when used as numbers (a distinction that is relevant only when $S \geq |\Lambda|$ and $\Lambda \neq 0$). This formulation is more symmetric than that proposed by *Huestis* et al. [33.23], in that it explicitly allows for either the upper or lower state to be mixed by rotation (of significance only for low J and $\Delta\Lambda > 1$).

33.9 Recent Developments

Added by Mark M. Cassar. Astronomical sky spectra are important for an understanding of processes both in Earth's and other terrestrial environments. These spectra are the background spectra obtained through the slit of a spectrometer while excluding the object of primary interest to the astronomer – the star, galaxy, etc. The sky spectrum is subsequently subtracted from the object spectrum so that the final product contains no emis-

sions from extraneous sources – nightglow, zodiacal light, and the light of other stellar objects. This operation then leaves the astronomer with purer astronomical spectra, which can then be compared to theoretical transition probability calculations to identify emission sources. This procedure has recently been used to identify the atomic oxygen green line in the Venus night airglow [33.77], which relied on an understanding of

molecular oxygen emissions. In addition, interpretation of the intensities of molecular oxygen emissions also furthers the understanding of the elementary processes occurring in the Earth's atmosphere [33.78].

Two recent studies have focused on the radiative properties of the CaN and $^{39}K^{85}Rb$ molecules. In the former study, the radiative transition probabilities and lifetimes for the $A^4\Pi - X^4\Sigma^-$ and $B^4\Sigma^- - X^4\Sigma^-$ band systems were calculated [33.79]. These results will in turn facilitate future spectroscopic studies of CaN showing the essential interplay between theory and experiment, which is required for a deeper un-

derstanding of these processes. (Radiative properties are sensitive to electronic coupling schemes and to configuration interaction, and thus present an important testing ground for theoretical models [33.80, 81].) The second study provides quantitative estimates for the radiative cooling of heteronuclear translationally ultracold molecules [33.82, 83]. By calculating the radiative transition probabilities for $^{39}K^{85}Rb$, which lead to the radiative lifetime through the total Einstein A coefficient, it has been shown that under appropriate laboratory conditions such a cooling process is not relevant [33.84].

34. Molecular Photodissociation

Molecular photodissociation is the photoinitiated fragmentation of a bound molecule [34.1]. The purpose of this chapter is to outline the ways in which molecular photodissociation is studied in the gas phase [34.2]. The results are particularly relevant to the investigation of the species involved in combustion and atmospheric reactions [34.3].

Conceptually the photodissociation process can be divided into three stages. During the first stage the molecule absorbs a photon and is promoted to an excited state. This is generally an excited electronic state, but can be a highly excited vibrational state in the ground electronic state. In the second stage, the transient complex evolves through a series of *transition states*, until finally, in the third stage, the molecule enters the *exit channel* and dissociates into the products. Schematically, this might be represented, for a triatomic molecule ABC (see Fig. 34.1), as

$$ABC + \hbar\omega \rightarrow (ABC)^{\ddagger} \rightarrow AB(v, j) + C . \qquad (34.1)$$
In the case of the triatomic molecule represented here, the dissociation involves the transformation of one of the vibrational modes to a translational, or dissociative, mode, another vibrational mode (the bending) to rotational motion of the products (j), whilst the third vibrational mode is preserved (v).

When the molecule is promoted to an electronic state which has a purely repulsive potential energy surface (PES), it undergoes very rapid dissociation, often in less than one vibrational period. This is called *direct dissociation*. However, the dissociation of the transient complex can be delayed, taking place over many vibrational periods. This is called *indirect dissociation*, or predissociation, and has been divided into three different categories [34.4], though as with the division between direct and indirect, this is sometimes somewhat arbitrary.

Vibrational Predissociation (Herzberg Type II)
In this case, the transient complex is on a vibrationally adiabatic potential energy surface (this is an effective potential for the molecule when it is in a particular vibrational state v) which is not dissociative, or which has a barrier to dissociation. Therefore, to dissociate it must either tunnel through the barrier, which is the only possibility for $v = 0$, or undergo a nonadiabatic transition to a lower vibrational state, thereby transferring energy from a vibrational degree of freedom to the dissociative mode. This process of energy exchange is commonly called the intramolecular redistribution of vibrational energy (IVR).

Rotational Predissociation (Herzberg Type III)
In this case, the transient complex is on a nondissociative rotationally adiabatic potential energy surface. Therefore, in a similar manner to vibrational predissociation, if it is to dissociate it must undergo a nonadiabatic transition to a lower rotational state, thereby transferring energy from rotation to the dissociative mode.

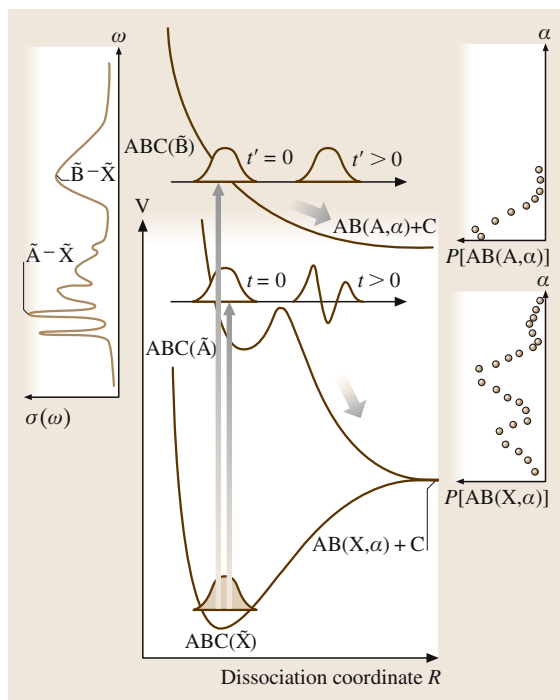
Electronic Predissociation (Herzberg Type I)
In this case, the PES of the electronic state of the transient complex is not dissociative at the given energy, and in order to dissociate the molecule must undergo a nonadiabatic transition to a second dissociative electronic state. This involves the coupling of nuclear and electronic motion and therefore leads to


Fig. 34.1 Schematic representation of the uv photodissociation of a triatomic molecule ABC into products AB(α) and C, illustrating the total absorption cross section $\sigma(\omega)$, evolution of the molecular wavepacket, and asymptotic product state distributions $P(\alpha)$, for direct and indirect dissociations on $\tilde{B}$ and $\tilde{A}$ state PESs respectively

a break down of the Born–Oppenheimer (BO) approximation. There are two main types of electronic predissociation. In the first case, there is only a very small coupling, and no actual crossing, between two different electronic states, and the transition between the two is driven by the very high density of vibrational states on the second electronic state. This is called internal conversion for spin-allowed processes, and intersystem crossing for spin-forbidden processes. In the second case, the transition between the electronic states is driven by strong coupling. This coupling can be vibronic (vibrational-electronic) in nature, e.g., for the Renner–Teller and Jahn–Teller effects, or purely electronic, as in the case of a *conical intersection*.

Selection Rules

Two sets of selection rules apply to photodissociation. The first set governs the allowed states to which the molecule can be promoted by the photon. These selection rules are simply those for bound-state spectroscopy (Sect. 33.4). Note in particular the selection rule $\Delta J = 0, \pm 1$. This has important practical implications since it means that a molecule which is initially rotationally cold remains so after absorption of a photon. Thus, those observables which are averaged over J will have a clear structure experimentally, and will be easier to calculate theoretically. This is in contrast to scattering experiments which in general involve a summation over many J states (Chapt. 36).

The second set of selection rules governs the dissociation process. The transient complex, or prepared (p) state, will undergo transitions to a final (f) vibrational, rotational or electronic state in order to dissociate; these transitions have their own set of selection rules. As for all selection rules, these are determined on the basis of symmetry. For a total wave function Ψ and a perturbation function W, which consists of the coupling terms or neglected terms in the Hamiltonian, $\int \Psi_p^* W \Psi_f \, d\tau$ must be nonzero for a transition to take place. As W forms a part of the Hamiltonian, it is totally symmetric, and therefore the integral is nonzero only if the prepared and final state irreducible representations are equal, $\Gamma_p = \Gamma_f$. If there is a transition to an excited electronic state, the point groups of the initial and final states are often not the same, in which case the point group formed by the joint elements of symmetry is used, or, in the case where there is no stable geometry for one of the states, the symmetry of the potential is used. For a diatomic molecule these selection rules are given in Table 49.2.

If the motion can be separated into vibrational, rotational, and electronic parts, so that $\Psi = \Psi^v \Psi^r \Psi^e$ and $W = W^v + W^r + W^e$, it is then possible to derive three separate selection rules: $\Gamma_p^r = \Gamma_f^r$ for the rotational motion, i. e. conservation of internal angular momentum; $\Gamma_p^e = \Gamma_f^e$ for the electronic motion; and $\Gamma_p^v = \Gamma_f^v$ for the vibrational motion. Since the final vibrational state is in the continuum, in practice all vibrational species (Γ_f^v) are available at a given energy, so that the vibrational selection rule is not significantly restrictive. This separation is not possible in the case of electronic predissociation occurring through the Renner–Teller or Jahn–Teller effect, where it is necessary to consider the vibronic species of the initial and final states.

34.1 Observables

Fundamental to any study of photodissociation is the measurement or calculation of the characteristic properties, or observables, of the reaction, from which the underlying dynamics of the fragmentation process can be inferred.

34.1.1 Scalar Properties

The absorption cross section $\sigma(\omega)$ is a measure of the capacity of the molecule to absorb photons with frequency ω. It is analogous to the line intensity in bound-state spectroscopy. Assuming that the light-matter interaction is weak (Chapt. 68), and that the light pulse is on for a long time, the absorption cross section is given by

$$\sigma(\omega) \propto \omega_{fi} \left| \langle \Psi_f | \boldsymbol{E} \cdot \hat{\boldsymbol{\mu}} | \Psi_i \rangle \right|^2 , \tag{34.2}$$

where Ψ_i and Ψ_f represent the initial and final states, whose energies differ by $\hbar\omega_{fi}$; $\boldsymbol{E}$ is a unit vector in the direction of the polarization of the electric field, and $\hat{\boldsymbol{\mu}}$ is the electric dipole operator of the molecule. Assuming the Born–Oppenheimer separation of electronic and nuclear motion, (34.2) can be rewritten as

$$\sigma(\omega) \propto \omega_{fi} \left| \langle \Psi_f^{\mathrm{rv}} | \mu_{fi} | \Psi_i^{\mathrm{rv}} \rangle \right|^2 , \tag{34.3}$$

where the electronic transition dipole moment μ_{fi} equals $\langle \Psi_f^{\mathrm{e}} | \boldsymbol{E} \cdot \hat{\boldsymbol{\mu}} | \Psi_i^{\mathrm{e}} \rangle$, and is in general dependent on the internal coordinates of the molecule. The superscripts (r, v) will be dropped from now on, and Ψ will refer to the wave function for the internal coordinates of the molecule.

The absorption cross section reflects not only the nature of the transient complex but also its evolution through the transition states. For direct dissociation the absorption cross section is usually very broad and structureless. In contrast, the absorption cross section for predissociation is structured, containing lines which are normally Lorentzian in shape, and whose widths Γ are related to the lifetime of the transient complex at that energy by $\tau = \hbar/\Gamma$.

The partial photodissociation cross sections $\sigma(\omega, \alpha)$ are a measure of the capacity of the molecule to absorb photons with frequency ω *and* to yield products in quantum state α. They are defined by

$$\sigma(\omega, \alpha) \propto \omega_{fi} \left| \langle \Psi_f^{\alpha} | \mu_{fi} | \Psi_i \rangle \right|^2 , \tag{34.4}$$

where Ψ_f^{α} is the final wave function for the products in the quantum state α. The partial cross sections for direct dissociation are broad and featureless. For predis-

sociation, similar structures are seen in the partial cross sections as in the absorption cross section. The absorption or total cross section is given by the sum of the partial cross sections over all final product states:

$$\sigma(\omega) = \sum_{\alpha} \sigma(\omega, \alpha) . \tag{34.5}$$

The rotational and vibrational product distributions $P(\omega, \alpha)$ provide information about the amount of product formed by a photon with frequency ω in a particular rotational or vibrational state α. These are related to the partial cross sections by $P(\omega, \alpha) = \sigma(\omega, \alpha)/\sigma(\omega)$. The rotational and vibrational product distributions reflect the nature of the transient complex as it enters the exit channel, as well as the dynamics in the exit channel.

The branching ratios for different chemical species produced in photodissociation are defined as the fraction of the total number of parent molecules that produce the particular species of interest. In (34.1), the molecule ABC dissociated into AB + C. It might equally well have dissociated to A + BC, or indeed A + B + C. It is clear then that there may be several different reaction schemes, or channels, for the photodissociation of one particular molecule. Thus, the branching ratio for forming AB is the yield of this first channel divided by the total dissociation yield into all possible channels. Further, it would sometimes be possible to produce AB, or any of the other chemical species, in various electronic, vibrational or/and rotational quantum states. In this case, the branching ratio for forming AB(α) is the yield of AB in the specific quantum state α divided by the total yield of AB; however, this describes the branching into only this particular reaction channel.

For the reaction scheme represented in (34.1), the quantum yields of the products AB and C are the same. However, for example, in the reaction

$$\mathrm{ABC_2} + \hbar\omega \rightarrow (\mathrm{ABC_2})^{\ddagger} \rightarrow \mathrm{AB}(v, j) + 2\mathrm{C} , \tag{34.6}$$
the quantum yield of C is twice that for AB. In general, the quantum yield of a particular product fragment for one reaction channel is the ratio of the number of fragments formed to the number of photons absorbed. However, it is again possible for a molecule to dissociate into various different reaction channels. In such a case, to obtain the overall quantum yield for a particular product, the quantum yield for each reaction channel must be summed over all the available reaction channels, taking into account the branching ratios for the channels.

34.1.2 Vector Correlations

Photodissociation is by its very nature an anisotropic process, as can be seen from (34.2). The operator $\hat{\boldsymbol{\mu}}$ defines a specific axis in the molecular body-fixed frame of reference. At the instant of photoexcitation, $\hat{\boldsymbol{\mu}}$ is preferentially aligned parallel to the polarization of the electric field $\boldsymbol{E}$ in the *external laboratory space-fixed* frame of reference. Hence, $\boldsymbol{E}$ defines a specific axis, and thus cylindrical symmetry in the body-fixed frame. If fragmentation occurs on a time scale which is short compared with overall rotation of the excited complex, this correlation persists between the body-fixed frame and the space-fixed frame, and a wealth of information can be obtained. However, rotation of the transient complex prior to fragmentation serves to degrade this symmetry in the external body-fixed frame.

Three vectors fully describe the photodissociation process for both the parent molecule and the products: (i) $\hat{\boldsymbol{\mu}}$ in the body-fixed frame (and hence $\boldsymbol{E}$, in the space-fixed frame, at the instant of photoexcitation); (ii) $\boldsymbol{v}$, the recoil velocity of the products; and (iii) $\boldsymbol{j}$, the rotational angular momenta of the fragments. Vector correlations can exist between all of these vectors [34.5].

The most commonly observed is the angular distribution of the photofragments $I(\theta, \alpha)$, i.e. the relation

$$I(\theta, \alpha) \propto \frac{1}{4\pi} \left[1 + \beta(\alpha) P_2(\cos\theta) \right] \qquad (34.7)$$

between $\boldsymbol{v}$ and $\boldsymbol{E}$. $P_2(x)$ is the second-order Legendre polynomial and θ is the angle between $\boldsymbol{v}$ and $\boldsymbol{E}$. The *anisotropy parameter* $\beta(\alpha)$ ranges between -1 for a perpendicular transition and $+2$ for a parallel transition. Thus, measuring the angular distribution of the fragments provides information about the type of electronic transition and hence the electronic symmetry of the excited state [34.6]. If the alignment between the body-fixed and space-fixed frames is destroyed, the angular distribution becomes *isotropic* and $\beta(\alpha) = 0$. The anisotropy parameter depends on the product channel α.

A second vector correlation concerns the direction of $\boldsymbol{j}$ with respect to $\boldsymbol{E}$. Fragmentation generates rotational motion in the nuclear plane: for a perpendicular transition this is perpendicular to the plane containing the atoms, leading to the projection of $\boldsymbol{j}$ being preferentially aligned parallel to $\hat{\boldsymbol{\mu}}$, and thus $\boldsymbol{E}$ in the space-fixed frame. For a parallel transition, the opposite would be true, i.e. $\boldsymbol{j}$ would be aligned
Fig. 34.2 Spatial recoil anisotropies and Doppler line shape profiles, for parallel and perpendicular transitions compared with an isotropic distribution

in the plane perpendicular to $\hat{\boldsymbol{\mu}}$. The alignment of $\boldsymbol{j}$ leads to polarized emission/absorption depending on whether molecules are created in an electronically excited/ground state. Therefore the orientation of the product polarization with respect to the original photolysis polarization $\boldsymbol{E}$ also yields information about the symmetry of the electronic states involved in dissociation.

The final association in this series is independent of the space-fixed frame, since $\boldsymbol{v}$ and $\boldsymbol{j}$ are both defined in the body-fixed frame. Unlike the two previous correlations, a long lifetime does not destroy the alignment, as it is not established until the bond breaks and the two fragments recoil. For a tetratomic (or larger) molecule there are, in principle, two possible sources of product rotational excitation: bending motion in a plane of the molecule producing fragments with $\boldsymbol{v}$ perpendicular to $\boldsymbol{j}$; or torsional motion leading to fragment rotation out of the plane. A prime example of this is the distinction between frisbee and propeller type motion of the two OH fragments in the dissociation of hydrogen peroxide [34.7, 8]. Measurement of only the scalar properties *cannot* discriminate between these two possibilities, highlighting the additional information that can be gained about the bond rupture and the exit channel dynamics by the study of vector correlations (Fig. 34.2).

34.2 Experimental Techniques

Early photochemical experiments used broad white-light continuum sources and large diffractometers [34.4]. However, it has been the development of lasers in combination with molecular-beam techniques that has dramatically increased the understanding of photodissociation processes. The ever increasing spectral and time resolutions of lasers, in addition to the power and range of wavelengths available, have made it possible to excite molecules selectively and with high efficiency. This has enabled state-specific preparation of the parent molecule, study of time evolution, as well as the measurement of the scalar and vector properties of the asymptotic products [34.9].

Specification of the Initial State

A room temperature sample of a gas will have a Boltzmann distribution over rotational states. Molecular beam techniques provide an improved specification of the initial angular momenta in the parent molecule by isentropically cooling its internal rotational energy [34.10]. Full quantum state specification can be achieved by various two-photon excitation schemes, e.g., stimulated emission pump (SEP) spectroscopy and vibrationally mediated dissociation. SEP is commonly used to study dissociation on the ground state PES; the molecules are excited to a stable upper electronic state, stimulated emission back to the ground state prepares a *single* quasibound state. Vibrationally mediated dissociation provides information about both ground and upper electronic states; the molecules are excited to a stable intermediate vibrational level on the ground state and further excitation promotes this fully defined wave function to an upper dissociative electronic state [34.11].

Detailed Measurement of the Absorption Cross Section

UV and VUV electronic spectroscopy has proven a very powerful tool for examining the interaction of a photon with a parent molecule (Chapt. 69). Absorption cross sections are typically measured by scanning the frequency domain and monitoring either the intensity of radiation absorbed or the flux of product molecules produced. State specific detection of the product flux yields the partial cross section $\sigma(\omega, \alpha)$. Explicit measurement of $\sigma(\omega)$ is a direct application of the Beer–Lambert law (Sect. 69.1) and thus depends on the length of the optical cavity: cavity ring-down spectroscopy with multiple passes through a cell provides an effective cell length of several tens of kilometers.

Evolution of the Transient Complex

The evolution of the molecular wavepacket can be probed by time-resolved spectroscopy, as discussed in Chapt. 35 and [34.12]. Real-time analysis of the molecular wavepacket provides a direct insight into the forces acting during molecular photodissociation. This type of time-resolved spectroscopy and the energy-resolved spectroscopy described above are mutually exclusive due to the time-energy uncertainty principle (Sect. 80.3.1).

Asymptotic Properties

The vast majority of photodissociation studies determine asymptotic properties of the dissociation process, measuring either internal energy, recoil velocity, or angular distributions of the dissociation products. The product state distributions are usually explicitly probed by laser-induced fluorescence (LIF), resonance-enhanced multiphoton ionization (REMPI) spectroscopy, or coherent Raman scattering with the relative populations of the products obtained via line intensities.

The distribution and anisotropy of the recoil velocities are measured using Doppler spectroscopy or time-of-flight (TOF) techniques [34.13]. Doppler spectroscopy uses the Doppler-broadening of lines in the LIF or REMPI excitation spectra (Sect. 69.5); the profile of the line shape also depends on the recoil anisotropy of the probed species (Fig. 34.2). However, many important molecular fragments are not amenable to spectroscopic detection. Thus, though lacking the ultimate state-specificity of spectroscopy, TOF techniques by virtue of their general applicability provide an appealing alternative route to determine the product state distributions. In TOF techniques, the time is recorded for photofragments to recoil a known distance from the interaction region to a detector. Due to total energy and momentum conservation, the translational energy distribution of a fragment state specifically detected directly implies the internal energy distribution of the other partner product. In less favorable cases where this is not possible, *coincidence* detection schemes are employed to define the partition between translational and internal energies. Rotation of the detection axis with respect to the polarization of the photolysis laser yields the recoil anisotropy.

Advances in spatially resolved detection schemes are now providing an improved measure of vector correlations.

Mass spectrometry can be used to measure branching ratios and quantum yields, which can also be obtained from the techniques described above.

34.3 Theoretical Techniques

The calculation of the observables of photodissociation can be carried out using quantum mechanics either in the time-independent or the time-dependent frame, as well as using classical mechanics [34.1]. Theoretical studies have contributed greatly to the understanding of photodissociation processes, as they provide the ability not only to calculate the observables, but also, through the knowledge of the wave function, to view directly the dissociation dynamics. This has enabled the inference of the underlying dynamics from the observables of the reaction to be more precisely established.

Due to computer limitations, the majority of quantum mechanical studies currently treat fully only three degrees of freedom, and thus have mainly concentrated on triatomic molecules. Jacobi coordinates are usually used, with the appropriate set for the dissociation of ABC into AB and C as follows: R, denoting the distance between the atom C and the centre of mass of the AB fragment; r, denoting the internal vibration coordinate of AB; and γ, denoting the bending angle between R and r.

The initial state Ψ_i is generally taken to be a single bound state. It is obtained either by the solution of the Schrödinger equation at a particular energy (Sect. 31.4), or simply by taking a product of three Gaussians in the three coordinates, with the parameters of the Gaussians being determined from spectroscopic information on the ground state.

Further, to calculate the observables it is also necessary to have information about μ_{fi}. However, this is often assumed to be a constant, i.e. independent of the internal coordinates of the molecule. The *Franck–Condon principle* assumes that the nuclear geometry changes after the electronic transition, and not during it. Therefore a molecule, with a particular geometry, will, when promoted by the photon to the excited electronic state, be centred around the same geometry, which is thus referred to as the Franck–Condon region, or point.

To carry out any dynamical calculations it is necessary to have PESs for the electronic states involved. These are usually obtained from *ab initio* calculations which are described in Chapt. 31. The accuracy of the PES surface largely determines the accuracy of the re-

sults obtained, as the PES essentially determines the dynamics of the fragmentation process.

In the *time-independent* approach, a solution of the time-independent Schrödinger equation

$$(\hat{H} - E)\Psi^\alpha = 0 , \tag{34.8}$$

is sought for a specific total energy E subject to appropriate boundary conditions at infinite product separation. There are many different approaches to solving this problem, but they can be broadly separated into two groups: scattering methods and $\mathcal{L}^2$ methods. The scattering methods involve the solution of the coupled channel equations described in Chapt. 36. These can be solved directly to yield the wave functions, which can then be used to calculate the observables, or can be solved indirectly to provide similar information. The use of $\mathcal{L}^2$ methods, which attempt to expand Ψ in a finite basis set, is not directly applicable since the wave functions are in the continuum and spread out to infinite distances in the R coordinate. Thus various modifications have been introduced in order to take this into account. The most important of these use variational principles [34.14], such as that due to *Kohn* [34.15]. In the Kohn variational principle the wave function in the inner or interaction region is expanded in a finite $\mathcal{L}^2$ basis. However, in the outer region, the wave function is expanded in an energy dependent basis of outgoing and incoming waves, which are approximate solutions of the coupled channel equations. Other methods which can sometimes be used to indirectly extract information about the observables are stabilization [34.16] and complex scaling [34.17].

In the *time-dependent* approach [34.18], one solves the time-dependent Schrödinger equation

$$i\hbar \frac{\partial}{\partial t} \Phi(t) = \hat{H}\Phi(t) \tag{34.9}$$

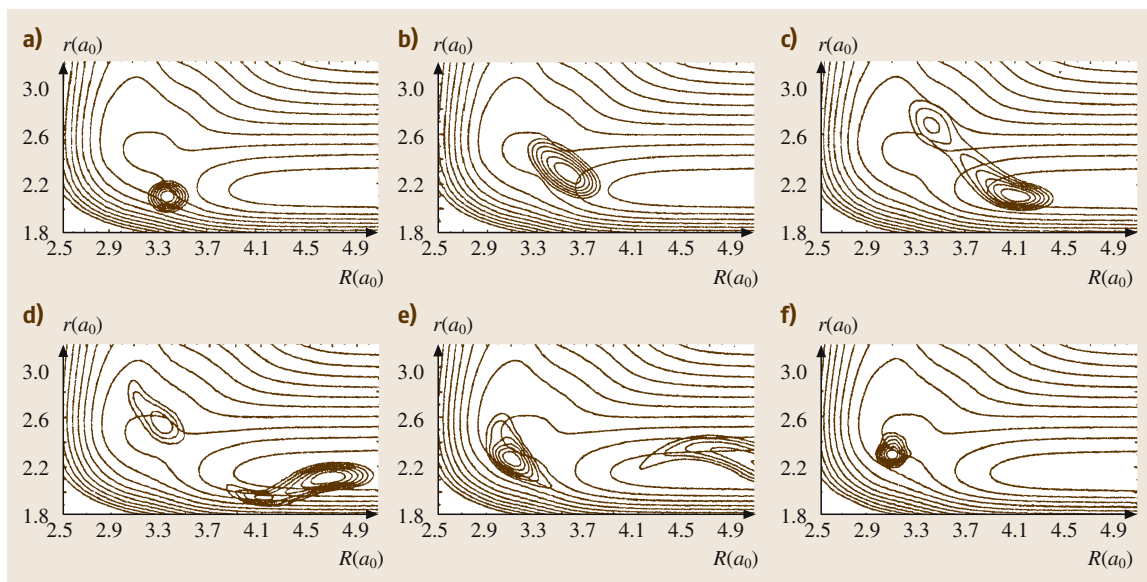
for the wavepacket $\Phi(t)$ with initial condition $\Phi(0) = \Psi_i$, i.e. it is assumed that the molecule is *vertically* promoted by an infinitely short pulse to the electronic state under consideration. The wavepacket is a coherent superposition of stationary wave functions Ψ^α (Chapt. 35), and since it comprises many of the stationary states, it contains all the information necessary to characterize the dissociation (see Fig. 34.3).


Fig. 34.3 Time evolution of a wavepacket in the dissociation of FNO in the S_1 state

The total absorption cross section is given by

$$\sigma(\omega) \propto \int\limits_{-\infty}^{+\infty} dt \, S(t) \, e^{-i\omega t} , \qquad (34.10)$$

where the autocorrelation function $S(t)$ is defined as

$$S(t) = \langle \Phi(0) \mid \Phi(t) \rangle . \qquad (34.11)$$

The autocorrelation function reflects the motion of the wavepacket, and therefore is a convenient means for visualizing the molecular dynamics. The individual partial cross sections can be obtained in the limit $t \rightarrow \infty$ by projection of the wavepacket onto the stationary wave functions of the products, i. e. plane waves in the dissociation coordinate and vibrational-rotational wave functions for the free products.

34.4 Concepts in Dissociation

There has been substantial experimental and theoretical work to elucidate the processes involved in photodissociation from knowledge of the observables, and much progress has been made. In this section, an attempt is made to present some of the simpler ideas which have emerged [34.1].

34.4.1 Direct Dissociation

Direct dissociation is the very fast rupture of a bond after a molecule has been promoted to an electronic state which has a purely repulsive PES. A very clear picture of this process can be obtained from wavepacket calculations: the wavepacket which is placed on the repulsive surface moves directly down the PES and into the exit channel. The autocorrelation function decays from one

to zero in a short time and does not show any recurrences, i. e. oscillations in the autocorrelation function. The absorption cross section $\sigma(\omega)$, which is the Fourier transform of the autocorrelation function (34.10), is therefore a very broad Gaussian with no structure. The breadth of $\sigma(\omega)$ is inversely proportional to the width of the autocorrelation function and can, using simple classical pictures, be taken to be approximately proportional to the steepness of the potential at the Franck–Condon point. The partial cross sections have a similar structure to the total cross section, though they have differing intensities and are shifted relative to each other on the energy scale.

The product distributions can be predicted using simple classical pictures. These methods can be divided into two groups, depending on the extent of the

excitation/de-excitation, or coupling, in the exit channel. If there is very little excitation/de-excitation in the exit channel, the rotational and vibrational product distributions are best described using Franck–Condon mapping. Another model which gives good results for the rotational distributions is the impact parameter, or impulsive, model. If excitation/de-excitation in the exit channel is not negligible, the product distributions are best described using the *reflection principle*. This relates the distribution of the initial wavepacket in γ to the final rotational distributions through the classical excitation function. Similarly, the distribution of the initial wavepacket in space is related to the final vibrational distributions through another classical excitation function.

Even for a purely repulsive PES, the potential may be very flat in the Franck–Condon region so that the molecule may be able to undergo one internal vibration before it dissociates. In this case, there is a diffuse structure in $\sigma(\omega)$, associated with recurrences in the autocorrelation function. The spacing of the structures in $\sigma(\omega)$ are related to the period of the internal vibrations by $\Delta E = 2\pi\hbar/T$. Diffuse structures in $\sigma(\omega)$ have also been linked to unstable periodic orbits.

34.4.2 Vibrational Predissociation

Vibrational predissociation is dissociation delayed due to the trapping of the energy of the molecule in modes orthogonal to the dissociation coordinate. It can be explained very clearly in the time-independent picture as resonances (sometimes known as Feshbach resonances), which are simply extensions of the bound states into the continuum. $\sigma(\omega)$ in this case consists of a series of Lorentzian lines, whose width is inversely proportional to the lifetime of the resonance. In the case where the internal modes of the molecule are not strongly coupled to each other or to the dissociation mode, these resonance states can often be assigned, with the number of quanta in each mode being specified. In this case, the lines in $\sigma(\omega)$ form a series of progressions. The widths of these lines, and thus the lifetimes of the resonance states, often show trends relating the lifetimes to the assignment. This is called *mode-specificity*. In the case that the system is strongly mixed, it is not possible to make an assignment of the resonances, and the lifetimes show strong fluctuations. This is called *statistical state-specificity* [34.19].

The resonances can also be seen in the time-dependent picture, where the autocorrelation function shows many recurrences with periods T, depending on the fundamental frequencies of the internal modes $\omega = 2\pi/T$ (Chapt. 35).

The partial cross sections for vibrational predissociation also consist of Lorentzian lines, with positions and widths exactly as for the total cross sections, but with differing intensities. The partial widths, which describe the rate of dissociation into each product channel, are given by

$$\Gamma_\alpha = \Gamma \frac{\sigma(\omega, \alpha)}{\sigma_{\text{tot}}(\omega)} \ . \tag{34.12}$$

In the weak coupling case, simple pictures can be used to describe the product distributions. The rotational product distributions can be explained using again the reflection principle; but in this case, instead of considering the distribution of the initial wave function in γ, the distribution of the wave function at the transition state is used. The vibrational product distributions can often be well described by examining vibrationally adiabatic curves.

In the case that the modes are strongly coupled, the simple models break down. It is then sometimes possible to use statistical models to describe both the rates and the product distributions. One example of these unimolecular-statistical theories is the Ramsperger–Rice–Karplus–Marcus (RRKM) theory, which is widely used for the description of unimolecular dissociations [34.20]. Another example is phase space theory (PST) [34.21, 22] which is often used to calculate the product distributions for reactions which have no barrier. The quantum mechanical results fluctuate about these average values. These fluctuations, which can be considered as being independent of the system, can be described well by the predications of random matrix theory [34.23].

34.4.3 Electronic Predissociation

Nonadiabatic transitions between two or more electronic states are a common phenomenon in photodissociation [34.24] as well as in other chemical reactions (Chapt. 49). Such transitions can result in the production of both electronically excited and ground state fragments.

Adiabatic molecular PESs can vary in complex fashions. Many of these contortions arise from avoided and real crossings of the surfaces, and in all such cases, the physical and chemical understanding is greatly facilitated by expressing the adiabats in terms of the diabatic states (Chapt. 31). The electronic diabatic states are chosen to simplify the structure of

the electronic wave functions by incorporating the off-diagonal or coupling elements as a pure potential energy term, rather than as a kinetic term, or a mixture of both.

Under these conditions, the BO approximation is inadequate since there is coupling between the different adiabatic states, and the electronic and nuclear motion cannot be separated. Therefore the solution of the time-dependent Schrödinger equation (Sect. 34.3) requires the set of coupled equations

$$
i\hbar \frac{\partial}{\partial t} \begin{pmatrix} \Psi_1 \\ \Psi_2 \end{pmatrix} = \begin{pmatrix} V_{11} + T_{11} & V_{12} \\ V_{12} & V_{22} + T_{22} \end{pmatrix} \begin{pmatrix} \Psi_1 \\ \Psi_2 \end{pmatrix} ,
$$

(34.13)

to be propagated, where the coupling between the diabatic surfaces is in the potential (V) and not the kinetic (T) terms. The wavepacket evolves on both diabatic (or adiabatic) surfaces, and shows a complicated motion in moving between the two surfaces. The coupling between the nuclear and electronic motion can be thought of as resulting in the nuclear motion forcing the transfer of a valence electron to another molecular orbital. Since the efficiency of this transfer is greatest when the orbitals are degenerate, the crossings of the wavepacket between the PESs are generally localized around their degeneracies. Finally, the wavepacket moves out on the adiabatic surfaces towards the products, with which they are correlated.

34.5 Recent Developments

In recent years, the field of photodissociation has seen a number of intriguing applications and comparisons between detailed experimental data and high-quality *ab initio* calculations. These applications have become feasible mainly because of the possibility to construct accurate potential energy surfaces from first principle electronic structure calculations. Cases in which the fragmentation proceeds via two or several electronic states have been especially concentrated on [34.26]. In these cases the Born–Oppenheimer approximation is not valid and the coupling between electronic and nuclear degrees of freedom is essential (Sect. 34.4.3). A nice example is the photodissociation of water in the second absorption band. Since water has only 10 electrons, highly accurate potential energy surfaces have been calculated theoretically, and these have been used in extensive dynamics calculations – including motion on three potential energy surfaces [34.27]. The agreement between the calculated and the measured absorption cross section at room temperature is outstanding [34.28]. From the elaborate analysis of product state distributions (rotational, vibrational, and electronic), many details about the coupled motion on several potential energy surfaces have been learned [34.29, 30]. The electronic density of water is small, and therefore the photodissociation can be treated on a nearly exact level. For other triatomic molecules, with more electrons and a higher density of electronic states, this is generally not feasible. An important example is ozone, which plays a vital role in the atmosphere. The electronic structure of O_3 is illustrated in Fig. 34.4, where many spin-allowed as well as spin-forbidden fragmentation pathways are

Fig. 34.4 Electronic structure of ozone. Shown are cuts through the potential energy surfaces for the singlet and triplet states. After [34.25]

Fig. 34.5 Overview of the calculated dissociation rates of HOCl as a function of the excess energy. The *solid line* is the prediction of a statistical model. After [34.32]

seen [34.25]. The photodissociation of ozone in the uv range has been the target of many experimental studies [34.31]. The interpretation of the many experimental results on the basis of realistic potential energy surfaces is a great challenge for theoretical chemistry.

Photodissociation studies are particularly rewarding if the lifetime in the excited electronic state is long because then the absorption spectrum shows well resolved lines (resonances), the widths of which are inversely related to the state-specific lifetimes [34.33]. A typical situation is the excitation of a particular vibrational-rotational state in a bound electronic state which can decay only via coupling to a dissociative electronic state. The lifetime then reflects the coupling of this state to the continuum of the dissociative state (predissociation). An example is the photodissociation of HCO [34.34, 35]; in this case, the upper and the lower state are coupled by Renner–Teller coupling. A similar example is the photodissociation of HNO. For this molecule, the lower state has a deep potential well which supports long-lived states in its own continuum. The mixing between the quasi-bound states of the upper state with the resonance states of the lower state leads to interesting behavior

in the lifetime as a function of the rotational quantum number [34.36] (resonance between resonances).

Resonances are also prominent features of ground state potential energy surfaces; they are the continuation of the true bound states into the continuum (Sect. 34.4.2). Since resonances determine the kinetics of chemical reactions, they are usually studied in the framework of *unimolecular dissociations* or *unimolecular reactions* [34.37]. On the other hand, these resonance states can be excited by photons, and therefore it is meaningful to discuss them also in the context of photodissociation. In the last few years, numerical methods have been developed to efficiently calculate the resonance parameters [34.38–40]; see [34.37] for a comprehensive overview. Several triatomic molecules with dramatically different intramolecular dynamics have been investigated. The main observation is a strong fluctuation in the resonance lifetimes over several orders of magnitude, even for molecules whose classical dynamics is chaotic, such as NO_2 [34.41]. Figure 34.5 shows the results for $HOCl \rightarrow HO + Cl$ [34.32, 42]. The large fluctuations of the lifetimes (or dissociation rates) are believed to affect the fall-off behavior of recombination rate coefficients [34.43].

The concept of first calculating a potential energy surface as function of all coordinates and then performing dynamics calculations is suitable only for triatomics. For molecules with more than four atoms it is not applicable, simply because of the rapidly increasing number of degrees of freedom. For larger molecules, *direct dynamics* simulations, in which the methodology of classical trajectory simulations is coupled directly to electronic structure calculations, are the method of choice [34.44, 45]. In these simulations, the derivatives of the potential, which are required for the numerical integration of the equations of motion, are obtained directly from electronic structure theory without the need for an analytic potential energy surface. An important application of direct dynamics is the study of post-transition state intramolecular and unimolecular dynamics. When the dissociation proceeds through a transition state, it may be sufficient to start trajectories at the transition state and to follow them into the product channels [34.46, 47]

34.6 Summary

Photodissociation of polyatomic molecules is an ideal field for studying the details of molecular dynamics. The primary goal of the experimental and theoretical approaches (Sects. 34.2, 34.3) is to understand the connection between the observables (Sect. 34.1) and the underlying chemical dynamics (Sect. 34.4).

Once this connection has been established, it is possible to have a detailed understanding of the dissociation dynamics, transition state geometries, and the PESs which ultimately govern the molecular chemical reactivity. The interplay between powerful experimental and theoretical techniques has enabled this goal to be realized for many photodissociation reactions.

35. Time–Resolved Molecular Dynamics

Time–resolved experiments have been performed on a diversity of molecular systems. Applications of spectroscopic techniques which work in the time-domain range from the detection of simple vibrational motion of a diatomic molecule to the direct determination of relaxation times in polyatomic molecules in a liquid environment, or the recording of isomerization processes in biomolecules. The underlying principles of these experiments are more or less the same. In this chapter, a brief description of the basic ideas of transient spectroscopy is given with the emphasis on gas–phase molecules under collision–free conditions, as are usually provided in a molecular beam.

For the development of ultrashort pulse techniques and their application to areas as different as optical engineering, solid state physics or biology see the series of conference proceedings in [35.1–14]. For special applications to molecular physics and chemistry consult [35.15–22] and the review in [35.23].

Besides an overall rotation and the translational motion of the molecular center of mass, nuclei within a molecule possess vibrational

Part C | 35

degrees of freedom. The real–time detection of internal vibrational dynamics is discussed in what follows, but the considerations apply equally well to the case of a fragmentation process where the dissociation dynamics is resolved.

Classically, a molecule can be imagined to consist of atoms connected by springs, each spring representing a chemical bond. The atoms vibrate, performing a periodic oscillation around an equilibrium position. Quantum mechanically, the molecule has discrete vibrational states φ_n, where n represents a set of vibrational quantum numbers and ϵ_n are the corresponding eigenenergies. A vibrational period T_{vib} is calculated from the energy spacing as:

$$T_{\text{vib}} = \frac{2\pi\hbar}{\epsilon_{n+1} - \epsilon_n} . \tag{35.1}$$

Typical vibrational periods for smaller molecules are of the order of several hundred femtoseconds.

Traditional high resolution spectroscopy uses laser pulses with a temporal width T_{P} much larger than any of the time-scales on which the internal molecular motion

takes place:

$$T_{\text{P}} \gg T_{\text{vib}} . \tag{35.2}$$

In the energy domain, this means that the spectral width of the laser pulse is small enough to excite a single eigenstate φ_n. The time-evolution of this state is that of a stationary state

$$\psi(t) = a_n \, e^{-i\epsilon_n t/\hbar} \varphi_n , \tag{35.3}$$

where a_n is a complex number determined by the particular preparation process and the molecular properties.

To detect molecular motion within a time-resolved measurement, pulses with a width T_{P} smaller than the vibrational period have to be used:

$$T_{\text{P}} < T_{\text{vib}} . \tag{35.4}$$

Thus, to resolve vibrational dynamics of smaller molecules, one needs ultrashort pulses in the femtosecond regime. Because a short pulse has a broad spectral distribution it is possible to excite several eigenstates simultaneously: a coherent superposition of the functions φ_n is prepared. The resulting wave function is a vibrational wave packet of the form

$$\psi(t) = \sum_n a_n \, e^{-i\epsilon_n t/\hbar} \varphi_n \ . \tag{35.5}$$

Due to the time-dependent phase factors, the average position of the wave packet changes as a function of time. The principle of time-resolved molecular dynamics is to create such wave packets within a molecule and follow their motion in time.

Pulses in the femtosecond regime are now commercially available. Schemes have been developed to use these pulses to detect wave-packet dynamics. This is, of course, not limited to bound state motion but applies as well to fragmentation processes. In the latter case, the sum in (35.5) has to be replaced by an integral over continuum functions. The condition (35.4) then reads $T_P < T_F$, where T_F is the time during which the atoms separate and do not interact with each other afterwards. It is then possible to monitor the breaking of a chemical bond.

Typical experimental schemes are described in Sect. 35.1, and a theoretical treatment which closely follows the experimental procedure is outlined in Sect. 35.2. Applications are listed in Sect. 35.3 and a brief overview highlighting recent developments is presented in Sect. 35.4.

35.1 Pump–Probe Experiments

The experimental setup for a time-resolved measurement commonly uses two ultra-short laser pulses which are delayed with respect to each other. Therefore, a single pulse is produced and split. The resulting two pulses are delayed by sending them along different paths until they reach the molecular sample. The temporal difference is adjusted by variation of the path length. The first pulse (pump) excites the molecule and prepares a wave packet, i. e., a coherent superposition of molecular eigenstates. The second pulse (probe) interacts with the molecular sample after a defined delay-time and prepares the system in yet another state. A signal is then measured as a function of the delay-time between the pulses. The idea is that, because the wave packet is located in different spatial regions at different times, the signal, in general, depends on the delay-time.

There are various detection schemes. If the probe-pulse prepares the molecule in an energetically higher electronic state, fluorescence can be measured. The pump–probe signal then consists of the total fluorescence yield, recorded as a function of the delay-time between the pulses. Because this signal is proportional to the population created in the state from which the radiative decay takes place, the signal reflects how effective the probe-pulse excitation occurs which, in turn, depends on the wave packet dynamics in the intermediate state accessed by the pump-pulse excitation. It is also possible to detect the transient absorption spectrum of the system which is subject to the probe-pulse excitation. If the parameters of the probe-pulse are chosen such that the molecule is ionized, a total ion signal or a photoelectron spectrum can be detected as a function of the pulse delay. Another technique involves time-resolved four-wave mixing schemes, where coherently emitted radiation is employed to track the system dynamics.

35.2 Theoretical Description

There are several theoretical approaches to describe the experiments which have been outlined in Sect. 35.1. They are based on classical, quantum mechanical or semi-classical descriptions [35.24, 25]. Under the conditions specified at the beginning of this chapter, the most straightforward approach is to solve the time-dependent Schrödinger equation for the field coupled nuclear motion in different electronic states. Here, we outline this approach when only three electronic states $|i\rangle (i = 1, 2, 3)$ participate in the excitation process and only the states $(|i\rangle, |i \pm 1\rangle)$ are coupled. Then, the nuclear wave function $\psi(r)$, where r denotes

the nuclear co-ordinates, consists of three components ψ_i. The equation of motion for the nuclei reads

$$\begin{pmatrix} H_1 & W_{12} & 0 \\ W_{12} & H_2 & W_{23} \\ 0 & W_{23} & H_3 \end{pmatrix} \psi(r,t) = \mathrm{i}\hbar \frac{\partial}{\partial t} \psi(r,t) , \quad (35.6)$$

with the field-matter interaction

$$W_{ji}(r,t) = -\mu_{ji}(r)\{f(t-T_1)\cos[\omega_1(t-T_1)] \\ + f(t-T_2)\cos[\omega_2(t-T_2)]\} . \quad (35.7)$$

Here, H_i denotes the nuclear Hamiltonian within the electronic state $|i\rangle$. The components $\psi_i(r,t)$ of the wave function are coupled by the dipole interaction terms $W_{ji}(r,t)$ containing the projection of the (classical) electric field vector on the transition dipole moment $\mu_{ji}(r)$ connecting states $|i\rangle$ and $|j\rangle$. The field envelope function $f(t)$ is assumed to be the same for pump- and probe-pulses having frequencies ω_1, ω_2, respectively. The pulses interact with the molecule around times T_1, T_2 so that the time-delay is $T = T_2 - T_1$.

Treating a pump-probe fluorescence set-up as an example, we may assume that the population in the state prepared by the probe-pulse is proportional to the total fluorescence signal. Then it is sufficient to determine the wave function $\psi_3(r,t)$ for a fixed pump-probe delay and obtain the signal from its norm. To do so it is, in principle, possible to integrate equation (35.6) numerically with a given initial condition. This indeed is necessary if the fields are of high intensity. In most cases, however, when the interest is in the molecular dynamics rather than in non-linear effects induced by high power laser pulses, a perturbative approach is of conceptual and technical advantage.

Except in the case when the two pulses have temporal overlap, the pump-process and probe-process may be separated. In first-order perturbation theory, the wave function created by the pump-pulse in state $|2\rangle$ is

$$\psi_2(r,0) = \frac{1}{\mathrm{i}\hbar} \int_{-\infty}^{+\infty} \mathrm{d}t\, U_2(-t)\, W_{21}(r,t)\, U_1(t)\, \varphi_{1,n}(r) , \quad (35.8)$$

where time $t = 0$ refers to the end of the pump-pulse interaction. The initial (stationary) vibrational state with vibrational quantum numbers n and eigenenergy ϵ_n is denoted as $\varphi_{1,n}$ and U_i is the propagator in electronic state $|i\rangle$.

Expanding ψ_2 in the set of vibrational eigenfunctions $\{\varphi_{2,m}\}$ with eigenenergies E_m in electronic state $|2\rangle$ yields:

$$\psi_2(r,0) = \sum_m \varphi_{2,m}(r)\, c_{mn}\, I_{mn}(\omega_1) \quad (35.9)$$

with the overlap integrals

$$c_{mn} = \int \mathrm{d}r \varphi_{2,m}(r) \mu_{21}(r) \varphi_{1,n}(r) \quad (35.10)$$

and the time integrals

$$I_{mn}(\omega_1) = \frac{1}{2} \int_{-\infty}^{\infty} \mathrm{d}t\, f(t)\, \mathrm{e}^{\mathrm{i}(E_m - \epsilon_n - \hbar\omega_1)t/\hbar} , \quad (35.11)$$

where we have set $T_1 = 0$ and replaced (within the 'rotating wave approximation') the cosine-term in (35.7) by $\frac{1}{2}\exp(-\mathrm{i}\omega_1 t)$.

From (35.9–35.11) it is clear that ψ_2 is a vibrational wave packet. The weights of the states which build the packet are determined by products of the overlap integrals and the Fourier-transform of the pulse envelope $f(t)$ taken with respect to the energy $E_m - \epsilon_n - \hbar\omega_1$. In the limit of an infinite long pulse, I_{mn} becomes proportional to a δ-function and, for resonance excitation, only a single vibrational state is excited.

Once the pump-pulse no longer interacts with the system, the packet propagates unperturbed. This motion is detected in a time-resolved experiment by exposing the molecule to a probe-pulse at time T, thereby inducing a transition to state $|3\rangle$. As above, the wave function in state $|3\rangle$ can be written as

$$\psi_3(r,T) \\ = \frac{1}{\mathrm{i}\hbar} \int_{-\infty}^{\infty} \mathrm{d}t\, U_3(-t)\, W_{32}(r,t)\, U_2(t'-T)\, \psi_2(r,T) . \quad (35.12)$$

There is an essential difference between the wave functions ψ_2 and ψ_3. The wave packet created by the pump-pulse results from a stationary initial wave function, whereas ψ_3, prepared by the probe-pulse, contains the wave packet ψ_2 as initial state. The latter packet changes its position and is centered around different distances r for different delay times T.

Because, during the short time the probe-pulse interacts with the molecule, the heavy nuclei do not move essentially, one may, to a good approximation, neglect

the kinetic energy part of the propagators U_i in (35.12). This approximation yields

$$\psi_3(r, T) \approx \mu_{32}(r)\psi_2(r, T)$$

$$\times \int\limits_{-\infty}^{\infty} dt\, f(t)\, e^{i(V_3(r)-V_2(r)-\hbar\omega_2)t/\hbar} ,$$

(35.13)

where V_i is the potential energy in electronic state $|i\rangle$. The time integral has its largest modulus at the point $r = r_M$, where the equation

$$V_3(r) - V_2(r) = \hbar\omega_2$$ (35.14)

holds. Assuming that the wave packet is localized, this implies that the norm of ψ_3, and thus the population in state $|3\rangle$, is maximal at those times T when the center of the moving wave packet ψ_2 is located around r_M, where the difference potential $V_3(r) - V_2(r)$ equals the photon energy $\hbar\omega_2$. This consideration shows the central idea of a pump–probe scheme: for a fixed frequency ω_2 it is possible to detect the wave packet each time it reaches the region around the position r_M because then the pump–probe signal exhibits a maximum. If ω_2 is changed, the packet is detected when it visits a different position r_M.

35.3 Applications

It is not possible to give a complete account of the numerous studies of molecular dynamics in the time-domain here. Only selected examples are listed in what follows, so that the cited work is to be taken as typical, being far from a complete compilation.

35.3.1 Internal Vibrational Dynamics of Diatomic Molecules in the Gas Phase

Prototype experiments investigated the simplest case of molecular motion: the vibration of a diatomic molecule. The change of the bond-length within an electronically excited state could be detected in real-time for molecules such as I_2 [35.26] or Na_2 [35.27]. It was shown that not only the vibrational periods but also the Born–Oppenheimer bound-state potentials [35.27, 28] and coordinate dependent transition dipole moments [35.29] can be constructed from the data. In this connection, the phenomena of wave packet dispersion and revival, i.e., the spreading and re-focusing of an initially localized wave packet, was documented [35.26, 30]. The interesting phenomenon of fractional revival, where a wave packet splits into two or several parts was also verified experimentally [35.31].

By using time-resolved CARS (coherent-antistokes-raman-scattering) spectroscopy, the particular temporal arrangement of three time-delayed pulses allows one to monitor electronic ground- and excited-state rotational/vibrational dynamics within a single experiment [35.32].

Employing time-resolved photoelectron spectroscopy [35.33, 34], the time-evolution of probability densities could be directly mapped into the kinetic energy distributions of the photoelectrons, thus obtaining a one-to-one picture of quantum mechanical wave packet dynamics [35.35, 36].

35.3.2 Elementary Gas–Phase Chemical Reactions

The study of gas phase chemical reactions in real-time has been pioneered by *Zewail* and coworkers [35.23]. It is of primary interest to chemistry to monitor how chemical bonds are formed and broken.

In the case of a direct bond rupture, the time-scale to be resolved is much shorter than in cases where long-lived resonances exist. In a first femtosecond experiment, the ICN molecule was prepared in an electronically excited state with a repulsive potential energy surface. and free CN was detected in a pump–probe arrangement [35.37]. By changing the probe-laser frequency, the atom-molecule separation could be recorded in time and for different inter-nuclear distances r_M.

The decay of a quasi-bound complex via electronic predissociation was monitored. From the time-signal the nonadiabatic coupling between a bound and a dissociative electronic state could be extracted for the NaI molecule [35.38]. Another type of indirect decay was studied in the OClO molecule which fragments via different decay channels with characteristic time scales [35.39]. The latter are determined by the coupling of internal nuclear degrees of freedom on one hand and the coupling between electronic and nuclear motion on the other.

As an example of a reaction triggered by multi-photon absorption, we mention the multiple fragmentation of $Fe(CO)_5$. This prototype organometallic compound was studied, and how the various CO-ligands emerge from the complex as a function of time [35.40] was determined.

35.3.3 Molecular Dynamics in Liquid and Solid Surroundings

One main application of time-resolved measurements is the study of molecules embedded in a surrounding. For example, transient spectroscopy has been applied to study diatomic molecules in matrices [35.41, 42], zeolites [35.43], and also nanotubes [35.44], thereby revealing information about coherent dynamics, non-adiabatic transitions and energy transfer mechanisms in a solid environment.

Characteristics of relaxation processes were determined for, e.g., I_2 in rare-gas environments which allowed one to monitor the gas-phase to liquid state transition dynamics [35.45–47]. Another important phenomenon is that of the caging of a molecule in a liquid. This effect describes the fragmentation and recombination of a molecule, the latter being induced by the cage consisting of the surrounding molecules. This effect has been detected within a time-resolved measurement [35.48].

As other prominent examples we mention proton-transfer processes in liquids [35.49], the dynamics of hydrogen bonds [35.50], and also time-dependent processes in carotenoids which have been reviewed recently [35.51].

35.4 Recent Developments

The rapid advance in laser technology and the development of sophisticated experiments have led to a revolution in the spectroscopy with ultrashort pulses. Experimental techniques used for time-resolved measurements are evolving with incredible speed. In what follows we list some recent developments which will, along with other efforts, be the basis of future applications.

35.4.1 Faster Dynamics

According to (35.1) and (35.4), the possibility of resolving molecular dynamics is determined by the relation between the average energy spacing in a system and the laser-pulse duration. Thus, if the aim is to observe the dynamics of electrons taking place within a few femtosecond, shorter pulses are necessary. The production of attosecond pulses has been reported [35.52]. Although such pulses are far from being used in an experiment needing a reasonable repetition rate, the first steps towards a sub-femtosecond time-resolution have been taken.

35.4.2 X–Ray Pulses

Much effort is spent in the generation of ultrashort pulses having wavelengths reaching into the X-ray regime [35.53, 54].

Concerning molecular motion, several prospects are emerging. Firstly, using a high photon-energy pump-pulse, it is possible to prepare core-excited states of a molecule such that the following dynamics could be detected with a time-delayed optical probe pulse. As a second scenario, a uv-pump pulse initiating a chemical reaction, could be followed by a time-delayed X-ray pulse which then is able to selectively excite core levels of the atoms involved in the process. Thus, a signal would track the transient chemical shift of an atom undergoing a molecular re-arrangement process. Here, the first experimental results of this kind have been reported. For example, employing soft X-ray laser pulses, it was possible to monitor the photo-dissociation of the Br_2 molecule [35.55]. Also, it became possible to synchronize an optical pulse from a laser source with an X-ray pulse from a storage ring [35.56] to monitor the temporal changes of an oxidation state of Ru bound in a transition metal complex [35.57].

35.4.3 Time–Resolved Diffraction

Diffraction experiments are of tremendous importance for structural analysis. Geometrical changes of molecules or molecular decomposition could, in principle, be followed using ultrashort light or particle pulses. Concerning time-resolved diffraction using electromagnetic waves, much success has been reported in recent years [35.58]. The applications, to date, are in material science. For example, it is now possible to follow phase transitions in time [35.59]. Concerning the application of time-resolved X-ray diffraction to molecules, the experimental difficulties are numerous. However, first experiments on a chemical reaction in solutions have been reported [35.60].

A promising technique employs not electromagnetic light but pulses of electrons (UED = ultrafast electron diffraction) [35.61]. Such pulses have been used in monitoring, e.g., the structural dynamics of pyridine molecules [35.62].

35.4.4 Dynamics and Control

As has been discussed throughout this chapter, molecular motion can be traced with the help of time-resolved spectroscopy. It is now possible to go one step further and use laser pulses to control molecular motion. Employing pulse shapers [35.63]

which allow for the amplitude- and phase-modulation of a given input field, it was shown that, e.g., the branching ratio of photo-products in a photochemical reaction can be influenced by modulating the excitation pulses using feedback algorithms [35.64]. The field of laser control has been recently reviewed extensively [35.65–67].

36. Nonreactive Scattering

The basic formulations of nonreactive scattering are presented in the sections to follow. The semiclassical and quantal approaches to this problem are outlined. Specific symmetries, and their closely related conservation laws, which reduce the complexity of computation are discussed, along with the usual coordinate systems used to express the necessary scattering equations. The chapter ends with prescriptions for determining the various matrix elements needed for a given calculation.

36.1 Definitions

The cross section σ for a transition from state j' to j is defined classically as

$$\sigma(j \leftarrow j') = 2\pi \int_0^\infty P_b(j \leftarrow j') b \, db \qquad (36.1)$$

where P_b is the transition probability for impact parameter b (Fig. 36.1). The impact parameter is related to the relative angular momentum quantum number, ℓ, by

$$2\mu E b^2 = \ell(\ell+1)$$
$$= k^2 b^2 \qquad (36.2)$$

where k is the wave number at relative collision energy E and μ is the reduced mass; atomic units ($e = m_e = \hbar = 1$) are used throughout. Differentiating (36.2) and setting $d\ell = 1$ in the quantal limit,

$$b \, db = \frac{2\ell + 1}{2k^2},$$

whence the quantum mechanical equivalent of (36.1) may be obtained

$$\sigma(j \leftarrow j') = \frac{\pi}{k_{j'}^2} \sum_\ell (2\ell + 1) P_\ell(j \leftarrow j'), \qquad (36.3)$$

$k_{j'}$ being the wave number in the initial channel. If the initial state is degenerate and the $\omega_{j'}$ degenerate sub-states are labelled by Ω', then

$$P_\ell(j \leftarrow j') = \frac{1}{\omega_{j'}} \sum_{\Omega',\Omega} |T_\ell(j\Omega, j'\Omega')|^2, \qquad (36.4)$$

where T_ℓ is an element of the transmission matrix T, which contains all the information on the scattering event. The scattering matrix S is related to the T matrix by

$$S = 1 - T \qquad (36.5)$$
Fig. 36.1 Classical scattering by a fixed scattering center. The trajectory is symmetric about the point of closest approach, which is the time origin

and thence to the reactance matrix K through

$$S = \frac{1 + iK}{1 - iK} .$$
(36.6)

The elements of the K matrix are real. Conservation of the incident flux of particles requires that

$$\sum_{j\Omega} |S(j\Omega, j'\Omega')|^2 = 1 .$$
(36.7)

Micro-reversibility (time-reversal symmetry) implies that the S matrix is symmetric,

$$S(j\Omega, j'\Omega') = S(j'\Omega', j\Omega) ,$$

and hence

$$\sigma(j \leftarrow j')k_{j'}^2\omega_{j'} = \sigma(j' \leftarrow j)k_j^2\omega_j .$$
(36.8)

The thermally averaged (Maxwellian) rate coefficient is

$$\langle \sigma v \rangle_{j \leftarrow j'} = \left(\frac{8k_BT}{\pi\mu} \right)^{\frac{1}{2}} \int_0^\infty x_{j'}\sigma(j \leftarrow j')\,e^{-x_{j'}}\,dx_{j'} ,$$
(36.9)

where $x_{j'} = \mu v_{j'}^2/2k_BT$, $v_{j'}$ being the relative collision velocity; k_B is Boltzmann's constant, and $(8k_BT/\pi\mu)^{\frac{1}{2}}$ may be identified with the mean thermal velocity at temperature T. From (36.8) and (36.9),

$$\langle \sigma v \rangle_{j \leftarrow j'}\omega_{j'}\exp(-\epsilon_{j'}/k_BT)$$
$$= \langle \sigma v \rangle_{j' \leftarrow j}\omega_j\exp(-\epsilon_j/k_BT) ,$$
(36.10)

where $\epsilon_{j'}, \epsilon_j$ denote the energies of the states j', j with respect to the reference level. Equation (36.10) relates the rate coefficients of inverse transitions to their relative degeneracies and excitation energies.

36.2 Semiclassical Method

If the collision dynamics are formulated using elements of both classical and quantum mechanics, then the method is called "semiclassical". Thus, the relative motion might be described by a classical trajectory, whilst internal degrees of freedom (rotation, vibration, ...) are quantized. The de Broglie wavelength associated with the linear motion of a proton attains the Bohr radius at a collision energy of $0.29\,\text{eV}$, and a classical trajectory is a good approximation at much higher energies.

The introduction of a classical trajectory leads to a time-dependent Hamiltonian, and Schrödinger's equation may be reduced to a set of coupled, first-order differential equations of the form

$$i\dot{a} = Va ,$$
(36.11)

where a is a column vector of transition amplitudes and $\dot{a}$ is the vector of their time derivatives. The square matrix V is the interaction matrix, whose elements incorporate oscillatory factors of the type $\exp[(\epsilon_{j'} - \epsilon_j)t]$. The trajectory is taken to be symmetric about the point of closest approach, $t = 0$, and a is initialized through

$$a_j \to \delta_{j'j} \quad \text{as } t \to -\infty.$$

The differential equations (36.11) may be integrated numerically, and the transition probabilities derived from

$$P_b(j \leftarrow j') \to |a_j(b)|^2 \quad \text{as } t \to \infty.$$

The cross sections are given by (36.1).

36.3 Quantal Method

The usual approach to nonreactive scattering [36.1] is based on the Born–Oppenheimer approximation. The interaction potential V is taken to be a known function of the *nuclear* coordinates, the electronic energy being minimized for each geometry and separation of target and projectile. The total Hamiltonian may then be written

$$H = -\frac{1}{2\mu}\nabla_R^2 + h_1(x_1) + h_2(x_2)$$
$$+ V(R, x_1, x_2) ,$$
(36.12)

where the first term represents the relative kinetic energy of the target and projectile, and h_1, h_2 are functions of the intramolecular nuclear coordinates x_1, x_2. The eigenfunctions ψ_1, ψ_2 of h_1, h_2 describe the vibrational and rotational motions of the isolated molecules and form a basis for expanding the total wave function Ψ of the system:

$$\Psi(R, x_1, x_2) = \sum_{\alpha_1 \alpha_2 \ell m} \frac{F(\alpha_1 \alpha_2 \ell m | R)}{R}$$
$$\times Y_{\ell m}(\Theta, \Phi) \psi_1(\alpha_1 | x_1) \psi_2(\alpha_2 | x_2) .$$

$$(36.13)$$

In (36.13), α_1, α_2 denote the sets of quantum numbers required to specify the states of the isolated molecules, and $Y_{\ell m}(\Theta, \Phi)$ is a spherical harmonic function of the angular coordinates of the intermolecular vector R. $F(\alpha_1 \alpha_2 \ell m | R)$ are R-dependent expansion coefficients which are solutions of the Schrödinger equation

$$(H - E)\Psi = 0 . \tag{36.14}$$

These solutions may be arranged as the columns of a square matrix, $F(R)$, in which each column is labelled by a different initial scattering state. The radial functions must satisfy the physical boundary conditions,

$$F(R) \to 0 \quad \text{as } R \to 0$$
$$F(R) \to J(R)A - N(R)B \quad \text{as } R \to \infty ,$$

where J and N are diagonal matrices whose non-vanishing elements are given by

$$J_{ii} = k_i^{\frac{1}{2}} R j_\ell(k_i R) \tag{36.15}$$
$$N_{ii} = k_i^{\frac{1}{2}} R n_\ell(k_i R) , \tag{36.16}$$

and j_ℓ, n_ℓ are spherical Bessel functions of the first, second kinds; k_i is the wave number in channel i (a given set of values of the quantum numbers $\alpha_1 \alpha_2 \ell m$). The reactance matrix,

$$K = BA^{-1} , \tag{36.17}$$

yields the state-to-state cross sections.

36.4 Symmetries and Conservation Laws

The expansion of the total wave function, (36.13), does not explicitly incorporate the invariance of the Hamiltonian under an arbitrary rotation in space or reflection in the coordinate origin. The Hamiltonian commutes with J^2, where J is the total angular momentum, and any component of J, J_x, J_y, or J_z, although these components do not commute amongst themselves. Eigenfunctions of H may, therefore, be chosen to be simultaneous eigenfunctions of J^2 and (conventionally) J_z, with eigenvalues $J(J+1)$ and M. If j_1 and j_2 are the angular momenta of the isolated molecules, then

$$j_{12} = j_1 + j_2$$

is their resultant and

$$J = j_{12} + \ell ,$$

where ℓ denotes the relative angular momentum of the two molecules. The coupling of the angular momenta to the multipolar expansion of the electromagnetic field gives rise to collisional selection rules.

The parity operator, P, reflects the coordinates in the origin. Because two successive operations with P restore the original values of the coordinates, the corresponding eigenvalue p satisfies the equation $p^2 = 1$, or $p = \pm 1$. For electromagnetic interactions, the commutation of P and H implies conservation of the parity of the system.

If one takes advantage of the conservation laws associated with these symmetries of the system, substantial savings in computing time can be made: only one value of the total angular momentum and of the parity need to be considered simultaneously.

36.5 Coordinate Systems

The natural choice of coordinate system in which to express the interaction potential, $V(R, x_1, x_2)$, is a body-fixed (BF) system in which the z-axis coincides with the direction of the intermolecular vector $R = (R, \Theta, \Phi)$. A rotation of the space-fixed (SF) coordinate system through the Euler angles $(\Phi, \Theta, 0)$ generates such a BF frame. The intramolecular coordinates x_1, x_2 must then be expressed relative to the BF frame, as must the Laplacian operator ∇_R^2 which appears in the expression for the total Hamiltonian, (36.12). The latter may

be written as

$$\nabla_R^2 = \frac{1}{R}\frac{\partial^2}{\partial R^2}R - \frac{\ell^2}{R^2}$$

$$= \frac{1}{R}\frac{\partial^2}{\partial R^2}R - \frac{(\boldsymbol{J} - \boldsymbol{j}_{12})^2}{R^2} \,, \qquad (36.18)$$

which are the forms suitable for calculations in SF and BF coordinates, respectively.

A unitary transformation relates the normalized eigenfunctions of a given parity in SF and BF coordinates. In Dirac notation,

$$|j_{12}\ell JM\rangle_{\mathrm{SF}}$$
$$= \sum_{\bar{\Omega}} |j_{12}\bar{\Omega}\epsilon JM\rangle_{\mathrm{BF}}\langle j_{12}\bar{\Omega}\epsilon JM|j_{12}\ell JM\rangle, \quad (36.19)$$

where $\bar{\Omega} = |\Omega|$ and Ω is the projection of $\boldsymbol{J}$ on the BF z-axis. As the projection of $\boldsymbol{\ell}$ on the intermolecular axis is zero, Ω is also the projection of $\boldsymbol{j}_{12}$ on the BF

36.6 Scattering Equations

Schrödinger's equation for the scattering system may be reduced to a set of coupled, ordinary, second-order differential equations for the radial functions $F(R)$. Expressed in matrix form, they become

$$\left[\mathbf{1}\frac{\mathrm{d}^2}{\mathrm{d}R^2} + \boldsymbol{W}(R)\right]\boldsymbol{F}(R) = 0 \,. \qquad (36.21)$$

There exists a set of equations (36.21) for each value of the total angular momentum J and parity p (Sect. 36.4). The matrix $\boldsymbol{W}$ may be written

$$\boldsymbol{W}(R) = \boldsymbol{k}^2 - 2\mu\boldsymbol{V}_{\mathrm{eff}} \,, \qquad (36.22)$$

36.7 Matrix Elements

36.7.1 Centrifugal Potential

When evaluated in the SF frame, the matrix of the centrifugal potential is diagonal, with non-vanishing elements $\ell(\ell+1)/(2\mu R^2)$. In the BF frame, the diagonal elements are [see (36.18)]

$$\langle j_{12}\bar{\Omega}\epsilon JM|(\boldsymbol{J} - \boldsymbol{j}_{12})^2/2\mu R^2|j_{12}\bar{\Omega}\epsilon JM\rangle$$
$$= \left[J(J+1) + j_{12}(j_{12}+1) - 2\bar{\Omega}^2\right]/(2\mu R^2) \,, \qquad (36.25)$$

z-axis. The absolute value of Ω appears in the transformation because $|j_{12} \pm \Omega JM\rangle$ are *not* eigenfunctions of the parity operator P, whereas the linear combinations

$$|j_{12}\bar{\Omega}\epsilon JM\rangle = \frac{|j_{12}\Omega JM\rangle + \epsilon|j_{12} - \Omega JM\rangle}{\left[2(1+\delta_{\bar{\Omega}0})\right]^{\frac{1}{2}}}$$

$(\epsilon = \pm 1)$ are eigenfunctions of P. The factor $[2(1+\delta_{\bar{\Omega}0})]^{\frac{1}{2}}$ ensures the correct normalization of these functions. The elements of the matrix which performs the unitary transformation (36.19) are

$$\langle j_{12}\bar{\Omega}\epsilon JM|j_{12}\ell JM\rangle$$
$$= \left(\frac{2(2\ell+1)}{(1+\delta_{\bar{\Omega}0})(2J+1)}\right)^{\frac{1}{2}} C_{\bar{\Omega}0\bar{\Omega}}^{j_{12}\ell J} \,, \qquad (36.20)$$

where $C_{\bar{\Omega}0\bar{\Omega}}^{j_{12}\ell J}$ is a Clebsch–Gordan coefficient.

where $\boldsymbol{k}^2$ is a diagonal matrix whose non-vanishing elements are

$$k_{\alpha_1\alpha_2}^2 = 2\mu(E - \epsilon_{\alpha_1} - \epsilon_{\alpha_2}) \,. \qquad (36.23)$$

$k_{\alpha_1\alpha_2}$ is the wave number at infinite separation ($R \to \infty$) when the molecules are in eigenstates α_1, α_2 with eigenenergies $\epsilon_{\alpha_1}, \epsilon_{\alpha_2}$. $\boldsymbol{V}_{\mathrm{eff}}$ is the matrix of the effective potential,

$$\boldsymbol{V}_{\mathrm{eff}} = V(\boldsymbol{R}, \boldsymbol{x}_1, \boldsymbol{x}_2) + \frac{\boldsymbol{\ell}^2}{2\mu R^2} \,, \qquad (36.24)$$

in which V is the interaction potential and $\boldsymbol{\ell}^2/(2\mu R^2)$ may be identified with the centrifugal potential. There exist standard computer codes for solving equations of the form (36.21) [36.2, 3].

and, in addition, there are off-diagonal elements

$$\langle j_{12}\bar{\Omega}\epsilon JM|(\boldsymbol{J} - \boldsymbol{j}_{12})^2/2\mu R^2|j_{12}\bar{\Omega} \pm 1\epsilon JM\rangle$$
$$= -\left\{(1+\delta_{\bar{\Omega}0})(1+\delta_{\bar{\Omega}\pm1,0})\right.$$
$$\times [J(J+1) - \bar{\Omega}(\bar{\Omega} \pm 1)]$$
$$\left.\times [j_{12}(j_{12}+1) - \bar{\Omega}(\bar{\Omega} \pm 1)]\right\}^{\frac{1}{2}}/(2\mu R^2) \,. \qquad (36.26)$$

The matrix elements (36.26), which are off-diagonal in $\bar{\Omega}$, are associated with the rotation in space of the BF

coordinate system (Coriolis coupling). In the "coupled states" approximation [36.4], the off-diagonal elements (36.26) are neglected, and the diagonal elements (36.25) are often replaced by their SF equivalent form $\ell(\ell+1)/(2\mu R^2)$. The matrix of the interaction potential, on the other hand, continues to be evaluated in BF coordinates. The net effect of these approximations is to ignore the rotation of the BF frame in the course of the collision, and the associated dynamical terms.

36.7.2 Interaction Potential

The interaction potential is usually expressed and computed in BF coordinates. For the purposes of the analysis, it is convenient to derive a multipolar expansion of the potential from a least-squares fit to the original data points. If the collision calculations are being done in the BF frame, the potential matrix elements may be evaluated directly. However, if the SF frame is to be used, the potential expansion must first be transformed into SF form.

Consider the interaction between a symmetric top, such as ammonia (NH_3), and a rigid rotor, such as H_2 [36.5, 6]. This complicated example serves as a paradigm, and simpler cases may be derived by reduction. In the BF frame, the potential can be expanded as

$$V\left(R, \hat{\omega}_1', \hat{r}_2'\right) = \sum_{\substack{\lambda_1\lambda_2 \\ \mu\nu}} v_{\lambda_1\lambda_2\mu\nu}(R)$$
$$\times \mathcal{D}_{\mu\nu}^{\lambda_1}\left(\hat{\omega}_1'\right) Y_{\lambda_2-\nu}\left(\hat{r}_2'\right), \qquad (36.27)$$

where the Euler angles $\hat{\omega}_1' = \left(\phi_1', \theta_1', \psi_1'\right)$ determine the orientation of the principal axes of the top and $\hat{r}_2' = \left(\theta_2', \phi_2'\right)$ the orientation of the axis of the rotor (Fig. 36.2). Expanding the rotation matrix element $\mathcal{D}_{\mu\nu}^{\lambda_1}$ and the spherical harmonic $Y_{\lambda_2-\nu}$, (36.27) becomes

$$V\left(R, \hat{\omega}_1', \hat{r}_2'\right) = \sum_{\substack{\lambda_1\lambda_2 \\ \mu\nu}} v_{\lambda_1\lambda_2\mu\nu}(R)\left(\frac{2\lambda_2+1}{4\pi}\right)^{\frac{1}{2}}$$
$$\times e^{i\mu\psi_1'} d_{\mu\nu}^{\lambda_1}\left(\theta_1'\right) e^{i\nu\phi_1'} d_{0-\nu}^{\lambda_2}\left(\theta_2'\right) e^{-i\nu\phi_2'}$$
$$(36.28)$$

where

$$d_{m'm}^j(\beta) = \langle jm' | \exp(i\beta J_y) | jm \rangle \qquad (36.29)$$

according to the definition in [36.7]. We note that the $d_{m'm}^j$ are real. The combination of positive and negative values of the index ν in (36.28) reflects the invariance of the potential under rotations about the intermolecu-
Fig. 36.2 The body fixed coordinate system: scattering of a rigid rotor and a symmetric top

lar axis (alternatively, its dependence on the *difference* between ϕ_1' and ϕ_2'). In SF coordinates, the potential becomes

$$V(\boldsymbol{R}, \hat{\omega}_1, \hat{r}_2)$$
$$= \sum_{\substack{\lambda_1\lambda_2 \\ \lambda\mu}} v_{\lambda_1\lambda_2\lambda\mu}(R)$$
$$\times \sum_{m_1m_2} C_{m_1m_2m}^{\lambda_1\lambda_2\lambda} \mathcal{D}_{\mu m_1}^{\lambda_1}\left(\hat{\omega}_1\right) Y_{\lambda_2 m_2}\left(\hat{r}_2\right) Y_{\lambda m}^*\left(\hat{\boldsymbol{R}}\right).$$
$$(36.30)$$

The expansion coefficients in the SF and BF frames are related by

$$v_{\lambda_1\lambda_2\lambda\mu}(R)$$
$$= \left(\frac{4\pi}{2\lambda+1}\right)^{\frac{1}{2}} \sum_{\nu\geq 0} C_{\nu-\nu0}^{\lambda_1\lambda_2\lambda}(1+\delta_{\nu0})^{-1}$$
$$\times \left[v_{\lambda_1\lambda_2\mu\nu}(R) + (-1)^{\lambda_1+\lambda_2+\lambda} v_{\lambda_1\lambda_2\mu-\nu}(R)\right].$$
$$(36.31)$$

The matrix elements of the potential given by (36.30) are

$$\left\langle j_1 k j_2 j_{12} \ell JM \left| V\left(\boldsymbol{R}, \hat{\omega}_1, \hat{r}_2\right) \right| j_1' k' j_2' j_{12}' \ell' JM \right\rangle$$
$$= \sum_{\substack{\lambda_1\lambda_2 \\ \lambda\mu}} v_{\lambda_1\lambda_2\lambda\mu}(R)(-1)^{j_1'+j_2'+j_{12}+k'-J}\left(\frac{2\lambda+1}{4\pi}\right)$$
$$\times \left[(2j_1+1)(2j_2+1)(2j_{12}+1)(2\ell+1)(2\lambda_2+1)\right.$$
$$\times \left.(2\ell'+1)(2j_{12}'+1)(2j_2'+1)(2j_1'+1)\right]^{\frac{1}{2}}$$
$$\times \begin{pmatrix} \lambda & \ell & \ell' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} \lambda_2 & j_2 & j_2' \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} \lambda_1 & j_1 & j_1' \\ \mu & k & -k' \end{pmatrix}$$
$$\times \begin{Bmatrix} \ell' & \ell & \lambda \\ j_{12} & j_{12}' & J \end{Bmatrix} \begin{Bmatrix} j_{12} & j_2 & j_1 \\ j_{12}' & j_2' & j_1' \\ \lambda & \lambda_2 & \lambda_1 \end{Bmatrix}$$
$$(36.32)$$

where k, k' denote the projection of j_1, j'_1 on the symmetry axis of the symmetric top; $\begin{pmatrix} \cdots \\ \cdots \end{pmatrix}$ is a Wigner 3j-, $\begin{Bmatrix} \cdots \\ \cdots \end{Bmatrix}$ a 6j-, and $\begin{Bmatrix} \cdots \\ \cdots \\ \cdots \end{Bmatrix}$ a 9j-coefficient. The potential matrix elements for other important cases may be derived from (36.32). Rigid rotor-rigid rotor [36.8] obtains when $k = \mu = 0$, and atom-rigid rotor when, additionally, $j_1 = \lambda_1 = 0$. References to numerical results for specific systems have been compiled in Appendix 2 of [36.9].

In order to exploit conservation of the parity of the total system, it is necessary to use symmetry adapted rotational eigenfunctions

$$\left| j_1 \bar{k} m \eta \right\rangle = \frac{\left| j_1 k m \right\rangle + \eta \left| j_1 - k m \right\rangle}{\left[2 \left(1 + \delta_{\bar{k}0} \right) \right]^{\frac{1}{2}}} , \qquad (36.33)$$

where $\bar{k}$ is the absolute magnitude of the projection of $\boldsymbol{j}_1$ on the symmetry axis of the top. The parity of the total wave function $\left| j_1 \bar{k} \eta j_2 j_{12} \ell JM \right\rangle$ is then $p = \eta(-1)^{j_1 + j_2 + \ell + \bar{k}}$ and is conserved during the collision. This fact enables the coupled equations to be separated into two non-interacting parity blocks. Because the orientation of the SF z-axis is arbitrary, the matrix elements (36.32) must be independent of M.

The rotational eigenfunctions of an asymmetric top, such as water (H_2O) or formaldehyde (H_2CO), may be written as linear combinations of the symmetric top functions of (36.33):

$$\left| j_1 \tau m \right\rangle = \sum_{\bar{k}} \left| j_1 \bar{k} m \eta \right\rangle \left\langle j_1 \bar{k} m \eta \middle| j_1 \tau m \right\rangle , \qquad (36.34)$$

where the expansion coefficients $\left\langle j_1 \bar{k} m \eta \middle| j_1 \tau m \right\rangle$ are labelled by $-j_1 \leq \tau \leq j_1$. The parity (inversion symmetry) of these functions is $\eta(-1)^{j_1 + \bar{k}}$. Because protons are fermions, the total (rotational and spin) nuclear wave function must be antisymmetric under exchange of the two protons in H_2O or in H_2CO. Proton exchange is equivalent to a rotation through π about the symmetry axis of the molecule. The rotational functions (36.34) are eigenfunctions of this operator with eigenvalues $(-1)^{\bar{k}}$. As the ortho nuclear spin function is symmetric under proton exchange, and the para function is antisymmetric, it follows that rotational states with $\bar{k}$ odd are ortho states, whereas those with $\bar{k}$ even are para states. Conservation of the parity $\eta(-1)^{j_1 + \bar{k}}$ then implies that η is *either* 1 *or* -1 in the summation on the right hand side of (36.34). Thus, the index τ implies $\bar{k} =$ even or $\bar{k} =$ odd and $\eta = 1$ or $\eta = -1$. The molecular internal Hamiltonian matrix has four non-interacting diagonal blocks, corresponding to the four possible combinations of $\bar{k}$ and η [36.10, 11].

Recent studies of the rotational excitation of H_2O by H_2 [36.12, 13] show that, at low energies, the cross sections can be much larger for collisions with ortho-H_2 (j_2 odd) than with para-H_2 (j_2 even). The long range interaction between the (large) dipole moment of H_2O and the quadrupole moment of H_2 – absent for para-H_2 in its ground state, $j_2 = 0$ – is responsible for this difference in behavior.

37. Gas Phase Reactions

The rates of gas phase chemical processes can generally be described by rate laws in which the rate of formation of products or disappearance of reactants is related to the product of the concentrations of reactants raised to various powers [37.1]. Rate laws are deterministic expressions that are usually accurate even though they are used to represent a stochastic reality. Rate equations may fail in the limit of small numbers of reacting particles, where both fluctuations and discrete aspects are important. Exceptions to the reliability of rate equations have been found recently in a variety of fields including surface chemistry on small particles [37.2]. Moreover, both Monte Carlo and master equation methods can be used in their place, given sufficient computing power [37.3–6].

As an example of a rate law, consider the rate of disappearance of reactant A in a gas mixture containing species A, B, and C. The rate law for this disappearance can be expressed by the equation

$$\mathrm{d}[A]/\mathrm{d}t = -k[A]^a[B]^b[C]^c , \qquad (37.1)$$

where the symbols [ ] refer to concentration, and the rate coefficient k is dependent on temperature, and possibly other parameters such as the total gas density. The above law is not the most general that can be envisaged. For example, if species A reacts via more than one set of processes, more than one negative term on the right-hand side of the equation will be needed. In addition, if the reverse reaction to form A from products is appreciable, a positive term must also be included. At equilibrium, the rate of change of reactant must be zero.

The relation above does not necessarily refer to one chemical reaction, but to a succession of elementary reactions known collectively as a mechanism. The most elementary reaction is a simple bimolecular process with a second order rate law of the type

$$\mathrm{d}[C]/\mathrm{d}t = -\mathrm{d}[A]/\mathrm{d}t = k[A][B] , \qquad (37.2)$$

where two species A and B collide to form products, one of which can be labeled C. In this law, the rate coefficient k is related simply to the reaction cross section σ via the equation

$$k = \sigma v , \qquad (37.3)$$

where v is the relative velocity of reactants. The rate coefficient in a bimolecular process has units of volume per time, typically $\mathrm{cm}^3\,\mathrm{s}^{-1}$. In a thermal system, the rate coefficient $k(T)$ is averaged over all degrees of freedom of the reactants, both internal and translational. The most specific rate coefficient is termed a state-to-state coefficient and refers to a process in which reactant A in quantum state a reacts with reactant B in quantum state b at a specific translational energy $\mathcal{T}$ to form products in specific states separating with a specific translational energy [37.7].

Although normal bimolecular processes produce more than one product, it is also possible for the two reactants A and B to stick together if sufficient energy is released in the form of a photon:

$$A + B \longrightarrow AB + h\nu . \qquad (37.4)$$

Such a process is called radiative association [37.8], and has mainly been studied for ion-molecule systems, i.e., reactions in which one of the two reactants is an

ion. The process of radiative association is normally thought to occur in two steps. The first step produces a collision complex AB^*, which is a molecule existing in a transitory fashion above its dissociation limit:

$$A + B \longrightarrow AB^* . \tag{37.5}$$

Once formed, the complex, which is often thought of as an ergodic entity retaining memory only of its total energy and angular momentum, can either redissociate into reactants, or emit a photon of sufficient energy to stabilize itself:

$$AB^* \longrightarrow AB + h\nu . \tag{37.6}$$

Since redissociation of the complex is generally more rapid than radiative emission, radiative association rate coefficients are normally small. Emission of one infrared photon is sufficient to achieve stabilization, but stabilization of a complex via electronic emission may be a more rapid mechanism if suitable electronic states exist [37.8,9]. The lifetime of the complex against redissociation into reactants is a strong direct function of the binding energy of the species and the number of atoms it possesses.

In addition to bimolecular processes, two other types of reactions often referred to as elementary are unimolecular and termolecular reactions. Although complex reaction mechanisms are sometimes divided into unimolecular and termolecular steps, these are not strictly elementary because they can be subdivided into a series of bimolecular steps. In a unimolecular reaction [37.10,11], a molecule A is destroyed at sufficiently high gas density by a process that has the seemingly simple first order rate law

$$d[A]/dt = -k[A] . \tag{37.7}$$

At low pressures, on the other hand, the rate law is second order. A simplified series of events, called the Lindemann mechanism, explains these limiting cases by invoking the activation of species A by strong inelastic collisions with bath gas M to form an activated complex A^* which can either be deactivated by inelastic collisions or spontaneously decompose, since it possesses sufficient energy to do so. The steps are written as

$$A + M \rightleftharpoons A^* + M , \tag{37.8}$$
$$A^* \longrightarrow B + C , \tag{37.9}$$

where the spontaneous destruction of A^* can be thought of as a truly elementary unimolecular reaction, akin to

spontaneous emission of radiation. Studies of spontaneous dissociation occupy an important place in gas phase reaction theory, and are discussed in Sects. 37.1.2 and 37.1.4 in the context of dissociation of intermediate complexes. If the rate coefficients for the forward and reverse processes in (37.8) are labeled k_1 and k_{-1} respectively, and the rate coefficient for spontaneous dissociation of A^* into products is labeled $k_2(s^{-1})$, application of the steady-state principle to the concentration of the activated complex, namely,

$$d[A^*]/dt = k_1[A][M] - k_{-1}[A^*][M] - k_2[A^*] \approx 0 \tag{37.10}$$

leads to the rate law

$$-d[A]/dt = k'[A][M] , \tag{37.11}$$

where

$$k' = k_1 k_2 / (k_{-1}[M] + k_2) . \tag{37.12}$$

At low pressures, $k_{-1}[M] \ll k_2$ and $k' \approx k_1$ so that a second order rate law prevails. At high pressures, $k_{-1}[M] \gg k_2$ and $k' \approx k_1 k_2 / k_{-1}[M]$ so that the rate law becomes first order:

$$-d[A]/dt \approx (k_1/k_{-1}) k_2[A] . \tag{37.13}$$

Since both the activation and deactivation of complexes occur stepwise, rather than in single strong collisions, reality is far more complex than the Lindemann mechanism [37.12], and, at the highest degree of detail, master equation treatments are needed, especially for intermediate pressures [37.13].

In a termolecular reaction, which is actually the inverse of a unimolecular process [37.13], two species B and C collide to form a collision complex A^*, which can be regarded as the activated complex of stable species A. The collision complex can be stabilized by subsequent strong collisions with other species:

$$A^* + M \longrightarrow A + M , \tag{37.14}$$
or can redissociate into reactants. If the complex formation step occurs with a bimolecular rate coefficient k_{-2}, and k_{-1} and k_2 refer to complex stabilization and dissociation as in the unimolecular case, the rate law for the termolecular process can be written

$$d[A]/dt = k'[B][C][M] , \tag{37.15}$$

where

$$k' = k_{-2} k_{-1} / (k_{-1}[M] + k_2) . \tag{37.16}$$

At low pressures, $k' \approx k_{-2}k_{-1}/k_2$ and the rate law is third order. At high pressures, when every activated complex is deactivated, the rate law becomes second order since $k' \approx k_{-2}/[M]$. Actually, at very low pressures radiative stabilization of the complex dominates and the rate law once again becomes second order. As in the unimolecular case, the complex does not really undergo strong inelastic collisions, so that reality is once

again more complex than pictured here [37.13]. For detailed theories of thermal reactions, there is the additional problem in (37.12) and (37.16) of deciding when thermalization of the partial rate coefficients should be undertaken. In reality, the partial rate coefficients refer to reactions with specific amounts of energy and angular momentum, and should not be thermally averaged before incorporation into the equations for k'.

37.1 Normal Bimolecular Reactions

The rates of elementary (bimolecular) chemical reactions are governed by Born–Oppenheimer potential surfaces, which contain electronic energies and nuclear-nuclear repulsions. Reactions can be classified as exoergic or endoergic depending upon whether the 0 K energies of the products lie below or above those of the reactants, respectively. In the simplest types of exoergic chemical reactions, the potential energy flows downhill from reactants to products, or flows downhill from reactants to a global minimum (the reaction complex) after which it flows uphill to products. More commonly, the morphology of the potential surface is such that after some long-range attraction, the potential rises as old chemical bonds are broken before falling as new bonds are formed. Generally, there is a minimum energy pathway through the region of large potential referred to as the reaction coordinate. The system is said to traverse a transition state barrier, which refers to the configuration of atoms at which a potential saddle point occurs. The height of this transition state barrier is related to the activation energy barrier E_a in the classical Arrhenius rate law

$$k(T) = A(T) \exp\left[- E_a/\left(k_{\mathrm{B}}T\right)\right],\qquad (37.17)$$

for rate coefficients of bimolecular reactions which contain short-range barriers [37.1]. In the Arrhenius expression, k_{B} is the Boltzmann constant, and the pre-exponential factor $A(T)$ can be related to the form of the long-range potential, or to an equilibrium coefficient between the transition state and reactants (see the discussion of activated complex theory in Sect. 37.1.3). Although fits of experimental data over short temperature ranges often assume the pre-exponential factor to be totally independent of temperature, theories show that this is not strictly true in most instances. A more serious problem with the expression undoubtedly occurs at low temperatures since tunneling will clearly lead to deviations.

Although, in principle, it is possible to calculate reaction cross sections and rate coefficients via the quantum theory of scattering, in practice few systems have been studied by this technique given the immense computational effort required [37.14, 15]. Another set of approaches, which has been used to study a large variety of systems, is known as classical molecular dynamics (see Chapt. 58). In these approaches, the atoms move classically on the quantum mechanically generated Born–Oppenheimer potential surfaces. For many reactions, however, neither technique is applicable, and a variety of simpler approaches has been developed, using capture and statistical approximations; these approaches will be emphasized here. Indeed, the use of an ergodic complex in our preliminary discussion of association and unimolecular reactions above presages the use of statistical approximations. An excellent high-level review article on many of the topics covered here has been written by *Troe* [37.16].

37.1.1 Capture Theories

For reactions that do not possess a potential energy barrier at short-range, it is tempting to apply long-range capture theories between structureless particles to calculate the reaction rate coefficient. Such theories assume that (a) all hard collisions lead to reaction, and (b) hard collisions occur for all partial waves up to a maximum impact parameter b_{max} or relative angular momentum quantum number L_{max}. This is normally defined so that the reactant translational energy $\mathcal{T}_{AB}$ is just sufficient to overcome a centrifugal barrier. The centrifugal barrier produces a long-range maximum in the effective potential energy function V_{eff} given by the relation

$$V_{\mathrm{eff}}(r, b) = V(r) + \mathcal{T}_{AB}b^2/r^2 ,\qquad (37.18)$$

where r is the separation between reactants and $\mathcal{T}_{AB}b^2/r^2$ is the angular kinetic energy. If the reactants

overcome the centrifugal barrier, they will spiral in towards each other in the absence of short-range repulsive forces. The approach has had its most notable success for exoergic reactions between ions and nonpolar neutral molecules [37.17]. The long-range potential in this situation is simply (in cgs-esu units)

$$V(r) = -e^2\alpha_d/2r^4 , \tag{37.19}$$

where α_d is the polarizability of the neutral reactant. This potential leads to the Langevin rate coefficient

$$k = v\pi b_{max}^2 = 2\pi e(\alpha_d/\mu)^{1/2} , \tag{37.20}$$

where μ is the reduced mass of the reactants. The theory leads to a temperature-independent rate coefficient with magnitude $\approx 10^{-9}\,\mathrm{cm^3\,s^{-1}}$. Numerous experiments from above room temperature to below $30\,\mathrm{K}$ confirm its validity for the majority of ion–molecule reactions, which appear rarely to possess potential energy surfaces with short-range barriers [37.18, 19].

An analogous central force potential for structureless neutral–neutral reactants is the van der Waals or Lennard–Jones attraction

$$V(r) = -C_6/r^6 , \tag{37.21}$$

where C_6 can be defined simply in terms of the ionization potentials and polarizabilities of the reactants [37.20, 21]. The rate coefficient obtained using a capture theory with this long-range potential is given, after translational thermal averaging, by the equation [37.21]

$$k(T) = 8.56\, C_6^{1/3}\mu^{-1/2}(k_B T)^{1/6} , \tag{37.22}$$

where all quantities are in cgs units. Equation (37.22) leads to estimates for the rate coefficient at room temperature in the range $\approx 10^{-10}$–$10^{-9}\,\mathrm{cm^3\,s^{-1}}$. Unlike the situation for ion–molecule reactions, this estimate has not received much attention mainly because most neutral–neutral reactions involve activation energy. Even for those systems without activation energy, the approximation appears to lead to rate coefficients that are too large by at least a factor of a few [37.21]. In place of the result of (37.22), kineticists often use the simple hardsphere model with atomic dimensions for the reaction cross section. The hard-sphere model leads to a temperature dependence of $T^{1/2}$, which is in disagreement with a whole series of new experiments by *Smith*, *Rowe*, and co-workers on fast neutral–neutral reactions down to temperatures near $10\,\mathrm{K}$ [37.22].

Both long-range potentials considered above are isotropic in nature. A variety of capture theories [37.23, 24] have been developed which take angular degrees of freedom into account. For ion–molecule systems in which the neutral species has a permanent dipole moment μ_d, the long-range potential becomes

$$V(r, \theta) = -\frac{e^2\alpha_d}{2r^4} - \frac{e\mu_d\cos\theta}{r^2} , \tag{37.23}$$

where θ is the angle between the radius vector from the charged species to the center-of-mass of the dipolar species and the dipole vector. Adiabatic effective (centrifugal) potential energy curves can be defined at any given fixed intermolecular separation r by diagonalizing angular kinetic energy and potential energy matrices using a suitable basis set. If an atomic ion is reacting with a linear neutral, a suitable basis set would consist of spherical harmonics for the rotation of the linear molecule (angular momentum j) as well as rotation matrices for the relative motion (angular momentum L) between the species. The eigenvalues of a matrix with fixed total angular momentum J then correspond to the effective radial potential energy functions V_{eff} at each r. The L, j labeling of the potential curves can be ascertained by starting the calculation at sufficiently large r so that L and j are reasonably good quantum numbers. Additional approximations, such as the centrifugal sudden approximation, can be made to facilitate the calculation [37.25]. Making the adiabatic assumption that transitions between these potentials are not allowed at long range, one obtains an adiabatic capture rate coefficient for each initial value of j and translational (radial kinetic) energy $\mathcal{T}_{AB}$ from the criterion

$$V_{eff}(j, L_{max}, R) = \mathcal{T}_{AB} , \tag{37.24}$$

where R is the separation corresponding to the maximum effective potential. Unlike the Langevin approach, the rate coefficients thermalized over translation for each j show an inverse dependence on temperature, with the $j = 0$ state showing the most severe dependence since the dipole is essentially "locked" for this state. Thermal averaging over j typically leads to rate coefficients with an inverse dependence on temperature between $T^{-1/2}$ and T^{-1} [37.26]. Rate coefficients as large as $10^{-7}\,\mathrm{cm^3\,s^{-1}}$ can be obtained as the temperature approaches $10\,\mathrm{K}$. Although most ion–dipole reactions seem to obey capture theory models at low temperature, there are exceptions.

An alternative approach to ion–dipole reactions using the classical concept of adiabatic invariants has been developed [37.27]. In addition, variants to the capture theory discussed here have been formulated. A statis-

tical adiabatic approach has been developed [37.23], in which adiabatic effective potential maxima are not used to define capture cross sections, but to define rate coefficients via the activated complex (transition state) theory discussed in Sect. 37.1.3, which posits thermal equilibrium between reactants and the species existing at the potential maxima. One advantage of this simplification is that it permits the adiabatic treatment to be more easily extended to complex geometries, especially if perturbation approximations are utilized. Other approaches involve the variational principle; an upper bound to the capture rate coefficient can be determined within the transition state, or bottleneck approach, which defines the transition state through minimization of the number of available vibrational/rotational states at the bottleneck [37.28] (see Sect. 37.1.3).

Nonspherical capture theories have also been used [37.29, 30] to study rapid neutral–neutral reactions. The role of atomic fine structure at low temperatures is an especially interesting application; reactions involving atomic C and O with a variety of reactants have been studied. Use of an electrostatic potential shows that the reactivity of C or O atoms in their $^3P_0$ states with dipolar species is minimal. This is particularly important for atomic carbon since at low temperatures it lies primarily in its ground $^3P_0$ state. The choice of an electrostatic potential has been disputed [37.21] because experimental results for C–hydrocarbon reactions at room temperature are best understood if the long-range potential is dispersive (Lennard–Jones) in character rather than electrostatic.

Reactions between radicals in $^2\Pi$ states (e.g. OH) and $^2\Sigma$ states (e.g. CN) and stable molecules have also been considered, especially at low temperature, with long range potentials that contain both electrostatic and dispersion terms. The results can be compared with new low temperature experimental results on the $CN-O_2$ reaction, but the temperature dependence is not matched by theory if the dispersion term is included [37.30, 31]. In general, even the most recent capture theories are not as reliable as those for ion–molecule systems [37.32]. Rapid neutral–neutral reactions can also be treated by transition state theories (see below) [37.33] or, rarely, by detailed quantum mechanical means [37.34].

The last five years have witnessed a burgeoning interest in rapid neutral–neutral reactions at low temperature studied with the so-called CRESU technique (an acronym for Cinétique de Réaction en Ecoulement Supersonique Uniforme) [37.22, 35–37]. The new data should provoke new attempts at theoretical understanding.

37.1.2 Phase Space Theories

Capture theories tell us neither the products of reaction, if several sets of exoergic products are available, nor the distributions of quantum states of the products. The simplest approach to these questions for reactions with barrierless potentials is to make a statistical approximation – all detailed outcomes being equally probable as long as energy and angular momentum are conserved. Such a result requires strong coupling at short range. The most prominent treatment along these lines is referred to as phase space theory [37.38]. In this theory, the cross section σ for a reaction between two species A and B with angular momentum quantum numbers J_A and J_B and in specific vibrational-electronic states colliding with asymptotic translational kinetic energy $\mathcal{T}_{AB}$ to form products C and D in specific vibrational-electronic states with angular momentum quantum numbers J_C and J_D is

$$\sigma(J_A, J_B \rightarrow J_C, J_D) = \frac{\pi \hbar^2}{2\mu \mathcal{T}_{AB}} \sum_{L_i, J} (2L_i + 1)$$
$$\times P(J_A, J_B, L_i \rightarrow J) P'(J \rightarrow J_C, J_D) , \quad (37.25)$$

where J is the total angular momentum of the combined system, L_i is the initial relative angular momentum of reactants, P is the probability that the angular momenta of the reactants add vectorially to form J, P' is the probability that the combined system with angular momentum J dissociates into the particular final state of C and D, μ is the reduced mass of reactants, and the summation is over the allowable ranges of initial relative angular momentum and total angular momentum quantum numbers. P' is equal to the sum over the final relative angular momentum L_f, of angular momentum allowed $(J \rightarrow L_f, J_C, J_D)$ combinations leading to the specific product state divided by the sum of like combinations for all energetically accessible product and reactant states. The ranges of initial and final relative angular momenta are given by appropriate capture models (e.g. Langevin, ion–dipole, Lennard–Jones) as well as angular momentum triangular rules. This procedure involves the implicit assumption that strong coupling does not occur at long range; rather, adiabatic effective potentials can be assumed for initial and final states. The state-to-state rate coefficient is simply the cross section multiplied by the relative velocity of the two reactants. Summation over all product states, as well as thermal averaging over the reactant state distributions and the translational energy distribution, can all be undertaken. Strategies for sum-

ming/integrating over rotational/vibrational degrees of freedom have been given [37.39]. As can be seen by writing out the expression for P', the phase space formula for the state-to-state cross section in (37.25) obeys microscopic reversibility:

$$2\mu \mathcal{T}_{AB}\sigma(J_A, J_B \rightarrow J_C, J_D)$$
$$= 2\mu' \mathcal{T}'_{AB}\sigma(J_A, J_B \leftarrow J_C, J_D) \qquad (37.26)$$

where the reduced mass and asymptotic translational energy of the products are denoted by primes. Thus, thermalization of the forward and backward rates leads to detailed balancing.

As a detailed theory for prediction of reaction products and their state distributions, phase space theory and its variants have had mixed success. It is true that the theory correctly predicts that exoergic reactions occurring on barrierless potential surfaces proceed on every strong collision. It is also true, however, that the theory is generally not useful in predicting the branching ratios among several sets of exoergic products because potential surfaces do not often show barrierless pathways for more than one set of products. When applied to product state distributions, the theory yields statistical results, so that population inversions in nondegenerate degrees of freedom (such as the vibrations of a diatomic molecule) are not replicated. With respect to more thermalized entities, such as total cross sections vs. collision energy for endoergic reactions [37.40], the theory can be quite successful, especially when the potential surface involves a deep minimum or intermediate complex. In this instance, the strong coupling hypothesis comes closest to actuality. A deep well is also associated with a high density of vibrational states in the quasicontinuum above the dissociation limit of the molecular structure defined by the potential minimum [37.1, 41, 42]. Such a high density renders direct (specific) dynamical processess less likely.

A useful variant of phase space theory if complex lifetimes are needed [37.43] (see Sects.37.1.4 and 37.2) is based on a unimolecular decay theory of *Klots* [37.44]. The reaction is considered to proceed via a capture cross section to form the intermediate complex, which then can dissociate into all available reactant and product states consistent with conservation of energy and angular momentum. The complex dissociation rate k_{uni} into a specific state can be obtained via the principle of microscopic reversibility in terms of the capture cross section from that state, obtained with $P' = 1$ in (37.25), to form the complex. In particular, if a complex with total angular momentum J can dissociate into one state of

reactants A and B separating with translational energy $\mathcal{T}_{AB}$, then

$$k_{uni} = \rho_{vib}^{-1} g(J)^{-1} g(J_A) g(J_B) 2\mu \mathcal{T}_{AB}\sigma(J_A, J_B \rightarrow J) , \qquad (37.27)$$

where ρ_{vib} is the density of complex vibrational states obtained via a variety of prescriptions [37.1, 41, 42], and g is the rotational degeneracy. A cross section analogous to that in (37.25) can be formulated in terms of capture to form the complex multiplied by the complex dissociation rate into a particular state divided by the total (summed) dissociation rate. Note that the dissociation rate of the complex is proportional to ρ_{vib}^{-1}. Since ρ_{vib} is a strong function of the well depth, long-lived complexes are associated with large well depths ($>1\,eV$). The Klots form for k_{uni} is especially useful for ion–molecule systems, where the cross section for complex formation can be assumed to be Langevin or ion–dipole. The concept of a long-range potential is less useful for most neutral–neutral systems, so that unimolecular rate coefficients for unstable entities are normally obtained quite differently in terms of ρ_{vib} at the transition state (Sect. 37.1.4).

For smaller reaction systems, especially those involving ions, it is quite common for the electronic states of reactants to correlate with more than one potential surface of the combined system, although typically only one surface leads to energetically accessible products. In such instances, it is normal to assume statistical partitioning, although fine structure effects can complicate this picture. A generalization of phase space theory to account for multiple potential surfaces has been proposed for the $C^+ + H_2$ reaction [37.45].

Phase space theory has been used to predict product branching ratios for dissociative recombination reactions between polyatomic positive ions and electrons [37.46]; its success here has been limited at best.

37.1.3 Short–Range Barriers

Most reactions involving neutral molecules, as well as a minority of ion–molecule reactions, possess potential surfaces with short-range barriers. The experimental rate coefficients of these systems over selected temperature ranges are normally fit to the Arrhenius expression (37.17).

The simplest theoretical method of taking short-range potential barriers into account is the line-of-centers approach, which resembles the capture theories previously discussed [37.7]. In this crude approxima-

tion, it is assumed that structureless reactants colliding with impact parameter b along a repulsive potential must reach some minimum distance, d, for reaction to occur. If the potential energy in the absence of angular momentum at d is E_0, this condition implies that the asymptotic translational energy of reactants $\mathcal{T}_{AB}$ must exceed the sum of E_0 and the centrifugal energy $\mathcal{T}_{AB}b^2/d^2$, which in turn yields a maximum impact parameter $b_{\max}$. Thermal averaging of the rate coefficient $k = v\pi b_{\max}^2$ over a Maxwell–Boltzmann distribution then yields

$$k(T) = \pi d^2 (8k_{\mathrm{B}}T/\pi\mu)^{1/2} \exp(-E_0/k_{\mathrm{B}}T) , \tag{37.28}$$

which bears some resemblance to the Arrhenius expression if one equates the parameter E_0 with the activation energy. Assuming $T = 300\,\mathrm{K}$, $\mu = 10\,\mathrm{u}$, and $d = 1\,\mathrm{\AA}$, the pre-exponential factor is $2.5 \times 10^{-11}\,\mathrm{cm}^3\,\mathrm{s}^{-1}$, which lies in a typical range.

The simple line-of-centers approach reduces the problem to that of structureless particles. The standard method of including all degrees of freedom is to use canonical ensemble statistical mechanics and to imagine that the transition state is in equilibrium with reactants. In the transition state, one of the vibrational degrees of freedom of a normal polyatomic molecule is replaced by a degree of freedom (the reaction coordinate) along which the potential is a maximum (with a corresponding imaginary frequency of vibration). The reaction coordinate is treated as a separable translation, so that the reaction rate coefficient can be envisaged as the equilibrium coefficient between transition state (minus one coordinate) and reactants multiplied by the (average) speed of the transition state structure over the saddle point in the potential energy surface. The canonical result for $k(T)$ is given by [37.1, 7]

$$k(T) = \frac{k_{\mathrm{B}}T}{h} \frac{q_{AB\dagger}}{q_A\,q_B} \exp(-E_0/k_{\mathrm{B}}T) \tag{37.29}$$

for reactants A and B, where E_0 is the energy difference between the transition state and the reactants referred to zero-point levels, the $\dagger$ refers to the transition state, and the q are partition functions per unit volume. The partition functions can be factored into products representing electronic, vibrational, rotational, and translational degrees of freedom [37.47]. This formulation for $k(T)$ is known as the activated complex theory (ACT); a more appropriate name would be transition state theory since the term activated complex is also used to refer to an unstable state of a molecule in a deep potential well. The rate coefficient can also be written in terms of the thermodynamic parameters $\Delta H^\dagger$ and $\Delta S^\dagger$ [37.1].

Both the size and temperature dependence of the pre-exponential factor depend critically on the characteristics of transition state and reactants. Originally, ACT theory was used mainly to fit transition state characteristics to rate data. Increasingly accurate ab initio calculations of potential surfaces now allow purely theoretical determinations of $k(T)$ [37.48].

In addition to the assumption of a separable reaction coordinate that can be treated as a translation, several other assumptions have gone into the derivation of the ACT rate coefficient. First, molecules at the saddle point configuration (the transition state) have been arbitrarily chosen to be in equilibrium with reactants. More recently, the transition state assumption has been generalized to refer to that portion of the potential surface in which the reaction flux or number of states is a minimum [37.49], whether or not this occurs at a well-defined saddle point. Loose transition states can thus be defined even if there is no barrier along the reaction coordinate [37.50]. The procedure can be undertaken for transition states as a function of temperature, energy, or, in its most detailed version, energy and angular momentum. The variational theorem shows rate coefficients determined in this way to be upper bounds to the true rate coefficients, the more detailed procedures leading to the better bounds [37.23, 49, 50]. Secondly, the implicit assumption is made that translation along the reaction coordinate at the transition state structure invariably leads to products. Sometimes a transmission coefficient κ is used as an unknown factor in the expression for $k(T)$ to account for the possibility that translation leads back to reactants instead. Thirdly, the assumption is made that two-body collisions can lead to canonical statistical equilibrium. This assumption becomes worse as temperature declines, because at low temperatures the long-range centrifugal constraints on angular momentum become more significant [37.8]. The influence of the long-range potential on ACT is contained in the statistical adiabatic theory discussed earlier [37.23]. Here loose transition states are defined as the maxima of effective adiabatic potential curves, and (37.29) must be modified since, as in detailed variational transition state theory, the transition states are themselves dependent on energy and angular momentum. A related problem is how to treat angular momentum constraints at low temperatures for potential surfaces which also contain a large short-range barrier or tight transition state. One approach is discussed in Sect. 37.1.4.

Rate coefficients derived from ACT do not indicate what the reaction products or sets of products might be. This information can be obtained from ab initio studies of the potential surface if different transition states lead to different products.

37.1.4 Complexes Followed by Barriers

Since long-range forces are always attractive, it makes sense to consider theories in which attraction and repulsion occur sequentially. For ion–molecule systems, this is especially important because many potential surfaces are monotonically attractive from long range to formation of a deep minimum at short range, but possess transition state barriers in their exit channels which are not large enough to prevent reaction but which affect the reaction dynamics. In addition, there are ion–molecule systems with potential surfaces closer to the norm for neutral–neutral species; in these systems there is only a weak long-range minimum followed by a short-range transition state barrier with energy above that of reactants. For the former type and, more arguably, for the latter type of potential surface, one can assume that the reaction proceeds through initial formation of an ergodic complex, followed by dissociation of the complex back into reactants or over the transition state barrier. If the reactants are labeled A and B, the complex AB^*, and the transition state $AB^\dagger$, the mechanism is

$$A + B \rightleftharpoons AB^* \longrightarrow AB^\dagger \longrightarrow \text{Product} , \quad (37.30)$$
which leads to the steady-state rate law

$$d[A]/dt = -k[A][B] , \quad (37.31)$$

$$k = \frac{k_{\text{cf}}}{k_{\text{cd}} + k_{\text{cd}'}} k_{\text{cd}'} , \quad (37.32)$$

where k_{cf}, k_{cd}, and $k_{\text{cd}'}$ are the rate coefficients for complex formation, redissociation into reactants, and dissociation into products over the transition state, respectively. One statistical approach to such systems is to use a capture theory for complex formation, to use the Klots formulation of complex redissociation into reactants, and to use a different theory for the unimolecular dissociation of the complex into products. Transition state theories of unimolecular complex decay have been studied for many years [37.1]. The current version is called RRKM theory, after the four authors *Rice*, *Ramsperger*, *Kassel*, and *Marcus* [37.10–13]. This theory builds upon the earlier RRK approach, in which random intramolecular vibrational energy transfer leads to large amounts of energy in the bond to be broken.

An alternative hypothesis, in which amplitudes of well-defined normal modes add up to extend the bond to be broken past a certain amount, is now discredited [37.51]. In the RRKM approach, which is perfectly analogous to ACT theory, an equilibrium is envisaged between the activated complex and transition state species. The main use of the theory is in thermal unimolecular decay where it explains complex activation, deactivation, and random unimolecular dissociation as a function of gas density. At high density in a thermal environment, an equilibrium among complex, activated complex, and transition state leads to a thermal unimolecular decay rate (37.13)

$$k_{\text{RRKM}}(T) = \frac{k_B T}{h} \frac{q_{AB}^\dagger}{q_{AB}} \exp(-E_0/k_B T) , \quad (37.33)$$

which is perfectly analogous to the ACT result. At lower pressures, the activated complex is not in thermal equilibrium with the stable complex and the details of complex activation and deactivation are important [37.12, 13].

In the microcanonical formulation of RRKM theory, the dissociation rate coefficient k_{RRKM} as a function of (activated) complex total energy E and angular momentum J is given by

$$k_{\text{RRKM}}(E, J) = \frac{N^\dagger[E - E_0 - E_{\text{rot}}(J)]}{h\rho^*[E - E_{\text{rot}}(J)]} , \quad (37.34)$$

where $N^\dagger$ refers to the total number of vibrational states of the transition state from its minimum allowable saddle point energy E_0 through E, and ρ^* refers to the density of vibrational states of the complex at energy E. For both the transition state and the complex, the available vibrational energy is the total available energy minus the rotational energy $E_{\text{rot}}(J)$, which is a function of the angular momentum J. The energy not used for vibration and rotation in the transition state is considered to belong to the separable reaction coordinate. The most common expressions for the number and density of vibrational states are the semiclassical empirical values [37.1, 41, 42]; direct counting schemes also exist [37.52]. Both empirical and direct counting refer to states representing a bath of harmonic oscillators; anharmonic effects are rarely treated.

A theory of reaction rates for the mechanism in (37.30) incorporating a capture theory, and the Klots and RRKM unimolecular decays has been applied successfully to a variety of ion–molecule reactions in competition with association channels for which the reaction proceeds via a deep well and an exit channel barrier (see Sect. 37.2.3) [37.53–55]. Some authors prefer to use RRKM theory to describe redissociation of the

complex into reactants [37.13, 56] by means of a loose transition state [37.57], which can be defined via a variety of variational and other methods [37.50]. Some recent work on unimolecular decay of polyatomic ions and neutrals following excitation indicates the superiority of the variational RRKM approach to unimolecular decay [37.58], especially if there is a significant amount of energy. Both the Klots and RRKM approaches to complex redissociation have problems associated with them: the Klots expression obeys microscopic reversibility but requires both a capture cross section and the assumption that the phase space formulation of the probability of individual quantum states is accurate; the RRKM expression does not obviously obey microscopic reversibility and, unless a variational calculation is performed, can create a somewhat artificial transition state.

Reaction mechanisms with more than one potential barrier can also be treated via a combination of ACT, capture, and unimolecular approaches [37.59, 60].

37.1.5 The Role of Tunneling

The role of tunneling in bimolecular and unimolecular reactions grows in importance as the temperature is lowered and hopping over potential barriers becomes more difficult. A simple one-dimensional correction for tunneling in the ACT expression for bimolecular rate coefficients, obtained by *Wigner* [37.1, 61], appears to be reasonable if the tunneling mechanism is not dominant. This correction $\Gamma > 1$ is simply the quantum correction to the partition function for the reaction coordinate:

$$\Gamma \approx 1 - \frac{(h\nu_i)^2}{24(k_B T)^2} + \cdots , \tag{37.35}$$

where ν_i is the (imaginary) harmonic frequency at the saddle point. Improved corrections have also been developed [37.62, 63] and, for the $H + H_2$ reaction, tested versus accurate quantum calculations [37.64]. At very low temperatures, such as those found in the interstellar medium, tunneling corrections are likely to be very large and to require proper multidimensional treatments.

A one-dimensional tunneling correction to the RRKM expression for the microcanonical unimolecular decay rate coefficient also exists [37.65]. The effective potential representing the reaction coordinate at the saddle point is assumed to be an Eckart barrier. The probability of tunneling for each vibrational state of the transition state is computed, and this probability takes the place of simply counting the state in the standard

formula for k_{RRKM}. In particular, $N^\dagger(E - E_0 - E_{rot})$ in the equation for $k_{RRKM}(E, J)$ is replaced by

$$N^\dagger_{QM}(E - E_0 - E_{rot}) = \sum_n P(E - E_0 - E_{rot} - \epsilon_n) , \tag{37.36}$$

where ϵ_n is the vibrational energy of state n of the transition state with respect to its zero point energy, and the sum is over all states n for which the energy in the reaction coordinate (the energy in parentheses on the right-hand-side) is negative, but not so negative that the classical energy in the reaction coordinate lies below the minimum of the complex potential well. In general, only a few vibrational states of the transition state need be considered for the tunneling correction.

This tunneling correction has been incorporated into statistical theories for the rate of reactions that proceed via complexes and transition state barriers [37.60]. It has been used recently in a calculation of the slow ion–molecule reaction

$$NH_3^+ + H_2 \longrightarrow NH_4^+ + H , \tag{37.37}$$
which successfully reproduces the observation that, despite initially decreasing as the temperature is reduced below 300 K, the reaction rate coefficient begins to increase as the temperature is decreased below 100 K [37.66]. The parameters for the calculation were obtained from an ab initio calculation of the potential surface, which shows the system to proceed through a weakly-bound long-range complex before encountering a transition state with a rather small barrier of $\approx 0.25\,eV$. Although the dynamical theory is not quantitative (presumably because of the one-dimensional tunneling approximation), it does reproduce the isotope effects seen when the reactants $NH_3^+ + D_2$ and $ND_3^+ + H_2$ are used, definitively showing that tunneling is the cause. The actual increase in rate at very low temperature comes from the fact that the tunneling rate is less dependent on temperature than the dissociation rate of the complex into reactants. Similar calculations have been performed for the analogous ion–molecule reaction

$$C_2H_2^+ + H_2 \longrightarrow C_2H_3^+ + H \tag{37.38}$$
to explain a similar observation, although in this latter instance there is still a controversy concerning whether or not the reaction is truly exoergic [37.67]. It is interesting to speculate on whether similar effects can be detected for analogous neutral radical–H_2 reactants with moderate activation energy barriers, such as

$$CCH + H_2 \longrightarrow C_2H_2 + H . \tag{37.39}$$
This system possesses a transition state of rather moderate energy [37.48], but the only long-range complex is presumably the very weakly-bound van der Waals structure. Unlike the ion–molecule case, there are very few experimental studies of low temperature neutral–neutral reactions. Studies of pressure broadening at very low temperatures do reveal, however, the strong influence of the van der Waals bond [37.68].

37.2 Association Reactions

Association reactions have been studied for both ion–molecule and neutral–neutral systems. For the ion–molecule case, association processes can be investigated in great detail at low densities near or in the radiative association regime because ions can be stored in low pressure traps. Review articles [37.69, 70] describe such experiments for small and large ions, respectively. The results of many higher pressure studies of termolecular ion–molecule association, especially those undertaken in the SIFT apparatus, are also available [37.71]. In general, below the high pressure limit, the rate of association reactions without activation energy is known to increase with (a) an increase in the size of the reactants, (b) an increase in the bond energy of the product species, and (c) a decrease in temperature. These trends are all reproduced by statistical theories in which association proceeds by the formation of a complex followed by radiative and/or collisional stabilization [37.8]. More limited data for termolecular neutral–neutral reactions, with and without short-range potential barriers, have also been reviewed [37.72]. Although radiative stabilization can proceed via a single photon, collisional stabilization proceeds most probably in a stepwise fashion rather than in a single strong collision. The most detailed statistical theories incorporating multistep collisional stabilization use master equation techniques; in general it is preferable to solve the inverse problem of unimolecular dissociation via detailed RRKM theory and then invoke detailed balance [37.13, 56]. Such theories are more successful than strong collision approaches, especially in considering the dependence of ternary association rates on pressure. This dependence can be especially difficult to treat when association competes with an exoergic channel which does not necessarily dominate because of a barrier in the exit channel.

37.2.1 Radiative Stabilization

The problem of radiative association in the absence of competitive exoergic channels is in principle much more simple. In addition to the rates of complex formation and dissociation, one needs only the rate of stabilization via spontaneous emission. If the complex abundance is at steady state, the rate law for radiative association of species A and B is simply

$$\mathrm{d}[A]/\mathrm{d}t = -k_{\mathrm{ra}}[A][B] , \tag{37.40}$$

$$k_{\mathrm{ra}} = \frac{k_{\mathrm{cf}}}{k_{\mathrm{cd}} + k_{\mathrm{rad}}} k_{\mathrm{rad}} , \tag{37.41}$$

where k_{ra} represents the rate coefficient for radiative association and k_{rad} refers to the rate coefficient for radiative stabilization. If ternary association is considered in addition, the rate coefficient for radiative association is the low pressure limit of a more complex rate expression.

Radiative stabilization, which is normally considered to proceed via emission of a single infrared photon, has been studied in some detail [37.73–75]. If the unstable complex is imagined to be a collection of harmonic oscillators, each vibrational state i, which is best regarded as a Feshbach resonance, can be expressed as a set of occupation numbers $n_1^i, n_2^i, \dots, [n^i]$ for the assorted modes. If it is further assumed that upon formation, the complex has a probability P_i of being formed in state i, the rate of single-photon vibrational emission $k_{\mathrm{rad}} \ (\mathrm{s}^{-1})$ is then given by

$$k_{\mathrm{rad}} = \sum_{i,j} P_i A_{i \to j} = \sum_{[n^i],[n^j]} P_{[n^i]} A_{[n^i] \to [n^j]} , \tag{37.42}$$

where the sum is over initial states i and final states j, and A is the Einstein coefficient for spontaneous emission. With some algebraic manipulation and the assumption that dipole selection rules apply, the result simplifies to

$$k_{\mathrm{rad}} = \sum_{k=1}^{s} \sum_{n_k} P_{n_k}^k n_k A_{1 \to 0}^k , \tag{37.43}$$

where the index k refers to each of the s normal modes, the index n_k to the occupation number of mode k, and the Einstein A coefficient, which here refers to the fundamental transition of mode k, can be expressed in terms of the absorption intensity (see Chapt. 10). The proba-

bility $P_{n_k}^k$ that mode k is excited to state n_k is given by the statistical formula

$$P_{n_k}^k = \rho'_{\text{vib}}(E_{\text{vib}} - n_k h \nu_k) / \rho_{\text{vib}}(E_{\text{vib}}) , \qquad (37.44)$$

where ρ_{vib} is the vibrational density of states and ρ'_{vib} is the reduced density of states when n_k quanta are assigned to mode k. The role of overtone and combination contributions to the radiative emission rate has also been investigated [37.74], as have a canonical approximation to the microcanonical formulation discussed here [37.75] and the small additional effect of stabilization by sequential emission [37.73]. With the use of the classical approximation to the standard vibrational density of state functions [37.41, 42], (37.43) for k_{rad} reduces to a linear function of the vibrational energy:

$$k_{\text{rad}} = \frac{E_{\text{vib}}}{s} \sum_{k=1}^{s} \frac{A_{1 \to 0}^k}{h \nu_k} . \qquad (37.45)$$

The constant of proportionality between k_{rad} and E_{vib} depends strongly on the fundamental intensities; many of these can be obtained from infrared absorption spectra, although there is normally insufficient information for all of the active modes in polyatomic molecules, especially ions. Reasonable estimates, as well as limited experimental data, show that k_{rad} varies between 10 and $1000 \, \text{s}^{-1}$ for vibrational energies up to a few eV [37.69, 70, 73–75]. The radiative stabilization rate typically decreases slightly with increasing molecular size due to the inclusion of infrared inactive modes of vibration. There also appears to be a distinction between ions and neutral species, with rates for ions apparently faster.

Since spontaneous emission rates between electronic states are often far more rapid than infrared vibrational rates, the possibility that radiative stabilization can proceed via electronic emission has been examined [37.9]. The well-studied association between C^+ and H_2 appears to proceed via electronic relaxation, with a radiative stabilization rate one to two orders of magnitude larger than would be the case for vibrational emission. Whether or not the association between CH_3^+ and H_2 proceeds via an electronically excited complex has been debated for some time; the answer is apparently negative [37.69].

37.2.2 Complex Formation and Dissociation

The formation and dissociation of the complex can be studied with a variety of statistical approximations other than what is discussed in this section. In particular, complex dissociation has been treated by a thermal RRKM

approach [37.70, 75], an energy but not angular momentum specific RRKM approach [37.73], variational transition state theory, statistical adiabatic theory, and flexible transition state theory [37.72]. We first consider a simple thermal approximation for systems without activation energy incorporating microscopic reversibility [37.8]. In the limit that the complex redissociation into reactants is much more rapid than radiative stabilization, the rate coefficient k_{ra} for radiative association in the thermal model is

$$k_{\text{ra}} = K(T) k_{\text{rad}} , \qquad (37.46)$$

where $K(T)$ is the ratio between k_{cf} and k_{cd} in a canonical ensemble, and the radiative stabilization rate has been assumed to be independent of temperature. The equilibrium coefficient $K(T)$ between complex and reactants can be rewritten in terms of partition functions in the standard way [37.47]. However, the partition function of the complex is best calculated via the equation

$$\begin{aligned} q_{AB^*} &= \int_0^\infty \rho_{\text{vr}}(E + D_0) \exp(-E/k_B T) \, dE , \\ &\approx \rho_{\text{vr}}(D_0) k_B T , \quad D_0 \gg k_B T , \end{aligned} \qquad (37.47)$$

where ρ_{vr} is the density of vibrational-rotational states [37.41, 42], E is the energy of reactants, and D_0 is the bond energy of the complex. One immediate prediction of this approach (deriving mainly from the rotational partition functions of the reactants) is that k_{ra} possesses a strong inverse dependence on temperature since

$$K(T) \propto T^{-(r_A + r_B + 1)/2} , \qquad (37.48)$$

where r refers to the number of rotational degrees of freedom (two for a linear molecule and three for a nonlinear one). It also predicts a strong dependence on well depth and size of the complex since the density of complex states is a strong function of both these parameters. Although the thermal model agrees with the strong inverse temperature dependence of the coefficients for both radiative and, more commonly, ternary ion–molecule association [37.8, 71] (in which case, the thermal model with strong collisions replaces k_{rad} with a collisional rate coefficient), the absolute rate coefficients calculated tend to range up to an order of magnitude too high. Given the large range of values exhibited by radiative association rate coefficients $\left(10^{-20}–10^{-9} \, \text{cm}^3 \, \text{s}^{-1}\right)$, this might not seem too large a problem. It has been shown, how-

ever, that the thermal model is deficient, especially at low temperatures because thermal equilibrium cannot be achieved by two-body collisions [37.8]. A revised approach, called the modified thermal theory, replaces the rovibrational density of complex states in the thermal model with a vibrational density of states coupled with sums over the allowable ranges of complex angular momentum achievable from the specific capture model assumed [37.8]. The result is a somewhat lessened inverse temperature dependence and somewhat smaller rate coefficients, especially at low temperatures. Both modifications result in better agreement with experiment [37.8].

The modified thermal approach considers structureless reactants; full consideration of the internal states of the reactants is achieved via the Klots version of phase space theory, in which k_{cf} and k_{cd} in (37.41) are the capture and unimolecular rates discussed in Sect. 37.1.2. The phase space treatment reduces to the modified thermal treatment for small reactant angular momentum if the possibility of saturation $[k_{cd}(E, J) < k_{rad}]$ may be ignored. Both conditions are normally met. The phase space approach has also been used for ion–molecule ternary association reactions, but here is coupled with the strong collision hypothesis and must be regarded as inferior to the more detailed RRKM calculations with master equation treatments for collisional stabilization [37.13, 56].

37.2.3 Competition with Exoergic Channels

There have been numerous reactions reported (especially ion–molecule reactions) in which exoergic reaction channels compete with association channels, both radiative (at low pressure) and ternary (at higher pressures). One view of such competition is that it occurs via a sequential mechanism in which the reactants form a long-lived collision complex which either redissociates, dissociates into exoergic products, or is stabilized [37.53, 54]. The rate coefficient for competitive radiative association is then given by the steady-state expression

$$k_{ra} = \frac{k_{cf}}{k_{cd} + k_{cd'} + k_{rad}} k_{rad} , \qquad (37.49)$$

where $k_{cd'}$ refers to complex dissociation into products. The additional and normally large $k_{cd'}$ term in the denominator means that the thermal and modified thermal theories cannot, in general, be used. The phase space treatment for this mechanism [37.53, 54, 76, 77] shows that association cannot compete with exoergic channels unless there is a significant barrier in the exit channel which considerably slows the dissociation rate of the complex into products, especially for partial waves of high angular momentum. Such barriers tend to be large enough to slow dissociation down, but not large enough to require tunneling. Although the results of phase space calculations are in good agreement with experiment for a variety of competitive systems [37.69, 76], they are once again inferior to RRKM calculations with master equation collisional deactivation when the competition involves collisional stabilization of the complex [37.13, 53, 54, 56].

Another mechanism exists for competition between association and normal exoergic channels [37.69]. Ab initio studies show that there is a parallel type of competition in which the product and association channels occur on different portions of the potential surface, with a branching at long range in the entrance channel. For example, the competing reactions [37.69, 78]

$$C_2H_2^+ + H_2 \longrightarrow C_2H_3^+ + H , \qquad (37.50)$$
$$C_2H_2^+ + H_2 \longrightarrow C_2H_4^+ , \qquad (37.51)$$
occur via distinct pathways. The former reaction is a possibly endoergic direct process in which the molecular hydrogen attacks perpendicularly, leading to the cyclic form of the $C_2H_3^+$ ion, whereas the association reaction occurs via the deep well of the ethylene ion. The competition in the analogous $C_3H^+ + H_2$ system is not currently well understood, with both parallel and series mechanisms suggested [37.69, 79].

37.3 Concluding Remarks

While the study of chemical reaction dynamics and kinetics is a relatively mature area of investigation, many challenges remain. A central one is the development of an efficient, fully quantum mechanical method for evaluating $k(T)$ that can be applied to a range of systems [37.80]. A second set of challenges comes in the

intrinsically non-adiabatic nature of chemical reactions. As a system moves from reactants to products, there is a dramatic change in the electronic wave function. In fact the very existence of a transition state reflects the avoided crossing of two potential energy surfaces. There is experimental and theoretical evidence that the

fact that the dynamics takes place on multiple potential surfaces has a large effect on the gas-phase state-to-state dynamics, and eventually the rate coefficients. Finally, as the evaluation of the electronic structure of atoms and molecules becomes more easily accomplished through the use of sophisticated computer packages, researchers will be able to ask more detailed questions about the relationships between the topology of potential surfaces and the corresponding rate coefficients than was possible as recently as ten years ago [37.81].

38. Gas Phase Ionic Reactions

Ionic reactions in the gas phase is a broad field encompassing a multitude of interactions between ions (both positively and negatively charged), electrons and neutrals. These can be as simple as the transfer of an electron between molecules, or can be complex with considerable bond breaking, reforming and rearrangement. Reactions of the general type

$$A^{+,-} + B^{-,n} \rightarrow \text{products} , \tag{38.1}$$

illustrating this diversity, are given in Table 38.1. The reaction process can be considered as consisting of three parts: (a) the initial interaction, in which the colliding particles, $A^{+,-}$ and $B^{-,n}$ are drawn together by an attractive potential, (b) the reaction intermediate and transition state, in which reactants are transformed into products

and (c) the weakening interaction as the product particles separate. Interactions can also occur where only elastic scattering is involved and these are considered in Chapt. 67.

38.1 Overview

Part (a) of the interaction is readily studied theoretically by classical mechanics in terms of reactant particle motions controlled by the interaction potential $u(r)$ between the particles, where r is the interparticle separation. For ion–neutral interactions, this can take the form (i) of an attractive ion-polarization or induced dipole potential [38.1] $u(r) = -\alpha_d q^2/2r^4$, where α_d is the polarizability of the neutral and q is the charge on the ion; anisotropy in the polarizability can also be taken into account [38.2], (ii) of an ion-permanent dipole potential [38.3] with $u(r) = -q\mu_D \cos\theta/r^2$, where μ_D is the permanent dipole of the neutral and θ is the angle that the dipole makes with r, and (iii) of an ion-quadrupole potential [38.4] with $u(r) = -Qq(3\cos^2\theta - 1)/2r^3$, where Q is the quadrupole moment and θ is the angle the quadrupole axis makes with r. Such capture theories are considered in Chapt. 37. Other interaction potentials can be considered, but these are of lesser significance. Coulombic interaction potentials $u(r) = -q_1 q_2/r$, where q_1 and q_2 are the charges on the interacting particles, are appropriate for positive ion–negative ion recombination (more correctly

termed mutual neutralization) and electron–ion recombination. For processes involving electrons, i. e., electron attachment and electron–ion recombination, the wave nature of the electron also has to be considered [38.5, 6].

In addition to providing a means of bringing the reactant particles together, the attractive interaction potential has another function. In part (b) of the reaction mechanism, where considerable rearrangement of the atoms in the colliding species may occur (i. e., in the intermediate complex and transition state), there may be barriers to reaction. Here, the kinetic energy gained from the interaction potential is available in the intermediate complex for overcoming such energy barriers (very much less interaction energy is available in neutral-neutral reactions and the effects of energy barriers are very much more evident [38.7]). Of course, this energy has to be reconverted to potential energy as the product particles separate, and is therefore not available to drive the overall reaction. However, the amount of energy returned may differ from that initially converted to kinetic energy since

Table 38.1 Examples illustrating the range of ionic reactions that can occur in the gas phase

Reaction Process	Reaction Type
$Ar^+ + O_2 \rightarrow O_2^+ + Ar$	Nondissociative charge transfer/charge exchange
$O_2^- + NO_2 \rightarrow NO_2^- + O_2$	
$He^+ + O_2 \rightarrow O^+ + O + He$	Dissociative charge transfer
$C_{60}^{3+} + Corannulene \rightarrow Corannulene^{2+} + C_{60}^+$	Multiple charge transfer
$O^+ + N_2 \rightarrow NO^+ + N$	Ion/atom interchange or atom abstraction
$O^- + CH_4 \rightarrow OH^- + CH_3$	Atom abstraction
$H_3O^+ + HCN \rightarrow H_2CN^+ + H_2O$	Proton transfer
$OH^- + HCN \rightarrow CN^- + H_2O$	
$OH^- + H \rightarrow H_2O + e^-$	Associative detachment
$C^+ + C_2H_2 \rightarrow C_3H^+ + H$	Atom insertion
$CH_3^+ + H_2 + M \rightarrow CH_5^+ + M$	Ternary collisional association
$Cl^- + BCl_3 + M \rightarrow BCl_4^- + M$	
$He_2^+ + e^- \rightarrow He_2(2He) + h\nu$	Radiative electron–ion recombination
$HCO^+ + e^- \rightarrow H + CO$	Dissociative electron–ion recombination
$NO^+ + NO_2^- \rightarrow NO + NO_2$	Ion–ion recombination (mutual neutralization)
$e^- + CCl_4 \rightarrow Cl^- + CCl_3$	Dissociative electron attachment
$e^- + C_7F_{14} \rightarrow C_7F_{14}^-$	Nondissociative electron attachment
$e^- + O_2 + M \rightarrow O_2^- + M$	Ternary collisionally stabilized attachment
$^{13}C^+ + {}^{12}CO \rightleftharpoons {}^{12}C^+ + {}^{13}CO$	Isotope exchange
$OD^- + NH_3 \rightleftharpoons OH^- + NH_2D$	

the polarizability/dipole moment of the product neutral(s) may differ from those of the reactant neutrals. Generally, the final part (c) of the interaction has little influence on the magnitude of the reaction rate coefficient or on the product distribution once the products have significantly separated (i. e., beyond the range at which processes such as long range electron transfer can occur). Thus, to a major degree, part (b) of the mechanism and the reaction energetics determine the products of the reaction. Theories which address this part of the interaction are also discussed in Chapt. 37 and these have met with mixed success. Thus, at present, experimental measurements are providing a more definitive understanding of reactions and their mechanisms.

Also, the situation is not in general clear as to the form of the thermodynamic energy that governs whether a reaction will proceed spontaneously, i. e., whether it is controlled by the enthalpy change ΔH in the reaction or by the Gibbs' free energy change $\Delta G = \Delta H - T \Delta S$, where ΔS is the entropy change in the reaction [38.8]. This is discussed in more detail in Sect. 38.2.

Rate coefficients and product distributions for these reaction processes are important in all ionized media where molecular species exist, such as interstellar gas clouds [38.9], planetary atmospheres [38.10] (including that of the Earth [38.11, 12]), comets (Chapt. 83), the space shuttle environment [38.13], laser plasmas [38.14], plasmas used to etch semiconductors [38.15], hydrocarbon flames [38.16], etc.

38.2 Reaction Energetics

The availability of sufficient energy is a primary consideration for determining whether a reaction can proceed spontaneously. Criteria for determining whether energy is given out or absorbed in a reaction are (i) exo- or endoergicity, ΔE representing the internal energy change involved in a single interaction, (ii) exo- or endothermicity for an ensemble of particles in ther-

mal equilibrium as defined by the enthalpy change per mole, ΔH, in the reaction and (iii) exergonic or endergonic as defined by the Gibbs' free energy change, ΔG [38.17]. ΔE is related to ΔH at temperature T by

$$\Delta H_T \approx -N \Delta E_T \,, \tag{38.2}$$

where N is Avogadro's number. ΔE is usually deduced from bond energies [38.18–20], ionization potentials [38.21], electron affinities [38.22, 23], proton affinities [38.22, 24, 25], gas phase basicities [38.22, 24–26], etc. ΔH_T^0 is determined from the heats of formation $H_{f,T}^0$ by [38.27]

$$\Delta H_T^0 = \sum_{\text{products}} H_{f,T}^0 - \sum_{\text{reactants}} H_{f,T}^0 , \qquad (38.3)$$

where the superscript 0 refers to the standard state [38.17] of the reactants and products [for example, see (38.1)]. ΔG_T^0 is determined from ΔH_T^0 and the entropy change ΔS_T^0 by

$$\Delta G_T^0 = \Delta H_T^0 - T\Delta S_T^0 , \qquad (38.4)$$

where

$$\Delta S_T^0 = \sum_{\text{products}} S_T^0 - \sum_{\text{reactants}} S_T^0 , \qquad (38.5)$$

and the S_T^0 are the standard entropies [38.17]. In cases where all of the $H_{f,T}^0$ and S_T^0 are not available, they can often be deduced by constructing other reactions involving the species of interest and other species for which the required thermodynamic information is known ([38.17] discusses the details of ways in which this can be achieved). Alternatively, the magnitude of a thermodynamic parameter can be calculated using equilibrium statistical thermodynamics, if the energies of all of the occupied molecular energy levels are known [38.28]. For studies where all reacting particles of a given type have the same energy, such as in beam/beam interactions where cross sections $\sigma(E)$ are measured, then ΔE is most appropriate. Alternatively, for reactions involving an ensemble of particles in thermal equilibrium at a temperature T, such as those studied in high pressure mass spectrometer ion sources or afterglows where rate coefficients $k(T)$ are measured, ΔH and ΔG are more appropriate. (The terms "rate coefficient" and "rate constant" are used interchangeably in the literature.) $\sigma(E)$ and $k(T)$ are directly related via

$$k(T) = \int_0^\infty v(E)f(E)\sigma(E)\,\mathrm{d}E , \qquad (38.6)$$

where $v(E)$ is the relative speed of the reactants and $f(E)$ is the Maxwell–Boltzmann energy distribution. Whether ΔH or ΔG is more important for determining reaction spontaneity depends on the degree of interaction of the reacting systems with the surroundings during the course of the whole reaction process. For example, if the reactions occur at low pressure such that the reaction time is much less than the collision time with the background gas, there will be no interactions with the surroundings, and the only energy available in the reactions will be ΔH. Here, ΔS can only determine the probability that the intermediate complex dissociates forward to products or back to reactants. At the other extreme, if the reactions are conducted at high pressure such that the reaction species are always in thermal equilibrium with the surroundings (the limiting case of this is reaction in solution), then the additional energy $T\Delta S$ is available, and ΔG determines whether the reactions are spontaneous. Obviously, for intermediate pressures, there is a varying degree of contact with the surroundings, and which of ΔH and ΔG is most applicable is more obscure. The definition of surrounding is also somewhat loose, since in the present context it represents anything that can provide a source of energy during the reaction (for example, vibrational modes of the reacting species that are not involved in the interaction and which could be cooled as the reaction proceeds). Usually, the $T\Delta S$ term is not sufficiently large that ΔH and ΔG have different signs so that confusion about the spontaneity of reactions often does not arise. Recently, however, reactions have been discovered which appear to proceed spontaneously even though ΔH is positive, and there has been considerable discussion of this [38.8].

Eventually, all reaction processes will reach equilibrium as defined by

$$\Delta G = -\mathrm{RT}\ln K , \qquad (38.7)$$

where

$$K = \left(p_C^c\, p_D^d\right) / \left(p_A^a\, p_B^b\right) \qquad (38.8)$$

is the equilibrium constant for the reaction

$$aA + bB \rightleftharpoons cC + dD . \qquad (38.9)$$

The subscripts to the pressures p denote the components A to D, and the superscripts represent the stoichiometries [38.17, 28]. The equilibrium constant K also equals k_f/k_r, the ratio of the forward to reverse rate coefficients, obtained for thermalized particles at temperature T. Thus, from measurements of k or the equilibrium constant at a series of temperatures, ΔH and ΔS of the reaction can be separately obtained.

38.3 Chemical Kinetics

The rate coefficient k for the reaction process

$$A + B \rightarrow C + D \qquad (38.10)$$

is defined by the rate equation [38.29]

$$\frac{d[A]}{dt} = \frac{d[B]}{dt} = -k[A][B] , \qquad (38.11)$$

where the square parentheses represent the concentrations of the enclosed species, and the units of k are typically $cm^3 \, molec^{-1} \, s^{-1}$ (often $molec^{-1}$ is not written explicitly in the units). These k are deduced from the time variation of specific concentrations of thermalized reactants under a variety of conditions. For ion–neutral reactions, with A being the positive or negative ion species, the situation can usually be achieved in the laboratory where $[B] \gg [A]$, i. e., a pseudo first-order reaction. Simple integration yields

$$[A]_t = [A]_0 \exp(-k[B]_0 t) , \qquad (38.12)$$

where the subscript 0 indicates that this concentration is time invariant. Similar circumstances apply to binary electron attachment reactions, where $[A] = [e]$, the electron number density (the symbol β is often used here in place of k). If the reaction proceeds by association that is stabilized by collision with a third body M then

$$A + B + M \rightarrow AB + M , \qquad (38.13)$$
and the solution is

$$[A]_t = [A]_0 \exp(-k[B]_0[M]_0 t) \qquad (38.14)$$

with k now having units of $cm^6 \, molec^{-2} \, s^{-1}$. Note that situations exist where binary and ternary reactions can occur simultaneously.

If $[B] \gg [A]$, the solution of (38.11) is different. For the special case $[B] = [A]$, integration yields

$$1/[A]_t - 1/[A]_0 = kt , \qquad (38.15)$$

and similarly for $[B]$. This situation is usually achieved in the laboratory for the determination of k for electron–ion and ion–ion recombination (the symbols α_e and α_i respectively are often used to replace k here). In many applications where several processes contribute to changes in $[A]$ and $[B]$, and where the simple limits are not applicable, the situation has to be analyzed numerically.

38.4 Reaction Processes

Recently, a nine volume series, concerned with all aspects of mass spectrometry, is being published of which Volume 1 deals with theoretical and experimental aspects of ionic reactions in great detail [38.30]. The reader is recommended to first consult the present chapter to get an overview of the reaction processes, and to go to this other text if more detail is required.

The wide variety of possible reaction processes is listed in Table 38.1 by specific examples. However, the reaction mechanisms illustrated are completely general. Magnitudes of the rate coefficients for binary interactions between charged and neutral particles, vary from $10^{-7} \, cm^3 \, s^{-1}$ for electron attachment [38.31,32] to 10^{-8} or $10^{-9} \, cm^3 \, s^{-1}$ for unit efficiency ion–molecule reactions [38.33–36]. The efficiency is defined as the ratio of the measured k to the theoretical collisional value, i. e., that determined using the appropriate interaction potential. Ion–molecule reactions involving molecules with large permanent dipoles (for example, HCN at 2.98 D and HCl at 1.08 D [38.37]), can have $k > 10^{-7} \, cm^3 \, s^{-1}$ at low T [38.37–39] due to locking of the dipole along the line joining the reactant species, thereby maximizing the strength of the interaction. Rate coefficients can be much smaller (by orders of magnitude) than these upper limits if the efficiency of part (b) of the mechanism is small. The part of the mechanism after collision occurs is treated by transition state theory in terms of the partition function of the transition state; where the transition state is, and its partition function, relates to the number of ways that the available energy can be distributed in the transition state [38.40]. More details of the theories are given in Chapt. 37 and [38.41].

For dissociative electron–ion recombination, the upper limits on k are generally much larger as a consequence of the long range Coulombic interaction potential, varying from $\approx 10^{-7} \, cm^3 \, s^{-1}$ for diatomic ions to $> 10^{-6} \, cm^3 \, s^{-1}$ for more polyatomic species [38.42–45]. For ion–ion recombination, the rate coefficients are about an order of magnitude smaller than these values because of the larger mass of the negative ion relative to the electron, and thus the smaller interaction velocity (the σ of the two processes are, in fact, similar) [38.46]. Electron–ion recombinations that are radiatively stabilized generally have a small k, as small as $\approx 10^{-12} \, cm^3 \, s^{-1}$ [38.47], be-

cause of the large magnitude of the radiative lifetime of the reaction intermediate compared with the time for autoionization. For most reaction types, experimental rate coefficients are available at room temperature, and for some, the temperature and/or energy dependencies have also been determined [38.31, 32, 43, 44, 46, 48]. Generally, only the ion products are identified using mass spectrometry, and the product neutrals are not determined (unless the energetics allow only one neutral product), and the states of excitation of the products are not identified.

For ternary processes involving association, k varies from totally saturated at the binary collision limit to very small ($\approx 10^{-32}\,\text{cm}^6\,\text{s}^{-1}$) for ion–neutral reactions [38.33, 34] and similarly for electron attachment [38.49]. Little is known about collision stabilized recombination [38.50]. Each type of reaction process has its own characteristic behavior and dependence on temperature. Rate coefficients, temperature dependencies, and product distributions (where available) have been tabulated for ion–neutral reactions [38.33, 34, 51] and electron attachment [38.31, 32]. Less data are available for electron–ion and ion–ion recombination, so no attempts have been made to compile these. Data are available in [38.6, 42–44, 46].

38.4.1 Binary Ion–Neutral Reactions

Over the years, these reaction processes have been reviewed several times, but from different perspectives. Most recently, studies of positive ion–molecules in flow tubes [38.52] and negative ion–molecule reactions from an organic mechanistic viewpoint [38.53] have been discussed.

Charge Transfer and Charge Exchange
These processes involve the exchange of an electron which can occur at relatively large interparticle separations (i.e., up to $\approx 6\,\text{Å}$ [38.54]). Thus, in principle, k values can be larger than the collision limiting value. Such reactions are, in general, relatively fast, although there are some notable exceptions (for example, $\text{He}^+ + \text{H}_2, k = 1 \times 10^{-13}\,\text{cm}^3\,\text{s}^{-1}; \text{Ne}^+ + \text{H}_2, k < 2 \times 10^{-14}$ and $\text{Ne}^+ + \text{N}_2, k = 1.1 \times 10^{-13}$ [38.33]). Attempts have been made to relate the efficiency of charge transfer to the Franck–Condon overlap between the neutral reactant and the product ion, with mixed success [38.55]. More energy is generally available in the positive ion reactions than the negative ion reactions since ionization potentials are much larger than electron affinities, and thus more dissociative products would be expected, as

is usually observed. The reaction

$$\text{He}^+ + \text{N}_2 \rightarrow \begin{cases} \text{N}^+ + \text{N} + \text{He} + 0.28\,\text{eV} \\ \text{N}_2^+ + \text{He} + 9.00\,\text{eV}, \end{cases}$$
is particularly interesting and has been studied in considerable detail. The product distribution slightly favors N^+ (60%) rather than N_2^+ [38.56], with the N^+ channel becoming even more important with increasing vibrational temperature of the N_2 [38.57]. Spectroscopic emission studies [38.58] have shown that a significant fraction ($\geq 5\%$) of the reactions proceed by charge transfer into the $\text{N}_2^+\left(\text{C}\,{}^2\Sigma_g^+\right)$ state followed by the radiative decay

$$\text{N}_2^+\left(\text{C}\,{}^2\Sigma_u^+\right) \rightarrow \text{N}_2^+\left(\text{X}\,{}^2\Sigma_g^+\right) + h\nu. \tag{38.16}$$
This channel competes with the predissociation

$$\text{N}_2^+\left(\text{C}\,{}^2\Sigma_u^+\right) \rightarrow \text{N}^+ + \text{N}. \tag{38.17}$$

A new mechanism has recently been observed in which charge transfer occurs in parallel with chemi-ionization (or, equivalently, electron detachment):

$$\text{He}^+ + \text{C}_{60} \rightarrow \text{C}_{60}^{2+} + \text{e}^- + \text{He}. \tag{38.18}$$
Such a process is, of course, only energetically possible for high recombination energy ions like He^+ and Ne^+ [38.59]. Also, multiply charged $\text{C}_{60}\left(\text{C}_{60}^{3+}\right)$ has been seen to undergo two electron transfer with Corannulene and some Polycyclic Aromatic Hydrocarbons (PAH's), generally in parallel with a whole series of other reaction channels [38.60].

Proton Transfer
Where proton transfer is significantly exoergic, as determined by the difference in the proton affinities of the reactant and product neutrals, reaction usually proceeds at the collisional rate [38.61]. If the reaction is close to thermoneutral, then the amount of phase space available when the intermediate complex dissociates to products is similar to that available when it dissociates back to the reactants, and the k approximates to one-half the collisional value. For proton transfer reactions which are not highly exo- or endoergic, k_f and k_r can be measured and thus ΔG determined [using (38.7)]. If ΔS can be determined in some way, or if k_f/k_r can be determined as a function of T, then ΔH can be deduced and used to obtain the proton affinity difference (ΔS can also be determined in the latter case). This has been used to construct proton affinity scales [38.24, 25]. Care is required in such studies to

ensure that no vibrational excitation remains in the reactant ion due to its formation, and that the identities (i. e., isomeric forms) of the reactant and product ions are known (e.g. whether the ion is HCO^+ or the higher energy form COH^+ [38.62]).

Often the individual reaction processes do not occur in isolation. For example, in the reactions of CH_4^+ with COS, H_2S, NH_3, H_2CO and CH_3OH, both charge transfer and proton transfer are energetically possible, and both channels are observed. Here, the least exoergic channel is favored in all cases [38.63]. Proton transfer also occurs in negative ion reactions, for example those of OH^- and NH_2^- giving H_2O and NH_3 respectively (e.g. see Table 38.1), and these types of reactions are production sources for many negative ions [38.53, 64].

Ion–Atom Interchange and Atom Abstraction

In many simple cases, these two processes are the same, for example

$$Ar^+ + H_2 \rightarrow ArH^+ + H , \tag{38.19}$$
but not so for the more complicated molecules (e.g., $O^- + CH_4$; see Table 38.1). Such reactions, when exoergic, usually occur close to the collisional rate although somewhat slower. Series of such reactions with H_2 occur in the interstellar medium and are responsible for producing the hydrogenation in many of the species observed there, for example, in CH_3^+ production from CH^+, NH_4^+ from NH^+ and H_3O^+ from OH^+ (see Chapt. 82). The reaction,

$$NH_3^+ + H_2 \rightarrow NH_4^+ + H , \tag{38.20}$$
is particularly interesting. At temperatures greater than 300 K, the reaction shows an activation energy barrier of $2\,kcal\,mol^{-1}$. The rate coefficient k decreases with decreasing T, reaching a minimum of $2 \times 10^{-13}\,cm^3\,s^{-1}$ at 80 K and then increases at lower T due to tunneling through the barrier [38.48]. This behavior occurs because, at the higher temperatures, the lifetime of the intermediate complex is not sufficient for significant tunneling to occur, but there is sufficient energy in the reacting species to overcome the barrier. At lower temperatures, there is not sufficient energy available to overcome the barrier, but the lifetime of the intermediate complex becomes long enough for significant tunneling to occur [38.65]. This explanation has been substantiated by the isotopic studies of the reactions $NH_3^+ + D_2$, and $ND_3^+ + H_2$ and D_2 [38.66].

For some reactions, isotopic labeling has been used to identify the reaction mechanism. For example, the reaction

$$O^+ + O_2 \rightarrow O_2^+ + O \tag{38.21}$$

has been shown to be predominantly charge transfer, rather than ion–atom interchange, by labeling the ion as $^{18}O^+$ [38.67, 68].

Associative Detachment

For negative ions, an additional process is possible for which there is no equivalent positive ion analog (although there is the related process of chemi-ionization, i. e., $AB + C \rightarrow ABC^+ + e^-$). In this process, the negative ion and the neutral associate, and the association is stabilized by the ejection of the electron (see Table 38.1). Such reactions can only occur when the electron detachment energy is less than the energy of the bond that is produced. Therefore, these reactions usually involve radical species which produce stable molecules. k values are usually an appreciable fraction of the collisional values [38.69, 70]. Infrared emissions have been detected from a series of these reactions [38.71], for example O^- with CO and F^-, Cl^- and CN^- with H, and show that the reactions populate the highest vibrational levels that are energetically accessible.

Other Binary Ion–Molecule Reaction Channels

As reactant species become more polyatomic, there is a greater variety of reaction processes that can occur, and these often occur in parallel. The processes that occur are too numerous to list so a few examples will have to suffice. Reactions that occur in isolation are insertion reactions of the type [38.72]

$$C^+ + C_nH_m \rightarrow C_{n+1}H_{m-x}^+ + xH \tag{38.22}$$

and

$$S^+ + C_nH_m \rightarrow H_{m-1}C_nS^+ + H . \tag{38.23}$$
Multiple channels are very evident in reactions of ions produced from species with large ionization potentials and small proton affinities, for example, NH^+ [38.73],

$$NH^+ + CH_3NH_2 \rightarrow \begin{cases} H_4CN^+ + NH_2 \\ CH_3NH_2^+ + NH \,(\text{charge tsfr.}) \\ CH_3NH_3^+ + N \,(\text{proton tsfr.}) \\ H_2CN^+ + (NH_3 + H) \\ H_3CN^+ + NH_3 \, . \end{cases}$$
In addition to charge and proton transfer, other channels requiring more rearrangement are evident.

Isotopically Labeled Reactants

A great deal can be learned about reaction mechanisms in significantly exoergic ion–neutral reactions by isotopic labeling. Some such reactions have been mentioned above, but a particularly graphic example is the reaction

$$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3 , \qquad (38.24)$$

which was assumed to be either proton transfer and/or H-atom abstraction, depending on the interaction energy. By studying the reaction with both the ion and the neutral reactants separately deuterated, the reaction was shown to be much more complex, with the product ions being CH_4D^+ (10%), $CH_3D_2^+$ (22%), $CH_2D_3^+$ (43%) and CHD_4^+ (25%) for the reaction of CH_4^+ with CD_4 [38.74]. The reaction clearly proceeds via a long-lived intermediate in which there is a large degree of isotope mixing before unimolecular decomposition to products.

A further class of isotopic reactions are those for which the exoergicity is provided only by the different zero point energies of the reactants and products. Many such reactions have been studied. Examples of the various types are: (i) The symmetrical charge transfer

$$^{15}N_2^+ + {}^{14}N_2 \rightarrow {}^{14}N_2^+ + {}^{15}N_2 , \qquad (38.25)$$
which proceeds in both directions at more than half the collisional rate. This implies that the reaction proceeds via long-range charge transfer, a conclusion substantiated by the fact that no mixed product $^{14}N\,^{15}N^+$ is produced [38.67]. (ii) Proton transfer reactions exemplified by $^{14}N_2H^+ + {}^{15}N_2$ and $H\,^{12}CO^+ + {}^{13}CO$, which are both exoergic by about 1 meV [38.48]. Some isotopic scrambling has been observed in the latter reaction by using the double isotopic substitution [38.75],

$$H^{12}C^{18}O^+ + {}^{13}C^{16}O \rightarrow \begin{cases} H^{13}C^{16}O^+ + {}^{12}C^{18}O \\ \quad (\geq 90\%) \\ H^{13}C^{18}O^+ + {}^{12}C^{16}O \\ \quad (\leq 10\%) . \end{cases}$$
Other examples where considerable isotope scrambling occurs are H/D exchange in the reaction systems $H_3^+ + H_2$, $CH_3^+ + H_2$, $H_3O^+ + H_2O$, $CH_5^+ + CH_4$, etc. [38.48]. Such scrambling reactions are believed to proceed via proton bound dimer intermediates (e.g., $H_2O \cdots H^+ \cdots D_2O$). (iii) Isotope exchange reactions such as $^{13}C^+ + {}^{12}CO \rightarrow {}^{12}C^+ + {}^{13}CO$ have also been studied. For this reaction, both k_f and k_r increase

with decreasing T due to an increase in the intermediate complex lifetime; k_r decreases at lower T due to the endoergicity in this reaction direction [38.74].

Isotope exchange is also observed to occur with negative ions, viz.

$$DO^- + MH \rightarrow HO^- + MD , \qquad (38.26)$$

and is a common process. Particularly significant is the comparison where MH is H_2 and NH_3. These species have very similar gas phase acidities, and thus the exoergicities of the reactions are similar. However, NH_3 has a larger polarizability than H_2 and, in addition, has a permanent dipole moment. The observation that the k for the NH_3 reaction is a factor of ten larger than that for the H_2 reaction is explained as being due to the stronger interaction potential which makes more energy available in the intermediate complex and facilitates H/D exchange [38.64].

Temperature Dependencies of Binary Reactions

When the k values at room temperature are close to the collisional value, appreciably exoergic reactions generally exhibit little temperature dependence. For slower reactions, a significant inverse temperature dependence is observed, being $\approx T^{-1/2}$ for several reactions. This behavior is rationalized as a decreasing lifetime of the intermediate complex with increasing temperature, thus allowing less time for reaction [38.48].

38.4.2 Ternary Ion–Molecule Reactions

In cases where binary channels are not energetically possible, association reactions can still occur, both for positive and negative ions. The reactions can be as simple as

$$He^+ + He + He \rightarrow He_2^+ + He , \qquad (38.27)$$
to associations more complex than those listed in Table 38.1. Rate coefficients k_3 at room temperature vary from $1 \times 10^{-31}\, \text{cm}^6\,\text{s}^{-1}$ for reactions such as (38.27) to in excess of $1 \times 10^{-25}\, \text{cm}^6\,\text{s}^{-1}$, this upper limit being due to experimental constraints rather than the reaction itself. The mechanism usually postulated is

$$A^\pm + B \rightleftharpoons \left(AB^\pm\right)^* , \qquad (38.28)$$
$$\left(AB^\pm\right)^* + M \rightarrow AB^\pm + M^* \qquad (38.29)$$
where M stabilizes the excited intermediate, $\left(AB^\pm\right)^*$ by removing energy in the collision. For this type of reaction, there is a considerable dependence of k on T.

Statistical theory predicts (see Chapt. 37),

$$k_3 \propto T^{-(\ell/2+\delta)} , \tag{38.30}$$

where ℓ is the number of rotational degrees of freedom in the separated reactants, and δ is a parameter attributed to the temperature variation of the collision efficiency of the stabilizing third body M. Experimentally, many association reactions exhibit such power law dependencies of the k_3 [38.48, 51] with δ being small (≈ 0.2 or 0.3) for a helium third body. Also, some evidence exists for a contribution of vibrational degrees of freedom to the temperature coefficient in cases where the vibrational levels in the reactant neutral are closely spaced [38.76].

For complex reactant species, lifetimes of intermediate complexes become very long so that, in the higher pressure experiments (see below), all intermediate complexes are stabilized, and thus the reaction is independent of the pressure of M. This form of "saturation" can be eliminated in many cases by using low pressure experiments, so that the time between collisions is long, and normal ternary kinetics (38.14) are restored. Under these conditions, sometimes there is still a pressure independent component to the k which is postulated as being due to radiative stabilization of the intermediate, viz.

$$\left(AB^{\pm}\right)^{*} \to AB^{\pm} + h\nu . \tag{38.31}$$
An example of this is the reaction [38.77]

$$CH_3^+ + CH_3CN \to CH_3^+ \cdot CH_3CN + h\nu . \tag{38.32}$$
38.5 Electron Attachment

These reactions have generally been studied by different techniques from those used to examine ion–neutral reactions and also by different workers [38.31, 32]. Analogous to the ion–neutral situation, there are dissociative processes,

$$e^- + CCl_4 \to Cl^- + CCl_3 , \tag{38.35}$$
and nondissociative processes,

$$e^- + C_6F_6 \to C_6F_6^- , \tag{38.36}$$

the former being stabilized by dissociation, and the latter occurring because of the long lifetime of the intermediate against autodetachment with eventual collisional stabilization (cf. saturation in ion–neutral association reactions; Sect. 38.4.2). Measured rate coefficients vary in the range 1×10^{-7} to the smallest measurable value of $\approx 1 \times 10^{-12}\,cm^3\,s^{-1}$ [38.31, 32]. The upper limit

The stabilizing photon is often considered to be in the infrared due to a vibrational transition within the ground electronic state (with a radiative lifetime of $\approx 10^{-2}$ to 10^{-3} s). Note that only a photon with $h\nu > 3/2k_BT$ is required for the complex (although still vibrationally excited) to be stable against unimolecular dissociation. However, there are cases where it is believed that an electronically excited state is accessed [38.78,79]. Examples are

$$C^+ + H_2 \to CH_2^+ + h\nu \tag{38.33}$$

and

$$Cl^- + BCl_3 \to BCl_4^- + h\nu . \tag{38.34}$$
As yet, radiative association has not been observed directly (i. e., by the detection of the emitted photon), however, the kinetic evidence is strong for the existence of this process.

For the more rapid collisional associations, competition with binary channels is possible, for example

$$CH_3^+ + NH_3 \to \begin{cases} H_4CN^+ + H_2 & (70\%) \\ NH_4^+ + CH_2 & (10\%) \\ \xrightarrow{He} CH_3^+ \cdot NH_3 + He & (20\%) \end{cases}$$
where the percentages refer to product abundances at a He pressure of 0.2 Torr [38.80].

on k for this process is determined, from a consideration of the electron de Broglie wavelength $\bar\lambda = \lambda/2\pi$, to be $\approx 5 \times 10^{-7}(300/T)^{1/2}cm^3\,s^{-1}$ [38.81], or, more rigorously,

$$k(E) = \sum_i \left(\sigma/\pi\bar\lambda^2\right)_i / [h\rho(E)] , \tag{38.37}$$

where $\rho(E)$ is the density of states and

$$\sigma/\pi\bar\lambda^2 \approx 1 - \exp\left[-\left(4\gamma^2\mathcal{T}\right)^{1/2}\right] , \tag{38.38}$$

with $\gamma^2 R_\infty = (2\mu/m)^2\alpha_d/a_0^3$ [38.5]; σ is the collision cross section, $\mathcal{T}$ the kinetic energy, α_d the polarizability, a_0 the Bohr radius, μ the reduced mass, and i represents the available product channels. Where k is less than the upper limit value, this is usually due to activation energy barriers, and k shows Arrhenius behavior

$$k(T) = k_0 \exp\left(-\Delta E/k_BT\right) , \tag{38.39}$$

where k_B is the Boltzmann constant, with the barrier height ΔE being in the range 0 to $\approx 300\,\text{meV}$ [38.32]. If the attachment is nondissociative, and the lifetime of the intermediate complex against autoionization is small compared with the collision time (as occurs for less complex species), the reaction exhibits normal ternary behavior, for example,

$$e^- + O_2 + M \rightarrow O_2^- + M \ . \tag{38.40}$$
Some interesting mechanisms have been identified for attachment. Different product ions have been observed in experiments conducted at very different pressures, for example, in the reaction

$$C_6F_5I + e^- \rightarrow C_6F_5^- + I \quad (\geq 95\%) \tag{38.41}$$
$$\rightarrow C_6F_5I^- \quad (\leq 5\%) \ . \tag{38.42}$$
at high pressures ($\approx 1\,\text{Torr}$), the products, as indicated, were observed with an association channel [see (38.42)]

being detected [38.82]. This association channel was not seen in low pressure experiments [38.83]. Such behavior is explained in terms of the relative magnitudes of the autodetachment lifetime and the time between collisions. When the former time is larger, the association product will dominate, whereas if the converse is true, dissociation products dominate. Thus, the different product distributions, rather than indicating discrepancies, yield information about the autodetachment lifetime.

In attachments to the Br-containing compounds, CF_2Br_2, $CFBr_3$, and CF_2BrCF_2Br and CH_2BrCH_2Br, in which the Br atoms are on different carbon atoms, up to a 20% Br_2^- product is observed [38.84]. This shows that atoms in product molecules can come from spatially separated parts of the reactant molecule. Thus, considerable distortion and rearrangement must occur in the intermediate complex.

38.6 Recombination

This process has been much less studied than ion–neutral reactions with only ≈ 100 reactions being studied [38.44] compared to about 10 000 in the former case [38.33]. Also, relatively little information is available concerning the products since these are neutral and very much more difficult to detect than ions.

38.6.1 Electron–Ion Recombination

Electron–ion recombination can proceed by series of mechanisms, which have been discussed in detail recently [38.85], and these are included in Table 38.1. In brief, these are radiative recombination, where the neutralized ion (excited into the continuum) is stabilized by radiation emission, dielectronic recombination, which is similar to radiative recombination, except that there is a double electron excitation into the continuum, collisionally stabilized recombination, where the intermediate is stabilized by collisions with electrons or a heavy third body (combined collisional radiative recombination is also possible), and dissociative recombination. Dissociative recombination can obviously only occur when the recombining ion is molecular, however, when it occurs it is usually several orders of magnitude faster than the other recombination processes. Thus, only dissociative recombination will be discussed here.

Rate coefficients for dissociative electron–ion recombination at room temperature vary from $> 1 \times 10^{-6}$

for polyatomic ions to $\approx 1 \times 10^{-7}\,\text{cm}^3\,\text{s}^{-1}$ for diatomic ions [38.42, 43]. For large k, there is little temperature dependence, temperature dependencies being more marked for the slower reactions. Two mechanisms were initially proposed: (i) the direct mechanism [38.86] where the neutralized ion undergoes a radiationless transition to a repulsive potential curve on which dissociation to products occurs, and (ii) the indirect mechanism [38.87] where the neutralized ion initially transfers to a Rydberg state and then undergoes a radiationless transition to the repulsive curve. For the former process, the theoretical temperature dependence is $T_e^{-0.5}$, while it is $T_v^{-1}\,T_T^{-1.5}$ for the latter, where the subscripts T and e refer to the thermal ion vibrational and electron temperatures respectively [38.6]. There is no reason why these two processes cannot occur in parallel, although it is not straightforward to determine the relative contributions [38.87]. Fortunately, both processes are automatically included in multichannel quantum defect theory (MQDT) [38.88]. Experimental T-dependencies for reactions which are not close to the collisional limit have power law dependencies in the range ≈ 0.7 to 1.5 [38.43, 89, 90], i.e., between the theoretical predictions. In cases where there is detailed temperature data, e.g., for some hydrocarbon ions $\left(CH_5^+, C_2H_3^+, C_2H_5^+, C_3H_7^+, C_6H_7^+\right)$ [38.89, 90], the dependence changes from the lower dependence at low temperature to the higher dependence at higher temperature.

Less is known about the products. Detailed theory carried out for the diatomic ions O_2^+, NO^+ and N_2^+, and to a large degree HCO^+, are in general agreement with experiment [38.91, 92]. For the more polyatomic ions, the theory is not yet sufficiently quantitative [38.93, 94] and reliance is placed on experiment. H-atom contributions to the product distributions for ten ions $\left(N_2H^+, HCO^+, HCO_2^+, N_2OH^+, OCSH^+, H_2CN^+, H_3O^+, H_3S^+, NH_4^+ \text{ and } CH_5^+\right)$ vary from $\approx 20\%$ for $OCSH^+$ to 120% for CH_5^+ [38.95]. OH is a substantial product (30 to 65%) in the above reactions where it is energetically possible [38.96] (i.e., excluding HCO^+), except in the case of $OCSH^+$, perhaps indicating that the proton is exclusively on the S-atom rather than the O-atom (i.e., in the lowest energy form [38.97, 98]). More complete product distributions are now being obtained, initially using flowing afterglows $\left(O_2H^+, HCO_2^+, H_2O^+, H_3O^+\right)$ [38.99], but more recently using storage rings $\left(\text{including } H_3^+, CH_2^+, H_2O^+, NH_2^+, H_3O^+, CH_3^+, NH_4^+, CH_5^+\right)$ [38.100]. These studies are showing that fragmentation to give three products is a common, indeed dominant, mechanism [38.101]. Dissociative recombination has recently benn reviewed by [38.102].

Electron–ion recombination is an energetic process and electronically excited states can also be populated. Vibrational population distributions for these states can readily be determined if Einstein A coefficients are known for the observed transitions ($I \propto A[*]$, where I is the photon intensity, and $[*]$ is the number density of the excited state). The N_2 (B $^3\Pi_g$) state and the CO (a $^3\Pi_r$) state vibrational population produced in the recombinations of N_2H^+, HCO^+, HCO_2^+ and CO_2^+ have been determined [38.103, 104]. Possible mechanisms [38.105] have been suggested for this vibrational excitation: (i) the impulsive force on the molecular fragments as the neutralized ion rapidly dissociates, and (ii) the Franck–Condon overlap between the wave functions of the molecular products (in various vibrational states) and the wave function of this particular fragment in the neutralized ion before it dissociates. Theory underestimates the populations of the higher levels, but does predict the small observed oscillation in the occupancy of the various vibrational levels in the CO (a $^3\Pi_r$) state generated in the recombination of HCO^+ [38.106].

The theories of recombination discussed above assume favorable potential curve crossings, however, it has been shown both experimentally [38.107, 108] and theoretically [38.109] that such are not necessary when quantum tunneling can occur. Experimental evidence has been obtained in the recombinations of N_2H^+ and N_2D^+ where the populations of the $\nu' = 6$ vibrational level of the N_2 electronically excited (B $^3\Pi_g$) state is greatly enhanced (≈ 6 at 100 K) for N_2H^+ over N_2D^+. This level is resonant with the $\nu = 0$ vibrational level of the recombining ion, making tunneling more facile; and H atom tunneling is further enhanced because of the smaller mass [38.108].

38.6.2 Ion–Ion Recombination (Mutual Neutralization)

Less information is available on this process than on electron–ion recombination; a detailed review has recently been published [38.110]. k values vary from about 4×10^{-8} to $1 \times 10^{-7}\,\text{cm}^3\,\text{s}^{-1}$ at room temperature [38.44, 46] with power law temperature dependencies of ≈ 0.4 for the only two systems that have been studied as a function of T ($NO^+ + NO_2^-$ and $NH_4^+ + Cl^-$) [38.46]. This is consistent with theory [38.111] in which the Landau–Zener approximation is used to determine the probability of a crossing between the Coulombic ion–ion attractive potential and the potentials of the neutral products. This transition occurs by an electron transfer (the optimum distance for such a transfer when a favorable crossing exists is about 10 Å). Theory gives that

$$k \approx 2\left(v^2 Q\right)\left(\mu / 2\pi k_B T\right)^{1/2}, \tag{38.43}$$

where Q is the cross section

$$Q = \pi R_c^2\left[1 + (R_c E)^{-1}\right]. \tag{38.44}$$

R_c is the crossing distance, E is the interaction energy and v is the relative velocity at the crossing point [38.111]. Once neutralized by electron transfer, the products continue undeflected with the velocity gained from the Coulombic field. Photon emission has been detected from a series of excited state products. Following the early detection [38.112] of NO (A $^2\Sigma^+$) emissions from $NO^+ + NO_2^-$, a variety of NO emissions have been detected from NO^+ recombinations with molecular $\left(SF_6^-, C_6F_6^-, \text{ and } C_6F_5CH_3^-\right)$ and atomic (Cl^- and I^-) negative ions [38.113, 114] and He_2 emissions from He_2^+ recombinations with $C_6F_6^-$ and $C_6F_5Cl^-$ [38.113]. These emissions were interpreted in terms of long-range electron transfer [38.112], however, in the recombination of Kr^+ and Xe^+ with SF_6^-, KrF, and XeF, excimer emissions have been seen [38.113], suggesting an intimate encounter in these cases. Also, few data are available on the effects of pressure. For the reactions $SF_3^+ + SF_5^-$ and $NO^+ + NO_2^-$, k increases by about a factor of 4 between 1 and 8 Torr [38.46, 50].

Clusters

<div style="text-align:right">

39. Clusters

</div>

Clusters are small aggregates of atoms or molecules which are transitional forms of matter between atoms or molecules and their corresponding bulk forms. Just as this definition spans an incredibly broad range of clusters from, say, He_2 to Na_{10000}, so do the properties of these clusters span a broad range. This chapter attempts to bring order to this diverse cluster kingdom by first sorting them into six general categories. Within each category, the physics and chemistry of the more or less similar cluster species are described. Particular emphasis is placed on the unique properties of clusters owing to their finite size and finite lattice.

This chapter summarizes one of the youngest topics in this volume. Much of what is known is highly qualitative and has not yet been assembled into overarching tables or equations. Thus, this review is best regarded as a progress report on the current knowledge in this rapidly advancing field. Many of the concepts and the language used to discuss clusters are derived from condensed matter physics. The nature of these clusters impels such descriptions.

Clusters discussed in this chapter are isolated species composed primarily of a single type of atom or molecule. Most of these clusters are highly reactive and can only be made and studied under rarified conditions such as in a molecular beam. In keeping with the definition of clusters given above, this chapter will not attempt to cover the truly vast literature on atomic and molecular dimers and trimers. A great many of these species have been thoroughly characterized, however they are better described as molecules rather than "tiny clusters". Stabilized clusters in the form of Zintl ions, colloids, and nanoparticles have also been made. While it is impossible to resist mentioning these clusters throughout this chapter, they are more appropriate to condensed matter physics. Finally, experimental and theoretical techniques for forming and studying clusters will not be covered; excellent reviews of these methods are available elsewhere [39.1–6].

39.1 Metal Clusters

Clusters of a wide variety of refractory and nonrefractory metals have been made and studied. These include clusters of alkali metals, transition metals, coinage metals, main group metals, and lanthanides. Clusters of alkali metals, particularly sodium, are the most well studied and understood. The emerging picture of alkali clusters is that they behave much like quasifree electron metal spheres. Thus, approximations such as the jellium model used for describing bulk metals explain a large number of alkali metal properties quite well [39.2]. Other metallic clusters, such as some main group metal and noble metal clusters, can also be understood within the jellium model. Nonetheless, there are examples of metallic clusters which deviate significantly from these simple models, particularly among the transition metal clusters.

39.1.1 Geometric Structures

The ground state geometry is known accurately for only a handful of small metal clusters. Examples include lithium and sodium clusters containing up to nine atoms, where electronic spectra are compared with accurate ab initio quantum chemical calculations to deduce their structures [39.5–7]. Such an approach is not a general one, either experimentally or theoretically. As the size and/or atomic valency of the metal cluster increases, the number of possible ground state structures grows enormously. Interpretation of experimental spectra requires theoretical guidance, which means that each one of these structures must be calculated using an accurate electronic structure calculational method. Thorough theoretical investigation is only practical with current computational tools for clusters containing up to about thirteen atoms. Methods such as molecular dynamics combined with density functional calculations have been used to speed up the process of finding and comparing various isomers [39.4, 8]. Such approaches are still restricted by available computational power to clusters with relatively few atoms and valence electrons per atom. Metal clusters of atoms with higher valency, e.g., mid-row transition metals, have proved to be quite difficult to treat accurately [39.9]. The large electron correlation problems inherent in these clusters must be treated semi-empirically, leading to large uncertainties in the relative energies between isomers of different spin and geometry.

Despite these difficulties, approximate geometries are known for many metal clusters. For cluster sizes greater than, roughly, several tens of atoms, there is strong experimental evidence that spherical close packed geometries, particularly the Mackay filled icosahedra, predominate the geometric structures [39.7, 10, 11] (The Mackay filled icosahedra contain concentric closed icosahedral shells of atoms plus one central atom. These structures are pentagonally symmetric and occur every n atoms by $n = 13, 55, \cdots 1/3(2n+1)(5n^2+5n+3)$ [39.4]). These geometries have been deduced by a variety of means. For example, abundance mass spectra of metal clusters up to sizes containing thousands of atoms show intensity enhancements, termed *magic numbers*, at each cluster size which corresponds to a complete Mackay icosahedron. Saturation coverages of transition metal clusters with various reagents can be explained in terms of covering the icosahedral faces of these clusters. The persistence of icosahedral structures to large cluster sizes raises the question about where the crossover to the metallic packing occurs. For example, a spherical piece of an fcc metal would have cuboctahedral symmetry rather than noncrystalline icosahedral symmetry. Ultrafine metal particles containing 10^4 to 10^5 atoms typically have bulk crystalline geometries [39.12]. Little theoretical or experimental data currently exist to resolve the question of when the bulk crystalline structure emerges [39.10]. The point of crossover must involve kinetic as well as energetic factors. Although icosahedral packing is seen in beam experiments on metal clusters containing hundreds to thousands of atoms, high resolution electron microscopy experiments on supported metal particles in this size range show fluctuating structures that can rapidly evolve between icosahedral, cuboctahedral, and other crystalline arrangements, depending on cluster temperature [39.13].

39.1.2 Electronic and Magnetic Properties

A number of electronic properties have been measured for metallic clusters, particularly alkali metal and noble metal clusters. These include ionization potentials, electronic affinities, polarizabilities, and photoabsorption cross sections.

The spherical jellium approximation is generally a good model for these properties in clusters of alkali and noble metals [39.2, 7]. This model treats the valence electrons of the cluster as a delocalized sea of electrons smeared over a uniform spherical background of ionic cores. The energy levels of such a jellium sphere can be calculated by confining the jellium electrons to a three dimensional potential. A suitable form of this po-

tential yields level spacings that are given by principal and angular momentum quantum numbers (n) and (l). There are no restrictions on l for a given n, and the degeneracy of a given l level is $2(2l + 1)$. The levels order as 1s, 1p, 1d, 2s, 1f, 2p, 1g, 2d, 3s, $\cdots$. The electron configuration of a cluster is given by filling successive energy levels (termed shells) with the available valence electrons. Special stability occurs for those clusters with a closed shell configuration. This stabilization can be seen in the experimental measurements of the dependences of total binding energies, ionization potentials, electron affinities, and polarizabilities on cluster size [39.2, 7, 10, 11, 13, 14]. The potential used to calculate the energy levels within the jellium model has been formulated to include elliptical distortions of open shell clusters [39.7]. This refinement has been successful in describing the fine structures of these trends. Despite the usefulness of the jellium model, it is not applicable for very small or very large clusters. In many smaller clusters containing up to a few tens of atoms, electron-ionic lattice interactions cannot be neglected, and the spherical approximation is poor. For these clusters, accurate quantum chemical calculations must be used to determine the electronic structure. Alternatively, for clusters larger than roughly 500 to 3000 atoms (depending on which clusters and the cluster temperature), the level spacings become increasingly continuous, blurring the shell structure. When this occurs, other effects are seen to dominate the trends in cluster stability, particularly the stability arising from completing a geometric shell of atoms on the cluster [39.7, 10, 11, 15, 16].

The convergence of cluster electronic structure to bulk metal electronic structure has been seen in the evolution of metal cluster ionization potentials (I_P) and electron affinities (A_e) as a function of cluster size. A good approximation for the overall trend in the I_P as a function of cluster size (N is the number of atoms) is given by the electrostatic model for the work function of a classical conducting sphere [39.2]

$$I_{P,N} = W_B + A \frac{e^2}{R_N},\tag{39.1}$$

where W_B is the work function of the bulk metal, e is the electron charge, and R is the cluster radius, which is often set proportional to $N^{1/3}$. A is a constant which is found experimentally to have values of about 0.3 to 0.5; the theoretically derived value for A depends on the model used [39.2, 11]. A similar form of (39.1), where A is replaced by $(A - 1)$, describes the A_e of a negatively charged cluster. Experimentally, the I_P and A_e of alkali metal, noble metal, and some main group metal

clusters behave as described by (39.1) with shell structure superimposed on the overall trend [39.2, 6, 14]. Equation (39.1) predicts a smooth convergence of the work function to the bulk value with increasing cluster size. This has been seen experimentally, such as in copper cluster valence and inner shell A_e which extrapolate smoothly to the corresponding bulk values [39.17]. In mercury clusters, the transition to bulk metallic behavior occurs more abruptly and clusters with less than ≈ 17 atoms appear to behave as nonmetals [39.18]. Transition metal clusters often deviate strongly from the trend in (39.1) [39.10].

Electronic spectra are available for a number of metal clusters including alkali, noble metal, transition metal, and aluminum clusters [39.7, 10, 11]. Small alkali clusters exhibit rich spectra in the visible. Many of these spectra have been assigned using accurate electronic structure calculations as described above. Visible spectra of larger alkali metal clusters and other metal clusters are typified by giant resonances with cross sections reaching values as large as $2000\,\text{Å}^2$ [39.6, 7]. In the absence of detailed electronic structure information, these spectra have been assigned using comparisons with bulk metal spectra. In particular, the giant resonances are assigned to collective excitations of the cluster valence electrons, in an analogy to bulk metal plasmon resonances. Theoretical treatments of these giant resonances for clusters have been derived from classical treatments of conducting spheres driven by an external electromagnetic field [39.7, 10]. While the blue shift of the resonance frequency with increasing cluster size is well predicted by the classical models, other details are less well described, such as the magnitude of the shift and the width of the resonance. Clusters which are known to be nonspherical from other measurements exhibit multiple resonance peaks; these have yet to be quantitatively described by theory. Transition metal clusters also show evidence of collective excitations; however, the magnitudes of these absorptions are 2 to 5 times larger than predicted by classical models [39.19]. An intriguing *non sequitur* occurs when the classical models are extended down to describe the resonances of small alkali clusters. This is illustrated by the example of Na$_8$, which exhibits a large single resonance in the photoabsorption spectrum. At first glance, the classical jellium model does fine: it predicts a spherical closed shell cluster which should exhibit a single resonance. Yet, a more thorough examination of the time dependence of this feature has revealed that it consists of four overlapping absorptions [39.10, 20]. These multiple absorptions clearly must arise from one-electron excitations, not a collective

all-electron excitation [39.5]. Further work is needed to weave together the two disparate pictures of collective versus one electron excitations in metal clusters.

Inner shell electrons of some metal clusters have been probed spectroscopically. Whereas excitations of the delocalized valence electrons primarily reflect the entire cluster environment, excitations of the localized inner shell electrons reflect the atomic environment. In mercury clusters, excitation of the 5d core electrons reveals a transition from insulating clusters at small sizes to more metal-like clusters with increasing s-p hybridization typical of bulk mercury [39.21]. Inner core electron spectra of copper and antimony clusters also reveal details regarding the evolution of the cluster lattice structure as a function of size [39.11, 17]. Such valuable information can be obtained from inner shell electron spectra of metal clusters that more experiments are warranted.

Magnetic moments have been measured and described theoretically for a range of transition metal, rare earth, and Group III metal clusters [39.5, 7, 10, 22–24]. Examples of clusters which exhibit a positive magnetic moment include cobalt, iron, nickel, gadolinium, and terbium clusters. Clusters of metals such as vanadium, palladium, chromium, and aluminum are observed to be diamagnetic. The effective moment per atom, μ, in magnetic clusters is greater than in the bulk because of the lower average coordination number in clusters [39.24]. As the cluster size increases, the surface to volume atom ratio decreases and μ converges to the bulk value. The size of these magnetic clusters is smaller than the critical domain size for bulk ferromagnetism, thus they are best described as paramagnetic with a single moment given by $N\mu$, where N is the number of atoms in the cluster. Stern–Gerlach deflection data have been obtained to measure μ. A critical parameter in interpreting these data is the so-called blocking temperature T_B, the temperature at which the cluster moment unlocks from the cluster axes and orients thermally in an external field. For clusters with temperatures $T > T_B$, the observed effective moment μ_{eff} for paramagnetic clusters is given by [39.24]

$$\mu_{eff} = \mu \left[\coth \left(\frac{N\mu H}{k_B T} \right) - \frac{k_B T}{N\mu H} \right], \tag{39.2}$$

where k_B is the Boltzmann constant, and H is the magnetic field strength. Medium size iron and cobalt clusters behave well according to this classically derived expression. Deviations from this model are observed in internally cold clusters and rare earth clusters which can be explained by partial and complete locking of the magnetic moment to the cluster lattice. Also, in very large clusters, $N\mu$ becomes sufficiently large that alignment overwhelms thermal statistical behavior.

39.1.3 Chemical Properties

The chemistry of both charged and neutral metal clusters has been studied, particularly for clusters of transition metals and Group III metals [39.6, 7, 25, 26]. Both chemisorption and physisorption are seen, depending on the type of metal cluster and reagent. In many cases, the observed chemistry is quite similar to that observed for the corresponding bulk metal. For example, platinum clusters dehydrogenate hydrocarbons, hydrogen chemisorbs on transition metal clusters with the exception of coinage metal clusters, and oxygen reacts readily with aluminum and iron clusters.

Chemisorption reactions of metal clusters have been seen with a wide variety of reagents. Products, reaction rates, and activation barriers have been measured as a function of cluster size. With a few notable exceptions, such as the reactions of hydrogen with nickel and aluminum clusters, none of these reactions are understood at the microscopic level [39.10, 11]. Macroscopically, some correlations have been seen between reaction rates and other measured cluster properties. For example, some cluster reactions show evidence that the shell structure affects reaction rates, with open shell clusters having much higher reaction rate and lower activation barriers than clusters with closed shells. In other cases, the pattern of cluster reaction rates with cluster size correlates with the cluster I_P's. These correlations have been used to infer the essential cluster-reagent interaction which governs the reactivity for a given set of clusters with a given reagent. For example, open shell clusters and clusters with low I_P's favor reactions which involve electron donation from the cluster to the reagent at a critical point along the reaction coordinate. Such generalities must be made with caution, however, since they do not hold up well over a broad range of cluster sizes, compositions, and reagents. Even a single cluster size can exhibit complex reactivity: isomers with different reactivity have been observed for niobium clusters and, in some cases, these isomers have been interconverted by annealing. Of course, complexity is to be expected, given the richness and diversity of chemistry that is known to occur for different metal systems in various electronic and geometric environments.

Geometric structures of transition metal clusters have been studied using physisorption reactions. Weakly bound adsorbates such as hydrogen, water, and ammonia

show strong saturation behavior in their uptake by metal clusters [39.10,11,27,28]. Trends in the saturation coverage with cluster size yield information about the type of binding site and total number of binding sites for a given cluster size. Additional information regarding the nature of the adsorbate site is often available from studies of the corresponding physisorption on bulk metal surfaces. This knowledge is used to sort through possible cluster structures and deduce which geometries exhibit the correct number and type of adsorbate binding sites. For example, saturation coverages of iron, cobalt, and nickel clusters correlate with icosahedrally packed geometries over a wide range of sizes. Adsorbate binding energies have also been determined in some cases [39.27, 28].

39.1.4 Stable Metal Cluster Molecules and Metallocarbohedrenes

Thus far, this section has focussed entirely on the properties of metal clusters isolated in the gas phase. This discussion would not be complete, however, without mentioning that a number of metal cluster molecules have been made which are sufficiently stable that they can be made in quantity and bottled [39.7,10,11,29,30]! Also, recently a new class of metal-carbon clusters has been discovered, termed metallocarbohedrenes, that are believed to be sufficiently stable and abundant that they can be made in bulk. The brief overview of these isolatable clusters given below is not meant to be complete but is intended to introduce the large and impressive body of work in this field. Interested readers are encouraged to consult the reviews cited and references therein.

Metal cluster molecules consist of a metal cluster core surrounded by a stabilizing ligand shell. A large number of such metal cluster molecules has been made, including some with metal cores as large as 300 platinum or 561 palladium atoms. In many cases, crystals of single size clusters have been made with an exactly known number of metal atoms in the core. The availability of macroscopic samples of these clusters has made it possible to measure a number of their properties. Exact structures are known for many metal cluster molecules from X-ray crystallography. Electronic and magnetic properties have been determined which reveal the development of metallic behavior within the metal core. The ligand shell is found to interact strongly with the metal atoms on the surface of the metal core. This outer shell of metal atoms does not behave as a surface of metal atoms with free valence electrons such as is found on the surface of a bulk metal. Undoubtedly, such strong interactions between surface metal atoms and coordinating ligands are necessary to make a cluster which is sufficiently stable to be isolated and crystallized without coalescing. The core of atoms inside the outer metal shell of atoms does not appear to be greatly perturbed by the coordinating ligands. Studies of the electronic and magnetic properties of the core show the onset of metallic properties as a function of particle size and atomic packing.

A distinct class of transition metal-carbon clusters has been recently been found which have been termed metallocarbohedrenes [39.31]. Within this class, the clusters M_8C_{12} (M = Ti, V, and Zr) are particularly abundant and stable. Extensive electronic structure calculations show that the structure of M_8C_{12} is metallic and should be viewed as a distorted M_8 cube where each face is decorated with a C_2 dimer [39.32]. This structure differs greatly from the corresponding bulk metal carbides, which have cubic rock salt crystalline forms. Furthermore, the metal carbide cluster formation conditions can be adjusted to yield cubic fragments of the bulk. The related metal nitride clusters are only observed to form cubic structures. Theoretical calculations on the metallocarbohedrene and cubic forms of these metal carbides and nitrides show that they are comparable in energy for the carbides, but that the cubic structures are much more stable in the metal nitride clusters [39.33]. Despite their apparent stability, none of the metallocarbohedrenes has yet been isolated and purified.

39.2 Carbon Clusters

The discovery of the especially stable, spherical cluster of sixty carbon atoms, named buckminsterfullerene, has ignited an intense research effort in carbon clusters [39.7, 8, 10, 11, 34–39]. The family of pure carbon clusters that have been made extends from the dimer all the way up to tubular shaped clusters containing thousands of atoms. Several of these clusters, most notably C_{60} and C_{70}, have been isolated as a single size in macroscopic quantities [39.40]. The fascinating properties of bulk materials made of pure and doped C_{60} and C_{70} are outside the scope of this review [39.8, 10, 11, 37, 39, 41].

Carbon clusters can be roughly grouped into three distinct classes. The first consists primarily of small carbon clusters which have linear or ring geometries.

Hollow spheres (termed fullerenes) appear at about 28 carbon atoms and persist up to at least several hundred atoms. Very large carbon clusters containing hundreds to thousands of atoms assume various forms, including onion-like structures of concentric spheres and hollow tubes.

39.2.1 Small Carbon Clusters

Theoretical and experimental studies have found that rings and linear chains are the most stable configurations for small carbon clusters. Below about ten atoms, linear cumulenes are the most stable structures for odd numbered carbon clusters and ionic carbon clusters [39.13, 26, 42, 43]. For the even numbered neutral carbon clusters, C_4, C_6, and C_8, however, cyclic and linear geometries are nearly isoenergetic [39.7, 11, 13, 42]. Various theoretical and experimental studies have yielded conflicting results as to which geometry is more stable for each of these three clusters [39.7, 42, 44]. Much of the controversy over the experimental evidence probably arises because the two structures are so close in energy that either isomer or both may be present, depending on the preparation conditions. By way of proof, direct experimental data have been found for coexisting linear and cyclic isomers of C_{7-9}^+ and C_{11} [39.26, 44]. Also, some experimental probes are not equally sensitive to the signature from a linear versus a cyclic geometry.

At ten carbon atoms, a distinct transition occurs from linear to cyclic structures [39.26, 43, 44]. Starting at this size, the additional bonding stabilization accrued by joining the two ends of the linear chain overcomes the strain energy resulting from ring closure. Stable monocyclic ring structures are observed for carbon clusters over a surprisingly wide range of sizes, even persisting into the size range where three dimensional fullerenes appear. Bicyclic rings, higher order polycyclic rings, and graphitic fragments also occur in this size range but many of these configurations appear to be metastable [39.43, 45].

A_e's and I_P's have been measured for these small carbon clusters. Dramatic effects appear in the size dependence of the A_e's as a result of the changeover from linear to ring structures [39.44]. A_e's of the chain structures are noticeably higher than for ring structures for carbon clusters containing similar numbers of atoms. Distinct odd-even alternations in the A_e's are also seen, plus there is evidence for aromatic stabilization according to the $4n + 2$ rule. No break in the I_P's is seen across the structural transition, but the trend in the I_P's also follows the $4n + 2$ rule expected for aromaticity.

Chemical reactions have been observed for both neutral and charged small carbon clusters, particularly for the cations [39.7, 26, 43]. In general, the linear cationic clusters, containing fewer than ten atoms, react readily with a variety of reagents and exhibit reactivity typical of carbenes. The ring shaped cationic clusters with ten or more atoms are much less reactive, and often show no detectable reaction with reagents that react efficiently with the smaller carbon clusters. It is this differential reactivity which has revealed the presence of coexisting linear and cyclic isomers. Evidence for polyacetylene versus cumulene structure in the small linear chains can also be seen in the cluster reaction patterns.

39.2.2 Fullerenes

Fullerenes make up a class of carbon clusters with closed hollow carbon atom cage morphologies. The term "*fullerene*" was inspired by the geodesic domes of architect R. Buckminster Fuller, and has come into widespread usage despite its nonstandard nomenclature. The fullerene cage network is composed of interlocking rings of sp^2 hybridized carbon atoms, where every carbon atom is bonded to three other carbon atoms. Five and six member rings predominate in the cages. Highly strained four and smaller membered rings are unfavorable. Seven and higher membered rings usually can facilely rearrange within the network to form five and six membered rings. Delocalization of the π electrons over the cage contributes significantly to the stabilization of the fullerenes.

Assuming at least five-membered rings, the smallest possible fullerene is C_{20}, consisting of twelve pentagons. However, the observed fullerenes all contain about 30 atoms or more. Larger fullerenes are formed by joining together pentagons, hexagons, and heptagons, with the pentagons providing the curvature necessary to close the cage. In fullerene structures composed entirely of pentagons, hexagons, and heptagons, it can be rigorously shown from Euler's theorem that, $N_5 = N_7 + 12$, where N_5 is the number of pentagons and N_7 the number of heptagons. By far the most abundant fullerene that is seen is C_{60}. There are 1812 possible isomers for C_{60} but only one forms in great abundance [39.37], which has each of its 12 pentagons isolated and surrounded by its 20 hexagons. The resulting molecule, resembling a soccer ball, belongs to the highest point symmetry group I_h, where all the carbon atoms are equivalent [39.34–37]. The *isolated pentagon rule* arises out of minimizing strain and maximizing resonance energy and is a powerful tool for predicting the most stable

fullerene isomers [39.37]. Besides C_{60}, a number of other fullerenes have been seen, most notably C_{70} which is the next larger fullerene that can be constructed using the isolated pentagon rule. The largest proven fullerene structure contains 84 carbon atoms. It is possible to construct increasingly larger fullerene cages containing hundreds of carbon atoms. Such giant fullerenes have yet to be conclusively verified in experiments, however evidence for their existence has been seen in bulk samples containing fullerene mixtures and in gas phase abundances of carbon clusters [39.36, 37, 39].

A number of the fullerenes has been made and purified as a single size in macroscopic quantities [39.37, 39, 40]. This has enabled their geometries to be determined quite accurately using a wide variety of spectroscopic and theoretical techniques. Even structures of fullerenes such as C_{76}, C_{78}, and C_{84} which occur as isomeric mixtures have been elucidated. The electronic structures of many of these fullerenes have been calculated and compared with experiment [39.37, 38].

Yet to be resolved is the issue of how these low entropy fullerene structures can form so efficiently in carbon vapor. One proposal is that cup-like prefullerenes form first which add new carbon moieties to close the cage. Other suggestions include coalescence of small carbon rings such as C_6 or C_{10}, or stacking of intermediate size rings on a small "seed" ring such as C_{10}, or folding up of large defective graphitic fragments to form closed hollow spheroids [39.8, 10, 36, 37]. Some intriguing insights into this open question are provided by experiments on nonfullerene metastable forms of carbon clusters in the fullerene size regime [39.43]. These species can be made in the gas phase and are found to have bicyclic, graphitic, and other polycyclic ring shapes which are not in the form of partial fullerene cages. Upon annealing, some of these ring forms are seen to convert into the fullerenes, which suggests that they are important intermediates for forming the fullerene cage. Similar polycyclic ring shapes are observed during the initial "melting" of fullerenes in molecular dynamics simulations [39.46].

Since the fullerenes are hollow, much attention has focussed on putting something inside. A wide variety of noble gas atoms and metal atoms has been successfully loaded into fullerenes, forming a family of so-called "endohedral" complexes [39.36, 37, 39, 47–51]. Noble gas atoms encapsulated in fullerenes appear to assume central positions within the cage and do not perturb the overall electronic structure of the fullerene [39.11, 47, 52]. Endohedral complexes where the encapsulated species is a metal atom, called *metallo-*

fullerenes, encompass a wide range of metals (M) and fullerene sizes from $U@C_{28}$ to $Sc_3@C_{82}$ (@ denotes that the metal atom is inside the fullerene). Separation and purification of a macroscopic amount has been achieved for several of these [39.48, 49, 51]. Theoretical and experimental data indicate that the endohedral metallofullerenes have considerable charge transfer from metal atom(s) to the fullerene cage [39.37, 47, 48, 51, 52]. This interaction affects the oxidation states of the metal atom(s) and the cage and, in some cases, causes the metal atom(s) to locate off-center. It is yet to be generally understood why, within the range of known fullerene sizes, only some form endohedral complexes, particularly C_{28}, C_{60}, C_{70}, C_{74}, C_{80}, C_{82}, and C_{84}. The $M@C_{28}$ endohedral complex is especially intriguing because it appears that C_{28} itself does not form as an empty fullerene.

The unsaturated surfaces of fullerenes undergo a broad range of chemical reactions. The availability of macroscopic samples of fullerenes, especially C_{60} and C_{70}, has enabled the preparation of numerous fullerene derivatives. With their high electron affinities, fullerenes readily form a wide variety of charge transfer compounds. These include the so-called *exohedral* complexes, where metal atoms are attached to the outside of the cage. Particularly stable exohedral metal-fullerene clusters have been observed which have one alkaline earth atom decorating each ring of the cage [39.53]. The unsaturated double bonds of the fullerenes can be functionalized with reagents such as halogens, aromatics, and alcohols [39.37, 39]. Some of the bulk forms of these complexes and derivatives exhibit amazing properties such as superconductivity at temperatures as high as 33 K seen in C_{60} films doped with alkali or alkaline earth metals [39.51]. References [39.37, 39, 51] contain recent reviews.

39.2.3 Giant Carbon Clusters: Tubes, Capsules, Onions, Russian Dolls, Papier Mâché …

Giant clusters of pure carbon have been found which have tubular, capsular, and spherical shapes [39.8, 10, 37, 51, 54]. These clusters occur both as single entities and with multiple concentric layers. The basic structure consists of a spiralled or rolled graphitic sheet made up of hexagonal rings of sp^2 hybridized carbon atoms. Just as in the fullerenes, pentagonal rings provide the curvature required to form a ball or to cap the ends of tube shapes. Negative curvature has also been seen which is believed to result from heptagonal rings. Carbon tubes and capsules are formed prolifically in

the same carbon arcs which produce fullerenes. Typical diameters range from about 5 to 100 nm, depending on the inner diameter and number of layers, and lengths of up to several microns are seen. For concentric or spiralled structures, the average interlayer spacing is 3.4 to 3.5 Å which is slightly larger than in crystalline graphite. Although tubes and capsules are the most commonly seen morphologies, these are observed to convert to layered spherical "onion" structures under intense irradiation [39.8]. This suggests that collapsed onion structures are more stable. Currently, there exists some debate over whether the multilayer tubes or capsules consist of layers of complete shells within shells, such as in a "Russian doll", or whether these layers are so highly defective that the overall structures are best described as "papier-mâché" consisting of numerous overlying graphitic fragments [39.54].

Little experimental detail is available on the electronic or mechanical properties of these tubes. Theoretical calculations have been performed on the electronic properties of perfect tubes constructed in various ways [39.37, 51]. Numerous configurations of tubes are possible, depending on the tube diameter and the overall screw axis formed by the rows of carbon hexagons wound around the tube waist. The geometrical arrangement strongly affects the electronic properties of a tube. Appropriate choices of diameter and tilt angle of the screw axis yield tubes which are metallic or semiconducting. Tubes and capsules with perfect lattice arrangements are calculated to be extremely stiff, forming the strongest carbon fibers known. Almost no data exist on the chemical properties of carbon tubes, capsules, and onions. While they are stable enough to isolate in air, reaction occurs with O_2 and CO_2 at high temperatures which destroy the tubes [39.51]. Finally, as for the fullerenes, tubes, capsules, and onions have a hollow cavity which can be filled. These "nanocapsules" have been successfully loaded with lead and gold atoms, as well as crystalline metal carbide particles [39.51].

39.3 Ionic Clusters

A growing body of experimental and theoretical evidence on alkali halide and alkaline earth oxide clusters shows that these tiny clusters of ionic materials are ionically bound. Most of these clusters have highly ordered crystal structures even at very small sizes. Thus, these clusters offer excellent systems for studying electron localization on finite-sized crystalline lattices.

39.3.1 Geometric Structures

Most ionic clusters of alkali halides and alkaline earth oxides assume the cubic rock salt lattice typical of bulk sodium chloride [39.6, 7, 10, 13, 55]. This lattice is favored not only for clusters of rock salt cubic solids such as NaCl and NaF, but also for other clusters such as $Cs_x I_y$ where the bulk form has the cesium chloride cubic crystal structure. Exceptions occur when the cluster size is smaller than, roughly, a unit cube, or when the cluster anions and cations differ greatly in ionic radius, such as in lithium bromide clusters (even though solid LiBr has the NaCl crystal structure) [39.10]. The bulk rock salt lattice is retained even for clusters where the number of anions and cations are unequal, as long as the deviation from stoichiometry is not too great. In clusters with a large excess of alkali atoms, the extra metal atoms segregate to a face of the cluster and form a metallic overlayer [39.55].

Maximization of ionic interactions and minimization of surface energy leads to cuboid crystal morphologies for these clusters which have as many (1 0 0) faces as possible. Particularly stable clusters occur for sizes where the cuboid lattice is completely filled and has nearly equal numbers of ions on all sides [39.55]. Excess electrons or holes also play a crucial role in the stability of ionic clusters. For example, while the $[Na_{14}Cl_{13}]^+$ cluster forms a particularly stable cube (with 9 atoms on each square face and one atom in the center), its counterpart $[Na_{13}Cl_{14}]^+$ does not because it has fewer holes than the available electrons; however, the anion $[Na_{13}Cl_{14}]^-$ does form a particularly stable cube [39.11, 55].

39.3.2 Electronic and Chemical Properties

The I_P's, A_e's, photoabsorption spectra and photoabsorption cross sections have all been measured for ionic clusters, particularly alkali halide $[M_j X_k]$ clusters. Understanding the role of the coulombic interactions, particularly excess electrons, in these clusters is key to understanding the trends in their electronic properties with cluster size, composition, and overall charge. Excess electrons are known to localize in at least four

distinct ways: at anion vacancies, in weakly bound surface states, on specific alkali metal ions, or in cation-anion pair dipole fields [39.11, 55, 56].

First, there is a large class of ionic clusters which contain equal numbers of electrons and holes, such as clusters in the series $\left[M_{j+1}X_j\right]^+$. I_P and A_e of clusters within this class reflect the overall stability associated with forming the *perfect* filled cuboid lattices described in Sect. 39.3.1. Such perfect clusters do not chemisorb polar molecules, whereas the *imperfect* clusters readily do [39.55]. The lowest energy absorptions for clusters in this class result from charge transfer excitations, just as in perfect ionic solids. Spectra obtained for $\left[Cs_{j+1}I_j\right]^+$ clusters show large cross sections for absorption, consistent with charge transfer, and features which converge towards the bulk for the perfectly cubic cluster, $[Cs_{14}I_{13}]^+$ [39.57].

Other ionic clusters do not contain equal numbers of electrons and holes; clusters with excess electrons have been the most studied. One such class consists of clusters with at least one anionic vacancy and one or more excess electrons. In this class, e.g., $[Na_{14}Cl_{12}]^+$, the excess electron localizes at the lattice site of the missing anion. This is conceptually similar to an *F*-center in an ionic bulk crystal. Enhanced stabilization is observed for those size clusters within this class where the excess electron sitting at an anionic site yields a filled cuboid lattice. Nonetheless, because the localized electron has a large zero-point energy, its binding energy is much less than an anion at the same site. This is reflected in both the first and second I_P's, as well as the A_e's of this class of clusters [39.55]. Just as for *F*-centers in ionic crystals, clusters with an excess electron localized on an anionic vacancy have strong optical absorptions at energies well below the charge transfer bands [39.55].

The next class of ionic clusters with excess electrons consists of perfect cuboid ionic clusters which contain one or more excess electrons, but do not have a defect binding site such as an anionic vacancy or an excess metal atom. In these clusters, e.g., $Na_{14}Cl_{13}$, the electron is quite weakly bound in a surface state which primarily involves the surface metal cations. These clusters have particularly low electron binding energies; for example, the I_P of ≈ 1.9 eV determined for $Na_{14}F_{13}$ is the lowest I_P measured for any compound [39.55].

In the other two known classes of ionic clusters with excess electrons, the extra electrons have been calculated to localize on a metal cation or in a dipole potential well [39.58]. Some evidence for these forms of localization has been seen in photoabsorption, I_P's and A_e's [39.10, 11, 55]. For example, the photoelectron spectra of some $\left[Na_{j+1}Cl_j\right]^-$ clusters show that the two excess electrons are singlet-coupled, and localized either at an anion vacancy, or at a single Na site so that they behave as a Na^- anion loosely bound to a neutral $\left[Na_jCl_j\right]$ cluster. The spectral behavior of other clusters within this same series, however, suggests they have the two excess electrons in a triplet coupled state, forming the analog of a bipolaron in a solid [39.10].

39.4 Semiconductor Clusters

Semiconductor clusters make up a class of clusters where, by analogy with bulk semiconductors, covalent forces are expected to dominate electronic and geometric structure. Silicon clusters are by far the most studied of the semiconductor clusters. Some information is available on germanium clusters and compound clusters made of Groups III and V atoms or Groups II and IV atoms. Also, there are the well known stable molecules of bulk semiconductors such as the P_4 tetrahedron and various sulfur rings; these have been reviewed in detail elsewhere [39.3]. Clusters of other possible semiconductors have been made, but little data beyond their nascent distributions are available [39.3]. There is also a growing body of data on silicon, III–V, and, especially II–VI semiconductor clusters in the nanometer size regime where bulk samples of stabilized forms of these clusters have been made and isolated. The crystalline and electronic structure properties, particularly quantum confinement effects, are reviewed in [39.10, 11, 59–61].

39.4.1 Silicon and Germanium Clusters

The geometries of small silicon clusters depart radically from microcrystalline fragments of the bulk silicon diamond lattice. The structures of silicon clusters containing up to about 13 atoms have been studied extensively both experimentally and theoretically [39.62]. These structures are more compact and, starting at Si_7 which has a pentagonal bipyramidal structure, have higher coordination than silicon in the bulk lattice. Multiple isomers of similar energy also appear starting at about Si_{10}. For example, the tetracapped trigonal prism and the symmetric tetracapped octahedron structures of

Si_{10} are nearly isoenergetic; microcrystalline fragments such as the adamantane form of Si_{10} are much higher in energy. The geometric structures of larger silicon clusters are less well known. The gross shapes of clusters containing up to about 60 silicon atoms have been found experimentally to undergo a transition between Si_{20} and Si_{30} from increasingly elongated structures to more spherical structures [39.26]. In the transition region, both prolate and oblate isomers are observed for a single cluster size. Multiple isomers over a wide range of silicon cluster sizes have been repeatedly observed in various experiments; it appears that somewhat different sets of isomers can be produced depending on the cluster formation conditions [39.26]. Elucidating the ground state structures of these larger clusters theoretically is, in general, an intractable problem and requires simplifying approaches. Use of semiempirical quantum mechanical techniques or silicon interaction potentials derived from bulk silicon, however, has led to unsatisfactory results, which suggests that the silicon atoms in silicon clusters are strongly reconstructed away from the usual sp^3 silicon atom environment [39.63, 64]. Some consensus has recently emerged that larger silicon clusters consist of internal silicon atoms strongly interconnected to a surrounding cage that has been described as a buckled fullerene [39.63, 65, 66]. Such a silicon cage must not be construed as a true fullerene, however, since silicon does not form the strong double bonds which stabilize the interconnected carbon rings of the fullerenes. Within this scenario, the shape change is believed to occur at the point where the cage begins to contain one or more internal atoms which provide the additional bonding needed to stabilize a spherical geometry.

I_P's and A_e's, cohesive energies, and photoabsorption spectra have been measured for silicon clusters containing up to several hundred atoms. Silicon cluster I_P's start near the Si atom I_P, fall abruptly between 20 and 22 silicon atoms where the shape change has been observed, and then slowly converge towards the bulk work function. This convergence is apparently quite gradual since little change is seen between Si_{100} and Si_{200} [39.67]. A_e's are only known for silicon clusters up to ≈ 15 atoms and reflect the large structural changes which occur in this small size regime [39.3]. Indication of a structural shape change is not observed in either the trends in the cohesive energies or the electronic spectra for silicon clusters. The cohesive energies increase smoothly with increasing size and exceed the cohesive energy of bulk silicon by 10–20% [39.68]. Silicon clusters exhibit strong sharp absorption spectra in the near UV. A common set of absorption features appears at $\approx Si_{15}$ and persists up to at least Si_{70} [39.69]. This suggests that the strong absorptions arise from localized Si−Si bond excitations, and that these obscure the delocalized excitations which are more sensitive to silicon cluster structure. The most unusual aspect of these spectra is that the common signature for these minute clusters which are strongly reconstructed from the bulk is, nonetheless, strikingly similar to the spectrum of bulk diamond-lattice crystalline silicon.

Silicon cluster ions are observed to react with a variety of reagents [39.3, 26, 68]. For example, silicon clusters chemisorb small organic molecules such as ethylene, and inorganic molecules such as O_2, NH_3, and XeF_2. Some of these reactions are sufficiently exothermic that they cause cluster fragmentation, or loss of small neutral fragments. The chemistry of silicon clusters often bears a close relationship to that known for bulk silicon surfaces; however, the clusters are often much less reactive by as much as several orders of magnitude. Silicon cluster reactions reveal the presence of numerous isomers which differ in their reaction rate for a given reagent. Isomerization has been induced by adding sufficient thermal energy to some clusters; the resulting more stable cluster form may or may not be more reactive than the higher energy isomer. This is particularly well illustrated in reactions of oblate versus prolate isomers where the more reactive isomer varies depending on cluster size [39.26]. In general, differential chemistry is not a useful predictor of cluster geometry *per se*, and appears to correlate more readily with other factors such as the number and type of dangling bonds available for reaction.

Much less is known about germanium clusters. The most stable structures that have been calculated for germanium clusters are quite similar to those for silicon clusters, although the overall binding energies are lower for germanium clusters [39.3, 7]. Available data such as A_e's and photoelectron spectra for germanium clusters also underscore their similarities to silicon clusters in general [39.3]. The chemistry of germanium clusters has not been reported.

39.4.2 Group III–V and Group II–VI Semiconductor Clusters

Geometric structures have been calculated for some of the smaller III–V and II–VI clusters, particularly aluminum phosphide, gallium arsenide, and magnesium sulfide clusters [39.3, 11, 70–72]. As for silicon clusters, these clusters differ significantly from microcrystalline fragments snipped from their corresponding bulk crys-

talline forms. Electronegativity differences between the two constituent atoms play a major role in determining and stabilizing these structures. This is manifested in several ways. The bonding arrangements in the most stable structures have, in general, alternating electropositive and electronegative atoms. In those clusters such as III–V clusters where electronegativity differences are smaller, covalent interactions predominate ionic interactions and the energetics of the various geometric structures are similar to those of the covalent silicon clusters. In II–VI clusters, electronegativity differences are much larger, and these clusters have structures more comparable to those seen in ionic clusters where ionic interactions are maximized.

Some data are available on the electronic structures of III–V clusters. A strong even-odd alternation occurs in both the I_P's and A_e's of gallium arsenide clusters where those clusters having a total even number of atoms have higher I_P's and lower A_e's than neighboring odd-numbered clusters [39.3, 73]. This has been explained by electronic structure calculations which find that, in general, the odd clusters are triplets while the even clusters

of gallium arsenide are singlets [39.70–72]. Electronic absorption spectra have also been recorded for indium phosphide clusters which exhibit strong differences with cluster size and stoichiometry [39.74]. These spectra are also consistent with odd-numbered In_xP_y clusters having open-shell configurations, and even-numbered In_xP_y clusters having closed-shell singlet ground states, even for clusters which are considerably off-stoichiometry. A strikingly similar strong continuum-like absorption appears in the blue end of spectra for the even-numbered In_xP_y clusters. The onset of these bsorptions lies close to the bulk indium phosphide band gap. The overall spectral behavior, however, is quantitatively similar to the absorptions seen in semiconductor glasses.

Little is known about the chemical properties of these clusters, with gallium arsenide clusters being the only ones studied. Hydrogen chloride is observed ubiquitously to etch $[Ga_xAs_y]^-$; however, multiple isomers are seen with differing degrees of reactivity [39.3]. Chemisorption of ammonia on $[Ga_xAs_y]^+$ has also been seen with the highest rates of reactivity occurring for the stoichiometric ($x = y$) clusters [39.75].

39.5 Noble Gas Clusters

Clusters have been made of all of the stable noble gases including helium. As a general class, these clusters are the most weakly bound of all clusters, and are held together only by van der Waals forces. These interactions are well understood theoretically, and thus noble gas clusters are excellent model systems for studying a variety of structural and electronic effects at finite sizes. Helium clusters behave much as quantum liquids, and are treated separately in the discussion below.

39.5.1 Geometric Structures

The overall evolution of noble gas cluster structures as a function of size is well established [39.4, 6, 11, 76, 77]. Icosahedral packing dominates at small cluster sizes. This packing involves polyicosahedral structures for the small cluster sizes, and different noble gas clusters exhibit somewhat different preferred arrangements. Starting at 100 to 250 atoms (depending on which noble gas), formation of closed-shell Mackay icosahedra dominates the structures [39.78]. Finally, at somewhere in the range 600 to 6000 atoms, the structures cross over to the close-packed fcc arrangement of the noble gas solids.

The increased coordination characteristic of the Mackay icosahedra explains why this morphology is

adopted at small cluster sizes. With the addition of each successive icosahedral shell however, this five-fold symmetric packing becomes increasingly strained as a result of both atom-atom radial compression and tangential dilation. At some size, icosahedral structures are no longer more stable than fcc structures, and the noble gas clusters undergo a phase change. Currently, the critical size required for fcc packing is a matter of some dispute. Experimental evidence for this transformation at ≈ 600 atoms comes from electron diffraction data [39.76]. The spectral signatures of molecules doped in noble gas clusters suggest however, that this transition occurs at ≈ 2000 atoms [39.77]. Theoretical studies find a range of critical sizes, depending on the treatment used, but typically favor an even larger size regime [39.4, 11, 13, 77].

Knowledge of accurate pair-wise interaction potentials for noble gases has enabled extensive simulations of the physical properties of noble gas clusters [39.4, 6, 7, 79–81]. Phenomena such as specific heat, bond length and coordination number fluctuations, phase equilibria, dynamical freezing and melting, isomerization, and solvation have been explored using various molecular dynamics simulations. Numerous effects peculiar to the finite sizes and proliferation of isomers in small noble gas clusters are observed. For example, the melting

temperature decreases significantly with an overall decrease in cluster size. Internal diffusion rates depend strongly on cluster size and the stability of certain favored structures such as the complete Mackay icosahedra. A well-studied finite size effect is the dependence of the mean energy per particle in a cluster versus the particle temperature (the so-called *caloric curve*) in the region where the particle is observed to "melt." Unlike in the bulk, calculations find hysteresis in the melting transition of small noble gas clusters where solid-like and liquid-like forms are observed to coexist. Such coexistence is quite size-dependent. It becomes more pronounced when the clusters are rapidly heated or cooled, and appears to be a finite time averaging effect [39.4, 6, 7].

39.5.2 Electronic Properties

The fragility of noble gas clusters has hampered measurements of their I_P's and A_e's. Extensive fragmentation is known to accompany ionization, making it difficult to establish the size of the ionized parent cluster. Nonetheless, I_P's have been measured for cluster sizes containing up to several tens of atoms [39.82]. Measured I_P's agree with theoretical predictions which are based on the assumption that the ionizing state within the cluster is a dimer, trimer, or higher n-mer cationic core [39.6, 82]. Absorption profiles of noble gas cations provide supporting evidence for the delocalization of the positive charge over a n-mer unit within the cluster, although consensus has yet to be reached on the size of this cationic cluster within the cluster [39.6, 11].

Several distinct types of electronic excitations are observed in absorption spectra of neutral noble gas clusters [39.6, 7, 11, 83]. Clusters containing less than ≈ 30 atoms exhibit broad absorptions near the atomic resonance lines. These absorptions are molecular-like, but have not been described in detail above the dimer. In addition, broad continuum absorptions assigned to Rydberg excitations are observed at these small sizes. Bulk-like excitations corresponding to surface and bulk excitons in solid noble gases emerge for clusters larger than ≈ 50 atoms. The profiles of these excitonic absorptions indicate that they arise from delocalized excitations analogous to Wannier excitons in bulk solids. These cluster exciton absorptions are blue-shifted relative to the bulk as a result of quantum confinement of the exciton within the small cluster. Another type of excitonic excitation has also been reported which appears to be a localized excitonic state whose character is sensitive to the cluster structure. Relaxation of cluster excited states

is accompanied by extensive fragmentation [39.7]. Details of the relaxation processes differ according to noble gas, cluster size and cluster structure. Again, these differences can be traced to finite size effects in these noble gas clusters [39.4].

39.5.3 Doped Noble Gas Clusters

Various chromophores have been added to noble gas clusters as a microscopic variation of matrix isolation [39.3, 4, 7, 10, 11, 77, 84]. A wide range of chromophores have been studied including other noble gas atoms, metal atoms, small polyatomic molecules such as SF_6, CH_3F, and HCl, and a variety of organic molecules such as benzene, carbazole, and naphthalene. Comparisons of the electronic and vibrational spectra of these guest molecules with their spectra in noble gas liquids or solid matrices have revealed information such as noble gas cluster structure, solvation effects, and solute diffusion.

A crucial issue in understanding the spectral signatures of doped noble gas clusters is the location of the solute in or on the noble gas cluster. Chromophores well-embedded in a noble gas cluster behave as molecules surrounded by a dielectric medium, which is most correctly viewed as both imperfect and finite sized [39.4, 7, 84, 85]. The evolution of the spectral changes with cluster size reflect the interplay of repulsive forces and collective dielectric effects as the cluster builds the solvent shell around the solute core. Both theoretical and experimental data illustrate this evolution and show how, once the first few solvent shells are established, the spectrum converges asymptotically to the matrix isolation value. For smaller clusters, the effects of too few or incomplete solvation shells appear as shifts and/or broadening of the spectral lines relative to the bulk [39.3, 4]. Differential solvation of the ground and excited states causes spectral shifts which are typically to lower energy since the excited state is usually more stabilized than is the ground state. Spectral broadening results from multiple isomers. Broadened electronic spectra have also been explained as a signature of cluster melting, although this interpretation has been questioned [39.3, 4, 84, 85]. Some infrared spectra of solute molecules have also yielded information on the nature of the solute binding site, revealing that the solvating noble gas cluster undergoes an icosahedral to fcc phase transition in a critical size regime [39.77].

Not all dopant species are found well-solvated, or *wetted* in the cluster interior. Both electronic and infrared dopant spectra indicate the existence of chro-

mophores bound to the cluster surface. In some cases, the chromophore is ubiquitously *nonwetting*, such as for SF_6-Xe_n and SiF_4-Ar_n, and resides exclusively on the cluster surface [39.77]. In other systems, e.g., carbazole$-Ar_n$ and CF_3Cl-Ar_n, both wetting and non-wetting are observed [39.7,77,84]. Systems such as these have enabled measurements of solute diffusion rates into or out of the cluster. Finally, wetting–nonwetting transitions have been observed which depend on cluster size and/or cluster temperature [39.7, 84]. Understanding this wide variety of behavior requires modeling cluster solute-solvent structures (in both ground and excited states in order to interpret electronic spectra) as a function of size and temperature. To date, most of the theoretical simulations have focussed on smaller clusters at a given temperature [39.4, 7, 77, 84, 85]. Nonetheless, theoretical models have provided qualitative and quantitative explanations for some of the observed spectral shifts, and have shown that the propensity for wetting/nonwetting can be related to the degree to which maximum possible coordination within the solvent is attainable.

39.5.4 Helium Clusters

Quantum effects play a dominant role in helium clusters since they consist of very weakly interacting small mass particles. Statistical effects are also expected since ^3He is a fermion and ^4He is a boson. Overall, helium clusters are believed to be in fluid-like or superfluid-like states with highly fluctional structures [39.86].

Neutral helium clusters have been made experimentally in sizes ranging from the dimer up to 10^6 atoms [39.4, 11, 77]. The diatomic He_2, has just been detected recently and is found to have a binding energy of only $\approx 10^{-7}$ eV with an average internuclear distance of ≈ 55 Å [39.87,88]. Evidence for magic numbers in the helium cluster abundances is seen; however, the sizes of these especially stable clusters differ substantially from what is seen in the other noble gas clusters [39.4]. Helium cluster structures have been theoretically investigated using fully quantum mechanical treatments [39.4, 86]. These studies find that ^4He_n clusters should be bound at all sizes, but that a minimum number of atoms, ≈ 30, are required for ^3He_n clusters to be stable. The latter prediction has not yet been verified experimentally, owing to the expense of ^3He, and the difficulties of ascertaining the true size of helium clusters since they easily boil off atoms upon ionization. Calculations reveal that the packing of helium clusters is highly delocalized with no evidence of icosahedral morphology. The structures derived have been found to be extremely sensitive to temperature and total angular momentum. Cluster binding energies and densities increase smoothly and monotonically with increasing size, approaching bulk behavior at about 300 atoms. Thus, helium clusters do not exhibit any especially stable sizes (magic numbers) such as the heavier noble gases do. In short, helium clusters behave as liquid-like quantum fluids, and may even be superfluid-like at the temperatures required to stabilize them in beam experiments. Based on these calculations, it appears that the magic numbers observed experimentally in abundance spectra pertain to the more strongly bound ionized helium clusters, rather than the neutral clusters which are the subject of this discussion.

Electronic absorption spectra have recently been recorded for clusters containing $\approx 50-10^6$ helium atoms [39.89]. Broad strong absorption bands are observed which do not behave like the Wannier exciton bands seen for the heavier noble gas clusters, nor are they well-described by the Frenkel excitonic model. Note that although the Wannier and Frenkel exciton models were originally developed for solids with translational symmetry, they are also good descriptions for excitations in liquid noble gases [39.4]. At this writing, the helium cluster electronic spectra cannot be compared with absorption spectra of liquid or solid helium because these latter spectra have not yet been measured! With this limitation and a current lack of sufficient theoretical guidance, the helium cluster spectra have not yet been thoroughly interpreted. Theoretical calculations are available which describe the collective excitations in helium clusters on the electronic ground state surface [39.86]. Spectra in this energy regime have not yet been recorded.

Experimentally, it has been quite easy to dope helium clusters with various atomic and molecular species such as other noble gas atoms, oxygen, and SF_6 [39.4,11,77]. Electrons, however, are not well-solvated and negatively charged helium clusters only appear for sizes containing more than 10^5-10^6 atoms [39.11]. Impurity species provide a spectroscopic probe for studying the properties of the solvating helium cluster. Infrared spectra of helium clusters doped with SF_6 show that the impurity molecule resides on the cluster surface, in contradiction of theoretical calculations which predict that it should be found inside a helium cluster. Understanding this discrepancy has stimulated further theoretical investigations that reveal the dramatic structural effects which can occur when angular momentum is added to these very fragile clusters during dopant pick-up [39.90].

39.6 Molecular Clusters

Molecular clusters are in many ways similar to noble gas clusters. Both are weakly bound, and the interactions between the particles which make up the cluster can usually be described to a good approximation as the sum of pairwise interactions. The molecule constituency adds complexity, however, which is reflected in the diversity seen amongst these clusters. Molecular clusters provide model systems for studying solvation, including electron solvation, nucleation, and phase transitions at finite sizes. Furthermore, properties which are often difficult to study in the bulk, such as phase transition dynamics, are much more amenable to study in molecular clusters.

Numerous molecular clusters have been made and studied. By far the most work has focussed on the smaller molecular clusters such as molecular dimers, trimers and tetramers. A number of outstanding reviews are available on this subset of molecular clusters [39.3,4,6,76,91,92].

39.6.1 Geometric Structures and Phase Dynamics

In contrast to noble gas clusters, molecular clusters typically assume bulk phase structures at relatively small sizes. Thus, the range of condensed phases of molecular solids is reflected in the variety of packing structures found in molecular clusters. At one extreme are clusters of small nearly-spherical molecules such CH_4 and N_2 which form clusters closely connected to noble gas clusters [39.76]. Small clusters of these molecules are packed in polyicosahedral arrangements at small sizes, and cross over to fcc structures at sizes containing several thousand atoms. At another extreme are clusters such as water clusters where stronger hydrogen bonding forces lead to the formation of crystalline networks such as in a diamond cubic phase [39.76]. Some molecular clusters appear to be liquid-like with thermal motion wiping out any persistent periodic order. The liquid-like structure observed in clusters of molecules such as benzene and various hydrocarbons may freeze into a crystalline or amorphous state at sufficiently low temperatures.

Some molecular clusters have been found to exhibit a panoply of phases, depending on size and temperature. For example, not only do clusters of TeF_6 assemble into the bulk body-centered cubic and orthorhombic phases, they can also be made in other phases including two trigonal forms, a rhombohedral phase, and two monoclinic phases [39.93, 94]. Similarly complex phase formation has been found in other clusters of other hexafluoride molecules such as SF_6, SeF_6, MoF_6, and WF_6.

Phase transitions in molecular clusters have been examined both experimentally and theoretically using molecular dynamics. Transition temperatures are found to depend on cluster size, and span a much broader range than in the corresponding bulk phase transitions. Large rates for nucleation and phase changes are seen in molecular clusters. Once the critical nucleus, which initiates the phase change, forms in the interior of the cluster, the remainder of the cluster transforms to the new phase extremely rapidly. Critical nucleus sizes depend on the cluster size and are typically quite small, e.g., for TeF_6 clusters, they contain only a few dozen molecules for clusters consisting of a few hundred molecules [39.10, 93, 94]. A key finding is that phase transitions in molecular clusters appear to violate *Ostwald's step rule*, which states that equilibrium systems must pass through all intermediate-energy stable phases during a transition from a higher energy to a lower energy phase [39.10]. This noncompliance apparently occurs because of the speed at which molecular clusters undergo phase transitions: intermediate phases simply do not have time to form.

39.6.2 Electronic Properties: Charge Solvation

I_P's, A_e's, and some spectral data are available for larger molecular clusters. Nearly all of the spectra measured pertain to clusters containing less than ten molecules [39.3, 4, 6, 76, 91, 92]. Precise molecular orientations within many of these clusters have been derived from detailed analyses of these spectra. Such information has not yet emerged from the few spectra that have been measured for larger molecular clusters [39.3, 6]. Alternatively, measurements of electronic properties of larger clusters have generally targeted a different issue: solvation of excess positive or negative charge in a restricted bulk-like system.

Charged molecular clusters provide model systems for studying the mechanism of charge stabilization within the confines of a finite system. Excess positive charge appears to be highly localized in molecular clusters, residing on a small unit containing at most a few monomers. This positive core is surrounded and stabilized by overlying shells of molecules. For example, $(CO_2)_n^+$ clusters behave as the dimer cation $(CO_2)_2^+$,

surrounded by the remaining CO_2 molecules [39.4]. Positively charged solutes such as alkali cations have also been introduced to study solvation of positive charge within molecular clusters [39.10]. For those dopants which have much lower ionization potentials than the solvating molecules, the positive charge remains strongly localized on the impurity. The cluster molecules are observed to build up solvation shells around this central impurity. The first few solvation shells are strongly affected by the positive charge, which has a decreasing influence with each successive layer. The structure of such a cluster reflects the accommodation between the geometry of the molecules influenced by the central positive charge, and those in the outer solvation layers where intermolecular forces predominate [39.10, 95]. Evidence for intracluster reactions in positively charged clusters has also been seen, such as proton transfer in cationic water or ammonia clusters [39.3, 11].

Whereas virtually every molecular cluster containing as little as two molecules exists stably as a positive ion, the same cannot be said for the negative cluster ions. Measurements of the minimum number of molecules required within the cluster to support an additional electron show that, while the dimeric $(HCl)_2^-$, $(SO_2)_2^-$, and $(H_2O)_2^-$ clusters are stable, ≈ 35 or ≈ 41 molecule-clusters of ND_3 or NH_3, respectively, are required to stabilize an electron [39.4]. Spectroscopic studies show evidence for internal and external solvation of the excess electron in these anionic clusters.

Charge solvation in water clusters has been examined in some detail. Of particular interest is the $(H_2O)_{20}$ cluster which, from experimental and theoretical data, appears to form an especially stable, well-defined clathrate cage. The interior of this cage is large enough that it can and does hold various cations such as NH_4^+, H_3O^+, and alkali ions [39.10]. This cage is not observed to surround negative ions or electrons, which instead, reside on the surface [39.10]. This is a general result for excess negative charge in water clusters in this size regime where excess charge can be external to the cluster. Excess electrons in water clusters are found on the cluster surface for small cluster sizes up to 60 to 70 water molecules. Above this size, the electron resides in the cluster interior, and behaves analogously to hydrated electrons in bulk water [39.4, 7].

39.7 Recent Developments

Added by Mark M. Cassar. Experimental and theoretical work on clusters has continued to be an active and rapidly growing area of research over the past decade. This Section provides a non-exhaustive snapshot of some recent work in the vast field of cluster science.

The original focus on the scalable properties of clusters (concerning a smooth transition from small particles to bulk matter) has now extended to include important non-scalable properties. These properties, particularly at the nanoscale level, have enormous potential for technological application [39.96–98]. Studies aimed at understanding the underlying atomic structure of noble-metal clusters and nanoparticles, which is the first step toward their controlled use in future nanotechnologies, e.g., catalysis, labeling, or photonics, have been carried out [39.99]. Ab initio all-electron molecular-orbital calculations for small ($n = 7 - 11$) and medium ($n = 12 - 20$) silicon clusters Si_n have been performed in order to study their structure and relative stability [39.100,

101]; such calculations are important in determining the scalability of present day semiconductor technology.

Other interesting work has been done on the electron transfer properties of metal clusters that could act as conducting bridges between molecular wires [39.102]; and in the role that tetramanganese clusters play in one of the active photosynthesis sites (photosystem II) in green plants, and in certain bacteria and algae [39.103].

The reader is referred to various reviews that can be found in the literature: for time-resolved photoelectron spectroscopy (TRPES) of clusters, which allows the dynamics along the entire reaction coordinate to be followed, see [39.104]; for ultrafast dynamics in cluster systems and atomic clusters, see [39.105, 106]; for small carbon clusters, important in the chemistry of carbon stars, comets, interstellar molecular clouds, and hydrocarbon flames, see [39.107]; for the relation between electronic structure, atomic structure and magnetism of clusters of transition elements, see [39.97].

40. Infrared Spectroscopy

Infrared spectroscopy consists of the measurement of interactions of waves of the infrared (IR) part of the electromagnetic spectrum with matter. The IR spectrum starts just beyond the red part of the visible spectrum at a wavelength $\lambda = 700$ nm and extends to the microwave region at $\lambda = 0.1$ cm. Electromagnetic waves are generally described in terms of their frequency ν in Hz. In IR spectroscopy it is common practice however to use the spatial frequency $\sigma = \nu/c$. These are called wavenumbers and have units of cm^{-1}. In this way the near, mid and far IR spectrum spans the frequencies from 14 300 cm^{-1} to 10 cm^{-1}. The interactions observed in the IR spectrum involve principally the energies associated with molecular structure change. Infrared spectroscopy is therefore useful for molecular structure elucidation and the identification and quantification of different molecular species in a sample [40.1].

The most common IR analysis of a sample is by IR *absorption* spectroscopy. This involves transmitting a beam of intense IR radiation through the sample and observing the distribution of wavenumbers absorbed by the molecules. Molecules in a sample may also be studied by IR *emission* spectroscopy simply by observing specific wavenumbers being emitted

by virtue of the nonzero absolute temperature of the sample. Finally, radiation *reflected* from a smooth surface of a solid sample also provides information about the molecular structure of the material by virtue of the anomalous dispersion associated with absorption bands.

40.1 Intensities of Infrared Radiation

For strong interactions of electromagnetic waves with matter, the emitted and absorbed intensities are governed by Planck's radiation law in addition to the emissivity and absorptivity of the material. Planck's radiation law for thermal radiation from an ideal black body is

$$P_{bb}(\sigma) \, d\sigma = \frac{c_1 \sigma^3 \, d\sigma}{\exp(h\sigma/k_B T) + 1} \, , \qquad (40.1)$$

where c_1 is a proportionality constant. Depending on the definition of c_1, $P_{bb}(\sigma)$ may represent a radiation

density per unit spectral interval $\left(\text{cm}^{-1}\right)$ in a cavity at temperature T in ergs/cm^3, or an energy flux emitted from a surface in W/cm^2 steradians. At frequencies low compared with $h/k_B T$, the energy distribution increases with σ^2 and is approximately proportional to T at a given σ. At high frequency, the energy distribution falls off exponentially. In the near IR, a high temperature is required to emit radiation. Room temperature objects emit strongest in the 300 to 600 cm^{-1} region, and emit negligible energy above 3000 cm^{-1}. Materials cooled to liquid nitrogen temperature (77 K)

only emit below $100\,\text{cm}^{-1}$, while materials cooled to liquid helium temperature ($4.2\,\text{K}$) only emit below $20\,\text{cm}^{-1}$. In contrast to visible spectroscopy, IR absorption spectroscopyis complicated by emission of IR radiation from the sample and the surrounding environment.

40.2 Sources for IR Absorption Spectroscopy

A silicon carbide element electrically heated to $1400\,\text{K}$ provides a strong continuum of IR radiation over a major part of the IR spectrum. It is commonly used as a source of radiation for IR absorption spectroscopy. For near IR spectroscopy, a tungsten filament lamp operated at $2800\,\text{K}$ provides a strong continuum all the way up to the visible part of the spectrum; it is not useful below $3000\,\text{cm}^{-1}$ because of absorption by the glass or quartz envelope. Various electrically heated ceramic elements, such as the Nernst glower and high temperature carbon rods, have been devised to serve as IR sources.

40.3 Source, Spectrometer, Sample and Detector Relationship

Since a sample at room temperature emits IR radiation in the mid IR, it is important to distinguish between transmitted radiation used in the determination of its absorption spectrum and its emission spectrum. By employing an intense IR beam, the effect of emission is minimized. Further distinction is achieved by encoding the IR beam before it impinges on the sample.

With classical grating or prism spectrometers, the source radiation is chopped by means of a mechanical chopper before it passes through the sample. The IR detector is provided with a means of synchronously decoding the chopped signal, thereby eliminating the emitted spectrum. Often the chopper is arranged such that it alternately switches between an empty reference beam and the sample. The logarithm of the ratio of the demodulated sample and reference spectra provides the absorption spectrum directly.

In *Fourier Transform infrared (FTIR) Spectroscopy*, a scanning Michelson interferometer provides the encoding function directly and no chopper is required. The interferometer is commonly placed before the sample so that it does not encode the thermally emitted radiation of the sample. Ratio recording of a sample against an empty beam is not common in FTIR. Instead, the absorption spectrum is obtained by sequentially recording the spectra of the sample and of the empty beam (sample removed), and computing the logarithm of the ratio numerically.

If it is not convenient to place the sample after the scanning Michelson interferometer, the absorption spectrum of a sample placed in front of the interferometer can be deduced by subtracting the separately recorded emission spectrum from the combined transmission plus emission spectrum.

Infrared emission and reflection spectroscopy form the basis for remote sensing. Solid and gaseous (cloud) objects may be identified and quantified by direct observation of their IR spectra at a distance. Gaseous clouds reflect poorly, providing only transmitted or emitted IR radiation. Their emission spectrum is contrasted directly with the spectrum of the scene or object beyond the cloud. With a background at lower temperature than the gas cloud, the gas spectrum appears in emission, while with a warmer background the gas spectrum appears in absorption.

Only a few solid materials transmit IR radiation over a substantial thickness. Remote sensing of solid objects relates therefore to surface emission and (diffuse) reflection of IR radiation from the surrounding environment.

40.4 Simplified Principle of FTIR Spectroscopy

In FTIR spectroscopy, the spectrum of a beam of incident IR radiation is obtained by first generating and recording an interferogram with a scanning Michelson interferometer. Subsequently the interferogram is inverted by means of a cosine Fourier transform into the spectrum.

40.4.1 Interferogram Generation: The Michelson Interferometer

The scanning Michelson interferometer shown in Fig. 40.1 consists of a beam splitter, which is a substrate with a dielectric coating such that 50% of an incident beam is reflected and the remaining 50% is transmitted, and two plane mirrors (M_1 and M_2), one or both of which are translated along the direction of the beam. After splitting, the two equal amplitude wave fronts are propagated along different optical paths. The mirrors at the end of each path return the wavefronts to the beamsplitter, which then acts as a wavefront combiner. Because of their common coherent origin, the wavefronts interfere with one another when they combine. The state of interference is varied by scanning one or both of the mirrors such that there is a variable time delay between the two separated beams. The resulting intensity variation of the combined output beam as a function of relative time delay is the interferogram.

40.4.2 Description of Wavefront Interference with Time Delay

The intensity $I_0(\nu)$ at frequency ν of a plane wave in space is given by the expectation value of its electric field vector $\boldsymbol{E}(\nu, t) = \mathcal{E}(\nu) \exp(\mathrm{i}2\pi\nu t)$ according to

$$I_0(\nu) = \langle \boldsymbol{E}(\nu, t) | \boldsymbol{E}(\nu, t) \rangle = \mathcal{E}(\nu)^2 . \tag{40.2}$$

The intensity at the output of the interferometer due to an incident intensity $I_0(\nu)$ is given by $I(\nu, \delta)$, where δ is the time delay between the two wavefronts which have been propagated along two different paths, and

$$\begin{aligned} I(\nu, \delta) &= \langle \boldsymbol{E}(\nu, t) + \boldsymbol{E}(\nu, t+\delta) | \boldsymbol{E}(\nu, t) + \boldsymbol{E}(\nu, t+\delta) \rangle \\ &= \frac{1}{4}\mathcal{E}(\nu)^2 \left(2 + \mathrm{e}^{-\mathrm{i}2\pi\nu\delta} + \mathrm{e}^{\mathrm{i}2\pi\nu\delta}\right) \\ &= \frac{1}{2}I_0(\nu)[1 + \cos(2\pi\nu\delta)] . \end{aligned} \tag{40.3}$$

As can be seen, the output intensity of a single frequency source at the output of an ideal scanning Michelson interferometer fluctuates sinusoidally between zero and the input intensity $I_0(\nu)$ as the time delay δ between the separated wavefronts is varied by means of scanning one of the mirrors.

The quantity δ is related to mirror displacement x with respect to equal distance of the mirrors from the
Fig. 40.1 The Michelson interferometer

beamsplitter by

$$\delta = 2x \cos\theta/c , \tag{40.4}$$

where θ is the angle between the wavefront and the optical axis of the spectrometer, and the optical axis is the normal to each plane mirror M_1 and M_2. From this, (40.3) becomes

$$I_0(\nu, x) = \frac{1}{2}I_0(\nu)\{1 + \cos[2\pi\nu(2x \cos\theta/c)]\} , \tag{40.5}$$

or, using $\sigma = \nu/c$,

$$I_0(\sigma, x) = \frac{1}{2}I_0(\sigma)\{1 + \cos[2\pi\sigma(2x \cos\theta)]\} . \tag{40.6}$$

Thus the output intensity fluctuates at frequency $\sigma' = 2\sigma \cos\theta$ as a function of the mirror displacement x.

The incident intensity generally consists of a distribution of intensities over many frequencies $S(\nu)\,\mathrm{d}\nu$ with integrated intensity

$$I_0 = \int S(\nu)\,\mathrm{d}\nu . \tag{40.7}$$

For this case, the output intensity of an ideal scanning Michelson interferometer is given by

$$I_0(\delta) = \frac{1}{2}\int S(\nu)[1 + \cos(2\pi\nu\delta)]\,\mathrm{d}\nu . \tag{40.8}$$

The second term on the right side of (40.8) has the form of the cosine Fourier transform of the spectrum.

By rearrangement of (40.8), it is given by

$$\int S(v)\cos(2\pi v\delta)\,\mathrm{d}v = 2I_0(\delta) - I_0 \,. \tag{40.9}$$

The constant term I_0 provides no useful information about the spectrum. The inverse cosine Fourier transform of $2I_0(\delta)$ results in the spectrum $S(v)$ according to

$$S(v) = \int 2I_0(\delta)\cos(2\pi v\delta)\,\mathrm{d}\delta \,, \tag{40.10}$$

$$S(\sigma) = \int 2I_0(x)\cos\left(2\pi\sigma'x\right)\,\mathrm{d}x \,. \tag{40.11}$$

Contrary to classical spectrometers, where the spectrum is sequentially scanned, there is no segregation of frequencies of the input intensity. All frequencies in the source are modulated simultaneously by the scanning Michelson interferometer into a single interferogram signal. This multiplex mode of spectrum determination was first exploited by *Felgett* [40.2]. It contributes to a large advantage in sensitivity compared with other spectrometers, and is referred to as the Felgett or multiplex advantage.

40.4.3 The Operation of Spectrum Determination

The output interferogram is detected by an IR detector which converts the intensity variations $I_0(x)$ as a function of different mirror positions x into an electrical signal. Continuous determination of the inverse cosine Fourier transform of the evolving interferogram requires continuous multiplication of the signal by cosine functions with all the different frequencies of the spectrum and integrating these products. Continuous Fourier analysis with a bank of narrow band filters has been implemented both in analog and digital form in early versions of FTIRs [40.3].

It is, however, far more practical to capture the interferogram signal in numeric form, using an analog to digital converter, store it in computer memory, and compute the Fourier transform numerically after the mirror displacement range has been covered.

The numerical representation of the interferogram is determined at known intervals of mirror displacement Δx. The computed spectrum is then determined at regular intervals of spatial frequency $\Delta\sigma$ by the discrete cosine Fourier transform

$$S(j\Delta\sigma) = \sum_n 2I_0(n\Delta x)\cos(2\pi jn\Delta\sigma\Delta x) \,. \tag{40.12}$$

The sampling interval Δx of optical path difference determines the extent of the numerically computed spectrum. A higher density of sampling permits a wider spectral range to be determined, up to

$$\sigma_{\max} = \frac{1}{2\Delta x} \,. \tag{40.13}$$

Beyond $\sigma_{\max}$, the spectrum repeats in reverse order, and beyond $2\sigma_{\max}$, the spectrum repeats as is. This is called spectral aliasing, and results from the incomplete knowledge of the full interferogram function between the discrete numeric representation. In order to insure that the numeric representation of the interferogram describes the continuous function uniquely, it is important to band limit the interferogram information to the range 0 to $\sigma_{\max}$ by means of optical and electrical filtering.

Conversely, the higher the density of sampling in the spectral domain, the longer the interferogram needs to be. For a wavenumber range $\Delta\sigma$, the length is

$$x_{\max} = \frac{1}{2\Delta\sigma} \,. \tag{40.14}$$

From the orthogonality property of the discrete cosine Fourier transform, unique linearly independent information can occur only at spectral intervals equal to or greater than the sampling interval. Hence the sampling interval in the spectrum is related to the achievable resolution. The full width at half maximum of the representation of a single frequency in the spectrum is $1.2\Delta\sigma$. This factor applies for the case where the single cosine wave interferogram has been abruptly truncated at the end of the mirror scan. The lineshape function for this case is quite oscillatory due to the abrupt termination of the interferogram signal at the end of the scan. This is not always satisfactory, and frequently the interferogram is modified by a windowing or apodization function to make the lineshape more localized and monotonic. Apodization always results in an increase in the full width at half maximum.

A particularly convenient and accurate way to establish the sampling intervals of the interferogram is the use of a single frequency laser directed coaxially with the source radiation through the scanning Michelson interferometer. The intensity of the laser at the output of the interferometer is a highly consistent cosine wave with one cycle per change in mirror movement of one half wavelength of the laser light.

40.5 Optical Aspects of FTIR Technology

The description of wavefront interference developed in Sect. 40.4.2 applies to interference of plane wave fronts only. A plane wave of IR radiation is obtained at the output of a collimator optics having an IR point source at its focus. In practice a point source has insignificant intensity. A finite size source, which may be represented by a distribution of point sources in the focal plane of the collimator, provides a distribution of plane wavefronts with different angles of propagation through the scanning Michelson interferometer.

As shown in (40.6), this distribution of angles results in a distribution of modulation frequencies as a function of mirror displacement x of the output intensity for a given IR wavenumber. This is illustrated in Fig. 40.2 which shows, for a single frequency IR source, the distribution of output intensity modulation frequencies for an ideal point source on the optical axis, a circularly symmetric distribution of uniform intensity about the optical axis, and finally a circularly symmetric distribution positioned slightly off the axis of the collimator.

As a result of illuminating the scanning Michelson interferometer with a finite size source, a single IR frequency source is observed having a distribution of modulation frequencies in its interferogram signal. This distribution limits the ability to resolve two closely spaced IR frequencies and determines the optical resolution limit of the FTIR: The larger the extent of the source, the more restricted the resolution becomes. The ratio $\sigma/\Delta\sigma$ is the resolving power R of the scanning Michelson interferometer and, based on (40.6), is given by

$$R = 1/(1 - \cos\theta_m) \,, \tag{40.15}$$

where θ_m is the maximum off-axis angle of illumination. For small θ_m, $\cos\theta_m \approx 1 - \frac{1}{2}\theta_m^2$, so that

$$R \sim 2/\theta_m^2 \,. \tag{40.16}$$

From (40.14), a resolution limit is also imposed by the maximum length of the interferogram recorded. The interferogram length dependent resolution is constant for all spectral regions, while the optical resolution is proportional to the spectral frequency. Both resolution limits combine to give the overall resolution of an FTIR. At low resolution, the available throughput is so high that the optical resolution is often negligible compared with the length resolution. At high resolution, throughput is at a premium and the optical resolution is often closely matched to the length resolution at the frequency of interest.

To insure a symmetrical frequency distribution, the area integrated illumination must increase as $\sin\theta$, which is approximately linear for small angles, up to its maximum θ_m, as shown with the centered circular illumination in Fig. 40.2. Any deviation from this, such as off-axis positioning of the circle, noncircular shapes, or a poorly focused centered symmetrical circle, will result in a gradual roll-off of the distribution on the low frequency side only [40.4]. This results in an asymmetric spectral line shape.

For a collimator of given focal length and for a given resolving power, it is easily shown that the area of the source, or the stop that delineates it, is much larger than the slit area for classical grating spectrometers. This is particularly the case at high resolving powers.

This throughput advantage was first pointed out by *Jacquinot* [40.5], and plays an important role in the large sensitivity advantage of FTIR. The stop that delineates the source extent for a scanning Michelson interferometer is often referred to as the Jacquinot stop or the field of view stop.

a) Point source on optical axis

b) Circular source centered on optical axis

c) Circular source off axis or out of focus
Fig. 40.2 Distribution of interferogram modulation frequencies for a single optical frequency source

40.6 The Scanning Michelson Interferometer

Optical throughput is not only determined by the area of the field of view stop, but also the solid angle subtended by the rays traversing this area. The solid angle Ω of rays traversing a Jacquinot stop positioned in the focal plane of an input collimator is given by the ratio of the interferometer beam area divided by the square of the focal length of the collimator.

For a given collimator focal length, the area of the Jacquinot stop is inversely proportional to the resolving power. To maintain equal throughput, the area of the interferometer optics should be increased as resolving power is increased in order to offset the decrease in the Jacquinot stop area.

It is common to construct interferometers with 2.5 cm diameter optics for resolving powers up to 5000, 5.0 cm diameter optics for resolving powers up to 40 000 and 7.5 cm diameter optics for resolving powers up to 1 000 000.

In order to obtain a uniform state of interference across the entire beam of the interferometer, the beam-splitter substrate and the two mirrors must be flat to within a small fraction of the wavelength used. Also, these elements must be oriented correctly so that the optical path difference error across the beam is less than a small fraction of the wavelength.

Figure 40.1 shows two substrates at the beam-splitter position. One of the substrates supports the beamsplitting coating, while the companion substrate of precisely the same thickness acts as a compensating element to insure identical optical paths through the two arms of the interferometer. To avoid secondary interference effects, both beamsplitter and compensator substrates are normally wedged. The direction of the wedges of the two substrates must be aligned again to insure symmetry in both arms of the interferometer.

The maintenance of a very close orientational alignment tolerance of the two mirrors with respect to the beamsplitter in a stable manner over time and while scanning one of the mirrors is the greatest challenge of interferometer design and is also the greatest weakness of FTIR.

In early models of FTIRs, alignment was maintained by means of a stable mechanical structure and a highly precise linear air bearing for the scanning mirror. Satisfactory operation required a stable environment and frequent alignment tuning and could be achieved for mirror displacements of only several centimeters, thus limiting the maximum resolution.

Different techniques have been developed to overcome this weakness in FTIR. The two most prominent are (1) Dynamic alignment of the interferometer, where optical alignment is servo-controlled using the reference laser not only for mirror displacement control but also for mirror orientation control, and (2) the use of cube corner mirrors in place of the flat mirrors in the interferometer. Dynamic alignment has the advantage of retaining a high degree of simplicity in the optical design of the interferometer. On the other hand it is more complex electronically. Cube corners have the property of always reflecting light 180° to incident light independent of orientation. Cube corners always insure wavefront parallelism at the point of recombination of the two beams in the interferometer. Cube corners lack a defined optical axis. In a cube corner interferometer, the optical axis is defined as the direction in which the wavefronts undergo zero shear.

The scanning Michelson Interferometer is normally provided with a drive mechanism to displace one of the mirrors precisely parallel to its initial position and at uniform velocity. The uniform velocity translates the mirror displacement dependent intensities into time dependent intensities. This facilitates signal processing electronics. In some measurement scenarios however, where the sample spectrum may vary with time, it is undesirable to deal with the multifrequency time-varying intensities of the interferogram signal. In this case it is preferable to scan the moving mirror in a stepwise mode, where the mirror is momentarily stationary at the time of signal measurement and then advanced rapidly to the next position. The mirror scan velocity v can be varied so that electrical signals can have different frequencies for the same optical frequencies:

$$f = \sigma/2v . \tag{40.17}$$

The scan velocity is normally selected to provide the most favorable frequency regime for the detector and electronics used and for the mechanical capabilities of the mirror drive. Typically the velocity range is from 0.05 cm/s to 4 cm/s, putting the frequencies in the audio range. At these velocities, the measurement scan may be completed in a shorter time than is desired for signal averaging purposes. In this case it is common to repeat the scan a number of times and add the results together: this is called co-adding of scans.

40.7 Recent Developments

Added by Mark M. Cassar. Infrared spectromicroscopy, which combines the well-established technique of Fourier transform infrared (FTIR) spectroscopy with a microscope, has been one of the main developments in this area in the past decade. Recently, array detectors have made infrared imaging practical and quick. The brightness attainable in an IR spectromicroscope has also been enhanced through the use of a synchrotron radiation (SR) source, allowing the source beam to be focused to a spot with a diameter $\leq 10\,\mu m$ [40.6]. This also allows, because of the high signal-to-noise ratio, the measurement of dilute sample concentrations. One important application of SR-FTIR microscopy is to study the effects of various stimuli on biomolecules in order to understand how diseases start and spread [40.7, 8].

A testament to the robustness and versatility of FTIR is given by its potential inclusion in future Mars expeditions [40.9].

40.8 Conclusion

The modern technique of Fourier transform IR spectroscopy has evolved rapidly from its beginnings in the early 1950s to being the dominant technique of IR spectroscopy in many diverse disciplines. The Aspen Conference on Fourier Spectroscopy in 1970 was the watershed for FTIR, where many fundamental issues of the technique were treated [40.10]. A practical book by *Griffith* and *de Haseth* gives many examples of applications of FTIR [40.11].

FTIR is a powerful technique for infrared spectroscopy. It has a large sensitivity advantage over conventional dispersive spectrometers because of the efficient multiplexing of all the spectral elements and the greater throughput of the Jacquinot stop. It can be used efficiently for resolving powers from less than 1000 up to 1 000 000. FTIR combines techniques of optical interferometry, laser metrology and digital signal processing.

The computation of the cosine Fourier transform was initially a daunting task. Today, with highly efficient factoring algorithms brought to FTIR by *Forman* [40.12], and the widespread availability of inexpensive high performance personal computers, the computation time for a Fourier transform is only a fraction of a second per 1000 data points in the interferogram.

A traditional weakness of FTIR is the severe demand of alignment stability and accuracy of the scanning Michelson interferometer. Newer optical designs and control procedures have largely overcome this weakness. Now FTIR can be justified not only for its high sensitivity but also for its high degree of reproducibility and stability, permitting demanding applications in quantitative IR analysis.

41. Laser Spectroscopy in the Submillimeter and Far–Infrared Regions

Recent technical developments in sub–millimeter and far–infrared laser spectroscopy are described. This includes new laser sources, both side–band and difference–frequency generation. An experiment which uses fixed–frequency far–infrared lasers to study open–shell molecules (free radicals) is described; the technique is known as laser magnetic resonance (LMR). Sub–millimeter and far–infrared laser spectroscopies are finding expensive use in the detection and monitoring of molecules in astrophysical sources and in the earth's atmosphere.

Research in the submillimeter and far-infrared (SM-FIR) regions of the electromagnetic spectrum (1000 to 150 μm, 0.3 to 2.0 THz; and 150 to 20 μm, 2.0 to 15 THz, respectively) had been relatively inactive until about 30 years ago. Three events were responsible for enhanced activity in this part of the electromagnetic spectrum: the discovery of far-infrared (FIR) lasers [41.1], the development of background-limited detectors [41.2], and the invention of the FIR Fourier transform (FT) spectrometer [41.3]. Following these developments major discoveries have taken place in laboratory spectroscopic studies [41.4, 5], in astronomical observations [41.6], and in spectroscopic studies of our upper atmosphere [41.7].

Rotational transition frequencies of light molecules (such as hydrides) lie in this region, and the associated electric dipole transitions are especially strong at these frequencies. In fact they are 10 000 times stronger than at microwave frequencies because they are 100 times typical microwave frequencies and their peak absorptivities depend approximately on the square of the frequency. Fine structure transitions of atoms and molecules also lie in this region; however, they are much weaker, magnetic dipole transitions. The observation of fine structure spectra is very important in determining atomic concentrations in astronomical and atmospheric sources and for determining the local physical conditions. Bending frequencies of larger molecules also lie in this region, but their transitions are not as

strong as rotational transitions (typically a factor of 10^3 weaker).

Spectral accuracy has been increased by several orders of magnitude with the extension of direct frequency measurement metrology into the SM-FIR region [41.8]. Transitions whose frequencies have been measured (including absorptions and laser emissions) are useful wavelength calibration sources ($\lambda_{vac} = c/\nu$) for FT spectrometers. FIR spectra of a series of rotational transitions have been measured in CO [41.9], HCl [41.10], HF [41.11], and CH_3OH [41.12] to be used for FT calibration standards. These lines are ten to a hundred times more accurately measured than can be realized in present state-of-the-art Fourier transform spectrometers; thus, they are excellent calibration standards. High-accuracy and high-resolution spectroscopy has permitted the spectroscopic assignment of the SM-FIR lasing transitions themselves [41.13] resulting in a much better understanding of the lasing process.

Astronomical spectroscopy in this region [41.6] may be in emission or absorption and is performed using either interferometric [41.14] (wavelength-based), or heterodyne (frequency-based) [41.15] techniques to resolve the individual spectral features.

Most high resolution spectra of our upper atmosphere have been taken with FT spectrometers flown above the heavily absorbing water vapor region in the lower atmosphere. Emission lines are generally observed in these spectrometers [41.7].

41.1 Experimental Techniques using Coherent SM−FIR Radiation

The earliest sources of coherent SM radiation came from harmonics of klystron radiation generated in point-contact semiconductor diodes [41.16]. Spectroscopically useful powers up to about one terahertz are produced. This technique is being replaced by electronic oscillators which oscillate to over one terahertz [41.17]. The group at Cologne University, Germany [41.18] has been particularly successful with this approach. Spectroscopy above this frequency generally is performed with either lasers or FT spectrometers (see Chapt. 40).

Laser techniques use either tunable radiation synthesized from the radiation of other lasers, or fixed-frequency SM-FIR laser radiation and tuning of the transition frequency of the species by an electric or magnetic field. Spectroscopy with tunable far-infrared radiation is called TuFIR spectroscopy. Spectroscopy

with fixed frequency lasers is called either laser electric resonance (LER) or laser magnetic resonance (LMR). LMR is applicable only to paramagnetic species and is noteworthy for its extreme sensitivity. LMR spectroscopy has been more widely applied than LER, and is discussed in this chapter.

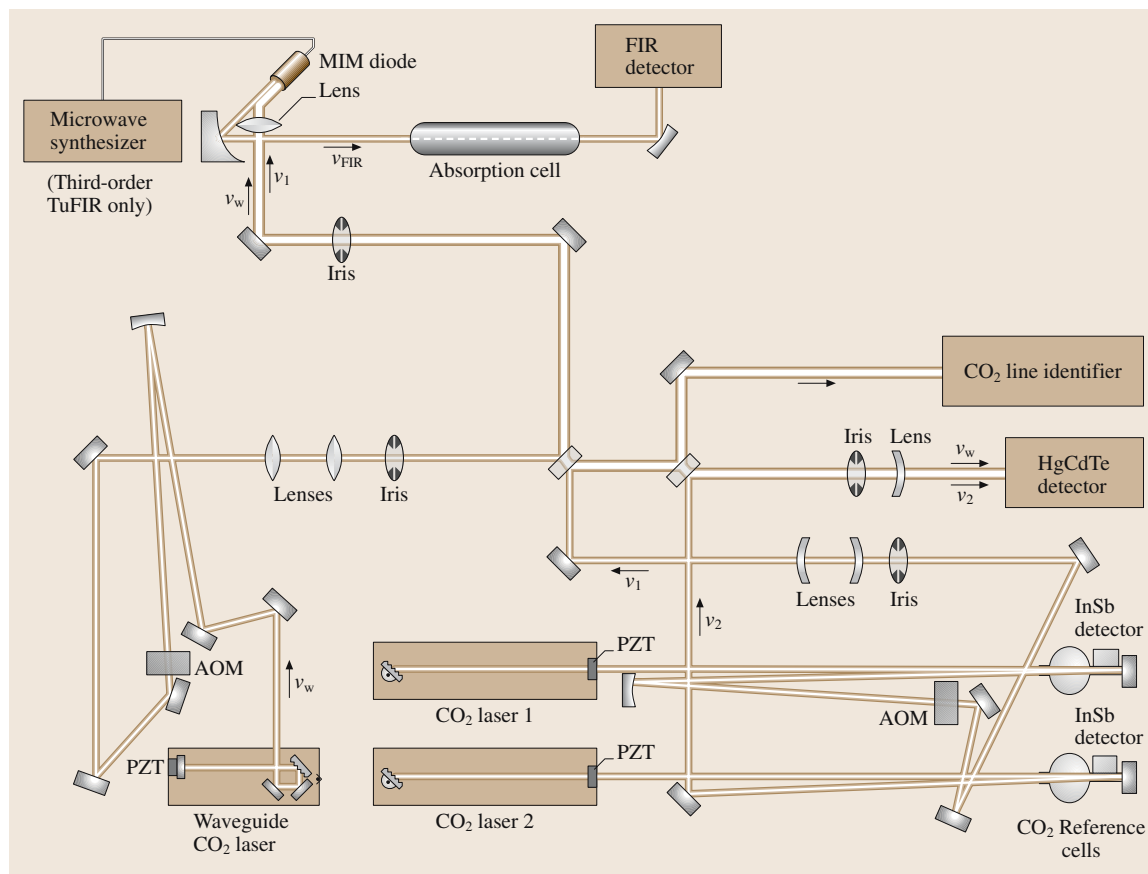
Tunable SM-FIR radiation has been generated either by adding microwave sidebands to radiation from a SM-FIR laser [41.19] or by using a pair of higher frequency lasers and generating the frequency difference [41.20]. The sideband technique was first reported by *Dymanus* [41.19] and uses a Schottky diode as the mixing element. It has been used up to 4.25 THz and produces a few microwatts of radiation [41.21]. Groups at Berkley, California [41.22] and Cologne, Germany [41.23] have developed this technique to good


Fig. 41.1 Tunable far-infrared (TuFIR) spectrometer for second- or third-order operation using CO_2 laser difference-frequency generation in the MIM diode

Laser Spectroscopy in the Submillimeter and Far−Infrared Regions | 41.1 Experimental Techniques using Coherent SM−FIR Radiation 617

Part C | 41.1

effect. The CO_2 laser frequency-difference technique with difference generation in the metal-insulator-metal (MIM) diode covers the FIR region out to over 6 THz and produces about 0.1 μW. This technique uses fluorescence-stabilized CO_2 lasers whose frequencies have been directly measured, and it is about two orders of magnitude more accurate than the sideband technique. However, it is somewhat less sensitive because of the decreased power available. There are several review articles on the laser sideband technique [41.21, 24], and only the laser difference technique is described here.

41.1.1 Tunable FIR Spectroscopy with CO_2 Laser Difference Generation in a MIM Diode

There are two different ways of generating FIR radiation using a pair of CO_2 lasers and the MIM diode. One is by second-order generation, in which tunability is achieved by using a tunable waveguide CO_2 laser as one of the CO_2 lasers; it is operated at about 8 kPa (60 Torr) and is tunable by about ±120 MHz. The second technique uses third-order generation, in which tunable microwave sidebands are added to the difference frequency of the two CO_2 lasers. The complete spectrometer which can be operated in either second or third order is shown in Fig. 41.1.

The FIR frequencies generated are:

$$\text{second-order: } \nu_{\text{fir}} = \left| \nu_{1,CO_2} - \nu_{W,CO_2} \right| \quad \text{(41.1a)}$$

$$\text{third-order: } \nu_{\text{fir}} = \left| \nu_{1,CO_2} - \nu_{W,CO_2} \right| \pm \nu_{\text{mw}}$$
$$\text{(41.1b)}$$

where ν_{fir} is the tunable FIR radiation, ν_{1,CO_2} and ν_{W,CO_2} are the CO_2 laser frequencies, and ν_{mw} is the microwave frequency.

Different MIM diodes are used for the two different orders: in second-order, a tungsten whisker contacts a nickel base and the normal oxide layer on nickel serves as the insulating barrier; in third-order, a cobalt base with its natural cobalt oxide layer is substituted for the nickel base. The third-order cobalt diodes produce about one third as much FIR radiation in each sideband as there is in the second-order difference; hence third-order generation is not quite as sensitive as second-order. The much larger tunability, however, makes it considerably easier to use.

The common isotope of CO_2 is used in both the waveguide laser and in laser 2; in laser 1, one of four isotopic species is used. Ninety percent of all frequencies

from 0.3 to 4.5 THz can be synthesized; the coverage decreases between 4.5 and 6.3 THz. Ninety megahertz acoustooptic modulators (AOMs) are used in the output beams of the two CO_2 lasers which irradiate the MIM diode; they increase the frequency coverage by an additional 180 MHz and isolate the CO_2 lasers from the MIM diode. This isolation decreases amplitude noise in the generated FIR radiation, caused by the feedback to the CO_2 laser from the MIM diode, by an order of magnitude; hence, the spectrometer sensitivity increases by an order of magnitude.

The radiations from laser 1 and the waveguide laser are focused on the MIM diode. Laser 2 serves as a frequency reference for the waveguide laser; the two lasers beat with each other in the HgCdTe detector and a servosystem offset-locks the waveguide laser to laser 2. Lasers 1 and 2 are frequency modulated using piezoelectric drivers on the end mirrors, and they are servoed to the line center of 4.3 μm saturated fluorescence signals obtained from the external low-pressure CO_2 reference cells. In both second and third order, the CO_2 reference lasers are stabilized to line center with an uncertainty of 10 kHz. The overall uncertainty in the FIR frequency due to two lasers is thus $\sqrt{2} \times 10$ or 14 kHz. This number was determined experimentally in a measurement of the rotational frequencies of CO out to $J = 38$ (4.3 THz), with the analysis of the data set determining the molecular constants [41.9].

The CO_2 radiation is focused by a 25 mm focal length lens onto the conically sharpened tip of the 25 μm diameter tungsten whisker. The FIR radiation is emitted from the 0.1 to 3 mm long whisker in a conical long-wire antenna pattern. Then it is collimated to a polarized beam by a corner reflector [41.25] and a 30 mm focal length off-axis segment of a parabolic mirror.

The largest uncertainty in the measurement of a transition frequency comes from finding the centers of the Doppler broadened lines. This is about 0.05 of the line width for lines observed with a signal-to-noise ratio of 50 or better and corresponds to about 0.05 to 0.5 MHz. A linefitting program [41.26] improves the line center determinations by nearly an order of magnitude. The FIR radiation is frequency modulated due to a 0.5 to 6 MHz frequency modulation of CO_2 laser 1; this modulation is at a rate of 1 kHz. The FIR detector and lock-in amplifier detect at this modulation rate; hence the derivatives of the absorptions are recorded.

Absorption cells from 0.5 to 3.5 m in length with diameters ranging from 19 to 30 mm have been used in the spectrometer. The cells have either glass, copper, or Teflon walls and have polyethylene or polypropylene

windows at each end. These long absorption cells lend themselves naturally to electrical discharges for the study of molecular ions. A measurement of the HCO^+ line at 1 THz exhibited a signal-to-noise ratio of 100 : 1 using a 1 s time constant; this is the same signal-to-noise ratio that was obtained using the laser sideband technique.

The instrumental resolution of the spectrometer is limited by the combined frequency fluctuation from each CO_2 laser (about 15 kHz). This is less than any Doppler-limited line width and, therefore, does not limit the resolution. The entire data system is computerized to facilitate the data recording and optimize the data handling.

Improvements in this TuFIR technique may come from either better diodes or detection schemes. The nonlinearity of the MIM diode is extremely small, and conversion efficiencies could be much larger if a more efficient diode is discovered. Differential detection (which requires more sensitive detectors) could also significantly improve the sensitivity and permit the detection of weaker lines.

41.1.2 Laser Magnetic Resonance

Laser magnetic resonance (LMR) is performed by magnetically tuning the transition frequencies of para-

magnetic species into coincidence with the fixed frequency radiation from a laser. LMR is a type of Zeeman spectroscopy [41.27], and its chief forte is its extreme sensitivity. Approximately one hundred species have been observed in the SM-FIR region. These include atoms, diatomics (especially hydrides), polyatomics, ions, metastables, metastable ions [41.28], and many "first observations" of free radicals. These observations are summarized in several review articles on LMR [41.29–31].

The FIR LMR spectrometer at NIST, Boulder is shown in Fig. 41.2. This spectrometer has an intracavity paramagnetic sample in a variable magnetic field which is labeled "sample volume" in the figure. A regular 38 cm EPR magnet with a 7.5 cm air gap is used. The laser cavity is divided into two parts by a Brewster angle polypropylene beam splitter about 12 μm thick. A CO_2 laser optically pumps the FIR laser gas. This pump beam makes many nearly perpendicular passes reflected by the walls of the gold-lined Pyrex tube. A 45° coupler serves to couple out the FIR radiation from the cavity to the helium-cooled detector. Mirrors each with an 89 cm radius of curvature are used in the nearly confocal geometry of the 94 cm cavity. One of the gold-coated end mirrors is moved with a micrometer to tune the cavity
Fig. 41.2 40 μm to 1000 μm Far-infrared laser magnetic resonance (LMR) spectrometer using an optically pumped FIR laser

Laser Spectroscopy in the Submillimeter and Far-Infrared Regions | 41.1 Experimental Techniques using Coherent SM–FIR Radiation 619

Part C | 41.1

to resonance and also to determine the oscillating wavelength by moving the end mirror several half-wavelengths. The beam splitter is rotatable so that the polarization of the laser can be varied with respect to the magnetic field. Quartz spacers are used to minimize the thermal expansion of the cavity. This LMR spectrometer oscillates at wavelengths between 40 and $1000\,\mu m$. The technology of FIR lasers has been reviewed by *Douglas* [41.32].

The LMR technique requires a close coincidence (typically within 20 GHz) between the absorption line and the frequency of the laser. Zero field frequencies which are 100 times more accurate than those obtained from optical spectra are obtained from the analysis of the Zeeman spectra observed (i. e. using the laser frequency and the magnetic field values). The accuracy is within 1 or 2 MHz and has permitted the far infrared astronomical observation of many of these species.

Atomic FIR LMR spectra are due to fine structure transitions and are magnetic dipole transitions; hence, they are several orders of magnitude weaker than electric dipole rotational spectra of molecules. The production of a sufficient atomic number density can be difficult; however, "atomic flames" have been very effective sources, and the high sensitivity of LMR has been the most successful spectroscopic technique for measuring these transitions. The atoms O, C, metastable Mg, S, Si, Fe, Al, N^+, C^+, P^+, Fe^+, and F^+ have been measured by FIR LMR. Atomic Zeeman spectra are relatively simple to analyze, and fine structure frequencies accurate to within 1 MHz can be determined.

In a FIR LMR spectrometer the sample is inside the laser cavity; hence, sub-Doppler line widths can be observed by operating the sample at low pressure and observing saturation dips in the signals. This has permitted the resolution of proton hyperfine structure in a number of hydrides. The observation of the resolved hyperfine structure is useful in the identification of the species involved and also yields accurate values of the hyperfine splittings.

Rotational spectra of most hydrides lie in this spectral region and many of the hydrides, such as OH, CH, SH, and NH have been observed. Others, such as CaH, MnH, TiH, and ZnH are excellent candidates for LMR studies. Ions are much more difficult because of their low concentrations; however, the use of a special microwave discharge operating in the magnetic field has proved to be an extremely productive source of ions for LMR studies [41.28].

The spectra of a number of polyatomic species has been observed by LMR: for example, NO_2, HO_2, HCO, PH_2, CH_2, NH_2, AsH_2, HO_2, HS_2, CH_3O, and CCH. The spectra of these polyatomic species are more difficult to analyze, resulting in a somewhat less accurate prediction of the zero-field frequencies. Spectra of the extremely elusive CH_2 and CD_2 radicals have finally yielded to analysis with the simultaneous observation of FIR LMR spectra [41.33] and IR LMR spectra [41.34]. The data yield rotational constants which predict the ground state rotational transition frequencies and permit the determination of the singlet–triplet splitting in that molecule [41.35].

In the last ten years, there has been an experimental push to higher frequencies in FIR spectroscopy. In the LMR spectrometer (shown in Fig. 41.2), this has been achieved principally by reducing the internal diameter of the gold-lined tube in the pumping region to 19 mm so as to increase the overlap between the laser gain medium and the FIR radiation field in the laser cavity. As a result, many new laser lines have been discovered; the system operates down to below $40\,\mu m$. This has enabled molecules with larger fine-structure intervals to be studied (e.g., FO and HF^+ [41.36, 37]) and has also led to the first detection of vibration-rotation transitions in molecules with low-frequency bending vibrations (CCN, HCCN, FeH_2) [41.38–40].

The sensitivity of TuFIR is only about 1% of that of laser magnetic resonance, but it is difficult to compare the two because the sample can be very large in the TuFIR spectrometer and is limited to about $2\,cm^3$ in the LMR spectrometer.

41.1.3 TuFIR and LMR Detectors

Four different detectors have been used in the TuFIR and LMR spectrometers: (1) an InSb 4 K, liquid ^{4}He-cooled, hot-electron bolometer, operating from 0.3 to 0.6 THz with a noise equivalent power (NEP) of about $10^{-13}\,W/\sqrt{Hz}$; (2) a gallium doped germanium bolometer, cooled to the lambda point of liquid-helium, operating from 0.6 to 8.5 THz with an NEP of about $10^{-13}\,W/\sqrt{Hz}$; (3) a similar, but liquid ^{3}He-cooled bolometer, with a NEP two orders of magnitude smaller; and (4) an unstressed Ge:Ga photoconductor, cooled to 4 K, with an NEP of $10^{-14}\,W/\sqrt{Hz}$, operating from 2.5 to 8.5 THz. The optimization of detector systems for this new technique has been responsible for a significant improvement in sensitivity of these spectrometers.

41.2 Submillimeter and FIR Astronomy

Submillimeter astronomy is reviewed in [41.6]. Many atomic species (both neutrals and ions) and more than 100 molecules have been detected in interstellar space; many were first observed in the submillimeter and FIR region. In the microwave and submillimeter region, radio (heterodyne) techniques are employed in the receivers. At higher frequencies, interferometric techniques are used [41.14]; however, heterodyne techniques recently have been employed at these higher frequencies and have resulted in the detection of CO [41.41] and OH [41.42] at 2.5 THz and a search for the IR band of methylene [41.43] at 30 THz. Submillimeter radio astronomy observatories (at high altitudes above much of the water vapor absorptions in our atmosphere) use laboratory determined frequencies. For example, the Kuiper Airborne Observatory and the submillimeter and FIR telescopes on Mauna Kea, Hawaii require frequencies accurate to about 1 MHz in their heterodyne receivers. For heterodyne detection, fixed frequency FIR gas lasers generally serve as local oscillators, and the frequencies of these lasers must be known.

The discovery and direct frequency measurement of FIR laser lines has continued apace since the last major review of this topic was published in 1986 [41.44]. Almost 1000 lines were listed in that publication; the present number is at least twice this. Two main factors have fuelled this progress. First, the design of CO_2 lasers has continued to develop so that now a single laser can produce 275 individual transitions

from the regular, hot [41.45], and sequence [41.46] bands of CO_2 with power levels from 2 to 30 W. Secondly, many new, short-wavelength laser lines have been discovered in a cavity specially designed to promote them. As a result, many high frequency lines have now been characterized, several in the range of 26 to 45 μm. The main lasing molecules used in this work are CH_3OH [41.47–50] and hydrazine, N_2H_4 [41.51].

Recent observations of FIR transitions in molecules in the interstellar medium have been made from satellite-based platforms such as the Infrared Space Observatory (ISO) [41.52] using Fourier Transform methods. Attention has been paid to the measurement of less abundant isotopic forms, such as ^{18}OH and ^{17}OH, because of the information that they provide about star formation processes.

There are four main goals of laboratory SM-FIR spectroscopy which serve the needs of the SM-FIR radio astronomy field:

1. to provide accurate frequencies of SM-FIR species for their detection,
2. to find new far infrared active species,
3. to measure the frequencies of FIR species which can be used to calibrate Fourier transform spectrometers, and
4. to measure frequencies of far-infrared lasers for use as local oscillators in radio astronomy receivers (and to be used in the analysis of laboratory LMR data).

41.3 Upper Atmospheric Studies

A very impressive set of SM-FIR spectra of our upper atmosphere has been observed using balloon-borne FT spectrometers flown at altitudes where the lines are narrow and the spectrometer is above the "black", heavily absorbing water vapor transitions [41.7]. A number of very important species with strong SM-FIR spectra have been observed. They include: O_2, H_2O, NO, ClO, OH, HO_2, O_3, and O. Numerous lines have not yet been identified. It is difficult to calibrate these instruments absolutely be-

cause the spectra come from the species emitting at temperatures of about 200 K, and from an indeterminate path length. The high sensitivity of LMR might provide an alternate way of measuring the paramagnetic species in our upper atmosphere by flying an LMR spectrometer to high altitudes. A light-weight solenoid magnet could be used to increase the path length. Absolute concentrations of the paramagnetic species such as OH, HO_2, NO, and O could be obtained.

42. Spectroscopic Techniques: Lasers

As a primary research tool, the laser plays a fundamental role in the spectroscopic study of atomic and molecular systems. This Chapter describes the basic operating principles, configurations, and characteristic parameters of lasers. Laser designs are discussed and then the details of the interaction of the laser light with matter delineated. The reader is also referred to Chapts. 70 (Laser Priciples) and 71 (Types of Lasers) for further information.

42.1 Laser Basics

42.1.1 Stimulated Emission

A cross section σ_{21} for absorption of radiation by a lower state 1 engenders a balancing cross section σ_{12} for emission stimulated by radiation interacting with an upper state 2. Detailed balance relates these two cross sections according to

$$g_2\sigma_{12} = g_1\sigma_{21} , \tag{42.1}$$

where g_1 and g_2 are the statistical degeneracies of their respective states [42.1].

For a collection of emitting and absorbing states with densities n_2 and n_1, amplification may occur when $n_2\sigma_{12} > n_1\sigma_{21}$, which leads to a requirement for an *inversion* of the state populations:

$$n_2/n_1 > g_2/g_1 . \tag{42.2}$$

The rate of spontaneous emission at frequency ν can be modeled itself by stimulated emission induced by a noise source of the magnitude of the density of states $\rho(\nu)$

$$\gamma_{12}(\nu) = \sigma_{12}(\nu)\rho(\nu)/c = \sigma_{12}(\nu)8\pi\lambda^{-2} . \tag{42.3}$$

42.1.2 Laser Configurations

A practical laser combines a population inversion with a means for controlling the radiation.

The basic laser source is the laser oscillator, an amplifier possessing positive feedback. The usual form is simply a piece of active gain medium placed inside a resonant optical cavity (Fig. 42.1). Tunability is produced if the resonant cavity is frequency selective and adjustable (Fig. 42.2). Many laser sources use an amplifier after the oscillator.

42.1.3 Gain

The fundamental gain per pass is given by

$$G = J/J_0 = \exp[(\kappa - \mu)L] , \tag{42.4}$$
Fig. 42.1 Simple laser oscillator and beam parameters. Distances z are generally measured from the minimum beam waist w_0. The beam appears with a far-field divergence angle θ_0
Fig. 42.2a–d Tunable laser oscillator geometries. (**a**) Fabry–Perot: tuning is usually done by changing the cavity length, although changing the index of refraction by changing the temperature or current is common with solid state laser diodes. (**b**) Littrow prism line selector: typical of atomic ion lasers capable of multiple line output. (**c**) Littrow grating tuning: common in pulsed dye lasers with high gain (> 10) per pass. Telescope increases resolution by filling, and reducing angular divergence at the grating. (**d**) Grazing incidence, mirror tuned, grating mount

where J/J_0 is the ratio of light output to input, κ is the gain coefficient, μ is the nonradiative loss rate, and L is the path length. The gain coefficient

$$\kappa = n^* \sigma_{12} \tag{42.5}$$

depends upon the net inversion n^*,

$$n^* = n_2 - (g_1/g_2) n_1 . \tag{42.6}$$

If λ is the wavelength of radiation, F_{12} is the emission line shape function normalized over frequency ν, τ_2 is the lifetime of the transition, and f_{12} is the branching ratio for the upper state to undergo this transition, then the stimulated emission cross section is

$$\sigma_{12} = \frac{\lambda^2 f_{12} F_{12}(\nu)}{8\pi\tau_2} . \tag{42.7}$$

For a Lorentzian lifetime-broadened line, the cross section for stimulated emission at the line center becomes

$$\sigma_{12} = \frac{\lambda^2 f_{12}}{4\pi^2 \Gamma_{12}\tau_2} , \tag{42.8}$$

where Γ_{12} is the full width at half maximum of the line.

42.1.4 Laser Light

Lasers are inherently bright sources of radiation: the radiation field within a practical laser must be high enough for stimulated emission to compete with spontaneous emission. The effective source of spontaneous

fluctuations approximates that of the density of states. In terms of the beam parameters photon flux J per solid angle Ω, and frequency ν, this is

$$\frac{d^2 J}{d\Omega\, d\nu} = \frac{2\nu^2}{\epsilon_r c^2} . \tag{42.9}$$

Beam *quality* is given by the product of the angular divergence times the beam width. Highest beam quality is associated with diffraction limited light emitted from a Gaussian spot. For circular laser beams traveling in the z-direction, this corresponds to a solution of the electromagnetic wave equation

$$u(r, \phi, z) = \psi(r, z) \exp(-ikz) , \tag{42.10}$$

where u is a polarization component of the field. For high values of $k = 2\pi/\lambda$, corresponding to short wavelength, the adiabatic radial solution is also Gaussian:

$$\psi(r, z) = \exp\left\{ -i\left[P + kr^2/(2q) \right] \right\} , \tag{42.11}$$

where the complex phase shift P, beam parameter q, and beam radius w are functions of z:

$$P(z) = -i \ln\left[1 - i\lambda z/(\pi w_0^2) \right]$$
$$= -i \ln\sqrt{1 + \left[\lambda z/(\pi w_0^2)\right]^2}$$
$$\quad - \tan^{-1}\left[\lambda z/(\pi w_0^2)\right] , \tag{42.12}$$

$$q(z) = i\pi w_0^2/\lambda + z , \tag{42.13}$$

$$w^2(z) = w_0^2 \left[1 + \left(\frac{\lambda z}{\pi w_0^2} \right)^2 \right] . \tag{42.14}$$

Here, w_0 is the beam waist parameter, the minimum width of the Gaussian beam at a focused spot. For Gaussian beams, the product of the minimum beam waist and beam divergence angle θ_0 is given by

$$\theta_0 w_0 = \lambda/\pi . \tag{42.15}$$

The beam waist and divergence follow optical imaging according to paraxial ray theory.

Higher order circular modes with p radial nodes and l angular node planes are specified by multiplying (42.11) and (42.12) by angular and radial factors to obtain

$$\psi_{pl}(r, \phi, z) = \left(\sqrt{2}r/w\right)^l L_p^l\left(2r^2/w^2\right) e^{il\phi} \psi(r, z) , \tag{42.16}$$

$$P_{pl}(z) = (2p + l + 1) P(z) . \tag{42.17}$$

Here, the functions $L_p^l(x)$ are the Laguerre polynomials as defined in Sect. 9.4.2. The radial phase shifts produce

a wave front curvature of effective radius

$$R = z + \left[(2p+l+1)/2 + w_0^2 \pi/\lambda^2\right] w_0^2 \pi/z \, .$$

(42.18)

Modes with the same values of $2p+l$ have identical axial and radial phase shifts. The two polarization components of the electromagnetic field double the degeneracies of all modes considered here. Often these degeneracies are split in practice by optical inhomogeneities of the medium through which they pass. More details can be found in the summary of *Kogelnick* and *Li* [42.2], or in the texts by *Verdeyen* [42.3] or *Svelto* [42.4].

Some applications require knowledge of the electric field in additionto the flux density J. For purely sinusoidal single mode beams, the rms field is

$$\langle E \rangle = \left(\frac{h\nu J}{c\epsilon_0}\right)^{1/2} \, .$$

(42.19)

Nonlinear effects are often expressed in terms of powers of the field by

$$\langle E^n \rangle = 2^{(n-1)/2} \langle E \rangle^n$$

(42.20)

for single mode and multimode radiation of random frequency spacings. For m equally spaced modes, this is increased by $m!/(m-n)!$.

42.2 Laser Designs

42.2.1 Cavities

The simple Fabry–Perot cavity consists of two spherical mirrors facing one another. The surfaces are chosen to be constant phase surfaces for the desired modes (42.18). Stability criteria are shown in Fig. 42.3. A cavity is stable when initial angles θ and displacements r of paraxial rays transform during a round trip into θ' and r' satisfying

$$-2 < \frac{\partial \theta'}{\partial \theta} + \frac{\partial r'}{\partial r} < 2 \, .$$

(42.21)

At frequencies for which the round-trip phase change per passage

$$\delta(\nu) = 2\pi(z_2 - z_1)\nu/c + 2\left[P_{pl}(z_2) - P_{pl}(z_1)\right]$$
$$\approx 2\pi(z_2 - z_1)/\lambda + \pi(2p+l+1)$$

(42.22)

is an integer multiple of 2π, the phases from different passages interfere constructively, giving longitudinal modes. (Here $P_{pl}(z_i)$ gives the additional phase shift for higher transverse modes at mirrors $i = 1, 2$.)

For a particular radial mode structure in an empty Fabry–Perot cavity, the ratio of the maximum cavity decay time for these standing waves to the minimum cavity decay time for frequencies between longitudinal modes is

$$(1+r)^2/(1-r)^2 \, .$$

(42.23)

Here r is the reflectivity of the end mirrors; for cavities with mirrors having different reflectivities, one may use the square root of the product of their reflectivities. A simple Fabry–Perot cavity may be tuned by changing

Fig. 42.3 Stability parameters for simple two-mirror laser cavities of length L and mirror radii of curvature R_1 and R_2. Here, $x = \frac{1}{2}(L/R_1 - L/R_2)$ is the mean curvature difference of the two mirrors; $y = \frac{1}{2}(L/R_1 + L/R_2)$ is the mean curvature of the two mirrors. Cavities with parameters in the unshaded region are stable

the cavity length or by changing the index of refraction of the cavity material. Since both of these may be properties of temperature, temperature tuning may be possible. The index of refraction of a material may also be sensitive to the intensity of excitation. Diode lasers consisting of a semiconductor die with polished, reflecting faces are often tuned by changing temperature and pumping current.

For lasers with a dispersive optical element within the cavity, highest selectivity is obtained when the light has low angular divergence and impinges upon the dispersive element as nearly plane waves. A beam expander may reduce the angular spread while simultaneously increasing the beam width. For a grating used as a mirror in a Littrow mount, the dispersion equation is

$$\Delta\lambda = (d/n) \cos\phi \, \Delta\phi \, , \tag{42.24}$$

where n is the diffraction order, d is the distance between lines, and ϕ is the angle of incidence off normal.

Cavities with prisms or gratings can be conveniently tuned by rotating the angle of the dispersive element. For a grating used as a mirror in a Littrow mount, the grating equation is

$$\lambda = (2d/n) \sin\phi \, . \tag{42.25}$$

Often, more than one longitudinal cavity mode operates within the selected frequency band, and tuning consists of "hopping" from mode to mode, rather than smoothly sweeping a single line across a band of frequencies. Smooth frequency tuning can be achieved, for example, in a design by *Wallenstein* and *Hänsch* [42.5], in which the grating and Fabry–Perot cavity are placed together inside a chamber. The whole laser is then tuned by changing the index of refraction of the gas inside by varying its pressure.

The current trend with pulsed lasers is to use a very lossy, short oscillator cavity in which the longitudinal modes are nearly absent, making up for the cavity losses with a very high gain lasing medium. The front, output mirror of such a cavity may actually be *anti*reflection coated, with a reflectivity of only a percent or less.

Low gain, continuous wave (cw) lasers often use a combination of cavity length tuning along with dispersive element rotation, such as a prism or Lyot filter. Often, lasing on a traveling wave in a ring configuration is used to avoid longitudinal modes, as illustrated in Fig. 42.4. Some commonly used gain media are listed in Tables 42.1 and 42.2.
Fig. 42.4 Ring laser. The Faraday rotator and half-wave plate permit circulation of the cavity fields in only one direction

42.2.2 Pumping

Many methods, including electrical discharges and flashlamps, have been used to pump the gain media of lasers. Generally, the best pump is another laser.

Two notable pump lasers have dominated the field of tunable, visible lasers: pulsed neodymium YAG, frequency doubled to ≈ 503 nm, and cw Ar II ion at 514.5 nm. Both are extremely effective at exciting the highly efficient rhodamine class dyes in the red–yellow portion of the visible spectrum. The typical pump beam of a Nd/YAG laser enters the amplifying dye cell transversely along one on the faces of the cell. The typical cw pump beam enters the dye almost collinearly with the laser axis.

By temporarily "spoiling" the Q by making the laser cavity lossy, lasing can be held off until the gain medium stores a greater energy density than the minimum required for lasing. Rapidly switching off the loss mechanism releases this energy in one giant pulse. An electronic optical shutter, such as a Pockels cell, or a saturable dye inside the laser cavity, designed to photobleach from the spontaneous emission just before the laser reaches threshold, are commonly used.

Periodically spoiling the laser gain or the cavity Q at the period of a round trip produces intense, short pulses. Viewed from the frequency domain, the phases of individual longitudinal modes are "locked" together to produce a light packet circulating at the frequency of the reciprocal of the mode spacing. Extremely short pulses (< 1 ps) can be produced by mode locking. Practically, mode locking can be achieved by using a thin, saturable absorber near one of the cavity mirrors [42.6], or by acoustically modulating an optical element in the cavity – even an end mirror itself. One of the best ways of mode locking is to pump a short lifetime gain medium, such as a dye, with mode locked laser light, such as from a mode locked argon ion laser [42.7].

Table 42.1 Fixed frequency lasers

Laser	Wavelength (nm)	Excitation method
ArCl	$\approx$170 (band)	Pulsed, gas discharge
ArF	$\approx$193	Pulsed, gas discharge
KrCl	$\approx$222	Pulsed, gas discharge
KrF	$\approx$248	Pulsed, gas discharge
XeBr	$\approx$282	Pulsed, gas discharge
XeCl	$\approx$308	Pulsed, gas discharge
XeF	$\approx$351, 353	Pulsed, gas discharge
N_2	$\approx$337.1 (other bands)	Pulsed (1-10 ns), gasdischarge
Ar^+	488.0, 514.5 (454.4, 457.9, 465.8, 472.7, 476.5, 501.7, 528.7)	cw, gas discharge
Ar^{+2}	351.1, 363.8	cw, gas discharge, high magnetic field
Kr^+	568.2, 647.1, (476.2, 520.8, 530.9)	cw, gas discharge
Kr^{+2}	350.7, 356.4, 406.7	cw, gas discharge, high magnetic field
Ne/He	632.8, 1152.3, 3390 (others)	cw, gas discharge
Cr^{+3}-Ruby	694.3	Pulsed, flashlamp
Nd^{+3}-YAG	$\approx$1065, $\approx$1300	Pulsed: flashlamp; cw: lamp, LED or laser diode
Nd^{+3}-glass(various)	$\approx$920, $\approx$1060, $\approx$1370	Pulsed, flashlamp
Yb^{+3}-glass	$\approx$1060	Pulsed, flashlamp
Er^{+3}-glass(various)	$\approx$1540, $\approx$1536, $\approx$1543, $\approx$1550	Pulsed: flashlamp; cw: lamp, LED or laser diode
Xe	3507	cw gas discharge
CO_2	$\approx$10 600 (lines)	cw: gas discharge or gas dynamic
Molecular vibration and rotation	1×10^5–3×10^6 (numerous lines)	IR laser (CO_2, CO, $\cdots$)

Table 42.2 Approximate tuning ranges for tunable lasers

Laser	Wavelengths (nm)	Notes
Dye solution	<330 – >1200 [$\approx$10 each dye]	Pulsed: laser, flashlamp; cw: laser
Alexandrite	700–820	Pulsed: lamp, laser; cw: laser
Ti^{+3}/Sapphire	680–1100	Pulsed: laser, lamp; cw: laser

42.3 Interaction of Laser Light with Matter

42.3.1 Linear Absorption

The absorption cross section σ_{fi} for transition to the final state $|f\rangle$, when integrated over frequency ν, is given theoretically by the leading first-order perturbation of the initial state $|i\rangle$ in the electric dipole approximation

$$\int \sigma_{fi}(\nu)\, d\nu = 4\pi^2 \alpha \bar{\nu} \left| \langle f| \sum_e r_e \cdot \hat{\epsilon} |i\rangle \right|^2 , \qquad (42.26)$$

where the sum is over all charges e at distances r_e, $\hat{\epsilon}$ is a unit polarization vector, and $\bar{\nu}$ is the averaged transition energy. Averaged over orientations and summed over possible final states, each electron contributes to the total integrated absorption cross section one electron oscillator, $\pi r_0 c \approx 0.03\,\text{cm}^2\,\text{s}^{-1}$; here, r_0 is the classical electron radius. Electronic absorption bands typically contain an oscillator strength $f = 0.01{-}0.5$ of an "electron oscillator", while weaker vibrational transitions have $f = 10^{-6}{-}10^{-4}$ in each band.

For narrow lines with radiation of broader band width $\Delta\nu$ at flux density J, the linear absorption rate constant can be usefully estimated as $(\pi r_0 c)\, fJ/\Delta\nu$.

42.3.2 Multiphoton Absorption

Second-order perturbation theory gives the theoretical two-photon contribution to the absorption. An absorption cross section $\sigma^{(2)} J_1$ for a photon of frequency ν_2 is induced by an off-resonance monochromatic field of frequency ν_1 and photon flux density J_1. When integrated over the frequency of the second photon, the second-order cross section can be related to the dipole matrix elements

$$\int \sigma_{fi}^{(2)}(\nu_1, \nu_2)\, J_1\, d\nu_2 = \frac{4\pi^2 \alpha^2}{\nu_1 \bar{\nu}_2} J_1$$

$$\times \left| \sum_m \frac{\nu_{fm} \nu_{mi} \langle r_{fm} \rangle \langle r_{mi} \rangle}{\nu_{mi} - \nu_1} \right|^2 \qquad (42.27)$$

where

$$\langle r_{fm} \rangle = \langle f| \sum_e r_e \cdot \hat{\epsilon}_2 |m\rangle ,$$

$$\langle r_{mi} \rangle = \langle m| \sum_e r_e \cdot \hat{\epsilon}_1 |i\rangle , \qquad (42.28)$$

and the sum is taken over intermediate states $|m\rangle$ having frequencies ν_{mi} and ν_{fm} for transitions to the initial and final states. The energy for the overall transition comes from two photons; hence the two-photon resonance condition $\nu_{fi} = \nu_1 + \nu_2$. A special case often occurs when only one radiation frequency is used: then $\nu_1 = \nu_2$, and two-photon resonance is achieved when the energy of the transition corresponds to twice the frequency of the radiation field.

This integrated, induced cross section is roughly of the order $\alpha(\pi c r_0)^2 J_1/(\nu_1 \bar{\nu}_2)$. Two-photon absorption becomes comparable to the one-photon absorption with off-resonance fields on the order of

$$J_1 \approx \frac{\nu_1 \nu_2}{\alpha \pi c r_0} , \qquad (42.29)$$

or about 10^{21} photons $\text{s}^{-1}\,\text{cm}^{-2}$ ($10^{17}\,\text{W}\,\text{m}^{-2}\,\text{s}^{-1}$ for typical green light).

Typical dipole-allowed molecular multiphoton absorption cross sections are $\approx 10^{-58}$ m^4 s for two photons and 10^{-94} m^6 s^2 for three photons.

Multiphoton absorption was one of the first effects explored with lasers. Two-photon absorption was first reported for inorganic crystals containing europium ions [42.8]. Blue and ultraviolet fluorescence appeared in the interaction of red ruby laser light with organic compounds [42.9–12]. Others observed two-photon absorption directly [42.13, 14]. Selection rules for multiphoton absorption are summarized by *McClain* [42.15]; recent work is reviewed by *Ashfold* and *Howe* [42.16].

Highly excited states may subsequently ionize in the intense fields in a multiphoton ionization (MPI) process. The ionization signal is often detected in a proportional ionization cell. A low pressure cell containing the vapor of a transition metal organometallic, such as iron carbonyl or ferrocene which photodissociates to give the metal atom, may be used for wavelength calibration by MPI.

42.3.3 Level Shifts

High radiation power causes resonant frequencies to shift, responding to the ac Stark effect [42.17, 18]. Even moderate fields, tuned near resonance, interact strongly with an atom or small molecule, which undergoes rapid excitation and stimulated emission at the characteristic power dependent Rabi frequency,

$$\nu_{\text{Rabi}} = \frac{2\pi g_1}{g_1 + g_2} \sigma_{21} J \;. \tag{42.30}$$

Fluorescence from such an interacting system has a characteristic "head and shoulders" spectrum best understood as radiation at the fundamental frequency amplitude modulated at the Rabi frequency [42.19].

42.3.4 Hole Burning

Radiation at a particular frequency generally moves population out of states that absorb that radiation. Molecules that interact resonantly with the radiation may also spontaneously emit at different frequencies, thereby ending in nonabsorbing states. This optical pumping effect can make resonance features in an absorption spectrum disappear at high power levels [42.20]. Depletion may appear as a "hole" in the absorption spectrum [42.21]. Recently, interest has shifted to permanent "hole burning" as a method of information storage in materials.

Hole burning is the basis for Doppler-free Lamb-dip spectroscopy, in which only absorbing atoms or molecules having little or no velocity component along the axis of two counterpropagating beams are temporarily depleted [42.22]. This technique is commonly used for laser frequency stabilization, such as with the iodine-locked He−Ne laser.

42.3.5 Nonlinear Optics

Multiplying

Nonlinear susceptibility of an optical medium can generate radiation at frequencies which are multiples of the frequency of laser radiation passing through. Phenomenologically, the second order polarization

$$\mathbf{P}_{2\nu} = \epsilon_0 \chi^{[2]} \mathbf{E}_\nu^2 \tag{42.31}$$

is given in terms of the second order nonlinear susceptibility $\chi^{[2]}$, a third rank tensor, and the electric field at the fundamental frequency (see Chapt. 72). This nonlinear susceptibility can range from 0.5–5 pm/V for typical materials used for frequency doubling. Typical materials and their use are reviewed by *Bordui* and *Fejer* [42.23].

For a nonlinear process occurring over a length l in a cylindrical region with Gaussian waist w_0 with polarization P_0 on axis, the far field flux is given by

$$J(R, \theta) = \frac{\pi^4 \nu^3 n^3 w_0^4 P_0^2}{4hc^3\epsilon_0 R^2} \left(\frac{\sin^2[(k_0 - k\cos\theta)l/2]}{(k_0 - k\cos\theta)^2} \right)$$
$$\times \exp\left[-k^2 w_0^2 \sin^2(\theta)/2\right] \;. \tag{42.32}$$

Here, n is the index of refraction and k the propagation constant for the induced radiation, while k_0 is that for the induced polarization, the vector sum of those of the original radiation. When phase matched, $k_0 - k\cos\theta = 0$, and the term in the brackets maximizes to $(l/2)^2$.

The greatest difficulty is in selecting materials which can be phase matched such that the relative phases of the fundamental and overtone radiation propagate together through the material; otherwise radiation at the higher frequency generated at different places inside the material destructively interfere. Phase matching is usually achieved by either angle tuning of a birefringent crystal, or by temperature tuning.

Only materials without a center of inversion in their crystal structures have a second order nonlinear susceptibility. All materials, including gases, will have a third order nonlinear susceptibility $\chi^{[3]}$. This can be used to generate third harmonics, especially in the vacuum ultraviolet (VUV), where doubling materials are not available [42.24, 25].

Mixing

The same materials that permit frequency doubling and tripling also allow 3-wave and 4-wave frequency mixing. The frequency matching conditions are, respectively,

$$\nu_1 \pm \nu_2 = \nu_3 \,,$$
$$\nu_1 \pm \nu_2 \pm \nu_3 = \nu_4 \,. \qquad (42.33)$$

Tunable UV radiation may be generated by adding the frequencies of a fixed and tunable visible outputs. Tunable IR has been obtained by differencing fixed and tunable visible lasers. Mixing of radiation from an Ar ion laser with that from a tuned R6G dye laser in lithium iodate to produce tunable 2200–4600 nm radiation is noteworthy.

Optical Parametric Oscillator

It is possible to reverse 3-wave mixing, generating two frequencies whose sum is that of the input radiation. In parametric generation, the output frequencies are given by the phase match conditions. Both the desired frequency and the secondary "idler" frequency must be allowed to build up in the nonlinear medium. The idler radiation is not present initially, but results from the frequency mixing process itself. The process has many of the characteristics of a laser oscillator, including that of a gain threshold. This makes tuning of an optical parametric oscillator similar to that of a laser, but with more degrees of freedom: now oscillation at two frequencies must be attained simultaneously, along with the correct *phase matching* of the nonlinear material [42.26].

42.3.6 Raman Scattering

It is possible to have one or more of the fields in a mixing process belong to just polarization, rather than radiation. The frequency additive case of multiphoton absorption has already been consisdered; the frequency subtractive case is Raman scattering.

Incoherent Raman Scattering

Radiation at a higher frequency can excite a lower frequency vibration or rotation within a material, with appearance of radiation at the frequency of the incident radiation minus that of the absorption. The integrated cross section for this effect is given by (42.27). However, in this case the cross section is for *emission* of the second photon. The rate of spontaneous Raman emission is obtained by multiplying (42.27) by the spectral flux density of the zero-point field, $8\pi\nu^2/\epsilon_r c$. Typical vibrational Raman cross sections for transparent molecules are about 10^{-34} m^2 sr^{-1} in the blue–green (488 nm) [42.27].

Alternatively, energy can be extracted from an excited state, with the inelastically scattered photon departing with the sum of the incident frequency and that of the deexcitation. The term "anti-Stokes" distinguishes it from the more usual "Stokes" type of Raman scattering.

Coherent Raman Emission

The integrated cross section for emission stimulated at the Raman frequency is given directly by (42.27).

A fourth-order mixing process that is less susceptible to saturation involves coherent anti-Stokes Raman scattering (CARS). Two beams excite the material: the difference of their frequencies corresponds to an excitation of the material. Stimulated Raman scattering excites the material, which then deexcites through an anti-Stokes process, giving rise to a third, higher frequency radiation field. The phase is determinate, and the radiation leaves the region of scattering as a beam [42.28].

If the incident radiation induces a Raman process over a sufficiently long path, the stimulated Raman process can be used for gain at both the Stokes and anti-Stokes frequencies. Since spontaneous Raman processes are proportional to the integrated cross section, while gain in the stimulated Raman process is proportional to the peak cross section, simple materials with sharp, simple line spectra are most suitable for Raman gain media. While Raman lasers have been produced using vibrational excitation of organic liquids, currently the most important technical application is for Raman shifting the output of lasers, tunable or otherwise, to frequencies which otherwise would be inaccessible. The high pressure H_2 Raman shifter produces, at low powers, beams consisting almost entirely of well separated, sharp lines shifted by 4160 cm^{-1} from the pump beam; at high powers, a series of Stokes and anti-Stokes bands appear, each separated by 4160 cm^{-1} from each other.

42.4 Recent Developments

One of the most exciting advancements in the past decade in laser physics has been the generation of optical frequency combs; and, more specifically, their applicability in the domain of high-resolution laser spec-

troscopy. Basically, through a superposition process of many continuous wave modes, a short train of frequency spikes may be produced from a mode-locked laser [42.29] (see also Sect. 30.1.5). These spikes are equally spaced and are referred to as a frequency comb. The frequency ω_n of the nth cavity mode may be expressed as

$$\omega_n = n\omega_r + \omega' , \tag{42.34}$$

where ω_r is characteristic of the laser and ω' is a frequency offset due to the difference between the phase and group velocity of the superposed waves.

The microwave frequencies ω_r and ω' are determined through the use of nonlinear optics. Once these two parameters are determined, any unknown optical frequency ω_o may be measured by recording the beat frequency between it and the closest comb frequency. This technique gives experimenters a high-precision method for the spectroscopic determination of such fundamental quantities as the fine structure constant, the Rydberg constant, and the Lamb shift [42.30, 31].

43. Spectroscopic Techniques: Cavity–Enhanced Methods

Cavity enhanced spectroscopy (CES) methodology provides a much higher degree of sensitivity than that available from conventional absorption spectrometers. The aim of this chapter is to present the fundamentals of the method, and the various modifications and extensions that have been developed. In order to set the stage, the limitations of traditional absorption spectrometers are first discussed, followed by a description of cavity ring–down spectroscopy (CRDS), the most popular CES embodiment. A few other well–known CES approaches are also described in detail. The chapter concludes with a discussion of recent work on extending CRDS to the study of liquids and solids.

Part C | 43

43.1 Limitations of Traditional Absorption Spectrometers

An absorption spectrometer measures the difference in intensity between the incident light intensity I_0 and the transmitted light intensity $I(x, \lambda)$. Beer's law relates the absorbed light to the sample absorption $\alpha(\lambda)$

$$I(x, \lambda) = I_0 e^{-\alpha(\lambda)x} , \tag{43.1}$$

where λ is wavelength, and x is path length. Absorption is related to concentration C through the extinction coefficient $\varepsilon(\lambda)$ namely $\alpha(\lambda) = C\varepsilon(\lambda)$. Typically, a spectral feature, called an absorption peak, of the target species is measured in order to obtain its concentration. The performance of a spectrometer has two figures of merit: sensitivity and selectivity.

Sensitivity is the smallest detectable change in one centimeter of path length that a spectrometer can measure during one second. If many measurements can be made within a second, averaging may be used to further improve (by a factor of the square root of the number of measurements or the square root of the data acquisition rate) the achievable sensitivity. Sensitivity has units of $\text{cm}^{-1}\,\text{Hz}^{-1/2}$. Sensitivity can also be quantified using the minimum detectable absorption loss (MDAL), i. e., the normalized standard deviation of the smallest detectable change in absorption (units of cm^{-1}). Equation (43.1) shows that the sensitivity of a spectrom-

eter depends not only on the light path length through the sample, but also on the intensity noise of the light source.

Selectivity is the ability of a spectrometer to distinguish between two different species absorbing at similar wavelengths. The instrument must be able to resolve the different spectral lines. Thus, selectivity depends on spectral resolution, which has units of frequency (MHz), wavelength (nm), or wavenumbers (cm^{-1}).

Traditional spectrometers, such as non-dispersive infrared (NDIR), and Fourier Transform infrared (FTIR), use incoherent thermal light sources. For both techniques, the physical length of their sample chamber limits their sensitivity. Some devices try to fold the light path several times through the sample chamber in order to improve sensitivity, but this approach encounters physical size and mechanical stability limitations. Typical MDAL are in the $10^{-5}\,\text{cm}^{-1}$ range. These instruments therefore rely on measuring the strongest absorption transitions available, which are found in the mid-infrared range (3 to $12\,\mu\text{m}$). Often, however, the strongest transitions overlap with features of other species found in the sample mixture. The instrument performance becomes a sensitivity-selectivity tradeoff.

Laser-based optical detection methods, called tunable diode laser absorption spectroscopy (TDLAS), circumvent some of these problems by exploiting the coherent nature of laser light. A tunable continuous-wave laser source brings two benefits:

- A narrow linewidth, which allows high spectral resolution scans to be performed, and
- Low spatial beam divergence, which allows it to be folded hundreds, if not thousands of times.

By transmitting laser light having a small beam size over long distances, multi-pass cells can be designed to achieve up to a kilometer of path length enhancement. Multi-pass cell laser spectroscopy systems have demonstrated MDAL down to $10^{-9}\,\mathrm{cm}^{-1}$. However, such instruments still remain limited by laser intensity fluctuations and interference fringes. Moreover, standard multi-pass techniques do not provide an absolute optical loss measurement.

43.2 Cavity Ring–Down Spectroscopy

Cavity ring-down spectroscopy (CRDS) is a more recently developed TDLAS approach that replaces a multi-pass cell with a stable optical resonator, called the ring-down cavity (RDC). CRDS is based on the principle of measuring the rate of decay of light intensity inside the RDC. The transmitted wave decays exponentially in time. The decay rate is proportional to the total optical losses inside the RDC.

In a typical CRDS setup, light from a laser is first injected into the RDC, and is then interrupted. The circulating light inside the RDC is both scattered and transmitted by the mirrors on every round-trip, and can be monitored using a photodetector placed behind one of the cavity mirrors. The decay constant, also called the ring-down time τ is then measured as a function of laser wavelength to obtain a spectrum of the cavity optical losses. Detailed mathematical treatments of CRDS can be found in [43.1]. A simple derivation is presented here.

For a given wavelength λ the transmitted light $I(t, \lambda)$ from the RDC is given by

$$I(t, \lambda) = I_0 \mathrm{e}^{-\frac{t}{\tau(\lambda)}} , \qquad (43.2)$$

where I_0 is the transmitted light at the time the light source is shut off, and $\tau(\lambda)$ is the ring-down time constant. The total optical loss inside the cavity is $L(\lambda) = [c\tau(\lambda)]^{-1} l_{\mathrm{rt}}$ where c is the speed of light. The total optical loss comprises the empty cavity optical loss and the sample optical loss. CRDS provides an absolute measurement of these optical losses. The empty cavity (round-trip) optical loss $L_{\mathrm{empty}}(\lambda)$ comprises the scattering and transmission losses of the mirrors. In general, better mirrors provide lower empty cavity losses and higher sensitivity. The sample (round-trip) optical loss is $A(\lambda) = \alpha(\lambda)l_{\mathrm{rt}}$ where l_{rt} is the cavity round-trip length, and is simply the difference between total cavity losses and empty cavity losses, namely

$A(\lambda) = L(\lambda) - L_{\mathrm{empty}}(\lambda)$. Once the absorption spectrum $\alpha(\lambda)$ of the sample has been measured, then the sample concentration can be readily computed using the absorption cross section and lineshape parameters.

The MDAL for a CRDS system is defined by

$$\alpha_{\min} = \frac{1}{l_{\mathrm{eff}}} \left(\frac{\Delta \tau}{\tau} \right) , \qquad (43.3)$$

where $(\Delta \tau / \tau)$ is called the shot-to-shot noise of the system. The effective path length of a CRDS measurement is $l_{\mathrm{eff}} = c\tau$. For typical RDC mirrors having a reflectivity of 99.995%, and scattering losses of less than 0.0005%, the path length enhancement can exceed 20 000. For a 20 cm long sample cell, the effective path length is 8 km, which exceeds the best performance of multi-pass spectroscopy by a factor of three, based on effective path length alone. A good CRDS system can achieve a shot to shot variation of 0.03%, leading to a MDAL of $4 \times 10^{-10}\,\mathrm{cm}^{-1}$. Note also that the CRDS measurement is not dependent on either the initial intensity of the light inside the cavity, provided that the signal has a sufficient signal to noise ratio at the detector, or on the physical sample path length like traditional absorption spectroscopy. Moreover, CRDS can use laser sources having narrow linewidths and achieving high spectral resolution.

CRDS can resolve all three limitations of absorption spectroscopy, namely sensitivity, selectivity, and dependence on intensity noise of the light source [43.1]. CRDS has been implemented using many different approaches. This chapter will discuss several commonly used variations on the CRDS technique.

43.2.1 Pulsed Cavity Ring–Down Spectroscopy

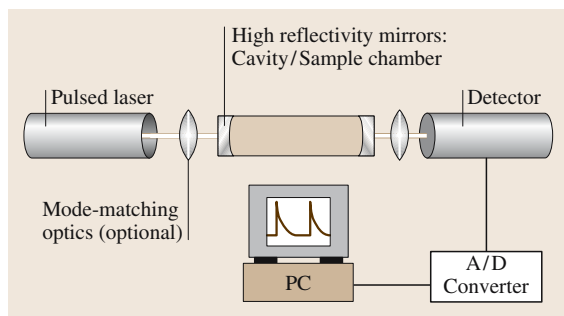
Early implementations of CRDS used pulsed lasers sources (P-CRDS) [43.2]. A typical P-CRDS setup


Fig. 43.1 Typical P-CRDS setup

is shown in Fig. 43.1. Today, CRDS has been implemented in the broadest possible range of wavelengths, from the UV (216 nm) to the mid-infrared (10 μm). Because of its experimental simplicity, P-CRDS has become a widespread tool for chemists and spectroscopists, finding applications in the measurement of predissociation dynamics, photolysis products, radiative lifetimes, aerosols or soot detection, temporal imaging, overtone vibrational spectroscopy, and kinetic studies. Typical P-CRDS sensitivity is 1×10^{-9} cm^{-1}Hz$^{-1/2}$.

P-CRDS methods have also been combined with other detection methodologies. Variations on P-CRDS include:

- Fourier-transform (FT) P-CRDS [43.3], where an RDC is excited with a broadband source and time-resolved FT scans of the RDC output waveform are taken. Inversion of the interferogram then produces time-dependent ring-down waveforms at all resolved frequencies within the source wavelength range.
- Polarization P-CRDS [43.4], where the spectral splitting induced by the magnetic field is observed from the difference of the ring-down spectra of the two orthogonal polarizations.
- Pulse-stacked P-CRDS [43.5], where the length of the RDC is set so that pulses from a very high repetition rate pulsed source coherently add together, which increases the effective cavity light throughput to yield improved detection of the ring-down waveform.

Spectral resolution and sensitivity of P-CRDS are, however, limited by the use of short-pulse lasers. The effects of pulsed laser bandwidth on spectral resolution of P-CRDS have been studied extensively and have led to system designs where only a single longitudinal and transverse mode of the RDC is excited [43.6]. However, single-mode P-CRDS is difficult to implement experimentally, and still has limited sensitivity because

the laser pulse is substantially attenuated by the RDC mirrors at the cavity output. The requirement for improving CRDS sensitivity by reducing the variability in the measurement of the decay constant from shot to shot with single-mode excitation, and improving the light transmission through the cavity to increase the signal to noise ratio of the decay waveform on the detector, provided the catalyst to implement continuous wave (CW) lasers in CRDS.

43.2.2 Continuous-Wave Cavity Ring-Down Spectroscopy (CW-CRDS)

CW lasers have narrow linewidths (< 50 MHz) and can be tuned in small spectral increments (< 50 MHz) to achieve high spectral resolution with excellent wavelength reproducibility. Moreover, owing to their narrow linewidths, they are better suited for efficiently coupling into a single mode of a high finesse RDC, thereby reducing shot-to-shot variations in measured ring-down decay constant. Furthermore, they can be directly modulated, thereby allowing higher data repetition rates, leading in turn to improved sensitivity.

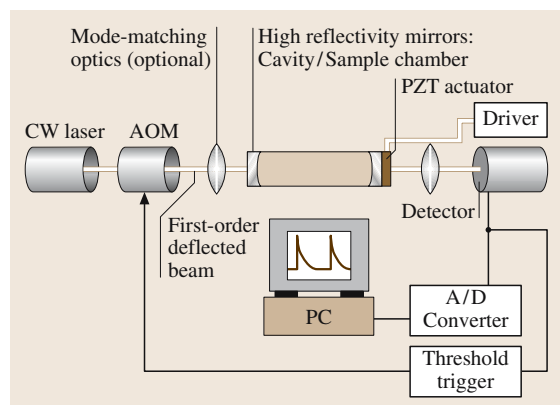
The first efforts in CW-CRDS involved optically locking a laser diode to a high-finesse cavity, but the performance was limited because the laser diode would drift and lock to different RDC modes. The use of sufficient optical isolation and an external optical switch resolved this issue. The most common approach used today is to sweep a RDC mode through the emission profile of a diode laser, and shut the laser off with an acousto-optic modulator (AOM) (Fig. 43.2) when sufficient light is injected into the cavity [43.7]. Numerous variations on this approach exist. For example, CW-CRDS can be implemented by rapidly sweeping the cavity mode into and


Fig. 43.2 Typical CW-CRDS setup

out of resonance with the laser. The simplest approach is to sweep the laser wavelength into and out of resonance with a cavity mode and directly modulate the laser source current [43.8]. The most popular CW lasers used today are distributed feedback (DFB) diode lasers.

In most CW-CRDS embodiments, the ring-down cavities are linear, i. e., consist of two mirrors. Ring resonators (e.g., triangular or bow-tie cavities) can also be used. Ring cavities provide the benefits of minimizing optical feedback and eliminating the need for extensive isolation or frequency shifting of the laser source. Moreover, ring resonators break the frequency degeneracy between cavity modes having orthogonal polarizations, effectively creating two coupled resonators having high and low finesse, respectively. The low finesse cavity can be used to lock the laser to a single cavity mode, while the high finesse cavity can be used for CRDS. The AOM acts as both a frequency-shifter and an on-off switch. This method was used to demonstrate the highest CRDS sensitivity achieved to date, namely 1.0×10^{-12} cm^{-1}Hz$^{-1/2}$ [43.9].

Prism-based, rather than mirror-based cavities have also been used [43.10]. Such cavities comprise two prisms whose intra-cavity facing angles are at Brewster's angle, and whose extra-cavity facing angles are such that total internal reflection occurs, and results in unit reflectivity. One of the prisms has a curved facet to create a stable optical resonator. The purpose of this design is to extend operation over a much broader range of wavelengths than can be achieved using dielectric coatings. Currently, high reflectivity mirrors are limited in bandwidth to about $\pm 15\%$ of their center wavelength.

CW-CRDS has been applied over a wide range of wavelengths. It has been used for medical breath an-

alysis, trace gas detection in environmental and process control applications, and isotopic analysis. In the near-infrared, CW-CRDS systems achieve sensitivities of 10^{-11} cm^{-1}Hz$^{-1/2}$, and a concentration measurement repeatability of 1 part in 5000. Similar performance in the mid-infrared (3 μm) resulted in the detection of parts-per-trillion ethylene concentrations [43.11].

Extensions of the basic CW-CRDS technique have also been developed:

- Phase-shifted CW-CRDS [43.12]: the phase shift accrued by a sinusoidally modulated CW laser is measured for both an empty RDC and one having a sample. The concentration is deduced from these two measurements.
- Heterodyne CW-CRDS [43.13]: enhances the power in the ring-down decay waveform by mixing with a local oscillator. For example, the local oscillator can be the orthogonal polarization used to lock the laser to the RDC, or can be the reflected signal from the RDC when laser is frequency-shifted (by the local oscillator frequency) off resonance from the RDC mode. Heterodyne CRDS can approach the shot-noise limit.
- V-cavity CW-CRDS [43.14]: a three-mirror V-shaped RDC is exploited to achieve consistent repetitive optical locking of a DFB diode laser to a single cavity mode, thereby significantly enhancing light throughput.

CW-CRDS is now maturing to a level of robustness and reliability that it can be commercially deployed in industrial applications, where the sensitivity requirements can no longer be met by FTIR, NDIR, or gas chromatography.

43.3 Cavity Enhanced Spectroscopy

Most CRDS systems capture the ring-down waveform using a digital oscilloscope. The Levenberg–Marquardt (LM) method produces the optimal fit, so that LM methods have become the de facto "gold standard" in CRDS [43.15]. However, the LM algorithm can require multiple iterations, thereby limiting the data acquisition times to several hundred Hz. Fast-fitting algorithms that closely approximate the LM fit, but allow data acquisition rates up to 10 kHz have recently gained widespread deployment [43.16]. Today, the data acquisition rates are no longer limited by the back-end numerical fit. Rather, the speed of CRDS systems is limited by the speed of laser modulation itself.

Cavity enhanced spectroscopy (CES) was developed in an effort to simplify CRDS and eliminate the requirement for digitization of a time-domain signal and laser modulation. CES has many different implementations. All CES methods are based on the principle that the build up of intracavity power, and hence cavity throughput, depends on intracavity losses, which include absorption by a sample. CES involves measuring the steady-state transmission through a cavity as a function of wavelength in order to determine changes in integrated transmitted intensity caused by the absorbing species.

For a cavity having two mirrors of intensity reflectivity, R, and length, L, the effective steady-state

path length is $L_{\text{eff}} = L/(1-R)$. If an absorbing gas is present, the reflectivity will be "reduced" by the Beer–Lambert factor $e^{-\alpha L}$ namely $R' = R e^{-\alpha L}$ so that one can effectively relate the ratio R'/R to the Beer–Lambert ratio I/I_0 for a single pass. The steady state transmitted laser intensity for such a cavity is given by $I = I_{\text{L}} C_p T [2(1-R)]^{-1}$ where T is the intensity transmissivity I_{L} is the laser intensity, and C_p is the coupling efficiency in the cavity mode. Thus, for an absorbing gas, the change in transmitted intensity at a given wavelength is:

$$\Delta I/I = GA (1+GA)^{-1} , \qquad (43.4)$$

where $A = 1 - e^{-\alpha L}$ and $G = R/(1-R)$ so that for $\alpha L \ll 1$, $(\Delta I/I) \approx GA \approx G\alpha L$. This latter relation has been interpreted as a linear response in absorption loss, multiplied by an effective cavity "gain" of $R/(1-R)$, i. e., the absorbance is measured over the effective length of the cavity which corresponds to the number of cavity passes occurring within the cavity ring-down time constant. Note that the transmitted power level will be attenuated by the mirror transmissivity, T, so that these methods are limited by laser power and detector sensitivity.

Because CES techniques measure transmitted light intensity, they are no longer immune to laser intensity noise. Furthermore, when the absorbance becomes comparable to the cavity loss, the sensitivity improvement of CES saturates, as the sample absorption begins to dominate the effective number of cavity passes. Note that for this case, the effective path length becomes a function of the sample concentration, which underlines another limitation of CES: this technique is not independent of the cavity length and hence depends on cavity alignment. Moreover, CES systems are not self-calibrated to the species extinction coefficient, and therefore require calibration against a known sample concentration, or against the absolute cavity loss, often measured using CRDS. Finally, it should be noted that the rate of data collection in CES is limited by the RDC time constant, because the cavity acts like a single-pole, low pass filter having a 3 dB frequency of $(2\pi\tau)^{-1}$ which can range from 5 to 50 kHz. Unlike CRDS, CES does not require fast digitization of the decay waveform followed by a non-linear fit, so that the data acquisition hardware can be a much slower, less expensive A/D converter and spectral data can be acquired almost instantaneously.

Five distinguishable variants of CES have been developed and are discussed. The first three methods, called cavity enhanced transmission spectroscopy (CETS), find their origins in CRDS. These

methods are cavity enhanced absorption spectroscopy (CEAS) [43.17], integrated cavity output spectroscopy (ICOS) [43.18], and off-axis ICOS [43.19]. For these three approaches, the laser intensity is no longer interrupted to observe a "ring-down event", although the path length enhancing properties of the RDC remain. More sensitive CES methods involve locking the laser to the cavity mode resonance. These will be referred to as locked cavity enhanced transmission spectroscopy and have two variations: locked cavity enhanced transmission spectroscopy (L-CETS) [43.20] and noise-immune, cavity-enhanced optical heterodyne molecular spectroscopy (NICE-OHMS) [43.21].

43.3.1 Cavity Enhanced Transmission Spectroscopy (CETS)

CETS has been implemented using several variations, all of which are based on measuring the time-integrated transmission through a high finesse RDC as function of wavelength. As stated earlier, the transmitted light provides an effectively enhanced path length to any sample absorption inside the cavity. The transmitted light intensity in all CETS approaches is a small fraction [about $(1-R)$] of the incident intensity, which reduces the signal to noise on detection, so that averaging is required. All CETS approaches are also dependent on laser intensity noise and sample path length.

The trade-off in using a high finesse cavity is that in steady state, its transmission is a non-uniform function of wavelength, and consists of a series of sharp cavity mode peaks, namely the transverse and longitudinal modes. This transmission pattern repeats itself periodically every free spectral range (FSR). The density of the mode spacing is a function of the cavity design: round-trip length and mirror radius of curvature. The quality of mode matching between the laser and the RDC determines the number of modes into which light can couple efficiently.

CEAS is the simplest CETS approach: the laser, coupled through a RDC, is tuned in wavelength over the absorption feature of interest, and the integrated cavity transmission is measured as a function of wavelength [43.17]. The cavity length is free-running (neither modulated nor locked to the laser). In order to minimize the non-uniformity of cavity transmission, CEAS exploits cavity geometries such that the inherent mode structure is as dense as possible. No mode-matching is employed, so that laser light is coupled into as many modes as possible. The laser is scanned multiple times over the cavity modes in order to time average over

the unstabilized cavity length. Extensive averaging can be required to achieve reasonable performance. The residual mode structure of the cavity can be significant and produces intensity modulation in the spectrum. Typically, the laser linewidth is larger than the individual cavity mode resonances, so that the output can be very noisy. CEAS does appear to have mechanical stability advantages, in that a cavity length change or deformation is in fact desirable to randomize the excited modes over wavelength. Typical sensitivities of CEAS range from are $5 \times 10^{-7}\,\mathrm{cm}^{-1}\mathrm{Hz}^{-1/2}$.

ICOS tries to achieve uniform transmission through the RDC by systematically disrupting the cavity mode resonances, in order to recover the frequency-averaged response of the cavity as a function of wavelength [43.18]. RDC length modulation was implemented by either moving one of the cavity mirrors using a piezo-electric transducer (PZT), or by slightly modulating the angle of injection in the cavity using a PZT-driven mirror mount. When the laser is scanned over the desired wavelength range with only the RDC modulation sweeping the modes (5 to 10 free spectral ranges), the resulting absorption spectra show an intensity modulation of about 10%. This intensity modulation results from a periodic non-uniformity in the mirror movement at the turning points of the PZT modulation, where the increased overlap time between the cavity mode and laser produces a higher transmitted light intensity. In order to eliminate this intensity modulation, the laser wavelength is frequency modulated simultaneously. The typical sensitivity of ICOS approach is about $2 \times 10^{-7}\,\mathrm{cm}^{-1}\mathrm{Hz}^{-1/2}$.

A third approach, called off-axis ICOS, resolves the cavity transmission uniformity problem of CEAS, and eliminates the need for modulation of ICOS. In off-axis ICOS, shown in Fig. 43.3, the RDC is aligned so as to generate a set of spatially separated reflections
Fig. 43.3 Typical off-axis ICOS setup

within the cavity that eventually satisfy the re-entrant condition [43.19]. Furthermore, the mirrors are slightly astigmatized, which results in Lissajous spot patterns on the mirrors. The combination of this alignment and slight astigmatism significantly reduces the RDC mode degeneracy. As a result, the cavity mode spacing can become smaller than the cavity mode width, the cavity transmission appears to become largely frequency independent, or "white". Thus, the RDC provides path length enhancement, without introducing intensity noise in the transmitted spectrum. However, increasing the number of spots on the mirrors usually requires larger mirrors (e.g., 2 inches for off-axis ICOS versus 0.5 inches for CRDS), which in turn results in a larger cavity (sample) volume. In cases of low sample flow, sample chamber filling times can limit the measurement time. Moreover, the system is now dependent on the mechanical stability of the cavity and the laser to cavity alignment. The best off-axis ICOS sensitivity achieved to date is $3 \times 10^{-11}\,\mathrm{cm}^{-1}\mathrm{Hz}^{-1/2}$ and is comparable to CW-CRDS.

43.3.2 Locked Cavity Enhanced Transmission Spectroscopy (L–CETS)

An alternative approach (L-CETS) achieves higher sensitivity by locking the laser frequency to a single cavity resonance and then scanning the cavity over the absorption feature of interest [43.20]. In this case, the cavity throughput becomes uniform across the entire spectral scan, and the cavity transmission increases to the maximum theoretical value, leading to better signal to noise at the detector than CETS approaches. Laser wavelength jitter at high frequencies, which cannot be compensated by the locking control loops, will lead to increased noise in the spectral scans. In order to lock the laser and cavity together robustly, the laser linewidth typically cannot exceed the cavity mode resonance linewidth, so that for a high finesse sample cavity, the laser choice can be limited. Sensitivities of $10^{-11}\,\mathrm{cm}^{-1}\mathrm{Hz}^{-1/2}$ have been demonstrated using L-CETS.

The NICE-OHMS technique was developed to overcome the dependence of L-CETS on laser wavelength jitter [43.21]. NICE-OHMS combines the benefits of frequency modulation (FM) spectroscopy with the path length enhancements of a high finesse optical resonator. The technique is called "noise immune", because it does not depend on the quality of the laser and cavity lock. Effectively, it is immune to laser frequency noise although residual amplitude modulation can reduce the performance. NICE- OHMS sensitivity depends on the transmitted laser power, the efficiency and bandwidth of

the photodetector, and the FM modulation index. NICE-OHMS has exploited cavities having a finesse of 100 000 to achieve sensitivities of 1×10^{-14} cm^{-1}Hz$^{-1/2}$. NICE-OHMS holds the world record in detection sensitivity of all cavity enhanced techniques.

In a NICE-OHMS experiment, phase modulation of the laser produces side bands that are set to equal the free spectral range of the high finesse resonator. Because the sidebands are transmitted by the cavity in the same manner as the carrier, any small wavelength fluctuations in the laser or small optical phase shifts of the transmitted carrier that contribute to noise in the transmitted intensity will appear identically in the sidebands. After demodulation, this noise will cancel out. Thus, the transmitted carrier and sidebands are an accurate representation of the carrier and sidebands impinging on the input mirror of the cavity. The carrier laser frequency is locked to the peak of the optical cavity mode and tracks

this mode if the cavity length is changed in order to produce a spectral scan. The sidebands are detected and demodulated as in conventional FM spectroscopy. The key to NICE-OHMS is that the noise level can approach the intrinsic shot noise of the laser at the FSR frequency (namely hundreds of MHz).

If there is no sample in the cavity, the transmitted sidebands will cancel after demodulation because they have opposite phases. No signal will be observed. If there is a sample in the cavity, the sidebands will experience different transmission amplitudes, so that demodulation will produce a signal proportional to the difference in absorption between the sideband frequencies. In addition, the absorption feature produces a phase shift that pulls the carrier cavity mode frequency, so that the sidebands become detuned from the mode peak and acquire a phase shift on transmission. This sideband phase shift contributes to the demodulated signal.

43.4 Extensions to Solids and Liquids

Thus far, the discussion of cavity-enhanced techniques has addressed traditional optical resonators formed using high reflectivity dielectric mirrors that encompass gas samples. Extensions of cavity enhanced methods to liquid and solid media has required additional innovation, specifically in the optical cavities used.

Evanescent-wave CRDS (EW-CRDS) exploits the fact that total internal reflection allows probing the surface layer of a sample in contact with a prism. The simplest configuration places a Brewster prism inside a linear ring-down cavity. The prism folds the cavity beam path by 90 degrees, thereby producing one point in the prism having total internal reflection [43.22]. The evanescent wave produced by this internal reflection can be used to probe liquid or solid samples. Another possible embodiment is a ring cavity having its optical path inside a multi-faceted polygon, where at each facet, total internal reflection occurs [43.23]. Light is coupled into and out from the polygon by photon tunneling – which effectively controls the overall finesse of the cavity. The absorbing sample material can then be placed on any one or more of the polygon facets, and its detection is done using the polygon's evanescent waves.

Fiber cavities are attractive because they can extend the use of CRDS into harsh environments, can probe liquids as well as gases, and can be used to measure pressure [43.24]. The high reflectivity mirrors on each end of the fiber can be either dielectrically coated, as in a traditional ring-down cavity design, or can con-

sist of Fiber Bragg gratings. Fiber-based CRDS has also been applied to detection in liquid media via a fiber loop cavity wherein a liquid sample replaced the index matching fluid in the gap between fibers at the connector splice [43.25]. This approach produced a 100-fold enhancement over linear detection.

More direct approaches to measuring liquid samples involved confining the liquid samples within a more traditional RDC. The most direct method involves placing a liquid directly into the cavity, but this approach results in very limited sensitivity. By placing a Brewster cell filled with liquid sample in a RDC, the sensitivity of the P-CRDS can be slightly improved. By matching the Brewster angles to the refractive indices of the adjacent media (the outside angle matches the air-filled RDC, while the inner angle matches the index of the liquid), the sensitivity can be dramatically improved [43.26]. The peak-to-peak baseline noise level of such a P-CRDS system was 1.0×10^{-5} absorbance units (AU), rivaling the best available commercial ultraviolet-visible (UV-VIS) direct absorption detectors. The performance remained limited by the excitation of multiple cavity modes A CW-CRDS system using the same angle-matched Brewster cell [43.27] improved the peak-to-peak baseline noise by a factor of 50 to 2×10^{-7} AU. This CRDS detector outperformed the best commercially available UV-VIS detector by a factor of 30, again illustrating the potential for CRDS to replace standard absorption spectroscopy techniques.

Solid samples have also been placed inside linear CRDS cavities for characterization. Mostly, P-CRDS are used. Examples of applications include characterization of C-60 films, thin-film coatings, and silicon wafers.

It is anticipated that CRDS will eventually reach sensitivities for liquid and thin film samples that are comparable to those achieved in gases. CRDS is also expected to find commercial applications in high performance liquid chromatography, thin film characterization, and biological detection. Combination techniques of CRDS and fluorescence, or CRDS and Raman spectroscopy, may also be on the not-so-distant horizon, where CRDS provides the quantification, while the complementary technique provides identification [43.28].

44. Spectroscopic Techniques: Ultraviolet

The design of UV spectroscopic experiments and apparatus must conform to the constraints associated with producing, dispersing, and detecting UV photons. In this chapter, we review the instrumentation available for UV spectroscopy, concentrating on the VUV, where special instrumentation is necessary. Recent advances are stressed, particularly in the areas of synchrotron radiation and the production of VUV laser light.

The most inclusive, up-to-date review of vacuum ultraviolet techniques is Vacuum Ultraviolet Spectroscopy I & II (1998), edited by *Samson* and *Ederer* [44.1]. This text significantly expands on Samson's classic, authoritative review of VUV instrumentation, first published in 1967 [44.2]. There are many comprehensive reviews of VUV light sources, spectrometers, and

detectors, which are referenced in the appropriate sections of this chapter.

The ultraviolet (UV) spectral region extends from the short wavelength side of the visible, about 400 nm, to the long wavelength side of the X-ray region at approximately 10 nm. Ultraviolet photon energies range from about 3 to 120 eV. Because laboratory air at STP does not transmit below about 200 nm, the UV region is conventionally subdivided into the near ultraviolet, wavelengths $\lambda > 200$ nm, and the vacuum ultraviolet (VUV), $\lambda < 200$ nm. Further subdivisions are widespread, but not uniformly adopted. The term middle ultraviolet (MUV) is sometimes used to designate the 200 to 300 nm wavelength region, with the term near UV used only for 300 to 400 nm. VUV wavelengths are often divided into the far ultraviolet (FUV), 100 to 200 nm, and the extreme ultraviolet (EUV), 10 to 100 nm. In this review, we will simply refer to the UV (10 to 400 nm), the

near UV (200 to 400 nm), and the VUV (10 to 200 nm).

The absorption of UV radiation by atoms and molecules involves transitions to highly excited discrete and continuum levels. The relevant atomic and molecular physics of highly excited states is discussed in Chaps. 14, 24, 25, and 61. Ultraviolet absorption initiates many important photochemical reactions; applications in astrophysics, aeronomy, and combustion are reviewed in Chaps. 82, 84, and 88. The experimental techniques used at ultraviolet wavelengths include high-resolution spectroscopic measurements of wavelengths and line shapes (Chapt. 10) , absolute photoabsorption oscillator strength and radiative lifetime measurements (Chapt. 17), fluorescence spectroscopy, and energy, angle, and spin-resolved photoelectron spectroscopy (Chapt. 61).

44.1 Light Sources

44.1.1 Synchrotron Radiation

Synchrotron radiation (SR) facilities provide intense continuum radiation in the visible, UV, and soft X-ray spectral regions. The radiation is emitted by relativistic electrons (or positrons) accelerated by the Lorentz force of a magnetic field. In addition to its continuum nature, synchrotron radiation is characterized by high degrees of collimation and polarization. Advances in specialized magnet designs, e.g., wigglers and undulators, that dramatically increase spectral brightness at selectable wavelengths, have stimulated continuing growth in synchrotron-radiation-based spectroscopic research. References [44.3–13] give general reviews on the nature of synchrotron radiation and on specific SR-based experimental techniques.

SR facilities use either a linear accelerator, a microtron, or a synchrotron to accelerate electrons or positrons to relativistic energies (0.1 to 10 GeV). The particles are then injected into a storage ring, where a series of bending magnets steers them in a closed orbit. The particles in the storage ring radiate energy, which is replaced by radio frequency accelerating cavities that are part of the ring. These accelerating systems produce well-defined, regularly spaced bunches of stored particles, so that radiation from SR facilities is characterized by sub-nanosecond pulses at 1 to 10 MHz repetition rates.

Typical storage ring currents are on the order of 100 to 1 A. The current decreases continuously because of collisions with residual gas molecules and electron–electron (or positron–positron) scattering. Beam lifetimes in most facilities range from a few to about 20 hours. The longest lifetimes are achieved by positron beams, which repel any ions produced in residual gas collisions. Storage ring pressures must be in the 10^{-10} Torr range in order to reduce collisions to acceptable levels; such pressure requirements can restrict the types of measurements performed at SR facilities.

The spectral properties of synchrotron radiation can be derived from Larmor's formula for an accelerating relativistic charged particle [44.4, 14–18]. The total power P radiated by a beam of current I and energy E in a bending magnet field B is

$$P = 0.0265 E^3 I B \text{ kW} , \tag{44.1}$$

where, throughout this chapter, I is in mA, E is in GeV, and B is in Tesla. For example, a 300 mA beam of 1 GeV electrons radiates about 8 kW when traversing the field of a typical 1.0 T bending magnet. One-half of the total power is radiated above the critical wavelength, λ_c, where

$$\lambda_c = 1.9/\left(BE^2\right) \text{ nm} . \tag{44.2}$$

For the example just considered, $\lambda_c = 1.9$ nm.

The power radiated by, and the flux from, synchrotron radiation sources is often expressed per fractional (or percent) bandwidth. For example the flux Φ, in units of photons $\left(\text{cm}^2\text{s}\right)^{-1}$, at 10 nm (124 eV) per 1% bandwidth is the flux in a 0.1 nm band at 10 nm, which is the same as that in a 1.24 eV energy band. The radiated power per fractional bandwidth peaks at $\lambda \approx 0.75\,\lambda_c$.

The flux per fractional bandwidth reaches a broad maximum at $\lambda \approx 3.3\,\lambda_c$ and decreases slowly at longer wavelengths, with a limiting behavior that is proportional to $\lambda^{-1/3}$ for $\lambda \gg \lambda_c$. Thus, although the photon flux typically peaks in the soft X-ray region, a high flux is also present throughout the VUV wavelength range. Below λ_c, the flux drops rapidly, with little usable radiation at wavelengths below about $0.1\,\lambda_c$.

The angular distribution of the radiated light is sharply peaked in the instantaneous direction of the beam of radiating particles. Practically all the radiation is emitted into an opening half-angle θ that at $\lambda = \lambda_c$ is equal to $1/\gamma$, where $\gamma = E/mc^2$; i. e.,

$$\theta = 1/\gamma = 5.11 \times 10^{-4}/E \text{ rad} . \tag{44.3}$$

Radiation from beams with energies of a few GeV has a divergence somewhat less than 1 mrad at λ_c. The divergence increases at longer wavelengths, with

$$\theta \approx (\gamma)^{-1}(\lambda/\lambda_c)^{1/3} \text{ rad} . \tag{44.4}$$

Radiation from bending magnets maintains this narrow divergence only in the vertical plane; in the orbital plane, the radiation is emitted in an opening angle equal to the bending angle of the magnet. Typical beam cross sections are 0.01 to 1 mm^2. Thus, the extremely high spectral brightness, i. e., photon flux per unit solid angle and % bandwidth, of synchrotron sources reflects both the very low divergence of the radiation and the small source size. A typical brightness associated with bending magnet radiation is on the order of 10^{12} photons $(\text{s mm}^2 \text{ mrad}^2 \text{ 0.1\% bandwidth})^{-1}$.

Synchrotron radiation has well-characterized polarization properties. Within the orbital plane the radiation is completely linearly polarized with the electric field

vector in the orbital plane; above and below the orbital plane the radiation is elliptically polarized, with the degree of polarization dependent on both wavelength and viewing angle. Undulator designs incorporating either crossed planar magnets or a helical array of magnets can produce circularly polarized light (e.g., [44.19]), allowing for the development of circular dichroism spectroscopies in the vacuum ultraviolet [44.20].

The pulsed nature of the radiation at synchrotron facilities is ideal for sub-nanosecond time-resolved spectroscopies [44.21–25]. Electron bunch lengths l_b are typically a few centimeters; radiation is observed from each bunch for a time interval approximately equal to $l_b/c \approx 100$ ps. The time for one full orbit is determined by the size of the storage ring and varies from about 20 ns at the smallest rings to 500 to 1000 ns at the larger rings. The number of bunches is typically on the order of a few hundred, resulting in pulse repetition rates from a few MHz to about 500 MHz.

Many synchrotron facilities incorporate straight sections between bending magnets to accommodate insertion devices such as wigglers and undulators. These are linear arrays of magnets with alternating polarities that cause the beam trajectory to oscillate, although no net displacement of the beam occurs. The oscillations produce synchrotron radiation that is characterized by extremely high brightness and that can be spectrally tailored to individual experiments [44.4, 13, 17, 26, 27].

Wigglers and undulators are distinguished by the value of their deflection parameter K, which is a measure of the maximum bending angle of the stored particle beam in units of θ, the angular divergence of the emitted radiation. The deflection parameter K is determined by the peak strength of the alternating magnetic field B_0 and its spatial period x_B by

$$K = 0.934 B_0 x_B , \qquad (44.5)$$

with x_B in cm.

In the wiggler regime, $K \gg 1$; i.e., the angle at which the magnets deflect the electron beam is large compared with θ. The resulting spectrum resembles that from a bending magnet, but is brighter by a factor of N_m, the number of magnet periods (usually 10 to 100). Wigglers are generally used as wavelength shifters; magnetic fields larger than those available in conventional bending magnets decrease the critical wavelength of the spectral distribution and shift the overall spectrum to shorter wavelengths.

In the undulator regime, $K \ll 1$; i.e., the angle at which the electrons are deflected is close to θ and radiation from individual oscillations adds coherently at certain resonant wavelengths, producing a gain of N_m^2. Undulator radiation is characterized by sharp peaks at a fundamental wavelength λ_1 and its odd harmonics. λ_1 is determined by the beam energy and x_B:

$$\lambda_1 \approx 0.1\, x_B / \left(2\gamma^2\right) = 1.3\, x_B\, E^{-2} \text{ nm} , \qquad (44.6)$$

where x_B is in cm. For example, the fundamental wavelength is 6.5 nm for a 1 GeV beam traversing an undulator with a spatial period of 5 cm. The fractional bandwidth of the peaks in an undulator spectrum is $\approx 1/N_m$. Unlike the radiation from a bending magnet, the angular divergence of undulator radiation is sharply peaked both vertically and in the orbital plane; the brightness of undulator radiation is $\approx 10^{18}$ to 10^{19} photons/(s mm^2 mrad^2 0.1% bandwidth), about six orders of magnitude greater than bending magnet radiation. The wavelength of the fundamental is tunable; the strength of the peak magnetic field is altered via changes in the size of the gaps between the poles of the magnets.

44.1.2 Laser–Produced Plasmas

When the output of a high-power pulsed laser is focused onto a solid target, a short-lived, high-temperature ($T \approx 50$ to 100 eV), high-density $\left(n_e \approx 10^{21} \text{ cm}^{-3}\right)$ plasma is created. The radiation from certain target materials, particularly the rare earths ($57 \le Z \le 71$) and neighboring metals on the periodic table, produces a strong VUV quasicontinuum that is essentially free of discrete lines [44.28, 29]. The continua are most intense in the 4 to 30 nm region but often extend to about 180 nm. A review of laser-produced plasmas and their applications in the VUV can be found in [44.30].

The primary mechanisms responsible for the continua are recombination radiation (ionization stages up to ≈ 16 are attained) and bremsstrahlung. The absence of discrete features in rare earth plasmas is thought to be caused by the extreme complexity of rare earth atomic energy level structures; individual emission lines are blended into an apparent continuum [44.31]. The necessary peak laser powers, which are in the range of 10^{10} to 10^{11} W cm^{-2} [44.32, 33], are easily achieved with most commercially available Q-switched lasers. The continuum pulse duration is comparable to the duration of the laser pulse. Peak output intensities are significantly greater than those from other pulsed table-top continuum sources such as spark discharges; synchrotron sources produce much higher average intensities [44.33]. The target material is usually a cylindrical rod that is rotated to present a fresh surface for each laser shot. References [44.32, 34–38]

present and discuss the spectral characteristics of several laser-produced plasma sources. Atomic photoabsorption techniques based on laser-produced plasma sources are described in [44.33, 39–41].

44.1.3 Arcs, Sparks, and Discharges

Several laboratory sources of VUV line and continuum radiation are based on gas discharges, high-pressure arcs, and low-pressure and vacuum sparks. While these well-established radiation sources are not as intense as synchrotron radiation and laser-produced plasmas, the traditional sources have the advantages of being portable and inexpensive. Reviews can be found in [44.42, 43].

H₂ and D₂ Discharges

Direct current discharges (approximately 100 to 500 mA) through 1 to 2 Torr of H_2 or D_2 generate continuum radiation from about 165 to 350 nm [44.2, 44]. The continuum is produced by transitions from the bound $1s\sigma\, 2s\sigma\, a^3 \Sigma_g^+$ state to the repulsive $1s\sigma\, 2p\sigma\, b^3 \Sigma_u^+$ state [44.45]; the very steep potential curve of the lower state results in the extended nature of the continuum. The photon flux per unit wavelength from such lamps peaks at about 185 nm; below 165 nm the many-line spectra of H_2 or D_2 begin to dominate.

Ar Mini–Arc

A high-current (20 to 50 A) wall-stabilized arc discharge through 1 to 2 atm of Ar, known as a mini-arc, produces a continuum associated with recombination radiation. The continuum extends from the near UV down to approximately 110 nm [44.44, 46]. The stability and reproducibility of the output of the mini-arc has led to its use as a secondary radiometric standard in the VUV [44.46, 47].

Noble Gas Discharges

High voltage (10 kV), mildly condensed, repetitive (5 kHz) discharges through the noble gases produce continua associated with molecular transitions between bound excited states and the very weakly bound ground states of the noble gas dimers [44.2, 48, 49]. These continua begin at the first resonance line of the atomic species and extend a few tens of nanometers to longer wavelengths. For example, the onset of the He continuum is approximately 59 nm, while the useful continuum extends from 65 to 95 nm with a peak intensity at about 80 nm. Discharges through He, Ar, Kr, and Xe cover the 65 to 180 nm region. Optimum discharge pressures vary from about 40 Torr for He up to a few hundred Torr

for Kr and Xe. Differential pumping is required when using these discharge sources at wavelengths shortward of 105 nm, the short wavelength transmission limit of window materials (see Sect. 44.5).

Flash Discharges and Vacuum Sparks

Flash discharges of approximately 1 μs duration through low-pressure (approximately 0.02 Torr) gases in ceramic or glass capillaries yield useful continua down to about 30 nm [44.2, 50]. The continua are produced by passage of the discharge through sputtered wall materials and are independent of the carrier gas. The BRV source [44.51], a pulsed vacuum spark with extremely low inductance, utilizes a high-Z anode (e.g., W or U) to generate a smooth continuum down to about 10 nm. The short pulse duration (approximately 50 ns) [44.52] and well-defined triggering make this source useful for transient absorption studies at short wavelengths.

Line Radiation Sources

Hollow cathode discharges [44.53, 54], which are easy and inexpensive to construct and operate, are the most common line-emission sources used in UV spectroscopy. Low power (approximately 5 W) lamps designed to produce the spectra of about 70 elements are commercially available for spectrochemical and atomic absorption spectroscopy. Line widths are narrow, so blends are avoided. Most manufacturers can provide lamps with special windows for use at VUV wavelengths (Sect. 44.5).

High-current, differentially-pumped hollow cathode sources, which have been developed for use as radiometric standards in the 40 to 125 nm wavelength range [44.55], can also be used as line sources. At shorter wavelengths, e.g., 5 to 40 nm, the Penning discharge has proved to be a useful source of line radiation [44.43, 56, 57]. Electron-beam excitation sources [44.43] produce stable and reproducible line emission spectra and find use as VUV calibration standards [44.54, 58]. Electron-beam ion trap (EBIT) sources [44.59, 60] generate VUV and X-ray spectra of highly ionized atomic species.

44.1.4 Supercontinuum Radiation

Continua extending throughout the near UV wavelength range to below 200 nm can be produced by focusing femtosecond laser pulses in both liquids and noble gases. This supercontinuum generation [44.61] allows for time-resolved, sub-picosecond spectroscopy of photochemical reactions [44.62, 63]. The supercontinuum arises from a number of competing nonlinear

processes [44.64–66]. Access to the UV has been demonstrated both by focusing 308 nm laser pulses in water [44.67] and by focusing 248 nm laser pulses in high pressure (10 to 40 atm) cells of Ne, Ar,

and Kr [44.68]. The continuum produced using H_2O is particularly broad, extending from 200 to 600 nm. The neon continuum extends into the VUV to at least 187 nm.

44.2 VUV Lasers

Advances in laser technologies have led to an impressive increase in spectroscopically useful VUV laser sources. Recent reviews can be found in [44.69, 70]. The following summary of VUV lasers does not cover the rapidly developing fields of X-ray and soft X-ray lasers [44.71, 72] or the development of free electron lasers operating in the VUV ([44.73, 74] and references therein).

Primary Lasers

Pulsed lasing at VUV wavelengths has been achieved in a number of media, including the molecular gases H_2, CO, and F_2, excimer systems (Ar_2, Kr_2, Xe_2, ArF), and Auger-pumped noble gases (Xe, Kr) [44.75]. The fundamental barrier to producing stimulated emission in the VUV is the ν^3 dependence of the spontaneous emission rate, which necessitates very high pump powers to create and maintain population inversions. Existing VUV primary lasers have generally not been widely used in spectroscopic applications because of either a lack of tunability or unacceptably broad line widths.

Pulsed lasing in CO, H_2, and F_2 occurs between rovibronic levels of a high-lying electronic state and excited vibrational levels of the ground electronic state. The lasing output consists of discrete lines and is not tunable. The CO and H_2 outputs [44.76, 77] span relatively broad regions (181 to 197 nm and 110 to 164 nm, respectively), while the F_2 laser output consists of two or three closely-spaced lines at 157 nm [44.78]. Pulse energies are in the 1 to 100 μJ range for CO and H_2 lasers. Commercially available F_2 lasers offer pulse energies of about 50 mJ at 50 Hz repetition rates.

Noble-gas and noble-gas-halide excimer lasers operate via bound-upper-level to continuum-lower-level transitions. (Retrospective reviews of excimer laser technologies can be found in [44.79, 80].) The resulting gain profiles are broad and the outputs are typically tunable over about 2 nm. ArF excimer systems (193 nm) are pumped by high pressure gas discharges; lasers with pulse energies of $\approx$ 20 to 40 mJ are commercially available. Xe_2 (173 nm), Kr_2 (146 nm), and Ar_2 (126 nm) lasers [44.81–83] produce comparable pulse energies but require electron beam excitation. Auger-pumped lasers

achieve a population inversion through the ejection of an inner-shell electron from a neutral atom to produce a highly excited singly ionized species, followed by Auger decay to excited states of the doubly ionized species. The soft X-ray (approximately 100 eV) pump photons often originate from a laser-produced plasma. The lasing output is nontunable. Lasing in Xe (108.9 nm) and Kr (90.7 nm) [44.84, 85] has been achieved with output pulses in the range of a few μJ, and Auger-pumped lasing in Zn (at approximately 130 nm) has also been reported [44.86].

Nonlinear Techniques

In the past thirty years, developments in the techniques of nonlinear optics have extended the range of tunable, pulsed coherent radiation to VUV wavelengths. Nonlinear frequency conversion techniques, such as stimulated anti-Stokes Raman scattering, harmonic generation, and sum- and difference-frequency mixing (see Chapt. 72) , can produce narrow-bandwidth radiation spanning the entire VUV. The generated VUV radiation has the spectral and spatial characteristics of the input laser radiation. Pulses of 10^{10} to 10^{12} photons are commonly generated with bandwidths on the order of 0.1 cm^{-1} (2×10^{-4} nm). Many reviews are available on this subject [44.75, 87–95]. The standard nonlinear techniques for producing tunable coherent radiation with $\lambda < 200$ nm are summarized below.

Second harmonic generation in nonlinear optical crystals is a well-established method for generating tunable laser light in the near UV (Chapt. 42). At the shortest wavelengths, second harmonic generation in β-barium borate (BBO) produces usable outputs down to approximately 205 nm, below which the phase matching requirement between the fundamental and the second harmonic cannot be met. Sum-frequency mixing ($\omega = \omega_1 + \omega_2$) in BBO [44.96, 97], where ω_1 is typically the Nd:YAG fundamental (1064 nm) and ω_2 is tunable UV light, extends the useful range of BBO to approximately 190 nm, where the crystal begins to exhibit strong absorption.

Stimulated anti-Stokes Raman scattering of UV laser light in molecular gases (e.g., H_2, N_2, CH_4) is used

to generate coherent radiation down to about 120 nm, although low conversion efficiencies often restrict the usable output to $\lambda > 160$ nm. The scattering is a four-wave mixing process resulting in a series of output frequencies shifted from the pump laser frequency by multiples of the vibrational splitting of the ground electronic state of the gas [44.98, 99]. Because high anti-Stokes orders are not efficiently generated, H_2, with its large ground state vibrational splitting of 4155 cm^{-1}, is often the gas of choice. The experimental requirements are relatively minimal; a tunable visible or UV source (e.g., a frequency-doubled dye laser) and a high pressure gas cell (about 2 to 10 atm of H_2 in a 1 m cell). Conversion efficiencies of a few percent are reported for the first few anti-Stokes orders in H_2 with pump laser energies of about 10 to 50 mJ [44.100, 101]; efficiencies then drop continuously, reaching about 10^{-5} to 10^{-6} for the highest orders ($n = 9$ to 13) reported. Stokes seeding techniques [44.102] have been shown to increase efficiencies for the highest anti-Stokes orders by as much as a factor of 100.

Third harmonic generation ($\omega = 3\omega_1$), sum-frequency mixing ($\omega = 2\omega_1 + \omega_2$), and difference-frequency mixing ($\omega = 2\omega_1 - \omega_2$) in appropriate noble gases and metal vapors are the most broadly applicable methods for producing tunable VUV light. These processes result from the presence of the third-order nonlinear term in the expansion of the induced macroscopic polarization of the gas as a power series in the electric field (Chapt. 72). (The second-order term, which is responsible for frequency doubling in crystals, is zero for isotropic media such as gases.) The power generated in third-order effects is proportional to

$$N^2 \left| \chi^{(3)} \right|^2 P_1^2 P_2 F \,, \tag{44.7}$$

where N is the number density of the gas, $\chi^{(3)}$ is the third-order nonlinear susceptibility, P_1 and P_2 are the input laser powers at ω_1 and ω_2, and the factor F describes the phase matching between the generated VUV light and the induced polarization [44.88, 89]. For third harmonic generation, $P_1^2 P_2$ is replaced by P_1^3.

The most critical constraint in third-order frequency conversion is the phase matching requirement; a comprehensive treatment is presented in [44.103]. The factor F is a function of the product $b\Delta k$, where b is the confocal beam parameter of the focused input radiation and Δk is the phase mismatch between the generated VUV light and the input radiation:

$$\Delta k = k - (2k_1 + k_2) \,. \tag{44.8}$$

where k_i is the wave vector of the radiation with frequency ω_i. In the standard case of tight focusing ($b \ll L$, where L is the linear dimension of the gas cell) for sum-frequency mixing and third harmonic generation processes, F is nonzero only for $\Delta k < 0$. Therefore, these techniques are applicable only in spectral regions where the gas exhibits negative dispersion. In contrast, for difference-frequency mixing, the factor F is nonzero in regions of both positive and negative dispersion, and wider tuning ranges are generally possible.

Conversion efficiencies for sum- and difference-frequency mixing schemes are usually in the range of 10^{-7} to 10^{-4} with input peak laser powers of 1 to 10 MW. Resonant enhancement of $\chi^{(3)}$, achieved by tuning the input radiation to transition frequencies in the gas, dramatically increases conversion efficiencies (by factors of about 10^4 and allows for much lower (≈ 1 kW) input laser powers. Most commonly, one of the incident frequencies is tuned to an allowed two-photon transition, with the second input frequency providing subsequent tunability in the VUV; resonant methods therefore require two tunable inputs.

Metal vapors (e.g., Mg, Zn, Hg) are negatively dispersive over fairly broad regions of the VUV between 85 and 200 nm and are consequently used for sum-frequency mixing and third harmonic generation. Conversion efficiencies are further enhanced in these vapors by three photon resonances ($2\omega_1 + \omega_2$) with the ionization continuum or broad autoionizing features [44.91]. One experimental drawback is the complexity associated with generating the metal vapors in ovens or heat pipes.

Noble gases are generally less suited for sum-frequency mixing because they exhibit negative dispersion over fairly limited spectral ranges in the VUV. However, they do provide an experimentally simple medium for difference-frequency mixing schemes. In particular, Xe, Kr, and Ar (as well as H_2) have been used in resonant and nonresonant difference-frequency mixing schemes to produce tunable radiation over the 100 to 200 nm region [44.104–110]. The noble gases are also used for sum-frequency mixing and third harmonic generation. Kr, Ar, and Ne are used for the generation of tunable radiation down to 65 nm [44.104, 111–114]. Below the LiF transmission cutoff (105 nm) the gases are introduced as pulsed jets. *Hollenstein* et al. [44.115] describe an ultra-narrow bandwidth (≈ 0.008 cm^{-1}) system, utilizing resonance-enhanced sum-frequency mixing in rare gases, capable of producing coherent radiation between 73 and 124 nm. A representative sum-

mary of third-order frequency conversion schemes is presented in Table 44.1

Higher-order frequency conversion techniques have been used to generate both fixed frequency and tunable coherent radiation shortward of 70 nm. For example, radiation at 53.2 nm and 38.0 nm has been produced via fifth and seventh harmonic generation in He, us-ing the 266.1 nm Nd:YAG fourth harmonic [44.116]. Tunable radiation at 58 nm has been produced through fifth harmonic generation in C_2H_2 using the frequency-doubled output of a dye laser [44.117, 118]. A system with continuous tunability over the 40 to 100 nm re-gion with sub-cm^{-1} resolution has been developed using high-order harmonic generation in Ar and Kr [44.119].

44.3 Spectrometers

44.3.1 Grating Spectrometers

The design and characteristics of VUV grating spectrometers and monochromators are reviewed by many authors [44.2, 50, 129–134]. Two basic types of spectrometer are used in the VUV; normal inci-dence instruments for 200 nm > λ > 30 nm and grazing incidence instruments for 50 nm > λ > 2 nm. The par-ticulars of these two types are largely dictated by the low reflectivities of both metal and dielectric surfaces in the VUV.

Concave gratings are used almost exclusively in VUV spectrometers. Such gratings provide both dis-persion and focusing, thus eliminating the need for additional mirrors and their associated reflection losses. Most VUV spectrometers make use of the focusing prop-erties of the Rowland circle, which is tangent to the grating at its center, lies in a plane perpendicular to the grating grooves, and has a diameter equal to the radius of curvature of the grating [44.2, 135]. A source on a hor-izontal Rowland circle is focused horozontally by the grating to a location also on the circle. The dispersion introduced by the grating results in a focused, diffracted spectrum lying on the Rowland circle. Almost all nor-mal incidence and grazing incidence VUV instruments are designed with the entrance and exit slits (or pho-tographic plate) lying on, or nearly on, the Rowland circle.

The image formed by a concave grating is not stig-matic, i. e., the vertical focus does not coincide with the horizontal focus. Hence, a point source is imaged into a vertical line on the Rowland circle [44.2, 131, 136]. Astigmatism is particularly severe at grazing incidence angles, resulting in both loss of signal (the image of the entrance slit being larger in extent than the exit slit) and loss of resolution (the image of the entrance slit is curved in the dispersion direction). Aspherical concave gratings (e.g., toroidal gratings) reduce the astigmatism associ-ated with conventional spherical gratings ([44.136] and references in [44.137]). The most important recent ad-vances in concave grating production are the use of interference techniques to produce holographic grat-ings [44.137–139] and the development of variable line spacing gratings [44.140, 141]. Interference techniques eliminate the periodic irregularities in conventionally ruled gratings that lead to spectroscopic "ghosts", re-duce the level of scattered light by significant amounts, allow for very high groove densities (e.g., 4800 mm^{-1}), and can be relatively easily applied to aspheric sur-faces. Mechanically-ruled variable line spacing gratings correct for spherical aberrations and allow for rela-tively simple focusing and scanning designs in EUV spectrometers and monochromators [44.141].

Table 44.1 Representative third-order frequency conver-sion schemes for generation of tunable coherent VUV light

Medium	λ (nm)	Process	Ref.
Sr	165–200	res. diff. mixing	[44.120]
	178–196	res. sum mixing	[44.121]
Mg	121–174	res. sum mixing	[44.91]
Zn	106–140	res. sum mixing	[44.122]
Hg	142–182	nonres. tripling	[44.88]
	117–122	res. sum mixing	[44.123]
	104–108	res. sum mixing	[44.124]
	85–125	res. sum mixing	[44.125]
Xe	160–206	nonres. diff. mixing	[44.105]
	140–147	nonres. tripling	[44.126]
	113–119	nonres. sum mixing	[44.105]
Kr	117–150	res. diff. mixing	[44.127]
	110–116	nonres. sum mixing	[44.105]
	120–124	nonres. tripling	[44.128]
	127–180	res. diff. mixing	[44.104]
	72–83	res. sum mixing	[44.104]
Ar	102–124	res. diff. mixing	[44.108]
	97–105	nonres. tripling	[44.111]
Ne	72–74	nonres. tripling	[44.112]

Normal incidence grating designs are appropriate for wavelengths greater than about 30 to 40 nm. The most common types include the Eagle, Wadsworth, and Seya–Namioka designs [44.129, 131, 132]. Eagle mounts, with entrance and exit slits on the Rowland circle and approximately equal angles of incidence and reflection ($< 10°$), can be either in-plane or off-plane. Photographic resolving powers $\lambda/\delta\lambda$ of more than 2.5×10^5 and photoelectric resolving powers of ≈ 1 to 2×10^5 have been achieved in the 100 nm region with 6.65 m Eagle mount instruments [44.142–145]. In the Wadsworth mount, the light source is at a large distance from the grating and no entrance slit is required. This design is appropriate for collimated light sources such as synchrotron radiation. It has the advantages of high throughput and minimal astigmatism [44.2, 130]. The Seya–Namioka mount is a Rowland circle instrument in which the angle subtended by the fixed entrance and exit slits relative to the center of the grating is approximately 70°. The spectrometer remains in good focus for small grating rotations, resulting in a simple scanning mechanism and thus an inexpensive design [44.2]. Seya–Namioka instruments provide high throughput at moderate spectral resolutions (typically 0.02 to 0.05 nm) [44.130].

The normal incidence reflectance of all standard metal coatings is no greater than a few percent for $\lambda < 30$ nm [44.131]; in this wavelength region grazing incidence instruments take advantage of the total reflection of photons at extreme grazing angles. There is a sharp reflectance cutoff at photon energies above a characteristic energy that typically limits the use of grazing incidence optics to $\lambda \gtrsim 1$ nm. Grazing incidence designs, tailored to the constraints of synchrotron radiation facilities, are described in [44.4, 130, 133]. Astigmatism becomes severe at grazing angles; interferometrically produced aspherical gratings and mechanically ruled variable line spacing gratings are used to reduce this aberration [44.139, 141]. The resolving power of a grazing incidence instrument is generally lower than that of a comparably sized normal incidence instrument, in large part because of the decreased effective width of the grating at grazing incidence [44.2]. The largest grazing incidence instruments

achieve resolving powers of about 10^5 in the 5 to 40 nm region [44.146, 147].

A number of nonstandard instrument designs are reported in the literature, often for use in VUV astronomy and aeronomy applications. These novel designs take advantage of the properties of conical diffraction [44.148–150] and dual-grating crossed dispersion or echelle mounts [44.151, 152] to reduce the effects of aberrations. Reference [44.129] reviews many specialized VUV spectrometer designs.

44.3.2 Fourier Transform Spectrometers

Fourier transform spectroscopy (FTS) is a well-established technique for high-resolution emission and absorption spectroscopy at infrared and visible wavelengths. The technique has been extended into the near UV and VUV regions, where FTS is characterized by the large optical throughput, high spectral resolution, and accurate linear wavenumber scale available at longer wavelengths [44.153]. However, the multiplex advantage of FTS is not realized at UV wavelengths because the signal-to-noise ratio is photon-noise limited rather than detector limited. A review of interferometric techniques in the VUV can be found in [44.154].

A scanning Michelson interferometer with a fused silica beamsplitter has achieved a resolving power of 1.8×10^6 at wavelengths down to 178 nm [44.153]. The same interferometer design, with a MgF_2 beamsplitter, has achieved a resolving power of 8.5×10^5 at wavelengths shorter than 140 nm [44.155]. This spectral resolution is significantly better than that realized by the best VUV grating instruments.

At shorter wavelengths, diffraction gratings can be used as division-of-amplitude beamsplitters to create all-reflecting interference spectrometers for VUV wavelengths. This technique has been used to create spatial heterodyned spectrometers for astronomical applications [44.156–158]. The interferometer mirrors are not moved in such instruments; the interferogram is viewed by an array detector. The design of a wave-front-division interferometer for wavelengths down to 60 nm is described in [44.159].

44.4 Detectors

There is a wide variety of photon detectors with useful response and sensitivity at VUV wavelengths. With the exception of those involving the photo-ionization of gases, VUV detectors are based on the same un-

derlying principles as their counterparts in the visible and infrared regions – the common detection schemes are initiated by surface photoemission, electron–hole pair creation in semiconducting materials, or chemical

changes in photographic emulsions. The details of the design of VUV detectors, and the constraints on their use, are most often determined by the low levels of transmission of VUV light through suitable window and semiconducting materials. Nevertheless, VUV detectors with single photon counting sensitivities and/or imaging capabilities are widely available. Reviews of VUV detectors can be found in [44.1, 2, 50, 160–163]. References [44.164–166] review the operating characteristics and calibration of VUV detector standards. A more general summary of photon detector technology is presented in [44.167, 168]. Below we summarize and compare the most common VUV detection schemes, including the use of photographic plates, photomultiplier tubes and vacuum photodiodes, multichannel plate detectors, silicon photodiodes, charge-coupled devices, and ionization chambers.

Photographic Plates

Photographic plates have long been used at VUV wavelengths for spectroscopic measurements, and they are still sometimes the detector of choice for both spectroscopic surveys and high resolution wavelength measurements. They have the advantages of being imaging detectors with very high spatial resolution; spectral line positions can be determined with an uncertainty of about $1 \mu m$. Plates also have multiplexing and very flexible integrating capabilities, being insensitive to fluctuations in signal intensities during the period of exposure. However, when compared with photoelectric detectors, photographic plates have the disadvantages of limited dynamic range and a nonlinear response, which makes radiometric measurements very problematic when plates are used. The gelatin base used in standard photographic emulsions strongly absorbs VUV radiation, so special plates with no gelatin base are required for VUV work [44.2].

Photomultiplier Tubes

Photomultiplier tubes (PMTs) [44.169] are used through the VUV for single-photon-counting, nonimaging, applications. Dark count rates are low (about $1 s^{-1}$) for solar-blind tubes with $1 cm^2$ photocathodes; pulse rise times are about 1 to 10 ns ([44.170] for a general review of amplifying detectors in the VUV). In the 105 to 200 nm region, useful PMT window materials are fused silica, MgF_2, and LiF; sapphire is also used in environments where ionizing radiation, which causes sapphire to fluoresce, is not present. In the windowless region of the VUV wavelength

range ($2 nm \leq \lambda \leq 105 nm$), two options are available: the PMT may be operated bare, i.e., without a window, or a fluorescent coating can be deposited on the window to down-convert the VUV light to longer wavelengths.

Peak quantum efficiencies for VUV photomultiplier tubes are about 15 to 20%. Some of the most useful coatings for photocathodes in the VUV are CsI, KBr, and other alkali halides. These materials combine high VUV quantum efficiencies with a solar blind response – their relatively high photoelectric work functions result in long wavelength cutoffs between 150 and 300 nm. Solar blind PMTs have low dark count rates and have minimal response to stray ambient light.

Bare PMTs, although used in some applications, are constrained by the degradation of many photocathode and dynode surfaces upon exposure to air and humidity. Metal surfaces such as tungsten and aluminum/Al_2O_3 [44.162] must be used rather than the higher efficiency alkali halide coated surfaces. Sodium salicylate is the most commonly used VUV-visible conversion phosphor; others include liumogen, terphenyl, and coronene [44.2, 171, 172]. The conversion efficiency of sodium salicylate (peak fluorescence about 430 nm) is relatively constant for VUV light from 30 to 200 nm. It displays some aging effects, which may be associated with contaminants such as oil vapor in the associated vacuum system [44.2]. The fluorescent decay time of sodium salicylate is ≈ 10 ns [44.2].

Vacuum Photodiodes

Vacuum photodiodes consist of a photocathode and an anode, with no amplifying dynode chain. The current leaving the photocathode is measured. (A review of vacuum photodiode designs and performance can be found in [44.173].) Because of their stability, spatial uniformity, and portability, vacuum photodiodes are used as radiometric transfer-standard detectors throughout much of the VUV [44.162, 174, 175]. There is no gain in vacuum photodiodes, so minimum signal levels that can be accurately measured are on the order of 10^6 photons/s. For fast timing applications, vacuum photodiodes have been designed with risetimes as short as about 60 ps [44.160].

Microchannel Plates

The microchannel plate (MCP) detector is a photoemissive array detector that combines the single-photon counting sensitivity of a PMT with high resolution imaging capability [44.161–163, 170, 176, 177]. An MCP

consists of an array of semiconducting glass channels with diameters of about 10 to 25 μm and length-to-diameter ratios of about 50 : 1. Electrons ejected from the front surface of an MCP via the photoelectric effect are accelerated through the channels; repeated collisions with the channel walls result in an amplification of the charge by about 10^6. The exiting charge clouds are detected by a variety of position-sensing anode structures.

Bare MCPs have quantum efficiencies of about 10% for $\lambda \leq 100$ nm and a long wavelength cutoff about 120 nm [44.178]. Alkali halide coatings increase the quantum efficiency to about 20% and extend MCP sensitivities toward longer wavelengths [44.178–180]. Feedback instabilities produced by positive ions created in the channels during the electron cloud amplification are minimized through two common channel geometries; the chevron configuration, where two or more straight-channel MCPs oriented at different angles are cascaded [44.176], or a configuration with one set of curved channels [44.181, 182].

Readout schemes for determining the position of individual detected photons rely on either direct detection of the resulting electron cloud, or conversion of the electron cloud into visible photons via a phosphor to produce an optical image [44.170, 183]. Direct detection schemes include centroid-detecting anodes such as the wedge and strip design [44.178, 184], cross strip anodes [44.185]. Other designs are described in [44.186, 187]. Discrete anode arrays that digitally locate event positions include the MAMA (multianode microchannel array) [44.188, 189] and the CODACON systems [44.190]. Spatial resolutions of 15 μm are possible.

Silicon Photodiodes

Broad use of silicon photodiodes at VUV wavelengths has traditionally been limited by the strong absorption of VUV photons in the outer SiO_2 passivation layer that covers the p–n junction of these devices. Standard silicon detectors are sensitive throughout the infrared and visible regions and also in the soft X-ray ($\lambda < 2$ nm) and X-ray regions. Significant improvements in silicon photodiode sensitivities in the VUV are realized by thinning the SiO_2 passivation region to thicknesses of about 5 to 10 nm. References [44.173, 191] review VUV semiconductor photodiode designs; references [44.192, 193] describe the development of non-silicon-based photodiodes, e.g., wide bandgap materials such as GaN, for this spec-

tral range. References [44.194–197] report devices with a quantum efficiency of 120% (electron–hole pairs per incident photon) at 100 nm. The development of such photodiodes with appreciable VUV sensitivity and good temporal stability has led to their use as radiometric transfer standards [44.198, 199]. Because silicon photodiodes respond strongly to radiation throughout the visible, ir, and X-ray regions, a method for rejection of stray light is essential for their effective use in the VUV. Reference [44.200] reports on the use of thin-film filters, deposited on the photodiode surface, to restrict the bandpass of the radiation impinging on the diode to selected VUV wavelengths. Wide bandgap semiconductors reject visible light with their natural solar-blind response [44.199].

Charge–Coupled Devices

CCDs are widely used for low light level imaging applications throughout the visible and near-ir regions. In the VUV, charge-coupled devices suffer from strong absorption both by surface gate structures and by the inactive passivation layer [44.170]. Two approaches are employed to overcome these limitations: the CCD front surface is overcoated with a photon down-converting phosphor [44.201, 202], or a thinned and surface-treated CCD is back-illuminated with VUV light [44.203, 204]. Such techniques have resulted in CCD VUV quantum efficiencies that rival those of photoemissive devices such as microchannel plates. A comparison of CCD and MCP performance in the VUV is given by [44.178]; they conclude that MCPs are most appropriate for low light-level imaging where photon counting is applicable, while the larger dynamic range and readout capabilities of CCDs make them suitable for higher light level applications.

Ionization Chambers

In gas ionization chambers, the impact of VUV photons with gas atoms or molecules produces electron–ion pairs which are then collected by the application of an appropriate voltage [44.205]. The photoionization efficiency and the detection efficiency approach 100% for photon energies above the ionization threshold of the gas [44.2, 162]. With appropriate gain, ionization chambers can detect individual photons (e.g., the Geiger counter); these chambers require relatively high gas pressures (100 to 2000 Torr) and therefore cannot be used in the windowless region of the VUV. The double ionization chamber described by [44.206] serves as a primary standard detector from 5 to 100 nm [44.162].

44.5 Optical Materials

The design of VUV instrumentation is dictated in large part by the constraints of VUV optical materials. Transmission through bulk materials is limited to $\lambda \gtrsim 105$ nm, the short wavelength transmission limit of LiF. Normal incidence reflectance from metal surfaces and coatings decreases dramatically at short wavelengths; polarizers and narrow-band interference filters are relatively difficult to produce because of the lack of materials with suitable optical constants. Below we briefly summarize the properties and uses of VUV optical materials. Comprehensive discussions can be found in [44.1, 2, 50].

Windows

Few bulk materials transmit light below 200 nm; none transmit light from about 2 nm to 105 nm. In the 105 to 200 nm wavelength region, the most common window materials are synthetic fused quartz or suprasil (with a short λ transmission cutoff about 160 nm), sapphire (145 nm), CaF_2 (125 nm) MgF_2 (112 nm), and LiF (105 nm). Compilations of the transmission characteristics of these and other materials are presented in [44.2, 50, 131, 207, 208]. Single crystal windows with dimensions up to 10 cm can be obtained for most of these materials. Sapphire fluoresces when struck by ionizing radiation and is therefore not suitable for certain environments.

Capillaries

In the windowless region, 2 to 105 nm, it is standard practice to use differentially pumped slits or circular apertures to isolate different pressure regions, e.g., to isolate an absorption cell from a vacuum spectrometer. This technique has the drawback of requiring large pumping capacities and limiting optical throughputs. Thin films (see below) can be used below 105 nm as windows, but they provide limited transmission in narrow bandpasses and cannot support large pressure differentials. Reference [44.209] describes a differentially pumped MCP capillary array as an alternative window in the VUV. The capillaries are typically ≈ 3 mm in length and have diameters of 10 to 100 μm. Measured optical transmissions are in the 20 to 50% range throughout the VUV; tradeoffs must be considered between optical throughput and gas conductance. The main limitation to an MCP window is its small angular aperture.

Thin Films

Below 105 nm, thin (about 10 to 200 nm) metallic films are used as transmission filters with bandpasses of ap-

proximately 10 to 50 nm. Details of filter properties are given in [44.208, 210]. A review of thin film filter preparation techniques is presented in [44.211]. Reference [44.212] describes composite metallic filters (e.g., Al/Ti/C, Ti/Sb/Al), developed for the Extreme Ultraviolet Explorer satellite, with transmission bandpasses of about 10 to 20 nm and high rejection at wavelengths of strong VUV geocoronal lines.

Coatings

Above 120 nm, the principal broadband reflector for VUV wavelengths is Al with a thin protective overcoat of MgF_2, having a normal incidence reflectance of ≈ 80 to 85% [44.2, 213]. The normal incidence reflectivities of all materials drop dramatically below about 100 nm. A compilation of coating reflectivities at normal and grazing incidence is presented in [44.214]. Materials with the highest reflectivities include Os, Pt, Au, and Ir, with reflectivities of 15 to 30% from 30 to 110 nm [44.2, 215]. [44.216] reviews the preparation of VUV reflectance coatings for diffraction gratings. Reference [44.217] reports grazing incidence reflection coefficients for Rh, Os, Pt, and Au from 5 to 30 nm; Rh has the highest reflectivity in this region.

Interference Filters and Multilayer Coatings

The development of interference filters for VUV wavelengths has been limited by the availability of coating materials with both high transmission and appreciable range of refractive differentials [44.218]. Multilayer dielectric reflectors thus require many layers to compensate for the small reflectivities at the material interfaces. The theory of multilayer reflecting optics and optic designs are reviewed in [44.219]. Reference [44.215] evaluates the commercially available VUV reflectance filters, antireflection coatings, and neutral density filters as of 1983. Developments as of the earlys 1990s are described in [44.220–223]. More recent advances are presented in [44.224–227].

Normal incidence optics with multilayer reflection coatings can be used in the nominally grazing incidence spectral region below 30 nm [44.228–231]. Reference [44.232] summarizes synthesis procedures and models of multilayer structures. References [44.233–238] describe normal incidence gratings coated with Mo/Si multilayers. The performances of other multilayer coatings are described in [44.239–242].

Polarizers

The production and detection of linearly polarized light in the VUV is discussed in [44.2, 131, 243–247]. Above about 112 nm, transmission polarizers, based on the birefringence of MgF_2, are employed [44.248, 249]. Reflection polarizers must be used below 112 nm. An analysis of double-reflection circular polarizers is given in [44.250].

Scattering Part D

Part D Scattering Theory

45. Elastic Scattering: Classical, Quantal, and Semiclassical

Scattering cross sections determine the rates at which gas phase processes and chemical reactions happen, whether in the atmosphere, or in an industrial reactor. This chapter provides a handy compendium of equations, formulae, and expressions for the classical, quantal, and semiclassical approaches to elastic scattering. Reactive systems and model potentials are also considered.

Part D | 45

45.1 Classical Scattering Formulae

Central Field. The total energy $E > 0$ and orbital angular momentum L of relative planar motion are conserved. For a particle of mass M with coordinates (R, ψ), a symmetric potential $V(R)$, and asymptotic speed v,

$$E = \frac{p^2(R)}{2M} + V(R) + \frac{L^2}{2MR^2} = \frac{1}{2}Mv^2 = \text{constant} \,, \tag{45.1}$$

$$L^2 = (2ME)b^2 = M^2v^2b^2$$
$$= \left[MR^2(t)\dot{\psi}(t) \right]^2 = \text{constant} \,. \tag{45.2}$$

Equation (45.2) implies constant areal velocity.

Radial momentum $p(R)$:

$$p(R; E, b) = (2ME)^{1/2} \left(1 - \frac{V(R)}{E} - \frac{b^2}{R^2} \right)^{1/2} \,. \tag{45.3}$$

Effective potential:

$$V_{\text{eff}}(R) = V(R) + \frac{L^2}{2MR^2} = V(R) + \frac{b^2}{R^2}E \,. \tag{45.4}$$

The turning points $R_i(E, b)$ are the roots of $E = V_{\text{eff}}(R)$. The smallest R_i is the distance of closest approach $R_c(E, b)$ at the pericenter. The maximum impact parameter b_X and angular momentum L_X for

approach to within a distance R_X are

$$b_X^2 = R_X^2 \left[1 - V(R_X)/E\right] , \qquad (45.5a)$$

$$L_X^2 = 2MR_X^2 \left[E - V(R_X)\right] . \qquad (45.5b)$$

The trajectory is defined by $R = R(t; E, b)$, $\psi = \psi(t; E, b)$, where R is the distance from the scattering center O and ψ is measured with respect to the apse line OA joining O to the pericenter R_c. Taking $t(R_c) = 0$, (45.1) implies

$$t(R) = \left(\frac{M}{2E}\right)^{1/2} \int_{R_c}^{R} \left(1 - \frac{V(R)}{E} - \frac{b^2}{R^2}\right)^{1/2} dR ,$$

$$(45.6)$$

which implicitly provides $R = R(t; E, b)$.

$$\psi(t; E, b) = \frac{L}{M} \int_0^t R^{-2}(t) \, dt$$

$$= \frac{\left(2MEb^2\right)^{1/2}}{M} \int_0^t R^{-2}(t) \, dt. \qquad (45.7)$$

Orbit integral ($0 \leq \psi \leq \pi$): ψ is symmetrical about and measured from the apse line joining O and R_c.

$$\psi(R; E, b) = b \int_{R_c}^{R} \frac{dR/R^2}{\left[1 - V(R)/E - b^2/R^2\right]^{1/2}}$$

$$(45.8)$$

$$= -\frac{\partial}{\partial b} \int_{R_c}^{R} \left(1 - \frac{V(R)}{E} - \frac{b^2}{R^2}\right)^{1/2} dR .$$

$$(45.9)$$

For large b and/or small $V(R)/E \ll 1$, (45.9) reduces to

$$\psi(R; E, b) = \frac{\pi}{2} - \sin^{-1}\frac{b}{R} + \frac{1}{2E}\frac{\partial}{\partial b}$$

$$\times \int_b^R \frac{V(R) \, dR}{\left[1 - b^2/R^2\right]^{1/2}} , \qquad (45.10)$$

$$\psi(R \to \infty; E, b) = \frac{\pi}{2} + \frac{b}{2E}$$

$$\times \int_b^\infty \left(\frac{dV}{dR}\right) \frac{dR}{\left(R^2 - b^2\right)^{1/2}} .$$

$$(45.11a)$$

For a straight-line path, $R^2 = b^2 + Z^2$, where Z is the distance along the scattering axis, and

$$\psi(R \to \infty; E, b) = \frac{\pi}{2} + \frac{1}{4E}\frac{\partial}{\partial b} \int_{-\infty}^{\infty} V(b, Z) \, dZ .$$

$$(45.11b)$$

45.1.1 Deflection Functions

The deflection function $\chi(E, b)$, $(-\infty \leq \chi < \pi)$, is defined to be $\chi(E, b) = \pi - 2\psi(R \to \infty; E, b)$. Then

$$\chi(E, b) = \pi - 2b \int_{R_c}^{\infty} \frac{dR/R^2}{\left[1 - V(R)/E - b^2/R^2\right]^{1/2}} ,$$

$$(45.12)$$

$$= \pi - 2$$

$$\times \int_0^1 \left(\left\{\frac{1 - V(R_c/x)/E}{1 - V(R_c)/E}\right\} - x^2\right)^{-1/2} dx .$$

$$(45.13)$$

An expression which avoids spurious divergences is

$$\chi(E, b) = \pi + 2\frac{\partial}{\partial b} \qquad (45.14)$$

$$\times \int_{R_c}^{\infty} \left[1 - V(R)/E - b^2/R^2\right]^{1/2} dR .$$

Small-angle scattering, $V(R_c)/E \ll 1$, $b \sim R_c$:

$$\chi(E, b) = \left(\frac{R_c}{E}\right) \int_{R_c}^{\infty} \frac{[V(R_c) - V(R)] \, R \, dR}{\left(R^2 - R_c^2\right)^{3/2}} \quad (45.15a)$$

$$= \frac{1}{E} \int_0^1 \frac{[V(R_c) - V(R_c/x)] \, dx}{\left(1 - x^2\right)^{3/2}} , \quad (45.15b)$$

where $x = R_c/R$. From (45.10)–(45.11b), other forms are

$$\chi(E, b) = -\frac{1}{E}\frac{\partial}{\partial b} \int_b^{\infty} \frac{V(R) \, dR}{\left(1 - b^2/R^2\right)^{1/2}} \quad (45.16a)$$

$$= -\frac{b}{E} \int_b^{\infty} \left(\frac{dV}{dR}\right) \frac{dR}{\left(R^2 - b^2\right)^{1/2}}$$

$$(45.16b)$$

$$= -\frac{1}{2E}\frac{\partial}{\partial b} \int_{-\infty}^{\infty} V(b, Z) \, dZ . \quad (45.16c)$$

For straight-line paths $R^2 = b^2 + v^2 t^2$, (45.12) yields the impulse-momentum result

$$\chi(E, b) = (Mv)^{-1} \int_{-\infty}^{\infty} F_\perp(t) \, dt = \Delta p_\perp / p_\infty \,,$$

(45.17)

where $\Delta p_\perp$ is the momentum transferred perpendicular to the incident direction and $F_\perp = -(\partial V / \partial R)(b/R)$ is the impulsive force causing scattering. Special cases are

Head-on collisions $(b = 0)$: $\chi(E, 0) = \pi$.

Overall repulsion:	$0 < \chi \le \pi$.
Overall attraction:	$-\infty \le \chi \le 0$.
Forward glory:	$\chi = -2n\pi$.
Backward glory:	$\chi = -(2n-1)\pi$,
	$n = 0, 1, 2, \ldots$.
Rainbow scattering:	$(d\chi / db) = 0$ at $\chi_r < 0$.
Deflection range:	$\chi_r \le \chi \le \pi$.
Orbiting collisions:	cf. (45.34).
Diffraction scattering:	$\chi \to 0$ as $b \to \infty$.

The scattered particle may wind or spiral many times around $(\chi \to -\infty)$ the scattering center. The experimentally observed quantity is the scattering angle θ $(0 \le \theta \le \pi)$ which is associated with various deflections

$$\chi_i = +\theta, -\theta, -2\pi \pm \theta, -4\pi \pm \theta, \ldots$$
$$(i = 1, 2, \ldots n)$$

resulting from n different impact parameters b_i.

Gauss–Mehler Quadrature Evaluation of the Deflection Function.

$$\chi(E, b) = \pi \left[1 - \left(\frac{b}{R_c} \right) \frac{1}{n} \sum_{j=1}^{n} a_k g(a_j) \right] \,,$$

(45.18)

where

$$a_k = \cos \left(\frac{2j-1}{4n} \pi \right) \,, \quad k = n+1-j \,, \text{ and}$$

$$g(x) = \left[1 - V(R_c/x)/E - b^2 x^2 / R_c^2 \right]^{-1/2} \,,$$
$$0 \le x \le 1 \,.$$

45.1.2 Elastic Scattering Cross Section

Differential cross section:

$$\frac{d\sigma(\theta, E)}{d\Omega} \equiv I(\theta; E) \equiv \sigma(\theta; E) \,,$$

$$\sigma(\theta, E) = \sum_{i=1}^{n} \left| \frac{b_i \, db_i}{d(\cos \chi_i)} \right| = \sum_{i=1}^{n} I_i(\theta) \,.$$

(45.19)

Integral cross section for scattering by angles $\theta \ge \theta_0$:

$$\sigma_0(E) = 2\pi \int_{\theta_0}^{\pi} I(\theta; E) \, d(\cos \theta) = 2\pi \int_0^{b_0(\theta_0)} b \, db \,,$$

(45.20)

where θ_0 results from one $b_0 = b(\theta_0)$. When θ_0 results from three impact parameters b_1, b_2, b_3, for example, then

$$\sigma_0(E) = 2\pi \int_0^{b_1} b \, db + 2\pi \int_{b_2}^{b_3} b \, db$$

$$= \pi \left(b_1^2 + b_3^2 - b_2^2 \right) \,.$$

(45.21)

Diffusion (momentum-transfer) cross section:

$$\sigma_d(E) = 2\pi \int_0^{\pi} [1 - \cos \theta(E, b)] \, I(\theta) \, d(\cos \theta) \,,$$

(45.22a)

$$= 2\pi \int_0^{\infty} [1 - \cos \theta(E, b)] \, b \, db \,,$$

(45.22b)

$$= 4\pi \int_0^{\infty} \sin^2 \left[\frac{1}{2} \theta(E, b) \right] b \, db \,.$$

(45.22c)

Viscosity cross section:

$$\sigma_v(E) = 2\pi \int_0^{\pi} \left[1 - \cos^2 \theta(E, b) \right] I(\theta) \, d(\cos \theta) \,,$$

(45.23a)

$$= 2\pi \int_0^{\infty} \left[1 - \cos^2 \theta(E, b) \right] b \, db \,,$$

(45.23b)

$$= 2\pi \int_0^{\infty} \left[\sin^2 \theta(E, b) \right] b \, db \,.$$

(45.23c)

Small–Angle Diffraction Scattering. The small-angle scattering regime is defined by the conditions $V(R_c)/E \ll 1$, $b \ge R_c$, where $\theta = |\chi|$. The main contribution to $d\sigma/d\Omega$ for small-angle scattering arises from the asymptotic branch of the deflection function χ at large impact parameters b, and is primarily determined by the long-range (attractive) part of the potential $V(R)$ (Sect. 45.3.6).

Large–Angle Scattering. The main contribution to $d\sigma/d\Omega$ for large-angle scattering arises from the positive branch of χ at small b and is mainly determined by the repulsive part of the potential.

45.1.3 Center–of–Mass to Laboratory Coordinate Conversion

Let ψ_1, ψ_2 be the angles for scattering and recoil, respectively, of the projectile by a target initially at rest in the lab frame. Then

$$\sigma_1(\psi_1)\, d\Omega_1 = \sigma_2(\psi_2)\, d\Omega_2 = \sigma_{cm}^{(1,2)}(\theta)\, d\Omega_{cm} ,$$
$$0 \le \theta \le \pi ; \tag{45.24}$$
$$\sigma_{cm}^{(2)}(\theta, \phi) = \sigma_{cm}^{(1)}(\pi - \theta, \phi + \pi) . \tag{45.25}$$

(A) Two-body elastic scattering process without conversion of translational kinetic energy into internal energy: $(1) + (2) \to (1) + (2)$.

$$\sigma_1(\psi_1) = \sigma_{cm}(\theta) \frac{\left(1 + 2x\cos\theta + x^2\right)^{3/2}}{|1 + x\cos\theta|} ; \tag{45.26}$$

$$\sigma_2(\psi_2) = \sigma_{cm}(\theta) \left| 4 \sin\frac{1}{2}\theta \right| ;$$

$$\psi_2 = \frac{1}{2}(\pi - \theta), \quad 0 \le \psi_2 \le \frac{1}{2}\pi ; \tag{45.27}$$

$$\tan\psi_1 = \frac{\sin\theta}{(x + \cos\theta)} , \quad x = M_1/M_2 . \tag{45.28}$$

$M_1 > M_2$: As $0 \le \theta \le \theta_c = \cos^{-1}(-M_2/M_1)$,
$$0 \le \psi_1 \to \psi_1^{max} = \sin^{-1}(M_2/M_1) < \frac{1}{2}\pi .$$
As $\theta_c \le \theta \to \pi$, $\psi_1^{max} \le \psi_1 \to 0$.
θ is a double-valued function of ψ ;
$M_1 = M_2$: $\sigma_1(\psi_1) = (4\cos\psi_1)\sigma_{cm}(\theta = 2\psi_1)$,
$$0 \le \psi_1 \le \frac{1}{2}\pi, \psi_1 + \psi_2 = \frac{1}{2}\pi ;$$
no backscattering .
$M_1 \ll M_2$: $\sigma_1(\psi_1) = \sigma_{cm}(\theta = \psi_1)$;
lab and cm frames identical.

(B) Two-body elastic scattering process with conversion of translational kinetic energy into internal energy: $(1) + (2) \to (3) + (4)$. For conversion of internal energy ε_i so that kinetic energy of relative motion (in the cm frame) increases from E_i to $E_f = E_i + \varepsilon_i$. For $j = 3, 4$,

$$\sigma_j(\psi_j) = \sigma_{cm}(\theta) \frac{\left[1 + 2x_j\cos\theta + x_j^2\right]^{3/2}}{|1 + x_j\cos\theta|} , \tag{45.29}$$

$$x_3 = \left(\frac{M_1 M_3 E_i}{M_2 M_4 E_f}\right)^{1/2} ,$$

$$x_4 = -\left(\frac{M_1 M_4 E_i}{M_2 M_3 E_f}\right)^{1/2} ,$$

$$\tan\psi_3 = \frac{\sin\theta}{(x_3 + \cos\theta)}, \quad \tan\psi_4 = \frac{\sin\theta}{(|x_4| - \cos\theta)} .$$

45.1.4 Glory and Rainbow Scattering

Glory. The deflection function χ passes through $-2n\pi$ (forward glory) or $-(2n+1)\pi$ (backward glory) at finite impact parameters b_g. Then $\sin\theta \to 0$ as $\theta \to \theta_g$ so that classical cross section diverges as

$$\sigma(E, \theta) = \left(\frac{2b_g}{\sin\theta}\right) \left|\frac{db}{d\chi}\right|_g \quad \text{as } \theta \to \theta_g . \tag{45.30}$$

Rainbow. The deflection function χ passes through a negative minimum at $b = b_r$; $(d\chi/db)_r \to 0$ so that

$$\chi(b) = \chi(b_r) + \omega_r(b - b_r)^2 , \tag{45.31}$$

$$\omega_r = \frac{1}{2}\left(\frac{d^2\chi}{db^2}\right)_{b_r} > 0 . \tag{45.32}$$

The classical cross section diverges as

$$\sigma(E, \theta) = \frac{b_r}{2\sin\theta} [\omega_r(\theta_r - \theta)]^{-1/2} , \quad \theta < \theta_r , \tag{45.33}$$

and is augmented by the contribution from the positive branch of $\chi(b)$.

45.1.5 Orbiting and Spiraling Collisions

Attractive interactions $V(R) = -C/R^n$ ($n \ge 2$) can support quasibound states with positive energy within the angular momentum barrier. Particles with $b < b_0$ spiral towards the scattering center. Those with $b = b_0$ are in

unstable circular orbits of radius R_0. The radius R_0 is determined from the two conditions

$$\left(\frac{\mathrm{d}V_{\mathrm{eff}}}{\mathrm{d}R}\right)_{R_0} = 0 , \quad E = V_{\mathrm{eff}}(R_0) , \tag{45.34}$$

which, when combined, yields

$$E = V_{\mathrm{eff}}(R_0) = V(R_0) + \frac{1}{2} R_0 \left(\frac{\mathrm{d}V}{\mathrm{d}R}\right)_{R_0} . \tag{45.35}$$

The angular momentum L_0 of the circular orbit is

$$L_0^2 = (2ME)b_0^2 = 2MR_0^2 \left[E - V(R_0)\right] . \tag{45.36}$$

Thus $b_0^2 = R_0^2 F$, where

$$F = 1 - \frac{V(R_0)}{E} = \frac{1}{2}\left(\frac{R_0}{E}\right)\left(\frac{\mathrm{d}V}{\mathrm{d}R}\right)_{R_0} \tag{45.37}$$

is the *focusing factor*. The orbiting and spiraling cross section is then

$$\sigma_{\mathrm{orb}}(E) = \pi b_0^2 = \pi R_0^2 F . \tag{45.38}$$

45.1.6 Quantities Derived from Classical Scattering

The semiclassical phase $\eta(E, b) \equiv \eta(E, \lambda)$, with $\lambda = \left(\ell + \frac{1}{2}\right) = kb$ is a function of b or λ. The quantitites $p(R) \equiv p(R; E, L)$ and $p_0(R) \equiv p_0(R; E, L)$ are radial momenta in the presence and absence of the potential $V(R)$, respectively.

$$\eta^{\mathrm{SC}}(E, b) = \frac{1}{\hbar}\left[\int_{R_c}^{\infty} p(R)\,\mathrm{d}R - \int_{b}^{\infty} p_0(R)\,\mathrm{d}R\right] \tag{45.39}$$

$$= k \int_{R_c}^{\infty}\left[1 - V/E - b^2/R^2\right]^{1/2}\mathrm{d}R$$

$$- k \int_{b}^{\infty}\left[1 - b^2/R^2\right]^{1/2}\mathrm{d}R . \tag{45.40}$$

Asymptotic speed v: $E = \frac{1}{2}Mv^2 = \hbar^2 k^2/2M$, $k/2E = 1/\hbar v$.

Jeffrey–Born phase function:
For small V/E and $b \sim R_c$,

$$\eta_{\mathrm{JB}}(E, b) = -\frac{k}{2E}\int_{b}^{\infty}\frac{V(R)\,\mathrm{d}R}{\left(1 - b^2/R^2\right)^{1/2}} . \tag{45.41}$$

Eikonal phase function:
For small V/E and a linear trajectory $R^2 = b^2 + Z^2$,

$$\eta_{\mathrm{E}}(E, \boldsymbol{b}) = -\frac{k}{4E}\int_{-\infty}^{\infty}V(\boldsymbol{b}, Z)\,\mathrm{d}Z . \tag{45.42}$$

Semiclassical cross sections:

$$\sigma(E) = 8\pi\int_{0}^{\infty}\left[\sin^2\eta(E, b)\right]b\,\mathrm{d}b , \tag{45.43}$$

$$= \left(8\pi/k^2\right)\int_{0}^{\infty}\sin^2\eta(E, \lambda)\lambda\,\mathrm{d}\lambda . \tag{45.44}$$

Landau–Lifshitz cross section:

$$\sigma_{\mathrm{LL}}(E) = 8\pi\int_{0}^{\infty}\left[\sin^2\eta_{\mathrm{JB}}(E, b)\right]b\,\mathrm{d}b . \tag{45.45}$$

Massey–Mohr cross section:

$$\eta(E, b_0) = \frac{1}{2} , \quad \left\langle\sin^2\eta(E, b < b_0)\right\rangle = \frac{1}{2} , \tag{45.46}$$

$$\sigma_{\mathrm{MM}}(E) = 2\pi b_0^2 + 8\pi\int_{b_0}^{\infty}\eta_{\mathrm{JB}}^2(E, b)b\,\mathrm{d}b . \tag{45.47}$$

Schiff cross section:

$$\sigma_{\mathrm{c}(E)} = 4\int_{-\infty}^{\infty}\mathrm{d}X\int_{-\infty}^{\infty}\mathrm{d}Y\left[\sin^2\eta_{\mathrm{E}}(X, Y)\right] . \tag{45.48}$$

This reduces to (45.45) for spherical $V(\boldsymbol{R})$; $b \equiv (x, y)$.
Random-phase approximation (RPA):
For angle α,

$$4\pi\int_{0}^{\infty}P(b)\sin^2\alpha(b)b\,\mathrm{d}b = 2\pi\int_{0}^{b_c}P(b)b\,\mathrm{d}b , \tag{45.49}$$

where $\alpha(b_c) = 1/\pi$.
Collision delay time function:

$$\tau(E, \lambda) = 2\hbar\frac{\partial\eta(E, \lambda)}{\partial E} = \frac{2}{v}\frac{\partial\eta_\ell(k)}{\partial k} . \tag{45.50}$$

Deflection-angle phase function relation:

$$\chi(E, \lambda) = \frac{2}{k}\frac{\partial\eta(E, b)}{\partial b} = 2\frac{\partial\eta(E, \lambda)}{\partial\lambda} . \tag{45.51}$$

45.1.7 Collision Action

The classical collision action along a classical path with deflection $\chi = \chi(E, L)$, measured relative to the action along the path of the undeflected particle, is

$$S^C(E, L; \chi) = S_R(E, L) - L\chi(E, L) \quad \text{(45.52a)}$$
$$= 2\eta^{SC}(E, L)\hbar - L\chi . \quad \text{(45.52b)}$$

Radial component of collision action S^C:

$$S_R(E, L) = 2 \int_{R_c(E, L)}^{\infty} p(R) \, dR - 2 \int_{b(E, L)}^{\infty} p_0(R) \, dR \quad \text{(45.53a)}$$

$$= 2\eta^{SC}(E, L)\hbar \quad \text{(45.53b)}$$

Collision delay time function:

$$\tau(E, L) = 2M \left(\int_{R_c}^{\infty} \frac{dR}{p(R)} - \int_{b}^{\infty} \frac{dR}{p_0(R)} \right) \quad \text{(45.54a)}$$

$$= \left(\frac{\partial S_R}{\partial E} \right)_L . \quad \text{(45.54b)}$$

Deflection angle function:

$$\chi(E, L) = \pi - 2L \int_{R_c}^{\infty} \frac{dR/R^2}{p(R)} \quad \text{(45.55a)}$$

$$= \left(\frac{\partial S_R}{\partial L} \right)_E . \quad \text{(45.55b)}$$

Radial collision action change:

$$dS_R = \tau(E, L) \, dE + \chi(E, L) \, dL = 2\hbar \, d\eta^{SC} \quad \text{(45.56)}$$

45.2 Quantal Scattering Formulae

The basic quantity in *quantal* elastic scattering is the complex scattering amplitude $f(E, \theta)$, expressed in terms of the phase shifts $\eta_\ell(E)$ associated with scattering of the ℓ th partial wave. Derived quantities are the diagonal elements of the scattering matrix S, transition matrix T and reactance matrix K.

Reduced Energy: $k^2 = (2M/\hbar^2) E$.
Reduced Potential: $U(R) = (2M/\hbar^2) V(R)$.

45.2.1 Basic Formulae

Wave function: As $R \to \infty$,

$$\Psi(\mathbf{R}) \to \exp(ikZ) + \frac{1}{R} f(\theta) \exp(ikR) \quad \text{(45.57)}$$

for symmetric interactions $V = V(R)$.
    Elastic scattering DCS:

$$\frac{d\sigma}{d\Omega} = I(\theta) = |f(\theta)|^2 . \quad \text{(45.58)}$$

Scattering, transition and reactance matrix elements in terms of η_ℓ:

$$S_\ell(k) = \exp(2i\eta_\ell) , \quad \text{(45.59a)}$$
$$T_\ell(k) = \sin \eta_\ell \exp(i\eta_\ell) , \quad \text{(45.59b)}$$
$$K_\ell(k) = \tan \eta_\ell . \quad \text{(45.59c)}$$

Scattering amplitudes $f(\theta)$:

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell + 1) \left[\exp(2i\eta_\ell) - 1 \right] P_\ell(\cos\theta)$$

$$= \sum_{\ell=0}^{\infty} f_\ell(\theta) , \quad \text{(45.60a)}$$

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell + 1) \left[S_\ell(k) - 1 \right] P_\ell(\cos\theta) , \quad \text{(45.60b)}$$

$$f(\theta) = \frac{1}{k} \sum_{\ell=0}^{\infty} (2\ell + 1) T_\ell(k) P_\ell(\cos\theta) , \quad \text{(45.60c)}$$

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} S_\ell(k) P_\ell(\cos\theta) , \quad \theta \neq 0 , \quad \text{(45.60d)}$$

$$= \frac{1}{k} \sum_{\ell=0}^{\infty} (2\ell + 1) T_\ell(k), \quad \theta = 0 . \quad \text{(45.60e)}$$

Integral cross sections $\sigma(E)$:

$$\sigma(E) = 2\pi \int_0^{\pi} I(\theta) \, d(\cos\theta) , \quad \text{(45.61a)}$$

$$= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell + 1) \sin^2 \eta_\ell . \quad \text{(45.61b)}$$

Optical theorem:

$$\sigma(E) = (4\pi/k)\,\mathrm{Im}[f(0)]\,. \tag{45.62}$$

Partial cross sections $\sigma_\ell(E)$:

$$\sigma(E) = \sum_{\ell=0}^{\infty} \sigma_\ell(E) \tag{45.63}$$

$$\sigma_\ell(E) = \frac{4\pi}{k^2}(2\ell+1)\sin^2\eta_\ell \tag{45.64a}$$

$$= \frac{4\pi}{k^2}(2\ell+1)|T_\ell|^2$$

$$= \frac{2\pi}{k}(2\ell+1)\,[1-\mathrm{Re}(S_\ell)]\,. \tag{45.64b}$$

Upper limit:

$$\sigma_\ell(E) \le \left(4\pi/k^2\right)(2\ell+1)\,. \tag{45.65}$$

Unitarity, flux conservation, η_ℓ is real:

$$|S_\ell|^2 = 1\,, \quad |T_\ell|^2 = \mathrm{Im}(T_\ell)\,. \tag{45.66}$$

Differential cross sections (DCS):

$$\frac{\mathrm{d}\sigma(E,\theta)}{\mathrm{d}\Omega} = |f(\theta)|^2 = I(\theta) = A(\theta)^2 + B(\theta)^2\,, \tag{45.67}$$

$$A(\theta) = \mathrm{Re}[f(\theta)]$$

$$= \frac{1}{2k}\sum_{\ell=0}^{\infty}(2\ell+1)\sin 2\eta_\ell\,P_\ell(\cos\theta)\,,$$

$$B(\theta) = \mathrm{Im}[f(\theta)]$$

$$= \frac{1}{2k}\sum_{\ell=0}^{\infty}(2\ell+1)\,[1-\cos 2\eta_\ell]\,P_\ell(\cos\theta)\,.$$

$$\int A(\theta)^2\,\mathrm{d}\Omega = \frac{4\pi}{k^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\eta_\ell\cos^2\eta_\ell\,, \tag{45.68a}$$

$$\int B(\theta)^2\,\mathrm{d}\Omega = \frac{4\pi}{k^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^4\eta_\ell\,, \tag{45.68b}$$

$$\frac{\mathrm{d}\sigma(E,\theta)}{\mathrm{d}\Omega} = \frac{1}{k^2}\sum_{L=0}^{\infty}a_L(E)\,P_L(\cos\theta)\,, \tag{45.69a}$$

$$a_L = \sum_{\ell=0}^{\infty}\sum_{\ell'=|\ell-L|}^{\ell+L}(2\ell+1)(2\ell'+1)$$

$$(\ell\ell'00\mid\ell\ell'L0)^2$$

$$\times \sin\eta_\ell\sin\eta_{\ell'}\cos(\eta_\ell-\eta_{\ell'})\,, \tag{45.69b}$$

where $(\ell\ell'mm'\mid\ell\ell'LM)$ are the Clebsch–Gordan Coefficients.

Three-term expansion:

$$\frac{\mathrm{d}\sigma(E,\theta)}{\mathrm{d}\Omega} = \frac{1}{k^2}\left[\left(a_0-\frac{1}{2}a_2\right)+a_1\cos\theta\right.$$

$$\left.+\frac{3}{2}a_2\cos^2\theta\right] \tag{45.70}$$

$$a_0(E) = \sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\eta_\ell\,, \tag{45.71a}$$

$$a_1(E) = 6\sum_{\ell=0}^{\infty}(\ell+1)\sin\eta_\ell\sin\eta_{\ell+1}$$

$$\times\cos(\eta_{\ell+1}-\eta_\ell)\,, \tag{45.71b}$$

$$a_2(E) = 5\sum_{\ell=0}^{\infty}\Big[b_\ell\sin^2\eta_\ell+c_\ell\sin\eta_\ell\sin\eta_{\ell+2}$$

$$\times\cos(\eta_{\ell+2}-\eta_\ell)\Big]\,. \tag{45.71c}$$

with coefficients

$$b_\ell = \frac{\ell(\ell+1)(2\ell+1)}{(2\ell-1)(2\ell+3)}\,, \tag{45.72a}$$

$$c_\ell = \frac{3(\ell+1)(\ell+2)}{(2\ell+3)}\,. \tag{45.72b}$$

S, P wave ($\ell = 0, 1$) net contribution:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{1}{k^2}\Big\{\sin^2\eta_0+[6\sin\eta_0\sin\eta_1\cos(\eta_1-\eta_0)]$$

$$\times\cos\theta+9\sin^2\eta_1\cos^2\theta\Big\}\,, \tag{45.73}$$

$$\sigma(E) = \frac{4\pi}{k^2}\left(\sin^2\eta_0+3\sin^2\eta_1\right)\,. \tag{45.74}$$

For pure S-wave scattering, the DCS is isotropic. For pure P-wave scattering, the DCS is symmetric about $\theta = \pi/2$, where it vanishes; the DCS rises to equal maxima at $\theta = 0, \pi$. For combined S- and P-wave scattering, the DCS is asymmetric with forward-backward asymmetry.

Transport cross sections ($n \ge 1$):

$$\sigma^{(n)}(E) = 2\pi\left(1-\frac{1+(-1)^n}{2(n+1)}\right)^{-1}$$

$$\times\int_0^\pi\left(1-\cos^n\theta\right)I(\theta)\,\mathrm{d}(\cos\theta)\,. \tag{45.75}$$

The diffusion and viscosity cross sections (45.22a) and (45.23a) are given by the transport cross sections $\sigma^{(1)}$ and $\frac{2}{3}\sigma^{(2)}$, respectively.

$$\sigma^{(1)}(E) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (\ell+1) \sin^2(\eta_\ell - \eta_{\ell+1}) \,,$$

(45.76a)

$$\sigma^{(2)}(E) = \frac{4\pi}{k^2} \left(\frac{3}{2}\right) \sum_{\ell=0}^{\infty} \frac{(\ell+1)(\ell+2)}{(2\ell+3)}$$
$$\times \sin^2(\eta_\ell - \eta_{\ell+2}) \,,$$

(45.76b)

$$\sigma^{(3)}(E) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} \frac{(\ell+1)}{(2\ell+5)}$$
$$\times \left[\frac{(\ell+2)(\ell+3)}{(2\ell+3)} \sin^2(\eta_\ell - \eta_{\ell+3}) \right.$$
$$\left. + \frac{3(\ell^2 + 2\ell - 1)}{(2\ell-1)} \sin^2(\eta_\ell - \eta_{\ell+1}) \right] \,,$$

(45.76c)

$$\sigma^{(4)}(E) = \frac{4\pi}{k^2} \left(\frac{5}{4}\right) \sum_{\ell=0}^{\infty} \frac{(\ell+1)(\ell+2)}{(2\ell+3)(2\ell+7)}$$
$$\times \left[\frac{(\ell+3)(\ell+4)}{(2\ell+5)} \sin^2(\eta_\ell - \eta_{\ell+4}) \right.$$
$$\left. + \frac{2(2\ell^2 + 6\ell - 3)}{(2\ell-1)} \sin^2(\eta_\ell - \eta_{\ell+2}) \right] \,.$$

(45.76d)

Collision integrals: Averages of $\sigma^{(n)}(E)$ over a Maxwellian distribution at temperature T are

$$\Omega^{(n,s)}(T) = \left[(s+1)! (kT)^{s+2} \right]^{-1} \int_0^{\infty} \sigma^{(n)}(E)$$
$$\times \exp(-E/kT) E^{s+1} \, dE \,.$$

(45.77)

Normalization factors are chosen so that the above expressions for $\sigma^{(n)}$ and $\Omega^{(n,s)}$ reduce to πd^2 for classical rigid spheres of diameter d.

Mobility: The mobility K of ions of charge e in a gas of density N is given by the Chapman–Enskog formula

$$K = \frac{3e}{8N} \left(\frac{\pi}{2MkT} \right)^{1/2} \left[\Omega^{(1,1)}(T) \right]^{-1} \,.$$

(45.78)

Phase shifts η_ℓ can be determined from the numerical solution of the radial Schrödinger equation (45.93), from an integral equation (45.179b), from solving a nonlinear first-order differential equation (45.179a), from Logarithmic Derviatives (Sect. 45.2.5) or from variational techniques (Sect. 45.2.4).

45.2.2 Identical Particles: Symmetry Oscillations

Colliding Particles, each with spin $\boldsymbol{s}$, in a Total Spin $\boldsymbol{S_t}$ Resolved State in the Range $(0 \to 2\boldsymbol{s})$. Particle interchange: $\Psi(\boldsymbol{R}) = (-1)^{S_t} \Psi(-\boldsymbol{R})$

$$I_{A,S}(\theta) = \frac{1}{2} |f(\theta) \mp f(\pi - \theta)|^2 \,,$$

(45.79)

$$\Psi_{A,S}(\boldsymbol{R}) \to \left[\exp(ikZ) \mp \exp(-ikZ) \right]$$
$$+ \frac{1}{R} \left[f(\theta) \mp f(\pi - \theta) \right] \exp(ikR) \,,$$

(45.80)

$$I_{A,S}(\theta) = \frac{1}{4k^2} \left| \sum_{\ell=0}^{\infty} \omega_\ell (2\ell+1) \left[\exp 2i\eta_\ell - 1 \right] \right.$$
$$\left. \times P_\ell(\cos\theta) \right|^2 \,,$$

(45.81)

$$\sigma_{A,S}(E) = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} \omega_\ell (2\ell+1) \sin^2 \eta_\ell \,,$$

(45.82)

where A and S denote antisymmetric and symmetric wave functions (with respect to particle interchange) for collisions of identical particles with odd and even total spin S_t

A: S_t odd $\omega_\ell = 0$ (ℓ even); $\omega_\ell = 2$ (ℓ odd);
S: S_t even$\omega_\ell = 2$ (ℓ even); $\omega_\ell = 0$ (ℓ odd).

Spin–States $\boldsymbol{S_t}$ Unresolved. S/A combination:

$$I(\theta) = g_A I_A(\theta) + g_S I_S(\theta) \,,$$

(45.83)

$$\sigma(E) = g_A \sigma_A(E) + g_S \sigma_S(E) \,,$$

(45.84)

where g_A and g_S are the fractions of states with odd and even total spins $S_t = 0, 1, 2, \ldots, 2s$. For Fermions (F) with half integer spin s, and Bosons (B) with integral spin s

F: $g_A = (s+1)/(2s+1)$, $g_S = s/(2s+1)$,
B: $g_A = s/(2s+1)$, $g_S = (s+1)/(2s+1)$,

so that (45.83) and (45.84) have the alternative forms

$$I(F) = |f(\theta)|^2 + |f(\pi-\theta)|^2 - \mathcal{I} \,,$$

(45.85a)

$$\sigma(F) = \frac{1}{2} [\sigma_S + \sigma_A] - \frac{1}{2} [\sigma_S - \sigma_A]/(2s+1) \,,$$

(45.85b)

$$I(B) = |f(\theta)|^2 + |f(\pi-\theta)|^2 + \mathcal{I} \,,$$

(45.85c)

$$\sigma(B) = \frac{1}{2} [\sigma_S + \sigma_A] + \frac{1}{2} [\sigma_S - \sigma_A]/(2s+1) \,,$$

(45.85d)

where the interference term is

$$\mathcal{I} = \left(\frac{2}{2s+1}\right) \mathrm{Re}\left[f(\theta)f^*(\pi - \theta)\right] . \tag{45.86}$$

Example: For fermions with spin 1/2,

$$\sigma(E) = \frac{2\pi}{k^2}\left[\sum_{\ell=\text{even}}^{\infty} (2\ell+1)\sin^2\eta_\ell \right.$$
$$\left. + 3\sum_{\ell=\text{odd}}^{\infty} (2\ell+1)\sin^2\eta_\ell\right] . \tag{45.87}$$

Symmetry oscillations originate from the interference between unscattered incident particles in the forward ($\theta = 0$) direction and backward scattered particles ($\theta = \pi$, $\ell = 0$). Symmetry oscillations are sensitive to the repulsive wall of the interaction.

Resonant Charge Transfer and Transport Cross Sections for $A^+ - A$ Collisions. The phase shifts for elastic scattering by the gerade (g) and ungerade (u) potentials of A_2^+ are, respectively, η_ℓ^g and η_ℓ^u. The charge transfer (X) and transport cross sections are

$$\sigma_X(E) = \frac{\pi}{k^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\left(\eta_\ell^g - \eta_\ell^u\right) ,$$
$$\tag{45.88a}$$

$$\sigma_{A,S}^{(1)}(E) = \frac{4\pi}{k^2}\sum_{\ell=0}^{\infty}(\ell+1)\sin^2(\beta_\ell - \beta_{\ell+1}) ,$$
$$\tag{45.88b}$$

$$\sigma_{A,S}^{(2)}(E) = \frac{4\pi}{k^2}\left(\frac{3}{2}\right)\sum_{\ell=0}^{\infty}\frac{(\ell+1)(\ell+2)}{(2\ell+3)}$$
$$\times \sin^2(\beta_\ell - \beta_{\ell+2}) ; \tag{45.88c}$$

A: $\beta_\ell = \eta_\ell^g$ (ℓ even), or η_ℓ^u (ℓ odd) ,
S: $\beta_\ell = \eta_\ell^u$ (ℓ even), or η_ℓ^g (ℓ odd) .

$\sigma_{A,S}^{(1)}$ contains (g/u) interference; $\sigma_{A,S}^{(2)}$ does not. When nuclear spin degeneracy is acknowledged, the cross sections $\sigma_{A,S}$ are summed according to (45.85b) or (45.85d).

Since there is no coupling between molecular states of different electronic angular momentum, the scattering by the $^2\Sigma_{g,u}$ pair and the $^2\Pi_{g,u}$ pair of Ne_2^+ potentials (for example) is independent and

$$\sigma_X(E) = \frac{1}{3}\sigma_\Sigma(E) + \frac{2}{3}\sigma_\Pi(E) . \tag{45.89}$$

Singlet–Triplet Spin Flip Cross Section.

$$\sigma_{ST}(E) = \frac{\pi}{k^2}\sum_{\ell=0}^{\infty}(2\ell+1)\sin^2\left(\eta_\ell^s - \eta_\ell^t\right) , \tag{45.90}$$

where $\eta_\ell^{S,T}$ are the phase shifts for individual scattering by the singlet and triplet potentials, respectively.

45.2.3 Partial Wave Expansion

$$\Psi(\boldsymbol{R}) = \frac{1}{kR}\sum_{\ell=0}^{\infty}A_\ell v_\ell(kR)P_\ell(\cos\theta) , \tag{45.91}$$

$$A_\ell = \mathrm{i}^\ell(2\ell+1)\exp(\mathrm{i}\eta_\ell) . \tag{45.92}$$

Radial Schrödinger equation (RSE):

$$\frac{\mathrm{d}^2 v_\ell}{\mathrm{d}R^2} + \left[k^2 - U(R) - \frac{\ell(\ell+1)}{R^2}\right]v_\ell(R) = 0 \tag{45.93}$$

where v_ℓ is normalized so that

$$v_\ell(R) \overset{R > R_0}{=} \cos\eta_\ell F_\ell(kR) + \sin\eta_\ell G_\ell(kR) \tag{45.94}$$
$$\rightarrow \sin\left(kR - \frac{1}{2}\ell\pi + \eta_\ell\right) \text{ as } R \rightarrow \infty .$$

The regular (nonsingular) solution (zero at $R = 0$) of the field-free RSE (45.93) with $U(R) = 0$ is

$$F_\ell(kR) = (kR)j_\ell(kR) = \left(\frac{1}{2}\pi kR\right)^{1/2}J_{\ell+1/2}(kR) \tag{45.95}$$

$$\rightarrow \begin{cases} (kR)^{\ell+1}/(2\ell+1)!!, & R \rightarrow 0 \\ \sin\left(kR - \frac{1}{2}\ell\pi\right), & R \rightarrow \infty, \end{cases} \tag{45.96}$$

where j_ℓ is the spherical Bessel function. Equation (45.91) with $v_\ell = F_\ell$ is the partial-wave expansion for the incident plane-wave $\exp(ikZ)$.

The irregular solution (divergent at $R = 0$) of the field-free RSE is

$$G_\ell(kR) = -(kR)n_\ell(kR)$$
$$= \left(\frac{1}{2}\pi kR\right)^{1/2}J_{-(\ell+1/2)}(kR) \tag{45.97}$$

$$\rightarrow \begin{cases} (2\ell-1)!!/(kR)^\ell, & R \rightarrow 0 \\ \cos\left(kR - \frac{1}{2}\ell\pi\right), & R \rightarrow \infty, \end{cases} \tag{45.98}$$

where n_ℓ is the spherical Neumann function.

The full asymptotic scattering solution is the combination (45.94) of the regular and irregular solutions. The mixture depends upon:

Forms of Normalization for v_ℓ. In (45.91), possible choices of normalization are:

(a) $A_\ell = i^\ell (2\ell + 1) \exp i\eta_\ell$,   (45.99a)

$v_\ell(R) \sim \sin\left(kR - \frac{1}{2}\ell\pi + \eta_\ell\right)$;   (45.99b)

(b) $A_\ell = i^\ell (2\ell + 1) \cos \eta_\ell$,   (45.100a)

$v_\ell(R) \sim \sin\left(kR - \frac{1}{2}\ell\pi\right) + K_\ell \cos\left(kR - \frac{1}{2}\ell\pi\right)$;

(45.100b)

(c) $A_\ell = i^\ell (2\ell + 1)$,   (45.101a)

$v_\ell(R) \sim \sin\left(kR - \frac{1}{2}\ell\pi\right) + T_\ell e^{i(kR - \ell\pi/2)}$;

(45.101b)

(d) $A_\ell = \frac{1}{2} i^{\ell+1} (2\ell + 1)$,   (45.102a)

$v_\ell(R) \sim e^{-i(kR - \ell\pi/2)} - S_\ell e^{i(kR - \ell\pi/2)}$;   (45.102b)

$S_\ell = 1 + 2iT_\ell ; \qquad K_\ell = T_\ell/(1 + iT_\ell)$;

(45.103)

$T_\ell = \sin \eta_\ell\, e^{i\eta_\ell} ; \quad 1 + iT_\ell = \cos \eta_\ell\, e^{i\eta_\ell}$.

(45.104)

Significance of η_ℓ, K_ℓ, T_ℓ, and S_ℓ. The effect of scattering is therefore to: (1) introduce a phase shift η_ℓ in (45.99b) to the regular standing wave, (2) leave the regular standing wave alone and introduce either an irregular standing wave of real amplitude K_ℓ in (45.100b) or, a spherical outgoing wave of amplitude T_ℓ in (45.101b), and (3) to convert in (45.102b) an incoming spherical wave of unit amplitude to an outgoing spherical wave of amplitude S_ℓ.

Levinson's Theorem. A local potential $U(R)$ can support n_ℓ bound states of angular momentum ℓ and energy E_n such that

$$\lim_{k\to 0} \eta_0(k) = \begin{cases} n_0\pi , & E_n < 0 \\ \left(n_0 + \frac{1}{2}\right)\pi , & E_{n+1} = 0 , \end{cases}$$

(45.105)

$$\lim_{k\to 0} \eta_\ell(k) = n_\ell\pi , \quad \ell > 0 .$$ (45.106)

45.2.4 Scattering Length and Effective Range

Blatt–Jackson Effective Range Formula. For short-range potentials,

$$k \cot \eta_0 = -\frac{1}{a_s} + \frac{1}{2} R_e k^2 + \mathcal{O}\left(k^4\right) .$$ (45.107)

Effective range:

$$R_e = 2 \int_0^\infty \left[u_0^2(R) - v_0^2(R)\right] dR ,$$ (45.108)

where $u_0 = \sin(kR + \eta_0)/\sin \eta_0$ is the $k = 0$ limit of the potential-free $\ell = 0$ radial wave function and normalized so that $u_0(R)$ goes to unity as $k \to 0$. The potential distorted $\ell = 0$ radial function v_0 is normalized at large R to $u_0(R)$. The effective range is a measure of the distance over which v_0 differs from u_0. The outside factor of 2 in (45.108) is chosen such that $R_e = a$ for a square well of range a.

Scattering length:

$$a_s = -\lim_{k\to 0} f(\theta) .$$ (45.109)

Relation with $k \to 0$ Elastic Cross Section.

$$\sigma(k \to 0) = \frac{4\pi}{k^2} \sin^2 \eta_0$$

$$= 4\pi a_s^2 \left[\left(1 - \frac{1}{2} k^2 a_s R_e\right)^2 + k^2 a_s^2\right]^{-1}$$

(45.110)

$$\sim 4\pi a_s^2 \left[1 + a_s k^2 (R_e - a_s)\right]$$ (45.111)

Relation with Bound Levels. If a $\ell = 0$ bound level of energy $E_n = -\hbar^2 k_n^2/2M$ lies sufficiently near the dissociation limit the effective range and scattering lengths, R_e and a_s, respectively, are related by,

$$-\frac{1}{a_s} = -k_n + \frac{1}{2} R_e k_n^2 + \cdots$$ (45.112)

Wigner Causality Condition. If η_ℓ provides the dominant contribution to $f(\theta)$ then

$$\frac{\partial \eta_\ell(k)}{\partial k} \geq -a_s$$ (45.113)

where a_s is the scattering length ($\ell = 0$) and is a measure of the range of the interaction.

Effective Range Formulae. The Blatt–Jackson formula must be modified [45.1–5] for long-range interactions as follows.

(1) Modified Coulomb potential: $V(R) \sim Z_1 Z_2 e^2 / R$

$$2(K/a_0) = -(1/a_s) + \frac{1}{2} R_e k^2 \qquad (45.114)$$

$$K = \frac{\pi \cot \eta_0}{e^{2\pi\alpha} - 1} - \ln \beta - 0.5772$$

$$+ \beta^2 \sum_{n=1}^{\infty} \left[n \left(n^2 + \beta^2 \right) \right]^{-1} \qquad (45.115)$$

where $\beta = Z_1 Z_2 e^2 / \hbar v = Z_1 Z_2 / (k a_0)$.

(2) Polarization potential: $V(R) = -\alpha_d e^2 / 2R^4$,

$$\tan \eta_0 = -a_s k - \frac{\pi}{3} C_4 k^2 - \frac{4}{3} C_4 a_s k^3 \ln(k a_0)$$
$$+ D k^3 + F k^4 , \qquad (45.116)$$

$$\tan \eta_1 = \frac{\pi}{15} C_4 k^2 - a_s^{(1)} k^3 , \qquad (45.117)$$

$$\tan \eta_\ell = \frac{\pi C_4 k^2}{(2\ell + 3)(2\ell + 1)(2\ell - 1)} + \mathcal{O}\left(k^{2\ell+1} \right) , \qquad (45.118)$$

for $\ell > 1$, where

$$C_4 = \frac{2M}{\hbar^2} \left(\frac{\alpha_d e^2}{2} \right) = \left(\frac{\alpha_d}{a_0} \right) \left(\frac{M}{m_e} \right) . \qquad (45.119)$$

Example: e^-–Ar low energy collisions: The values
$a_s = -1.459 a_0$; $D = 68.93 a_0^3$
$a_s^{(1)} = 8.69 a_0^3$; $F = -97 a_0^4$

provide an accurate fit to recent measurements [45.6] of (45.76a) for the diffusion cross section σ_d.

(3) Van der Waals potential: $V(R) = -C/R^6$

$$k \cot \eta_0 = -\frac{1}{a_s} + \frac{1}{2} R_e k^2 - \frac{\pi}{15 a_s^2} \left(\frac{2MC}{\hbar^2} \right) k^3$$
$$- \frac{4}{15 a_s} \left(\frac{2MC}{\hbar^2} \right) k^4 \ln(k a_0) + \mathcal{O}\left(k^4 \right) . \qquad (45.120)$$

e−Atom Collisions with Polarization Attraction. As $k \to 0$, the differential cross section is

$$\frac{d\sigma}{d\Omega} = a_s^2 \left[1 + \frac{C_4}{a_s} k \sin \frac{\theta}{2} + \frac{8}{3} C_4 k^2 \ln(k a_0) + \cdots \right] \qquad (45.121)$$

and the elastic and diffusion cross sections are

$$\sigma(k \to 0) = 4\pi a_s^2 \left[1 + \frac{2\pi C_4 k}{3 a_s} \right.$$
$$\left. + \frac{8}{3} C_4 k^2 \ln(k a_0) + \cdots \right] \qquad (45.122)$$

$$\sigma_d(k \to 0) = 4\pi a_s^2 \left[1 + \frac{4\pi C_4 k}{5 a_s} \right.$$
$$\left. + \frac{8}{3} C_4 k^2 \ln(k a_0) + \cdots \right] \qquad (45.123)$$

For e^-–noble gas collisions, the scattering lengths are

	He	Ne	Ar	Kr	Xe
a_s (a_0)	1.19	0.24	-1.459	-3.7	-6.5

For atoms with $a_s < 0$, a Ramsauer–Townsend minimum appears in both σ and σ_d at low energies, provided that scattering from higher partial waves can be neglected, because from (45.116), $\eta_0 \simeq 0$ at $k = -3a_s / \pi C_4$.

Semiclassical Scattering Lengths. For heavy particle collisions, $\eta^{SC}(E \to 0, b)$ tends to

$$\eta_0^{SC} = \left(\frac{2M}{\hbar^2} \right)^{1/2} \int_{R_0}^{\infty} |V(R)|^{1/2} \, dR . \qquad (45.124)$$

(a) Hard-core + well:

$$V(R) = \begin{cases} \infty, & R < R_0 \\ -V_0, & R_0 \le R < R_1 \\ 0, & R_1 < R , \end{cases}$$

$$a_s = \left[1 - \tan \eta_0^{SC} / (k R_1) \right] R_1 , \qquad (45.125)$$

$$\eta_0^{SC} = k(R_1 + R_0) , \quad k^2 = 2MV_0 / \hbar^2 . \qquad (45.126)$$

The phase-averaged scattering length is $\langle a_s \rangle = R_1$.

(b) Hard-core + power-law ($n > 2$):

$$V(R) = \begin{cases} \infty, & R < R_0 \\ \pm C/R^n, & R > R_0 \end{cases} . \qquad (45.127)$$

Repulsion (+): with $\gamma^2 = 2MC/\hbar^2$,

$$a_s^{(+)} = \left(\frac{\gamma}{n-2} \right)^{2/(n-2)} \Gamma \left(\frac{n-3}{n-2} \right) / \Gamma \left(\frac{n-1}{n-2} \right) . \qquad (45.128)$$

Attraction $(-)$: with $\theta_n = \pi/(n-2)$,

$$a_s^{(-)} = a_s^{(+)} \left[1 - \tan\theta_n \tan\left(\eta_0^{SC} - \frac{1}{2}\theta_n \right) \right] \cos\theta_n , \tag{45.129}$$

$$\eta_0^{SC} = \gamma \int_{R_0}^{\infty} R^{-n/2}\,dR = \frac{2\gamma R_0^{1-n/2}}{n-2} , \tag{45.130}$$

$$\langle a_s^{(-)} \rangle = a_s^{(+)} \cos\theta_n . \tag{45.131}$$

Number of bound states:

$$N_b = \text{int}\left\{ \frac{1}{\pi} \left[\eta_0^{SC} - \frac{1}{2}(n-1)\theta_n \right] \right\} + 1 , \tag{45.132}$$

where $\text{int}(x)$ denotes the largest integer of the real argument x. For integer x, $a_s^{(-)}$ is infinite and a new bound state appears at zero energy.

45.2.5 Logarithmic Derivatives

Phase shift calculations can be based on the logarithmic derivative at $R = a$ separating internal and external regions. Two equivalent forms using sets (R_ℓ, j_ℓ, n_ℓ) or (v_ℓ, F_ℓ, G_ℓ) when $R_\ell = v_\ell/kR$ are

$$K_\ell(k) = \frac{kj_\ell'(ka) - \gamma_\ell(k)j_\ell(ka)}{kn_\ell'(ka) - \gamma_\ell(k)n_\ell(ka)} = \tan\eta_\ell , \tag{45.133a}$$

$$= -\frac{kF_\ell'(ka) - L_\ell(k)F_\ell(ka)}{kG_\ell'(ka) - L_\ell(k)G_\ell(ka)} , \tag{45.133b}$$

where the logarithmic derivative of the internal solution at $R = a$ appropriate to either set, is

$$\gamma_\ell = \left(R_\ell^{-1}\,dR_\ell/dR \right)_{R=a} , \tag{45.134}$$

or alternatively, $L_\ell = [v_\ell^{-1}dv_\ell/dR]_{R=a}$. The primes denote differentiation with respect to the argument, i. e.

$$B_\ell'(ka) = \left(\frac{dB_\ell(x)}{dx} \right)_{x=ka} = \frac{1}{k}\left(\frac{dB_\ell(kR)}{dR} \right)_{R=a} , \tag{45.135}$$

where B_ℓ denotes the functions F_ℓ, G_ℓ, j_ℓ, and n_ℓ.

Decomposition of the S–Matrix Element.

$$S_\ell(k) = e^{2i\eta_\ell} = \left(\frac{\gamma_\ell - (r_\ell - is_\ell)}{\gamma_\ell - (r_\ell + is_\ell)} \right) e^{2i\eta_\ell^H} , \tag{45.136}$$

where

$$\eta_\ell^H(k) = -\frac{j_\ell(ka) - in_\ell(ka)}{j_\ell(ka) + in_\ell(ka)} , \tag{45.137}$$

$$r_\ell + is_\ell = k\left(\frac{j_\ell'(ka) + in_\ell'(ka)}{j_\ell(ka) + in_\ell(ka)} \right) . \tag{45.138}$$

Decomposition of the Phase Shift.

$$\eta_\ell = \eta_\ell^H + \delta_\ell , \tag{45.139}$$

where η_ℓ^H is determined by (45.137), and where δ_ℓ is determined by

$$\tan\delta_\ell = \frac{s_\ell}{\gamma_\ell - r_\ell} , \tag{45.140}$$

which depends on the shape of U via the logarithmic derivative γ_ℓ of (45.134), and can vary rapidly with k, thereby giving rise to resonances.

Examples. (1) Hard sphere: if $V(R) = \infty$ for $R < a$, and $V(R) = 0$ for $R > a$, then $\gamma_\ell = \infty$, and

$$K_\ell^{(HS)}$$
$$= \tan\eta_\ell^{(HS)}(k) = \frac{j_\ell(ka)}{n_\ell(ka)} \tag{45.141}$$

$$\rightarrow \begin{cases} -(ka)^{2\ell+1}/[(2\ell+1)!!(2\ell-1)!!], & ka \ll 1 \\ -\tan\left(ka - \frac{1}{2}\ell\pi \right), & ka \gg 1 \end{cases} \tag{45.142}$$

$$S_\ell^{(HS)} = \exp\left(2i\eta_\ell^{(HS)} \right) = -\frac{j_\ell(ka) - in_\ell(ka)}{j_\ell(ka) + in_\ell(ka)}$$
$$= 1 + 2iT_\ell^{(HS)} . \tag{45.143}$$

The phase shift η_ℓ^H in the decomposition (45.139) is therefore identified as $\eta_\ell^{(HS)}$ for hard sphere scattering.

$$\sigma(E \rightarrow 0) = 4\pi a^2 . \tag{45.144}$$

Diffraction pattern: As $E \rightarrow \infty$,

$$\frac{d\sigma}{d\Omega} \rightarrow \frac{1}{4}a^2 \left[1 + \cot^2\left(\frac{1}{2}\theta \right) J_1^2(ka\sin\theta) \right] , \tag{45.145}$$

$$\sigma(E) \rightarrow 2\pi a^2 . \tag{45.146}$$

Classical hard sphere scattering and diffraction about the sharp edge each contribute πa^2 to σ.

(2) Spherical Well: if $U(R) = -U_0$ for $R \le a$, and $U(R) = 0$ for $R > a$, then

$$\gamma_\ell(k) = \kappa \frac{j_\ell'(\kappa a)}{j_\ell(\kappa a)}; \qquad \kappa^2 = U_0 + k^2 \equiv k_0^2 + k^2 . \tag{45.147}$$

S-wave ($\ell = 0$) properties:

$$\eta_0(k) = -ka + \tan^{-1}\left[(k/\kappa)\tan\kappa a\right] . \qquad (45.148)$$

As $k \to 0$, $\sigma_0(E) \to 4\pi a_s^2$, where the scattering length is

$$a_s = [1 - \tan(k_0 a)/(k_0 a)] \, a . \qquad (45.149)$$

For a shallow well $k_0 a \ll 1$: $\sigma_0(E) = (4\pi/9)U_0^2 a^6$, which agrees with the Born result (45.171) as $k \to 0$.

The condition for $\ell = 0$ bound state with energy $E_n = -(\hbar^2 k_n^2/2M)$ is

$$k_n \tan\kappa' a = -\kappa', \quad \kappa'^2 = k_0^2 - k_n^2 . \qquad (45.150)$$

As the well is further deepened, $\sigma_0(E)$ oscillates between zero, where $\tan k_0 a = k_0 a$, and ∞, where $k_0 a = n\pi/2$, the condition both for appearance of a new level n at energy E and for $a_0 \to \infty$. In the neighborhood of these infinite resonances,

$$\sigma_0(E) = \frac{4\pi}{k^2 + \kappa'^2} , \qquad (45.151)$$

where $\kappa' = \kappa/\tan\kappa a$.

45.2.6 Coulomb Scattering

Direct solution of RSE (45.93) yields

$$v_\ell \sim \sin\left(kR - \frac{1}{2}\ell\pi + \eta_\ell^{(C)} - \beta\ln 2kR\right) , \qquad (45.152)$$

$$\beta = Z_1 Z_2 e^2 / \hbar v = Z_1 Z_2/(ka_0) . \qquad (45.153)$$

Coulomb phase shift:

$$\eta_\ell^{(C)} = \arg\Gamma(\ell + 1 + \mathrm{i}\beta) = \mathrm{Im}\left[\ln\Gamma(\ell + 1 + \mathrm{i}\beta)\right] . \qquad (45.154)$$

Coulomb S-matrix element:

$$S_\ell^{(C)} = \exp\left(2\mathrm{i}\eta_\ell^{(C)}\right) = \frac{\Gamma(\ell + 1 + \mathrm{i}\beta)}{\Gamma(\ell + 1 - \mathrm{i}\beta)} . \qquad (45.155)$$

Coulomb scattering amplitude:

$$f_C(\theta) = -\frac{\beta\exp\left[2\mathrm{i}\eta_\ell^{(C)} - \mathrm{i}\beta\ln\left(\sin^2\frac{1}{2}\theta\right)\right]}{2k\sin^2\frac{1}{2}\theta} . \qquad (45.156)$$

Coulomb differential cross section:

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\beta^2}{4k^2\sin^4\frac{1}{2}\theta} = \frac{Z_1^2 Z_2^2 e^4}{16E^2}\csc^4\frac{1}{2}\theta , \qquad (45.157)$$

which is the Rutherford scattering cross section.

Mott Formula. For the Coulomb scattering of two identical particles: From (45.85a) and (45.85c)

(a) spin-zero bosons (e.g. ^{4}He–^{4}He):

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\beta^2}{4k^2}\left(\csc^4\frac{1}{2}\theta + \sec^4\frac{1}{2}\theta\right.$$
$$\left. +2\csc^2\frac{1}{2}\theta\sec^2\frac{1}{2}\theta\cos\Gamma\right) , \qquad (45.158)$$

(b) spin-$\frac{1}{2}$ fermions (e.g. H$^+$–H$^+$, $e^\pm$–$e^\pm$)

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{\beta^2}{4k^2}\left(\csc^4\frac{1}{2}\theta + \sec^4\frac{1}{2}\theta\right.$$
$$\left. -\csc^2\frac{1}{2}\theta\sec^2\frac{1}{2}\theta\cos\Gamma\right) , \qquad (45.159)$$

where $\Gamma = 2\beta\ln\left(\tan\frac{1}{2}\theta\right)$.

45.2.7 Resonance Scattering

Zero-Energy Broad Resonances. The spherical well example (45.147) serves to illustrate broad resonances. When the well depth U_0 is strong enough to accomodate the $(n_0 + 1)$ th energy level at zero energy, the bound state condition (45.150) implies that $\eta_0(k \to 0) = (n_0 + 1)\pi$, illustrating Levinson's theorem (45.105). As k increases, η_0 generally decreases through either $(2n - 1)\pi/2$, or $(n - 1)\pi$, where σ_0 has, respectively, a maximum value $4\pi/k^2$ and a minimum value of zero. If the phase shifts η_ℓ for $\ell > 0$ are small, then a nonzero minimum value in $\sigma(E)$ is evident. This is the Ramsauer–Townsend minimum manifest when the potential is just strong enough to introduce one or more wavelengths into the well with no observable scattering. Since the rate of decrease of η_0 cannot be arbitrarily rapid, (45.105), broad resonances will be exhibited in contrast to narrow (Breit–Wigner) resonances when η_ℓ increases rapidly through $(2n - 1)\pi/2$ over a small energy range ΔE.

Narrow Resonances. The general decomposition (45.139) can be used to analyze narrow resonances. When γ_ℓ varies rapidly within an energy width Γ about a resonance energy E_r then δ_ℓ increases through odd multiples of $\pi/2$ and

$$\delta_\ell = \delta_\ell^r = \tan^{-1}\frac{\Gamma}{2(E_r - E)} , \qquad (45.160)$$

so that (45.60a) with (45.59a) and (45.59b) is

$$f_\ell = \frac{(2\ell + 1)}{k}\left(T_\ell^{(HS)} + S_\ell^{(HS)}\frac{\Gamma/2}{E_r - E - \frac{1}{2}\Gamma}\right)$$
$$\times P_\ell(\cos\theta) . \qquad (45.161)$$

Part D | 45.2

Breit–Wigner Formula. For a pure resonance with no background phase shift, $S_\ell^{(\mathrm{HS})} = 1$ and the cross section has the Lorentz shape

$$\sigma(E) = \frac{4\pi(2\ell + 1)}{k^2} \times \left(\frac{\Gamma^2/4}{(E - E_\mathrm{r})^2 + \Gamma^2/4} \right) . \qquad (45.162)$$

Shape Resonances. (Also called quasibound state or tunneling resonances). At very low impact energies near or below the energy threshold for orbiting, sharp spikes superimposed on the glory oscillations may be evident in the E-dependance of $\sigma(E)$. These are due to quasibound states with positive energy $E_{n\ell}$ supported by the effective potential $V(r) + L^2/(2Mr^2)$. In heavy particle collisions, quasibound levels are the continuation of the bound rotational levels to positive energies $E_{n\ell} > 0$.

Systems in quasibound states $(n\ell)$, with nonresonant eigenenergy $E_{n\ell}$ and phase shift $\eta_\ell^{(0)}$, have

$$E = E_{n\ell} - \frac{\mathrm{i}}{2}\Gamma_{n\ell} , \qquad (45.163a)$$

$$\eta_\ell = \eta_\ell^{(0)} + \eta_\ell^{(\mathrm{r})} , \qquad (45.163b)$$

$$\eta_\ell = \eta_\ell^{(0)} + \tan^{-1}\frac{\Gamma_{n\ell}}{2(E_{n\ell} - E)} ; \qquad (45.163c)$$

$$S_\ell(E) = \mathrm{e}^{2\mathrm{i}\eta_\ell} = \left(\frac{E - E_{n\ell} - \frac{\mathrm{i}}{2}\Gamma_{n\ell}}{E - E_{n\ell} + \frac{\mathrm{i}}{2}\Gamma_{n\ell}} \right) \mathrm{e}^{2\mathrm{i}\eta_\ell^{(0)}} . \qquad (45.164)$$

The phase shift $\eta_\ell^{(\mathrm{r})}$ increases by π as E increases through $E_{n\ell}$ at a rate determined by $\Gamma_{n\ell}$. The dominant amplitude shifts from the external to the quasibound internal regions at $E = E_{n\ell}$.

Partial-Wave Scattering Amplitude.

$$f_\ell(\theta) = \frac{1}{2\mathrm{i}k}(2\ell + 1)\exp\left(2\mathrm{i}\eta_\ell^0\right)P_\ell(\cos\theta)$$
$$\times \left(1 - \frac{\mathrm{i}\Gamma_{n\ell}}{(E - E_{n\ell} + \frac{1}{2}\Gamma_{n\ell})} \right) ; \qquad (45.165)$$

$$= \text{background potential scattering amplitude}$$
$$+ \text{resonance scattering amplitude.}$$

The partial-wave cross section is composed of the following: potential resonance and interference contri-

butions to $\sigma_\ell = |f_\ell(\theta)|^2$:

$$\sigma_\ell = \frac{4\pi}{k^2}(2\ell + 1)\left(\sin^2\eta_\ell^{(0)} \right.$$
$$\left. + \frac{\Gamma_{n\ell}^2\cos 2\eta_\ell^{(0)} + 2\Gamma_{n\ell}(E_{n\ell} - E)\sin 2\eta_\ell^{(0)}}{4(E - E_{n\ell})^2 + \Gamma_{n\ell}^2} \right) \qquad (45.166a)$$

$$= \frac{4\pi}{k^2}(2\ell + 1)\left[\sin^2\eta_\ell^{(0)} \right.$$
$$\times \left(\frac{(E - E_{n\ell})^2}{(E - E_{n\ell})^2 + (\Gamma_{n\ell}/2)^2} \right)$$
$$+ \cos^2\eta_\ell^{(0)}\left(\frac{(\Gamma_{n\ell}/2)^2}{(E - E_{n\ell})^2 + (\Gamma_{n\ell}/2)^2} \right)$$
$$\left. + \sin 2\eta_\ell^{(0)}\left(\frac{(\Gamma_{n\ell}/2)(E_{n\ell} - E)}{(E - E_{n\ell})^2 + (\Gamma_{n\ell}/2)^2} \right) \right] , \qquad (45.166b)$$

$$\sigma(E) = \sum_{\ell=0}^{\infty}\sigma_\ell = \sigma_0(E) + \sigma_\mathrm{res}(E) . \qquad (45.166c)$$

Resonance Shapes. Resonance shapes depend on the value of the background phase shift $\eta_\ell^{(0)}$. The case $\eta_\ell^{(0)} = 0$ gives a Lorentz line shape through the Breit–Wigner formula

$$\sigma_\ell = \frac{4\pi(2\ell + 1)}{k^2}\frac{\Gamma_{n\ell}^2/4}{(E - E_{n\ell})^2 + \Gamma_{n\ell}^2/4} . \qquad (45.167)$$

The other cases from (45.166b) are

$$\begin{aligned}
\eta_\ell^{(0)} &= n\pi & &\text{large positive spike;} \\
\eta_\ell^{(0)} &= \left(n + \tfrac{1}{2}\right)\pi & &\text{large negative spike;} \\
n\pi &< \eta_\ell^{(0)} < \left(n + \tfrac{1}{2}\right)\pi & &\text{positive then negative;} \\
\left(n + \tfrac{1}{2}\right)\pi &< \eta_\ell^{(0)} < (n+1)\pi & &\text{negative then positive.}
\end{aligned} \qquad (45.168)$$

Time Delay.

$$\tau = 2\hbar\left(\frac{\partial\eta_\ell}{\partial E} \right)_\ell = 2\hbar\left(\frac{\partial\eta_\ell^{(0)}}{\partial E} \right) + \frac{4\hbar}{\Gamma_{n\ell}} . \qquad (45.169)$$

The time for capture into quasibound levels is $\tau_\mathrm{c} = 4\hbar/\Gamma_{n\ell}$, and the capture frequency is $\nu_\mathrm{c} = \Gamma_{n\ell}/4\hbar$.

45.2.8 Integral Equation for Phase Shift

$$\sin \eta_\ell = -\frac{1}{k} \int_0^\infty F_\ell(kR) U(R) v_\ell^{(A)}(kR) \, dR ,$$

$$(45.170a)$$

$$K_\ell = \tan \eta_\ell = -\frac{1}{k} \int_0^\infty F_\ell(kR) U(R) v_\ell^{(B)}(kR) \, dR ,$$

$$(45.170b)$$

$$T_\ell = e^{i\eta_\ell} \sin \eta_\ell$$
$$= -\frac{1}{k} \int_0^\infty F_\ell(kR) U(R) v_\ell^{(C)}(kR) \, dR ,$$

$$(45.170c)$$

$$S_\ell - 1 = \exp(2i\eta_\ell) - 1 \qquad (45.170d)$$
$$= -\frac{1}{k} \int_0^\infty F_\ell(kR) U(R) v_\ell^{(D)}(kR) \, dR ,$$

$$(45.170e)$$

where $v_\ell^{(A)}$, $v_\ell^{(B)}$, $v_\ell^{(C)}$, $v_\ell^{(D)}$ are so chosen to have asymptotes prescribed by (45.99b)–(45.102b), respectively.

Born Approximation for Phase Shifts. Set $v_\ell = F_\ell$ in (45.170a)–(45.170d) to obtain

$$\tan \eta_\ell^B(k) = -k \int_0^\infty U(R) [j_\ell(kR)]^2 R^2 \, dR .$$

$$(45.171)$$

For $\lambda = (\ell + 1/2) \gg ka$, substitute

$$\langle k^2 R^2 [j_\ell(kR)]^2 \rangle = \frac{1}{2} \left(1 - \lambda^2/k^2 R^2 \right)^{-1/2} .$$

$$(45.172)$$

For the Jeffrey–Born (JB) phase shift function, $\ell \gg ka$,

$$\tan \eta_{JB}(\lambda) = -\frac{k}{2E} \int_{\lambda/k}^\infty \frac{V(R) \, dR}{\left[1 - \lambda^2/(kR)^2 \right]^{1/2}} ,$$

$$(45.173)$$

which agrees with (45.41) since $bk = \ell + \frac{1}{2} = \lambda$. For linear trajectories $R^2 = b^2 + Z^2$, the eikonal phase (45.42) is recovered.

Born S-Wave Phase Shift.

$$\tan \eta_0^B(k) = -\frac{1}{k} \int_0^\infty U(R) \sin^2(kR) \, dR \qquad (45.174)$$

Examples: (i) $U = U_0 \dfrac{e^{-\alpha R}}{R}$, (ii) $U = \dfrac{U_0}{\left(R^2 + R_0^2 \right)^2}$;

$$(i) \tan \eta_0^B = -\frac{U_0}{4k} \ln \left(1 + 4k^2/\alpha^2 \right) , \qquad (45.175)$$

$$(ii) \tan \eta_0^B = -\frac{\pi U_0}{4k R_0^3} \left[1 - (1 + 2k R_0) e^{-2k R_0} \right] .$$

$$(45.176)$$

Born Phase Shifts (Large ℓ). For $\ell \gg ka$,

$$\tan \eta_\ell^B = -\frac{k^{2\ell+1}}{[(2\ell + 1)!!]^2} \int_0^\infty U(R) R^{2\ell+2} \, dR ,$$

$$(45.177)$$

valid only for finite range interactions $U(R > a) = 0$. Example: $U = -U_0$, $R \le a$ and $U = 0$, $R > a$.

$$\tan \eta_\ell^B(\ell \gg ka) = U_0 a^2 \frac{(ka)^{2\ell+1}}{[(2\ell + 1)!!]^2 (2\ell + 3)} .$$

$$(45.178)$$

For $\ell \gg ka$, $\eta_{\ell+1}/\eta_\ell \sim (ka/2\ell)^2$.

45.2.9 Variable Phase Method

The phase function $\eta_\ell(R)$ is defined to be the scattering phase shift produced by the part of the potential $V(R)$ contained within a sphere of radius R. It satisfies the nonlinear differential equation for $\eta_\ell(R)$

$$\frac{d\eta_\ell}{dR} = -k R^2 U(R) [\cos \eta_\ell(R) j_\ell(kR) - \sin \eta_\ell(R) n_\ell(kR)]^2 .$$

$$(45.179a)$$

The corresponding integral equation for $\eta_\ell(R)$ is

$$\eta_\ell(R) = -k \int_0^R \left[\cos \eta_\ell(R) j_\ell(kR) - \sin \eta_\ell(R) n_\ell(kR) \right]^2 U(R) R^2 \, dR .$$

$$(45.179b)$$

The Born approximation (45.171) is recovered by substituting $\eta_\ell = 0$ on the RHS of (45.179b) as $R \to \infty$.

45.2.10 General Amplitudes

For a general potential $V(\mathbf{R})$, define the reduced potential $U(\mathbf{R}) = \left(2M/\hbar^2\right) V(\mathbf{R})$. The plane wave scattering states are

$$\phi_{\mathbf{k}}(\mathbf{R}) = \exp\left(i\mathbf{k}\cdot\mathbf{R}\right) = \phi_{-\mathbf{k}}^*(\mathbf{R}) , \qquad (45.180)$$

and the full scattering solutions have the form

$$\Psi_{\mathbf{k}}^{(\pm)}(\mathbf{R}) \sim \phi_{\mathbf{k}}(\mathbf{R}) + \frac{f(\mathbf{k},\mathbf{k}')}{R} \exp\left(\pm ikR\right) , \tag{45.181}$$

where the scattering amplitude is

$$f(\mathbf{k},\mathbf{k}') = -\frac{1}{4\pi}\left\langle\phi_{\mathbf{k}'}(\mathbf{R}) \mid U(\mathbf{R}) \mid \Psi_{\mathbf{k}}^{(+)}(\mathbf{R})\right\rangle \tag{45.182a}$$

$$= -\frac{1}{4\pi}\left\langle\Psi_{\mathbf{k}'}^{(-)}(\mathbf{R}) \mid U(\mathbf{R}) \mid \phi_{\mathbf{k}}(\mathbf{R})\right\rangle \tag{45.182b}$$

$$\equiv -\frac{1}{4\pi}\left\langle\phi_{\mathbf{k}'}(\mathbf{R}) \mid T \mid \phi_{\mathbf{k}}(\mathbf{R})\right\rangle . \tag{45.182c}$$

The last equation defines the T-matrix element.

First Born Approximation.
Set $\Psi_{\mathbf{k}}^{+} = \phi_{\mathbf{k}}$ in (45.182a). Then

$$f_{\mathrm{B}}(K) = -\frac{1}{4\pi}\int U(\mathbf{R}) \exp\left(i\mathbf{K}\cdot\mathbf{R}\right) d\mathbf{R} , \quad (45.183)$$

where the momentum change is $\mathbf{K} = \mathbf{k} - \mathbf{k}'$, and $K = 2k\sin\frac{1}{2}\theta$. For a symmetric potential,

$$f_{\mathrm{B}}(K) = -\int \frac{\sin KR}{KR} U(R) R^2 \, dR . \tag{45.184}$$

Connection with partial wave analysis:

$$\frac{\sin KR}{KR} = \sum_{\ell=0}^{\infty}(2\ell+1)\left[j_\ell(kR)\right]^2 P_\ell(\cos\theta) . \tag{45.185}$$

which is consistent with (45.171).

The static e^-–atom scattering potential and Born scattering amplitude are

$$V(R) = -\frac{Ze^2}{R} + e^2\int \frac{|\psi(\mathbf{r})|^2 \, d\mathbf{r}}{|\mathbf{R}-\mathbf{r}|} , \tag{45.186}$$

$$f_{\mathrm{B}}(K) = \frac{2Me^2}{\hbar^2}\frac{[Z - F(K)]}{K^2} . \tag{45.187}$$

where the *elastic form factor* is

$$F(K) = \int |\psi(\mathbf{r})|^2 \exp\left(i\mathbf{K}\cdot\mathbf{r}\right) d\mathbf{r} .$$

For a pure Coulomb field, $F(K) = 0$ and $\sigma_{\mathrm{B}}(\theta, E) = |f_{\mathrm{B}}(K)|^2$ reduces to (45.157).

Two Potential Formulae. For scattering from the combined potential $U(\mathbf{R}) = U_0(\mathbf{R}) + U_1(\mathbf{R})$,

$$f(\mathbf{k},\mathbf{k}') = -\frac{1}{4\pi}\Big[\left\langle\phi_{\mathbf{k}'}(\mathbf{R}) \mid U_0(\mathbf{R}) \mid \chi_{\mathbf{k}}^{(+)}(\mathbf{R})\right\rangle$$
$$+ \left\langle\chi_{\mathbf{k}'}^{(-)}(\mathbf{R}) \mid U_1(\mathbf{R}) \mid \Psi_{\mathbf{k}}^{(+)}(\mathbf{R})\right\rangle\Big] , \tag{45.188a}$$

where $\chi_{\mathbf{k}}^{(\pm)}(\mathbf{R})$ and $\Psi_{\mathbf{k}}^{(\pm)}(\mathbf{R})$ are full solutions for scattering by V_0 and $V_0 + V_1$, respectively. For symmetric interactions,

$$f(\theta) = \frac{1}{k}\sum_{\ell=0}^{\infty}(2\ell+1)\left(T_\ell^{(0)} + T_\ell^{(1)}\right) P_\ell(\cos\theta) , \tag{45.189}$$

$$T_\ell^{(0)} = \exp\left(i\eta_\ell^{(0)}\right)\sin\eta_\ell^{(0)} \tag{45.190a}$$

$$= -\frac{1}{k}\int_0^{\infty} dR\left[F_\ell(R)U_0(R)u_\ell(R)\right] , \tag{45.190b}$$

$$T_\ell^{(1)} = \exp\left(2i\eta_\ell^{(0)}\right)\exp\left(i\eta_\ell^{(1)}\right)\sin\eta_\ell^{(1)} , \tag{45.191a}$$

$$T_\ell^{(1)} = -\frac{1}{k}\int_0^{\infty} dR\left[u_\ell(R)U_1(R)v_\ell(R)\right] , \tag{45.191b}$$

where u_ℓ and v_ℓ are the radial wave functions in (45.93), with phase-shifts $\eta_\ell^{(0)}$ and $\eta_\ell = \eta_\ell^{(0)} + \eta_\ell^{(1)}$, for scattering by V_0 and $V_0 + V_1$, respectively, normalized according to (45.101b).

Distorted–Wave Approximation.

$$\Psi_{\mathbf{k}}^{(+)}(\mathbf{R}) \sim \chi_{\mathbf{k}}^{(+)}(\mathbf{R})$$

$$f(\mathbf{k},\mathbf{k}') = -\frac{1}{4\pi}\Big[\left\langle\phi_{\mathbf{k}'}(\mathbf{R}) \mid U_0(\mathbf{R}) \mid \chi_{\mathbf{k}}^{(+)}(\mathbf{R})\right\rangle$$
$$+ \left\langle\chi_{\mathbf{k}'}^{(-)}(\mathbf{R}) \mid U_1(\mathbf{R}) \mid \chi_{\mathbf{k}}^{(+)}(\mathbf{R})\right\rangle\Big] . \tag{45.192}$$

45.3 Semiclassical Scattering Formulae

45.3.1 Scattering Amplitude: Exact Poisson Sum Representation

Poisson Sum Formula. With $\lambda = \ell + \frac{1}{2}$,

$$\sum_{\ell=0}^{\infty} F\left(\ell + \frac{1}{2}\right) = \sum_{m=-\infty}^{\infty} (-1)^m \int_0^{\infty} F(\lambda)\, e^{i2m\pi\lambda}\, d\lambda \ .$$

(45.193)

When applied to (45.60b),

$$f(\theta) = (ik)^{-1} \sum_{m=-\infty}^{\infty} (-1)^m \int_0^{\infty} \lambda \left(e^{2i\eta(\lambda)} - 1 \right)$$

$$\times P_{\lambda-\frac{1}{2}}(\cos\theta)\, e^{i2m\pi\lambda}\, d\lambda \ ,$$

(45.194)

where $\eta(\lambda)$ and $P_{\lambda-1/2} \equiv P(\lambda, \theta)$ are now phase functions and Legendre functions of the continuous variable λ, being interpolated from discrete to continuous ℓ. This infinite-sum-of-integrals representation for $f(\theta)$ is in principle exact. It is the appropriate technique for conversion from a sum over (quantal) discrete values of a variable to a continuous integration over that variable which classically can assume any value. The particular merit here is that the index m labels the classical paths that have encircled the (attractive) scattering center m times, and that the terms with $m < 0$ have no regions of stationary phase (SP). For deflections χ in the range $-\pi < \chi < \pi$, the only SP contribution is the $m = 0$ term.

45.3.2 Semiclassical Procedure

Semiclassical analysis [45.7–9] involves reducing (45.194) by the three approximations represented by cases A to C below. Since the integrands can oscillate very rapidly over large regions of λ, the main contributions to the integrals arise from points λ_i of stationary phase of each integrand. The amplitude can then be evaluated by the method of stationary phase, the basis of semiclassical analysis.

A. Legendre Function Asymptotic Expansions
Main range: $\sin\theta > \lambda^{-1}$, θ not within λ^{-1} of zero or π.

$$P_\ell(\cos\theta) = (2/(\pi\lambda\sin\theta))^{1/2} \cos(\lambda\theta - \pi/4) \ .$$

(45.195)

Forward formula: θ within λ^{-1} of zero.

$$P_\ell(\cos\theta) = [\theta/\sin\theta]^{1/2} J_0(\lambda\theta) \ ,$$

(45.196a)

$$J_0(\lambda\theta) \frac{1}{\pi} \int_0^{\pi} e^{-i\lambda\theta\cos\phi}\, d\phi \ .$$

(45.196b)

Backward formula: θ within λ^{-1} of π.

$$P_\ell(\cos\theta) = \left(\frac{\pi-\theta}{\sin\theta}\right)^{1/2}$$

$$\times J_0\left[\lambda(\pi-\theta)\right] e^{-i\pi(\lambda-1/2)} \ .$$

(45.197)

Equations (45.195–45.197) are useful for analysis of caustics (rainbows), diffraction and forward and backward glories, respectively. Also, a useful identity is

$$\sum_{\ell=0}^{\infty} (2\ell+1) P_\ell(\cos\theta) = \begin{cases} 4\delta(1-\cos\theta), & \theta > 0 \\ 0 & \theta = 0 \end{cases}$$

where $\delta(x)$ is the Dirac delta function.

B. *JWKB* Phase Shift Functions

$$\eta(\lambda) = \int_{R_c}^{\infty} k_\lambda(R)\, dR - \int_{\lambda/k}^{\infty} \left(k^2 - \frac{\lambda^2}{R^2}\right)^{1/2} dR$$

(45.198a)

$$= \lim_{R\to\infty} \left[\int_{R_c}^{\infty} k_\ell(R')\, dR' - kR \right] + \frac{1}{2}\lambda\pi \ .$$

(45.198b)

Local wave number:

$$k_\lambda^2(R) = k^2 - U(R) - \lambda^2/R^2 \ .$$

(45.199)

The *Langer modification*:

$$b = \frac{\sqrt{\ell(\ell+1)}}{k} = \frac{\ell+1/2}{k} = \frac{\lambda}{k} \ .$$

(45.200)

Useful identity: As $R \to \infty$,

$$\sin\left[\int_{\lambda/k}^{R} \left(k^2 - \lambda^2/R^2\right)^{1/2} dR + \frac{\pi}{4} \right]$$

$$\to \sin\left(kR - \frac{1}{2}\ell\pi \right)$$

(45.201)

JWKB phase functions are valid when variation of the potential over the local wavenumber $k_\lambda^{-1}(R)$ is a small fraction of the available kinetic energy $E - V(R)$. Many wavelengths can then be accomodated within a range ΔR for a characteristic potential change ΔV. The classical method is valid when $(1/k)(\mathrm{d}V/\mathrm{d}R) \ll (E - V)$.

Phase–Deflection Function Relation.

$$\chi(\lambda) = 2\frac{\partial \eta(\lambda)}{\partial \lambda} . \tag{45.202}$$

C. Stationary Phase Approximations (SPA) to Generic Integrals

$$A^\pm(\theta) = \int_{-\infty}^{\infty} g(\theta; \lambda) \exp[\pm i\gamma(\theta; \lambda)] \, \mathrm{d}\lambda \tag{45.203}$$

for parametric θ. In cases where the phase function γ has two stationary points, a phase minimum γ_1 at λ_1 and a phase maximum γ_2 at λ_2, then $\gamma_i' = 0, \gamma_1'' > 0, \gamma_2'' < 0$ where $\gamma_i' = (\mathrm{d}\gamma/\mathrm{d}\lambda)$ at λ_i and $\gamma_i'' = (\mathrm{d}^2\gamma/\mathrm{d}\lambda^2)$ for $i = 1, 2$. Since g is real, $A^- = (A^+)^*$, $g_i(\theta) = g(\theta, \lambda_i)$.

Uniform Airy result.

$$A^+(\theta) = a_1(\theta) e^{i(\gamma_1 + \pi/4)} F^*(\gamma_{21})$$
$$+ a_2(\theta) e^{i(\gamma_2 - \pi/4)} F(\gamma_{21}) , \tag{45.204}$$

$$a_i(\theta) = \left[2\pi/|\gamma_i''|\right]^{1/2} g_i(\theta) , \quad i = 1, 2 , \tag{45.205}$$

$$\gamma_{21}(\theta) = \gamma_2 - \gamma_1$$
$$\equiv \frac{4}{3}|z(\theta)|^{3/2} > 0 , \tag{45.206}$$

$$F[\gamma_{21}(\theta)] = \left[z^{1/4}\mathrm{Ai}(-z) + iz^{-1/4}\mathrm{Ai}'(-z)\right]\sqrt{\pi}$$
$$\times e^{-i(\gamma_{21}/2 - \pi/4)} , \tag{45.207}$$

where Ai and Ai' are the Airy function and its derivative.

This result holds for all separations $(\lambda_2 - \lambda_1)$ in location of stationary phases including a caustic (or rainbow), which is a point of inflection in γ, i.e. $\gamma_1 = \gamma_2$, $\gamma_i' = 0 = \gamma_i''$. An equivalent expression is [45.9].

$$A^+(\theta) = \left[(a_1 + a_2)z^{1/4}\mathrm{Ai}(-z)\right.$$
$$\left. - i(a_1 - a_2)z^{-1/4}\mathrm{Ai}'(-z)\right]\sqrt{\pi}\, e^{i\bar{\gamma}} , \tag{45.208}$$

where the mean phase is $\bar{\gamma} = \frac{1}{2}(\gamma_1 + \gamma_2)$. The first form (45.204) is useful for analysis of widely separated regions of stationary phase when $\gamma_{21} \gg 0$ and

$F \to 1$. The equivalent second form (45.208) is valuable in the neighborhood of caustics or rainbows when the stationary phase regions coalesce as $a_1 \to a_2$.

Primitive result. For widely separated regions λ_1 and λ_2, $F \to 1$ and

$$A^\pm(\epsilon) = \left[a_1(\epsilon) \mp i a_2(\epsilon) e^{\pm i\gamma_{21}}\right] e^{\pm i(\gamma_1 + \pi/4)} , \tag{45.209a}$$

$$A^\pm(\epsilon) = a_1(\epsilon) \exp\left[\pm i\left(\gamma_1 + \frac{\pi}{4}\right)\right]$$
$$+ a_2(\epsilon) \exp\left[\pm i\left(\gamma_2 - \frac{\pi}{4}\right)\right] . \tag{45.209b}$$

Note that the minimum phase γ_1 is increased by $\pi/4$ and the maximum phase γ_2 is reduced by $\pi/4$.

Transitional Airy Result. In the neighborhood of a caustic or rainbow where $\gamma'' = 0$, at the inflection point $\lambda_1 = \lambda_2 = \lambda_r$, then

$$A^\pm(\theta) = 2\pi \left|\frac{2}{\gamma'''(\lambda_r)}\right|^{1/3} g(\theta; \lambda_r) \mathrm{Ai}(-z) e^{\pm i\gamma(\theta; \lambda_r)} \tag{45.210}$$

$$z = \left|\frac{2}{\gamma'''(\lambda_r)|^{1/3}\gamma'(\theta; \lambda_r)}\right| . \tag{45.211}$$

Only over a very small angular range does this result agree in practice with the uniform result (45.204), which uniformly connects (45.209a) and (45.210). These stationary-phase formulae are not only applicable to integrals involving (λ, θ) but also to (t, E) and (R, p) combinations which occur in the Method of Variation of Constants and in Franck–Condon overlaps of vibrational wave functions, respectively.

45.3.3 Semiclassical Amplitudes: Integral Representation

A. Off-Axis Scattering: $\sin \theta > \lambda^{-1}$

Except in the forward and backward directions, (45.194) with (45.195) reduces to

$$f(\theta) = -\frac{1}{k(2\pi \sin \theta)^{1/2}} \sum_{m=-\infty}^{\infty} (-1)^m$$
$$\times \int_0^\infty \mathrm{d}\lambda \, \lambda^{1/2}$$
$$\times \left(e^{i\Delta^+(\lambda, m)} - e^{i\Delta^-(\lambda; m)}\right) , \tag{45.212}$$

$$\Delta^\pm(\lambda; m) = 2\eta(\lambda) + 2m\pi\lambda \pm \lambda\theta \pm \pi/4 \tag{45.213}$$
$$\equiv S^{\mathrm{C}} \pm \pi/4 , \tag{45.214}$$

where S^C is the classical action (45.52b) divided by $\hbar$.

The stationary phase condition $d\Delta^\pm / d\lambda = 0$ yields the deflection function χ to scattering angle θ relation

$$\chi(\lambda_i) = \mp\theta - 2m\pi , \qquad (45.215)$$

where λ_i are points of stationary phase (SP). Since $\pi \geq \chi \geq -\infty$, integrals with $m < 0$ have no SP's and vanish under the SPA. For cases involving no orbiting (where $\chi \to -\infty$) and when $\pi > \chi > -\pi$, then integrals with $m > 0$ also vanish under SPA so that the only remaining contribution from $m = 0$ to (45.214) is

$$f(\theta) = -\frac{1}{k(2\pi \sin\theta)^{1/2}}$$
$$\times \int_0^\infty \lambda^{1/2} \left[e^{i\Delta^+(\lambda)} - e^{i\Delta^-(\lambda)} \right] d\lambda ,$$
$$(45.216)$$

$$\Delta^\pm(\lambda) = 2\eta(\lambda) \pm \lambda\theta \pm \pi/4 . \qquad (45.217)$$

The attractive branch Δ^+ contributes only negative deflections and the repulsive branch Δ^- contributes only positive deflections and has one SP point at λ_1 where Δ^- is maximum.

Rainbow angle θ_r: $(\Delta^+)''_{\lambda_r} = 0$, so that $\chi'(\lambda_r) = 0$ where $\chi(\lambda_r) < 0$ has reached its most negative value.

$\theta < \theta_r$: Δ^+ has two SP points $\lambda_{2,3}$;
  a maximum at λ_2 and
  a minimum at λ_3.

$\theta = \theta_r$: $\lambda_2 = \lambda_3$: SP's coalesce.

$\theta > \theta_r$: no classical attractive scattering.
  Δ^+ has no SP points.

B. Forward Amplitude: $\sin\theta \sim \theta < \lambda^{-1}$

$$f(\theta) = \frac{1}{ik} \left(\frac{\theta}{\sin\theta}\right)^{1/2} \sum_{m=-\infty}^{\infty} e^{-im\pi} \int_0^\infty \lambda J_0(\lambda\theta)$$
$$\times \left(e^{2i\eta(\lambda)} - 1 \right) e^{2im\pi\lambda} d\lambda . \qquad (45.218)$$

Stationary phase points: $\gamma'(\lambda_m) = 0$.

$$\chi(\lambda_m) = 2\left(\frac{\partial\eta}{\partial\lambda}\right) = -2m\pi . \qquad (45.219)$$

Terms with $m < 0$ therefore make no SP contribution to $f(\theta)$ since $\chi \leq \pi$. The $m = 0$ term provides diffraction due to $\chi \to 0$, $\chi' \to 0$ at long range, and a forward glory due to $\chi \to 0$ at a finite λ_g and nonzero χ'_g.

C. Backward Amplitude: $\theta \sim \pi - \mathcal{O}(\lambda^{-1})$.

$$f(\theta) = \frac{1}{k}\left(\frac{\pi - \theta}{\sin\theta}\right)^{1/2}$$
$$\times \sum_{m=-\infty}^{\infty} e^{im\pi} \int_0^\infty \lambda J_0\left[\lambda(\pi - \theta)\right]$$
$$\times e^{i[2\eta(\lambda) + (2m-1)\pi\lambda]} d\lambda . \qquad (45.220)$$

Stationary phase points:

$$\chi(\lambda_m) = 2\left(\frac{\partial\eta}{\partial\lambda}\right) = -(2m-1)\pi . \qquad (45.221)$$

There are no SP for $m < 0$. The $m = 0$ term provides a normal backward amplitude due to repulsive collisions ($\chi = \pi$), and $m > 0$ terms are due to attractive half-windings.

D. Eikonal Amplitude
The $m = 0$ term of (45.218) gives

$$f_E(\theta) = \frac{1}{ik} \int_0^\infty \lambda \left(e^{2i\eta(\lambda)} - 1 \right) J_0(\lambda\theta) d\lambda \qquad (45.222a)$$

$$= -ik \int_0^\infty \left(e^{2i\eta(b)} - 1 \right) J_0(kb\theta) b \, db . \qquad (45.222b)$$

From the optical theorem,

$$\sigma_E(E) = 8\pi \int_0^\infty \sin^2 \eta(b, E) b \, db . \qquad (45.223)$$

For potentials with cylindrical symmetry, $kb\theta$ can be replaced by $2kb\sin\frac{1}{2}\theta = \boldsymbol{K} \cdot \boldsymbol{b}$, and

$$f_E(\theta) = -\frac{ik}{2\pi} \int \left(e^{2i\eta(b)} - 1 \right) J_0(\boldsymbol{K} \cdot \boldsymbol{b}) d\boldsymbol{b} . \qquad (45.224)$$

45.3.4 Semiclassical Amplitudes and Cross Sections

Amplitude addition:

$$f(\theta) = \sum_{j=1}^{N} f_j(\theta) , \qquad (45.225)$$

where each classical path $b_j = b_j(\theta)$ or SP-point $\lambda_j = \lambda_j(\theta)$ contributes $f_j(\theta)$ to the amplitude.

Primitive amplitudes:

$$f_j(\theta) = -i\alpha_j \beta_j \sigma_j^{1/2}(\theta) \exp\left[iS_j^C(\theta)\right] \qquad (45.226)$$

$$\chi'_j = (\mathrm{d}\chi/\mathrm{d}\lambda)_j \qquad (45.227)$$

$$\alpha_j = \mathrm{e}^{\pm \mathrm{i}\pi/4}; \quad (+),\ \chi'_j > 0; \quad (-),\ \chi'_j < 0; \qquad (45.228a)$$

$$\beta_j = \mathrm{e}^{\pm \mathrm{i}\pi/4}; \quad (+),\ \chi_j > 0; \quad (-),\ \chi_j < 0. \qquad (45.228b)$$

Classical cross section:

$$\sigma_j(\theta) = \left| \frac{b\,\mathrm{d}b}{\mathrm{d}(\cos\chi)} \right|_{\chi_j} = \frac{1}{k^2} \frac{\lambda_j}{\sin\theta\,|\chi'_j|}. \qquad (45.229)$$

N classical deflections χ_j provide the same θ:

$$\chi_j = \chi(\lambda_j) = \theta,\ -\theta,\ -2\pi \pm \theta,\ -4\pi \pm \theta,\ \dots. \qquad (45.230)$$

Classical collision action $S^{\mathrm{C}}(E, L; \chi)/\hbar$:

$$S^{\mathrm{C}}_j = 2\eta(\lambda_j) - \lambda_j \chi(\lambda_j) \qquad (45.231a)$$
$$= 2\eta(\lambda_j) - \lambda_j \theta, \quad 0 \le \chi \le \pi \qquad (45.231b)$$
$$= 2\eta(\lambda_j) + \lambda_j \theta - m\pi, \quad \chi < 0, \qquad (45.231c)$$

where $m = 0, 1, 2, \dots$ is the number of times the ray has traversed the backward direction during its attractive windings about the scattering center.

A. Amplitude Addition: For Three Well Separated Regions of Stationary Phase $\lambda_1 < \lambda_2 < \lambda_3$

A scattering angle θ in the range $0 < \theta < \theta_{\mathrm{r}}$ (rainbow angle) typically results from deflections χ_j at three impact parameters b (or λ): $\theta = \{\chi(b_1), -\chi(b_2), -\chi(b_3)\} \equiv \{\chi_j\}$. Scattering in the range $\theta_{\mathrm{r}} \le \theta < \pi$ results from one deflection at b_1. b_1 is in the positive branch (inner repulsion) and $b_{2,3}$ are in the negative branch (outer attraction) of the deflection function $\chi(b)$ such that $b_1 < b_2 < b_3$. $kb = (\ell + 1/2) = \lambda$. Thus

$$f(\theta) = \sum_{j=1}^{3} f_j(\theta) = \sum_{j=1}^{3} [\sigma_j(\theta)]^{1/2} \exp(\mathrm{i}S_j), \qquad (45.232)$$

where the overall phases of each f_j are

$$S_1 = 2\eta(\lambda_1) - \lambda_1 \theta - \pi/2, \qquad (45.233a)$$
$$S_2 = 2\eta(\lambda_2) + \lambda_2 \theta - \pi, \qquad (45.233b)$$
$$S_3 = 2\eta(\lambda_3) + \lambda_3 \theta - \pi/2, \qquad (45.233c)$$

which are appropriate, respectively, to deflections $\chi_1 = \theta$ at λ_1, $\chi_2 = -\theta$ at λ_2 and $\chi_3 = -\theta$ at λ_3, within the range $-\pi \le \chi \le \pi$.

The elastic differential cross section

$$\sigma(\theta) = \sum_{j=1}^{3} \sigma_j(\theta)$$
$$+ 2 \sum_{i<j}^{3} [\sigma_i(\theta)\sigma_j(\theta)]^{1/2} \cos(S_i - S_j)$$
$$\equiv \sigma_{\mathrm{c}}(\theta) + \Delta\sigma(\theta) \qquad (45.234)$$

exhibits interference effects. The first term σ_{c} is the classical background DCS with no oscillations. The second term $\Delta\sigma$ provides the oscillatory structure which originates from interference between classical actions associated with the different trajectories resulting in a given θ. The part of $S_{ij} = S_i - S_j$ most rapidly varying with θ are the angular action changes $(\lambda_1 + \lambda_2)\theta$, $(\lambda_1 + \lambda_3)\theta$ and $(\lambda_2 - \lambda_3)\theta$. Interference oscillations between the action phases S_1 and S_2 or between S_1 and S_3 then have angular separations

$$\Delta\theta_{1;(2,3)} = \frac{2\pi n}{(\lambda_1 + \lambda_{2,3})}, \qquad (45.235)$$

which are much smaller than the separation

$$\Delta\theta_{2;3} = \frac{2\pi n}{(\lambda_2 - \lambda_3)} \qquad (45.236)$$

for interference between phases S_2 and S_3. The oscillatory structure in $\Delta\sigma(\theta)$ is composed therefore of supernumerary rainbow oscillations with large angular separations $\Delta\theta_{2;3}$ from S_2 and S_3 interference, with superimposed rapid oscillations with smaller separation $\Delta\theta_{1,(2,3)}$ from interference between S_1 and S_2 or S_1 and S_3.

For deflections $\chi_j = \theta,\ -\theta,\ -2\pi \mp \theta,\ -4\pi \mp \theta, \cdots$, then the Δ^+-branch of (45.212) provides additional contributions to (45.232) with phases

$$S^{\pm}_{2m} = 2\eta(\lambda_{2m}) \pm \lambda_{2m}\theta - 2m\pi - \pi, \qquad (45.237a)$$
$$S^{\pm}_{3m} = 2\eta(\lambda_{3m}) \pm \lambda_{3m}\theta - 2m\pi - \pi/2, \qquad (45.237b)$$

for $m = 1, 2, 3, \dots$.

B. Uniform Airy Result: For Two Regions of Stationary Phase Which can Coalesce

The combined contribution $f_{23}(\theta)$ from the λ_2 and λ_3 attractive regions in Δ^+ branch is

$$f_{23}(\theta) = \sigma_2^{1/2}\,\mathrm{e}^{\mathrm{i}S_2}\,F_{23} + \sigma_3^{1/2}\,\mathrm{e}^{\mathrm{i}S_3}\,F_{23}^*, \qquad (45.238a)$$

$$F_{23} = (A + iB)\, e^{-i(S_{23}/2)}\,, \qquad (45.238b)$$

$$S_{23} = S_2 - S_3$$

$$= 2(\eta_2 - \eta_3) + (\lambda_2 - \lambda_3)\theta - \frac{1}{2}\pi\,, \qquad (45.238c)$$

$$A(z) = \pi^{1/2} z^{1/4}\,\mathrm{Ai}(-z)\,, \qquad (45.238d)$$

$$B(z) = \pi^{1/2} z^{-1/4}\,\mathrm{Ai}'(-z)\,, \qquad (45.238e)$$

$$\frac{4}{3}|z|^{3/2} = S_2^C - S_3^C = S_{23} + \frac{1}{2}\pi\,. \qquad (45.238f)$$

The amplitude f_{23} tends to the primitive result $f_2(\theta) + f_3(\theta)$ in the limit of well-separated regions $(z \gg 1)$ when $F_{23} \to 1$. An equivalent form of (45.238a) is

$$f_{23}(\theta) = \left[A\left(\sigma_2^{1/2} + \sigma_3^{1/2}\right) + iB\left(\sigma_2^{1/2} - \sigma_3^{1/2}\right)\right]$$
$$\times \exp(i\bar{S})\,, \qquad (45.239)$$

where the mean phase $\bar{S} = \frac{1}{2}(S_2 + S_3)$. This form is useful for analysis of caustic regions at $\theta \sim \theta_r$ where $z \to 0$.

C. Transitional Result: Neighborhood of Caustic or Rainbow at $(\theta_r, b_r, \lambda_r)$

In the vicinity of rainbow angle $\theta \approx \theta_r$,

$$\chi' = \frac{\partial \chi}{\partial \lambda} = \left[2(\theta_r - \theta)\chi''(\lambda_r)\right]^{1/2} \qquad (45.240)$$

$$z = (\theta_r - \theta)\left[2/\chi''(\lambda_r)\right]^{1/3} > 0 \qquad (45.241)$$

$$S_r = \frac{1}{2}(S_1 + S_2) = 2\eta(\lambda_r) + \lambda_r\theta_r - \frac{3}{4}\pi\,. \qquad (45.242)$$

The scattering amplitude

$$f_{23}(\theta_r) = \left(\frac{2\pi\lambda_r}{k^2 \sin\theta_r}\right)^{1/2}\left(\frac{2}{\chi''(\lambda_r)}\right)^{1/3}\mathrm{Ai}(-z)\, e^{iS_r}\,, \qquad (45.243)$$

is finite at the rainbow angle θ_r. In (45.239), the $(\theta_r - \theta)^{-1/4}$ divergence in $|\chi'_\ell|^{1/2}$ of (45.240) arising in the constructive interference term $\left(\sigma_2^{1/2} + \sigma_3^{1/2}\right)$ is exactly balanced by the $z^{1/4}$ term of $A(z)$. Also $\left(\sigma_2^{1/2} - \sigma_3^{1/2}\right) \to 0$ in (45.239) more rapidly than $z^{-1/4}$ in $B(z)$ so that (45.239) at θ_r is finite and reproduces (45.243).

The uniform semiclassical DCS

$$\frac{d\sigma}{d\Omega} = \left| \sigma_1^{1/2}(\theta)\, e^{iS_1} + \sigma_2^{1/2}(\theta)\, F_{23}\, e^{iS_2} \right.$$
$$\left. + \sigma_3^{1/2} F_{23}^*\, e^{iS_3} \right|^2 \qquad (45.244)$$

contains, in addition to the S_i/S_j interference oscillations in the primitive result (45.234), the θ-variation

of the Airy Function $|\mathrm{Ai}(z)|^2$, which has a principal finite (rainbow) maximum at $\theta \leq \theta_r$, the classical rainbow angle, and subsidiary maxima (supernumary rainbows) at smaller angles. The DCS decreases exponentially as θ increases past θ_r into the classical forbidden region and tends to $\sigma_1(\theta)$ at larger angles. For $\theta_r < \theta < \pi$,

$$f(\theta) = \sigma_1^{1/2}(\theta)\exp(iS_1)\,. \qquad (45.245)$$

45.3.5 Diffraction and Glory Amplitudes

Diffraction. Diffraction arises from the outer (attractive) part of the potential. Many contributions arise from the attractive Δ^+ branch appropriate for negative χ at large b where η is small. Here χ, χ' both tend to zero.

Glory. The deflection function χ passes through zero at a finite λ_g. A confluence of the two maxima of each phase shift from the positive and negative branches of $\chi(b)$ occurs at $b_1 = b_2 = b_g = \lambda_g/k$. η_g is maximum for $\chi = 0$. In general $\chi(b_m) = -2m\pi$ (forward glory); $\chi(b_m) = -(2m - 1)\pi$ (backward glory); $m = 0, 1, 2, \ldots$. There is only a forward glory at $\chi = 0$ when the deflection at the rainbow is $|\chi_r| < 2\pi$. In contrast to diffraction, the glory contribution can be calculated by the *stationary phase approximation*.

Transitional Results for Forward and Backward Glories

Forward Glories. Contributions arise from $\chi = \pm\theta$, $-2\pi \pm \theta, \cdots, -2m\pi \pm \theta$ as $\theta \to 0$. The stationary phase points λ_m are located at

$$\chi(\lambda_m) = \chi_m = -2m\pi; \quad m \geq 0\,. \qquad (45.246)$$

The phase function in the neighborhood of a glory is

$$\eta(\lambda) = \eta_m - m\pi(\lambda - \lambda_m) + \frac{1}{4}\chi'_m(\lambda - \lambda_m)^2\,. \qquad (45.247)$$

The $m = 0$ term provides zero deflection χ due to a net balance of attractive and repulsive scattering for a finite impact parameter b_g or λ_g where $\eta(\lambda)$ attains its maximum value η_m. The glories at θ are due to a confluence of the two contributions from the deflections $\chi_m = -2m\pi \pm \theta$ at the stationary phase points $\lambda_{mn} = \lambda_{m1}$ and λ_{m2}. SP integration of (45.218) with

(45.247) yields the forward glory amplitude

$$f_{\mathrm{FG}} = \frac{1}{k} \sum_{n=1}^{2} \sum_{m=0}^{\infty} \lambda_{mn} \left(\frac{2\pi}{|\chi'_m|} \right)^{1/2}$$

$$\times J_0(\lambda_{mn}\theta)\, e^{i S_{mn}^{(g)}} , \qquad (45.248)$$

$$S_{mn}^{(g)} = 2\eta(\lambda_{mn}) + m\pi(\lambda_{mn} - 1) - \frac{3}{4}\pi . \qquad (45.249)$$

Backward Glories. Contributions arising from $\chi = -\pi \pm \alpha$, $-3\pi \pm \alpha$, $\cdots$, $-(2m-1)\pi \pm \alpha$ coalesce as $\alpha \equiv \pi - \theta \to 0$. The phase function near a backward glory is

$$\eta(\lambda) = \eta(\lambda_m) + \frac{1}{2}\chi_m(\lambda - \lambda_m) + \frac{1}{4}\chi'_m(\lambda - \lambda_m)^2 . \qquad (45.250)$$

The $m = 0$ term provides the normal backward amplitude due to head-on ($b = 0$) repulsive collisions. $m > 0$ terms provide contributions from attractive collisions for which there are two points λ_{mn} of stationary phase for each m in $\chi_m = -(2m-1)\pi \pm \alpha$.

The backward glory amplitude at $\theta = \pi - \alpha$ is

$$f_{\mathrm{BG}} = \frac{1}{k} \sum_{n=1}^{2} \sum_{m=0}^{\infty} \lambda_{mn} \left(\frac{2\pi}{|\chi'_{mn}|} \right)^{1/2}$$

$$\times J_0(\lambda_{mn}\alpha)\, e^{i S_{mn}^{(g)}} , \qquad (45.251)$$

$$S_{mn}^{(g)} = 2\eta(\lambda_{mn}) + \pi(2m-1)\left(\lambda_{mn} - \frac{1}{2}\right) - \frac{3}{4}\pi . \qquad (45.252)$$

In contrast to the Bessel amplitudes (below), these transitional formulae do not uniformly connect with the primitive semiclassical results for $(f_1 + f_2)$ away from the critical glory angles.

Uniform Bessel Amplitude for Glory Scattering
The combined contributions from $\chi_1 = -N\pi + \theta$ and $\chi_2 = -N\pi - \theta$, where $N = 2m$, for forward and $N = 2m - 1$ for backward scattering, yield [45.9]

$$f_{\mathrm{G}}(\theta) = \frac{\alpha_j}{2i}\, e^{-iN\pi/2} \left(\pi S_{21}^{(C)}\right)^{1/2} \exp\left[i\bar{S}^{(C)}(\theta)\right]$$

$$\times \left[(\sigma_1^{1/2} + \sigma_2^{1/2}) J_0\left(\frac{1}{2}S_{21}^{(C)}\right) \right.$$

$$\left. - i(\sigma_1^{1/2} - \sigma_2^{1/2}) J_1\left(\frac{1}{2}S_{21}^{(C)}\right) \right] , \quad (45.253)$$

where $S_{21}^{(C)}(\theta) = S_2^{(C)} - S_1^{(C)}$ is the difference of the collision actions (45.231a),

$$S_i^{(C)}(\theta) = 2\eta(\lambda_i) - \lambda_i \chi_i , \quad i = 1, 2 , \qquad (45.254)$$

with mean

$$\bar{S}_{21}^{(C)}(\theta) = \frac{1}{2}\left(S_2^{(C)} + S_1^{(C)}\right) , \qquad (45.255)$$

and phases

$$\alpha_j = e^{\pm i\pi/4}; \quad (+),\ \chi'_j > 0; \quad (-),\ \chi'_j < 0 , \qquad (45.256)$$

and the ordinary Bessel functions $J_n(Z)$ satisfy the relationships $J_1(z) = -J'_0(z)$, $J_1(-z) = -J_1(z)$. This formula, valid for both forward ($\theta \sim 0$) and backward ($\theta \sim \pi$) glories, does uniformly connect the primitive result for $(f_1 + f_2)$, valid when $S_{21}^{(C)} \gg 1$ to the transitional results (45.248) and (45.251), valid only in the vicinity of the glories.

45.3.6 Small-Angle (Diffraction) Scattering

Diffraction originates from scattering in the forward direction by the long-range attractive tail of $V(R)$ where χ, χ' and $\eta \to 0$. The main contributions to (45.222a) arise from a large number of small $\eta(\lambda)$ at large λ. The Jeffrey–Born phase function (45.173) can therefore be used in (45.222b) for $f(\theta)$ and in (45.45) and (45.47), respectively, for $\sigma(E)$. A finite forward diffraction peak as $\theta \to 0$ is obtained for $f(\theta)$ in contrast to the classical infinite result.

Integral Cross Sections
For $V(R) = -C/R^n$, the Landau–Lifshitz (LL) and Massey–Mohr (MM) cross sections are [cf. (45.346)]

$$\sigma_{\mathrm{LL}}(E) = \pi \left(\frac{2CF(n)}{(n-1)\hbar v} \right)^{2/(n-1)}$$

$$\times \pi \left[\sin\left(\frac{\pi}{n-1}\right) \Gamma\left(\frac{2}{n-1}\right) \right]^{-1} , \qquad (45.257)$$

$$\sigma_{\mathrm{MM}}(E) = \pi \left(\frac{2CF(n)}{(n-1)\hbar v} \right)^{2/(n-1)} \left(\frac{2n-3}{n-2} \right) , \qquad (45.258)$$

where $F(n) = \sqrt{\pi}\,\Gamma\left(\frac{1}{2}n + \frac{1}{2}\right)/\Gamma\left(\frac{1}{2}n\right)$ and v is the relative speed. For σ_{MM}, the phases are $\eta(\lambda) = \frac{1}{2}$ ($0 < \lambda < \lambda_0$) and $\eta(\lambda) = \eta_{\mathrm{JB}}$ ($\lambda > \lambda_0$). For σ_{LL}, phases are η_{JB}

for all λ. Both σ_{LL} and σ_{MM} have the general form

$$\sigma_D(E) = \gamma \left(\frac{C}{\hbar v} \right)^{2/(n-1)} . \tag{45.259}$$

Ion–Atom Collisions. For $n = 4$ attraction at low energy, $\sigma_D \sim v^{-2/3}$. $\gamma_{LL} = 11.373$, $\gamma_{MM} = 10.613$. For $n = 12$ repulsion at high energy, $\sigma_D \sim v^{-2/11}$. $\gamma_{LL} = 6.584$, $\gamma_{MM} = 6.296$.

Atom–Atom Collisions. For $n = 6$ (attraction), $\sigma_D \sim v^{-2/5}$, $\gamma_{LL} = 8.083$, $\gamma_{MM} = 7.547$ Fig. 45.1.

Exact numerical calculations favor σ_{LL} over σ_{MM} ([45.10], pp. 1325 for details).

Differential Cross Section

$$\frac{d\sigma}{d\Omega} = f_i^2(\theta) + f_r^2(\theta) , \tag{45.260a}$$

$$f_i = \frac{2}{k} \int_0^\infty \lambda \sin^2 \eta(\lambda) \left(1 - \frac{1}{4}\lambda^2\theta^2 \right) d\lambda \tag{45.260b}$$

$$= \frac{k\sigma_D(E)}{4\pi} \left[1 - \left(\frac{k^2\sigma_D}{16\pi} \right) g_1(n)\theta^2 \right] , \tag{45.260c}$$

$$f_r = \frac{1}{k} \int_0^\infty \lambda \sin 2\eta(\lambda) \left(1 - \frac{1}{4}\lambda^2\theta^2 \right) d\lambda \tag{45.260d}$$

$$= \frac{k\sigma_D(E)}{4\pi} \left[1 - \left(\frac{k^2\sigma_D}{16\pi} \right) g_2(n)\theta^2 \right]$$
$$\times \tan \left(\frac{\pi}{n-1} \right) , \tag{45.260e}$$

where σ_D is given by (45.259), and

$$g_j(n) = \pi^{-1} \tan \left(\frac{j\pi}{n-1} \right) \frac{\{\Gamma[2/(n-1)]\}^2}{\Gamma[4/(n-1)]} . \tag{45.261}$$

The optical theorem (45.62) is satisfied, and

$$f_D(\theta \sim 0) = \sigma_D^{1/2}(E) \, e^{iS_D(n)} , \tag{45.262}$$

where the (energy-independent) phase is

$$S_D(n) = \frac{\pi(n-3)}{2(n-1)} . \tag{45.263}$$

45.3.7 Small–Angle (Glory) Scattering

Amplitude and Cross Section. The other contribution to forward scattering is the forward glory, which originates from the combined null effect of attraction and repul-

sion at a specified glory impact parameter $b_g = \lambda_g/k$, where $\eta(\lambda)$ attains a maximum value of η_g. The $m = 0$ term of (45.248) yields

$$f_G(\theta) = \sigma_G^{1/2}(\theta) \exp\left[iS_G(E) \right] , \tag{45.264a}$$

$$\sigma_G(\theta) = \frac{\lambda_g^2}{k^2} \left(\frac{2\pi}{|\chi_g'|} \right) J_0^2(\lambda_g\theta) , \tag{45.264b}$$

$$S_G(E) = 2\eta_g(E) - \frac{3}{4}\pi , \tag{45.264c}$$

where $J_0^2(x) \sim 1 - \frac{1}{4}x^2 + \cdots$. The classical result (45.30) is recovered by averaging (45.264b) over several oscillations with $\langle J_0^2(x) \rangle = (\pi x)^{-1}$.

Diffraction–Glory Oscillations.

$$\sigma(E) = \frac{4\pi}{k} \text{Im}\left[f_D(0) + f_G(0) \right] \tag{45.265a}$$

$$= \sigma_D(E) + \Delta\sigma_G(E) , \tag{45.265b}$$

where the diffraction cross section is (45.259), and where

$$\Delta\sigma_G(E) = \frac{4\pi}{k^2} \lambda_g \left(\frac{2\pi}{|\chi_g'|} \right)^{1/2} \sin\left(2\eta_g(E) - \frac{3}{4}\pi \right) \tag{45.266}$$

oscillates with E.

For sufficiently deep attractive wells, the phase shift η_g successively decreases with increasing E
Fig. 45.1 Illustration of all the various oscillatory effects for elastic scattering by a Lennard–Jones (12,6) potential of well depth ϵ and equilibrium distance R_e. Ordinate $\sigma^* = \sigma/(2\pi R_e^2)$, abscissa $v^* = \hbar v/(\epsilon R_e)$

through a series of multiples of $\pi/2$. Writing $\eta_g(E) = \pi(N - 3/8)$, maxima appear at $N = 1, 2, \ldots$, and minima at $N = 3/2, 5/2, 7/2, \ldots$. The glories are indexed by N in order of appearance, starting at high energies. $\eta_g(E \to 0)$ is related to the number n of bound states by Levinson's theorem: $\eta_0(E \to 0) = (n + 1/2)\pi$. Diffraction-glory oscillations also occur in the DCS at a frequency governed entirely by the energy variation of $\eta_g(E)$ and n of (45.263).

JWKB Formulae for Shape Resonances and Tunneling Predissociation

For the three classical turning points $R_1 < R_2 < R_3$ at energies E below the orbiting threshold $V_{\max}$ at R_X, the JWKB phase shift

$$\eta_\ell = \left[\eta_\ell^{(0)} - \frac{1}{2}\phi(\gamma_\ell) \right] + \eta_\ell^{(r)} \qquad (45.267)$$

is composed of (a) the phase shift

$$\eta_\ell^{(0)} = \lim_{R \to \infty} \left[\int_{R_3}^{\infty} k(R)\, dR - kR + \frac{1}{2}(\ell + \frac{1}{2})\pi \right] \qquad (45.268)$$

appropriate to one turning point at R_3, (b) a contribution $\eta^{(r)}$ arising from the region between the two inner turning points R_2 and R_3 due to penetration of the centrifugal barrier and given by

$$\tan \eta_\ell^{(r)}(E) = \left(\frac{[1 + \exp(-2\gamma_\ell)]^{1/2} - 1}{[1 + \exp(-2\gamma_\ell)]^{1/2} + 1} \right)$$
$$\times \tan\left(\alpha_\ell - \frac{1}{2}\phi_\ell \right), \qquad (45.269)$$

and (c) a phase correction factor

$$\phi_\ell(\gamma_\ell) = \arg \Gamma\left(\frac{1}{2} + i\epsilon \right) - \epsilon \ln|\epsilon| + \epsilon, \qquad (45.270)$$

where $\epsilon = -\gamma_\ell/\pi$. The radial action $J_R(E)$ is $2\hbar\alpha_\ell(E)$. For motion within the potential well α_ℓ is

$$\alpha_\ell(E) = \int_{R_1}^{R_2} k(R)\, dR, \qquad (45.271)$$

and is

$$\gamma_\ell(E < E_{\max}) = \int_{R_2}^{R_3} |k(R)|\, dR \qquad (45.272)$$

in the classically forbidden region of the potential hump.

The above expressions also hold for energies $E > V_{\max}$, except that (45.272) is replaced by

$$\gamma_\ell(E > E_{\max}) = -i \int_{R_-}^{R_+} k(R)\, dR, \qquad (45.273)$$

where $R_\pm$ are the complex roots of $k_\ell(R) = 0$. For the quadratic form

$$V(R) = V_{\max} - \frac{1}{2} M\omega_*^2 (R - R_{\max})^2, \qquad (45.274)$$

appropriate in the vicinity of the potential hump, γ for both cases reduces to

$$\gamma = \pi(V_{\max} - E)/\hbar\omega_*. \qquad (45.275)$$

The deflection function $\chi_\ell = 2(\partial\eta_\ell/\partial\ell)$ no longer diverges at the orbiting angular momentum ℓ_0 or impact parameter b_0. The singularities in η_ℓ of (45.51) are exactly canceled by $-\frac{1}{2}(\partial\phi/\partial\ell)$ in (45.270).

Limiting cases:

(a) $E \gg V_{\max}$. Then $\gamma_\ell \to -\infty$ and $\phi \to -(\pi/24\gamma_\ell) \to 0$, so that $\eta_\ell^{(r)} \to \alpha_\ell$ and η_ℓ reduces to the single turning point result (45.268) with $R_3 = R_1$.

(b) $E \ll V_{\max}$. Then $\gamma_\ell \gg 1$ and

$$\eta_\ell^{(r)}(E) = \tan^{-1}\left[\frac{1}{2} e^{-2\gamma_\ell} \tan\left(\alpha_\ell - \frac{1}{2}\phi_\ell \right) \right], \qquad (45.276)$$

which remains negligible except for those energies E close to quasibound energy levels $E_{n\ell}$ determined via the Bohr quantization condition

$$\alpha_\ell(E) - \frac{1}{2}\phi_\ell(E) = \left(n + \frac{1}{2} \right)\pi. \qquad (45.277)$$

As E increases past each $E_{n\ell}$, $\eta_\ell^{(r)}$ increases rapidly by π. Since $(\partial J/\partial E)_{n\ell} = v_{n\ell}^{-1} = 2\pi/\omega_{n\ell}$, the time period for radial oscillation within the potential barrier, the level spacing is $\hbar\omega_{n\ell} = h v_{n\ell} = \pi(\partial E/\partial\alpha)_{n\ell}$.

Shape Resonance. In the neighborhood of $E_{n\ell} \sim E$,

$$\alpha_\ell(E) = \alpha_{n\ell}(E_{n\ell}) + \left(\frac{\pi}{\hbar\omega_{n\ell}} \right)(E - E_{n\ell}), \qquad (45.278)$$

and, under the assumption that the energy variation of ϕ_ℓ can be neglected, (valid for E not close to $V_{\max}$), then η_ℓ reduces to the Breit–Wigner form

$$\eta_\ell(E) = \eta_\ell^{(0)}(E) + \tan^{-1}\left(\frac{\Gamma_{n\ell}/2}{E_{n\ell} - E} \right), \qquad (45.279)$$

with resonance width

$$\Gamma_{n\ell} = 2 \left(\frac{\hbar\omega_{n\ell}}{\pi} \right) \frac{\left[1 + \exp(-2\gamma_{n\ell})\right]^{1/2} - 1}{\left[1 + \exp(-2\gamma_{n\ell})\right]^{1/2} + 1} ,$$

(45.280)

where $\gamma_{n\ell} = \gamma(E_{n\ell})$. The partial cross sections are then determined by (45.166a,b) with $\eta_\ell^{(0)}$ replaced by $\eta_\ell^{(0)} - \frac{1}{2}\phi(\gamma)$ of (45.268).

Gamow's Result. For $E \ll V_{\max}$, $\gamma_{n\ell} \gg 1$, then

$$\Gamma_{n\ell} \xrightarrow{\gamma \gg 1} \left(\frac{\hbar\omega_{n\ell}}{2\pi} \right) \exp(-2\gamma_{n\ell}) .$$

(45.281)

The probabilities of transmission through and reflection from a barrier for unit incident flux from the left are:

Transmission Probability:

$$T = \left(1 + e^{2\gamma} \right)^{-1} \xrightarrow{\gamma \gg 1} e^{-2\gamma} .$$

(45.282)

Reflection Probability:

$$R = \left(1 + e^{-2\gamma} \right)^{-1} \xrightarrow{\gamma \gg 1} 1 .$$

(45.283)

Frequency of leakage:

$$\nu_{\mathrm{T}} = \Gamma_{n\ell}/\hbar = \left(\frac{\omega_{n\ell}}{2\pi} \right) e^{-2\gamma} .$$

(45.284)

45.3.8 Oscillations in Elastic Scattering

Figure 45.1 is an illustration [45.11] of all the various oscillatory structure and effects – Ramsauer–Townsend minimum (Sect. 45.2.4), orbiting resonances (45.340), diffraction-glory oscillations (45.265b) and symmetry oscillations (45.82) – for elastic scattering by a Lennard–Jones $(12, 6)$ potential. Note the shift of velocity dependence from $v^{-2/5}$ at low v to $v^{-2/11}$ at high v. $\sigma = 2\pi R_{\mathrm{e}}^2$ is the averaged cross section $2\pi b_0^2$ in (45.47) at $b_0 = R_{\mathrm{e}}$. The region $\sigma^* > 1$ probes the attractive part of the potential at low speeds and $\sigma^* < 1$ probes the repulsive part at high speeds. The four distinct types of structure originate from nonrandom behavior of $\sin^2 \eta$ in (45.45). Orbiting trajectories exist for $E < 0.8\epsilon$ (Sect. 45.5).

45.4 Elastic Scattering in Reactive Systems

All nonelastic processes (e.g. inelastic scattering and rearrangement collisions/chemical reactions) can be viewed as a net absorption from the incident beam current vector J and modeled by a complex optical potential

$$V(R) = V_{\mathrm{r}}(R) + \mathrm{i}V_{\mathrm{i}}(R) .$$

(45.285)

The continuity equation is then

$$\nabla \cdot J = -\frac{2}{\hbar} V_{\mathrm{i}}(R) |\Psi(R)|^2 ,$$

(45.286)

so that particle absorption implies $V_{\mathrm{i}} > 0$ and particle creation $V_{\mathrm{i}} < 0$. Since particle conservation implies $|S_\ell|^2 = 1$, the phase shift

$$\delta_\ell(k) = \eta_\ell(k) + \mathrm{i}\gamma_\ell(k)$$

(45.287)

is also complex since then

$$S_\ell = A_\ell(k) \exp(2\mathrm{i}\eta_\ell) ,$$

(45.288)

where the absorption (inelasticity) factor is

$$A_\ell = \exp(-2\gamma_\ell) \leq 1 .$$

(45.289)

45.4.1 Quantal Elastic, Absorption and Total Cross Sections

$$f_{\mathrm{el}}(\theta) = \frac{1}{2\mathrm{i}k} \sum_{\ell=0}^{\infty} (2\ell+1) \left(A_\ell \, e^{2\mathrm{i}\eta_\ell} - 1 \right) P_\ell(\cos\theta) ,$$

(45.290a)

$$\sigma_{\mathrm{el}}(k) = \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell+1) |A_\ell \, e^{2\mathrm{i}\eta_\ell} - 1|^2 ,$$

(45.290b)

$$\sigma_{\mathrm{abs}}(k) = \frac{\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell+1) \left(1 - A_\ell^2 \right) ,$$

(45.290c)

$$\sigma_{\mathrm{tot}}(k) = \sigma_{\mathrm{el}}(k) + \sigma_{\mathrm{abs}}(k)$$

$$= \frac{2\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell+1) \left(1 - A_\ell \cos 2\eta_\ell \right) .$$

(45.290d)

Upper limits to the partial cross sections are

$$\sigma_\ell^{\mathrm{el}} \leq \frac{4\pi}{k^2} (2\ell+1), \quad \sigma_\ell^{\mathrm{abs}} \leq \frac{\pi}{k^2} (2\ell+1) ,$$

(45.291a)

$$\sigma_\ell^{\text{tot}} \le \frac{4\pi}{k^2}(2\ell+1) = \frac{4\pi}{k}\,\text{Im}\left[f_\ell^{\text{el}}(\theta=0)\right]\,.$$

$$(45.291b)$$

For pure elastic scattering with no absorption, $A_\ell = 1$. All nonelastic processes ($0 \le A_\ell < 1$) are always accompanied by elastic scattering, even in the ($A_\ell = 0$) limit of full absorption.

Eikonal Formulae for Forward Reactive Scattering.

$$f_{\text{el}}(\theta) = -\mathrm{i}k \int_0^\infty \left(\mathrm{e}^{2\mathrm{i}\delta} - 1\right) J_0(2kb\sin\tfrac{1}{2}\theta)b\,\mathrm{d}b\,,$$

$$(45.292a)$$

$$\sigma_{\text{el}}(k) = 2\pi \int_0^\infty |\left(1 - \mathrm{e}^{-2\gamma}\,\mathrm{e}^{2\mathrm{i}\eta}\right)|^2 b\,\mathrm{d}b\,,\quad (45.292b)$$

$$\sigma_{\text{abs}}(k) = 2\pi \int_0^\infty \left(1 - \mathrm{e}^{-4\gamma}\right)b\,\mathrm{d}b\,,\qquad (45.292c)$$

$$\sigma_{\text{tot}}(k) = 4\pi \int_0^\infty \left(1 - \mathrm{e}^{-2\gamma}\cos 2\eta\right)b\,\mathrm{d}b\,,\quad (45.292d)$$

where the phase shift function $\delta = \eta + \mathrm{i}\gamma$ at impact parameter b can be either the Jeffrey–Born phase

$$\delta_{\text{JB}}(b) = -\frac{1}{2k}\int_b^\infty \frac{U(R)\,\mathrm{d}R}{\left(1 - b^2/R^2\right)^{1/2}}\,,\qquad (45.293)$$

where $kb = \lambda = (\ell + 1/2)$, or the eikonal phase

$$\delta_{\text{E}}(b) = -\frac{1}{4k}\int_{-\infty}^\infty U(b, Z)\,\mathrm{d}Z\,,\qquad (45.294)$$

where the reduced interaction is $U = \left(2m/\hbar^2\right)V$.

Fraunhofer Diffraction by a Black Sphere.

Fraunhofer Diffraction by a Black Sphere. For a complex spherical well U

$$U = \begin{cases} U_{\text{r}} + \mathrm{i}U_i, & R < a \\ 0, & R > a\,. \end{cases} \qquad (45.295)$$

The eikonal phase function (45.294) is

$$\delta(b) = \begin{cases} (U/2k)\left(a^2 - b^2\right)^{1/2}, & 0 \le b \le a \\ 0 & b > a\,. \end{cases}$$

$$(45.296)$$

The absorption factor is

$$A(b)^2 \equiv \mathrm{e}^{-4\gamma} = \exp\left[-2\left(a^2 - b^2\right)^{1/2}/\lambda\right]\,,$$

$$(45.297)$$

where $\lambda = k/U_i$ is the mean free path towards absorption. For strong absorption, $\lambda \ll a$, so that

$$f_{\text{el}}(\theta) = \mathrm{i}k \int_0^a J_0(2kb\sin\tfrac{1}{2}\theta)b\,\mathrm{d}b\,,\qquad (45.298)$$

$$\frac{\mathrm{d}\sigma_{\text{el}}}{\mathrm{d}\Omega} = (ka)^2\left(\frac{J_1\left(2ka\sin\tfrac{1}{2}\theta\right)}{2ka\sin\tfrac{1}{2}\theta}\right)^2 a^2\,,\quad (45.299)$$

which has a diffraction shaped peak of width $\sim\theta \le (ka)^{-1}$ about the forward direction, and

$$\sigma_{\text{tot}} = \frac{4\pi}{k}\,\text{Im}\left[f_{\text{el}}(\theta=0)\right] = 2\pi a^2 \qquad (45.300)$$

is composed of πa^2 for classical absorption and πa^2 for edge diffraction or shadow (nonclassical) elastic scattering. This result also holds for the perfectly reflecting sphere (πa^2 for classical elastic and πa^2 for edge diffraction).

45.5 Results for Model Potentials

Exact results for various quantities in classical, quantal, and semiclassical elastic scattering are obtained for the model potentials (a)–(s) in Table 45.1.

Classical Deflection Functions for Model Potentials

(a) Hard Sphere.

$$\theta(b; E) = \chi = \begin{cases} \pi - 2\sin^{-1}b/a, & b \le a\,; \\ 0, & b > a\,. \end{cases} \quad (45.301)$$

$$b(\theta) = a\cos\frac{1}{2}\theta\,,\qquad (45.302)$$

$$\sigma(\theta) = \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \frac{1}{4}a^2;\quad \text{isotropic},\qquad (45.303)$$

$$\sigma = \pi a^2 = \text{geometric cross section};\qquad (45.304)$$

θ, $\sigma(\theta)$ and σ are all independent of energy E.

(b) Potential Barrier. For $E < V_0$, classical scattering is the same as for hard sphere reflection as given by (45.301–45.304). For $E > V_0$ and $\theta = \chi$, define

$n^2 = 1 - V_0/E$, $b_0 = na$. Then

$$\theta(b) = \begin{cases} 2\left[\sin^{-1}(b/na) - \sin^{-1}(b/a)\right] & 0 \le b \le b_0 \\ \pi - 2\sin^{-1}(b/a), & b_0 \le b \le a \end{cases}$$

(45.305)

and $\theta_{max} = 2\cos^{-1} n$. For a given θ, the two impact parameters which contribute are

$$b_1(\theta) = \frac{an\sin\frac{1}{2}\theta}{\left(1 - 2n\cos\frac{1}{2}\theta + n^2\right)^{1/2}}, \quad 0 < b_1 \le b_0$$

(45.306)

$$b_2(\theta) = a\cos\frac{1}{2}\theta, \quad b_0 < b_2 \le a$$

(45.307)

For $0 \le \theta \le \theta_{max}$,

$$\frac{d\sigma}{d\Omega} = \frac{1}{4}a^2 + \frac{a^2 n^2 \left(n\cos\frac{1}{2}\theta - 1\right)\left(n - \cos\frac{1}{2}\theta\right)}{4\cos\frac{1}{2}\theta\left(1 + n^2 - 2\cos\frac{1}{2}\theta\right)},$$

(45.308)

and $d\sigma/d\Omega = 0$ for $\theta_{max} \le \theta \le \pi$. Finally,

$$\sigma = \int_{\theta=0}^{\theta_{max}} \left(\frac{d\sigma}{d\Omega}\right) d\Omega = \pi a^2.$$

(45.309)

(c) Potential Well. Results are similar to the potential barrier case above, except that there is only a single scattering trajectory with $\theta = -\chi$, and $n = (1 + V_0/E)^{1/2}$ is the effective index of refraction for the equivalent problem in geometrical optics. Refraction occurs on entering

Table 45.1 Model interaction potentials

	Potential	$V(R)$
(a)	Hard sphere	$\infty,\ R \le a;\ 0,\ R > a$
(b)	Barrier	$V_0,\ R \le a;\ 0,\ R > a$
(c)	Well	$-V_0,\ R \le a;\ 0,\ R > a$
(d)	Coulomb ($\pm$)	$\pm k/R$
(e)	Finite-range Coulomb	$-k/R + k/R_s\ R \le R_s;\ 0,\ R > R_s$
(f)	Pure dipole	$\pm\alpha/R^2$
(g)	Finite-range dipole	$\pm\alpha\left(\dfrac{1}{R^2} - \dfrac{1}{a^2}\right),\ R \le a;\ 0,\ R > a$
(h)	Dipole + hard sphere	$\pm\alpha/R^2,\ R \le a;\ 0,\ R > a$
(i)	Power law attractive	$-C/R^n,\ (n > 2)$
(j)	Fixed dipole + polarization	$-\dfrac{De\cos\theta_d}{R^2} - \dfrac{\alpha_d e^2}{2R^4}$
(k)	Fixed dipole + Coulomb	$-\dfrac{De\cos\theta_d}{R^2} + \dfrac{e^2}{R}$
(l)	Lennard-Jones $(n, 6)$	$\dfrac{\epsilon n}{n-6}\left[\dfrac{6}{n}\left(\dfrac{R_e}{R}\right)^n - \left(\dfrac{R_e}{R}\right)^6\right]$
(m)	Polarization $(n, 4)$	$\dfrac{\epsilon n}{n-4}\left[\dfrac{4}{n}\left(\dfrac{R_e}{R}\right)^n - \left(\dfrac{R_e}{R}\right)^4\right]$
(n)	Multiple-term power law	$\dfrac{C_m}{R^m} - \dfrac{C_n}{R^n} = V_m(R) - V_n(R)$
(o)	Exponential	$V_0\exp(-\alpha R)$
(p)	Screened Coulomb	$V_0\exp(-\alpha R)/R$
(q)	Morse	$\epsilon\left[e^{2\beta(R_e - R)} - 2e^{\beta(R_e - R)}\right]$
(r)	Gaussian	$V_0\exp(-\alpha^2 R^2)$
(s)	Polarization finite	$-V_0/(R^2 + R_0^2)^2$

and exiting the well. Then

$$\theta(b) = -2\left[\sin^{-1}(b/na) - \sin^{-1}(b/a)\right] ,$$

$$(45.310)$$

$$\theta(b = a) = \theta_{max} = 2\cos^{-1}(1/n) ,$$ (45.311)

$$b(\theta) = \frac{-an\sin\frac{1}{2}\theta}{\left(1 - 2n\cos\frac{1}{2}\theta + n^2\right)^{1/2}} ,$$ (45.312)

$$\frac{d\sigma}{d\Omega} = \frac{a^2 n^2 \left(n\cos\frac{1}{2}\theta - 1\right)\left(n - \cos\frac{1}{2}\theta\right)}{4\cos\frac{1}{2}\theta \left(n^2 + 1 - 2n\cos\frac{1}{2}\theta\right)^2} ,$$

$$(45.313)$$

$$\sigma = \pi a^2$$ (45.314)

(d) Rutherford or Coulomb.

$$\theta(b, E) = |\chi| = 2\csc^{-1}\left[1 + (2bE/k)^2\right]^{1/2} ,$$

$$(45.315)$$

$$b(\theta, E) = (k/2E)\cot\frac{1}{2}\theta ,$$ (45.316)

$$\sigma(\theta) = \frac{d\sigma}{d\Omega} = \left(\frac{k}{4E}\right)^2 \csc^4\frac{1}{2}\theta .$$ (45.317)

(e) Finite Range Coulomb.

$$R_0(E) = \frac{k}{2E}, \quad \alpha(E) = R_0(E)/R_s ,$$

$$\frac{d\sigma}{d\Omega} = \frac{R_0^2}{4}\left(\frac{1 + \alpha}{\alpha^2 + (1 + 2\alpha)\sin^2\frac{1}{2}\theta}\right)^2 .$$ (45.318)

(f) Pure Dipole. $R_0^2(E) = \alpha/E$.
Repulsion (+): $\chi > 0$, $\chi = \theta$,

$$b^2(\chi) = R_0^2\left[\left(\frac{1}{\chi} + \frac{1}{2\pi - \chi}\right)\frac{\pi}{2} - 1\right] ,$$ (45.319)

$$\frac{d\sigma}{d\Omega} = \frac{\pi R_0^2}{4\sin\theta}\left|\frac{1}{\theta^2} - \frac{1}{(2\pi - \theta)^2}\right| .$$ (45.320)

Attraction (−): $\chi < 0$.

$$b^2(\chi) = R_0^2\left[\left(\frac{1}{|\chi|} - \frac{1}{|\chi| + 2\pi}\right)\frac{\pi}{2} + 1\right] .$$ (45.321)

There is an infinite number of (negative) deflections $\chi = \chi_n^{\pm}$ associated with a given scattering angle θ:

$$|\chi_n^+| = 2\pi n + \theta, \quad n = 0, 1, 2, \dots ,$$ (45.322a)

$$|\chi_n^-| = 2\pi n - \theta, \quad n = 1, 2, 3, \dots .$$ (45.322b)

The infinite sum over contributions from $b_n^{\pm} = b(\chi_n^{\pm})$ for the attractive dipole yields

$$\frac{d\sigma}{d\Omega} = \frac{\pi R_0^2}{4\sin\theta}\left|\frac{1}{\theta^2} + \frac{1}{(2\pi - \theta)^2}\right| .$$ (45.323)

(g) Finite Range Dipole Scattering. $R_0^2 = \alpha/E$, $(R_c^{\pm})^2 = b^2 \pm R_0^2, (b_0^{\pm})^2 = a^2 \pm R_0^2$.
Repulsion (+): for $b \le a$,

$$\chi(b) = \frac{\pi\left(R_c^+ - b\right)}{R_c^+} + \frac{2b}{R_c^+}\sin^{-1}\left(\frac{R_c^+}{b_0^+}\right)$$

$$- 2\sin^{-1}\left(\frac{b}{a}\right) ,$$ (45.324)

$$\chi(0) = \pi , \quad \chi(b \ge a) = 0 , \quad \sigma = \pi a^2 .$$

Attraction (−): for $b > R_0$,

$$\chi(b) = \frac{\pi\left(R_c^- - b\right)}{R_c^-} + \frac{2b}{R_c^-}\sin^{-1}\left(\frac{R_c^-}{b_0^-}\right)$$

$$- 2\sin^{-1}\left(\frac{b}{a}\right) ,$$ (45.325)

$$\chi(R_0) \to \infty , \quad \chi(b \ge a) = 0 , \quad \sigma = \pi a^2 .$$

(h) Dipole + Hard Sphere Scattering. $R_0^2 = \alpha/E$, $(R_c^{\pm})^2 = b^2 \pm R_0^2, (b_0^{\pm})^2 = a^2 \pm R_0^2$.
Repulsion (+): for $0 \le b \le b_0$,

$$\chi(b) = \frac{\pi\left(R_c^+ - b\right)}{R_c^+} + \frac{2b}{R_c^+}\sin^{-1}\left(\frac{R_c^+}{a}\right)$$

$$- 2\sin^{-1}\left(\frac{b}{a}\right) ,$$ (45.326)

$$b_0 \le b \le a; \quad \chi(b) = \pi - 2\sin^{-1}(b/a) ,$$

$$(45.327)$$

$$\chi(0) = \pi , \quad \chi(b \ge a) = 0 , \quad \sigma = \pi a^2 .$$

$$(45.328)$$

Attraction (−): for $b > R_0$,

$$\chi(b) = \frac{\pi(R_c^- - b)}{R_c^-} + \frac{2b}{R_c^-}\sin^{-1}\left(\frac{R_c^-}{a}\right)$$

$$- 2\sin^{-1}\left(\frac{b}{a}\right) ,$$ (45.329)

$$\chi(b) = \chi_{min} \text{ at } b = a ,$$

$$\chi(0) = \pi , \quad \chi(b \ge a) = 0 , \quad \sigma = \pi a^2 .$$

Orbiting or Spiraling Collisions

From Sect. 45.1.7, the parameters are

Orbiting radius: R_0.
Focusing factor: $F = [1 - V(R_0)/E]$.
Orbiting cross section: $\sigma_{\text{orb}} = \pi R_0^2 F$.

(i) Attractive Power Law Potentials.

$$V_{\text{eff}}(R_0) = (1 - \tfrac{1}{2}n)V(R_0), \quad n > 2,$$

$$R_0(E) = \left(\frac{(n-2)C}{2E}\right)^{1/n}, \quad F = \left(\frac{n}{(n-2)}\right),$$
$$(45.330)$$

$$\sigma_{\text{orb}}(E) = \pi\left(\frac{n}{(n-2)}\right)\left(\frac{(n-2)C}{2E}\right)^{2/n}.$$
$$(45.331)$$

For the case $n = 4$ with $V(R) = -\alpha_d e^2/2R^4$, this gives the Langevin cross section

$$\sigma_L(E) = 2\pi R_0^2 = 2\pi\left(\frac{\alpha_d e^2}{2E}\right)^{1/2} \qquad (45.332)$$

for orbiting collisions, and the Langevin rate

$$k_L = v\sigma_L(E) = 2\pi\left(\alpha_d e^2/M\right)^{1/2}, \qquad (45.333)$$

which is independent of E.

The case $n = 6$ with $V(R) = -C/R^6$ is the van der Waals potential for which

$$\sigma_{\text{orb}}(E) = \frac{3}{2}\pi R_0^2 = \frac{3}{2}\pi (2C/E)^{1/3}. \qquad (45.334)$$

(j) Fixed Dipole plus Polarization Potential.

$$R_0^2(E) = \left(\frac{\alpha_d e^2}{2E}\right)^{1/2}, \qquad (45.335)$$

$$\sigma_{\text{orb}}(E) = 2\pi\left(\frac{\alpha_d e^2}{2E}\right)^{1/2} + \left(\frac{\pi De\cos\theta_d}{E}\right). \qquad (45.336)$$

For a locked-in dipole, the orientation angle is $\theta_d = 0$, and $\sigma_{\text{orb}}(E) > 0$ for all θ_d when $E > E_c = (D^2/2\alpha_d)$.

On averaging over all θ_d from 0 to $\theta_{\max} = \left[\frac{1}{2}\pi + \sin^{-1}\left(2ER_0^2/De\right)\right]$, which satisfies $\sigma_{\text{orb}}(E) > 0$ for all E, then

$$\langle\sigma_{\text{orb}}(E)\rangle_{\theta_d} = \pi\left[\left(\frac{\alpha_d e^2}{2E}\right)^{1/2} + \left(\frac{\alpha_d e^2}{2E_c}\right)^{1/2}\right]$$

$$+ \frac{\pi De}{4E}\left(1 - \frac{E}{E_c}\right) \qquad (45.337a)$$

$$\rightarrow \sigma_L(E) \text{ as } E \rightarrow E_c. \qquad (45.337b)$$

(k) Fixed Dipole + Coulomb Repulsion.

$$R_0^2(E) = e^2/2E. \qquad (45.338)$$

For all E and fixed rotations in the range $0 \le \theta_d \le \theta_{\max} = \cos^{-1}\left(e^2/2De\right)$,

$$\sigma_{\text{orb}}(E) = (\pi De\cos\theta_d)/E - \pi R_0^2(E). \qquad (45.339)$$

(l) Lennard–Jones (n,6).

For the following two interactions, there are two roots of $E = V_{\text{eff}}(R_0) = V(R_0) + \frac{1}{2}R_0 V'(R_0)$. They correspond to stable and unstable circular orbits [with different angular momenta associated with the minimum and maxima of the different $V_{\text{eff}}(R)$]. Analytical expressions can only be derived for the orbiting cross section at the critical energy $E_{\max}$ above which no orbiting can occur.

For the Lennard–Jones $(n, 6)$ potential, orbiting occurs for $E < E_{\max} = 2\epsilon[4/(n-2)]^{6/(n-6)}$. The orbiting radius at $E_{\max}$ is

$$R_0(E_{\max}) = R_e\left[(n-2)/4\right]^{1/(n-6)}.$$

The orbiting cross section at $E_{\max} = 2\epsilon(R_e/R_0)^6$ is

$$\sigma_{\text{orb}}(E_{\max}) = \pi b_0^2(E_{\max}) = \frac{3}{2}\pi R_0^2\left(\frac{n}{n-2}\right). \qquad (45.340)$$

$$n = 12: \quad E_{\max} = 4\epsilon/5, \quad R_0 = 1.165 R_e,$$
$$\sigma_{\text{orb}} = 2.4\pi R_e^2.$$

(m) Polarization (n,4).

As discussed for case (l),

$$E_{\max} = \epsilon\left(\frac{2}{n-2}\right)^{4/(n-4)}, \qquad (45.341)$$

$$R_0(E_{\max}) = R_e\left(\frac{n-2}{2}\right)^{1/(n-4)}, \qquad (45.342)$$

$$\sigma_{\text{orb}}(E_{\max}) = 2\pi R_0^2\frac{n}{(n-2)}, \qquad (45.343)$$

$$n = 12: \quad E_{\max} = \epsilon/\sqrt{5};$$
$$R_0 = 1.22 R_e; \quad \sigma_{\text{orb}} = 3.6\pi R_e^2.$$

Small-Angle Scattering

For the power law potential $V(R) = -C/R^n$, (45.12) can be expanded in powers of $V(R)/E$ to obtain analytic expressions for χ and η_{JB}. The general form is

$$\chi(b) = \sum_{j=1}^{\infty}\left(\frac{V(b)}{E}\right)^j F_j(n) = \frac{2}{k}\frac{\partial\eta}{\partial b}, \qquad (45.344)$$

$$F_j(n) = \frac{\pi^{1/2}\Gamma\left(\frac{1}{2}jn + \frac{1}{2}\right)}{\Gamma(j+1)\Gamma\left(\frac{1}{2}jn - j + 1\right)}. \qquad (45.345)$$

The leading $j = 1$ terms equivalent to (45.16b) are $F_1(n) \equiv F(n)$, as defined following (45.257). Then to first order in V/E,

$$\eta_{\mathrm{JB}} = -\left(\frac{k}{2E}\right)\left(\frac{CF(n)}{n-1}\right)b^{1-n}, \qquad (45.346)$$

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = I_{\mathrm{c}}(\theta) = \left(\frac{CF(n)}{E\theta}\right)^{2/n}\frac{1}{n\theta\sin\theta}. \qquad (45.347)$$

From a log–log plot of $\sin\theta(\mathrm{d}\sigma/\mathrm{d}\Omega)$ versus E, C and n can both be determined.

The integral cross sections for scattering by $\theta \geq \theta_0$ is

$$\sigma(E) = 2\pi\int_{\theta_0}^{\pi} I_{\mathrm{c}}(\theta)\,\mathrm{d}(\cos\theta) = 2\pi\int_0^{b_{\max}} b\,\mathrm{d}b$$

$$= \pi\left(\frac{CF(n)}{E\theta_0}\right)^{2/n}, \qquad (45.348)$$

where θ_0 is the smallest measured scattering angle corresponding to a trajectory with impact parameter, $b_{\max} = [CF(n)/E\theta_0]^{1/n}$. A plot of $\ln\sigma(E)$ versus $\ln E$ is a straight line with slope $(-2/n)$.

The Landau–Lifshitz cross section (45.257) and the Massey–Mohr cross section (45.258) follow from use of the JB phases (45.346).

The diffusion cross section in the Random Phase Approximation (45.49) is

$$\sigma_{\mathrm{d}}(E) = 4\pi\int_0^{b_{\mathrm{c}}}\langle\sin^2\theta/2\rangle b\,\mathrm{d}b, \quad |\chi(b_{\mathrm{c}})| = \frac{2}{\pi}$$

$$= \pi(C/2E)^{2/n}[\pi F(n)]^{2/n}. \qquad (45.349)$$

(n) Multiple–Term Power–Law Potentials.

$$\chi(E, b) = \frac{1}{E}[V_m(b)F(m) - V_n(b)F(n)]. \qquad (45.350)$$

For example a Lennard–Jones $(n, 6)$ potential Table 45.1 has the following features:

Forward Glory: $\chi = 0$ when $b_{\mathrm{g}} = \alpha_n^{1/(n-6)}R_{\mathrm{e}}$,
where $\alpha_n = 6F(n)/[nF(6)]$.
Rainbow: $\mathrm{d}\chi/\mathrm{d}b = 0$ at $b_{\mathrm{r}} = (n\alpha_n/6)^{1/(n-6)}R_{\mathrm{e}}$.

$$\chi_{\mathrm{r}} = -F(n)(\mathcal{E}/E)(R_{\mathrm{e}}/b_{\mathrm{r}})^n, \qquad (45.351)$$

$$\omega_{\mathrm{r}} = \frac{1}{2}\left(\mathrm{d}^2\chi_{\mathrm{r}}/\mathrm{d}b^2\right)_{\mathrm{r}} = \frac{3n}{b_{\mathrm{r}}^2}|\chi(b_{\mathrm{r}})|. \qquad (45.352)$$

(o) Exponential Potential.

$$\eta_{\mathrm{JB}}(E, b) = -\frac{1}{2}kb\frac{V_0}{E}K_1(\alpha b)\,R\to\infty$$

$$-\frac{1}{2}kb\frac{V(b)}{E}\left(\frac{\pi b}{2\alpha}\right)^{1/2}.$$

(p) Screened Coulomb Potential.

$$\chi(E, b) = \alpha\,(V_0/E)\,K_1(\alpha b)$$

$$\xrightarrow{\text{large } b}\left(\frac{1}{2}\pi\alpha b\right)^{1/2}V(b)/E, \qquad (45.353)$$

$$\eta_{\mathrm{JB}}(E, b) = -\frac{k}{2E}V_0 K_0(\alpha b)$$

$$\xrightarrow{\text{large } b} -\frac{k}{2E}V(b)\left(\frac{\pi b}{2\alpha}\right)^{1/2}. \qquad (45.354)$$

(q) Morse Potential.

$$\chi(E, b) = (2\beta b)\left(\frac{\epsilon}{E}\right)\left[e^{2\beta R_{\mathrm{e}}}K_0(2\beta b)\right.$$

$$\left. - e^{\beta R_{\mathrm{e}}}K_0(\beta b)\right]$$

$$\xrightarrow{\text{large } b}(\pi\beta b)^{1/2}\left(\frac{\epsilon}{E}\right)\left[e^{2\beta(R_{\mathrm{e}}-b)}\right.$$

$$\left. -\sqrt{2}e^{\beta(R_{\mathrm{e}}-b)}\right],$$

$$b_{\mathrm{r}} = R_{\mathrm{e}} + (2\beta)^{-1}\ln 2,$$

$$\chi_{\mathrm{r}} = -(\pi\beta b_{\mathrm{r}})^{1/2}(\epsilon/2E),$$

$$\omega_{\mathrm{r}} = \beta^2|\chi_{\mathrm{r}}|R_{\mathrm{e}}^2.$$

Large–Angle Scattering

For power law potentials $V(R) = C/R^n$,

$$\chi(b) = \pi - \sum_{j=1}^n\left(\frac{E}{V(b)}\right)^{(2j-1)/n}G_j(n), \qquad (45.355)$$

$$G_j(n) = \frac{(-1)^{j-1}}{\Gamma(j)\Gamma(k)}\left(\frac{2\pi^{1/2}}{n}\right)\Gamma\left(\frac{2j-1}{n}\right), \qquad (45.356)$$

with $k = [(2j-1)/n] - j - \frac{1}{2}$. For the $j = 1$ term,

$$\chi(b) = \pi - \left(\frac{E}{C}\right)^{1/n}G_1(n)b, \qquad (45.357)$$

$$I_{\mathrm{c}}(\theta) = \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} = \left(\frac{C}{E}\right)^{2/n}G_1^{-2}(n), \qquad (45.358)$$

which is isotropic. Including both $j = 1$ and 2 terms provides a good approximation to the entire repulsive

branch of the deflection function χ. Series (45.355) for large angles and (45.344) for small angles eventually diverge for impact parameters $b < b_c$ and $b > b_c$, respectively, where

$$b_c = n^{1/2} \left(\frac{C}{2E} \right)^{1/n} \frac{|n-2|^{1/n}}{|n-2|^{1/2}} . \tag{45.359}$$

45.5.1 Born Amplitudes and Cross Sections for Model Potentials

$$k^2 = 2ME/\hbar^2 , \quad K = 2k \sin \frac{1}{2}\theta ,$$
$$U_0 = 2MV_0/\hbar^2 , \quad U_0/k^2 = V_0/E .$$

(a) Exponential. $V(R) = V_0 \exp(-\alpha R)$

$$f_B(\theta) = -\frac{2\alpha U_0}{(\alpha^2 + K^2)^2} , \tag{45.360}$$

$$\sigma_B(E) = \frac{16}{3} \pi U_0^2 \left(\frac{3\alpha^4 + 12\alpha^2 k^2 + 16k^4}{\alpha^4 (\alpha^2 + 4k^2)^3} \right) ,$$

$$\xrightarrow{E \to \infty} \frac{4}{3} \pi \left(\frac{V_0}{E} \right) \left(\frac{U_0}{\alpha^4} \right) . \tag{45.361}$$

(b) Gaussian. $V(R) = V_0 \exp\left(-\alpha^2 R^2 \right)$

$$f_B(\theta) = -\left(\frac{\pi^{1/2} U_0}{4\alpha^2} \right) \exp\left(-K^2/4\alpha^2 \right) , \tag{45.362}$$

$$\sigma_B(E) = \left(\frac{\pi^2 U_0}{8\alpha^4} \right) \left(\frac{V_0}{E} \right) \left[1 - \exp\left(-2k^2/\alpha^2 \right) \right] . \tag{45.363}$$

(c) Spherical Well. $V(R) = V_0$ for $R < a$, $V(R) = 0$ for $R > a$

$$f_B(\theta) = -\frac{U_0}{K^3} (\sin Ka - Ka \cos Ka) , \tag{45.364}$$

$$\sigma_B(E) = \frac{\pi}{2} \frac{V_0}{E} (U_0 a^4) \left[1 - (ka)^{-2} + (ka)^{-3} \sin 2ka \right.$$
$$\left. - (ka)^{-4} \sin^2 2ka \right] . \tag{45.365}$$

(d) Screened Coulomb. $V(R) = V_0 \exp(-\alpha R)/R$, $V_0 = Ze^2$, $U_0 = 2Z/a_0$

$$f_B(\theta) = -\frac{U_0}{\alpha^2 + K^2} , \tag{45.366}$$

$$\sigma_B(E) = \frac{4\pi U_0^2}{\alpha^2 (\alpha^2 + 4k^2)} \to \pi \left(\frac{V_0}{E} \right) \left(\frac{U_0}{\alpha^2} \right) . \tag{45.367}$$

When $\alpha \to 0$, then $f_B(\theta) = -U_0/K^2$.

(e) e^-–Atom.

$$V(R) = -Ne^2 \left[Z/a_0 + 1/R \right] \exp(-2ZR/a_0) , \tag{45.368}$$

H(1s): N= 1, Z= 1; He$(1s^2)$: N= 2; Z= 27/16.

$$f_B(\theta) = \frac{2N}{a_0} \left(\frac{2\alpha^2 + K^2}{(\alpha^2 + K^2)^2} \right) , \quad \alpha = 2Z/a_0 , \tag{45.369}$$

$$\sigma_B(E) = \frac{\pi a_0^2 N^2 \left(12Z^4 + 18Z^2 k^2 a_0^2 + 7k^4 a_0^4 \right)}{3Z^2 \left(Z^2 + k^2 a_0^2 \right)^3} . \tag{45.370}$$

Also, f_B decomposes (45.187) as

$$f_B(K) = f_B^{eZ}(K) + f_B^{ee}(K) F(K) , \tag{45.371}$$

where f_B^{ij} are two-body Coulomb amplitudes for (i, j) scattering, and where

$$F(K) = \int |\Psi_0(\mathbf{R})|^2 \exp(i\mathbf{K} \cdot \mathbf{R}) \, d\mathbf{R} \tag{45.372}$$

is the elastic form factor.

(f) Dipole. $V(R) = V_0/R^2$.

$$f_B(\theta) = \pi U_0/2K . \tag{45.373}$$

(g) Polarization potential. $V(R) = V_0/\left(R^2 + R_0^2 \right)^2$

$$f_B(\theta) = -\frac{1}{4}\pi \left(\frac{U_0}{R_0} \right) \exp(-KR_0) , \tag{45.374}$$

$$\sigma_B(E) = \left(\frac{\pi^3 U_0}{32 R_0^4} \right) \left(\frac{V_0}{E} \right) [1 - (1 + 4kR_0) \exp(-4kR_0)] . \tag{45.375}$$

46. Orientation and Alignment in Atomic and Molecular Collisions

This chapter deals with the concepts of orientation and alignment in atomic and molecular physics. The terms refer to parameters related to the shape and dynamics of an excited atomic or molecular level, as it is manifested in a nonstatistical population of the magnetic sublevels. To take full advantages of the possibilities of this approach, one utilizes "third generation experiments", i. e., scattering experiments which exploit the planar scattering symmetry, contrary to an angular differential cross section determination (a "second generation experiment") having cylindrical symmetry, or a total cross section measurement (a "first generation experiment") integrating over all scattering angles. In this way one is often able to probe atomic collision theories at a more fundamental level, and in favorable cases approach a "perfect scattering experiment" in which the complex quantal scattering amplitudes are completely determined. This term was coined by *Bederson* [46.1] and has since served as an ideal towards which scattering experiments attempt to strive.

The study of anisotropies has a long history in atomic physics, with light polarization, or Stokes parameter analysis, as a prominent example. A pioneering review by *Fano* and *Macek* [46.2] laid the mathematical and conceptual foundation for most of the later work. Advances in coincidence techniques, laser preparation methods, and development of efficient sources for polarized electrons [46.3] have boosted the field further. Parallel developments of powerful computational codes have enabled a matching theoretical effort. In this way, detailed insights into the collision dynamics have been obtained, such as the locking radius model for low energy atomic collisions, propensity rules for orientation in fast electronic and atomic colli-

sions, and spin effects in polarized electron-heavy atom scattering. Presentations of these developments are contained in [46.4] and Chapts. 37, 50, 51, 63, 64, and 66. A comprehensive and critical review of the literature and the mathematical formalism was initiated by NIST [46.5–7].

Space limitations allow only presentation of the formalism for the simplest case of excitation. Recent developments in the description of processes involving polarized beams are included. The presentation is restricted to atomic outer-shell excitation. Other reviews describe excitation of inner shells [46.8] and molecular levels [46.9]. Related material on density matrices is contained in Chapt. 7 [46.10].

46.1 Collisions Involving Unpolarized Beams

46.1.1 The Fully Coherent Case

Consider first the simplest nontrivial case of S → P excitation. A general property of an atomic collision is that the total reflection symmetry with respect to the scattering plane of the total wave function describing the system is conserved. In simple cases, such as electron impact excitation of He singlet states, or atom excitation by fast, heavy particle impact, the projectile acts as a structureless particle, with only the target atom changing its quantum state. In this case, the reflection symmetry of the target wave function alone is conserved.

Figure 46.1 shows the angular parts of the simplest $|lm\rangle$ states with $l = 0, 1, 2$. The arrows indicate how the two families of states with positive or negative reflection symmetry may couple internally. Thus, in an S → P transition, an atom initially in an S-state may be excited to the (p_{+1}, p_{-1}) subspace, while the p_0 state is not accessible. A characteristic feature of the corresponding electron charge cloud is that it has "zero height", i.e., zero electron density in the direction perpendicular to the scattering plane. Furthermore, the expectation value of the orbital angular momentum has a nonvanishing component in this direction only.

The resulting electron charge cloud may thus have a shape as shown on Fig. 46.2a. We shall now discuss the parametrization of the wave function of this state and analyze the connection between the wave function and the corresponding photon radiation pattern emitted when the state decays back to the initial S-state, using the properties of electric dipole radiation.

Basic Definitions and Coordinate Frames

The coordinate frames of particular use in describing the wave function are as follows. The *collision frame*, (x^c, y^c, z^c), is defined by $\hat{z}^c \parallel k_{in}$ and $\hat{y}^c \parallel k_{in} \times k_{out}$. The *natural frame*, (x^n, y^n, z^n), is defined by $\hat{x}^n \parallel k_{in}$ and $\hat{z}^n \parallel k_{in} \times k_{out}$. Finally, the *atomic frame* is identical to the natural frame, except that the frame is rotated by an angle γ around $z^n = z^a$ such that x^a is parallel to the major symmetry axis of the P-state charge cloud, as shown in Fig. 46.2. Most scattering

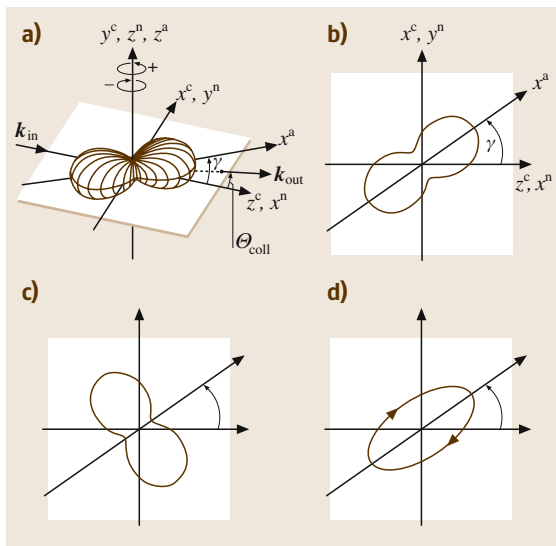
Fig. 46.1 Illustration of the reflection symmetry of the simplest spherical harmonics, corresponding to S, P, and D states


Fig. 46.2 (a) Shows the shape, or the angular part, of a P-state with positive reflection symmetry with respect to the scattering plane. Some relevant coordinate frames are also indicated; **(b)** shows a cut of this shape in the scattering plane. **(c)** is the angular distribution of photons emitted in the scattering plane; **(d)** is the polarization ellipse for light emitted in the direction perpendicular to the plane, as observed from above

calculations use the collision coordinate system as reference frame, while mathematical analysis is often most conveniently performed in the natural frame, where the algebra is particularly simple. Many expressions are even simpler in the atomic frame, but it has the disadvantage that the angle γ varies with collision parameters, such as impact velocity, impact parameter, etc.

The expansion of the P-state wave function in the three coordinate systems is

$$|\Psi\rangle = a_{+1}^c |p_{+1}^c\rangle + a_0^c |p_0^c\rangle + a_{-1}^c |p_{-1}^c\rangle \tag{46.1}$$

$$= a_{+1}^n |p_{+1}^n\rangle + a_{-1}^n |p_{-1}^n\rangle \tag{46.2}$$

$$= a_{+1}^a |p_{+1}^a\rangle + a_{-1}^a |p_{-1}^a\rangle . \tag{46.3}$$

Conservation of reflection symmetry in the scattering plane implies

$$a_{+1}^c = -a_{-1}^c , \tag{46.4}$$

$$a_0^n = 0 , \tag{46.5}$$

$$a_0^a = 0 . \tag{46.6}$$

The normalization condition implies

$$|a_0^c|^2 + 2|a_{+1}^c|^2 = |a_{+1}^n|^2 + |a_{-1}^n|^2 = |a_{+1}^a|^2 + |a_{-1}^a|^2$$
$$= 1 . \tag{46.7}$$

Finally, the a_m coefficients are related to the scattering amplitudes f_m and the differential cross section $\sigma(\theta)$ by

$$a_m = f_m (k_{\text{out}}/k_{\text{in}})^{\frac{1}{2}} \sigma(\theta)^{-\frac{1}{2}} \tag{46.8}$$

$$\sigma(\theta) = (k_{\text{out}}/k_{\text{in}}) \left(|f_0^c|^2 + 2|f_{+1}^c|^2 \right) , \text{ etc.} \tag{46.9}$$

Except for an arbitrary phase factor, the pure state (46.1) may thus be characterized by two dimensionless parameters. Traditionally, they have been chosen as (λ, χ) defined as [46.11]

$$\lambda = \frac{|a_0^c|^2}{|a_0^c|^2 + 2|a_{+1}^c|^2} , \tag{46.10}$$

$$\chi = \arg\left(a_{+1}^c a_0^{c*}\right) . \tag{46.11}$$

An alternative parametrization $(L_\perp, \gamma)$ is given by [46.5]

$$L_\perp = \frac{|a_{+1}^n|^2 - |a_{-1}^n|^2}{|a_{+1}^n|^2 + |a_{-1}^n|^2} , \tag{46.12}$$

$$\gamma = \frac{1}{2} \arg\left(a_{-1}^n a_{+1}^{n*}\right) \pm \frac{\pi}{2} ,$$

$$= -\frac{1}{2}(\delta \pm \pi) , \tag{46.13}$$
Fig. 46.3 Fully coherent S $\rightarrow$ P excitation may be described by two independent scattering amplitudes, characterized by their relative size and phase

with the notation of Fig. 46.3. Referring to the natural coordinate frame, the expectation value of the electronic orbital angular momentum is thus

$$\langle \Psi | L | \Psi \rangle = (0, 0, L_\perp) . \tag{46.14}$$

Coherence Analysis: Stokes Parameters

We now discuss the information obtainable from a polarization analysis of the emitted light. In the notation of classical optics (see, e.g., *Born* and *Wolf* [46.12]) the components of the Stokes vector (P_1, P_2, P_3) measured in the direction $+y^c$ $(+z^n)$ perpendicular to the scattering plane and defined by

$$IP_1 = I(0°) - I(90°) , \tag{46.15}$$

$$IP_2 = I(45°) - I(135°) , \tag{46.16}$$

$$IP_3 = I(\text{RHC}) - I(\text{LHC}) , \tag{46.17}$$

with

$$I = I(0°) + I(90°)$$
$$= I(45°) + I(135°)$$
$$= I(\text{RHC}) + I(\text{LHC}) , \tag{46.18}$$

are given by

$$P_1 = 2\lambda - 1 , \tag{46.19}$$

$$P_2 = -2\sqrt{\lambda(1-\lambda)} \cos\chi , \tag{46.20}$$

$$P_3 = 2\sqrt{\lambda(1-\lambda)} \sin\chi , \tag{46.21}$$

or, alternatively,

$$P_1 = P_l \cos 2\gamma , \tag{46.22}$$

$$P_2 = P_l \sin 2\gamma , \tag{46.23}$$

$$P_3 = -L_\perp , \tag{46.24}$$

with

$$P_l = \sqrt{P_1^2 + P_2^2} . \tag{46.25}$$

Here, $I(\theta)$ is the intensity transmitted through an ideal linear polarizer with transmission direction tilted by an angle θ with respect to the z^c or x^n direction. Similarly, RHC (LHC) refers to photons with negative (positive) helicity. Inspection of (46.19) to (46.25) shows that determination of the Stokes vector in the direction perpendicular to the collision plane determines the wave function (46.1) completely. A determination of the Stokes vector thus constitutes a "perfect scattering experiment".

The Stokes vector (P_1, P_2, P_3) is a unit vector characterizing the state $|\Psi\rangle$, and it may be represented by a point on the Poincaré sphere, see Fig. 46.4.

Correlation Analysis

Another experimental approach is to map the angular distribution of the photons emitted in the subsequent S $\rightarrow$ P decay. For this purpose we first note that the angular part $\Upsilon(\theta, \phi)$ of the electron probability density $\langle\Psi|\Psi\rangle$ corresponding to the wave function (46.1) may be written as

$$\Upsilon(\theta, \phi) = \frac{1}{2}[1 + P_l \cos 2(\phi - \gamma)]\sin^2\theta . \quad (46.26)$$

Figure 46.2(b) shows a cut of this charge cloud in the scattering plane,

$$\Upsilon\left(\frac{1}{2}\pi, \phi\right) = \frac{1}{2}[1 + P_l \cos 2(\phi - \gamma)] . \quad (46.27)$$
Fig. 46.4 The Poincaré sphere. The Stokes vector for a pure state $|\Psi\rangle$ corresponds to a characteristic polarization ellipse, represented by a point on the unit sphere

The relative length, l, and width, w of the charge cloud are given by

$$l = \frac{1}{2}(1 + P_l) , \quad (46.28)$$

$$w = \frac{1}{2}(1 - P_l) . \quad (46.29)$$

The degree of linear polarization P_l is thus a measure of the shape of the charge cloud, since

$$P_l = \frac{l - w}{l + w} . \quad (46.30)$$

According to the properties of electric dipole radiation, the pattern $I(\phi)$ in the scattering plane is

$$I(\phi) = \frac{1}{2}[1 - P_l \cos 2(\phi - \gamma)] . \quad (46.31)$$

A mapping of the radiation pattern in the collision plane determines γ and P_l, and thereby the absolute value of the angular momentum by

$$|L_\perp| = \sqrt{1 - P_l^2} . \quad (46.32)$$

However, the sign of $L_\perp$ cannot be determined by correlation analysis, and this approach accordingly does not qualify for classification as "a perfect scattering experiment".

Density Matrix Representation

Recalling that $\rho_{mn} = a_m a_n^*$, the density matices in the various basis sets introduced above are

$$\rho^c = \frac{1}{\sqrt{8}}\begin{pmatrix} \frac{1}{\sqrt{2}}(1-P_1) & -P_2+iP_3 & -\frac{1}{\sqrt{2}}(1-P_1) \\ -P_2-iP_3 & \sqrt{2}(1+P_1) & P_2+iP_3 \\ -\frac{1}{\sqrt{2}}(1-P_1) & P_2-iP_3 & \frac{1}{\sqrt{2}}(1-P_1) \end{pmatrix} , \quad (46.33)$$

$$\rho^n = \frac{1}{2}\begin{pmatrix} 1+L_\perp & 0 & -P_l\,e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l\,e^{2i\gamma} & 0 & 1-L_\perp \end{pmatrix} , \quad (46.34)$$

$$\rho^a = \frac{1}{2}\begin{pmatrix} 1+L_\perp & 0 & -P_l \\ 0 & 0 & 0 \\ -P_l & 0 & 1-L_\perp \end{pmatrix} . \quad (46.35)$$

The density matrices illustrate the algebraic simplifications obtained using the natural coordinate frame. In the following, this frame will be used unless otherwise stated, and we therefore suppress the superscript n below.

Postcollisional Depolarization due to Fine Structure and Hyperfine Structure Effects

After the collision, the isolated atom evolves under the influence of internal forces, such as fine structure and hyperfine structure, until the optical decay. While typical collision times are of the order 10^{-15} s, the light emission occurs after a time interval of 10^{-9} s. This is long compared with the Larmor precession time of the electron spin ($\sim 10^{-12}$ s) and one can thus assume that the atom has completely relaxed into, e.g., its $^2P_{1/2}$ and $^2P_{3/2}$ states before the photon emission. For the simplest nontrivial case of electron spin $S = \frac{1}{2}$, the Stokes vector $\boldsymbol{P}(S)$ of the subsequent $^2P \to {}^2S$ transition is modified to become

$$P_{1,2}\left(\frac{1}{2}\right) = \frac{3}{7}P_{1,2}(0) , \qquad (46.36)$$

$$P_3\left(\frac{1}{2}\right) = P_3(0) , \qquad (46.37)$$

and the Stokes vector is thus no longer a unit vector. In general, the Stokes vector components are reduced by depolarization factors c_i (a table of c_i coefficients for the most common values of electron and nuclear spin is given in Appendix B of [46.5])

$$P_i(S) = c_i P_i(0) . \qquad (46.38)$$

This suggests introduction of *reduced polarizations*

$$\overline{P}_i = P_i(S)/c_i . \qquad (46.39)$$

The *reduced* Stokes vector $(\overline{P}_1, \overline{P}_2, \overline{P}_3)$ is again a unit vector, and the formalism developed above for the spinless case can then be applied. We shall assume that this correction has been made, and the "bar" will be dropped.

46.1.2 The Incoherent Case with Conservation of Atomic Reflection Symmetry

The picture outlined above has to be modified in cases where the experiment sums over several, in principle distinguishable, channels, each of which, however, conserves reflection symmetry. Prototype examples are electron impact excitation of hydrogen or light alkali atoms. Here, the excitation process is described by singlet and triplet scattering amplitudes respectively, and we have the possibility of direct and exchange scattering. This doubles the number of scattering amplitudes from two to four. The experimental results are thus an incoherent sum over these channels (singlet and triplet), the unraveling of which would require application of spin-polarized beams, see Sect. 46.2. The atomic P-state can no longer be described as a single pure state, (46.1), but as a mixed state (Chapt. 7). The expressions (46.33) to (46.35) for the density matrix are unchanged, but the matrix elements are now sums of the contributions from the individual channels (We shall discuss its decomposition below). P_l and $L_\perp$ are now independent quantities, and the (reduced) Stokes vector $\boldsymbol{P}$ is generally no longer a unit vector. The degree of polarization P may thus be less than one, i.e.,

$$P^2 = P_1^2 + P_2^2 + P_3^2 = P_l^2 + L_\perp^2 \leq 1 . \qquad (46.40)$$

For electron impact excitation, deviation of the parameter P from unity may thus serve as a measure of the effect of electron exchange. We have accordingly three independent observables, e.g., $(L_\perp, \gamma, P_l)$. This set of variables is frame-independent. A photon correlation experiment in the scattering plane may extract the (γ, P_l) pair, while coherence analysis in the z direction provides the complete set. An alternative set of (frame-dependent) parameters used in particular for hydrogen is (λ, R, I), with

$$\lambda = \frac{1}{2}(1 + P_1) , \qquad (46.41)$$

$$R = -\frac{1}{\sqrt{8}} P_2 , \qquad (46.42)$$

$$I = \frac{1}{\sqrt{8}} P_3 . \qquad (46.43)$$

46.1.3 The Incoherent Case without Conservation of Atomic Reflection Symmetry

In the general case, the assumption of positive reflection symmetry with respect to the scattering plane for the wave function of the excited atom cannot be maintained. For example, for electron impact excitation of a P-state of a heavy atom, spin-orbit effects may be so strong that they flip the electron spin, thereby allowing population of the $|p_0^n\rangle$ state. Thus, the total number of scattering amplitudes is now six. Typical examples are mercury, or the heavy noble gases. The total angular momentum of the excited state is $J = 1$, the fine structure being completely resolved in these cases. Strictly speaking, the density matrix elements no longer describe the electronic charge cloud, but rather the excited state ($J = 1$) distribution. Similarly, $L_\perp$ should be

replaced by $J_\perp$, but for simplicity we keep the notation. This state radiates as a set of classical oscillators, completely analogous to the $^1P_1$ state described above, so we shall maintain our previous notation, simply replacing the term charge cloud density by oscillator density. The main difference from the cases considered above is that the density now displays a height, see Fig. 46.5.

Blum, *da Paixão* and collaborators, [46.13, 14], were the first to formulate a parametrization of the general case. Here, we shall use as starting point the expression for the density matrix in the natural frame and decompose it into the two terms with positive and negative reflection symmetry, respectively,

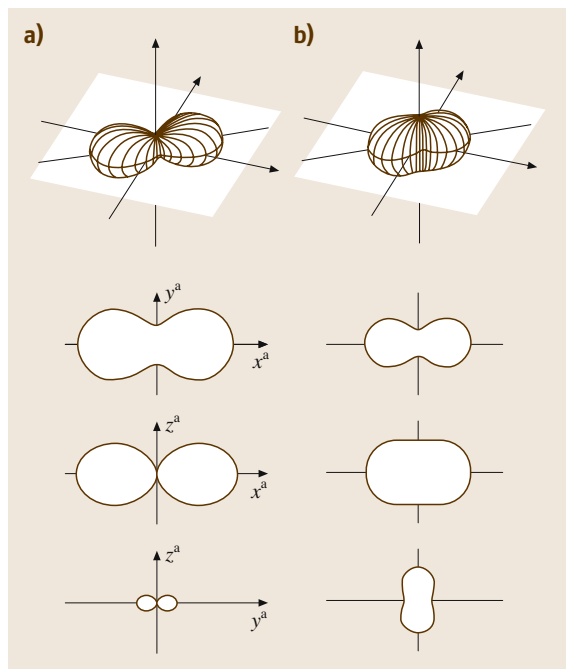
$$\rho^n = (1-h)\frac{1}{2}\begin{pmatrix} 1-P_3 & 0 & -P_l^+ \, e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l^+ \, e^{2i\gamma} & 0 & 1+P_3 \end{pmatrix}$$
$$+ h \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} , \tag{46.44}$$


Fig. 46.5 The *top row* shows classical oscillator densities for height parameters $h = 0$ and $h = 1/3$, respectively. The alignment angle is $\gamma = 35°$ and $P_l^+ = 0.6$ in both cases. *Below* are shown cuts along the symmetry axes

where the linear polarization P_l^+ is labeled with a "+" referring to the positive reflection symmetry. Similarly, we define

$$L_\perp^+ \equiv -P_3 , \tag{46.45}$$
$$P^{+2} \equiv P_1^2 + P_2^2 + P_3^2 \le 1 . \tag{46.46}$$

The shape of the density is now characterized by the three parameters

$$l = (1-h)\frac{1}{2}(1+P_l) , \tag{46.47}$$
$$w = (1-h)\frac{1}{2}(1-P_l) , \tag{46.48}$$
$$h = \rho_{00} , \tag{46.49}$$

with $l + w + h = 1$. There are thus four independent observables, chosen as $(L_\perp^+, \gamma, P_l^+, h)$. Again, this set of variables is frame-independent. Determination of the height parameter evidently requires observation from a direction other than the z^n-direction. Traditionally, the Stokes parameter $(P_4, 0, 0)$ is measured from the y^n-direction to obtain

$$h = \frac{(1+P_1)(1-P_4)}{4-(1-P_1)(1-P_4)} . \tag{46.50}$$

Thus, all four parameters may be obtained from analysis of the light coherence, but two directions of observation are necessary. Similarly, photon correlation analysis in two planes are required to extract (γ, P_l^+, h), see, e.g., [46.5] for a discussion.

The various cases with unpolarized beams discussed in this Section are summarized in Table 46.1.

Table 46.1 Summary of cases of increasing complexity, and the orientation and alignment parameters necessary for unpolarized beams. N_p is the number of independent parameters, and N_d is the number of observation directions required

Variable	Sect. 46.1.1	Sect. 46.1.2	Sect. 46.1.3
Forces	Coulomb	+exchange	+spin–orbit
Representation	wave func.	ρ_{mn}	ρ_{mn}
Refl. symmetry	+	+	+, −
Ang. mom.	$L_\perp$	$L_\perp$	$L_\perp^+$
Align. angle	γ	γ	γ
Linear pol.	P_l	P_l	P_l^+
Degree of pol.	$P = 1$	$P \le 1$	$P^+ \le 1$
Height	$h = 0$	$h = 0$	$h \ge 0$
N_p	2	3	4
N_d	1	1	2

46.2 Collisions Involving Spin–Polarized Beams

In this section we discuss the additional information that can be gained by application of a polarized beam compared with an unpolarized beam. Collisions with polarized electron beams are discussed in particular, but most of the ideas presented are easily generalized to beams of atoms in polarized, or otherwise prepared, states. We shall keep the order of increasing complexity introduced in the previous section.

46.2.1 The Fully Coherent Case

As seen in Sect. 46.1.2, a simple example of a fully coherent excitation process is He $1\,{}^1\mathrm{S} \to n\,{}^1\mathrm{P}$ excitation, for which complete information can be obtained from experiments using unpolarized beams. Consequently, in this case application of polarized electrons will add nothing new. Also, the polarization of the scattered electron can be trivially predicted, since no change is possible in the scattering process.

46.2.2 The Incoherent Case with Conservation of Atomic Reflection Symmetry

The targets of interest here are hydrogen or light alkali atoms with an electron spin $S = \frac{1}{2}$. Since we now have the possibility of triplet (t) and singlet (s) scattering, this doubles the number of scatter-

ing amplitudes from two to four (recall that $f_0 = 0$) see Fig. 46.6.

The amplitudes of interest are

$$f_{+1}^{\mathrm{t}} = \alpha_+ \, \mathrm{e}^{\mathrm{i}\phi_+} \, , \tag{46.51}$$

$$f_{-1}^{\mathrm{t}} = \alpha_- \, \mathrm{e}^{\mathrm{i}\phi_-} \, , \tag{46.52}$$

$$f_{+1}^{\mathrm{s}} = \beta_+ \, \mathrm{e}^{\mathrm{i}\psi_+} \, , \tag{46.53}$$

$$f_{-1}^{\mathrm{s}} = \beta_- \, \mathrm{e}^{\mathrm{i}\psi_-} \, . \tag{46.54}$$

Neglecting an overall phase, seven independent parameters are needed to characterize the amplitudes completely. Traditionally, one is chosen as the differential cross section σ_{u} corresponding to unpolarized particles. Six additional dimensionless parameters may be defined: three to characterize the relative lengths of the four vectors, and three to define their relative phase angles.

The density matrix is parametrized, in analogy to the unpolarized beam case, according to [46.15]

$$\rho^{\mathrm{t}} = \sigma^{\mathrm{t}} \frac{1}{2} \begin{pmatrix} 1 + L_\perp^{\mathrm{t}} & 0 & -P_l^{\mathrm{t}} \, \mathrm{e}^{-2\mathrm{i}\gamma^{\mathrm{t}}} \\ 0 & 0 & 0 \\ -P_l^{\mathrm{t}} \, \mathrm{e}^{2\mathrm{i}\gamma^{\mathrm{t}}} & 0 & 1 - L_\perp^{\mathrm{t}} \end{pmatrix} \, , \tag{46.55}$$

$$\rho^{\mathrm{s}} = \sigma^{\mathrm{s}} \frac{1}{2} \begin{pmatrix} 1 + L_\perp^{\mathrm{s}} & 0 & -P_l^{\mathrm{s}} \, \mathrm{e}^{-2\mathrm{i}\gamma^{\mathrm{s}}} \\ 0 & 0 & 0 \\ -P_l^{\mathrm{s}} \, \mathrm{e}^{2\mathrm{i}\gamma^{\mathrm{s}}} & 0 & 1 - L_\perp^{\mathrm{s}} \end{pmatrix} \, , \tag{46.56}$$

where

$$\sigma^{\mathrm{t}} = \alpha_+^2 + \alpha_-^2 \, , \tag{46.57}$$

$$\sigma^{\mathrm{s}} = \beta_+^2 + \beta_-^2 \, , \tag{46.58}$$

$$L_\perp^{\mathrm{t}} = \frac{1}{\sigma^{\mathrm{t}}} \left(\alpha_+^2 - \alpha_-^2 \right) \, , \tag{46.59}$$

$$L_\perp^{\mathrm{s}} = \frac{1}{\sigma^{\mathrm{s}}} \left(\beta_+^2 - \beta_-^2 \right) \, , \tag{46.60}$$

$$P_l^{\mathrm{t}} \, \mathrm{e}^{2\mathrm{i}\gamma^{\mathrm{t}}} = P_1^{\mathrm{t}} + \mathrm{i}\, P_2^{\mathrm{t}} = -\frac{2\alpha_+\alpha_-}{\sigma^{\mathrm{t}}} \, \mathrm{e}^{-\mathrm{i}\delta^{\mathrm{t}}} \, , \tag{46.61}$$

$$P_l^{\mathrm{s}} \, \mathrm{e}^{2\mathrm{i}\gamma^{\mathrm{s}}} = P_1^{\mathrm{s}} + \mathrm{i}\, P_2^{\mathrm{s}} = -\frac{2\beta_+\beta_-}{\sigma^{\mathrm{s}}} \, \mathrm{e}^{-\mathrm{i}\delta^{\mathrm{s}}} \, . \tag{46.62}$$

In the case of an unpolarized beam, the total density matrix becomes the weighted sum of the two matrices

Fig. 46.6 For ${}^2\mathrm{S} \to {}^2\mathrm{P}$ electron impact excitation of hydrogen or light alkali atoms, four scattering amplitudes come into play

ρ^s and ρ^t, i.e.,

$$\rho_u = \sigma_u \frac{1}{2} \begin{pmatrix} 1+L_\perp & 0 & -P_l\, e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l\, e^{2i\gamma} & 0 & 1-L_\perp \end{pmatrix}$$

$$= 3w^t \sigma_u \frac{1}{2} \begin{pmatrix} 1+L_\perp^t & 0 & -P_l^t\, e^{-2i\gamma^t} \\ 0 & 0 & 0 \\ -P^{t_l}\, e^{2i\gamma^t} & 0 & 1-L_\perp^t \end{pmatrix}$$

$$+ w^s \sigma_u \frac{1}{2} \begin{pmatrix} 1+L_\perp^s & 0 & -P_l^s\, e^{-2i\gamma^s} \\ 0 & 0 & 0 \\ -P_l^s\, e^{2i\gamma^s} & 0 & 1-L_\perp^s \end{pmatrix}$$

(46.63)

where

$$w^t = \frac{\sigma^t}{\sigma^s+3\sigma^t} = \frac{\sigma^t}{4\sigma_u} , \tag{46.64}$$

$$w^s = \frac{\sigma^s}{\sigma^s+3\sigma^t} = \frac{\sigma^s}{4\sigma_u} = 1-3w^t , \tag{46.65}$$

$$\sigma_u = (3w^t+w^s)\sigma_u = \frac{3}{4}\sigma^t + \frac{1}{4}\sigma^s . \tag{46.66}$$

The six parameters σ_u, w^t, $L_\perp^t$, $L_\perp^s$, γ^t, and γ^s have now been introduced, leaving one parameter still to be chosen. Inspection of Fig. 46.6 suggests, for example, the angle Δ^+. The fourth angle, Δ^-, is then fixed through the relation

$$\Delta^+ - \Delta^- = \delta^t - \delta^s = 2\left(\gamma^s - \gamma^t\right) . \tag{46.67}$$

The following set of six dimensioness parameters is thus complete:

$$w^t, L_\perp^t, L_\perp^s, \gamma^t, \gamma^s, \Delta^+ . \tag{46.68}$$

Detailed recipes for extraction of the parameters from coherence experiments are somewhat complicated, and we refer to discussions in the literature [46.7, 15, 16]. Using spin-polarized electrons and spin-polarized targets, all parameters may be determined, except for information about singlet-triplet phase differences, such as Δ^+.

The reduced Stokes vector P of the unpolarized beam experiment is given by the singlet and triplet (unit) Stokes vectors $P^{s,t}$ as

$$P = 3w^t P^t + w^s P^s , \tag{46.69}$$

from which the set of parameters $(L_\perp, \gamma, P_l)$ for the unpolarized beam experiment may be evaluated from

$$L_\perp = 3w^t L_\perp^t + w^s L_\perp^s , \tag{46.70}$$

$$P_l\, e^{2i\gamma} = 3w^t P_l^t\, e^{2i\gamma^t} + w^s P_l^s\, e^{2i\gamma^s}. \tag{46.71}$$

Since in general, $L_\perp^t \neq L_\perp^s$ and $\gamma^t \neq \gamma^s$, this causes the (reduced) degree of polarization P to be smaller than unity.

To summarize this section, Stokes parameter analysis may provide five dimensionless parameters, the relative phase between the two f_{+1}^t and f_{-1}^t amplitudes and the relative phase between the two f_{+1}^s and f_{-1}^s amplitudes, as well as the relative sizes of all four amplitudes. However, none of the relative phases between any triplet and singlet amplitude can be determined, and coherence analysis alone is thus not able to provide a "perfect scattering experiment". The missing phase may be extracted from the STU parameters of the scattered electron, ([46.16, 17] and Chapt. 7).

46.2.3 The Incoherent Case without Conservation of Atomic Reflection Symmetry

The results of coherence analysis of a $J = 0^e \to J = 1^o$ transition will now be discussed. We only analyze the photon polarization in the exit channel, not the electron spin parameters. There are six independent scattering amplitudes for a $J = 0 \to J = 1$ transition (Fig. 46.7), thereby requiring the determination of one absolute differential cross section, five relative magnitudes, and another five relative phases of the scattering amplitudes.

This large number of independent parameters leads to considerable complications. Nevertheless, the
Fig. 46.7 For $J = 0 \to J = 1$ electron impact excitation of heavy atoms six scattering amplitudes come into play since spin-flip may occur

natural coordinate system enables disentangling of the scattering amplitudes and generalization of the parametrization of the density matrix for the case of unpolarized beams in a straightforward way [46.7, 18]. The nonvanishing amplitudes $f^n(M_f, m_f, m_i)$ in the natural frame (Fig. 46.7) for a $J = 0 \rightarrow J = 1$ transition are

$$f^n\left(1, \frac{1}{2}, \frac{1}{2}\right) \equiv f_{+1}^\uparrow = \alpha_+ \, e^{i\phi_+} , \qquad (46.72)$$

$$f^n\left(1, -\frac{1}{2}, -\frac{1}{2}\right) \equiv f_{+1}^\downarrow = \beta_+ \, e^{i\psi_+} , \qquad (46.73)$$

$$f^n\left(-1, \frac{1}{2}, \frac{1}{2}\right) \equiv f_{-1}^\uparrow = \alpha_- e^{i\phi_-} , \qquad (46.74)$$

$$f^n\left(-1, -\frac{1}{2}, -\frac{1}{2}\right) \equiv f_{-1}^\downarrow = \beta_- \, e^{i\psi_-} , \qquad (46.75)$$

$$f^n\left(0, \frac{1}{2}, -\frac{1}{2}\right) \equiv f_0^\downarrow = \beta_0 \, e^{i\psi_0} , \qquad (46.76)$$

$$f^n\left(0, -\frac{1}{2}, \frac{1}{2}\right) \equiv f_0^\uparrow = \alpha_0 e^{i\phi_0} , \qquad (46.77)$$

where we have omitted $J_i = M_i = 0$ and $J_f = 1$. Equations (46.72–46.75) represent noflip amplitudes that leave the projectile spin unchanged while (46.76) and (46.77) describe the cases where the electron spin is flipped.

We first assume a polarization perpendicular to the scattering plane, i.e., along the z-direction. In (46.44), the density matrix for heavy atoms such as Xe or Hg was decomposed into a pair of matrices with one having positive reflection symmetry with respect to the scattering plane and the other one having negative reflection symmetry, respectively. The extension of this decomposition to the case of polarized electron beams is a pair of density matrices, one for spin-up electron impact excitation and one for spin-down excitation where "up" and "down" correspond to the initial spin component orientation with respect to the scattering plane. Hence,

$$\rho_u$$

$$= \sigma_u \left[(1 - h) \frac{1}{2} \begin{pmatrix} 1 + L_\perp^+ & 0 & -P_l^+ \, e^{-2i\gamma} \\ 0 & 0 & 0 \\ -P_l^+ \, e^{2i\gamma} & 0 & 1 - L_\perp^+ \end{pmatrix} \right.$$

$$\left. + h \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \right]$$

$$= w^\uparrow \rho^\uparrow + w^\downarrow \rho^\downarrow$$

$$= w^\uparrow \sigma_u \left[(1 - h^\uparrow) \frac{1}{2} \right.$$

$$\times \begin{pmatrix} 1 + L_\perp^{+\uparrow} & 0 & -P_l^{+\uparrow} \, e^{-2i\gamma^\uparrow} \\ 0 & 0 & 0 \\ -P_l^{+\uparrow} \, e^{2i\gamma^\uparrow} & 0 & 1 - L_\perp^{+\uparrow} \end{pmatrix}$$

$$\left. + h^\uparrow \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \right]$$

$$+ w^\downarrow \sigma_u \left[(1 - h^\downarrow) \frac{1}{2} \right.$$

$$\times \begin{pmatrix} 1 + L_\perp^{+\downarrow} & 0 & -P_l^{+\downarrow} \, e^{-2i\gamma^\downarrow} \\ 0 & 0 & 0 \\ -P_l^{+\downarrow} \, e^{2i\gamma^\downarrow} & 0 & 1 - L_\perp^{+\downarrow} \end{pmatrix}$$

$$\left. + h^\downarrow \begin{pmatrix} 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{pmatrix} \right] . \qquad (46.78)$$

Here we have defined

$$L_\perp^{+\uparrow} = \frac{\alpha_+^2 - \alpha_-^2}{\alpha_+^2 + \alpha_-^2} = -P_3^\uparrow , \qquad (46.79)$$

$$L_\perp^{+\downarrow} = \frac{\beta_+^2 - \beta_-^2}{\beta_+^2 + \beta_-^2} = -P_3^\downarrow , \qquad (46.80)$$

$$P_l^{+\uparrow} \, e^{2i\gamma^\uparrow} = P_1^\uparrow + iP_2^\uparrow = -\frac{2\alpha_+\alpha_- \, e^{i(\phi_- - \phi_+)}}{\alpha_+^2 + \alpha_-^2} , \qquad (46.81)$$

$$P_l^{+\downarrow} \, e^{2i\gamma^\downarrow} = P_1^\downarrow + iP_2^\downarrow = -\frac{2\beta_+\beta_- \, e^{i(\psi_- - \psi_+)}}{\beta_+^2 + \beta_-^2} , \qquad (46.82)$$

$$\sigma^\uparrow = \alpha_+^2 + \alpha_-^2 + \alpha_0^2 , \qquad (46.83)$$

$$\sigma^\downarrow = \beta_+^2 + \beta_-^2 + \beta_0^2 , \qquad (46.84)$$

$$\sigma_u = \frac{1}{2} \left(\alpha_+^2 + \alpha_-^2 + \alpha_0^2 + \beta_+^2 + \beta_-^2 + \beta_0^2 \right)$$

$$= \frac{1}{2} \left(\sigma^\uparrow + \sigma^\downarrow \right) , \qquad (46.85)$$

$$h^\uparrow = \alpha_0^2/\sigma^\uparrow , \qquad (46.86)$$

$$h^\downarrow = \beta_0^2/\sigma^\downarrow , \qquad (46.87)$$

$$w^\uparrow = \sigma^\uparrow/(2\sigma_u) , \qquad (46.88)$$

$$w^\downarrow = \sigma^\downarrow/(2\sigma_u) = 1 - w^\uparrow . \qquad (46.89)$$

From these definitions it follows that

$$(1-h)\, L_\perp^+ = w^\uparrow \left(1 - h^\uparrow\right) L_\perp^{+\uparrow}$$
$$+ w^\downarrow \left(1 - h^\downarrow\right) L_\perp^{+\downarrow}\,, \quad (46.90)$$

$$(1-h)\, P_l^+ \, e^{2i\gamma} = w^\uparrow \left(1 - h^\uparrow\right) P_l^{+\uparrow}\, e^{2i\gamma^\uparrow}$$
$$+ w^\downarrow \left(1 - h^\downarrow\right) P_l^{+\downarrow}\, e^{2i\gamma^\downarrow}\,, \quad (46.91)$$

$$h = w^\uparrow h^\uparrow + w^\downarrow h^\downarrow$$
$$= (\alpha_0^2 + \beta_0^2)/(2\sigma_u)\,, \quad (46.92)$$

$$P_l^{+\uparrow\,2} + L_\perp^{+\uparrow\,2} = P_l^{+\uparrow\,2} + P_3^{\uparrow\,2} = 1\,, \quad (46.93)$$

$$P_l^{+\downarrow\,2} + L_\perp^{+\downarrow\,2} = P_l^{+\downarrow\,2} + P_3^{\downarrow\,2} = 1\,. \quad (46.94)$$

Extraction of these parameters is facilitated by introduction of "generalized Stoke parameters" [46.18]. In this way, $L_\perp^{+\uparrow}$, $L_\perp^{+\downarrow}$, $\gamma^\uparrow$, $\gamma^\downarrow$ may be determined. If, in addition, h is known, e.g., by polarization analysis in the y-direction, the following set of seven dimensionless independent parameters can be derived from the generalized Stokes parameters in the z-direction:

$$L_\perp^{+\uparrow},\ L_\perp^{+\downarrow},\ h^\uparrow,\ h^\downarrow,\ w^\uparrow; \gamma^\uparrow,\ \gamma^\downarrow\,. \quad (46.95)$$

This leaves three relative phases unknown. In the notation of Fig. 46.7, we see from inspection that

$$\Delta^+ - \Delta^- = \delta^\uparrow - \delta^\downarrow = 2\left(\gamma^\downarrow - \gamma^\uparrow\right)\,, \quad (46.96)$$

in analogy to (46.67). A convenient choice for the remaining phase angles is $\left(\Delta^+,\ \Delta^0,\ \delta^{\uparrow\downarrow}\right)$, with

$$\delta^{\uparrow\downarrow} \equiv \phi_+ - \psi_0\,. \quad (46.97)$$

A complete set of dimensionless independent parameters is then given by

$$(w^\uparrow, L_\perp^{+\uparrow}, L_\perp^{+\downarrow}, h^\uparrow, h^\downarrow, \gamma^\uparrow, \gamma^\downarrow, \Delta^+, \Delta^0, \delta^{\uparrow\downarrow})\,. \quad (46.98)$$

Information about the remaining three phase angles may be obtained in experiments with *in-plane* spin polarization. Further analysis shows that the generalized Stokes parameters in the y (or x) direction with in-plane spin polarization P_y or P_x provides two additional phases. None of the relative phases Δ^+ between $f_{+1}^\uparrow$ and $f_{+1}^\downarrow$, etc. enter. Determination of the final remaining angle requires determination of generalized STU parameters, describing the electron spin in the exit channel.

Table 46.2 summarizes the various cases with polarized beams discussed in this section.

Table 46.2 Summary of cases of increasing complexity for spin-polarized beams. The number of independent dimensionless parameters N_p is listed, along with N_{OA}, the number determined from orientation and alignment only. N_d is the number of observation directions required

Variable	Sect. 46.2.1	Sect. 46.2.2	Sect. 46.2.3
Forces	Coulomb	+exchange	+spin–orbit
Representation	wave func.	$\rho_{mn}^{t,s}$	$\rho_{mn}^{\uparrow,\downarrow}$
Refl. symmetry	+	+	+, −
N_p	2	6	10
N_{OA}	2	5	9
N_d	1	1	2

46.3 Example

46.3.1 The First Born Approximation

As a simple, illustrative example, consider the predictions of the first Born approximation (FBA). Here, S → P excitation by electron impact is described as creation of a pure p-orbital along the direction of the linear momentum transfer $\Delta k = k_{in} - k_{out}$, along which there is axial symmetry. Evidently

$$L_\perp^{FBA} = 0\,, \quad (46.99)$$

and consequently

$$P_l^{FBA} = 1\,. \quad (46.100)$$

The alignment angle is found from simple geometrical considerations, see Fig. 46.8. Denoting the incident

energy by E and the energy loss by ΔE, the relation between the projectile scattering angle Θ_{col} and the alignment angle γ is directly read from the
Fig. 46.8 Diagram for evaluation of the alignment angle γ in the first Born approximation

figure,

$$\tan \gamma^{\text{FBA}} = \frac{\sin \Theta_{\text{col}}}{\cos \Theta_{\text{col}} - x} \, , \qquad (46.101)$$

where $x = [E/(E - \Delta E)]^{1/2}$. For $\Delta E > 0$, γ^{FBA} is always negative, with its minimum value when $\Delta \boldsymbol{k} \perp \boldsymbol{k}_{\text{out}}$. Any theoretical effort beyond the FBA involves serious computations.

46.4 Recent Developments

46.4.1 S → D Excitation

The generalization of the formalism of Sect. 46.2.2 to the case of S → D excitation involves the introduction of three scattering amplitudes, corresponding to a complete parameter set of one cross section, two relative amplitude sizes, and two relative phases. Analysis shows that a full coherence analysis of the light emitted in the subsequent D → P optical decay is not sufficient for a complete experiment, instead two solutions are obtained. A triple coincidence experiment may resolve the ambiguity [46.19].

46.4.2 P → P Excitation

By proper optical preparation of the atomic target, collision studies involving specific excited states may be performed as a function of scattering angle. For collision-induced P → P transitions, a systematic preparation of specific initial P states, combined with Stokes parameter analysis of the radiation pattern from the final P state, may lead to a complete scattering experiment. The corresponding complete set of nine parameters describes the process in terms of five independent

scattering amplitudes. In addition to the charge cloud shape and orientation parameters, three Euler angles are needed to describe the atomic reference frame of the charge cloud with respect to the laboratory frame [46.20].

46.4.3 Relativistic Effects in S → P Excitation

It has been discussed to what extent relativistic effects can be studied for excitation of the two fine structure components of the resonance transitions of heavy alkali atoms, such as Rb or Cs. For electron-impact excitation, standard Stokes parameter analysis turns out to be extremely insensitive to the inclusion of relativistic effects in the numerical treatment, which explains the success of nonrelativistic theories. If spin-polarized electrons are used, either in the incident channel through measurement of spin asymmetries, or in the final channels by performing a time-reversed generalized Stokes parameter experiment with a laser-prepared target and a spin-polarized electron beam, distinct relativistic effects, typically at the 5% level, may be revealed [46.21].

46.5 Summary

A selection of fundamental formulas describing orientation and alignment in atomic collisions is given, with emphasis on the simplest case, S → P excita-

tion. A tutorial introduction to the field with a series of examples and applications may be found in a recent textbook [46.22].

47. Electron–Atom, Electron–Ion, and Electron–Molecule Collisions

This chapter reviews the theory of electron collisions with atoms, ions and molecules. Section 47.1 discusses elastic, inelastic and ionizing collisions with atoms and atomic ions from close to threshold to high energies where the Born series becomes applicable. Section 47.2 extends the theory to treat electron collisions with molecules. Finally in Sect. 47.3 the theory of electron atom collisions in intense laser fields is discussed. This chapter will not present detailed comparisons of theoretical predictions with experiment. Such comparisons are given in recent review articles [47.1–3] and in Chapt. 63.

47.1 Electron–Atom and Electron–Ion Collisions

47.1.1 Low-Energy Elastic Scattering and Excitation

In this section we consider the process

$$e^- + A_i \rightarrow e^- + A_j , \qquad (47.1)$$

where A_i and A_j are bound states of the target atom or ion and where the velocity of the incident or scattered electron is of the same order or less than that of the target electrons actively involved in the collision.

Assume initially that all relativistic effects can be neglected, which restricts the treatment to low-Z atoms and ions. The Schrödinger equation describing the scattering of an electron by a target atom or ion containing N electrons and nuclear charge Z is then

$$H_{N+1}\Psi = E\Psi , \qquad (47.2)$$

where E is the total energy of the system. The $(N+1)$-electron nonrelativistic Hamiltonian H_{N+1} is given in atomic units by

$$H_{N+1} = \sum_{i=1}^{N+1} \left(-\frac{1}{2}\nabla_i^2 - \frac{Z}{r_i} \right) + \sum_{i>j=1}^{N+1} \frac{1}{r_{ij}} , \qquad (47.3)$$

where $r_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$, and $\mathbf{r}_i$ and $\mathbf{r}_j$ are the vector coordinates of electrons i and j relative to the origin of coordinates taken to be the target nucleus, which is assumed to have infinite mass.

The target eigenstates Φ_i and the corresponding eigenenergies w_i satisfy the equation

$$\langle \Phi_i | H_N | \Phi_j \rangle = w_i \delta_{ij} , \qquad (47.4)$$

where H_N is defined by (47.3) with $N + 1$ replaced by N. The calculation of accurate target states is discussed in Chapt. 21. The solution of (47.2), corresponding to the

process (47.1), then has the asymptotic form

$$
\Psi_i \underset{r \to \infty}{\approx} \Phi_i \chi_{\frac{1}{2} m_i} \, \mathrm{e}^{\mathrm{i} k_i z} + \sum_j \Phi_j \chi_{\frac{1}{2} m_j} f_{ji} (\theta, \phi) \, \mathrm{e}^{\mathrm{i} k_j r} .
$$

(47.5)

In (47.5), $\chi_{\frac{1}{2} m_i}$ and $\chi_{\frac{1}{2} m_j}$ are the spin eigenfunctions of the incident and scattered electrons, where the direction of spin quantization is usually taken to be the incident beam direction, and $f_{ji} (\theta, \phi)$ is the scattering amplitude, the spherical polar coordinates of the scattered electron being denoted by r, θ and ϕ. Also the wave numbers k_i and k_j are related to the total energy of the system by

$$
E = w_i + \frac{1}{2} k_i^2 = w_j + \frac{1}{2} k_j^2 .
$$

(47.6)

The outgoing wave term in (47.5) contains contributions from all target states that are energetically allowed; i. e., for which $k_j^2 \geq 0$. If the energy is above the ionization threshold, this includes target continuum states. For an atomic ion, a logarithmic phase factor is also needed as discussed below.

The differential cross section for a transition from an initial state $|i\rangle = \left| k_i, \Phi_i, \chi_{\frac{1}{2} m_i} \right\rangle$ to a final state $|j\rangle = \left| k_j, \Phi_j, \chi_{\frac{1}{2} m_j} \right\rangle$ is given by

$$
\frac{\mathrm{d}\sigma_{ji}}{\mathrm{d}\Omega} = \frac{k_j}{k_i} | f_{ji} (\theta, \phi) |^2 ,
$$

(47.7)

and the total cross section is obtained by averaging over initial spin states, summing over final spin states and integrating over all scattering angles.

In order to solve the Schrödinger equation to obtain the scattering amplitude and cross section at low energies, we make a partial wave expansion of the total wave function

$$
\Psi_j^\Gamma (X_{N+1})
$$

$$
= \mathcal{A} \sum_{i=1}^n \overline{\Phi}_i^\Gamma (x_1, \dots, x_N; \hat{\boldsymbol{r}}_{N+1} \sigma_{N+1})
$$

$$
\times r_{N+1}^{-1} F_{ij}^\Gamma (r_{N+1})
$$

$$
+ \sum_{i=1}^m \chi_i^\Gamma (x_1, \dots, x_{N+1}) \, b_{ij}^\Gamma ,
$$

(47.8)

where $X_{N+1} \equiv x_1, x_2 \cdots x_{N+1}$ represents the space and spin coordinates of all $N+1$ electrons, $x_i \equiv r_i \sigma_i$ represents the space and spin coordinates of the ith electron and $\mathcal{A}$ is the operator that antisymmetrizes the first summation with respect to exchange of all pairs of electrons in accordance with the Pauli exclusion principle. The

channel functions $\overline{\Phi}_i^\Gamma$, assumed to be n in number, are obtained by coupling the orbital and spin angular momenta of the target states Φ_i with those of the scattered electron to form eigenstates of the total orbital and spin angular momenta, their z components and the parity π, where

$$
\Gamma \equiv L M_L S M_S \pi
$$

(47.9)

is conserved in the collision. The square integrable correlation functions χ_i^Γ allow for additional correlation effects not included in the first expansion in (47.8) that goes over a limited number of target eigenstates, and possibly pseudostates.

By substituting (47.8) into the Schrödinger equation (47.2), projecting onto the channel functions $\overline{\Phi}_i^\Gamma$ and onto the square integrable functions χ_i^Γ, and eliminating the coefficients b_{ij}^Γ, we obtain n coupled integrodifferential equations satisfied by the reduced radial functions F_{ij}^Γ representing the motion of the scattered electron of the form

$$
\left(\frac{\mathrm{d}^2}{\mathrm{d}r^2} - \frac{\ell_i (\ell_i + 1)}{r^2} + \frac{2(Z - N)}{r} + k_i^2 \right) F_{ij}^\Gamma (r)
$$

$$
= 2 \sum_\ell \left\{ V_{i\ell}^\Gamma (r) \, F_{\ell j}^\Gamma (r) \right.
$$

$$
\left. + \int_0^\infty \left[K_{i\ell}^\Gamma (r, r') + X_{i\ell}^\Gamma (r, r') \right] F_{\ell j}^\Gamma (r') \, \mathrm{d}r' \right\} .
$$

(47.10)

Here ℓ_i is the orbital angular momentum of the scattered electron, and $V_{i\ell}^\Gamma$, $W_{i\ell}^\Gamma$ and $X_{i\ell}^\Gamma$ are the local direct, nonlocal exchange and nonlocal correlation potentials respectively. If the correlation potential which arises from the χ_i^Γ terms in (47.8) is not included, then (47.10) are called the close coupling equations.

The direct potential can be written as

$$
V_{ij}^\Gamma (r_{N+1})
$$

$$
= \Bigg\langle \overline{\Phi}_i^\Gamma (x_1, \dots, x_N; \hat{\boldsymbol{r}}_{N+1} \sigma_{N+1})
$$

$$
\times \left| \sum_{i=1}^N \frac{1}{r_{iN+1}} - \frac{N}{r_{N+1}} \right|
$$

$$
\times \overline{\Phi}_j^\Gamma (x_1, \dots, x_N; \hat{\boldsymbol{r}}_{N+1} \sigma_{N+1}) \Bigg\rangle ,
$$

(47.11)

where the integral is taken over all electron space and spin coordinates, except the radial coordinate of the

$(N+1)$th electron. This potential has the asymptotic form

$$V_{ij}^\Gamma (r) = \sum_{\lambda=1}^{\lambda\,\mathrm{max}} a_{ij}^\lambda r^{-\lambda-1}, \; r \geq a \qquad (47.12)$$

where a is the range beyond which the orbitals in the target states Φ_i included in the first expansion in (47.8), are negligible. The $\lambda = 1$ term in (47.12) gives rise, in second-order, to the long-range attractive polarization potential

$$V(r) \underset{r\to\infty}{\longrightarrow} -\frac{1}{2}\frac{\alpha}{r^4} \qquad (47.13)$$

seen by an electron incident on an atom. For an s-state atom in a state Φ_0 the dipole polarizability α is given by

$$\alpha = 2\sum_j \frac{\left|\langle\Phi_0|\left(\frac{4\pi}{3}\right)^{1/2}\sum_{i=1}^N r_i Y_{10}(\hat{r}_i)|\Phi_j\rangle\right|^2}{w_j - w_0}.$$

$$(47.14)$$

These long-range potentials have a profound influence on low-energy scattering.

The exchange and correlation potentials, unlike the direct potential, are both nonlocal and the exchange potential vanishes exponentially for large r. Explicit expressions for these potentials are too complicated to write down, except in the case of e^-–H scattering where the direct and exchange potentials were first given by *Percival* and *Seaton* [47.4]. Instead they are determined by general computer programs.

The scattering amplitude and cross section can be obtained by solving (47.10) for all relevant conserved quantum numbers Γ subject to the following K-matrix asymptotic boundary conditions

$$F_{ij}^\Gamma \underset{r\to\infty}{\approx} k_i^{-\frac{1}{2}}\left(\sin\theta_i\delta_{ij} + \cos\theta_i K_{ij}^\Gamma\right),$$

$$\text{open channels } k_i^2 \geq 0$$

$$F_{ij}^\Gamma \underset{r\to\infty}{\approx} 0,$$

$$\text{closed channels } k_i^2 < 0 \qquad (47.15)$$

where

$$\theta_i = k_i r - \frac{1}{2}\ell_i\pi + \frac{z}{k_i}\ln(2k_i r) + \sigma_i \qquad (47.16)$$

with $z = Z - N$, and $\sigma_i = \arg\Gamma(\ell_i + 1 - iz/k_i)$. The S-matrix and T-matrix are related to the K-matrix defined by (47.15) by the matrix equations

$$S^\Gamma = \frac{I + iK^\Gamma}{I - iK^\Gamma}, \quad T^\Gamma = S^\Gamma - I = \frac{2iK^\Gamma}{I - iK^\Gamma},$$

$$(47.17)$$

where the dimensions of the matrices in these equations are $n_a \times n_a$, where n_a is the number of open channels at the energy under consideration for the given Γ. The Hermiticity and time reversal invariance of the Hamiltonian ensures that K^Γ is real and symmetric, and S^Γ is unitary and symmetric.

The scattering amplitude defined by (47.5) can be expressed in terms of the T-matrix elements. For a neutral target,

$$f_{ji}(\theta,\phi) = i\left(\frac{\pi}{k_ik_j}\right)^{\frac{1}{2}}\sum_{\substack{LS\pi\\ \ell_i\ell_j}} i^{\ell_i-\ell_j}(2\ell_i+1)^{\frac{1}{2}}$$

$$\times (L_iM_{L_i}\ell_i 0|L_i\ell_i LM_L)$$

$$\times \left(S_iM_{S_i}\frac{1}{2}m_i|S_i\frac{1}{2}SM_S\right)$$

$$\times (L_jM_{L_j}\ell_j m_{\ell_j}|L_j\ell_j LM_L)$$

$$\times \left(S_jM_{S_j}\frac{1}{2}m_j|S_j\frac{1}{2}SM_S\right)T_{ji}^\Gamma Y_{\ell_jm_{\ell_j}}(\theta,\phi),$$

$$(47.18)$$

which describes a transition from an initial state $\alpha_i L_i S_i M_{L_i} M_{S_i} m_i$ to a final state $\alpha_j L_j S_j M_{L_j} M_{S_j} m_j$, where α_i and α_j represent any additional quantum numbers required to completely define the initial and final states. The corresponding total cross section, obtained by averaging over the initial magnetic quantum numbers, summing over the final magnetic quantum numbers, and integrating over all scattering angles, is

$$\sigma_{\mathrm{tot}}(i\to j) = \frac{\pi}{k_i^2}\sum_{\substack{LS\pi\\ \ell_i\ell_j}}\frac{(2L+1)(2S+1)}{2(2L_i+1)(2S_i+1)}\left|T_{ji}^\Gamma\right|^2,$$

$$(47.19)$$

which describes a transition from an initial target state $\alpha_i L_i S_i$ to a final target state $\alpha_j L_j S_j$. In applications, it is also useful to define a collision strength by

$$\Omega(i,j) = k_i^2(2L_i+1)(2S_i+1)\sigma_{\mathrm{tot}}(i\to j), \qquad (47.20)$$

which is dimensionless and symmetric with respect to interchange of the intial and final states denoted by i and j. For scattering by an ion, the above expression for $f_{ji}(\theta,\phi)$ is modified by the inclusion of the Coulomb scattering amplitude when the initial and final states are identical.

For incident electron energies insufficient to excite the atom or ion, only elastic scattering is possible and the

above expressions simplify. Consider low energy elastic electron scattering by a neutral atom is a ^1S ground state. Then the expression for the scattering amplitude (47.18) reduces to

$$f(\theta) = \frac{1}{2ik} \sum_{\ell=0}^{\infty} (2\ell+1) \left(e^{2i\delta_\ell} - 1 \right) P_\ell (\cos\theta) ,$$

(47.21)

where $\ell \left(= L = \ell_i = \ell_j \right)$ is the angular momentum of the scattered electron, k is its wave number, and the phase shift δ_ℓ can be expressed in terms of the K-matrix, which now has only one element since $n_a = 1$, by

$$\tan \delta_\ell = K_{11}^\Gamma .$$

(47.22)

The corresponding expression for the total cross section is then

$$\sigma_{\text{tot}} = \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (2\ell+1) \sin^2 \delta_\ell .$$

(47.23)

A diffusion, or momentum transfer cross section, can also be defined as

$$\sigma_D = 2\pi \int_0^\pi |f(\theta)|^2 (1 - \cos\theta) \sin\theta \ d\theta$$

$$= \frac{4\pi}{k^2} \sum_{\ell=0}^{\infty} (\ell+1) \sin^2 (\delta_{\ell+1} - \delta_\ell) ,$$

(47.24)

which is important when considering the diffusion of electrons through gases.

At low incident electron energies, the behavior of the phase shift for an atom in a s-state is dominated by the long-range polarization potential (47.13). *O'Malley* et al. [47.5] showed that for s-wave scattering $k \cot \delta_0$ satisfies the effective range expansion

$$k \cot \delta_0 = -\frac{1}{a_s} + \frac{\pi\alpha}{3a_s^2} k$$

$$+ \frac{2\alpha}{3a_s} k^2 \ln \left(\frac{\alpha k^2}{16} \right) + O(k^2) ,$$

(47.25)

where a_s is the scattering length, while for $\ell \geq 1$

$$k^2 \cot \delta_\ell = \frac{8 \left(\ell + \frac{3}{2} \right) \left(\ell + \frac{1}{2} \right) \left(\ell - \frac{1}{2} \right)}{\pi\alpha} + \cdots .$$

(47.26)

It follows that close to threshold, the total elastic cross section has the form

$$\sigma_{\text{tot}} = 4\pi a_s^2 + \frac{8}{3}\pi^2 \alpha a_s k + \cdots .$$

(47.27)

When an electron is elastically scattered by a positive or negative ion, then these formulae for the low-energy behavior of the phase shift are modified. For scattering by a positive ion, *Seaton* [47.6] has shown that

$$\frac{\cot \delta_\ell (k)}{1 - e^{2\pi\eta}} = \cot \left[\pi\mu \left(k^2 \right) \right] ,$$

(47.28)

where $\eta = -z/k$, and where $\mu \left(k^2 \right)$ is the analytic continuation of the quantum defects of the electron–ion bound states to positive energies. This quantum defect theory enables spectroscopic observations of bound state energies to be extrapolated to positive energies to yield electron–ion scattering phase shifts. For a negative ion, where the Coulomb potential is repulsive, the phase shift behaves as

$$\delta_\ell \underset{k\to 0}{\to} \exp(2\pi z/k) ,$$

(47.29)

which vanishes rapidly as k tends to zero since z is now negative.

47.1.2 Relativistic Effects for Heavy Atoms and Ions

As the nuclear charge Z of the target increases, relativistic effects become important even for low energy scattering. There are two ways in which relativistic effects play a role. First, there is a direct effect corresponding to the relativistic distortion of the wave function describing the scattered electron by the strong nuclear Coulomb potential. Second, there is an indirect effect caused by the change in the charge distribution of the target due to the use of relativistic wave functions discussed in Chapt. 22. We will concentrate on the direct effect in this section.

For atoms and ions with small Z, the K-matrices can first be calculated in LS coupling, neglecting relativistic effects. The K-matrices are then recoupled to yield transitions between fine-structure levels. We introduce the pair-coupling scheme

$$\boldsymbol{L}_i + \boldsymbol{S}_i = \boldsymbol{J}_i, \quad \boldsymbol{J}_i + \boldsymbol{\ell}_i = \boldsymbol{K}_i, \quad \boldsymbol{K}_i + \boldsymbol{s} = \boldsymbol{J} ,$$

(47.30)

where $\boldsymbol{J}_i$ is the total angular momentum of the target, $\boldsymbol{\ell}_i$ is the orbital angular momentum of the scattered electron, $\boldsymbol{s}$ is its spin, and $\boldsymbol{J}$ is the total angular momentum, which with the parity π is conserved in the collision.

The transition from *LS* coupling involves the recoupling coefficient

$$\left\langle [(L_i S_i) J_i, \ell_i] K_i, \frac{1}{2}; JM_J | (L_i \ell_i) L, \left(S_i \frac{1}{2}\right) S; JM_J \right\rangle$$

$$= [(2J_i + 1)(2L + 1)(2K_i + 1)(2S + 1)]^{\frac{1}{2}}$$

$$\times W(L\ell_i S_i J_i; L_i K_i) W\left(LJS_i \frac{1}{2}; SK_i\right),$$

(47.31)

and the corresponding *K*-matrix transforms as

$$K_{ij}^{J\pi} = \sum_{LS} \left\langle ((L_i S_i) J_i, \ell_i) K_i, \frac{1}{2}; \right.$$

$$\times JM_J | (L_i \ell_i) L, \left(S_i \frac{1}{2}\right) S; JM_J \right\rangle \times K_{ij}^{\Gamma}$$

$$\times \left\langle (L_j \ell_j) L, \left(S_j \frac{1}{2}\right) S; \right.$$

$$\times JM_J | ((L_j S_j) J_j, \ell_j) K_j, \frac{1}{2}; JM_J \right\rangle .$$

(47.32)

This transformation has been implemented in a computer program by *Saraph* [47.7, 8].

For intermediate-*Z* atoms and ions, relativistic effects can be included by adding terms from the Breit–Pauli Hamiltonian to the nonrelativistic Hamiltonian (*Jones* [47.9], *Scott* and *Burke* [47.10]). We write

$$H_{N+1}^{\mathrm{BP}} = H_{N+1}^{\mathrm{nr}} + H_{N+1}^{\mathrm{rel}}$$

(47.33)

where H_{N+1}^{nr} is defined by (47.3) and H_{N+1}^{rel} consists of one- and two-body relativistic terms. The one-body terms are (Sect. 21.1)

$$H_{N+1}^{\mathrm{mass}} = -\frac{1}{8}\alpha^2 \sum_{i=1}^{N+1} \nabla_i^4 \quad \text{mass-correction term},$$

$$H_{N+1}^{\mathrm{D_1}} = -\frac{1}{8}\alpha^2 Z \sum_{i=1}^{N+1} \nabla_i^2 \left(\frac{1}{r_i}\right)$$

one-body Darwin term,

$$H_{N+1}^{\mathrm{so}} = \frac{1}{2}\alpha^2 \sum_{i=1}^{N+1} \frac{1}{r_i}\frac{\partial V}{\partial r_i} (\boldsymbol{\ell}_i \cdot \boldsymbol{s}_i) \quad \text{spin–orbit term}.$$

The two-body terms are less important and are usually not included in collision calculations.

The modified Schrödinger equation defined by (47.2), with H_{N+1} replaced by H_{N+1}^{BP}, is solved by adopting an expansion similar in form to (47.8), but now using

the pair coupling scheme in the definition of the channel functions and quadratically integrable functions. We then obtain coupled integrodifferential equations similar in form to (47.10), from which the *K*-matrix, *S*-matrix and *T*-matrix can be obtained. The corresponding total cross section in the pair-coupling scheme analogous to (47.19) is

$$\sigma_{\mathrm{tot}}(i \to j)$$

$$= \frac{\pi}{2k_i^2(2J_i + 1)} \sum_{\substack{J\pi \\ K_i K_j \ell_i \ell_j}} (2J + 1) \left|T_{ji}^{J\pi}\right|^2,$$

(47.34)

which describes a transition from an initial target state $\alpha_i J_i$ to a final target state $\alpha_j J_j$. The corresponding collision strength is

$$\Omega(i, j) = k_i^2 (2J_i + 1) \sigma_{\mathrm{tot}}(i \to j) .$$

(47.35)

For high-*Z* atoms and ions, the Dirac Hamiltonian [47.11, 12] (Sect. 47.2)

$$H_{N+1}^{\mathrm{D}} = \sum_{i=1}^{N+1} \left(c\boldsymbol{\alpha} \cdot \boldsymbol{p}_i + \beta'c^2 - \frac{Z}{r_i}\right) + \sum_{i>j=1}^{N+1} \frac{1}{r_{ij}}$$

(47.36)

must be used instead of (47.3), where $\beta' = \beta - 1$ and $\boldsymbol{\alpha}$ and β are the usual Dirac matrices. The expansion of the total wave functions for a particular $JM_J\pi$ takes the general form of (47.8). However, now both the bound orbitals in the target, and correlation functions and the orbitals representing the scattered electron are represented by Dirac orbitals. These are defined in terms of large and small components $P(r)$ and $Q(r)$ by

$$\phi(\boldsymbol{r}, \sigma) = \frac{1}{r}\begin{pmatrix} P_a(r) \chi_{\kappa m}(\hat{\boldsymbol{r}}, \sigma) \\ Q_a(r) \chi_{-\kappa m}(\hat{\boldsymbol{r}}, \sigma) \end{pmatrix}$$

(47.37)

for the bound orbitals, and

$$F(\boldsymbol{r}, \sigma) = \frac{1}{r}\begin{pmatrix} P_c(r) \chi_{\kappa m}(\hat{\boldsymbol{r}}, \sigma) \\ Q_c(r) \chi_{-\kappa m}(\hat{\boldsymbol{r}}, \sigma) \end{pmatrix}$$

(47.38)

for the continuum orbitals, where $a = n\kappa m$, $c = k\kappa m$ and the spherical spinor

$$\chi_{\kappa m}(\hat{\boldsymbol{r}}, \sigma)$$

$$= \sum_{m_\ell m_i} \left(\ell m_\ell \frac{1}{2}m_i | \ell \frac{1}{2} jm\right) Y_{\ell m_\ell}(\theta, \phi) \chi_{\frac{1}{2}m_i}(\sigma) ,$$

(47.39)

where $\kappa = j + \frac{1}{2}$ when $\ell = j + \frac{1}{2}$, and $\kappa = -j - \frac{1}{2}$ when $\ell = j - \frac{1}{2}$. We can now derive coupled integrodifferential equations for the functions $P_c(r)$ and $Q_c(r)$

in a similar way to the derivation of (47.10), except that these are now coupled first-order equations instead of coupled second-order equations. The K-matrix, and hence the S-matrix and T-matrix, can be obtained from the asymptotic form of these equations. The total cross section in the j–j coupling scheme, is then given by (47.34), and the corresponding collision strength is given by (47.35).

47.1.3 Multichannel Resonance Theory

General resonance theories have been developed by *Fano* [47.13, 14], *Feshbach* [47.15, 16], and *Brenig and Haag* [47.17]. They are also discussed in Chapt. 25. Here we will limit our discussion to the effect that resonances have on electron collision cross sections.

Following Feshbach, we introduce the projection operators P and Q, where P projects onto a finite set of low energy channels in (47.8) and Q projects onto the orthogonal space, where we restrict our consideration to the space corresponding to a particular set of conserved quantum numbers Γ. In this space we have

$$P^2 = P, \quad Q^2 = Q, \quad P + Q = 1 . \tag{47.40}$$

The Schrödinger equation (47.2) can then be written as

$$P\,(H - E)\,(P + Q)\,\Psi = 0 \tag{47.41}$$

and

$$Q\,(H - E)\,(P + Q)\,\Psi = 0 \tag{47.42}$$

where we have omitted the subscript $N + 1$ on H and the superscript Γ on Ψ. After solving (47.42) for $Q\Psi$ and substituting into (47.41), we find that

$$P\left(H - PHQ\frac{1}{Q\,(H - E)\,Q}QHP - E\right)P\Psi = 0 , \tag{47.43}$$

where the term

$$V_{\mathrm{op}} = -PHQ\frac{1}{Q\,(H - E)\,Q}QHP , \tag{47.44}$$

called the *optical potential*, allows for propagation in the Q-space channels.

We now introduce the eigenfunctions ϕ_i and eigenvalues ε_i of the operator QHQ by

$$QHQ\phi_i = \varepsilon_i\phi_i . \tag{47.45}$$

It follows that the discrete eigenvalues ε_i each give rise to poles in V_{op} at ε_i. If the energy E is in the neighborhood

of an isolated pole or bound state ε_i, we can rewrite (47.43) as

$$\left(PHP - \sum_{j\neq i} PHQ\frac{|\phi_j\rangle\langle\phi_j|}{\varepsilon_j - E}QHP - E\right)P\Psi$$
$$= PHQ\frac{|\phi_i\rangle\langle\phi_i|}{\varepsilon_i - E}QHP\Psi , \tag{47.46}$$

where the rapidly varying part of the optical potential has been separated and put on the right-hand-side of (47.46). This equation can be solved by introducing the Green's function G_0 and the solutions ψ_{0j} of the operator on the left-hand side of (47.46). We find that the pole term on the right-hand side of this equation gives rise to a Feshbach resonance whose position is

$$E_i = \varepsilon_i + \Delta_i - \frac{1}{2}i\Gamma_i = E_{i,\mathrm{r}} - \frac{1}{2}i\Gamma_i , \tag{47.47}$$

is where the resonance shift

$$\Delta_i = \langle\phi_i|QHP\,G_0\,PHQ|\phi_i\rangle , \tag{47.48}$$

and the resonance width is

$$\Gamma_i = 2\pi\sum_j |\langle\phi_i \mid QHP \mid \psi_{0j}\rangle|^2 , \tag{47.49}$$

where the summation in this equation is taken over all continuum states corresponding to the operator on the left-hand-side of (47.46) and these states are normalized to a delta function in energy.

In the neighborhood of the resonance energy $E_{i,\mathrm{r}}$, the S-matrix is rapidly varying with the form

$$\boldsymbol{S} = \boldsymbol{S}_0^{\frac{1}{2}}\left(\boldsymbol{I} - \mathrm{i}\Gamma\frac{\boldsymbol{\gamma}_i \times \boldsymbol{\gamma}_i}{E - E_{i,\mathrm{r}} + \frac{1}{2}\mathrm{i}\Gamma_i}\right)\boldsymbol{S}_0^{\frac{1}{2}} , \tag{47.50}$$

where $\boldsymbol{S}_0$ is the slowly varying nonresonant or background S-matrix corresponding to $\boldsymbol{\psi}_0$, and the partial widths $\boldsymbol{\gamma}_i$ are defined by

$$\langle\phi_i \mid QHP \mid \boldsymbol{\psi}_0\rangle = \Gamma_i^{\frac{1}{2}}\boldsymbol{\gamma}_i \cdot \boldsymbol{S}_0^{\frac{1}{2}} , \tag{47.51}$$

where $\boldsymbol{\gamma}_i \cdot \boldsymbol{\gamma}_i = 1$. A corresponding resonant expression can be derived for the K-matrix (*Burke* [47.18]).

Let us now diagonalize the S-matrix as follows:

$$\boldsymbol{S} = \boldsymbol{A}\exp(2\mathrm{i}\boldsymbol{\Delta})\,\boldsymbol{A}^{\mathrm{T}} , \tag{47.52}$$

where $\boldsymbol{A}$ is an orthogonal matrix and $\boldsymbol{\Delta}$ is a diagonal matrix whose diagonal elements, δ_i, $i = 1, \ldots, n_a$, are called the eigenphases. If we define the eigenphase sum δ_{sum} by

$$\delta_{\mathrm{sum}} = \sum_{i=1}^{n_a}\delta_i , \tag{47.53}$$

then we can show from (47.50) that in the neighborhood of the resonance

$$\delta_{\text{sum}}(E) = \delta_{0,\text{sum}}(E) + \tan^{-1}\left(\frac{\frac{1}{2}\Gamma_i}{E_{i,\text{r}} - E}\right) ,$$

(47.54)

where $\delta_{0,\text{sum}}$ is the slowly varying background eigenphase sum obtained by replacing S by S_0 in (47.52) and (47.53). It follows from (47.54) that the eigenphase sum increases by π radians in the neighborhood of the resonance energy. If there are m resonances, that may be overlapping, (47.54) generalizes to

$$\delta_{\text{sum}}(E) = \delta_{0,\text{sum}}(E) + \sum_{i=1}^{m} \tan^{-1}\left(\frac{\frac{1}{2}\Gamma_i}{E_{i,\text{r}} - E}\right) .$$

(47.55)

This result has proved to be very useful in analyzing closely spaced resonances to obtain the individual resonance positions and widths.

47.1.4 Multichannel Quantum Defect Theory

When an electron scatters from a positive ion, the operator QHQ in (47.45) has an infinite series of bound states, supported by the long-range attractive Coulomb potential, converging to the lowest energy threshold of QHQ. Multichannel quantum defect theory (MQDT), developed by *Seaton* [47.6, 19, 20], relates the S-matrices and K-matrices above and below thresholds using general analytic properties of the Coulomb wave function. In this way the cross sections above and below threshold can be related and whole Rydberg series of resonances rather than individual resonances can be predicted.

When all the channels are open, the S-matrix is related to the K-matrix by (47.17), rewritten here as

$$S = (i\mathbf{I} - \mathbf{K})(i\mathbf{I} + \mathbf{K})^{-1} .$$

(47.56)

In the energy region where some channels are closed, Seaton showed that the S-matrix can be written as

$$S = (i\mathbf{I} - \mathbf{K})(t\mathbf{I} + \mathbf{K})^{-1} ,$$

(47.57)

where t is a diagonal matrix with nonzero matrix elements given by

$$\begin{aligned} t_{ii} &= i , & \text{open channels} \quad k_i^2 \geq 0 \\ t_{ii} &= \tan \pi \nu_i , & \text{closed channels} \quad k_i^2 < 0 \end{aligned}$$

(47.58)

where ν_i is defined in the closed channels by

$$k_i^2 = -z^2/\nu_i^2 .$$

(47.59)

When some channels are closed, Rydberg series of resonances occur because of the terms $\tan \pi \nu_i$. We now introduce the matrix

$$\boldsymbol{\chi} = (i\mathbf{I} - \mathbf{K})(i\mathbf{I} + \mathbf{K})^{-1} ,$$

(47.60)

which is analytic through the thresholds. When all the channels are open then clearly $S = \boldsymbol{\chi}$. Let us partition the S-matrix and the $\boldsymbol{\chi}$-matrix into open (subscript o) and closed (subscript c) channel matrices as follows:

$$S = \begin{pmatrix} S_{\text{oo}} & S_{\text{oc}} \\ S_{\text{co}} & S_{\text{cc}} \end{pmatrix} , \quad \boldsymbol{\chi} = \begin{pmatrix} \chi_{\text{oo}} & \chi_{\text{oc}} \\ \chi_{\text{co}} & \chi_{\text{cc}} \end{pmatrix} .$$

(47.61)

Then eliminating K between (47.57) and (47.60) and using (47.61), the open–open submatrix of S is

$$S_{\text{oo}} = \chi_{\text{oo}} - \chi_{\text{oc}}\left(\chi_{\text{cc}} - e^{-2\pi i \nu_c}\mathbf{I}\right)^{-1}\chi_{\text{co}} .$$

(47.62)

This is an expression for the open channel S-matrix in terms of quantities that can be analytically continued through the thresholds.

A similar expression can be obtained for the open channel, or contracted, K-matrix $\mathbf{K}_{\text{op}}$ defined in analogy with (47.56) by

$$S_{\text{oo}} = (i\mathbf{I} - \mathbf{K}_{\text{op}})(i\mathbf{I} + \mathbf{K}_{\text{op}})^{-1} .$$

(47.63)

Partitioning the K-matrix into open and closed channels as

$$\mathbf{K} = \begin{pmatrix} K_{\text{oo}} & K_{\text{oc}} \\ K_{\text{co}} & K_{\text{cc}} \end{pmatrix} ,$$

(47.64)

and substituting into (47.57) yields the expression

$$\mathbf{K}_{\text{op}} = K_{\text{oo}} - K_{\text{oc}}\left(K_{\text{cc}} + \tan \pi \nu_c\right)^{-1} K_{\text{co}} .$$

(47.65)

This equation enables cross sections and the resonance parameters in an energy region where some channels are closed to be predicted by calculating K at a few energies where all channels are open and then extrapolating it to the region where some channels are closed.

A simple one channel example has already been discussed following (47.28). In this case, it follows from (47.22) that $K = \tan \delta_\ell$. Also, from (47.57), a pole in the S-matrix occurs below threshold when

$$\tan \pi \nu + K = 0 .$$

(47.66)

Since from (47.59), the bound state energies correspond to $\nu = n - \mu$, where n is an integer and μ is the quantum defect, then (47.66) shows that δ_ℓ extrapolates below threshold to give $\pi \mu$. This result agrees with (47.28) since $1 - \exp(2\pi\eta) \approx 1$ close to threshold.

The above theory has been extended by *Gailitis* [47.21] who showed that the collision strengths defined by (47.20) can also be extrapolated through thresholds. Provided that the separation between the resonances is large compared with their widths, then the collision strength averaged over resonances below a threshold denoted by $\overline{\Omega}\,(i, f)$, can be written as

$$\overline{\Omega}\,(i, f) = \Omega^>\,(i, f) + \sum_j \frac{\Omega^>(i, j)\Omega^>\,(j, f)}{\sum_k \Omega^>\,(j, k)}\,,$$

(47.67)

where $\Omega^>$ are the collision strengths determined above the threshold and extrapolated to energies below this threshold. Also in (47.67), j is summed over the degenerate closed channels of the new threshold and k is summed over all open channels. This result is particularly useful in applications to plasmas where it is often only the collision strength averaged over a Maxwellian distribution of electron energies that is required.

Multichannel quantum defect theory has been extended to molecules by *Fano* [47.22], where it has proved to be important in the analysis of resonances occuring in partial cross sections involving rovibrational and dissociating channels as well as electronic channels [47.23, 24].

47.1.5 Solution of the Coupled Integrodifferential Equations

This section considers methods that have been developed for solving the coupled integrodifferential equations (47.10). These equations arise in low-energy electron–atom and electron–ion collisions. Section 47.2.2 shows that similar equations also arise in low energy electron–molecule collisions in the fixed-nuclei approximation. Thus the methods discussed in this section are also applicable for electron–molecule collisions.

R–Matrix Method

This method was first introduced in nuclear physics [47.25, 26] in a study of resonance reactions. It has now been applied to wide range of atomic, molecular and optical processes, as reviewed in [47.27].

This method starts by partitioning configuration space into two regions by a sphere of radius a, chosen so that the direct potential has achieved its asymptotic form given by (47.12) and the exchange and correlation potentials are negligible for $r \geq a$. The objective is then

to calculate the *R*-matrix $R_{ij}^\Gamma(E)$, which is defined by

$$F_{ij}^\Gamma\,(a) = \sum_{\ell=1}^n R_{i\ell}^\Gamma\,(E) \left(a \frac{\mathrm{d}F_{\ell j}^\Gamma}{\mathrm{d}r} - b_\ell F_{\ell j}^\Gamma \right)_{r=a}\,,$$

(47.68)

by solving (47.10) in the internal region.

The collision problem is solved in the internal region by expanding the wave function, in analogy with (47.8), in the form

$$\begin{aligned}
\Psi_k^\Gamma\,&(X_{N+1}) \\
&= \mathcal{A} \sum_{ij} \overline{\Phi}_i^\Gamma\,\left(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_N; \hat{\boldsymbol{r}}_{N+1}\sigma_{N+1}\right) \\
&\quad \times r_{N+1}^{-1} u_j\,(r_{N+1})\, a_{ijk}^\Gamma \\
&\quad + \sum_i \chi_i^\Gamma\,(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_{N+1})\, b_{ik}^\Gamma\,,
\end{aligned}$$

(47.69)

where the u_j are radial basis functions defined over the range $0 \leq r \leq a$. For radial basis functions u_j satisfying arbitrary boundary conditions at $r = a$, the Hamiltonian H_{N+1} defined by (47.3) is not Hermitian in the internal region due to the kinetic energy operators. It can however be made Hermitian by adding the Bloch operator [47.28]

$$L_\mathrm{b} = \sum_{i=1}^n \left|\overline{\Phi}_i^\Gamma\right\rangle \frac{1}{2}\delta(r - a) \left(\frac{\mathrm{d}}{\mathrm{d}r} - \frac{b_i - 1}{r} \right) \left\langle \overline{\Phi}_i^\Gamma \right|$$

(47.70)

to H_{N+1}, where b_i is an arbitrary parameter. The Schrödinger equation (47.2) then becomes

$$(H_{N+1} + L_\mathrm{b} - E)\, \Psi^\Gamma = L_\mathrm{b}\Psi^\Gamma\,,$$

(47.71)

which can be formally solved, giving

$$\Psi^\Gamma = (H_{N+1} + L_\mathrm{b} - E)^{-1}\, L_\mathrm{b}\Psi^\Gamma\,.$$

(47.72)

Next, expand the Green's function $(H_{N+1} + L_\mathrm{b} - E)^{-1}$ in terms of the basis Ψ_k^Γ, where the coefficients a_{ijk}^Γ and b_{ik}^Γ in (47.69) are chosen to diagonalize $H_{N+1} + L_\mathrm{b}$, giving

$$\left\langle \Psi_k^\Gamma \middle| H_{N+1} + L_\mathrm{b} \middle| \Psi_{k'}^\Gamma \right\rangle = E_k^\Gamma \delta_{kk'}\,.$$

(47.73)

Equation (47.72) can then be written as

$$\left|\Psi^\Gamma\right\rangle = \sum_k \frac{\left|\Psi_k^\Gamma\right\rangle\left\langle\Psi_k^\Gamma\right|}{E_k^\Gamma - E} L_\mathrm{b} \left|\Psi^\Gamma\right\rangle\,.$$

(47.74)

Finally, we project this equation onto the channel functions $\overline{\Phi}_i^\Gamma$, and evaluate it at $r = a$. Assuming Ψ^Γ is given

by (47.8), we retrieve (47.68), where the R-matrix can be calculated from the expansion

$$R_{ij}^{\Gamma}(E) = \frac{1}{2a} \sum_{k} \frac{w_{ik}^{\Gamma} w_{jk}^{\Gamma}}{E_k^{\Gamma} - E} ,\qquad (47.75)$$

and where we have introduced the surface amplitudes

$$w_{ik}^{\Gamma} = \sum_{j} u_j(a) a_{ijk}^{\Gamma} .\qquad (47.76)$$

The main part of the calculation involves setting up and diagonalizing the matrix given by (47.73). This has to be carried out once to determine the R-matrix for all energies E.

In the external region $r \geq a$, (47.10) reduces to coupled differential equations, coupled by the potential $V_{ij}^{\Gamma}(r)$ which has achieved its asymptotic form (47.12). These equations can be integrated outwards from $r = a$ for each energy of interest, subject to the boundary conditions (47.68), to yield the K-matrix given by (47.15), and hence the S-matrix and collision cross sections.

Kohn Variational Method

The application of variational methods in electron atom collision theory has been reviewed by *Nesbet* [47.29]. An S-matrix or complex Kohn version of this method has been developed [47.30], which has eliminated singularities present in earlier K-matrix versions of the theory. This new method has been particularly important in electron–molecule collision calculations [47.31].

This approach starts from the basic expansion given by (47.8), where the reduced radial functions are chosen to satisfy the T-matrix asymptotic boundary conditions

$$F_{ij}^{\Gamma} \underset{r \to \infty}{\sim} k_i^{-\frac{1}{2}} \left(\sin \theta_i \delta_{ij} + (2i)^{-1} e^{i\theta_i} T_{ij}^{\Gamma} \right) ,\quad (47.77)$$

which follows by taking linear combinations of the n_a solutions defined by (47.15) and using (47.17). We then define the integral

$$I^{\Gamma} = -\frac{1}{2} \int_0^{\infty} \left(F^{\Gamma} \right)^T L F^{\Gamma} \, dr ,\qquad (47.78)$$

where L is the integrodifferential operator given by (47.10) with all terms taken onto the left-hand side of the equation.

Now consider variations of the integral I^{Γ} resulting from arbitrary variations δF^{Γ} of the functions F^{Γ} about the exact solution of (47.10), where these solutions satisfy the boundary conditions (47.77), and the variations

satisfy the boundary condition

$$\delta F^{\Gamma} \underset{r \to \infty}{\sim} (2i)^{-1} k^{-\frac{1}{2}} e^{i\theta} \delta T^{\Gamma} .\qquad (47.79)$$

The corresponding variation in I^{Γ} to first-order is

$$\delta I^{\Gamma} = -\frac{1}{2} \int_0^{\infty} \left[\left(\delta F^{\Gamma} \right)^T L F^{\Gamma} + \left(F^{\Gamma} \right)^T L \delta F^{\Gamma} \right] dr ,$$
$$(47.80)$$

which after some manipulation yields

$$\delta I^{\Gamma} = (4i)^{-1} \delta T^{\Gamma} .\qquad (47.81)$$

It follows that the functional

$$\left[T^{\Gamma} \right] = T^{\Gamma} - 4i\, I^{\Gamma} \qquad (47.82)$$

is stationary for small variations about the exact solution. This is the complex Kohn variational principle.

This variational principle can be used to solve (47.10) by representing the reduced radial functions F_{ij}^{Γ} by the expansion

$$F_{ij}^{\Gamma}(r) = w_{1i}^{\Gamma}(r) \delta_{ij} + (2i)^{-1} w_{2i}^{\Gamma}(r) T_{ij}^{\Gamma}$$
$$+ \sum_{k} \phi_k^{\Gamma}(r) c_{ijk}^{\Gamma} ,\qquad (47.83)$$

where w_{1i}^{Γ} and w_{2i}^{Γ} are zero at the origin and have the asymptotic forms

$$w_{1i}^{\Gamma}(r) \underset{r \to \infty}{\sim} k_i^{-\frac{1}{2}} \sin \theta_i ;\qquad (47.84)$$

$$w_{2i}^{\Gamma}(r) \underset{r \to \infty}{\sim} k_i^{-\frac{1}{2}} \exp i\theta_i ,\qquad (47.85)$$

while ϕ_k^{Γ} are square integrable basis functions. The coefficients c_{ijk}^{Γ} and the T-matrix elements T_{ij}^{Γ} can then be determined as variational parameters in the variational principle (47.82).

Schwinger Variational Method

This method has been used to calculate electron–molecule collision cross sections by *McKoy* and co-workers [47.32]. The method starts from the Lippmann–Schwinger integral equation, which corresponds to the integrodifferential equations (47.10), together with the K-matrix or T-matrix boundary condition defined by (47.15) or (47.77) respectively. The T-matrix form of the Lippmann–Schwinger integral equation is

$$F_{ij}^{\Gamma}(r) = w_{1i}^{\Gamma}(r) \delta_{ij} + \sum_{k\ell} \int_0^{\infty} \int_0^{\infty} G_{ik}^{\Gamma(+)}(r, r')$$
$$\times U_{k\ell}^{\Gamma}(r', r'') F_{\ell j}^{\Gamma}(r'') \, dr' \, dr'' \qquad (47.86)$$

where $U_{k\ell}^\Gamma$ represents the sum of the potential terms $2\left(V_{k\ell}^\Gamma + K_{k\ell}^\Gamma + X_{k\ell}^\Gamma\right)$ in (47.10), and the multichannel outgoing wave Green's function $G_{ik}^{\Gamma(+)}$ is defined assuming all channels are open by

$$G_{ij}^{\Gamma(+)}\left(r, r'\right) = \begin{cases} -w_{1i}^\Gamma(r)\, w_{2i}^\Gamma(r')\, \delta_{ij}, & r < r' \\ -w_{2i}^\Gamma(r)\, w_{1i}^\Gamma(r')\, \delta_{ij}, & r \ge r' \end{cases}$$
(47.87)

where w_{1i}^Γ and w_{2i}^Γ are solutions of the Coulomb equation

$$\left(\frac{\mathrm{d}^2}{\mathrm{d}r^2} - \frac{\ell_i(\ell_i+1)}{r^2} + \frac{2(Z-N)}{r} + k_i^2\right) w_i(r) = 0$$
(47.88)

that satisfy the asymptotic boundary conditions (47.84) and (47.85), respectively.

An integral expression for the T-matrix can be obtained by comparing (47.77) and (47.86). This gives

$$T_{ij}^\Gamma = -2\mathrm{i} \sum_k \int_0^\infty \int_0^\infty w_{1i}^\Gamma(r)\, U_{ik}^\Gamma\left(r, r'\right) F_{kj}^\Gamma(r')\, \mathrm{d}r\, \mathrm{d}r'$$
(47.89)

or, rewriting this equation using Dirac bracket notation,

$$\boldsymbol{T} = -2\mathrm{i}\langle \boldsymbol{w}_1 | \boldsymbol{U} | \boldsymbol{F}^{(+)} \rangle,$$
(47.90)

where the plus sign indicates that $\boldsymbol{F}^{(+)}$ satisfies the outgoing wave boundary condition (47.77), and where for convenience we have suppressed the superscript Γ. In a similar way, the Lippmann–Schwinger equation corresponding to the ingoing wave boundary condition

$$F_{ij}^\Gamma \underset{r\to\infty}{\sim} k_i^{-\frac{1}{2}}\left(\sin\theta_i\delta_{ij} - (2\mathrm{i})^{-1}\, \mathrm{e}^{-\mathrm{i}\theta_i} T_{ij}^{\Gamma*}\right),$$
(47.91)

can be introduced, from which follows the integral expression

$$\boldsymbol{T} = -2\mathrm{i}\langle \boldsymbol{F}^{(-)} | \boldsymbol{U} | \boldsymbol{w}_1 \rangle,$$
(47.92)

where $\boldsymbol{F}^{(-)}$ satisfies the ingoing wave boundary condition (47.91). A further integral expression for the T-matrix is obtained by substituting for $\boldsymbol{w}_1$ in (47.92) from (47.86) giving

$$\boldsymbol{T} = -2\mathrm{i}\langle \boldsymbol{F}^{(-)} | \boldsymbol{U} - \boldsymbol{U}\boldsymbol{G}^{(+)}\boldsymbol{U} | \boldsymbol{F}^{(+)} \rangle.$$
(47.93)

Hence, a combination of (47.90), (47.92) and (47.93) yields the functional

$$\begin{aligned}[\boldsymbol{T}] = &-2\mathrm{i}\langle \boldsymbol{w}_1 | \boldsymbol{U} | \boldsymbol{F}^{(+)} \rangle \\ &\times \left(\langle \boldsymbol{F}^{(-)} | \boldsymbol{U} - \boldsymbol{U}\boldsymbol{G}^{(+)}\boldsymbol{U} | \boldsymbol{F}^{(+)} \rangle\right)^{-1} \\ &\times \langle \boldsymbol{F}^{(-)} | \boldsymbol{U} | \boldsymbol{w}_1 \rangle.\end{aligned}$$
(47.94)

This functional is stationary for small variations of $\boldsymbol{F}^{(+)}$ and $\boldsymbol{F}^{(-)}$ about the exact solution of (47.10) satisfying the boundary conditions (47.77) and (47.91) respectively, and forms the basis of numerical calculations.

Linear Algebraic Equations Method

In this method, the integrodifferential (47.10) are reduced directly to a set of linear algebraic (LA) equations [47.33], or alternatively, (47.10) are first converted to integral form, given by (47.86), which are then reduced to a set of linear algebraic equations [47.34].

A direct approach [47.33] has been widely used for electron–atom and electron–ion collisions. As in the R-matrix method, configuration space is first divided into two regions. A mesh of N points is then used to span the internal region $r \le a$ where

$$r_1 = 0; \quad r_{k-1} < r_k, \quad k = 1, \ldots, N; \quad r_N = a.$$
(47.95)

In addition, two further mesh points r_{N+1} and r_{N+2} are introduced to enable the solution in the internal region to be matched to the solution in the external region $r \ge a$. In the external region, (47.10) reduces to coupled differential equations that can be solved by one of the same methods as adopted in the R-matrix approach.

The n functions $F_{ij}^\Gamma(r)$, $i = 1, \ldots, n$, in (47.10) are represented by their values at the mesh points r_k. Using a finite difference representation of the differential and integral operators, (47.10) then reduces to a set of linear algebraic equations for the unknown values $F_{ij}^\Gamma(r_k)$ in the internal region. These equations can be solved using standard methods for each linearly independent solution $j = 1, \ldots, n_a$ defined by the asymptotic boundary conditions (47.15).

47.1.6 Intermediate and High Energy Elastic Scattering and Excitation

For electron–atom and electron–ion collisions at electron impact energies greater than the ionization threshold of the target, an infinite number of channels is open so that they cannot all be included explicitly in the expansion of the total wave function. Several approaches have been developed to treat collisions at these energies, such as extensions of low energy methods based on expansion (47.8) to intermediate energies, the development of optical potentials that take account of loss of flux into the infinity of open channels in some average way, and extensions of the Born approximation to lower energies by including higher-order terms in the Born Series.

Pseudostate Methods

In this approach, expansion (47.8) is extended by including a set of suitably chosen square-integrable pseudostates Φ_i^p that are orthogonal to the eigenstates Φ_i retained in expansion (47.8). These pseudostates are usually defined by diagonalizing the target Hamiltonian H_N in a square-integrable basis yielding an equation analogous to (47.4), viz

$$\langle \Phi_i^p | H_N | \Phi_j^p \rangle = \omega_i^p \delta_{ij} , \qquad (47.96)$$

where the energies ω_i^p lie just below the ionization threshold or in the continuum. The pseudostates Φ_i^p thus represent in an average way the high lying Rydberg states and the continuum states of the target rather than just the low lying target bound states as in (47.4). This enables loss of flux into the continuum states to be represented enabling accurate excitation cross sections to be calculated at intermediate energies. In addition, by calculating the amplitudes for exciting these pseudostates accurate ionization cross sections can be determined, as discussed in Sect. 47.1.7.

A proposal to include pseudostates in expansion (47.8) for e–H scattering was first made by *Burke* and *Schey* [47.35]. Also a modification of this expansion to include polarized pseudostates which allowed for the long-range dipole and quadrupole polarizability in e–H scattering was proposed by *Damburg* and *Karule* [47.36]. Later detailed e–H scattering calculations which included pseudostates were carried out by a number of authors [47.37–40] with considerable success showing the validity of this approach.

More recently the *R*-matrix method, discussed in Sect. 47.1.5, has been extended to include pseudostates giving rise to the intermediate energy *R*-matrix (IERM) method [47.41–44] and the *R*-matrix with pseudostates (RMPS) method [47.45–48], the latter approach being applicable to multi-electron atoms and ions. Both of these methods have enabled excitation and ionization cross sections to be accurately calculated above the ionization threshold.

Methods have also been developed in which the pseudostates are represented by Sturmian functions. An expansion of this type was first proposed by *Rotenberg* [47.49] and in a more recent major development the convergent close coupling (CCC) method has been developed by *Bray*, *Stelbovics* and co-workers [47.50–56] which has been applied with considerable success for both electron impact excitation and ionization.

As an example of the CCC method, we consider e^-–H scattering. In this case the radial basis of the target states are expanded in the complete Laguerre basis

$$\xi_{k\ell}(r) = \left(\frac{\lambda_\ell(k-1)!}{(2\ell+1+k)!} \right)^{1/2}$$
$$\times (\lambda_\ell r)^{\ell+1} \exp(\lambda_\ell r/2) L_{k-1}^{2\ell+2}(\lambda_\ell r) , \quad (47.97)$$

where $L_{k-1}^{2\ell+2}(\lambda_\ell r)$ are associated Laguerre polynomials and k ranges from 1 to the basis size N_ℓ which depends on the angular momentum ℓ. The target states $\Phi_{i\ell}$ are expanded for each angular momentum as follows

$$\Phi_{i\ell} = \sum_{k=1}^{N_\ell} \xi_{k\ell}(r) c_{ki\ell} , \quad i = 1, \ldots, N_\ell , \qquad (47.98)$$

where the coefficients $c_{ki\ell}$ are obtained by diagonalizing the target Hamiltonian H_1 as follows

$$\langle \Phi_{i\ell} | H_1 | \Phi_{j\ell} \rangle = w_{i\ell} \delta_{ij} . \qquad (47.99)$$

The states $\Phi_{i\ell}$ corresponding to the lowest energies $w_{i\ell}$ provide an accurate representation of the lowest bound eigenstates of the target for each ℓ, while the states corresponding to the higher energies $w_{i\ell}$ correspond to pseudostates representing the high lying Rydberg states and the continuum. As N_ℓ is increased for fixed range parameter λ_ℓ in (47.98), more bound target eigenstates are accurately represented while at the same time the states corresponding to the higher energies provide a denser and more accurate representation of the continuum. The scattering amplitude is written in the close coupling approximation as

$$\langle \psi_f | H_2 - E | \Psi_i^{S+} \rangle$$
$$\simeq \langle \psi_f | I(H_2 - E) \left[1 + (-1)^{\text{SP}} \right] I | \Psi_i^{S+} \rangle , \qquad (47.100)$$

where P is the space exchange operator which ensures that the total wave function has the correct symmetry for each total spin S, I is the projection operator onto the target states $\Phi_{i\ell}$ retained in the calculation and $\langle \psi_f |$ is an eigenstate of the asymptotic Hamiltonian. The scattering amplitude is then obtained by solving the close coupling equations in momentum space [47.50].

Optical Potential Methods

An approach which is also capable in principle of including the effect of all excited and continuum states is the optical potential method [47.57]. Adopting Feshbach projection operators P and Q as in (47.40), an optical potential V_{op} is defined by (47.44), where now P projects onto those low-energy channels that can be treated exactly, for example by solving equations (47.10), and

Q allows for the remaining infinity of coupled channels, including the continuum.

At sufficiently high energies, it is appropriate to make a perturbation expansion of V_{op}, where the second-order term is given by

$$V^{(2)} = PVQ \frac{1}{E - \mathcal{T}_e - H_N + i\epsilon} QVP , \qquad (47.101)$$

V being the electron–atom (ion) interaction potential, $\mathcal{T}_e$ the kinetic energy operator of the scattered electron, and H_N the target Hamiltonian. *Byron* and *Joachain* [47.58] converted the lowest-order terms of perturbation theory into an ab initio local complex potential for the elastic scattering of electrons and positrons from a number of atoms.

The optical potential calculated in second-order has also been used by *Bransden* et al. [47.59, 60] to describe e^-–H collisions, while *McCarthy* [47.61] has studied an optical-potential approximation that goes beyond second order, and also makes allowance for exchange. This method is called the coupled channels optical (CCO) model. Finally, *Callaway* and *Oza* [47.62] have constructed an optical potential using a set of pseudostates to evaluate the sum over intermediate states and have obtained encouraging results for elastic scattering and excitation of the $n = 2$ states in e^-–H collisions.

Born Series Methods

In the high energy domain, which can usually be assumed to extend from several times the ionization threshold of the target upwards, methods based on the Born series give reliable results. Ignoring electron exchange for the moment, the Born series for the direct scattering amplitude can be written as [47.63, 64]

$$f = \sum_{n=1}^{\infty} f_{n,B} , \qquad (47.102)$$

where the nth Born term $f_{n,B}$ contains the interaction V between the scattered electron and the target atom or ion n times, and the Green's function

$$G_0^{(+)} = (H_N + \mathcal{T}_e - E - i\epsilon)^{-1} \qquad (47.103)$$

$(n - 1)$ times, where $\mathcal{T}_e$ and H_N are defined following (47.101).

It is important to retain consistently all terms in the Born series with similar energy and momentum-transfer $\Delta = |\mathbf{k}_i - \mathbf{k}_f|$ dependencies. For elastic scattering, the scattering amplitude converges to the first Born approximation for all Δ, but at lower energies it is necessary to include $\mathrm{Re}(f_{3,B})$, as well as the second Born terms, to obtain the cross section correct to k^{-2}. In the forward direction, convergence to the first Born approximation is

slow because of the contribution from $\mathrm{Im}(f_{2,B})$ which, from the optical theorem, corresponds to loss of flux into all open channels.

For inelastic scattering, the first Born approximation does not give the correct high energy limit for large Δ. Instead this comes from $\mathrm{Im}(f_{2,B})$. Physically, this can be understood by noting that inelastic scattering at large angles involves two collisions: a collision of the incident electron with the nucleus to give the large scattering angle, followed or preceeded by an inelastic collision with the bound electrons to give excitation. Again, in the forward direction, it is necessary to retain $\mathrm{Re}(f_{3,B})$ to obtain the cross section correct to k^{-2}.

Since the third Born term is difficult to calculate, *Byron* and *Joachain* [47.65] suggested that to third-order, the scattering amplitude should be calculated using the eikonal Born series (EBS) approximation

$$f_{EBS} = f_{1,B} + f_{2,B} + f_{3,G} + g_{och} , \qquad (47.104)$$

where $f_{3,G}$ is the third-order term in the expansion of the Glauber amplitude [47.66] in powers of V, which can be more easily calculated than $f_{3,B}$, and g_{och} is the Ochkur electron exchange amplitude [47.67]. The EBS method has been very successful when perturbation theory converges rapidly; namely, at high energies, at small and intermediate scattering angles, and for light atoms.

Distorted Wave Methods

Distorted wave methods are characterized by a separation of the interaction into two parts, one which is treated exactly and the other which is treated in first-order. The usual approach is based on the integral expressions for the T-matrix given by (47.90) or (47.92). The distorted wave approximation is obtained by replacing the exact solution of (47.10), denoted by $\mathbf{F}^{(+)}$ and $\mathbf{F}^{(-)}$ in (47.90) and (47.92) respectively, by approximate solutions, usually obtained by omitting all channels except the final or initial channels of interest. In addition, the potential interaction $\mathbf{U}$ is often approximated by just the direct term in (47.10).

This method becomes more accurate at intermediate energies as $Z - N$ increases, and as the angular momentum of the scattered electron becomes large. However, it gives poor results at low energies where the coupling between the channels in (47.10) is strong, and where resonances are often important. It has proved to be a very useful way of calculating electron–ion total and differential cross sections at intermediate and high energies well removed from threshold.

47.1.7 Ionization

This section discusses processes where electrons are ejected from the target during the collision, giving rise to ionization. The main focus is single ionization, or (e, 2e) processes given by

$$
\mathrm{e}^- (E_\mathrm{i}) + A_i \rightarrow A_j^+ + \mathrm{e}^- (E_\mathrm{A}) + \mathrm{e}^- (E_\mathrm{B}) ,
$$
(47.105)
where E_i, E_A and E_B are the incident, scattered and ejected electron energies respectively. They are related through the energy conservation relation

$$
E_\mathrm{i} = E_\mathrm{A} + E_\mathrm{B} + \varepsilon ,
$$
(47.106)

where ε is the binding energy of the ejected atomic electron. The threshold behavior of the ionization cross section leading to the Wannier threshold law is treated in Chapt. 52.

The scattering amplitude for the direct ionization process is [47.68]

$$
\begin{aligned}
f_i (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B}) = {} & - (2\pi)^{\frac{1}{2}} \, \mathrm{e}^{\mathrm{i}\chi(\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B})} \\
& \times \left\langle (H_{N+1} - E) \, \Phi \middle| \Psi_i^{(+)} \right\rangle
\end{aligned}
$$
(47.107)

where $\Psi_i^{(+)}$ is an exact solution of (47.2) satisfying plane wave plus outgoing wave boundary conditions given by (47.5), and where Φ is a solution of the equation

$$
(H_{N+1} - V - E) \, \Phi = 0
$$
(47.108)

satisfying ingoing wave boundary conditions. Also, $\boldsymbol{k}_\mathrm{A}$ and $\boldsymbol{k}_\mathrm{B}$ are the momenta of the two outgoing electrons defined in terms of E_A and E_B by

$$
\frac{1}{2} k_\mathrm{A}^2 = E_\mathrm{A}, \qquad \frac{1}{2} k_\mathrm{B}^2 = E_\mathrm{B} .
$$
(47.109)

In practice the potential V is chosen so that Φ has a simple form. Thus, for electron scattering by H-like ions with nuclear charge Z, V is often chosen as

$$
V = -\frac{Z - Z_\mathrm{A}}{r_1} - \frac{Z - Z_\mathrm{B}}{r_2} + \frac{1}{r_{12}} ,
$$
(47.110)

so that

$$
\Phi (\boldsymbol{r}_1, \boldsymbol{r}_2) = \Psi_\mathrm{C}^{(-)}(Z_\mathrm{A}, \boldsymbol{k}_\mathrm{A}, \boldsymbol{r}_1) \, \Psi_\mathrm{C}^{(-)}(Z_\mathrm{B}, \boldsymbol{k}_\mathrm{B}, \boldsymbol{r}_2) ,
$$
(47.111)

where the $\Psi_\mathrm{C}^{(-)}$ are Coulomb wave functions satisfying ingoing-wave boundary conditions, and Z_A and Z_B are the effective charges seen by the two electrons. In order

that the scattering amplitude does not contain a divergent phase factor, Z_A and Z_B must satisfy

$$
\frac{Z_\mathrm{A}}{k_\mathrm{A}} + \frac{Z_\mathrm{B}}{k_\mathrm{B}} = \frac{Z}{k_\mathrm{A}} + \frac{Z}{k_\mathrm{B}} - \frac{1}{|\boldsymbol{k}_\mathrm{A} - \boldsymbol{k}_\mathrm{B}|} ,
$$
(47.112)

and the phase factor in (47.107) is then given by

$$
\chi (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B}) = \frac{Z_\mathrm{A}}{k_\mathrm{A}} \ln \frac{k_\mathrm{A}^2}{k_\mathrm{A}^2 + k_\mathrm{B}^2} + \frac{Z_\mathrm{B}}{k_\mathrm{B}} \ln \frac{k_\mathrm{B}^2}{k_\mathrm{A}^2 + k_\mathrm{B}^2} .
$$
(47.113)

The exchange ionization amplitude $g_i (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B})$ can be obtained from the Peterkop theorem [47.69]

$$
g_i (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B}) = f_i (\boldsymbol{k}_\mathrm{B}, \boldsymbol{k}_\mathrm{A}) .
$$
(47.114)

This result follows from the fact that the amplitudes $f_i (\boldsymbol{k}_\mathrm{B}, \boldsymbol{k}_\mathrm{A})$ and $g_i (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B})$ describe the same physical process where the electron at $\boldsymbol{r}_{N+1}$ has momentum $\boldsymbol{k}_\mathrm{A}$, and the electron at $\boldsymbol{r}_N$ has momentum $\boldsymbol{k}_\mathrm{B}$. In practice, the Peterkop theorem is not valid if approximate wave functions are used to calculate the ionization amplitude. For this reason, a relative phase $\tau_i (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B})$ between these two amplitudes is sometimes introduced by

$$
g_i (\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B}) = \mathrm{e}^{\mathrm{i}\tau(\boldsymbol{k}_\mathrm{A}, \boldsymbol{k}_\mathrm{B})} f_i (\boldsymbol{k}_\mathrm{B}, \boldsymbol{k}_\mathrm{A}) .
$$
(47.115)

This adds an element of arbitrariness into the calculation since different choices of this phase leads to different cross sections [47.70].

The ionization cross sections can be obtained directly from the scattering amplitudes. For random electron spin orientations, the triple differential cross section (TDCS) for ionization of a target with one active electron from an initial state denoted by $|i\rangle$ is given by

$$
\frac{\mathrm{d}^3 \sigma_i}{\mathrm{d}\Omega_\mathrm{A} \, \mathrm{d}\Omega_\mathrm{B} \, \mathrm{d}E} = \frac{k_\mathrm{A} k_\mathrm{B}}{k_\mathrm{i}} \left(\frac{1}{4} |f_i + g_i|^2 + \frac{3}{4} |f_i - g_i|^2 \right) .
$$
(47.116)

By integrating the TDCS with respect to $\mathrm{d}\Omega_\mathrm{A}$, $\mathrm{d}\Omega_\mathrm{B}$ or $\mathrm{d}E$, we can form three different double differential cross sections, and three different single differential cross sections. The total ionization cross section obtained by integrating (47.116) over all outgoing electron scattering angles and energies is

$$
\begin{aligned}
\sigma_i = {} & \frac{1}{k_\mathrm{i}} \int_0^{E/2} \mathrm{d}E \, k_\mathrm{A} k_\mathrm{B} \int \mathrm{d}\Omega_\mathrm{A} \\
& \times \int \mathrm{d}\Omega_\mathrm{B} \left[\frac{1}{4} |f_i + g_i|^2 + \frac{3}{4} |f_i - g_i|^2 \right] ,
\end{aligned}
$$
(47.117)

where the upper limit of integration over the energy variable is $E/2$ because the two outgoing electrons are indistinguishable.

We conclude this general discussion of the theory of electron impact ionization by mentioning recent work in which an integral representation for the ionization amplitude has been developed [47.71] which is free from the ambiguity and divergence problems associated with earlier work [47.68, 69, 72, 73]. An important aspect of this new development is that it has a form which can be used for practical calculations.

We now consider several approaches which have been used to obtain accurate ionization cross sections commencing, as in electron impact excitation with low energy methods and concluding with Born and distorted wave methods.

Pseudostate Methods

An important recent development is the realization that accurate ionization cross sections close to threshold can be obtained by representing the ionization continuum by suitably chosen square-integrable pseudostates. As already discussed when we considered pseudostate methods in Sect. 47.1.6 several methods including the intermediate energy R-matrix method [47.41–44], the R-matrix with pseudostates method [47.45–48] and the convergent close coupling method [47.50–56] have been used to obtain accurate ionization cross sections in this energy range.

Time–Dependent Close Coupling Method

Electron impact excitation and ionization amplitudes and cross sections can also be determined by solving the time-dependent Schrödinger equation directly [47.74–77]. In the case of electron scattering by atomic hydrogen or by an atom or atomic ion with one electron outside a closed inert shell, the total wave function can be expanded for each conserved $LS\pi$ symmetry as

$$\Psi^\Gamma(\boldsymbol{r}_1, \boldsymbol{r}_2, t) = \sum_{\ell_1\ell_2}(r_1 r_2)^{-1} P^{LS}_{\ell_1\ell_2}(r_1, r_2, t)$$
$$\times \mathcal{Y}^{LM_L}_{\ell_1\ell_2}(\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2) , \qquad (47.118)$$

where Γ is defined by (47.9) and the coupled spherical harmonics $\mathcal{Y}^{LM_L}_{\ell_1\ell_2}$ are defined by

$$\mathcal{Y}^{LM_L}_{\ell_1\ell_2}(\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2)$$
$$= \sum_{m_1 m_2}(\ell_1 m_1 \ell_2 m_2 | \ell_1 \ell_2 L M_L)$$
$$\times Y_{\ell_1 m_1}(\theta_1, \phi_1) Y_{\ell_2 m_2}(\theta_2, \phi_2) . \qquad (47.119)$$

Substituting (47.118) into the time-dependent Schrödinger equation and projecting onto the coupled spherical harmonics $\mathcal{Y}^{LM_L}_{\ell_1\ell_2}$ then yields the following coupled differential equations

$$\mathrm{i}\frac{\partial P^{LS}_{\ell_1\ell_2}(r_1, r_2, t)}{\partial t}$$
$$= T_{\ell_1\ell_2}(r_1, r_2) P^{LS}_{\ell_1\ell_2}(r_1, r_2, t)$$
$$+ \sum_{\ell'_1\ell'_2} V^L_{\ell_1\ell_2\ell'_1\ell'_2}(r_1, r_2, t) P^{LS}_{\ell'_1\ell'_2}(r_1, r_2, t) , \qquad (47.120)$$

where

$$T_{\ell_1\ell_2}(r_1, r_2) = -\frac{1}{2}\frac{\partial^2}{\partial r_1^2} - \frac{1}{2}\frac{\partial^2}{\partial r_2^2}$$
$$+ V_{\ell_1}(r_1) + V_{\ell_2}(r_2) . \qquad (47.121)$$

In this equation V_ℓ is an ℓ-dependent pseudopotential representing the interaction of the valence or scattered electrons with the closed shell core and $V^L_{\ell_1\ell_2\ell'_1\ell'_2}$ are the radial coupling potentials obtained by taking the matrix elements of the r_{12}^{-1} interaction between the valence and scattered electrons. Equations (47.120) are solved on a two-dimensional grid using an explicit time propagator which can be readily implemented on parallel computers. Commencing at time $t = 0$ with a wave function which is constructed as the appropriately symmetrized product of an incoming radial wave packet for one electron and the lowest energy bound stationary state for the other electron, the time-dependent equations (47.120) are integrated forward in time. Electron impact excitation and ionization amplitudes and cross sections are determined by projecting the time-evolved radial wave function $P^{LS}_{\ell_1\ell_2}(r_1, r_2, t)$ onto a complete set of target states.

Exterior Complex Scaling Method

In this approach, developed by *Rescigno* et al. [47.78–80], the time-independent Schrödinger equation for three charged particles is solve numerically on a two-dimensional grid without explicitly imposing asymptotic boundary conditions for three-body breakup. In the case of electron hydrogen atom scattering, the total wave function is partitioned into the sum of an appropriately symmetrized unperturbed wave function $\psi^\Gamma_{k_i}$ describing a free electron with momentum k_i incident on the target ground state and a scattered wave function Ψ^Γ_{sc} which is expanded in the form

$$\Psi^\Gamma_{sc}(\boldsymbol{r}_1, \boldsymbol{r}_2) = \sum_{L\ell_1\ell_2} r_1^{-1} r_2^{-1} \psi^{LS}_{\ell_1\ell_2}(r_1, r_2) \mathcal{Y}^{L0}_{\ell_1\ell_2}(\hat{\boldsymbol{r}}_1, \hat{\boldsymbol{r}}_2) . \qquad (47.122)$$

Since the z-axis is defined to lie along the incident beam direction then M_L in the coupled spherical harmonics defined by (47.119) is zero. Also, since parity is conserved the summation in (47.122) is limited to terms for which $L + \ell_1 + \ell_2$ is even.

Substituting the expression for the total wave function into the Schrödinger equation then yields the following set of coupled two-dimensional equations for the radial functions $\psi_{\ell_1\ell_2}^{LS}$ for each L and S:

$$(E - H_{\ell_1}(r_1) - H_{\ell_2}(r_2))\psi_{\ell_1\ell_2}^{LS}(r_1, r_2)$$
$$- \sum_{\ell_1'\ell_2'} V_{\ell_1\ell_2\ell_1'\ell_2'}^{L}(r_1, r_2)\psi_{\ell_1'\ell_2'}^{LS}(r_1, r_2)$$
$$= \chi_{\ell_1\ell_2}^{LS}(r_1, r_2) . \tag{47.123}$$

In this equation $H_\ell(r)$ is the radial hydrogenic Hamiltonian

$$H_\ell(r) = -\frac{1}{2}\frac{d^2}{dr^2} + \frac{\ell(\ell+1)}{2r^2} - \frac{1}{r} , \tag{47.124}$$

$V_{\ell_1\ell_2\ell_1'\ell_2'}^{L}$, as in (47.120), are the radial coupling potentials obtained by taking the matrix elements of the electron–electron interaction r_{12}^{-1} and the inhomogeneous term $\chi_{\ell_1\ell_2}^{LS}(r_1, r_2)$ arises from the partial wave expansion of the incident wave term.

The coupled differential equations (47.123) are solved on a two-dimensional grid using exterior complex scaling (ECS) boundary conditions which avoid imposing detailed asymptotic boundary conditions. The ECS transformation is taken as a mapping $r \to z(r)$ of all radial coordinates to a contour

$$z(r) \equiv \begin{cases} r, & r \le R_0 \\ R_0 + (r - R_0)\, e^{i\eta} & r > R_0 \end{cases} , \tag{47.125}$$

that is real for $r \le R_0$ but is rotated into the upper half of the complex plane for $r > R_0$. This transformation has the desirable property that any outgoing wave evaluated on this contour dies exponentially as the coordinate becomes large. Thus the ECS procedure transforms any outgoing wave into a function that falls off exponentially outside R_0 but is equal to the infinite range wave over the finite region of space where the coordinates are real. Producing meaningful ionization cross sections at energies several eV above the ionization threshold requires R_0 to be at least 100 a_0. The grid must extend beyond R_0 far enough to allow the complex scaled radial function to decay effectively to zero at the edge of the grid requiring grids that extend an additional 25 a_0 beyond R_0. A detailed discussion of this method is given by *McCurdy* et al. [47.80].

Born and Distorted Wave Methods

The integral expression (47.107) for the direct ionization amplitude provides a starting point for the calculation of cross sections at higher energies. Both the Born series methods and distorted wave methods, which were described in Sect. 47.1.6 when we considered intermediate and high energy elastic scattering and excitation, have been used to obtain ionization amplitudes.

Recently an important development of the distorted wave method has been made by *Jones* and *Madison* [47.81–83]. This new approach entitled the continuum distorted wave with eikonal initial state (CDW-EIS), commences from the two-potential expression for the transition amplitude given by *Gell-Mann* and *Goldberger* [47.84]

$$T_{fi} = \langle \chi_f^- | W_f^+ | \Psi_i^+ \rangle + \langle \chi_f^- | V_i - W_f^+ | \beta_i \rangle . \tag{47.126}$$

In the first term in this equation Ψ_i^+ is the exact scattering wave function developed from the initial state satisfying outgoing wave boundary conditions, χ_f^- is a distorted wave corresponding to the final state satisfying incoming wave boundary conditions and the corresponding perturbation W_f^+ is the adjoint of the operator W_f and operates to the left. In the second term, β_i is the unperturbed initial state which in the case of electron hydrogen atom scattering is

$$\beta_i = (2\pi)^{-3/2} \exp(i\mathbf{k}_0 \mathbf{r}_1)\psi_i(\mathbf{r}_2) , \tag{47.127}$$

and V_i is the initial state interaction potential given in this case by

$$V_i = -\frac{1}{r_1} + \frac{1}{r_{12}} . \tag{47.128}$$

An eikonal approximation is made for the initial state wave function Ψ_i^+ in (47.126) and the final state wave function χ_f^- is represented by a CDW wave function [47.85]. In this way distortion effects are included in both initial and final state wave functions. Results using the CDC-EIS approximation have been compared with ECS calculations for electron hydrogen atom triple ionization cross sections at 54.4 eV [47.86]. The two calculations are generally in very good agreement for equal energy sharing between the outgoing electrons which was considered in this work.

A further development of the distorted wave method for ionization has been made when the incident electron is fast and interacts weakly with the target atom or ion and the ejected electron is slow and interacts strongly with the residual ion [47.87, 88]. In this case (47.107) is applicable where the ionizing electron is represented

by plane waves or distorted waves while the initial target state and the ejected electron and residual ion state are both represented by the close coupling expansion (47.8). This approximation is particularly useful when the ejected electron can be captured into an autoionizing state of the target atom or ion which then decays giving rise to the following excitation-autoionization (EA) process

$$e^- + A^{q+} \rightarrow \left[A^{q+}\right] + e^- \rightarrow \left[A^{(q+1)+}\right] + 2e^- \ .$$

(47.129)
In this equation the bracket indicates a resonance state, while q is the charge on the atom A. This process together with related resonant excitation double autoionization (REDA) process

$$e^- + A^{q+} \rightarrow \left[A^{(q-1)+}\right] \rightarrow \left[A^{q+}\right] + e^-$$
$$\rightarrow \left[A^{(q+1)+}\right] + 2e^- \ ,$$

(47.130)
and the resonant excitation auto-double ionization (READI) process

$$e^- + A^{q+} \rightarrow \left[A^{(q-1)+}\right] \rightarrow \left[A^{(q+1)+}\right] + 2e^- \ ,$$

(47.131)
have attracted considerable experimental and theoretical interest [47.89–93]. However, while the EA process can be accurately treated using a distorted wave method if the incident electron is fast, both the REDA and READI processes involve capture of the incident electron into a resonant state and a strong coupling approach is required.

An Example and Conclusions

We conclude this section by mentioning a recent comparison that has been made between theory and experiment for electron impact ionization of hydrogen at 17.6 eV [47.94]. At this energy, which is only 4 eV above the ionization threshold, strong coupling effects between the incident and ejected electrons and the residual proton are important and hence Born series and distorted wave methods are not applicable. This comparison thus provides a stringent test of theoretical calculations. In this work triple-differential cross section measurements with coplanar outgoing electrons both having 2 eV energy were compared with exterior complex scaling (ECS) and convergent close coupling (CCC) calculations. The two calculations show excellent overall agreement both with the shape and the magnitude of the experiment for a wide range of scattering angles.

It is clear that a detailed theoretical understanding of electron hydrogen atom ionization has now been obtained over a wide range of energies. Although further work is required to predict accurate cross sections involving highly excited states of interest in plasma physics and astrophysical applications, for example in astrophysical H II regions [47.95], methods have been developed which should enable these cross sections to be accurately determined.

Good progress has also been made in the study of electron impact ionization of multi-electron atoms and ions. However major problems still remain both due to the need to obtain accurate target states, which also applies to elastic scattering and excitation, and due to fundamental difficulties in carrying out accurate calculations for REDA and READI processes defined by (47.130) and (47.131) respectively. In the latter case major theoretical difficulties still arise in the accurate treatment of resonance states which decay with the emission of more than one electron.

47.2 Electron–Molecule Collisions

47.2.1 Laboratory Frame Representation

The processes that occur in electron collisions with molecules are more varied than those that occur in electron collisions with atoms and atomic ions because of the possibility of exciting degrees of freedom associated with the motion of the nuclei. In addition, the multicenter and nonspherical nature of the electron molecule interaction considerably complicates the solution of the collision problem by reducing its symmetry and by introducing multicenter integrals that are more difficult to calculate than those occurring for atoms and ions.

We first consider the derivation of the equations describing the collision in the laboratory frame of reference discussed by *Arthurs* and *Dalgarno* [47.96]. The Schrödinger equation describing the electron–molecule system is

$$(H_m + \mathcal{T}_e + V) \Psi = E\Psi \ ,$$

(47.132)

where H_m is the molecular Hamiltonian, $\mathcal{T}_e$ is the kinetic energy operator of the scattered electron and V is the electron–molecule interaction potential

$$V(\boldsymbol{R}, \boldsymbol{r}_m, \boldsymbol{r}) = \sum_i \frac{1}{|\boldsymbol{r} - \boldsymbol{r}_i|} - \sum_i \frac{Z_i}{|\boldsymbol{r} - \boldsymbol{R}_i|} \ .$$

(47.133)

Here, R represents the coordinates R_i of all the nuclei, r_{m} represents the coordinates r_i of the electrons in the target molecule, and r represents the coordinates of the scattered electron. The total energy E in (47.132) refers to the frame of reference where the c.m. of the whole system is at rest.

As in the case of electron–atom and electron–ion collisions, introduce target eigenstates, and possibly pseudostates Φ_i, by the equation

$$\langle \Phi_i \,|H_{\mathrm{m}}|\, \Phi_j \rangle = w_i \delta_{ij} \;, \tag{47.134}$$

and then expand the total wave function Ψ, in analogy with (47.8), in the form

$$
\begin{aligned}
\Psi_j = \mathcal{A} \sum_i \Phi_i \left(R, r_{\mathrm{m}} \right) \mathcal{F}_{ij} \left(r \right) \\
+ \sum_i \chi_i \left(R, r_{\mathrm{m}}, r \right) b_{ij} \;,
\end{aligned}
\tag{47.135}
$$

where the spin variables have been suppressed for notation simplicity, and we have not carried out a partial-wave decomposition of the wave function $\mathcal{F}_{ij}$ representing the scattered electron. The subscripts i and j now represent the rotational and vibrational states of the molecule as well as its electronic states.

Coupled equations for the functions $\mathcal{F}_{ij}$ can be obtained by substituting expansion (47.135) into (47.132), and projecting onto the target states Φ_i and onto the square integrable functions χ_j. After eliminating the coefficients b_{ij}, the coupled integrodifferential equations

$$\left(\nabla^2 + k_i^2 \right) F_{ij} \left(r \right) = 2 \sum_\ell \left(V_{i\ell} + W_{i\ell} + X_{i\ell} \right) F_{\ell j} \left(r \right)$$

$$\tag{47.136}$$

are obtained, where $k_i^2 = 2\left(E - w_i \right)$ and where $V_{i\ell}$, $W_{i\ell}$, and $X_{i\ell}$ are the direct, nonlocal exchange, and nonlocal correlation potentials. By expanding F_{ij} in partial waves, a set of coupled radial integrodifferential equations result, analogous to (47.10) for atoms and ions.

The scattering amplitude and cross section for a transition from an initial state $|i\rangle = |k_i, \Phi_i, \chi_{\frac{1}{2}m_i}\rangle$ to a final state $|j\rangle = |k_j, \Phi_j, \chi_{\frac{1}{2}m_j}\rangle$ is then given by (47.7), where now the subscripts i and j refer collectively to the ro-vibrational and electronic states of the molecule.

47.2.2 Molecular Frame Representation

The theory described in the previous section is completely general, and has been the basis of a number of early calculations for simple diatomic molecules such as H_2. However, major computational difficulties arise

because of the very large number of rovibrational channels that need to be retained in expansion (47.135) for all but the simplest low-energy calculations.

This difficulty can be overcome by making a Born–Oppenheimer separation of the electronic and nuclear motion. The electronic motion is first determined with the nuclei held fixed. This is referred to as the fixed-nuclei approximation. The molecular rotational and vibrational motion is then included in a second step of the calculation. This procedure owes its validity to the large ratio of the nuclear mass to the electronic mass, and can be adopted when the collision time is much shorter than the periods of molecular rotation and vibration. Thus it is expected to be valid when the scattered electron energy is not close to a threshold, or when the energy does not coincide with that of a narrow resonance. In these cases, further developments described below are needed to obtain reliable cross sections.

In order to formulate the collision process in this representation, adopt a frame of reference that is rigidly attached to the molecule. The fixed-nuclei approximation then starts from the Schrödinger equation

$$\left(H_{\mathrm{el}} + \mathcal{T}_{\mathrm{e}} + V \right) \psi = E \psi \;, \tag{47.137}$$

where H_{el} is the electronic part of the target Hamiltonian obtained by assuming that the target nuclei have fixed coordinates denoted collectively by R. It follows that H_{el} is related to H_{m} in (47.132) by

$$H_{\mathrm{m}} = H_{\mathrm{el}} + \mathcal{T}_{\mathrm{R}} \;, \tag{47.138}$$

where $\mathcal{T}_{\mathrm{R}}$ is the kinetic energy operator for the rotational and vibrational motion of the nuclei. The remaining quantities $\mathcal{T}_{\mathrm{e}}$ and V are the same as in (47.132).

The solution of (47.137) proceeds in an analogous way to the solution of (47.2) for electron collisions with atoms and ions. We adopt an expansion similar to (47.8), where we now expand the function representing the motion of the scattered electron in terms of symmetry-adapted angular functions that transform as an appropriate irreducable representation (IRR) of the molecular point group (*Burke* et al. [47.97]). Substituting this expansion into (47.137), and projecting onto the corresponding channel functions and onto the square integrable functions, yields a set of coupled integrodifferential equations with the form given by (47.10), where now the channel indices i, j and ℓ represent the component of the IRR, as well as the electronic state of the target, and where Γ represents the conserved quantum numbers that now include the IRR and the total spin.

The final step is to solve these coupled integrodifferential equations for each set of nuclear coordinates R

of importance in the collision, using one of the methods discussed in Sect. 47.1.5. This yields the K-matrices, S-matrices and cross sections for fixed $\boldsymbol{R}$. For scattering calculations where only the ground electronic state has been included in the expansion, a number of approaches have been developed that replace the nonlocal exchange and correlation potentials by local potentials [47.2]. These approaches have proved particularly important in describing electronically elastic collisions of electrons with polyatomic molecules.

47.2.3 Inclusion of the Nuclear Motion

This section discusses how observables involving the nuclear motion, such as rotational and vibrational excitation cross sections, and dissociative attachment cross sections, can be obtained from the solutions of the fixed-nuclei equations.

The most widely used approach is the adiabatic-nuclei approximation [47.98–100]. In the case of diatomic molecules in a $^1\Sigma$ state, the scattering amplitude for a transition between electronic, vibrational and rotational states represented by $ivjm_j$ and $i'v'j'm'_j$ is given by

$$f_{i'v'j'm'_j,ivjm_j}\left(\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{r}}\right) =$$
$$\left\langle\chi_{i'v'}(R)Y_{j'm'_j}\left(\hat{\boldsymbol{R}}\right)\left|f_{i'i}\left(\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{r}};\,\boldsymbol{R}\right)\right|\chi_{iv}(R)Y_{jm_j}\left(\hat{\boldsymbol{R}}\right)\right\rangle,$$

(47.139)

where $f_{i'i}\left(\hat{\boldsymbol{k}}\cdot\hat{\boldsymbol{r}};\,\boldsymbol{R}\right)$ is the fixed-nuclei scattering amplitude, which depends parametrically on the nuclear coordinates $\boldsymbol{R}$, and χ_{iv} and Y_{jm_j} are the molecular vibrational and rotational eigenfunctions, respectively. This approximation is valid provided that the collision time is short compared with the vibration and/or rotation times, and is widely used in such situations.

The cross section is usually averaged over the degenerate sublevels m_j and summed over m'_j, giving the cross section for the transition ivj to $i'v'j'$. This leads to the relation

$$\frac{\mathrm{d}\sigma_{i'v'j',ivj}}{\mathrm{d}\Omega} = \sum_{j_t=|j-j'|}^{j+j'}\left[\left(j0j_t0\mid jj_tj'0\right)\right]^2\frac{\mathrm{d}\sigma_{i'v'j_t,iv0}}{\mathrm{d}\Omega}\,,$$

(47.140)

provided that the small differences in the wave numbers for the different rotational channels can be neglected. A similar relation holds for symmetric top molecules such as NH_3. For spherical top molecules such as CH_4,

the equivalent relation is [47.101, 102]

$$\frac{\mathrm{d}\sigma_{i'v'j',ivj}}{\mathrm{d}\Omega} = \frac{2j'+1}{2j+1}\sum_{j_t=|j-j'|}^{j+j'}\frac{1}{2j_t+1}\frac{\mathrm{d}\sigma_{i'v'j_t,iv0}}{\mathrm{d}\Omega}\,.$$

(47.141)

The sum in (47.140) or (47.141) over the final rotational state j' is independent of the initial state j. Also, if the cross section is multiplied by the transition energy and then sum over j', the result, which is in the mean energy loss by the incident electron, is still independent of j.

The adiabatic-nuclei approximation breaks down close to threshold or in the neighborhood of narrow resonances [47.103]. A straightforward way of including nonadiabatic effects that arise in vibrational excitation is to retain the vibrational terms in the Hamiltonian, but still to treat the rotational motion adiabatically. Hence, instead of (47.137), the equation

$$(H_{\mathrm{el}}+\mathcal{T}_{\mathrm{vib}}+\mathcal{T}_{\mathrm{e}}+V)\,\widetilde{\psi}=E\widetilde{\psi}$$

(47.142)

is solved, where $\mathcal{T}_{\mathrm{vib}}$ is the kinetic energy operator for the nuclear vibrational motion, and where the other quantities have the same meaning as in (47.137). Adopting a frame of reference in which the molecule has fixed spacial orientation, and separating out the angular variables of the scattered electron, coupled integrodifferential equations coupling the target vibrational states as well the electronic states can be obtained. This approach has been adopted with success [47.104, 105], but is computationally demanding since the number of coupled channels can become very large.

Vibrational excitation and dissociative attachment are particularly important in resonance regions when the scattered electron spends an appreciable time in the neighborhood of the molecule. As a result, a number of approaches has been developed describing these processes based on electron molecule resonance theories (e.g., [47.106–110]). The basic idea is that a series of fixed-nuclei resonance states $\psi_n^{(\mathrm{r})}$ are introduced for a range of values of R, either by imposing Siegert outgoing wave boundary conditions [47.111], or by introducing Feshbach projection operators [47.15, 16]. The amplitude for a transition from an initial electronic–vibrational state iv to a final state $i'v'$ is then given by

$$T_{i'v',iv} = \sum_n\left\langle\chi_{i'v'}\left(R'\right)\zeta_{ni'}\left(R'\right)\left|G_n^{(\mathrm{r})}\left(R',\,R\right)\right.\right.$$
$$\left.\times\left|\zeta_{ni}\left(R\right)\chi_{iv}\left(R\right)\right\rangle,\right.$$

(47.143)

where χ_{iv} are the vibrational eigenfunctions, ζ_{ni} are the "entry amplitudes" from the initial or final electronic

states into the resonance states $\psi_n^{(r)}$, and $G_n^{(r)}$ are the Green's functions that describe the propagation in the intermediate resonance states $\psi_n^{(r)}$. Dissociative attachment can be described by a straightforward extension of this theory.

The fixed-nuclei R-matrix method has also been extended to treat vibrational excitation and dissociative attachment [47.112]. A generalized R-matrix is introduced by an equation which, in analogy with (47.143), can be written as

$$R_{i'v',iv} = \frac{1}{2a} \sum_k \langle \chi_{i'v'}\left(R'\right) w_{i'k}^{\Gamma}\left(R'\right) | G_k^{RM}\left(R', R\right)$$
$$\times | w_{ik}^{\Gamma}\left(R\right) \chi_{iv}\left(R\right) \rangle , \qquad (47.144)$$

where the surface amplitudes $w_{ik}^{\Gamma}(R)$ are defined by (47.76), and the Green's function G_k^{RM} now describes the propagation in the intermediate R-matrix states defined by (47.73). Once the generalized R-matrix has been determined, the final step in the calculation is to solve the collision problem in the external region which, for diatomic molecules, is defined by the condition that the scattered electron coordinate r is greater than some given radius a, and the internuclear coordinate R is greater than some given radius A.

Another approach that includes nonadiabatic effects is the energy-modified adiabatic approximation introduced by *Nesbet* [47.113]. In this approach, the S-matrix elements connecting the vibrational states are defined by

$$S_{i'v',iv} = \langle \chi_{i'v'} | S_{i'i}\left(E - H_i; R\right) | \chi_{iv} \rangle , \qquad (47.145)$$

where $S_{i'i}\left(E - H_i; R\right)$ is the S-matrix calculated in the fixed nuclei approximation at the internuclear separation R at an energy defined by the operator $H_i = E_i\left(R\right) + \mathcal{T}_{vib}$. This has the effect of including the internal energy of the target into the S-matrix elements, giving the correct threshold energies.

Finally, we mention an off-shell T-matrix approach for including nonadiabatic effects discussed first by *Shugard* and *Hazi* [47.114]. This approach can also extend the range of validity of the adiabatic-nuclei approximation, while retaining much of its inherent simplicity. This has recently been applied with success to low-energy vibrational excitation of H_2 and CH_4 [47.115].

47.2.4 Electron Collisions with Polyatomic Molecules

In the last few years computer programs based on the ab initio methods described in Sect. 47.1.5 have been developed and used to calculate cross sections for electron collisions with polyatomic molecules of importance in many applications.

Recent work includes electron collisions with nitrous oxide which is an important species in the upper atmosphere where it plays a role in ozone destruction. N_2O lasers are also of importance. Fixed-nuclei total cross sections, calculated using independent Bonn [47.116] and UK [47.117] polyatomic R-matrix programs are in good agreement with experiment [47.118], showing a $^2\Pi$ shape resonance near 2 eV. The UK R-matrix program has also been used to study electron collisions with the open-shell radical OClO [47.119]. An important process in the stratospheric polar vortex involves the coupling of chlorine and bromine chemistry, in which OClO plays a key role. In this case OClO is formed by the reaction $BrO + ClO \rightarrow Br + OClO$. Fixed-nuclei total cross sections were calculated including eight electronic states in the R-matrix expansion, giving good agreement with experiment [47.120], reproducing a shoulder in the cross section between 2 and 6 eV.

Important advances have also been made in the theoretical treatment of vibrational excitation in polyatomic molecules. Electron collisions with CO_2 molecules were calculated in the fixed-nuclei approximation using an electron–polyatomic molecular scattering program based on the complex Kohn variational method [47.121]. At low energies the cross section is dominated by a virtual state at threshold and a $^2\Pi_u$ shape resonance at 3.8 eV. As the molecule bends from its ground state linear configuration, the shape resonance splits into nondegenerate $^2A_1$ and $^2B_1$ configurations. The fixed-nuclei complex resonance energy surfaces are parametrized and motion on these surfaces is computed using a generalization of the Boomerang model [47.122]. The results reproduce the oscillations resulting from the interference between the nuclear and electronic motion seen experimentally by *Allen* [47.123, 124].

47.3 Electron–Atom Collisions in a Laser Field

Electron–atom collisions in the presence of an intense laser field have recently attracted considerable attention because of the importance of these processes in applica-

tions such as laser plasma interactions, and also because of their fundamental interest in atomic collision theory. This section summarizes the basic theory, commenc-

ing with the scattering of electrons by a potential in the presence of a laser field. The discussion is then generalized to the scattering of electrons by complex atoms and ions, where 'dressing' of the atomic eigenstates by the laser field must be considered, and where simultaneous electron photon excitation (SEPE) processes, defined by

$$nh\nu + e^- + A_i \rightarrow e^- + A_j \ , \tag{47.146}$$

can occur. Recent reviews of aspects of this subject have been given by *Mason* [47.3], *Newell* [47.125] and *Mittleman* [47.126].

47.3.1 Potential Scattering

We adopt a semiclassical description of the collision process in which the electrons and the target atom are described by the nonrelativistic Schrödinger equation, and the laser field is described classically. This is valid for most high intensity fields of current interest, where a typical coherence volume of the field contains a very large number of photons [47.126].

The time-dependent Schrödinger equation describing an electron scattered by a potential $V(r)$ in the presence of an external electromagnetic (laser) field is then

$$i\frac{\partial}{\partial t}\Psi(r,t) = \left[-\frac{1}{2}\nabla^2 - \frac{i}{c}A(r,t)\cdot\nabla \right.$$
$$\left. + \frac{1}{2c^2}A^2(r,t) + V(r)\right]\Psi(r,t) \ , \tag{47.147}$$

in the Coulomb gauge such that the vector potential satisfies $\nabla \cdot A = 0$. We also assume that the laser field is monochromatic, monomode, linearly polarized, and spacially homogeneous (i. e., its wavelength is large compared with the range of the potential, or more generally with the size of the atom). Hence we can write

$$A(r,t) = A(t) = \hat{\epsilon} A_0 \cos \omega t \ , \tag{47.148}$$

where $\hat{\epsilon}$ is a unit vector along the field polarization direction and ω is the angular frequency. The A^2 term in (47.147) can be removed by the unitary transformation

$$\Psi(r,t) = \exp\left(-\frac{i}{2c^2}\int^t A^2(t')\,dt'\right)\Psi_V(r,t) \ , \tag{47.149}$$

where Ψ_V satisfies the Schrödinger equation in the velocity gauge given by

$$i\frac{\partial}{\partial t}\Psi_V(r,t) = \left[-\frac{1}{2}\nabla^2 - \frac{i}{c}A(t)\cdot\nabla + V(r)\right]$$
$$\times \Psi_V(r,t) \ . \tag{47.150}$$

The corresponding equation for the free electron with $V = 0$ is readily solved to give the Volkov wave function [47.127]

$$\chi_k(r,t)$$
$$= (2\pi)^{-\frac{3}{2}} \exp\left[i\left(k\cdot r - k\cdot\alpha_0\sin\omega t - Et\right)\right] \ , \tag{47.151}$$

where k is the wave vector and $E = \frac{1}{2}k^2$ the kinetic energy. The quantity $\alpha(t)$ is defined by

$$\alpha(t) = \frac{1}{c}\int^t A(t')\,dt' = \alpha_0\sin\omega t \ , \tag{47.152}$$

where $\alpha_0 = \mathcal{E}_0/\omega^2$, $\mathcal{E}_0$ being the electric field strength.

To solve (47.150), introduce the causal Green's function $G_0^{(+)}(r,t;r',t')$ satisfying the equation

$$\left(i\frac{\partial}{\partial t} + \frac{1}{2}\nabla^2 + \frac{i}{c}A(t)\cdot\nabla\right)G_0^{(+)}(r,t;r',t')$$
$$= \delta(r-r')\delta(t-t') \ . \tag{47.153}$$

This Green's function is given by

$$G_0^{(+)}(r,t;r',t')$$
$$= -i\theta(t-t')\int \chi_k(r,t)\chi_k^*(r',t')\,dk \ , \tag{47.154}$$

where $\theta(x) = 1$ for $x > 0$ and $\theta(x) = 0$ for $x < 0$. The corresponding causal outgoing wave solution of (47.150) is

$$\Psi_k^{(+)}(r,t) = \chi_k(r,t) + \int_{-\infty}^t dt'\int dr'\, G_0^{(+)}(r,t;r',t')$$
$$\times V(r')\Psi_k^{(+)}(r',t) \ , \tag{47.155}$$

and the S-matrix element for a transition $k_i \rightarrow k_f$ in the presence of the laser field is given by

$$S_{k_f,k_i} = -i\left\langle\chi_{k_f}\left|V\right|\Psi_{k_i}^{(+)}\right\rangle, \tag{47.156}$$

where an integration is carried out over all space and time in this matrix element. The time integration in (47.156) can be performed using the relation

$$\exp(ix\sin u) = \sum_{n=-\infty}^{\infty} J_n(x)\exp(inu) \ , \tag{47.157}$$

where $J_n(x)$ is an ordinary Bessel function of order n. Then

$$S_{\boldsymbol{k}_f, \boldsymbol{k}_i} = -2\pi\mathrm{i} \sum_{n=-\infty}^{\infty} \delta\left(E_{\boldsymbol{k}_f} - E_{\boldsymbol{k}_i} - n\omega\right) T^n_{\boldsymbol{k}_f, \boldsymbol{k}_i} \tag{47.158}$$

where the delta function ensures energy conservation, and n is the number of photons absorbed or emitted. The differential cross section for the scattering process $\boldsymbol{k}_i \to \boldsymbol{k}_f$ with exchange of n photons can then be defined in terms of the T-matrix elements $T^n_{\boldsymbol{k}_f, \boldsymbol{k}_i}$ by

$$\frac{\mathrm{d}\sigma_n}{\mathrm{d}\Omega} = (2\pi)^4 \frac{k_f}{k_i} \left| T^n_{\boldsymbol{k}_f, \boldsymbol{k}_i} \right|^2 . \tag{47.159}$$

There are two limiting cases in which considerable simplification in this expression occurs. First, at high energies or for weak potentials, the first Born approximation can be used to describe scattering by the potential $V(\boldsymbol{r})$. In this case (47.159) reduces to

$$\frac{\mathrm{d}\sigma_n^{1,\mathrm{B}}}{\mathrm{d}\Omega} = (2\pi)^4 \frac{k_f}{k_i} J_n^2\left(\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0\right) |\mathcal{V}(\boldsymbol{\Delta})|^2 , \tag{47.160}$$

where $\boldsymbol{\Delta} = \boldsymbol{k}_i - \boldsymbol{k}_f$ is the momentum transfer vector and

$$\mathcal{V}(\boldsymbol{\Delta}) = (2\pi)^{-3} \int \exp(\mathrm{i}\boldsymbol{\Delta} \cdot \boldsymbol{r}) V(\boldsymbol{r}) \,\mathrm{d}\boldsymbol{r} . \tag{47.161}$$

It follows immediately that

$$\frac{\mathrm{d}\sigma_n^{1,\mathrm{B}}}{\mathrm{d}\Omega} = J_n^2(\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0) \frac{\mathrm{d}\sigma^{1,\mathrm{B}}}{\mathrm{d}\Omega} , \tag{47.162}$$

where $\mathrm{d}\sigma^{1,\mathrm{B}}/\mathrm{d}\Omega$ is the field-free first Born differential cross section. Using the sum rule

$$\sum_{n=-\infty}^{\infty} J_n^2(x) = 1 , \tag{47.163}$$

(47.162) immediately yields

$$\sum_{n=-\infty}^{\infty} \frac{\mathrm{d}\sigma_n^{1,\mathrm{B}}}{\mathrm{d}\Omega} = \frac{\mathrm{d}\sigma^{1,\mathrm{B}}}{\mathrm{d}\Omega} . \tag{47.164}$$

The second limiting case is the low frequency (soft photon) limit, where the laser photon energy ω is small compared with the electron energy E_{k_i}. In this limit, the T-matrix element is given by [47.128]

$$T^n_{\boldsymbol{k}_f, \boldsymbol{k}_i} = J_n(\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0)\langle \chi_{\boldsymbol{k}'_f} | \mathcal{T}(E_{k'_i}) | \chi_{\boldsymbol{k}'_i} \rangle + O(w^2) , \tag{47.165}$$

where $\boldsymbol{k}'_i$ and $\boldsymbol{k}'_f$ are the shifted wave vectors

$$\boldsymbol{k}'_i = \boldsymbol{k}_i + \frac{n\omega}{\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0} \boldsymbol{\alpha}_0 , \quad \boldsymbol{k}'_f = \boldsymbol{k}_f + \frac{n\omega}{\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0} \boldsymbol{\alpha}_0 \tag{47.166}$$

and $\mathcal{T}(E_{k'_i})$ is the T-operator in the absence of the laser corresponding to the energy $E_{k'_i} = k'^2_i/2$. The differential cross section for the transfer of n photons is then

$$\frac{\mathrm{d}\sigma_n}{\mathrm{d}\Omega} = \frac{k_f}{k_i} J_n^2(\boldsymbol{\Delta} \cdot \boldsymbol{\alpha}_0) \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega}\left(\boldsymbol{k}'_f, \boldsymbol{k}'_i\right) + O(\omega^2) , \tag{47.167}$$

where $\mathrm{d}\sigma(\boldsymbol{k}'_f, \boldsymbol{k}'_i)/\mathrm{d}\Omega$ refers to the transition $\boldsymbol{k}'_i \to \boldsymbol{k}'_f$ in the absence of the laser. If the frequency is small enough to neglect the n dependence of $\boldsymbol{k}'_i$ and $\boldsymbol{k}'_f$, then using the sum rule (47.163), (47.167) becomes

$$\sum_{n=-\infty}^{\infty} \frac{\mathrm{d}\sigma_n}{\mathrm{d}\Omega} = \frac{\mathrm{d}\sigma}{\mathrm{d}\Omega} , \tag{47.168}$$

where $\mathrm{d}\sigma/\mathrm{d}\Omega$ is the field-free differential cross section. The Kroll–Watson result (47.167) has been found to be surprisingly accurate, even for cases where $\omega/E_{k_i} \approx 0.5$ [47.129, 130]. A nonrigorous extension of the Kroll–Watson result to inelastic processes has been considered by a number of authors, and has been found to give qualitative agreement with experiments on helium [47.131].

47.3.2 Scattering by Complex Atoms and Ions

The time-dependent Schrödinger equation describing an electron scattered by an N-electron atom or ion in the presence of a laser field can be written in analogy with (47.147) as

$$\mathrm{i}\frac{\partial}{\partial t} \Psi\left(X_{N+1}, t\right)$$
$$= \left[H_{N+1} - \frac{\mathrm{i}}{c} \sum_{i=1}^{N+1} \boldsymbol{A}\left(\boldsymbol{r}_i, t\right) \cdot \nabla_i \right.$$
$$\left. + \frac{1}{2c^2} \sum_{i=1}^{N+1} \boldsymbol{A}^2\left(\boldsymbol{r}_i, t\right) \right] \Psi\left(X_{N+1}, t\right) , \tag{47.169}$$

where H_{N+1} is the $(N+1)$-electron Hamiltonian defined by (47.3) and X_{N+1} represents the space and spin coordinates of all $N + 1$ electrons defined as in (47.8).

With the same assumptions made in the reduction of (47.147) to (47.150), (47.163) can be rewritten in the velocity gauge form

$$\mathrm{i}\frac{\partial}{\partial t} \Psi_{\mathrm{V}}\left(X_{N+1}, t\right)$$
$$= \left(H_{N+1} + \frac{1}{c}\boldsymbol{A}(t) \cdot \boldsymbol{P}_{N+1} \right) \Psi_{\mathrm{V}}\left(X_{N+1}, t\right) , \tag{47.170}$$

where

$$P_{N+1} = \sum_{i=1}^{N+1} -\mathrm{i}\nabla_i \qquad (47.171)$$

is the total momentum operator.

The solution of (47.170) for $\mathrm{e}^--\mathrm{H}$ scattering in a strong laser field at high electron impact energies has been considered by *Francken* and *Joachain* [47.132]. They discussed the use of the Born series and the eikonal Born series (EBS) approximations, given by (47.104), to describe the electron–atom collision, and included the dressed wave function of the atomic hydrogen target to first-order in the field strength $\mathcal{E}_0$. Important effects related to the dressing of the target are the appearance in the cross sections of asymmetries between the absorption and the emission of a given number of laser photons, as well as the appearance of new resonance structures in the cross sections.

So far, detailed studies of low-energy electron–atom and electron–ion collisions in laser fields have been very limited. Pioneering work on $\mathrm{e}^--\mathrm{H}^+$ collisions by *Dimou* and *Faisal* [47.133], and by *Collins* and *Csanak* [47.134] have shown important resonance effects caused by the field coupling bound states to the continuum. In addition, multichannel quantum defect theory has been applied by *Zoller* and co-workers [47.135, 136] to study the behavior of Rydberg states in laser fields. We conclude this section by briefly describing the R-matrix–Floquet method [47.137] for treating electron collisions with complex atoms and ions in a laser field, based on the R-matrix method discussed in Sect. 47.1.5.

In this approach, configuration space is divided into internal and external regions, as in the field-free case. In the internal region, a further gauge transformation of the field is made to the length gauge, so that the time-dependent Schrödinger equation (47.170) now becomes

$$\mathrm{i}\frac{\partial}{\partial t}\Psi_\mathrm{L}(X_{N+1}, t)$$
$$= [H_{N+1} + \mathcal{E}(t)\cdot R_{N+1}]\Psi_\mathrm{L}(X_{N+1}, t) , \qquad (47.172)$$

where $R_{N+1} = \sum_{i=1}^{N+1} r_i$, and we assume that the electric field $\mathcal{E}(t)$ is given by

$$\mathcal{E}(t) = -\frac{1}{c}\frac{\mathrm{d}}{\mathrm{d}t}A(t) = \hat{\epsilon}\mathcal{E}_0\cos\omega t . \qquad (47.173)$$

In order to solve (47.172), we introduce the Floquet–Fourier expansion [47.138, 139]

$$\Psi_\mathrm{L}(X_{N+1}, t) = \mathrm{e}^{-\mathrm{i}Et}\sum_{n=-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}n\omega t}\Psi_n^\mathrm{L}(X_{N+1}) .$$
$$(47.174)$$

Substituting this equation into (47.172), using (47.173) and equating the coefficients of $\exp[-\mathrm{i}(E+n\omega)t]$ to zero gives

$$(H_{N+1} - E - n\omega)\Psi_n^\mathrm{L} + D_{N+1}(\Psi_{n-1}^\mathrm{L} + \Psi_{n+1}^\mathrm{L}) = 0 , \qquad (47.175)$$

where we have introduced the operator

$$D_{N+1} = \frac{1}{2}\mathcal{E}_0\hat{\epsilon}\cdot R_{N+1} . \qquad (47.176)$$

The functions Ψ_n^L can be regarded as the components of a vector Ψ^L in photon space. Equation (47.175) can then be written in this space as

$$(H_\mathrm{F} - EI)\Psi^\mathrm{L} = 0 , \qquad (47.177)$$

where the Floquet Hamiltonian H_F is an infinite tridiagonal matrix.

In order to solve (47.177) in the internal region, the components Ψ_n^L are expanded in a basis which, in analogy with (47.69), has the form

$$\Psi_{kn}^\mathrm{L}(X_{N+1})$$
$$= \mathcal{A}\sum_{\Gamma ij}\overline{\Phi}_i^\Gamma(x_1, \ldots, x_N; \hat{r}_{N+1}\sigma_{N+1})r_{N+1}^{-1}$$
$$\times u_j(r_{N+1})a_{ijkn}^\Gamma$$
$$+ \sum_{\Gamma i}\chi_i^\Gamma(x_1, \ldots, x_{N+1})b_{ikn}^\Gamma , \qquad (47.178)$$

where the summation over Γ is required since the total orbital angular momentum L and the total parity π in (47.9) are no longer conserved. The coefficients a_{ijkn}^Γ and b_{ikn}^Γ are then determined by diagonalizing $H_\mathrm{F} + L_\mathrm{b}$, where L_b is an appropriate Bloch operator.

In the external region, the wave function describing the scattered electron is transformed to the velocity gauge, and the corresponding coupled equations integrated outwards from the internal region boundary for each energy of interest [47.140]. After a further transformation to the acceleration frame (or Kramers–Henneberger frame [47.141]) the wave function can be fitted to an asymptotic form to yield the K-matrix, S-matrix and collision cross sections. This approach has been used to calculate laser-assisted electron scattering by H and He atoms [47.142, 143] and a detailed discussion of the theory has been given [47.144].

48. Positron Collisions

The positron is the antiparticle of the electron, having the same mass but opposite charge. Positrons undergo collisions with atomic and molecular systems in much the same way as electrons do. Thus, the standard scattering theory for electrons (see Chapt. 47) can also be applied to positron scattering. However, there are a number of important differences from electron scattering which we outline below.

Since the positron is a distinct particle from the atomic electrons, it cannot undergo an exchange process with the bound electrons during a collision, as is possible with electrons. Thus, the nonlocal exchange terms which arise in the description of electron scattering are not present for positrons. This leads to a simplification of the scattering equations from those for electrons. However, there are scattering channels available with positron scattering which do not exist with electrons. These are dealt with in Sect. 48.1.

Historically beams of low-energy positrons were difficult to obtain and consequently there is considerably less experimental data available for positrons than for electrons. This was particularly true for quantities which required large incident

positron fluxes, such as differential scattering cross sections and coincidence parameters. However, the recent development of cold trap-based positron beams with high resolution and high brightness by the San Diego group [48.1] has the potential to revolutionize this field and put it on a par with electron scattering.

Throughout this chapter we will employ atomic units unless otherwise noted.

48.1 Scattering Channels

Positrons colliding with atomic and molecular systems have the same scattering channels available as for electrons, viz., elastic, inelastic, ionization, and for molecules, dissociation. However, two channels exist for positrons which do not exist for electrons, viz., positronium formation and annihilation.

48.1.1 Postronium Formation

Positronium, a bound state of an electron–positron pair (Chapt. 27), can be formed during the collision of a positron with an atomic or molecular target. The positronium 'atom' can escape to infinity leaving the target in a ionized state with a positive charge of one.

Thus, this process can be difficult to distinguish experimentally from true ionization where both the incident positron and the ionized electron are asymptotically free particles. The positronium atom can exist in its ground state or in any one of an infinite number of excited states after the collision. The level structure of positronium is, to order α^2, where α is the fine-structure constant, identical to that of hydrogen but with each level having half the energy of the corresponding hydrogenic state.

Positronium formation is a rearrangement channel, and thus, is a two-centre problem. Because positronium is a light particle, having a reduced mass one-half of that of an electron, the semi-classical type of approximations used in ion–atom collisions (Chapt. 50) are not

applicable here. We will discuss various theoretical approaches to this process in Sect. 48.2 and give references to experimental results in Sect. 48.3.

Positronium formation in the ground state has a threshold which is 1/4 of a Hartree (6.802 85 eV) below the ionization threshold of the target. This means that it is normally the lowest inelastic channel in positron scattering from neutral atoms. For atoms with a small ionization potential, such as the alkalis, this channel is always open. The energy range between the positronium threshold and the first excited state of the atom is known as the Ore gap. In this range, positronium formation is the only possible inelastic process.

48.1.2 Annihilation

Annihilation is a process in which an electron–positron pair is converted into two or more photons. It can occur either directly with a bound atomic electron or after positronium formation has taken place. The direct annihilation cross section for a positron of momentum k colliding with an atomic or molecular target can be written as [48.2]

$$\sigma_a = \frac{\alpha^3 Z_{eff}}{k} \left(\pi a_0^2 \right) , \tag{48.1}$$

where Z_{eff} can be thought of as the effective number of electrons in the target with which the positron can annihilate. If $\Psi(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N, \mathbf{x})$ is the wave function for the system of a positron, with coordinate $\mathbf{x}$, colliding with an N-electron target, then

$$Z_{eff} = \sum_{i=1}^{N} \int d\mathbf{r}_1 \, d\mathbf{r}_2 \ldots d\mathbf{r}_N \left| \Psi(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N; \mathbf{r}_i) \right|^2 . \tag{48.2}$$

While this formula can be naively derived by assuming that the positron can only annihilate with an electron if it is at the identical location, it actually follows from a quantum electrodynamical treatment of the process [48.3]. If the wave function Ψ is approximated by the product of the undistorted target wave function times a positron scattering function $F(\mathbf{x})$, then

$$Z_{eff} = \int d\mathbf{r} \, \rho(\mathbf{r}) \left| F(\mathbf{r}) \right|^2 , \tag{48.3}$$

where ρ is the electron number density of the target. Thus, in the Born approximation, where F is taken as a plane wave, Z_{eff} simply becomes the total number of electrons Z in the target. However, a pronounced enhancement of the annihilation rate in the vicinity of the

Ps formation threshold due to virtual Ps formation was predicted [48.4, 5]. Subsequently, the Born approximation was shown to be grossly inadequate by the San Diego group, who found annihilation rates Z_{eff} at room temperature which are an order of magnitude larger for some atoms and even up to five orders of magnitude larger in large hydrocarbon molecules. Furthermore, there is evidence that only the outer shell of electrons takes part in the annihilation process. Two mechanisms have been proposed in order to explain these large values for Z_{eff}. One involves the enhancement of the direct annihilation process below the Ps formation threshold due to the attractive nature of the positron–electron interaction, which increases the overlap of positron and electron densities on the atom or molecule. The second mechanism is referred to as resonant annihilation, which occurs after the positron has been captured into a Feshbach resonance, where the positron is bound to a vibrationally excited molecule. A summary of the above results can be found in the recent article by *Barnes* et al. [48.6].

When a positron annihilates with an atomic electron, two 511 keV photons is the most likely result, if the positron–electron pair are in a singlet spin state (para-positronium). In the centre-of-mass frame of the pair, the photons are emitted in opposite directions to conserve momentum. However, in the laboratory frame the bound electron has a momentum distribution which is reflected in the photon directions not being exactly 180 degrees apart. This slight angular deviation, called the angular correlation, can be measured, and gives information about the momentum distribution of the bound electrons. This quantity is given by [48.3]

$$S(\mathbf{q}) = \sum_{i=1}^{N} \int d\mathbf{r}_1 \ldots d\mathbf{r}_{i-1} \, d\mathbf{r}_{i+1} \ldots d\mathbf{r}_N \tag{48.4}$$

$$\times \int d\mathbf{r}_i d\mathbf{x} \, e^{i\mathbf{q} \cdot \mathbf{x}} \left| \Psi(\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_N; \mathbf{x}) \, \delta(\mathbf{r}_i - \mathbf{x}) \right|^2 ,$$

where $\mathbf{q}$ is the resultant momentum of the annihilating pair. In evaluating this quantity, the positron is assumed to be thermalized in the gas before undergoing annihilation. Experimentally, only one component of $\mathbf{q}$ is measured, so that $S(\mathbf{q})$ is integrated over the other two components of the momentum to obtain the measured quantity. The spin triplet component of an electron–positron pair (orthopositronium) can only decay with the emission of three or more photons which do not have well defined energies. This is a much less probable process than the two photon decay from the singlet component.

48.2 Theoretical Methods

The basic theoretical approaches to the calculation of positron scattering from atoms and molecules were originally developed for electron scattering and later applied to the positron case. Thus, we emphasize here only the differences that arise between the electron and positron cases, both in the theoretical formulations, and in later sections, in the nature of the results.

The lowest-order interaction between a free positron and an atomic or molecular target is the repulsive static potential of the target

$$V_s = \langle \psi_0 | V | \psi_0 \rangle, \tag{48.5}$$

where ψ_0 is the unperturbed target wave function and V is the electrostatic interaction potential between the positron and the target. Since this interaction has the opposite sign from that for electron scattering, the static potential also has the opposite sign in these two cases. On the other hand, the next higher-order of interaction is polarization, which arises from the distortion of the atom by the incident particle. If we represent this distortion of the target to first-order by the wave function ψ_1, as in the polarized-orbital approximation, for example [48.9], then the polarization interaction can be represented by the potential

$$V_p = \langle \psi_0 | V | \psi_1 \rangle. \tag{48.6}$$

This potential is attractive for both positron and electron scattering and has an asymptotic form with leading term $-\alpha_d/2r^4$, where α_d is the static dipole polarizability (Sect. 23.2.3) of the target. Thus, the static and polarization potentials for positron scattering from ground state systems are of opposite sign and tend to cancel one another. This leads to very different behaviour from the electron case where they are of the same sign. In particular, the elastic scattering cross sections for positron scattering from an atom are much smaller than for electron scattering, and the phase shifts (Sect. 47.1.1) have very different magnitudes and dependences on energy. This is illustrated for the case of scattering from helium in Figs. 48.1–48.3, where the results of the highly accurate variational calculations for scattering by electrons and positrons are shown. Note the difference in sign between the electron and positron s-wave phase shifts for very small values of the incident momentum. The fact that the positron phase shift goes through zero leads to the Ramsauer minimum in the positron total cross section, as shown in Fig. 48.3. The large difference in magnitudes between the electron and positron s- and
Fig. 48.1 Variational s-wave phase shifts for electron [48.7] (*dashed line*) and positron [48.8] (*solid line*) scattering from helium atoms

p-wave phase shifts leads to the large difference in the total elastic cross sections as shown.

Higher-order terms in the interaction potential may also give important contributions to scattering cross sections. For a detailed discussion, see the article by *Drachman* and *Temkin* [48.10].

A simple potential scattering calculation using the sum of the static and polarization potentials, but without the exchange terms that are present for the electron case, can be applied to elastic scattering calculations for closed shell systems (see Sect. 48.3.3).

The potentials defined above can also be used in a distorted-wave approximation (Chapt. 47) which can be applied to excitation and ionization by positron impact. Once again, the complicated exchange terms which arise in electron scattering are absent here. *Sienkiwicz* and *Baylis* [48.11] have included such potentials in a Dirac–Fock formulation of positron scattering which treats the positron as an electron with negative energy.

For positrons with high enough incident energies ($\approx 1\,keV$), the first Born approximation will become valid (Chapt. 47). Since the first Born approximation is independent of the sign of the charge of the incident particles, this indicates that as the incident energy increases, the corresponding cross sections for electron
Fig. 48.2 Variational *p*-wave phase shifts for electron [48.7] (*dashed line*) and positron [48.15] (*solid line*) from helium atoms

Fig. 48.3 Total elastic cross sections for electron (*dashed line*) and positron (*solid line*) from helium atoms calculated from the phase shifts shown in Figs. 48.1 and 48.2. The higher-order phase shifts were calculated from effective range theory (Sect. 47.1.1)

and positron scattering will eventually merge. From flux conservation arguments, this means that the positronium formation cross section will rapidly decrease as the incident energy increases. In fact, from experimental measurements, the total cross sections (summed over all possible channels) for electron and positron scattering appear to merge at a much lower energy than the cross sections for individual channels [48.12]. More elaborate calculations for high energy scattering have been carried out in the eikonal-Born series [48.13] (Chapt. 47). These approximations allow for both polarization and absorption (i. e., inelastic processes) and yield good agreement with elastic experimental measurements of differential cross sections at energies above 100 eV. A detailed analysis [48.13, 14] of the various contributions to the scattering indicates that absorption effects due to the various open inelastic channels plays a much more important role here than for electron scattering.

A more elaborate treatment of positron scattering is based on the close-coupling approximation (Chapt. 47), where the wave function for the total system of positron plus target is expanded using a basis set comprised of the wave functions of the target. Once again, there are no exchange terms involving the positron and, in principle, a complete expansion including the continuum states of the target would include the possibility of positronium formation. However, such an expansion is not practi-

cable if one wants to calculate explicit cross sections for positronium formation. Even in cases where such cross sections are not required, the considerable effect that the positronium formation channels can have on the other scattering cross sections is best included by a close-coupling expansion that includes terms representing positronium states plus the residual target ion. There is a problem of double counting of states in such an expansion but, in practice, this does not appear to be a problem if the number of states in the expansion is not large. Also, in many cases, additional pseudostates have to be included in the expansion in order to correctly represent the long-range polarization interaction.

A close-coupling expansion including positronium states is a two-centre problem, i. e., it includes the centres of mass of both the target and the positronium states. Since positronium is a light system, the semi-classical approach often used to treat rearrangement collisions between heavy systems (Chapt. 50) is not applicable here. This means that one is faced with a problem of considerable computational complexity [48.16–21].

Another way to take into account the effects of open inelastic channels without the complications of a full close-coupling approach is to use optical potentials. These are often based on a close-coupling formal-

ism [48.14, 22] and lead to a complex potential, the real part of which represents distortions of the target (such as polarization) while the complex part allows for absorption (i. e., flux into open channels not explicitly represented).

Bray and *Stelbovics* [48.23] have applied the convergent close-coupling method to the scattering of positrons from atoms. This method includes contributions from the continuum states of the target and sufficient terms in the expansion are included to ensure numerical convergence. At the present time, however, positronium states have not been explicitly included.

Finally, there is the variational method (Chapt. 47), which uses an analytic form of trial wave function to represent the total system. The parameters of this analytic function are determined as part of the method. Given a trial wave function with sufficient flexibility and a large enough number of parameters, essentially exact results can be obtained in the elastic energy range and

the Ore gap. Because the complexity of the trial function increases as the square of the number of electrons in the target, only positron scattering from hydrogen, helium and lithium and the hydrogen molecule have been treated by this method, to date [48.8, 24].

In the case of ionization there appears to be quite distinct threshold behaviour of the cross sections for electron and positron collisions. For electrons, the Wannier threshold law (Sect. 52.2.1) has exponent 1.127, while a similar analysis for positrons [48.25] yields an exponent of 2.651. However, the existence of the positronium formation channel leaves in question whether this analysis will give the dominant term at threshold. For a fuller discussion see [48.26], and references therein.

There has been an investigation [48.27] of the behaviour of the elastic cross sections at the positronium formation threshold which predicts the occurrence of a Wigner cusp for the lighter noble gases.

48.3 Particular Applications

48.3.1 Atomic Hydrogen

Because of the difficulty of making measurements in atomic hydrogen, the available experimental data is restricted so far to total cross sections, as well as to total ionization and positronium formation cross sections. Essentially exact variational calculations have been carried out in the elastic energy regime and the Ore gap [48.8].

Ionization cross sections have been measured by both the Bielefeld and London groups [48.28, 29] (and references therein) and have been calculated in a number of approximations [48.23, 30–32]. However, disagreements between the experimental measurements mean that there is at present no reliable way of assessing the various approximations used. More elaborate calculations with asymptotically correct wave functions have been used to determine triple differential cross sections for ionization [48.33, 34]. However, the task of integrating these to produce total cross sections is a formidable one.

The total positron–hydrogen cross section has also been measured by the Detroit group [48.35], and is in quite good agreement with calculations based upon the coupled-pseudostate method [48.32] except at very low energies where the experimental uncertainties are the greatest.

In order to determine reliable positronium formation cross sections, the explicit positronium states have to be included. Several such calculations have been carried out [48.17–20]. These indicate the necessity of explicitly including positronium formation channels in the expansion of the total wave function in order to obtain accurate results, even for elastic scattering. The most recent calculations [48.32, 36] are in quite good agreement with various experiments [48.28, 37] over the majority of the energy range.

As is the case for electron scattering, positron cross sections exhibit resonances (Sect. 47.1.3). These have been extensively studied by *Ho* [48.38] using variational and complex rotation methods.

48.3.2 Noble Gases

Because the noble gases are convenient experimental targets, a good deal of effort has gone into calculations for these targets, particularly for elastic scattering, ionization, and Ps formation. In the purely elastic energy range, i. e., for energies below the positronium formation threshold, the simple potential scattering approach using the static and polarization potentials defined above yields quite good results. Since the long-range behaviour of the sum of the potentials is attractive, the scattering phase shifts for positrons must be positive for suffi-

ciently low energies. However, as its incident energy increases, the positron probes the repulsive inner part of the potential and the phase shifts become negative. This behaviour leads to the well-known Ramsauer minimum in the integral elastic cross sections (Chapt. 47) for the lighter noble gases (helium, neon and possibly argon), but not for krypton and xenon [48.15, 39] (and references therein). This differs from electron scattering, where some low-energy phase shifts can be negative (modulo π) because of the existence of bound orbitals of the same symmetry.

Another difference between positron and electron scattering is exhibited by the differential cross sections (Chapt. 47). As a result of the low intensity and width of positron beams, most measurements of differential cross sections are relative, with the normalization often being made to theoretical calculations at specific angles. For electrons, the shape of the cross section is determined by a few dominant phase shifts, whereas for positrons, many phase shifts contribute to the final shape [48.40]. Because of this behaviour, the differential cross sections for positron scattering have much less overall structure than for electron scattering. However, the differential cross sections for positrons for many of the noble gases have a single minimum at relatively small angles, both below and above the first inelastic channel. These have been reviewed by *Kauppila* et al. [48.41]. At intermediate energies, the simple potential scattering approximation is no longer sufficient and the inelastic channels have to be taken into account via, for example, the use of an optical potential [48.13, 14, 42]. Furthermore, in the inelastic scattering regime, the existence of open channels has a much more marked effect on the shape of the differential cross sections for positron scattering than for electrons [48.43].

The first absolute differential cross sections were measured for argon and krypton at very low energies using a magnetized beam of cold positrons [48.44, 45]. These results are in excellent agreement with a variety of different theoretical predictions [48.46–48].

There is relatively very little experimental data for the excitation of the noble gases. Some experimental work has been carried out for the lighter noble gases, helium, neon and argon [48.49] (and references therein), and there is satisfactory agreement between these measurements and close-coupling [48.50], as well as distorted-wave [48.51] calculations.

The first state-resolved absolute excitation cross sections for the $4s[1/2]_1^o$ and $4s[3/2]_1^o$ states of argon and the $6s[3/2]_1^o$ state of xenon have been measured by the San Diego group [48.6, 52]. Relativistic distorted-wave calculations are in satisfactory agreement with the experiment for argon [48.53], but less so for xenon [48.54].

The total ionization and positronium cross sections have been measured extensively for all of the noble gases. In general, there is good agreement amongst the various experiments for the ionization cross section, but much less so for the positronium formation cross section. A summary of the experimental work on the ionization and positronium cross sections for neon, argon, krypton and xenon can be found in the article by *Laricchia* et al. [48.55] (and references therein), while a more detailed analysis of these cross sections in argon can be found in recent articles by the San Diego group [48.6, 56].

There has also been an extensive investigation of the energy dependence of the elastic and positronium formation cross section near the Ps formation threshold for all the inert gases [48.57] (and references therein).

There exist some measurements of Z_{eff} and angular correlation parameters for these gases [48.58], mainly at room temperature, and calculations for them have been made in the polarized-orbital approximation [48.59].

48.3.3 Other Atoms

In the case of positron scattering from the alkali atoms, the positronium formation channel is always open and the simple potential scattering approach does not yield reliable results. The Detroit group has measured the total cross section, as well as upper and lower bounds to the positronium formation cross section for sodium, potassium, and rubidium. Although early close-coupling calculations of the elastic and excitation cross sections [48.60–62] were in surprisingly good agreement with the experimental total cross section, these calculations did not include the positronium formation channel. Subsequently, much more sophisticated calculations were carried out by the Belfast group using the coupled-pseudostate method, which included both eigenstates of the target as well as positronium [48.32, 63–65]. These calculations also showed the increasing importance of positronium formation in excited states for the alkalis potassium, rubidium, and caesium. The overall agreement between experimental results and those from the coupled-pseudostate method are quite good for both potassium and rubidium, however, for sodium, the experimental positronium formation cross section is significantly above these theoretical calculations. A summary of the experimental work on the alkalis can be found in [48.35], while

a corresponding summary of theoretical work is given in [48.32].

Substantial resonance features have been found in these positron–alkali atom cross sections [48.66].

The positronium formation threshold for magnesium is very low, only 0.844 eV, and hence, the elastic and positronium formation cross sections will dominate in the low energy region. Upper and lower bounds to the Ps formation cross section in magnesium have been determined [48.35, 67], and are in agreement with both close-coupling calculations [48.68] and the results of many-body theory [48.69].

48.3.4 Molecular Hydrogen

By its fundamental nature, molecular hydrogen has attracted considerable attention both experimentally and theoretically. The total elastic cross section has been measured by both the Detroit group [48.37] and the London group [48.70], with good agreement between both sets of data. There have been several theoretical calculations of this cross section by a variety of methods: Kohn variational [48.71], R-matrix [48.72], distributed positron model [48.73], and recently, a Schwinger multichannel method [48.74], with [48.72, 73] being in satisfactory agreement with experiment. Once again, the elastic cross section is strongly influenced by the positronium formation channel near threshold.

Quite recently the vibrational $(0 \rightarrow 1)$ excitation cross section of molecular hydrogen has been measured between 0.55 and 4 eV by *Sullivan* et al. [48.75]. Their data are in quite good agreement with theoretical calculations. The San Diego group has also measured the electronic excitation of the $B^1 \Sigma$ state from threshold to 30 eV [48.52]. Their data are in reasonable agreement with the Schwinger multichannel calculation of *Lino* et al. [48.76]. Interestingly, the measured positron excitation cross section appears to be larger than that determined for electron excitation.

The ionization cross section has been determined over a wide range of energies by a number of different groups [48.77–81] (and references therein). Since all of the above measurements are relative, they must be normalized to one another at particular energies. Although

there are some differences between these experiments, near threshold the positron cross section increases less rapidly, in general, than the corresponding electron cross section, in accordance with the Wannier law. Theoretical calculations are in satisfactory agreement with the measurements [48.82] (and references therein).

The positronium formation cross section has also been measured by a number of different groups with coupled-channels calculations being carried out for this process [48.83].

48.3.5 Other Molecules

For diatomic and triatomic molecules, most of the experimental and theoretical work has been carried out for CO, CO_2, O_2, and N_2. Total cross sections for O_2, N_2, and CO_2 have been measured from threshold to several hundred eV [48.70] (and references therein). Relative differential cross sections have been measured for CO, CO_2, O_2, N_2, as well as N_2O, on both sides of the positronium formation threshold [48.84]. Absolute differential cross sections have been measured for CO at 6.75 eV [48.45]. At low energies the gases N_2, O_2, and CO exhibit a minimum in the DCS at small angles, as per the heavier noble gases. This minimum gradually disappears as the energy increases.

Vibrational excitation cross sections for CO and CO_2 have been measured [48.75] and are in excellent agreement with the theoretical calculations of [48.85] for CO, and in satisfactory agreement with theory [48.86] for CO_2. Electron excitation of the $a^1 \Pi$ and $a'^1 \Sigma$ states of N_2 have been measured from threshold to 20 eV [48.52]. Interestingly, the positron cross section near threshold is approximately double that for electrons.

For polyatomic molecules, the majority of experimental and theoretical work has been carried out for CH_4. This includes the total cross section and quasi-elastic (summed over vibration–rotational levels) differential cross sections. At low energies there is a minimum in these DCS at small angles, as per the heavier noble gases which, in turn, also disappears at higher energies. The positronium formation cross section has also been measured.

48.4 Binding of Positrons to Atoms

There have been many recent investigations of the possible binding of positrons to a variety atoms. As was mentioned in Sect. 46.2.2, such binding could

greatly enhance the annihilation cross section and help to explain the large measured values of Z_{eff} for both atoms and molecules. It has been shown theoretically

that a positron will bind to a large number of one- and two-electron atomic systems [48.87] (and references therein). For one-electron systems, where the ionization potential is less than 6.802 85 eV, the dominant configuration is a polarized positronium (Ps) cluster moving in the field of the residual positive ion, while for two-electron systems, with an ioniza-tion potential greater than 6.802 85 eV, the dominant configuration involves a positron orbiting a polarized neutral atom [48.88]. So far, there is no experimental evidence for these positronic atoms. However, there is considerable evidence that positrons will bind to large hydrocarbon molecules [48.6] (and references therein).

48.5 Reviews

For a number of years a Positron Workshop has been held as a satellite of the International Conference on the Physics of Electronic and Atomic Collisions. Their proceedings [48.89–100] give an excellent summary of the state of positron scattering research, both experimental and theoretical, including such additional topics as positronium scattering from atoms, the formation of antihydrogen, inner shell ionization, and applications to astrophysics.

There are several review articles on positron scattering in gases, including the early historical development [48.101], more comprehensive articles [48.2, 102–104], as well as a more recent review [48.105], which also discusses the future for positron physics.

A recent book [48.106] discusses various aspects of both experimental and theoretical positron physics.

49. Adiabatic and Diabatic Collision Processes at Low Energies

Adiabatic and diabatic electronic states of a system of atoms are defined and their properties are described. Nonadiabatic interaction for slow quasiclassical motion of atoms is discussed within two-state common-trajectory approximation. Analytical formulae for nonadiabatic transition probabilities are presented for particular modles with reference to single and double passage of coupling regions (Landau–Zener–Stückelberg, Rosen–Zener–Demkov, Nikitin models). Generalization for multiple passage is described.

49.1 Basic Definitions

49.1.1 Slow Quasiclassical Collisions

Slow collisions of atoms or molecules (neutral or charged) are defined as collisions for which the velocity of the relative motion of colliding particles v is substantially lower than the velocity of valence electrons v_e:

$$v/v_e \ll 1 . \tag{49.1}$$

If v_e is estimated as $v_e \approx 1$ a.u. $\approx 10^8$ cm/s, then (49.1) is fulfilled for medium mass nuclei (~ 10 amu) up to several keV.

Quasiclassical collisions are those for which the de Broglie wavelength λ_{dB} for the relative motion is substantially smaller than the range parameter a of the interaction potential

$$\lambda_{dB} \ll a . \tag{49.2}$$

The two conditions (49.1) and (49.2) define the energy range within which collisions are slow and quasiclassical. For medium mass nuclei, this energy range covers collision energies above room temperature and below hundreds of eV. The paramater a should not be confused with another important parameter L_0 which character-

izes the extent of the interaction region. For instance, for the exchange interaction between two atoms, L_0 corresponds to the distance of closest approach of the colliding particles, while a is the range of the exponential decrease of the interaction. Typically, L_0 noticeably exceeds a.

49.1.2 Adiabatic and Diabatic Electronic States

Let r refer to a set of electronic coordinates in a body-fixed frame related to the nuclear framework of a colliding system, and let $\mathcal{R}$ refer to a set of nuclear coordinates determining the relative position of nuclei in this system. A configuration of electrons and nuclei in a frame fixed in space is completely determined by r, $\mathcal{R}$, and the set of Euler angles Ω, which relate the body-fixed frame to the space-fixed frame. If the total Hamiltonian of the system is $\mathcal{H}(r, \mathcal{R}, \Omega)$, the stationary state wave function satisfies the equation

$$\mathcal{H}(r, \mathcal{R}, \Omega)\Psi_{\mathrm{E}}(r, \mathcal{R}, \Omega) = E\Psi_{\mathrm{E}}(r, \mathcal{R}, \Omega) . \quad (49.3)$$

The electronic adiabatic Hamiltonian $H(r; \mathcal{R})$ is defined to be the part of $\mathcal{H}(r, \mathcal{R}, \Omega)$ in which the kinetic energy of the nuclei is ignored. The adiabatic electronic functions $\psi_n(r; \mathcal{R})$ are defined as eigenfunctions of $H(r; \mathcal{R})$ at a fixed nuclear configuration $\mathcal{R}$:

$$H(r; \mathcal{R})\psi_n(r; \mathcal{R}) = U_n(\mathcal{R})\psi_n(r; \mathcal{R}) . \quad (49.4)$$

The eigenvalues $U_n(\mathcal{R})$ are called adiabatic potential energy surfaces (adiabatic PES). In the case of a diatom, the set $\mathcal{R}$ collapses into a single coordinate, the internuclear distance R, and the PES become potential energy curves, $U_n(R)$. The functions $\psi_n(r; \mathcal{R})$ depend explicitly on $\mathcal{R}$ and implicitly on the Euler angles Ω. The significance of the adiabatic PES is related to the fact that in the limit of very low velocities, a system of nuclei will move across a single PES. In this approximation, called the adiabatic approximation, the function $U_n(\mathcal{R})$ plays the part of the potential energy which drives the motion of the nuclei.

An electronic diabatic Hamiltonian is defined formally as a part of H, i.e., $H_0 = H + \Delta H$. The partitioning of H into H_0 and ΔH is dictated by the requirement that the eigenfunctions of H_0, called diabatic electronic functions ϕ_n, depend weakly on the configuration $\mathcal{R}$. The physical meaning of this weak dependence is different for different problems. A perfect diabatic basis set $\phi_n(r)$ is $\mathcal{R}$-independent; for practical purposes one can use a diabatic set which is considered as $\mathcal{R}$-independent within a certain region of the configuration space $\mathcal{R}$.

Two basis sets ψ_n and ϕ_n generate the matrices

$$\langle\phi_m|H|\phi_n\rangle = H_{mn} ,$$
$$\langle\phi_m|\mathcal{H}|\phi_n\rangle = H_{mn} + D_{mn} ,$$
$$\langle\psi_m|\mathcal{H}|\psi_n\rangle = U_n(\mathcal{R})\delta_{mn} + \mathcal{D}_{mn} . \quad (49.5)$$

The eigenvalues of the matrix H_{mn} are U_n. D_{mn} is the matrix of dynamic coupling in the diabatic basis, and $\mathcal{D}_{mn}$ is the matrix of dynamic coupling in the adiabatic basis; the former matrix vanishes for a perfect diabatic basis. All the above matrices are, in principle, of infinite order. For low-energy collisions, the use of finite matrices of moderate dimension, will usually suffice.

Diabatic PES are defined as the diagonal elements H_{nn}. The significance of the diabatic PES is that for velocities which are high [but still satisfy (49.1)] the system moves preferentially across diabatic PES, provided that the additional conditions discussed in Sect. 49.3 are fulfilled.

For a given finite adiabatic basis $\psi_n(r; \mathcal{R})$, a perfect diabatic basis $\phi_{n'}(r)$ can be constructed by diagonalizing the matrix $\mathcal{D}_{nm}(\mathcal{R})$. The two basis sets are related by a unitary transformation

$$\psi_n(r; \mathcal{R}) = \sum_{n'} C_{nn'}(\mathcal{R})\phi_{n'}(r) . \quad (49.6)$$

49.1.3 Nonadiabatic Transitions: The Massey Parameter

Deviations from the adiabatic approximation manifest themselves in transitions between different PES which are induced by the dynamic coupling matrix $\mathcal{D}$. At low energies, the transitions usually occur in localized regions of nonadiabatic coupling (NAR). In these regions, the motion of nuclei in different electronic states is coupled, and in general it cannot be interpreted as being driven by a single potential.

An important simplifying feature of slow adiabatic collisions is that typically the distance between different NAR is substantially larger than the extents of each NAR. This makes it possible to formulate simple models for the coupling in isolated NAR, and subsequently to incorporate the solution for nonadiabatic coupling into the overall dynamics of the system.

For a system of s nuclear degrees of freedom, there are the following possibilities for the behavior of PES within NAR:

(i) If two s-dimensional PES correspond to electronic states of different symmetry, they can cross along an $(s-1)$-dimensional line. For a system of two atoms, $s = 1$, and so two potential curves of different symmetry can cross at a point.

(ii) If two s-dimensional PES correspond to electronic states of the same symmetry, they can cross along an $(s-2)$-dimensional line. For a system of two atoms, $s = 1$, and so two potential curves of different symmetry cannot cross. If they have a tendency to cross, they will exhibit a pattern which is called an avoided crossing or a pseudocrossing.

(iii) If two s-dimensional PES correspond to electronic states of the same symmetry in the presence of spin–orbit coupling, they can cross along an $(s-3)$-dimensional line.

Statement (ii) applied to a two-atom system is known as the Wigner–Witmer noncrossing rule.

The efficiency of the nonadiabatic coupling between two adiabatic electronic states is determined, according to the adiabatic principle of mechanics (both classical and quantum), by the value of the Massey parameter ζ, which represents the product of the electronic transition frequency ω_{el} and the time τ_{nuc} that characterizes the rate of change of electronic function due to nuclear motion. Putting $\omega_{el} \approx \Delta U(\mathcal{R})/\hbar$, ($\Delta U$ is the spacing between any two adiabatic PES), and $\tau_{nuc} = \Delta L/v(\mathcal{R})$, ($\Delta L$ is a certain range which depends on the type of coupling), we get

$$\zeta(\mathcal{R}) = \omega_{el}\tau_{nuc} = \Delta U(\mathcal{R})\Delta L/\hbar v(\mathcal{R}) . \qquad (49.7)$$

The nonadiabatic coupling is inefficient at those configurations $\mathcal{R}$ where $\zeta(\mathcal{R}) \gg 1$. If $\zeta(\mathcal{R})$ is less than or of the order of unity, the nonadiabatic coupling is efficient, and a change in adiabatic dynamics of nuclear motion is very substantial.

49.2 Two–State Approximation

49.2.1 Relation Between Adiabatic and Diabatic Basis Functions

In the two-state approximation, the basis of electronic functions consists of two states. In this case, the elements of the matrix C in (49.6) are expressed through a single parameter only, a mixing or rotation angle θ:

$$\psi_1(r; \mathcal{R}) = \cos\theta(\mathcal{R})\phi_1(r) + \sin\theta(\mathcal{R})\phi_2(r) ,$$

The following relations usually hold for the parameters ΔL, a, L_0 for slow collisions:

$$\Delta L \ll a \ll L_0 . \qquad (49.8)$$

When the nonadiabatic coupling is taken into account, the total (electronic and nuclear) wave function Ψ_E can be represented as a series expansion in ψ_n or ϕ_n (the Euler angles Ω are suppressed for brevity):

$$\Psi_E(r, \mathcal{R}) = \sum_n \psi_n(r; \mathcal{R})\chi_{nE}(\mathcal{R})$$
$$= \sum_n \phi_n(r)\kappa_{nE}(\mathcal{R}) . \qquad (49.9)$$

Here $\chi_{nE}(\mathcal{R})$ and $\kappa_{nE}(\mathcal{R})$ are the functions which have to be found as solutions to the coupled equations formulated in the adiabatic or diabatic electronic basis, repectively [49.1, 2]. In general, different contributions to the first sum in (49.9) can be associated with nonadiabatic transition probabilities between different electronic states.

A practical means of calculating functions $\chi_{nE}(\mathcal{R})$ [or $\kappa_{nE}(\mathcal{R})$] consists of expanding them over certain basis functions $\Xi_{n\nu}(\mathcal{R}')$, where $\mathcal{R}'$ denotes all coordinates $\mathcal{R}$ except for the interparticle distance R. Writing

$$\chi_{nE}(\mathcal{R}) = \sum_\nu \Xi_{n\nu}(\mathcal{R}')\xi_{n\nu E}(R) , \qquad (49.10)$$

one arrives at a set of coupled second-order equations for the unknown functions $\xi_{n\nu E}(R)$ (the scattering equations) [49.1]. In the semiclassical approximation, these equations become a set of first-order equations for the amplitudes of the WKB counterparts of $\xi_{n\nu E}(R)$. At the next step of simplification, in the common trajectory approximation, the variable R is changed into the time variable t, the latter being related to R via the classical trajectory $R = R(t)$ [49.2]. In the adiabatic approximation, the total wave function is represented by a single term in the first sum of (49.9):

$$\Psi_E(r, \mathcal{R}) = \psi_n(r; \mathcal{R})\chi_{nE}(\mathcal{R}) . \qquad (49.11)$$

$$\psi_2(r; \mathcal{R}) = -\sin\theta(\mathcal{R})\phi_1(r) + \cos\theta(\mathcal{R})\phi_2(r) . \qquad (49.12)$$

The rotation angle, $\theta(\mathcal{R})$, is expressed via the diagonal and off-diagonal matrix elements of the adiabatic Hamiltonian H in the diabatic basis ϕ_1, ϕ_2:

$$\tan 2\theta(\mathcal{R}) = \frac{2H_{12}(\mathcal{R})}{H_{11}(\mathcal{R}) - H_{22}(\mathcal{R})} . \qquad (49.13)$$

The eigenvalues of H in terms of H_{ik} are

$$U_{1,2}(\mathcal{R}) = [H_{11}(\mathcal{R}) + H_{22}(\mathcal{R})]/2 \pm \Delta U(\mathcal{R})/2 , \tag{49.14}$$

where

$$\Delta U(\mathcal{R}) = \left\{ [H_{11}(\mathcal{R}) - H_{22}(\mathcal{R})]^2 + 4H_{12}^2(\mathcal{R}) \right\}^{1/2} . \tag{49.15}$$

The matrix elements H_{ik} are expressed via the adiabatic potentials and the rotation angle by

$$H_{11}(\mathcal{R}) + H_{22}(\mathcal{R}) = U_1(\mathcal{R}) + U_2(\mathcal{R}) ,$$
$$H_{11}(\mathcal{R}) - H_{22}(\mathcal{R}) = \Delta U(\mathcal{R}) \cos 2\theta(\mathcal{R}) ,$$
$$H_{12}(\mathcal{R}) = (1/2)\Delta U(\mathcal{R}) \sin 2\theta(\mathcal{R}) . \tag{49.16}$$

49.2.2 Coupled Equations and Transition Probabilities in the Common Trajectory Approximation

A two-state nonadiabatic wave function $\Psi(r, \mathcal{R})$ can be written as an expansion into either adiabatic or diabatic electronic wave functions:

$$\Psi(r; \mathcal{R}) = \psi_1(r; \mathcal{R}) \alpha_1(\mathcal{R}) + \psi_2(r; \mathcal{R}) \alpha_2(\mathcal{R}) ,$$
$$\Psi(r; \mathcal{R}) = \phi_1(r) \beta_1(\mathcal{R}) + \phi_2(r) \beta_2(\mathcal{R}) , \tag{49.17}$$

in which the nuclear wave functions satisfy two coupled s-dimensional Schrödinger equations [49.1].

In the common trajectory approximation, the motion of the nuclei is described by the classical trajectory, i. e., by a one-dimensional manifold $\mathcal{Q}(t)$ embedded in the s-dimensional manifold $\mathcal{R}$. A section of PES along this one-dimensional manifold determines a set of effective potential energy curves (PEC). In the case of atomic collisions, Q coincides with the interatomic distance R, and the effective PEC are just ordinary PEC.

A common trajectory counterpart of (49.17) is

$$\Psi(r, t) = \psi_1 [r; \mathcal{Q}(t)] a_1(t) + \psi_2 [r; \mathcal{Q}(t)] a_2(t) ,$$
$$\Psi(r; t) = \phi_1(r) b_1(t) + \phi_2(r) b_2(t) . \tag{49.18}$$

The adiabatic expansion coefficients $a_k(t)$ satisfy the set of equations

$$i\hbar \frac{da_1}{dt} = U_1(\mathcal{Q})a_1 + i\dot{\mathcal{Q}} g(\mathcal{Q})a_2 ,$$
$$i\hbar \frac{da_2}{dt} = -i\dot{\mathcal{Q}} g(\mathcal{Q})a_1 + U_2(\mathcal{Q})a_2 , \tag{49.19}$$

where $g(\mathcal{Q}) = \langle \psi_1 | \partial/\partial \mathcal{Q} | \psi_2 \rangle = d\theta/d\mathcal{Q}$, and $\mathcal{Q} = \mathcal{Q}(t)$. The diabatic expansion coefficients $b_k(t)$ satisfy the set of equations

$$i\hbar \frac{db_1}{dt} = H_{11}(\mathcal{Q})b_1 + H_{12}(\mathcal{Q})b_2 ,$$
$$i\hbar \frac{db_2}{dt} = H_{21}(\mathcal{Q})b_1 + H_{22}(\mathcal{Q})b_2 . \tag{49.20}$$

Clearly, for a system of two atoms, $\mathcal{Q} \equiv R$.

Solutions to (49.19) and (49.20) are equivalent, provided that the initial conditions are matched, and the transition probability is properly defined.

For a given trajectory, it is customary to identify the center of the NAR with a value of $\mathcal{Q} = \mathcal{Q}_p$ which corresponds to the real part of the complex-valued coordinate $\mathcal{Q}_c$ at which two adiabatic PES cross. The crossing conditions in the adiabatic and diabatic representations are

$$U_1(\mathcal{Q}_c) - U_2(\mathcal{Q}_c) = 0 , \tag{49.21}$$

or

$$\left[H_{11}(\mathcal{Q}_c) - H_{22}(\mathcal{Q}_c) \right]^2 + 4H_{12}^2(\mathcal{Q}_c) = 0 . \tag{49.22}$$

Since $\mathcal{Q}$ represents a one-dimensional manifold, the crossing condition (49.22) is satisfied for a complex value of $\mathcal{Q} = \mathcal{Q}_s$ unless $H_{12} = 0$. Then, by definition, the location of the NAR center is identified with $\mathcal{Q}_p$ through

$$\mathcal{Q}_p = \text{Re}(\mathcal{Q}_c) , \tag{49.23}$$

where $\mathcal{Q}_c$ is that value of $\mathcal{Q}_s$ which possesses the smallest imaginary part, and Re denotes the real part.

For the case when the regions of nonadiabatic coupling are well localized, the function $g(\mathcal{Q})$ possesses a pronounced maximum at (or close to) $\mathcal{Q}_p$, the width $\Delta \mathcal{Q}_p$ of which determines the range of the NAR; normally $\Delta \mathcal{Q}_p$ is about Im $(\mathcal{Q}_c)$, with Im denoting the imaginary part. The two Eqs. (49.19) decouple on both sides of this maximum. A solution of the equations for the nonadiabatic coupling across an isolated maximum of $g(\mathcal{Q})$ yields the so-called single-passage (or one-way) transition amplitude and transition probability. For this problem, the time $t = 0$ can be assigned to the maximum point of $g[\mathcal{Q}(t)]$. Assuming that away from $t = 0$ the decoupling occurs rapidly enough, the nonadiabatic transition probability

$$P_{12} = |a_2(\infty)|^2 , \tag{49.24}$$

provided that a solution to (49.19) corresponds to the initial conditions,

$$a_1(-\infty) = 1 , \quad a_2(-\infty) = 0 . \tag{49.25}$$

In the limit of almost adiabatic conditions where P_{12} is very small, the following equation holds [49.3]:

$$P_{12} = \exp\left[-\frac{2}{\hbar}\left|\text{Im}\left(\int\limits_{t_r}^{t_c} \{U_1[\mathcal{Q}(t)] - U_2[\mathcal{Q}(t)]\}\,dt\right)\right|\right],$$

(49.26)

where t_c is a root of

$$\mathcal{Q}(t_c) = \mathcal{Q}_c .$$

(49.27)

Here t_r is any real-valued time. Equation (49.26) is valid when the exponent is large, so that P_{12} is exponentially small.

The property of the function $g(\mathcal{Q})$ to pass through a single narrow maximum ensures that the rotation angle away from the maximum tends to constant values, and adiabatic functions in these regions are expressed by certain linear combinations of diabatic functions with constant mixing coefficients. These linear combinations should serve as the initial condition on one side of the coupling region, and as the proper final state on the other, when the problem of a nonadiabatic transition between adiabatic states is treated in the diabatic representation. The same property of the function $g(\mathcal{Q})$ implies that a common trajectory needs to be defined only locally, within a given NAR, and not globally, in the full configuration space.

49.2.3 Selection Rules for Nonadiabatic Coupling

In the general case, the coupling between adiabatic states or diabatic states is controlled by certain selection rules. The most detailed selection rules exist for a system of two colliding atoms, since this system possesses a high symmetry ($\mathcal{C}_{\infty v}$ or, for identical atoms, $D_{\infty h}$ point symmetry in the adiabatic approximation). In the adiabatic representation, the coupling is due to the elements of the matrix $\mathcal{D}$. They fall into two different categories: those proportional to the radial nuclear velocity (coupling by radial motion or radial coupling), and those proportional to the angular velocity of rotation of the molecular axis (coupling by rotational motion or Coriolis coupling).

In a diabatic representation, provided that the effect of the D matrix is neglected, the coupling is due to the parts of the interaction potential neglected in the definition of the diabatic Hamiltonian H_0. In typical cases, these parts are the electrostatic interaction between different electronic states constructed as certain electronic configurations (H_0 corresponds to a self-consistent field Hamiltonian); spin–orbit interaction (H_0 corresponds to a nonrelativistic Hamiltonian); hyperfine interaction (H_0 ignores the magnetic interaction of electronic and nuclear spins as well as the electrostatic interaction between electrons and nuclear quadrupole moments). The selection rules for the above interactions in the case of two atoms are listed in Table 49.1 for two conventional nomenclatures for molecular states: Hund's case (a), $^{2S+1}\Lambda_w^{(\sigma)}$ and Hund's case (c), $\Omega_w^{(\sigma)}$ [49.3].

For molecular systems with more than two nuclei, the selection rules cannot be put in a detailed form since, in general, the symmetry of the system is quite low. For the important case of three atoms, a general configuration is planar ($\mathcal{C}_s$ symmetry); particular configurations correspond to an isosceles triangle if two atoms are identical ($\mathcal{C}_{2v}$ symmetry), to an equilateral triangle for three identical atoms (D_{3h} symmetry) or to a linear configuration. For the last case, the selection rules are the same as for a system of two atoms.

Table 49.1 Selection rules for the coupling between diabatic and adiabatic states of a diatomic quasimolecule ($w = g, u$; $\sigma = +, -$)

Interaction	$^{2S+1}\Lambda_w^{(\sigma)}$ nomenclature	$\Omega_w^{(\sigma)}$ nomenclature
Configuration interaction (electrostatic)	$\Delta\Lambda = 0,\ \Delta S = 0$ $g \neq u, + \neq -$	$\Delta\Omega = 0$ $g \neq u, + \neq -$
Spin–orbit interaction	$\Delta\Lambda = 0,\ \pm 1,\ \Delta S = 0,\ \pm 1$ $g \neq u, + \rightleftharpoons -$	$\Delta\Omega = 0$ $g \neq u, + \neq -$
Radial motion	$\Delta\Lambda = 0,\ \Delta S = 0$ $g \neq u, + \neq -$	$\Delta\Omega = 0$ $g \neq u, + \neq -$
Rotational motion	$\Delta\Lambda = \pm 1,\ \Delta S = 0$ $g \neq u, + \neq -$	$\Delta\Omega = \pm 1$ $g \neq u, + \neq -$
Hyperfine interaction	$\Delta\Lambda = 0,\ \pm 1,\ \Delta S = 0,\ \pm 1$ $g \rightleftharpoons u, + \rightleftharpoons -$	$\Delta\Omega = 0,\ \pm 1$ $g \rightleftharpoons u, + \rightleftharpoons -$

The selection rules for the dynamic coupling between adiabatic states classified according to the irreducible representations of the $\mathcal{C}_s$ and $\mathcal{C}_{2v}$ groups are listed in Table 49.2. In this table, z and y refer to two modes of the relative nuclear motion in the system plane, R_z and R_y refer to two rotations about principal axes of inertia lying in the system plane, and R_x refers to a rotation about the principal axis of inertia perpendicular to the system plane.

Table 49.2 Selection rules for dynamic coupling between adiabatic states of a system of three atoms

$\mathcal{C}_s$		A'		A''	
	$\mathcal{C}_{2v}$	A_1	B_1	A_2	B_2
A'	A_1	z	$y,\ R_x$	R_z	R_y
	B_1	$y,\ R_x$	z	R_y	R_z
A''	A_2	R_z	R_y	z	$y,\ R_x$
	B_2	R_y	R_z	$y,\ R_x$	z

49.3 Single-Passage Transition Probabilities: Analytical Models

49.3.1 Crossing and Narrow Avoided Crossing of Potential Energy Curves: The Landau–Zener Model in the Common Trajectory Approximation

The Landau–Zener model applies to a situation when the effective adiabatic PEC cross or show a narrow avoided crossing. The latter is defined by the condition that the spacing between adiabatic PEC within a NAR is much smaller than the spacing between adiabatic PEC away from the NAR. The cases of crossing and narrow avoided crossing of adiabatic PEC can be considered within a unified model since a narrow avoided crossing of adiabatic PEC corresponds to a crossing of diabatic PEC. Therefore, in both cases, one considers the crossing of zero-order PES (adiabatic or diabatic) and the interaction between them (dynamic or static). However, the definition of transition probability is different for crossing and avoided crossing.

In the framework of the Landau–Zener model [49.4–6], the two zero-order PEC which cross at a point $\mathcal{Q}_p$ along a trajectory $\mathcal{Q}(t)$ are approximated by functions linear in $\Delta\mathcal{Q} = \mathcal{Q} - \mathcal{Q}_p$, and the off-diagonal matrix element is assumed to be a constant.

For the avoided crossing adiabatic PEC (crossing diabatic PEC), the matrix H_{jk} within a NAR is approximated as

$$H_{11}(\mathcal{Q}) = E_0 - F_1(\mathcal{Q} - \mathcal{Q}_p) ,$$
$$H_{22}(\mathcal{Q}) = E_0 - F_2(\mathcal{Q} - \mathcal{Q}_p) ,$$
$$H_{12}(\mathcal{Q}) = V = \text{constant} , \tag{49.28}$$

from which the spacing between adiabatic PEC is

$$\Delta U = \left[(\Delta F)^2 (\mathcal{Q} - \mathcal{Q}_p)^2 + 4|V|^2 \right]^{1/2} , \tag{49.29}$$

with $\Delta F = |F_1 - F_2|$.

The common trajectory is assumed to be a linear function of t,

$$\mathcal{Q} = \mathcal{Q}_p + v_p t , \tag{49.30}$$

where v_p is the velocity of $\mathcal{Q}$-motion at point $\mathcal{Q}_p$.

For this model, adiabatic wave functions on both sides of the nonadiabaticity region (in the limits $-\infty < t < +\infty$) coincide with diabatic functions, but their ordering is reversed. Explicitly,

$$\psi_1 = \phi_1 ; \quad \psi_2 = \phi_2 \quad \text{for } t \to -\infty ,$$
$$\psi_1 = \phi_2 ; \quad \psi_2 = -\phi_1 \quad \text{for } t \to +\infty . \tag{49.31}$$

The transition probability between pseudocrossing adiabatic curves for the Hamiltonian (49.28) and the trajectory (49.30) is given by the Landau–Zener formula

$$P_{12}^{\text{psc}} = P_{12}^{\text{LZ}} = \exp\left(-2\pi\zeta^{\text{LZ}}\right) ;$$
$$\zeta^{\text{LZ}} = V^2/(\hbar \Delta F v_p) , \tag{49.32}$$

where ζ^{LZ} is the appropriate Massey parameter at the pseudocrossing point. Note that for the LZ model, the single-passage transition probability depends on one dimensionless parameter ζ^{LZ}. A remarkable property of the Landau–Zener model is that the probability P_{12}^{LZ} is given by (49.26) for an arbitrary value of the exponent, and not only for large ones when the probability is very low.

With a change of the velocity from very low to very high values, the transition probability varies from zero to unity. In the near-adiabatic limit, $\zeta^{\text{LZ}} \gg 1$, the nuclei preferentially move across single adiabatic PEC, while in the sudden limit, $\zeta^{\text{LZ}} \ll 1$, they move across single diabatic PEC. It is the latter property of the LZ transition probability that allows one to interpret diabatic energies H_{11} and H_{22} as the potentials which drive the nuclear motion at high velocities.

Adiabatic and Diabatic Collision Processes at Low Energies | 49.3 Single-Passage Transition Probabilities: Analytical Models   747

Part D | 49.3

The region of applicability of the Landau–Zener formula is determined by the condition that the extension of the region of nonadiabatic interaction ΔQ should be small compared with the range a over which potential curves deviate substantially from linear functions. The condition $\Delta Q \ll a$ actually implies the two conditions [49.2]

$$2V/\Delta F \ll a , \tag{49.33}$$

and

$$2\left(\hbar v_\mathrm{p}/\Delta F\right)^{1/2} \ll a . \tag{49.34}$$

Clearly, the range parameter a does not enter the LZ formula since it controls the behavior of adiabatic curves away from the crossing point.

The constant velocity approximation (49.30) imposes yet another condition:

$$V \ll \mu v_\mathrm{p}^2/2 . \tag{49.35}$$

The actual application of (49.32) requires the specification of V and v_p for each particular trajectory $Q(t)$. For the case of avoided crossing between two potential curves of a diatom, V does not depend on the trajectory and represents, according to Table 49.2, the matrix element of the electrostatic interaction, spin–orbit interaction or hyperfine interaction.

For crossing adiabatic PEC, the Landau–Zener model assumes the following approximation for adiabatic potentials and the dynamic coupling:

$$\begin{aligned}
U_1(Q) &= E_0 - F_1(Q - Q_\mathrm{c}) , \\
U_1(Q) &= E_0 - F_2(Q - Q_\mathrm{c}) , \\
\mathcal{D}_{12}(Q) &= D = \text{constant} ,
\end{aligned} \tag{49.36}$$

with the trajectory parametrization given by (49.30) where v_p is replaced by v_c. Since the ordering of adiabatic PEC for crossing and pseudocrossing is reversed on one side of a NAR, the following relation exists between transition probabilities for the crossing case P_{12}^c, and the survival probability for the pseudocrossing case $1 - P_{12}^\mathrm{psc}$:

$$P_{12}^\mathrm{c} = 1 - P_{12}^\mathrm{psc} , \tag{49.37}$$

provided that D and v_c in the crossing situation are replaced by V and v_p in the pseudocrossing situation. Conditions (49.33) and (49.34) applied to the case of the dynamic coupling often imply that this coupling is weak [49.2]. Therefore, (49.37) yields

$$P_{12}^\mathrm{c} = \frac{2\pi D^2}{\hbar \Delta F v_\mathrm{c}} . \tag{49.38}$$

Usually, the matrix element D is related to the Coriolis coupling, and it is proportional to the angular velocity of rotation of the molecular frame at the crossing point Q_c.

49.3.2 Arbitrary Avoided Crossing and Diverging Potential Energy Curves: The Nikitin Model in the Common Trajectory Approximation

The restrictions of narrow avoided crossing [(49.33) and (49.34) for the LZ model] are relaxed in a more general model suggested by *Nikitin* [49.7]. This model uses a more flexible exponential parametrization, instead of the linear parametrization for diabatic matrix elements (49.36).

In a diabatic basis, the model is formulated with the Hamiltonian

$$\begin{aligned}
H_{11}(Q) &= U_0(Q) - \Delta E/2 + (A/2)\cos 2\vartheta \exp(-\alpha Q) , \\
H_{22}(Q) &= U_0(Q) + \Delta E/2 - (A/2)\cos 2\vartheta \exp(-\alpha Q) , \\
H_{12}(Q) &= (A/2)\sin 2\vartheta \exp(-\alpha Q) .
\end{aligned} \tag{49.39}$$

The spacing between adiabatic PEC is

$$\begin{aligned}
\Delta U = \Delta E \big\{ 1 - 2\cos 2\vartheta \; &\exp\left[-\alpha(Q - Q_\mathrm{p})\right] \\
&+ \exp\left[-2\alpha(Q - Q_\mathrm{p})\right] \big\}^{1/2} ,
\end{aligned} \tag{49.40}$$

where Q_p is introduced instead of A via (49.21) and (49.23). At the center of an NAR, where $Q = Q_\mathrm{p}$, the spacing between adiabatic PEC, $\Delta U_\mathrm{p} = \Delta U(Q_\mathrm{p})$, is

$$\Delta U_\mathrm{p} = 2\Delta E \sin \vartheta . \tag{49.41}$$

The common trajectory within the NAR is taken in a form identical to (49.30) in which v_p is now the velocity of Q motion at the center of the coupling region Q_p.

For this model, adiabatic wave functions coincide with diabatic functions before entering the coupling region (in the limit $\alpha(Q - Q_\mathrm{p}) \gg 1$), but after exiting the coupling region [in the limit $\alpha(Q - Q_\mathrm{p}) \ll -1$] they are linear combinations of the diabatic functions

$$\begin{aligned}
\psi_1(\boldsymbol{r}; Q) &= \phi_1(\boldsymbol{r}) , \quad \psi_2(\boldsymbol{r}; Q) = \phi_2(\boldsymbol{r}) , \\
&\quad \text{for } \alpha(Q - Q_\mathrm{p}) \gg 1 ; \\
\psi_1 &= \phi_1 \cos \vartheta + \phi_2 \sin \vartheta , \\
\psi_2 &= -\phi_1 \sin \vartheta + \phi_2 \cos \vartheta , \\
&\quad \text{for } \alpha(Q - Q_\mathrm{p}) \ll -1 .
\end{aligned} \tag{49.42}$$

The latter equation identifies the parameter ϑ that enters into the definition of the diabatic Hamiltonian in (49.39)

with the asymptotic value of the mixing angle θ (49.12) for $\alpha(Q - Q_p) \ll -1$.

The transition probability P_{12} between adiabatic PEC for the Hamiltonian (49.39) and the trajectory (49.30) is

$$P_{12}^N = \exp(-\pi\zeta_p) \frac{\sinh(\pi\zeta - \pi\zeta_p)}{\sinh(\pi\zeta)} , \qquad (49.43)$$

where $\zeta = \Delta E/(\hbar\alpha v_p)$ and $\zeta_p = \zeta \sin^2 \vartheta$. With the change in velocity from very low to very high values, the transition probability varies from zero to $\cos^2 \vartheta$. As ϑ changes from very small values to π, the pattern of adiabatic potential curves changes from narrow to wide pseudocrossing and ultimately to strong divergence.

Since the single-passage transition probability (49.43) depends on two parameters, the Nikitin model is more versatile than the Landau–Zener one.

In three limiting cases, $\vartheta \ll 1$, $\zeta \gg 1$, $\vartheta = \pi/4$, ζ arbitrary, and ϑ arbitrary, $\zeta = 0$, (49.43) may be simplified. In the first case, the diabatic Hamiltonian (49.39) becomes the Landau–Zener Hamiltonian (49.28). Also, (49.43) reduces to a single exponential which gives the LZ transition probability,

$$P_{12}^N = P_{12}^{LZ} = \exp(-2\pi\zeta_p) , \qquad (49.44)$$

with ζ_p identical to ζ^{LZ}. The two conditions $\vartheta \ll 1$ and $\zeta \gg 1$ are equivalent to the two conditions (49.33) and (49.34). In the second case ($\vartheta = \pi/4$), the diabatic Hamitonian reads

$$\begin{aligned} H_{11}(R) &= E_0 - \Delta E/2 , \\ H_{22}(R) &= E_0 + \Delta E/2 , \\ H_{12}(R) &= (A/2) \exp(-\alpha Q) . \end{aligned} \qquad (49.45)$$

The transition probability in this case is given by the Rosen–Zener–Demkov formula [49.8, 9]

$$P_{12}^{RZD} = \frac{\exp(-\pi\zeta)}{1 + \exp(-\pi\zeta)}, \quad \zeta = \Delta E/(\hbar v_p \alpha) . \quad (49.46)$$

In the third case ($\zeta = 0$), also called the resonance case since $\Delta E = 0$, the transition probability reads

$$P_{12}^{Res} = \cos^2 \vartheta . \qquad (49.47)$$

Equation (49.47) is a particular example of transitions between initially degenerate states. This kind of transition occurs in the recoupling of angular momenta in collisions of atoms possessing nonzero electronic angular momentum [49.10].

For the general case, the nuclei preferentially move across single adiabatic PEC in the near-adiabatic limit,

$\zeta \gg 1$, while in the sudden limit, $\zeta \ll 1$, they move across both diabatic PEC, unless the condition of narrow avoided crossing, $\vartheta \ll 1$, is fulfilled.

49.3.3 Beyond the Common Trajectory Approximation

The common trajectory approximation is valid when the spacing between adiabatic PEC within an NAR is small compared to the local kinetic energy of the nuclei. The relaxation of this restriction is not unambiguous since one should pass from a one-dimensional manifold (time as a progress variable) to a multi-dimensional coordinate (configuration space manifold). Only if the latter is one-dimensional (a single coordinate as a progress variable, as is the case for atom-atom collisions), one can suggest a generalization of the common trajectory transition probability. We consider this case, taking R to be such a single coordinate, and assume that the quantum motion across the adiabatic PEC satisfies standard quasiclassical conditions [49.3]. For a two-state problem with adiabatic potentials $U_1(R)$ and $U_2(R)$, the general condition of the common trajectory apporximation reads

$$E - \frac{1}{2}\left[U_1(R_p) + U_2(R_p)\right] \gg \left|U_1(R_p) - U_2(R_p)\right| , \qquad (49.48)$$

where E is the total (conserved) energy and R_p is the coordinate of the NAR center.

The quantum generalization of the expression for the transition probability in the near-adiabatic condition, (49.26), is given by the original Landau formula [49.4, 5]

$$P_{12} = \exp\left\{ -\frac{2}{\hbar}\left| \text{Im}\left(\int_R^{R_c} \sqrt{2\mu[E - U_1(R)]}\, dR \right.\right.\right.$$
$$\left.\left.\left. - \int_R^{R_c} \sqrt{2\mu[E - U_2(R)]}\, dR \right)\right| \right\} , \qquad (49.49)$$

where μ is the reduced mass of the colliding atoms, R_c is the complex-valued coordinate of the crossing of $U_1(R)$ and $U_2(R)$ and R is any value of the coordinate in the classically accessible region of motion of the nuclei. The nonadiabatic transition is localized in the region of width $\Delta R = \text{Im}(R_c)$ centered at $R_p = \text{Re}(R_c)$. Equation (49.49) becomes the common trajectory equation (49.26) under the condition (49.48).

The quantum generalization of the LZ transition probability can not be represented by an exact analytical expression though it is known that it depends on two

Adiabatic and Diabatic Collision Processes at Low Energies | 49.4 Double–Passage Transition Probabilities and Cross Sections   749

Part D | 49.4

parameters (and not on one, as in the case for the common trajectory approximation) [49.2]. A recommended approximate expression for $E > E_0$ reads [49.11]

$$P_{12}^{\mathrm{LZ}} = \exp\left[-2\pi\zeta^{\mathrm{LZ}}\left(\frac{2}{1+\sqrt{1+\epsilon_{\mathrm{p}}^{-2}\left[\frac{1}{160}\epsilon_{\mathrm{p}}(\zeta^{\mathrm{LZ}})^2+0.7\right]}}\right)^{1/2}\right],$$
(49.50)

where

$$\epsilon_{\mathrm{p}} = \frac{\mu v_{\mathrm{p}}^2}{2V}\frac{\Delta F}{2\sqrt{|F_1 F_2|}}.$$

Equation (49.50) becomes the common trajectory (49.32) under the condition $\epsilon_{\mathrm{p}} \gg 1$; it turns out that the latter condition may be less restrictive than the general condition (49.48).

The quantum generalization of the Nikitin transition probability is possible provided $U_0(R)$ in (49.39) is given by an exponential function, $U_0(R) \approx \exp(-\alpha R)$. The transition probability reads [49.11]:

$$P_{12}^{\mathrm{N}} = \exp(-\pi\delta_{\mathrm{p}})\frac{\sinh(\pi\delta - \pi\delta_{\mathrm{p}})}{\sinh(\pi\delta)}$$
(49.51)

and depends on three parameters of the model (and not two as is the case for the common trajectory approximation). These parameters enter into δ_{p} and δ through complicated contour integrals. If the general condition of the common trajectory approximation, (49.48), is fulfilled, δ_{p} and δ reduce to ζ_{p} and ζ so that (49.51) becomes (49.43).

More discussions of two-state models within and beyond the common trajectory approximation can be found elsewhere [49.2, 11–14].

49.4 Double–Passage Transition Probabilities and Cross Sections

49.4.1 Mean Transition Probability and the Stückelberg Phase

In the case of an atomic collision, the set $\mathcal{R}$ shrinks into a single coordinate R. If there is only one NAR over the whole range of R, the colliding system traverses it twice, as the atoms approach and then recede. In this case, there are two different paths between the center of the NAR, R_{p}, and the turning points R_{t1} and R_{t2} on the adiabatic potential curves $U_1(R)$ and $U_2(R)$. The double-passage transition probability $\mathcal{P}_{12}$ is expressed via the single-passage transition probability P_{12}, the single-passage survival probability $1 - P_{12}$, and the Stückelberg interference term $\cos\Delta\Phi_{12}$ [49.15],

$$\mathcal{P}_{12} = 2P_{12}(1 - P_{12})(1 - \cos\Delta\Phi_{12})$$
$$= 4P_{12}(1 - P_{12})\sin^2(\Delta\Phi_{12}/2).$$
(49.52)

The Stückelberg phase $\Delta\Phi_{12}/2$ is expressed as the phase difference $\Delta\Phi_{12}^{(0)}/2$ which is accumulated during the motion of a diatom from the center of the NAR to the turning points, together with an additional phase ϕ_{12} by

$$\Delta\Phi_{12}/2 = \Delta\Phi_{12}^{(0)}/2 + \phi_{12}.$$
(49.53)

Generally, (49.53) is valid provided $\Delta\Phi_{12}/2 \gg 1$. For transitions between electronic states of the same axial symmetry, the relative angular momentum ℓ of the

colliding atoms is conserved, and we have

$$\Delta\Phi_{12}^{(0)}/2 =$$
$$\int_{R_{\mathrm{p}}}^{R_{\mathrm{t1}}} \left[2\mu E - \hbar^2\ell(\ell+1)/R^2 - 2\mu U_1(r)\right]^{1/2}\mathrm{d}R/\hbar$$
$$- \int_{R_{\mathrm{p}}}^{R_{\mathrm{t2}}} \left[2\mu E - \hbar^2\ell(\ell+1)/R^2 - 2\mu U_2(r)\right]^{1/2}\mathrm{d}R/\hbar,$$
(49.54)

where R_{t1} and R_{t2} are the turning points for adiabatic motion on potential curves U_1 and U_2, E is the total energy. Once R_{p} is chosen, $\Delta\Phi_{12}^{(0)}/2$ is well-defined and is independent of the dynamic details of a nonadiabatic transition. On the other hand, P_{12} and ϕ_{12} do depend on these details. In particular, for the models discussed in Sect. 49.3, the velocity v_{p} that enters into the Massey parameter, is

$$v_{\mathrm{p}} = \left(\frac{2}{\mu}\right)^{1/2}\left(E - U_{\mathrm{p}} - \frac{\hbar^2\ell(\ell+1)}{2\mu R_{\mathrm{p}}^2}\right)^{1/2},$$
(49.55)

where $U_{\mathrm{p}} \approx U_1(R_{\mathrm{p}}) \approx U_2(R_{\mathrm{p}})$. As a function of E and ℓ, the double-passage transition probability is symmetric with respect to the initial and final states.

In many applications, one can use the mean transition probability $\langle \mathcal{P}_{12} \rangle$, which is obtained from $\mathcal{P}_{12}$ by averaging over several oscillations:

$$\langle \mathcal{P}_{12} \rangle = 2 P_{12}(1 - P_{12}) \,. \tag{49.56}$$

The important limiting cases of the double-passage Nikitin model are:
(i) Double-passage Landau–Zener–Stückelberg equation,

$$\mathcal{P}_{12}^{\text{LZS}} = 4 \exp\left(-2\pi\zeta^{\text{LZ}}\right) \left[1 - \exp\left(-2\pi\zeta^{\text{LZ}}\right)\right]$$
$$\times \sin^2\left(\Delta\Phi_{12}^{(0)}/2 + \phi_{12}^{\text{LZS}}\right) \,, \tag{49.57}$$

where ζ^{LZ} is given by (49.32), $\Delta\Phi_{12}^{(0)}/2$ by (49.54) and the expression for ϕ_{12}^{LZS} is available [49.2]. When ζ^{LZ} changes from zero to infinity, $\langle \mathcal{P}_{12}^{\text{LZS}} \rangle$ passes through a maximum, $\langle \mathcal{P}_{12} \rangle_{\max} = 1/2$, and ϕ_{12}^{LZS} decreases from $\pi/4$ to zero.
(ii) Double-passage Rosen–Zener–Demkov equation:

$$\mathcal{P}_{12}^{\text{RZD}} = \frac{\sin^2\left(\Delta\Phi_{12}^{(0)}/2 + \phi_{12}^{\text{RZD}}\right)}{\cosh^2(\pi\zeta/2)} \,. \tag{49.58}$$

where ζ is given by (49.46) and the expression for ϕ_{12}^{RZD} is available [49.2]. Under certain conditions [49.2, 9], the Stückelberg phase in (49.58) can be identified with the phase accumulated during the motion of a diatom from infinitely large distance to the turning points.
(iii) Double-passage equation for a resonance process ($\Delta E = 0$):

$$\mathcal{P}_{12}^{\text{res}} = \sin^2\left(2\vartheta\right) \sin^2\left(\Delta\Phi_{12}/2\right) \,. \tag{49.59}$$

The general resonance case (zero energy change, $\Delta E = 0$) is also called an accidental resonance. For the accidental resonance, the diagonal diabatic matrix elements are not equal to each other. A particular case of an accidental resonance is a symmetric resonance, for which the diabatic matrix elements are the same. For the Nikitin model, symmetric resonance corresponds to $\vartheta = \pi/4$, and (49.59) reads

$$\mathcal{P}_{12}^{\text{symm}} = \sin^2\left(\Delta\Phi_{12}/2\right) \,. \tag{49.60}$$

Equation (49.60) also follows from (49.58) in the limit $\zeta \to 0$. Actually, (49.60) is valid for any symmetric resonance case [not necessarily for the model Hamiltonians (49.39) and (49.45)] and for the arbitrary values of the phase $\Delta\Phi_{12}/2$. This phase can be identified with $\Delta\Phi_{12}^{(0)}/2$ from (49.54) provided R_p is taken to be infinitely large.

49.4.2 Approximate Formulae for the Transition Probabilities

Several approximate formulae are available for $\langle \mathcal{P}_{12} \rangle$ in the case where H_{12} depends on time in a bell-shaped manner, and $\Delta H = H_{11} - H_{22}$ can be represented as $\hbar\omega + \Delta V$, with ΔV also having a bell-shaped form. Define

$$v = \left(\frac{1}{\hbar}\right) \int\limits_{-\infty}^{+\infty} H_{12}(t) \, \mathrm{d}t \,;$$

$$w_0 = \left(\frac{1}{\hbar}\right) \int\limits_{-\infty}^{+\infty} H_{12}(t) \exp(\mathrm{i}\omega t) \, \mathrm{d}t \,,$$

$$w = \left(\frac{1}{\hbar}\right) \int\limits_{-\infty}^{+\infty} H_{12}(t) \exp\left[(\mathrm{i}/\hbar) \int\limits_{0}^{t} \Delta H(t) \, \mathrm{d}t\right] \mathrm{d}t \,,$$

$$u = \left(\frac{1}{2\hbar}\right) \int\limits_{-\infty}^{+\infty} \Delta V_{12}(t) \, \mathrm{d}t \,, \tag{49.61}$$

and

$$S(t) = (1/\hbar) \int\limits_{0}^{t} \left[\Delta H^2(t) + 4 H_{12}^2(t)\right]^{1/2} \mathrm{d}t \,. \tag{49.62}$$

Then the various approximate formulae, as suggested by different authors [49.2], read

$$\mathcal{P}_{12} \cong (w_0/v)^2 \sin^2 v \,, \tag{49.63}$$

$$\mathcal{P}_{12} \cong \sin^2 w \,, \tag{49.64}$$

$$\mathcal{P}_{12} \cong \frac{w_0^2}{u_0^2 + w_0^2} \sin^2 \sqrt{(u_0^2 + w_0^2)} \,, \tag{49.65}$$

$$\mathcal{P}_{12} \cong \left| \int\limits_{-\infty}^{+\infty} H_{12}(t) \exp[\mathrm{i}S(t)] \, \mathrm{d}t/\hbar \right|^2 \,, \tag{49.66}$$

$$\mathcal{P}_{12} \cong \frac{\sin^2 S_{\text{c}}'}{\cosh^2 S_{\text{c}}''} \,. \tag{49.67}$$

In (49.67), S_{c}' and S_{c}'' are the real and imaginary parts of the complex quantity $S_{\text{c}} = S(t_{\text{c}})$ from (49.62). The complex-valued time t_{c} is found from

$$\Delta H^2(t_{\text{c}}) + 4 H_{12}^2(t_{\text{c}}) = 0 \,, \tag{49.68}$$

under the condition that t_{c} possesses the smallest imaginary part of all roots of this equation.

49.4.3 Integral Cross Sections for a Double-Passage Transition Probability

The quasiclassical inelastic integral cross section σ_{if} for the transition $i \to f$ is related to P_{if} by

$$\sigma_{if} = \frac{\pi}{\mu E_i} \int_0^\infty P_{if} \ell \, d\ell \,, \tag{49.69}$$

where E_i is the initial collision energy, $E_i = E - U_i(\infty)$. The cross section defined by (49.69) typically shows the following qualitative dependence on the collision velocity: σ_{if} increases rapidly with E_i at low energies, reaches a maximum and then slowly falls off at high energies. The position of the maximum roughly corresponds to the energy $E_i = E_i^*$ at which the relevant Massey parameter at the NAR center, $\zeta(R_p)$, is of the order of unity. The conditions $E_i < E_i^*$ and $E_i > E_i^*$ correspond to the near-adiabatic and strongly nonadiabatic (also called diabatic) regimes, respectively.

In calculating σ_{if}, one usually neglects the Stückelberg oscillating term and sets the upper limit in the integral in (49.69) to a value $\ell = \ell_m$ beyond which the integrand begins to fall off quickly. Yet another simplification is possible, in the framework of the impact parameter approximation, when the relative motion of atoms is described by a rectilinear trajectory $R(t)$ with constant velocity v and impact parameter $b = \hbar\ell/\mu v$:

$$R(t) = \left(b^2 + v^2 t^2 \right)^{1/2} \,. \tag{49.70}$$

For instance, for the Landau–Zener model $\ell_m = \mu v R_p/\hbar$, and the cross section depends on one dimensionless parameter $\gamma = 2\pi V^2/(\Delta F \hbar v)$ according to

$$\sigma_{12}(\gamma) = 2\pi R_p^2 \int_0^1 \exp(-\gamma/\sqrt{x}\,) \left[1 - \exp(-\gamma/\sqrt{x}\,) \right] dx$$
$$= 4\pi R_p^2 \left[E_3(\gamma) - E_3(2\gamma) \right] \,, \tag{49.71}$$

where $E_3(z)$ is the exponential integral.

For the symmetric resonance, the cross section reads

$$\sigma_{if}(v) = 2\pi \int_0^\infty \sin^2\left(\frac{\Delta\Phi_{if}^{\text{Res}}(b, v)}{2} \right) b \, db \approx \frac{\pi}{2} b_m^2(v) \,, \tag{49.72}$$

where b_m is found from the Firsov criterion [49.2]:

$$\frac{\Delta\Phi_{if}^{\text{Res}}(b_m, v)}{2} = \int_{b^*}^\infty \frac{\left[U_i(R) - U_f(R) \right]}{\hbar v \sqrt{R^2 - b_m^2}} \, dR = \frac{2}{\pi} \,. \tag{49.73}$$

The cross section in (49.71) first increases and then decreases with the collision velocity v, while that in (49.72) slowly decreases with v.

49.5 Multiple-Passage Transition Probabilities

49.5.1 Multiple Passage in Atomic Collisions

In the case of atomic collisions, there is only one nuclear coordinate R. If there exist several NAR on the R-axis, those which are classically accessible (for given total energy E and total angular momentum J) can be traversed several times. In the semiclassical approximation [49.16], the multiple-passage transition amplitude A_{if} for a given transition between initial state i and final state f can be calculated as a sum of transition amplitudes $A_{if}^{\mathscr{L}}$, over all possible classical ways $\mathscr{L}$ which connect these states, and which run along a one-dimensional manifold R:

$$A_{if} = \sum_{\mathscr{L}} A_{if}^{\mathscr{L}} \,, \tag{49.74}$$

where each $A_{if}^{\mathscr{L}}$ can be expressed through the probability $\mathscr{P}_{if}^{\mathscr{L}}$ and the phase $\Phi_{if}^{\mathscr{L}}$ by [49.13]

$$A_{if}^{\mathscr{L}} = \left[\mathscr{P}_{if}^{\mathscr{L}} \right]^{1/2} \exp\left(i\Phi_{if}^{\mathscr{L}} \right) \,. \tag{49.75}$$

The net transition probability is then

$$\mathscr{P}_{if} = |A_{if}|^2 \tag{49.76}$$
$$= \sum_{\mathscr{L}} \mathscr{P}_{if}^{\mathscr{L}} + \sideset{}{'}\sum_{\mathscr{L},\mathscr{L}'} \left[\mathscr{P}_{if}^{\mathscr{L}} \mathscr{P}_{if}^{\mathscr{L}'} \right]^{1/2} \cos\left(\Phi_{if}^{\mathscr{L}} - \Phi_{if}^{\mathscr{L}'} \right) \,.$$

The first sum runs over all different paths, and the second (primed) over all different pairs of paths. The primed sum usually yields a contribution to the transition probability which oscillates rapidly with a change of the parameters entering into $\mathscr{P}_{if}$ (i. e., E and J) and represents a multiple-passage counterpart to the Stückelberg oscillations.

If the Stückelberg oscillations are neglected, $\mathscr{P}_{if}$ is equivalent to a mean transition probability $\langle \mathscr{P}_{if} \rangle$:

$$\langle \mathscr{P}_{if} \rangle = \sum_{\mathscr{L}} \mathscr{P}_{if}^{\mathscr{L}} \,. \tag{49.77}$$

For one NAR, there are two equivalent paths, and $\mathscr{P}_{if}^{(1)} = \mathscr{P}^{(2)}{}_{if} = P_{if}(1 - P_{if})$. Then (49.77) yields (49.56).

49.5.2 Multiple Passage in Molecular Collisions

For molecular collsions, (49.74) and (49.75) apply as well. However, the manifold of $\mathcal{R}$ to which a trajectory $\mathcal{Q}(t)$ belongs now comprises $3N-5$ (for a linear arrangement of nuclei) or $3N-6$ (for a nonlinear arrangement) degrees of freedom, where N is the number of atoms in the system. The approximation (49.77) is called, in the context of inelastic molecular collisions, the surface-hopping approximation [49.17, 18]. Each time a trajectory reaches an NAR, it bifurcates, and the system makes a hop from one PES to another with a certain probability. Keeping track of all the bifurcations and associated probabilities, one calculates $\mathcal{P}_{if}^{\mathcal{L}}$ along a path $\mathcal{L}$ made up of different portions of trajectories running across different PES. Because of the complicated sequence of nonadiabatic events leading from the initial state to the final state, each $\mathcal{P}_{if}^{\mathcal{L}}$ is a complicated function of different single passage transition probabilities P_{nm}, and survival probabilities $1-P_{nm}$. Even if all P_{nm} are known in analytical form, the calculation of $\langle \mathcal{P}_{if} \rangle$ requires numerical computations to keep track of individual nonadiabatic events [49.17].

The manifold $\mathcal{R}$ can be reduced in size if one treats other degrees of freedom, besides electronic ones, on the same footing. In this way one introduces adiabatic vibronic (vibrational + electronic) states and adiabatic vibronic PES, and considers nonadiabatic transitions between them [49.19]. In the vibronic representation, the formal theory remains the same; however its implementation is more difficult since there are many more possibilities for trajectory branching. Finally, under certain conditions, one can use a fully adiabatic description of all degrees of freedom save one – the intermolecular distance R. This approach provides a basis for the statistical adiabatic channel model (SACM) of unimolecular reactions [49.20] where the receding fragments are scattered adiabatically in the exit channels after leaving the region of a statistical complex.

For a latest review of the theory of molecular nonadiabatic dynamics, see [49.21] and papers in [49.22].

50. Ion–Atom and Atom–Atom Collisions

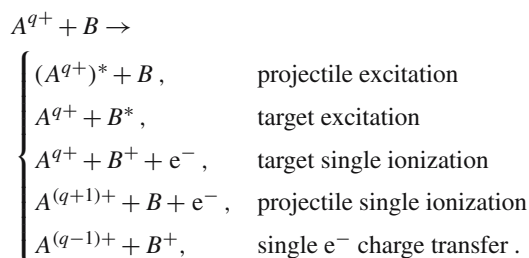
This chapter summarizes the principal features of theoretical treatments of ion–atom and atom–atom collisions. This is a broad topic and the goal here is a general overview that introduces the main concepts, terminology, and methods in the field. Attention will focus on intermediate and high collision velocities, for which the relative velocity between the projectile and target is on the order of, or larger than, the orbital speed of the electrons active in the transition.

Part D | 50

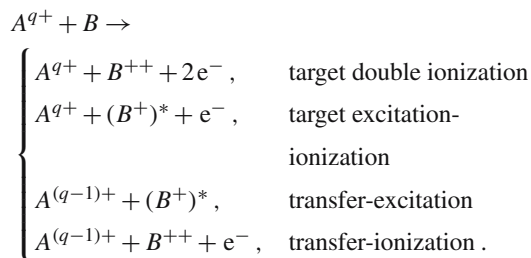
Low energy collisions are treated in Chapt. 49. Charge transfer reactions are treated in Chapt. 51. We will emphasize therefore excitation and ionization transitions, and discuss charge transfer only as it is interrelated with these transitions. The description of these heavy particle collisions has many features in common with electron and positron collisions with atoms and ions (Chapts. 47 and 48) and this chapter should be studied in parallel with those. There are also chapters dealing with special phenomena in ion–atom collisions: excitation at high collision energies and the Thomas peak (Chapt. 57), electron emission in high energy ion–atom collisions (Chapt. 53), and alignment and orientation (Chapt. 46). Other chapters deal with certain specific theoretical methods: continuum distorted wave (CDW) approximations (Chapt. 52), the binary encounter approximation (Chapt. 56), and classical trajectory Monte Carlo (CTMC) techniques (Chapt. 58). The emphasis of the present chapter is coupled-states calculations of excitation and ionization. There are several review articles and monographs [50.1, 2].

The collisions considered here involve a projectile ion or atom and a target atom. The collision kinematics can be described in the lab frame, where the target atom is assumed to be initially at rest and the collision energy is the kinetic energy of the projectile when it is far from the target prior to the collision, or in the center of mass frame. The primary quantities of interest are the cross sections for producing various final states of

the system for given initial states of the target and projectile. The total cross sections depend on the initial and final quantum state of the target and projectile and on the collision energy. Let A denote the projectile atom or ion with ionic charge q, and B denote the target atom. Let A^* and B^* denote excited states. Some examples of processes for which the cross section is of interest are

$$A^{q+} + B \rightarrow$$
$$\begin{cases} (A^{q+})^* + B, & \text{projectile excitation} \\ A^{q+} + B^*, & \text{target excitation} \\ A^{q+} + B^+ + e^-, & \text{target single ionization} \\ A^{(q+1)+} + B + e^-, & \text{projectile single ionization} \\ A^{(q-1)+} + B^+, & \text{single } e^- \text{ charge transfer}. \end{cases}$$


For a multi-electron collision system, combinations of the above quantities are possible. A few representative examples are

$$A^{q+} + B \rightarrow$$
$$\begin{cases} A^{q+} + B^{++} + 2e^-, & \text{target double ionization} \\ A^{q+} + (B^+)^* + e^-, & \text{target excitation-} \\ & \text{ionization} \\ A^{(q-1)+} + (B^+)^*, & \text{transfer-excitation} \\ A^{(q-1)+} + B^{++} + e^-, & \text{transfer-ionization}. \end{cases}$$


For each of these processes, the projectile and/or target can be initially in excited states. A class of ion–atom collisions that has received much theoretical attention because of the relative simplicity is the one where the projectile ion is initially bare, with charge $q = Z_p$, the projectile nuclear charge. One can also consider various differential cross sections: differential in the projectile scattering angle, in the energy and angle of emission of ionized electrons, in recoil momentum of the target, etc.

Theoretical calculations of these cross sections can be classified according to the approximations and/or methods used. We will discuss four such classifications: treatment of the heavy particle motion, independent particle model (IPM) versus inclusion of correlation in multi-electron systems, analytical approximations (PWBA, SCA, Glauber, etc.) versus numerical methods (such as coupled-states) for obtaining cross sections, and treatments of the ionization continuum.

50.1 Treatment of Heavy Particle Motion

Only at very low energies must the motion of the nuclei be described quantum mechanically. At the intermediate and high collision velocities considered here the semiclassical approximation, in which the motion of the nuclei can be described classically and only the electrons need be described by quantum mechanical wave functions, is accurate [50.3]. The projectile nucleus then moves on a predetermined classical path. At high collision energies this path can often be taken to be a straight line path with constant speed. At somewhat lower energies the deflection and change in speed of the projectile due to the projectile–target interaction is often incorporated [50.4–6]. The Coulomb trajectory due to the nucleus–nucleus interaction can be used, and the screening effects of the projectile and target electrons can be included. For a bare positive ion projectile, the Coulomb trajectory effects increase the distance of closest approach for a given impact parameter and reduce the projectile speed in the interaction region. Projectile trajectory effects are particularly strong for projectiles less massive than protons (positive or negative muons [50.7], for example). The semiclassical approach with trajectory effects has even been used for electron impact excitation and ionization [50.7]. Coulomb trajectories are also important when small impact parameter collisions are considered. The recoil of the target nucleus can also be treated classically and this recoil can affect the cross sections [50.8–10].

In the semiclassical approximation, the vector $\mathbf{R}(b, t)$ that locates the projectile relative to the target nucleus is a function of the impact parameter b and time t. The specific functional dependence is determined by the trajectory being used. For a straight line, constant velocity $\mathbf{v}$ path, $\mathbf{R} = \mathbf{b} + \mathbf{v}t$. For the case of a bare projectile ion and a one-electron target, the time-dependent projectile–target interaction is given by

$$V(b, t) = \frac{-Z_P e^2}{|\mathbf{r} - \mathbf{R}(b, t)|} + \frac{Z_P Z_T e^2}{R(b, t)} \, , \qquad (50.1)$$

where Z_P and Z_T are the projectile and target nuclear charges and $\mathbf{r}$ is the position vector of the electron relative to the target nucleus. If the collision calculation starting from (50.1) is done exactly the nuclear repulsion term $Z_P Z_T e^2 / R(b, t)$ does not involve the electronic coordinates and makes no contribution to total cross sections for anything other than elastic scattering. This term makes a nonzero contribution in an approximate calculation, such as a first-order perturbation theory calculation with nonorthogonal initial and final states, and this is a defect of such calculations.

A deficiency of the semiclassical approximation as described above is that, since a predetermined classical path is used, there is no coupling between the energy and momentum given to the target electron and that lost by the projectile. A simple improvement, in cases where the energy lost by the projectile when the target transition occurs is an appreciable fraction of its total energy, is to use some average of the projectile's initial and final speeds as the asymptotic projectile speed. This results in a projectile trajectory that depends on the cross section being calculated. This lack of coupling between the projectile motion and the states of the electrons can be a particular deficiency when cross sections differential in the scattering angle Θ of the projectile are computed. If the collision energy is large and the projectile is scattered primarily by the static potential of the target, a classical treatment of the scattering can be used to relate b to Θ. Even when straight line, constant speed projectile paths are used to calculate the transition probabilities, differential cross sections can be extracted by relating b to Θ. At lower energies, where the de Broglie wavelength of

the projectile is not small compared with the range of the interaction, eikonal methods can be used to convert impact parameter dependent probabilities to differential cross sections [50.11–13]. A particularly striking example where there is strong coupling between the projectile motion and the final quantum state of the electron is proton impact single and double ionization of helium differential in the projectile scattering angle [50.14, 15]. The projectile can be deflected by interaction with the target nucleus. In this case the projectile scattering angle can be related to the impact parameter by the equations of classical mechanics, and the projectile can be scat-

tered by up to 180° as b is decreased to zero. But the projectile can also be scattered by a close interaction with a target electron, and the kinematics then can be quite different. Such an interaction has a low probability for scattering the projectile to a large angle. Classically, from energy and momentum considerations, the maximum angle through which a proton can be scattered by an electron initially at rest is about 0.5 mrads; and if the proton is scattered through 0.5 mrads, the electron acquires large energy and momentum. The combined effects of both projectile scattering mechanisms are difficult to treat in a semiclassical model [50.16].

50.2 Independent–Particle Models Versus Many–Electron Treatments

In the semiclassical impact parameter method, as described in Sect. 50.1, for a single electron collision system one has to calculate a single particle wave function and from it single-electron transition amplitudes. A multi-electron collision problem can be treated as an effective single-electron problem if only one projectile–electron interaction is considered and the other electrons merely provide an effective single-particle potential in which the active electron moves.

In an independent particle model (IPM), the electron–electron interactions are replaced by effective single-electron potentials. Since the projectile–target interaction is a sum of single-electron interactions, the many-electron collision problem reduces to an uncoupled set of single electron problems. Their solution at each impact parameter gives single electron transition amplitudes a_{ij} and transition probabilities $\rho_{ij} = |a_{ij}|^2$. Cross sections for multi-electron transitions can still be calculated by combining the single-electron amplitudes in an appropriate way [50.17, 18]. In doing this, it is important to distinguish between inclusive and exclusive processes. For an inclusive cross section, one final orbital occupancy, or a few final orbital occupancies, is specified, but the final states of the remaining electrons are not specified and all possibilities are summed over. For a totally exclusive process, all final orbital occupancies are specified. For example, consider a $p + \text{Ne}$ collision. For the inclusive cross section for K-shell vacancy production, at least one K-shell vacancy in the final state is specified. The other electrons could remain in their original orbitals, there could be two K-shell vacancies, the K-shell vacancy could be accompanied by any number of L-shell vacancies, etc., and all these possible final states are summed over. An example of an

exclusive cross section is the cross section for producing a single K-shell vacancy with the specification that the final state of the target have no additional vacancies.

In calculating inclusive cross sections from single-electron transition amplitudes in an IPM it is important to take proper account of time-ordering and Pauli exclusion effects, as well as all multi-electron processes that lead to the specified final state. Again using the $p + \text{Ne}$ collision example, a two-electron process that leads to a K-shell vacancy is for the projectile to first ionize an L-shell electron, and then in the same collision to excite a K-shell electron into the L-shell hole just produced. But the K-shell electron must have the same spin component as the L-shell electron that was removed, and the K to L excitation can occur only after the L-hole has been made. This can lead to correlations among the single-electron amplitudes that have been called Pauli correlations or Pauli blocking effects.

For a totally inclusive process where only one final occupancy is specified, all the multi-electron contributions cancel in any IPM and the probability for producing, for example, a hole in the initially occupied orbital labeled 1, without any other specification of final state orbital occupancies, is given by

$$\rho_1 = \sum_{k < N} |a_{k1}|^2 , \qquad (50.2)$$

where k runs over the unoccupied bound orbitals of the target, the bound orbitals of the projectile, and the continuum orbitals. This expression says that the inclusive probability of producing a hole in the initially occupied orbital 1 is given by the sum of the probabilities of exciting an electron from this orbital to any initially unoccupied orbitals of the projectile–target system. The

cross section is then exactly the same as if only a single target electron were interacting with the projectile. However, for an inclusive process in which two vacancies in orbitals of the same spin are specified in the final state, say orbitals 1 and 2, then the probability of producing this final state is not the product of the independent probabilities of producing a vacancy in orbital 1 and in orbital 2 [50.17, 18]. The correlation produced by antisymmetry destroys the independence of probabilities for this process. Specific expressions, and also a discussion of how to derive the correct expressions to use for any particular inclusive process, can be found in the literature [50.17–19]. If these Pauli correlations are neglected, and products of independent single-electron transition probabilities are used, then the distribution of multiple vacancies within a shell, such as the L-shell, are given in terms of a binomial distribution [50.20–22].

The IPM treatment is inadequate if electron correlation plays an important role in the collision. One notable set of examples is two-electron transitions in which the projectile–target interaction is weak, such as at high collision energies. It is useful to characterize multi-electron transitions as being either externally or internally induced [50.23]. In an externally induced two-electron process, the projectile interacts with both electrons and induces the transition of each. In the internal process, energy is transferred to just one electron; this energy is then shared with the other electron through the internal action of the correlating electron–electron force.

Consider double ionization. At sufficiently high energies, the external reaction has an amplitude proportional to Z_P^2. To lowest order, the reaction proceeds through two consecutive first-order Born collisions, perhaps more correctly described as a two-particle second-order Born collision. This is called a two step mechanism, TS2. The internal reaction amplitude, again at sufficiently high energies, is proportional to Z_P; one first-order Born reaction initiates the process. The sharing of energy with the second electron can be thought of in two ways. If the first electron leaves without interacting with the second, there is a change in the screening that can be thought of as being responsible for shaking the second electron off. The main role of the electron–

electron force here is to introduce correlation into the initial ground state wave function. A second way for both electrons to be ionized is for the first electron to strike the second on the way out. This has been variously called interception or TS1 [50.21, 24–26]. The role of the electron–electron force here is to introduce correlation into the final two-electron wave function. At asymptotic energies the first Born term will eventually dominate, and the internal correlated mechanism is solely responsible for double ionization. At lower energies, the external and internal amplitudes are of the same order, and thus they interfere. The interference produces terms in the transition probability that are proportional to odd powers of Z_P, and therefore produces a cross section that changes when the sign of the projectile charge changes. One example is the double ionization of helium in the MeV/amu collision energy region, where antiprotons ($Z_P = -1$) produce a double ionization cross section a factor of two larger than that for protons ($Z_P = +1$) around 1 MeV/amu [50.25, 26]. It is possible to account for electron correlation directly by putting the electron-electron interaction into the Hamiltonian and solving for the many-electron correlated wave function of the collision system. In coupled-states calculations (Sect. 50.3), this approach is computationally intractable if more than a few coupled channels are important, which is usually the case at intermediate collision energies; but some full electron calculations have been carried out [50.27–31]. In low-energy collisions where molecular basis expansions are appropriate, only a few channels can be important, i. e., those involved in potential curve crossings or near crossings, and full electron calculations are more feasible. Some alternatives to full electron quantum calculations have been developed, such as the independent event model [50.32], classical dynamics calculations (Chapt. 58), time-dependent Hartree–Fock (TDHF) [50.33, 34], and the forced impulse method (FIM) [50.25, 26]. The FIM divides the collision time into short sequential segments such that an impulse approximation is forced to be valid. The system is allowed to collapse back into a fully correlated eigenstate at the end of each segment, but the electrons propagate independently during each segment.

50.3 Analytical Approximations Versus Numerical Calculations

There is a wide variety of techniques used for computing cross sections for ion–atom and atom–atom collisions. One class uses approximate analytical methods. The expressions and the wave functions that enter into them may be sufficiently complicated that they must be evaluated on a computer, but they can be written down as

closed form expressions. One important example is the first Born approximation, in which the projectile–target interaction is treated in first-order. Hence, the first Born approximation is most accurate for weak interactions, for example for small projectile charge and large collision energy. The first Born approximation is commonly expressed in either of two forms: the plane wave Born approximation (PWBA) [50.35], where the projectile nuclear motion wave function is taken to be a plane wave, or the semiclassical approximation (SCA) [50.3] which is an impact parameter approach that uses a classical path for the projectile motion. At the high collision velocities where the first Born approximation is accurate, and for projectiles that are at least as massive as a proton, the PWBA and SCA give identical results. Since it is based on first-order perturbation theory, the first Born approximation only requires computation of the matrix element of the projectile interaction between initial and final state wave functions. For example, the first Born transition amplitude for a bare ion (charge Z_P, mass M) incident on a one electron target is

$$f_{ji} = \frac{2MZ_P e^2}{\hbar^2 K^2} \int \phi_j^*(\boldsymbol{r}) \, \mathrm{e}^{\mathrm{i}\boldsymbol{K}\cdot\boldsymbol{r}} \phi_i(\boldsymbol{r}) \, \mathrm{d}^3\boldsymbol{r} \ , \tag{50.3}$$

where $\hbar\boldsymbol{K}$ is the momentum transfer vector and ϕ_i, ϕ_j are the initial and final state wave functions. For a hydrogenic system, analytical expressions for the PWBA amplitudes for bound–bound transitions can be derived [50.36] and for bound–continuum transitions (ionization) the cross section can be expressed in terms of a two-dimensional integral over energy and momentum transfer, where the integrand is given by a simple analytical expression [50.37]. First Born calculations are also carried out with relativistic wave functions; relativistic target wave function effects are important for the inner shells of heavy atoms [50.38].

There is a number of other approximate methods that lead to simple analytic expressions, such as the Glauber approximation [50.39–41], continuum distorted wave (CDW) and eikonal methods (Chapt. 52), the binary encounter approximation (BEA, Chapt. 56), and second Born calculations [50.42]. A difficulty with all these methods is that they do not admit to a sequence of successive improvements; there is no procedure for systematically driving them to convergence.

One class of approximation methods very widely used for inner shell processes, such as inner shell vacancy production, is based on perturbed stationary state (PSS) methods. One variation is the energy loss and Coulomb deflection effects perturbed stationary state approximation with relativistic correction (ECPSSR)

theory, developed originally by *Brandt* and co-workers and since extended and applied by others [50.43, 44]. This approximation involves procedures for correcting the first Born approximation. It is quite successful in fitting K-, L-, and M-shell vacancy production cross sections.

Another approach is to calculate the electronic wave function for the collision system by expanding it in some basis set [50.45, 46]. This procedure is called the coupled-channels, coupled-states, or close-coupling method. It is convenient to diagonalize the target and projectile systems in the chosen basis to produce matrix eigenfunctions for the target and projectile. Putting this expansion into the time-dependent Schrödinger equation leads to a set of coupled first-order equations for the time-dependent expansion coefficients. This set of equations is solved subject to the boundary condition that long before the collision, the expansion coefficient for the initial state wave function is unity and all other coefficients are zero. Then the expansion coefficients a long time after the collision give the transition amplitudes for transitions into those states.

Several types of expansions are used. The notation appropriate to a single-electron problem will be used for simplicity.

50.3.1 Single–Centered Expansion

In the single-centered expansion [50.47, 48], the wave function is expanded in a set of target centered basis functions. Diagonalization of the target Hamiltonian in this basis yields a set of target eigenfunctions $\phi_j^{\mathrm{T}}(\boldsymbol{r})$ and energies E_j. The expansion of the time-dependent wave function for the collision system is then

$$\psi_i(\boldsymbol{r}, b, t) = \sum_j a_{ji}(b, t) \, \mathrm{e}^{-\mathrm{i}(E_j - E_i)t/\hbar} \phi_j^{\mathrm{T}}(\boldsymbol{r}) \ . \tag{50.4}$$

If the electron is initially in the target state i, the initial boundary condition is $a_{ji}(b, -\infty) = \delta_{ji}$. The expansion coefficients at times long after the collision, $a_{ji}(b, +\infty)$, give the transition amplitudes for transitions from target state i to j. Ionization probabilities and the description of the ionization continuum will be described in the next section. It will suffice to say here that some of the $\phi_j(\boldsymbol{r})$ represent ionized states and account for transitions that leave the electron no longer in a target bound state. This single centered expansion does not directly allow for calculation of charge transfer amplitudes. However, it has been shown that if the number of angular momenta included in the set of $\phi_j(\boldsymbol{r})$ is large enough, the basis can accurately describe electron loss from the target

bound states even in cases where the charge transfer probability is large [50.47, 48]. If the charge transfer amplitude is small, it can be extracted from $\psi_i(\mathbf{r}, b, t)$ by use of a first-order T-matrix expression of the form

$$a_{ki}^{\mathrm{P}}(b, +\infty) = \langle \phi_k^{\mathrm{P}}(\mathbf{r} - \mathbf{R}) | U(\mathbf{r}, \mathbf{R}) | \psi_i(\mathbf{r}, b, t) \rangle , \tag{50.5}$$

where ϕ_k^{P} is a projectile state eigenfunction and $U(\mathbf{r}, \mathbf{R})$ is the projectile–target interaction [50.49, 50].

50.3.2 Two-Centered Expansion

In a two-centered expansion [50.45, 46, 51–54], the time-dependent wave function for the collision system is expanded in two sets of functions: a set of eigenfunctions centered on the target $\phi_j^{\mathrm{T}}(\mathbf{r})$ and a set of projectile centered eigenfunctions $\phi_k^{\mathrm{P}}(\mathbf{r} - \mathbf{R})$,

$$\begin{aligned}
\psi_i(\mathbf{r}, b, t) = &\sum_j a_{ji}^{\mathrm{T}}(b, t) \\
&\times \exp\left[-\mathrm{i}(E_j - E_i)t/\hbar\right] \phi_j^{\mathrm{T}}(\mathbf{r}) \\
&+ \sum_k a_{ki}^{\mathrm{P}}(b, t) \exp\left[-\mathrm{i}(E_k - E_i)t/\hbar\right] \\
&\times \exp\left[\mathrm{i}\mathbf{p} \cdot \mathbf{r}/\hbar\right] \phi_k^{\mathrm{P}}(\mathbf{r} - \mathbf{R}) .
\end{aligned} \tag{50.6}$$

Here $\exp\left[\mathrm{i}\mathbf{p} \cdot \mathbf{r}/\hbar\right]$ is an electron translation factor that accounts for the momentum $\mathbf{p}$ that the electron has relative to the target when it moves with the projectile. The energies E_k also contain the kinetic energy in the target frame that the electron has when it moves with the projectile. The problem of electron translation factors when a two centered molecular basis is used instead of the atomic basis has been extensively addressed [50.45, 46].

The coefficients $a_{ji}^{\mathrm{T}}(b, +\infty)$ and $a_{ki}^{\mathrm{P}}(b, +\infty)$ are the transition amplitudes for transitions into target and projectile states. The two-centered expansion allows for charge transfer amplitudes to be calculated directly and is capable of an accurate description of the electron flux

loss from the target due to charge transfer, but the computational difficulty is significantly greater. It is difficult in practice to include enough basis functions for convergence. Also, computational linear dependence can arise if the projectile and target are close because the projectile-centred basis set can become nearly identical to the target-centred basis set.

Calculations have also been done with a triple-centered expansion [50.55, 56]. Bound atomic states are centered on each nucleus and on a third center (the center of charge) in order to simulate the molecular character of slow collisions. The orbitals on this third center represent the united-atom character of the wave function.

50.3.3 One-and-a-Half Centered Expansion

To account for flux loss from the target region due to charge transfer, while retaining the computational efficiency of the single-centered expansion, a hybrid method called the one-and-a-half centered expansion (OHCE) was developed [50.57]. It is of the same form as the two-centered expansion except that the coefficients $a_{ki}^{\mathrm{P}}(b, t)$ of the projectile-centered states have predetermined rather than variable time dependence. The time dependence of the $a_{ki}^{\mathrm{P}}(b, t)$ must be such that the a_{ki}^{P} are all zero as $t \to -\infty$, and as $t \to +\infty$ they become constants that are identified as the charge transfer amplitudes. This ansatz greatly reduces the computational cost of propagating the coupled equations forward in time, but the projectile-centered functions are still present to allow explicitly for charge transfer channels at large times. At intermediate times, when the projectile and target separation is within the range of the target-centered basis, the target-centered part of the expansion, if enough basis functions are used, is sufficient to describe the time dependence of $\psi_i(\mathbf{r}, b, t)$ and the projectile-centered part of the expansion is redundant. The OHCE has been applied to several collision systems with good success [50.58].

50.4 Description of the Ionization Continuum

In ion–atom and atom–atom collision calculations description of the ionization continuum presents particular difficulties. For hydrogenic systems, the exact continuum wave functions are known analytically, and these may be used in analytic approximations such as the PWBA. For nonhydrogenic systems, screened hydrogenic wave functions or numerical wave func-

tions computed from some local effective potential, such as the Hartree–Fock–Slater approximation, can be used [50.59]. But for coupled states calculations, that involve expansion of the system wave function in terms of a discrete set of functions, some discretization of the continuum must be performed.

A simple procedure for generating a discrete representation of the continuum is to diagonalize the target (or projectile) Hamiltonian in a finite basis of square integrable basis functions. Some commonly used basis functions are Sturmian [50.45, 46], Gaussian, or Slater-type orbitals. This diagonalization produces a set of discrete matrix eigenvalues and eigenvectors, called pseudostates. For a one-electron or effective one-electron system, the exact energy spectrum of the Hamiltonian consists of an infinite set of discrete bound states and an ionization continuum and the interpretation of the pseudostates is straightforward. The N matrix eigenvalues below the first ionization threshold represent the bound states. By the Hylleraas–Undheim Theorem, they are upper bounds to the first N exact energies (Sect. 11.2.1). The matrix eigenvectors with positive eigenvalues provide a discrete representation of the ionization continuum [50.60]. Each pseudostate is accurately proportional to the exact continuum wave function at the pseudostate energy for values of r out to the range of the basis. The proportionality constant gives the energy width of the pseudostate – the energy region of the continuum represented by that pseudostate [50.49, 50]. These widths are approximately equal to the energy spacing between pseudostates. The pseudostates represent the continuum in the sense that the total ionization cross section is equal to the sum of the continuum pseudostate cross sections. Coupled-states calculations have also been carried out with wave packets constructed at discrete energies from the exact continuum wave functions [50.61]. What all these discretization methods do is to provide a quadrature rule for evaluating the integration over the energy of the ionized electron. Differential cross sections, differential in the ionized electron's energy, have also been extracted from discretized continuum calculations [50.62–65].

The situation is more complex for two-electron or multi-electron systems. The energy spectrum of a two-electron atom consists of an infinite set of bound states, an infinite set of overlapping single ionization continua that correspond to different residual ion states, and overlapping the higher energy part of these single ionization continua, a double ionization continuum where both electrons are unbound. The exact wave function for two electrons in the continuum of an ion is not known, but there are a number of approximate forms [50.66–68]. The interpretation of two electron pseudostates is also complicated. For energies below the second single ionization threshold the energy of a pseudostate clearly identifies whether it represents a bound state or an ionized state. But in the energy region where there are overlapping continua there are ambiguities. For example, a pseudostate with energy above the double ionization threshold can represent a doubly ionized state, a singly ionized state of the same total energy, or some admixture of the two. A method has been developed to solve this pseudostate interpretation problem [50.25, 26].

51. Ion–Atom Charge Transfer Reactions at Low Energies

Ion–atom charge exchange reactions contribute significantly to the ionization balance of complex ions in many natural environments (astrophysical photoionized plasmas such as planetary nebulae, nova shells, etc.) [51.1]. For electron temperatures lower than 10^6 K, the abundance of neutral atomic H or He can be sufficient for the charge exchange rate to exceed the radiative (direct or dielectronic) recombination rate for ions with charge $q \geq 2$ [51.2]. In the case of singly charged ions, accidental resonance conditions are required for the charge exchange rate to be large at thermal energies. In this chapter, we shall limit discussion to the case of $q \geq 2$. We may distinguish two types of reaction: type I, for which electron capture takes place with no change in the configuration of the core electrons, and type II, for which electron capture is accompanied by a rearrangement of the core electron configuration.

We shall concentrate on the low energy range (less than a few hundred eV), where an adiabatic representation of the collision complex can successfully describe the collision dynamics [51.3]. Nonadiabatic transitions tend to occur in the vicinity of avoided potential energy crossings. For the transition probability to be appreciable, the energy separation Δ_X at the crossing radius R_X

Part D | 51

must be neither too large nor too small ($0.1 < \Delta_X < 3$ eV). Since the size of Δ_X is determined by electron exchange, whose effect varies exponentially with internuclear distance, only crossings in the range $3 \leq R_X \leq 15a_0$ induce nonadiabatic transitions. Because of this constraint, the number of effective curve crossings is quite small and the electron capture process is very state selective [51.3].

In general, electron capture is of type I for $q \geq 3$ and of type II for $q = 2$. In a few cases, type II processes can also occur for $q = 3$.

Although there are a few direct experimental measurements at eV energies [51.4], most measurements have been carried out at collision energies exceeding a few 100 eV [51.5]. Unfortunately, the processes which dominate in the higher energy range become negligible at eV energies (and vice versa). Most estimates of the cross sections in the thermal–eV range are based on theoretical models. Since at thermal energies, orbiting and tunneling effects may be considerable, a quantum mechanical description of the collision is preferable.

The dynamic coupling matrix elements between different molecular states depend on the origin of the electronic coordinates, and the corresponding scattering equations are not invariant with respect to a Galilean transformation. In a semiclassical formulation of the dynamics, this defect can be removed by the introduction of translation factors [51.6–12]. However, in a quantum mechanical formulation, it is more appropriate to introduce reaction coordinates of a more flexible form than those used traditionally in the Born–Oppenheimer approximation. The most convenient is the Eckart coordinate system [51.9], which leads to a simple modification of the nonadiabatic coupling matrix elements, and which is well

adapted to cases where long range avoided crossings are dominant [51.10]. If a semiclassical approximation is introduced, the scattering equations become almost identical to those obtained directly using translation factors of the CTF (common translation factor) type [51.11, 12].

Three representative systems are chosen to illustrate the basic features of the problem: Al^{3+}/H and B^{3+}/He which are typical of type I, and O^{2+}/H which is typical of type II. In the Al^{3+}/H system, charge transfer takes place via the reaction [51.13]

$$Al^{3+}(3s^2)^2S + H \rightarrow Al^{2+}(3s^23p)^2P + H^+ \quad (51.1)$$
51.1 Molecular Structure Calculations

The construction of the network of adiabatic states of the molecular ion complex constitutes the first step in analyzing the dynamics of the ion–atom system. In principle, standard techniques of quantum chemistry can be employed. For doubly charged ions, where type II processes dominate and the effective avoided crossings take place at relatively short range, ab initio methods are required. On the other hand, for trebly and more highly charged ions, where type I processes dominate, the effective avoided crossings occur at long range where ab initio methods can be quite inaccurate. Model potential methods are then often more satisfactory.

51.1.1 Ab Initio Methods

Both molecular orbital and valence-bond methods have been extensively used and (provided a sufficient number of configurations are included) should be satisfactory in principle. A simple test is the location of the long range crossings, which is very sensitive to the energy difference of the initial and final channels. But this test is insufficient. For example, in the C^{3+}/H system, for which both the molecular orbital and valence bond methods yield comparable results in regions well away from avoided crossings, there are significant discrepancies in the important region of the avoided acrossings [51.17, 18]. In the present state of the art, the absolute accuracy of theoretical calculations in the crossing region is difficult to ascertain. Of course, since the computed electron capture cross sections depend sensitively on the minimum energy separation, experimental data at low collision energies makes some tests possible. Unfortunately, there is not yet much reliable data at low eV energies.

involving a network of two Σ and one Π adiabatic states. In the B^{3+}/He system, charge exchange occurs via a network of three Σ and one Π states involving two avoided crossings [51.14]. The two possible capture channels are

$$B^{3+}(1s^2) + He \rightarrow B^{2+}(1s^2nl) + He^+,$$
$$nl = 2s, 2p . \quad (51.2)$$
The O^{2+}/H system is a good example of a type II reaction which plays an important role in astrophysical plasmas [51.15, 16]. The dominant reaction at low energies

$$O^{2+}(2s^22p^2)^3P + H \rightarrow O^+(2s2p^4)^4P + H^+ \quad (51.3)$$
involves only quartet states.

Figures 51.1 and 51.2 present the adiabatic network of the $^4\Sigma^-$, $^4\Pi$ and $^2\Sigma^+$, $^2\Pi$, $^2\Delta$ states of the O^{2+}/H system. These have been obtained by means of a configuration interaction molecular orbital method with several hundred configurations [51.15]. It is clear from these calculations that the only effective avoided crossings are those involving the $^4\Sigma^-$ and $^4\Pi$ at 3.7 and 4.8 a_0, for
Fig. 51.1 Adiabatic potential energy curves of the $^4\Sigma^-$ and $^4\Pi$ states of the OH^{2+} molecular ion. The *solid curves* designate $^4\Pi$ states, the *dashed curves* $^4\Sigma^-$ states. The dissociation limits A and B correspond respectively to $[O^{2+}(^3P) + H(^2S)]$ and $[O^+(^4P) + H^+]$
Fig. 51.2 Adiabatic potential energy curves of the $^2\Sigma^+$, $^2\Pi$ and $^2\Delta$ states of the OH^{2+} molecular ion. The *solid curves* designate $^2\Sigma^+$ states, the *dashed curves* $^2\Pi$ states and the *dotted curve* a $^2\Delta$ state. The dissociation limits A, B, C and D correspond respectively to $[O^{2+}\,(^1S) + H\,(^2S)]$, $[O^{2+}\,(^1D) + H\,(^2S)]$, $[O^+\,(^2D) + H+]$ and $[O^{2+}\,(^3P) + H\,(^2S)]$

which the energy separation is $\approx 0.1\,\text{eV}$. The avoided crossings involving the doublet states at 8.0, 8.5 and $10\,a_0$, for which the energy separation is $\approx 0.02\,\text{eV}$, are diabatic. The avoided crossings for type II transitions occur at much shorter distances than for type I transitions.

51.1.2 Model Potential Methods

Model potential methods offer an attractive alternative to ab initio methods in treating type I reactions. To illustrate the method [51.19, 20], we consider an effective one-electron system composed of a spherically symmetric ion X^{q+} and a hydrogen atom. The model Hamiltonian of the molecular ion XH^{q+} is written as

$$H = T + V_X(r_b) - \frac{1}{r_a} + V_X(R) \,, \tag{51.4}$$

where T is the electronic kinetic energy, r_a and r_b are respectively the position vectors of the Rydberg electron with respect to nuclei A and B, and $V_X(r)$ is the effective potential of the ion core. The latter is usually expressed in the parametric form

$$V_X(r) = -\left[q + (Z - q)(1 + \alpha r + \beta r^2 + \gamma r^3)\,e^{-\delta r}\right] \,, \tag{51.5}$$

where Z is the ionic nuclear charge and the parameters $\alpha, \beta, \gamma, \delta, \ldots$ are optimized to the spectroscopic data so that the asymptotic energies of those Rydberg states of $X^{(q-1)+}$ which govern the charge transfer process are essentially exact.

The eigenvalues of H for a given internuclear distance R are determined by standard variational techniques, using a basis set of Slater-type orbitals in prolate spheroidal coordinates [51.3]. As an example, we present in Fig. 51.3 the potential energy curves of the Al^{3+} system which presents one Σ–Σ avoided crossing around $R_X = 7.2\,a_0$. Model potential methods can also be used to treat multielectron systems such as $(XHe)^{q+}$. In long range collisions, the transition probabilities are primarily determined by the asymptotic form of the electron wave functions far from the nuclei. Thus even when multielectron targets are involved, the effect of dynamic correlation can be small. Since the asymptotic form of the wave functions may be easily generated by model potential techniques, the effect of static correlation can be taken into account in a rather simple way. The method proposed here is quite similar to that used by *Grice* and *Herschbach* [51.21] to treat the long range configuration interaction of ionic and covalent states in neutral atom–atom collisions.
Fig. 51.3 Adiabatic potential energies of AlH^{3+}. The *full curve* designates the $^2\Sigma$ state correlated to the $[Al^{3+}(3p) + H\,(1s)]$ entry channel. The *dotted* and *dashed curves* designate respectively the $^2\Sigma$ and $^2\Pi$ states correlated to the $[Al^{2+}(3p) + H^+]$ electron capture channel

For example, in the system X^{q+} He, where as previously X^{q+} is a closed shell ion, the energy separation at a long range avoided crossing is given by [51.22]

$$\Delta\varepsilon(R_c) \equiv 2\sqrt{2}\langle b_{1\sigma}|b'_{1s}\rangle\langle a_{nl\lambda}|V_X + q/R|b\rangle , \quad (51.6)$$

where the molecular orbitals $a_{nl\lambda}$ (dissociating to $X^{(q-1)+}_{nl}$) and $b_{1\sigma}$ (dissociating to a 1s orbital of He) are generated from a model Hamiltonian of the form

$$H = T + V_X(r_b) - V_{He}(r_a) + V_{X,He}(R) , \quad (51.7)$$

where V_{He} is an effective potential describing the 1s orbital of He. The orbital b'_{1s} is the 1s orbital of He$^+$. This expression is the optimal form of $\Delta\varepsilon(R_c)$ which can be achieved without the use of explicitly correlated wave functions. Since both the $a_{nl\lambda}$ and $b_{1\sigma}$ orbitals are generated from the same model Hamiltonian, the calculation of the interaction matrix element in (51.6) is simple. As an example, Fig. 51.4 presents the adiabatic energies of the B^{3+}/He system which has two avoided $\Sigma - \Sigma$ crossings, one at 4.6 a_0, the other at 7.4 a_0.

A similar extension to treat the case of capture by an ion with one electron in a p shell can be made along the same lines. See [51.23] for an application to the reaction

$$O^{3+}(2p)^2P + H \rightarrow O^{2+}(2p3p)^3P + H^+ . \quad (51.8)$$
A combination of model potential methods to represent the core electrons and ab initio molecular orbital methods for the valence electrons has been successfully developed [51.24] to treat some complex systems such as C^{3+}/H where both type I and II transitions take place. The flexibility of the model potential parameters makes it possible to choose them so that the energies of the initial and final states are accurately reproduced.

51.1.3 Empirical Estimates

Electron capture cross sections at low energies are largely controlled by two parameters: the crossing radius R_X and the minimum energy separation Δ_X. These are the basic parameters required for the Landau–Zener model, and it is useful to have a simple way of estimating them without having recourse to a complex molecular structure calculation. Many empirical estimates [51.25–27] have been proposed. However, it is generally necessary to take into account the strong ℓ-dependence of the electron capture channel states. Defining $\alpha = \sqrt{I_t/13.6}$, where I_t is the ionization potential of the target (in eV), then Taulbjerg's formula

Adiabatic energies (arb. units)
Fig. 51.4 Adiabatic potential energies of BHe^{3+}. The *dotted curve* designates the $^1\Sigma$ state correlated to the [B^{3+} + He(1s^2)] entry channel. The *short* and *long dashed curves* designate respectively the $^1\Sigma$ and $^1\Pi$ states correlated to the [B^{2+} (2p) + He$^+$(1s)] electron capture channel. The *full curve* designates the $^1\Sigma$ state correlated to the [B^{2+} (2s) + He$^+$(1s)] entry channel

is [51.27]

$$\Delta_X(R_c) = \frac{18.26}{\sqrt{q}} f_{nl} \exp(-1.324\alpha R_c\sqrt{q}) , \quad (51.9)$$

where

$$f_{nl} = (-1)^{n+l-1}\sqrt{2l+1}\frac{\Gamma(n)}{[\Gamma(n+l+1)\Gamma(n-l)]^{1/2}} . \quad (51.10)$$

For type I systems, (51.9) is generally quite satisfactory when the energy levels of the capture states are well separated [51.28]. In that case, it can be used to predict the main electron capture reaction windows and obtain a reliable first estimate of the cross sections (in the energy range for which the Landau–Zener model is valid). On the other hand, in cases where there is a near degeneracy of the l states, serious errors can occur [51.28] and the predictions are less satisfactory.

For type II reactions, (51.9) must be modified by a corrective factor to take account of the simultaneous excitation of an electron from a 2s to 2p orbital. One such modification, proposed by *Butler* and *Dalgarno* [51.29], may give some useful idea of the main electron capture processes, but its precision is uncertain.

51.2 Dynamics of the Collision

The first step is to introduce a suitable set of scattering coordinates which can automatically describe both the excitation and rearrangement channels. The particular choice of coordinate system is conditioned by practical considerations. We have found Eckart coordinates to be convenient [51.10]. Their application is straightforward since it involves nonadiabatic matrix elements which can be calculated by the conventional techniques of quantum chemistry. The practical implementation of Eckart coordinates leads to the introduction of an adiabatic variable ξ defined as

$$\xi = \sqrt{\mu}\left(\boldsymbol{R} + \frac{1}{\mu}\boldsymbol{s}\right) ,$$

where

$$\boldsymbol{s} = \frac{\boldsymbol{r} \cdot \boldsymbol{R}}{R^2}\left(\boldsymbol{r} - \frac{\boldsymbol{r} \cdot \boldsymbol{R}}{2R^2}\boldsymbol{R}\right) , \qquad (51.11)$$

μ is the reduced mass of the colliding system, $\boldsymbol{r}$ the coordinate of the active electron with respect to the c.m. of the colliding system and $\boldsymbol{R}$ the relative position vector of the nuclei.

The adiabatic Eckart and Born–Oppenheimer equations differ only by terms of the order of $1/\mu$. It may be assumed that the Eckart states are given to sufficient accuracy by the Born–Oppenheimer adiabatic states designated by $\chi_i(\boldsymbol{r}; R)$. We expand the total wave function of the system in the form

$$\Psi(\boldsymbol{r}, \xi) = \sum \chi_i(\boldsymbol{r}; \xi) F_i(\xi) . \qquad (51.12)$$

(For a many-electron system, $\boldsymbol{r}$ represents the ensemble of electron coordinates.) Decomposing $F_i(\xi)$ on a basis set of symmetric top functions according to

$$F_i(\xi) = \sum_{K,M}(-1)^K \left(\frac{2K+1}{4\pi}\right)^{1/2} \\ \times D^K_{\Lambda,M}(\theta, \phi)\frac{g_i^{(k)}(\xi)}{\xi} , \qquad (51.13)$$

where $\{\theta, \phi\}$ are the spherical polar coordinates of ξ, then the radial functions $g_i^{(k)}(\xi)$ are solutions of the equation

$$\frac{\mathrm{d}^2}{\mathrm{d}\xi^2}\boldsymbol{g}^{(K)} + 2\boldsymbol{A}\frac{\mathrm{d}}{\mathrm{d}\xi}\boldsymbol{g}^{(K)} + \boldsymbol{W}\boldsymbol{g}^{(K)} = 0 , \qquad (51.14)$$

where

$$A_{mn}(\xi) = \left\langle \chi_m \left| \frac{\partial}{\partial\xi} + \frac{z}{\xi}\frac{\partial}{\partial z} \right| \chi_n \right\rangle \delta(\Lambda_m, \Lambda_n) , \qquad (51.15)$$

$$B_{mn} = \left\langle \chi_m \left| \frac{\partial^2}{\partial\xi^2} \right| \chi_n \right\rangle , \qquad (51.16)$$

$$W_{mn} = \left[2\mu(E - \varepsilon_n) - \frac{[K(K+1) - \Lambda_n^2]}{R^2} \right]\delta_{mn} \\ + B_{mn} + \frac{2}{R^2}\sqrt{K(K+1)}\,L_{mn} , \qquad (51.17)$$

$$L_{mn} = \mp\left\langle \chi_m \left| -2x\frac{\partial}{\partial z} \right| \chi_n \right\rangle \delta(\Lambda_m, \Lambda_m \pm 1) , \qquad (51.18)$$

z, x are the components of $\boldsymbol{r}$ parallel to and perpendicular to the direction of ξ in the classical collision plane, respectively.

Since the ratio $1/\mu$ is small, it is legitimate to replace the matrix element $\langle \chi_m|\partial/\partial\xi|\chi_n\rangle$ by $\langle \chi_m|\partial/\partial R|\chi_n\rangle$ in (51.15) and (51.16). Furthermore, all the matrix elements A_{mn} and L_{mn} vanish asymptotically to first order in $1/\mu$. The modified radial and rotational matrix elements are identical to those obtained in the semiclassical formalism with common translation factors.

The simplest way to solve (51.14) is to eliminate the first-order derivative by transforming to a diabatic representation in which the radial matrix elements vanish [51.30]

$$\boldsymbol{g}^{(K)} = \boldsymbol{C}\boldsymbol{h}^{(K)} , \qquad (51.19)$$

where

$$\frac{\mathrm{d}}{\mathrm{d}\xi}\boldsymbol{C} + \boldsymbol{A}\boldsymbol{C} = 0 , \qquad \boldsymbol{C}(\infty) = \boldsymbol{I} . \qquad (51.20)$$

Equation (51.14) then reduces to

$$\frac{\mathrm{d}^2}{\mathrm{d}\xi^2}\boldsymbol{h}^{(K)} - 2\mu\boldsymbol{V}^d\boldsymbol{h}^{(K)} \\ + \left(2\mu E - \frac{K(K+1)}{\xi^2} \right)\boldsymbol{h}^{(K)} = 0 \qquad (51.21)$$

with

$$\boldsymbol{V}^d = \boldsymbol{V}_E^d - \frac{\sqrt{K(K+1)}}{\mu R^2}\boldsymbol{V}_R^D , \qquad (51.22)$$

$$\boldsymbol{V}_E^d = \boldsymbol{C}^{-1}\varepsilon\boldsymbol{C} , \qquad \boldsymbol{V}_R^D = \boldsymbol{C}^{-1}\boldsymbol{L}\boldsymbol{C} . \qquad (51.23)$$

The solution of (51.21) and the subsequent extraction of the scattering matrix S may be carried out using an extension of the log derivative method [51.31], adapted to the case of a repulsive Coulomb potential in one or more of the scattering channels [51.32].

This method is particularly stable and advantageous to use at low energies for problems of the type considered here. Of course, at energies exceeding a few hundred eV, rapid oscillations of the radial function ren-

der the method rather time consuming. But the method is usable up to keV energies. However, for higher energies exceeding 1 keV, semiclassical methods are preferable.

51.3 Radial and Rotational Coupling Matrix Elements

Two independent methods are employed for the determination of radial coupling matrix elements A_{mn}: the first based on a direct numerical differentiation of the expansion coefficients of the wave function, the second on a variant of the Hellman–Feynman (HF) theorem. In principle, the HF method is three times faster than the direct numerical method, since the eigenvectors need to be calculated only at the value of R concerned. However, the real gain in computing is not always appreciable, the HF theorem being more sen-

sitive to errors in the wave function than the direct method. To achieve comparable accuracy, a larger basis set would be required in the molecular calculations, and this offsets much of the theoretical gain in computing time. The rotational coupling matrix elements L_{mn} are calculated numerically for each internuclear distance.

Typical results for the radial and rotational matrix elements are presented in Figs. 51.5 and 51.6 for the Al^{3+}/H system, illustrating the influence of translation effects. The origin dependence of the matrix element (without inclusion of translation) is weak in the vicinity of an avoided crossing. Away from the crossing, the origin dependence can be considerable. The corresponding diabatic energies and couplings are given in Figs. 51.7 and 51.8. For internuclear distances on the inward side of the crossing, the diabatic states correspond to a mixing of adiabatic states: it is clear that the mathematical definition (51.20) of the diabatic representation does not correspond to the empirical definition of the Landau–Zener model (Sect. 51.5).
Fig. 51.5 Radial coupling matrix elements between the two $^2\Sigma$ states of AlH^{3+}. The *full curve* designates the matrix element of the CTF (or Eckart) type. The *short and long dashed curves* designate the radial derivative with the origin of electron coordinates respectively on the Al and H nuclei

Fig. 51.8 Off-diagonal diabatic matrix element between the two $^2\Sigma$ states of AlH^{3+}

51.4 Total Electron Capture Cross Sections

Although the selection rules for electron capture at low energies are primarily governed by the avoided crossings between adiabatic states of the same symmetry, the combined effects of radial and rotational coupling can be quite complex. In general, rotational coupling effects are weak when capture occurs via an S state, but they can be strong for capture to P, D and higher L states.

In the case of Al^{3+}/H, where capture to the (3p) ^{2}P state of Al^{2+} takes place via a three-state network of two Σ and one Π states, rotational coupling between the Σ and Π states is strong in the vicinity of the avoided crossing and enhances the capture cross section considerably. This phenomenon is illustrated in Fig. 51.9, which shows the calculated total cross section at different energies as a function of Δ, the energy separation of the quasidegenerate diabatic $^2\Sigma$ and $^2\Pi$ exit channels at the $^2\Sigma$–$^2\Sigma$ crossing radius. The total cross section has a maximum for $\Delta = 0.08$ eV. The cause can be easily seen from the corresponding adiabatic potential energies (Fig. 51.10). For $\Delta = 0.8$ eV, the potential energies of the adiabatic $^2\Sigma$ entry channel and the $^2\Pi$ exit channel become tangential to one another, thereby inducing a resonant effect.
Fig. 51.9 Results of three state (two $^2\Sigma$ and one $^2\Pi$) calculations for electron capture in the Al^{3+}/H system. The cross sections are plotted as a function of the parameter Δ (see text). The extreme sensitivity to Δ illustrates the necessity of knowing the $^2\Sigma - ^2\Pi$ energy separation to high accuracy. The numerical values on the curves designate the collision energies in units of eV/amu
Fig. 51.10 Schematic diagram of the nondiagonal matrix elements of AlH^{3+} in the vicinity of the curve crossing. The three *broken curves* correspond to different $^2\Pi$ state potentials shifted from their calculated value by small amounts

In the case of the B^{3+}/He system, four molecular states are implicated in the collision process: three Σ states (Σ_1 correlated to the ^2S exit channel, Σ_2 correlated to the ^2P exit channel and Σ_3 correlated to the entry channel) and one Π state (correlated to the ^2P exit channel). In order to understand better the rota-
Fig. 51.11 Transition amplitudes for ^2S and ^2P electron capture as a function of impact parameter in B^{3+}/He collisions. The *solid curve* refers to the ^2P contribution, the *dotted curve* to the ^2S contribution
Fig. 51.12 Influence of rotational coupling on the ^2P electron capture cross section in B^{3+}/He collisions. The *solid curve* refers to the complete calculation, the *dotted curve* to the calculation with only radial coupling included

tional coupling mechanism, Figs. 51.11 and 51.12 show the ^2S and ^2P electron capture transition amplitudes as a function of angular momentum (impact parameter) for an energy of 6 keV, where rotational coupling is of major importance [51.14, 33]. The ^2P electron capture transition amplitude exhibits 2 maxima, one for an impact parameter of 1.6 a_0, the other for an impact parameter of 5.7 a_0, corresponding respectively to capture via $\Sigma_2-\Pi$ crossing around $R = 2\ a_0$ and the outer $\Sigma_2-\Sigma_3$ crossing around $R = 7.4\ a_0$. It is clear from Fig. 51.12 that at very short internuclear distances, rotational coupling is much more important than radial coupling. At the outer crossing (which is nearly diabatic), radial coupling is dominant. This result may be generalized. When the avoided crossing has a largely diabatic character, as for 3p capture in Si^{2+}/H [51.34] or 3d capture in C^{4+}/H [51.10], the inclusion of rotational coupling is fairly weak, affecting principally the population of the sub-m levels and less appreciably the total capture cross section into a given l state. In this case, translation effects are of more importance than rotational coupling.

In the case of O^{2+}/H (a particularly important system in astrophysical plasmas), the existence of several adiabatic states correlated to the entry channel leads to many interesting features, typical of open p shell ions. The favored reaction channel via the $^4\Sigma^-$ and $^4\Pi$ states involves simultaneous electron capture into a 2p orbital

and excitation of a 2s orbital. The avoided crossing is due to electron correlation. Rotational mixing of the $^4\Sigma^-$ and $^4\Pi$ states leads to a large enhancement of the cross section at energies exceeding a few tens of eV [51.16]. On the other hand, the avoided crossings involving the $^2\Sigma^+$ and $^2\Pi$ states around 8 a_0 are too diabatic to contribute to an electronic transition. As a consequence, the metastable ^{1}D ions can only react via a curve crossing at small distances (2.5 a_0). The cross section is much smaller than for ground ^{3}P state capture.

51.5 Landau–Zener Approximation

If a rapid estimation of the cross sections is all that is needed, the Landau–Zener method can be used with advantage, provided that the molecular structure parameters are known accurately. This method, based on an approximate solution of the dynamical equations in a semiclassical formalism (Chapt. 49), is satisfactory for the dominant channels. Aside from the transition being assumed to be localized at the crossing point, the method can easily take account of trajectory effects at low energies. On the other hand, it is unreliable for the weaker channels and it makes allowance neither for translation effects nor for rotational coupling.

The cross section for capture into a state n via a curve crossing located at R_X is given by

$$Q_n^{\mathrm{LZ}} = 2\pi \int\limits_0^{\rho_{\max}} 2p(1-p)\rho \, d\rho \, , \qquad (51.24)$$

where p, the probability for a single passage trajectory (impact parameter) through the crossing, is given by

$$p = \exp\left[-2\pi \left(\frac{\Delta E_{nl}}{2} \right)^2 \frac{1}{v\Delta F} \right] \, , \qquad (51.25)$$

ΔF being the difference in slope of the covalent and ionic diabatic curves at R_X, Δ_X the energy separation

of the diabatic curves at R_X and v the radial velocity at R_X. It should be recalled that there is no very rigorous definition of the diabatic curves (which are required to obtain DF). For long distance crossings, the simplest (and probably the most satisfactory) estimate is that based on the asymptotic forms of the diabatic states

$$\Delta F = \frac{\partial}{\partial R} \left[V_1(R) - \frac{q-1}{R} \right]_{R=R_X} \, ,$$
$$V_1(R) = -\frac{q^2\alpha_{\mathrm{d}}}{2R^4} \, , \qquad (51.26)$$

where α_{d} is the polarizability of the target. The radial velocity is given by

$$v = \left[\frac{2E}{\mu} \left(1 - \frac{\rho^2}{R_X^2} - \frac{V_1(R_X)}{E} \right) \right]^{1/2} \, . \qquad (51.27)$$

The inclusion of the attractive polarization potential V_1 considerably increases the cross section at low energies, since trajectories with impact parameters much greater than R_X contribute to the cross section. This effect can introduce a negative energy dependence of the cross section in the limit of low energies, of the same kind as the Langevin model for ion–molecule reactions.

51.6 Differential Cross Sections

Differential cross sections at large scattering angles (corresponding to small impact parameters) enable one to probe details of the collision dynamics not readily obtainable from total cross sections, which tend to be dominated by the contribution from small angle scattering (large impact parameters).

Their determination is staightforward once the S matrix elements have been extracted from the asymptotic solution of the coupled equations (51.21). The scattering

amplitude $f_{fi}(\vartheta)$ for scattering through the c.m. angle ϑ is given by

$$f_{fi}(\vartheta) = \frac{1}{2i(k_ik_f)^{1/2}} \sum_{l=0}^{\infty}(2l+1)\left[S_{fi}^l - \delta_{fi}\right]$$
$$\times P_l(\cos\vartheta) \exp[i\alpha_f(l)] \, , \qquad (51.28)$$

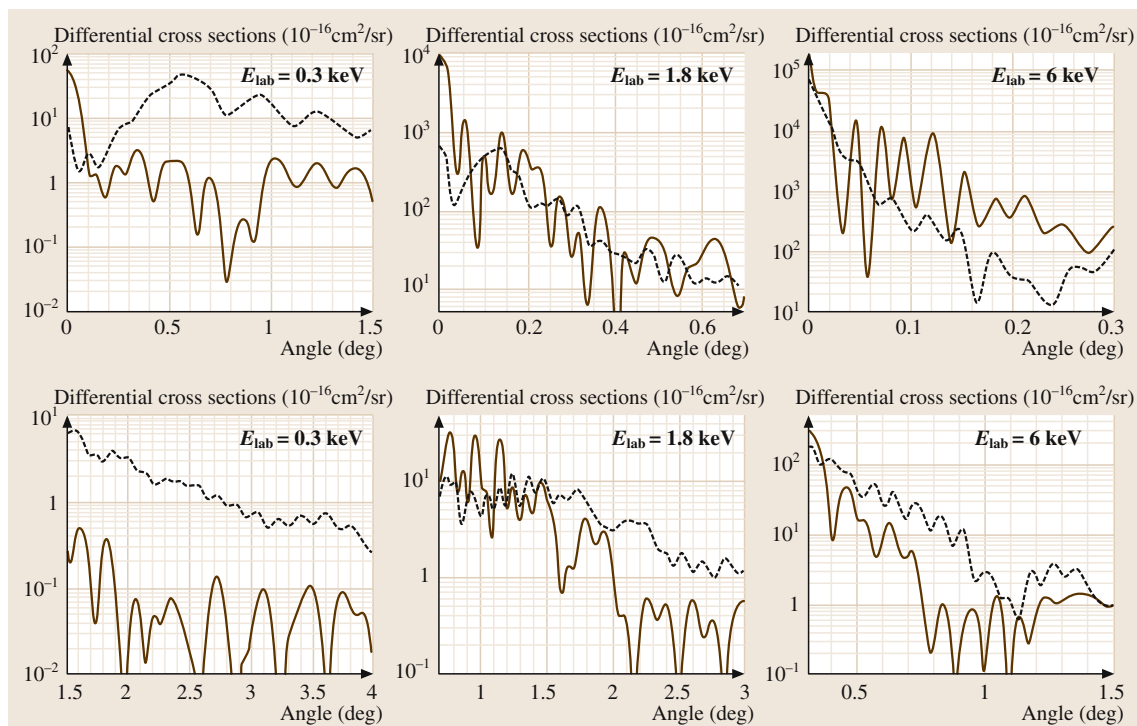
where k_i and k_f are the wave numbers of the initial and final channels, S_{fi}^l the S-matrix element for the i to


Fig. 51.13 Differential cross sections (10^{-16} cm^2/sr) for electron capture in B^{3+}/He collisions as a function of scattering angle for ion energies of 0.3, 1.8 and 6 keV. The *solid curves* refer to ^{2}S capture, the *dotted curves* to ^{2}P capture

f transition, and $\alpha_f(l)$ the partial wave Coulomb phase shift for the final channel:

$$\alpha_f(l) = \arg \Gamma(l+1+\mathrm{i}\gamma_f), \quad \gamma_f = \frac{\mu q_1 q_2}{k_f} .$$

$$(51.29)$$

The charges of the two collision partners in the final state are designated q_1 and q_2, and μ is the nuclear reduced mass. The differential cross section is evaluated as

$$\frac{\mathrm{d}\sigma_{fi}}{\mathrm{d}\Omega}(\vartheta) = \frac{k_f}{k_i} |f_{fi}(\vartheta)|^2 .$$

$$(51.30)$$

Figure 51.13 shows some typical differential cross sections for capture to the $(2\mathrm{s})^2$S and $(2\mathrm{p})^2$P states of B^{2+} in the B^{3+}/He system. The oscillations observed in the differential cross sections are of Stückelberg type. A knowledge of differential cross sections is essential for estimating acceptance angles in laboratory experiments.

51.7 Orientation Effects

Recent experiments on the B^{3+}/He system [51.35, 36] show that there is a strong tendency for electron capture to produce strongly oriented states at small scattering angles. This propensity for orientation is a direct measure of rotational coupling between the Σ and Π molecular states converging to the ^{2}P asymptotic state [51.37].

   The orientation and alignment parameters, which characterize the polarization of the emitted photons,

can be simply expressed in terms of the scattering amplitudes for electron capture to the magnetic sublevels. These scattering amplitudes can be directly obtained from the scattering matrix. However, care must be exercised in the definition of the scattering amplitudes. In most applications where an adiabatic representation of the collision dynamics is used, the quantization axis is taken to be in the direction of the internuclear axis. For most polarization measure-

ments, it is more convenient to define the quantization axis with respect to an axis perpendicular to the collision plane. But it is straightforward to express the orientation and alignment parameters in terms of the scattering amplitudes obtained with respect to the molecular frame.

In accordance with customary conventions, in Fig. 51.14, the scattering plane contains the X and Z axes. The Y axis, perpendicular to the scattering plane, is taken to be the quantization axis. Let XYZ be the laboratory frame and xyz the body-fixed frame defined as above. The scattering amplitudes calculated in Sect. 51.3 are expressed with respect to the body-fixed frame xyz. The scattering amplitudes $f_{M_Y = \pm 1}$ in the laboratory frame are related to the amplitudes f_{Σ_Z}, $f_{\Pi_Z^+}$ in the body-fixed frame by

$$f_{M_Y = \pm 1} = \frac{1}{\sqrt{2}} \left(f_{\Sigma_Z} \mp f_{\Pi_Z^+} \right) . \tag{51.31}$$

The right-hand and left-hand circular polarizations (RHC and LHC respectively) are then defined as

$$\text{RHC} = |f_{M_Y = -1}|^2$$
$$= \frac{1}{2} \left(|f_{\Sigma_Z}|^2 + |f_{\Pi_Z^+}|^2 \right) + \text{Im} \left(f_{\Sigma_Z} f_{\Pi_Z^+}^* \right) , \tag{51.32}$$

$$\text{LHC} = |f_{M_Y = +1}|^2$$
$$= \frac{1}{2} \left(|f_{\Sigma_Z}|^2 + |f_{\Pi_Z^+}|^2 \right) - \text{Im} \left(f_{\Sigma_Z} f_{\Pi_Z^+}^* \right) , \tag{51.33}$$

and the circular polarization as

$$\text{L} = \frac{\text{RHC} - \text{LHC}}{\text{RHC} + \text{LHC}} = \frac{2 \, \text{Im} \left(f_{\Sigma_Z} f_{\Pi_Z^+}^* \right)}{|f_{\Sigma_Z}|^2 + |f_{\Pi_Z^+}|^2} . \tag{51.34}$$

Figures 51.15 and 51.16 show the RHC, LHC and L quantities for an incident ion energy of 1.5 keV, where comparison with experiments [51.35, 36] can

be made. The strong propensity for orientation of the ^{2}P state is clearly exhibited for small scattering angle ($\vartheta < 0.2°$). At larger angles (smaller impact parameters), the propensity decreases and even reverses ($\vartheta > 0.4°$). We have also plotted on Fig. 51.16 the experimental data of *Roncin* et al. [51.35]. The agreement with experiment is very satisfactory.

51.8 New Developments

During the last eight years there have been some interesting new developments [51.38–40] using hyperspherical coordinates to describe the dynamics of ion–atom collisions. Of particular interest for this chapter are the calculations of *Le* et al. [51.40] for charge transfer in the $Si^{4+}/H(D)$ and Be^{4+}/H systems. Their calculated cross sections are almost identical to those obtained by *Pieksma* et al. [51.41] using the Thorson–Delos-type [51.8] approximate Jacobi coordinates introduced in Sect. 49.3. This confirms the close connection between the hyerspherical and the Thorson–Delos-type coordinates which had already been observed by *Gargaud* et al. [51.10] for two-state systems.

Another aspect of the theoretical formulation which has been clarified recently concerns the adiabatic–diabatic transformation (51.20). The radial differential

equations (51.21) only take this simple form if it can be assumed that

$$B = \frac{d}{d\xi} A - A^2 \ . \tag{51.35}$$

However, (51.35) is only strictly satisfied if the basis set is complete. And indeed, it has been found [51.10] from direct calculations of the matrix elements B_{mn} that it is not well satisfied for any choice of Jacobi coordinates. On the other hand, the calculations show that (51.35) is well satisfied for a minimal basis set using the Thorson–Delos reaction coordinates. This result confirms that convergence of an adiabatic basis set can indeed be achieved using appropriate reaction coordinates and also explains why the calculations of *Le* et al. [51.40] and *Pieksma* et al. [51.41, 42] agree so well.

52. Continuum Distorted Wave and Wannier Methods

The continuum distorted wave model has been extensively applied to charge transfer and ionization processes. We present both the perturbative and variational capture theories as well as highlighting the suitability of this model in describing the continuum final states in both heavy and light particle ionization. We then develop the Wannier theory for threshold ionization, and further theoretical work which led to the modern quantal semiclassical approximation. This very successful theory has provided the first absolute cross sections which are in good agreement with experiment.

Part D | 52

The most recent developments include third-order continuum distorted wave double-scattering 1s–1s transitions (Sect. 52.1.1), relativistic continuum distorted waves (Sect. 52.1.2), and new theory on magnetically quantized continuum distorted waves [52.1, 2] (Sect. 52.1.4). A novel ionization theory for low energies (below 80 keV) is also reported in which the target is considered as a one electron atom and the interactions between this active electron and the remaining target electrons are treated by a model potential including both short and long range effects. In the final channel the usual product of two continuum distorted wave functions, each associated with a distinct electron–nucleus interaction, is used [52.3].

In addition, Sect. 52.2 on the Wannier Method reports the major progress made over the last eight years. These major advances include (a) the development of below-threshold semiclassical theory for the study of doubly excited states [52.4–7] (b) a more accurate variant of the semi-classical quantum-mechanical treatment of *Crothers* [52.8].

52.1 Continuum Distorted Wave Method

52.1.1 Perturbation Theory

Continuum distorted wave theory (CDW) is one of the most advanced and complete perturbative theories of heavy particle collisions which has been formulated to date. It was originally introduced by *Cheshire* [52.9] to model the process of charge transfer during the collision of an atom/ion with an ion (specifically the resonant process of $p + H(1s) \rightarrow H(1s) + p$). These types of three-body collisions are made amenable to the perturbative approach when the ratio of the projectile impact velocity v to the electron initial bound state mean velocity v_b

satisfies

$$\frac{v}{v_b} \gtrsim 3 \ . \tag{52.1}$$

The criterion for nonrelativistic collisions, in which electron capture is a dominant process, is that both v and v_b are small compared with the speed of light. The theoretical description of collisions which involve the disturbance of a bound electron of mass m_e by the field of a fast moving heavy particle of mass M can be greatly simplified by exploiting the fact that since the ratio m_e/M is so small, the heavy particle follows a straight-line trajectory throughout the collision.

This allows the parametrization of the internuclear vector $\boldsymbol{R}$ in terms of an impact parameter $\boldsymbol{b}$, such that

$$\boldsymbol{R} = \boldsymbol{b} + \boldsymbol{v}t . \tag{52.2}$$

This impact parameter picture (IPP) of the collision is equivalent to the full quantal or wave treatment when the eikonal criterion for small angle scattering is satisfied [52.10].

It has become standard to work in a generalized nonorthogonal coordinate system in which the vectors $\boldsymbol{r}_T$ ($\boldsymbol{r}_P$) from the target (projectile) to the electron are treated, along with $\boldsymbol{R}$, as independent variables [52.11]. Working in the frame centered on the target nucleus and using atomic units, the Lagrangian is given by

$$H - i\frac{d}{dt}_{\boldsymbol{r}_T} = -\frac{1}{2}\nabla_{\boldsymbol{r}_T}^2 + V_T(\boldsymbol{r}_T) - i\frac{\partial}{\partial t} - \frac{1}{2}\nabla_{\boldsymbol{r}_P}^2$$
$$+ V_P(\boldsymbol{r}_P) + i\boldsymbol{v}\cdot\boldsymbol{\nabla}_{\boldsymbol{r}_P}$$
$$+ V_{TP}(\boldsymbol{R}) - \boldsymbol{\nabla}_{\boldsymbol{r}_P}\cdot\boldsymbol{\nabla}_{\boldsymbol{r}_T} , \tag{52.3}$$

where $d/dt_{\boldsymbol{r}_T}$ refers to differentiation with respect to t, keeping $\boldsymbol{r}_T$ fixed, and where

$$V_T = \frac{-Z_T}{r_T}, \quad V_P = \frac{-Z_P}{r_P}, \quad V_{TP} = \frac{Z_T Z_P}{R} . \tag{52.4}$$

Since these potentials are pure Coulomb potentials, they continue to affect the relevant wave functions even at infinity. These long range Coulomb boundary conditions are defined in (52.10) and (52.11). The $+i\boldsymbol{v}\cdot\boldsymbol{\nabla}_{\boldsymbol{r}_P}$ term gives rise to the Bates–McCarroll electron translation factors which are required to satisfy Galilean invariance.

The Lagrangian above has been written in such a way as to highlight the three two-body decompositions exploited in CDW, with the $-\boldsymbol{\nabla}_{\boldsymbol{r}_P}\cdot\boldsymbol{\nabla}_{\boldsymbol{r}_T}$ term, the so-called nonorthogonal kinetic energy, coupling the systems. The essence of CDW is to treat the bound electron as simultaneously being in the continuum of the other heavy particle.

The initial wave function can be written as

$$\xi_i^\pm = D_{-\boldsymbol{v}}^\pm(\boldsymbol{r}_P)\Phi_i(\boldsymbol{r}_T, t)C(\boldsymbol{R}, t) , \tag{52.5}$$

where $D_{-\boldsymbol{v}}^\pm$ is the distortion from the projectile, and C is due to the internuclear potential, V_{TP}. The bound state $\Phi_i = \phi_i(\boldsymbol{r}_T)\exp(-i\epsilon_i t)$, where $\phi_i(\boldsymbol{r}_T)$ is the initial eigenstate, and ϵ_i is the initial eigenenergy.

In this form, the action of the Lagrangian can be split into three separate differential equations plus a residual interaction. This gives the following solutions: for the distortion D,

$$D_{-\boldsymbol{v}}^+ = N(\zeta_P){}_1F_1(i\zeta_P; 1; i\boldsymbol{v}\cdot\boldsymbol{r}_P + i v r_P) ,$$
$$D_{\boldsymbol{v}}^- = \left(D_{-\boldsymbol{v}}^+\right)^* , \tag{52.6}$$

with

$$N(\zeta) = \exp(\pi\zeta/2)\Gamma(1 - i\zeta) , \quad \zeta_{T,P} = Z_{T,P}/v ; \tag{52.7}$$

and for the internuclear function C,

$$C(\boldsymbol{R}, t) = \exp\left[i\frac{Z_P Z_T}{v}\ln(vR - v^2 t)\right] . \tag{52.8}$$

Similarly it can be shown that

$$\xi_f^\pm = D_{\boldsymbol{v}}^\pm(\boldsymbol{r}_T)\Phi_f(\boldsymbol{r}_P, t)C^*(\boldsymbol{R}, -t)$$
$$\times \exp\left(i\boldsymbol{v}\cdot\boldsymbol{r}_T - i\frac{v^2}{2}t\right) , \tag{52.9}$$

where $i\boldsymbol{v}\cdot\boldsymbol{r}_T - i\frac{v^2}{2}t$ results from the Galilean transformation to the target frame. The superscripts plus and minus refer to outgoing and incoming Coulomb boundary conditions respectively. These are determined by the asymptotic form of the wave functions

$$\lim_{t\to-\infty} \xi_i^+ \sim \Phi_i(\boldsymbol{r}_T, t)$$
$$\times \exp\left[i\frac{Z_P(Z_T - 1)}{v}\ln(vR - v^2 t)\right] , \tag{52.10}$$

and

$$\lim_{t\to+\infty} \xi_f^- \sim \Phi_f(\boldsymbol{r}_P, t)\exp\left(i\boldsymbol{v}\cdot\boldsymbol{r}_T - i\frac{v^2}{2}t\right)$$
$$\times \exp\left[-i\frac{Z_T(Z_P - 1)}{v}\ln(vR + v^2 t)\right] . \tag{52.11}$$

Of course, ξ_i^+ and ξ_f^- are not exact solutions of the three-body Schrödinger equation; in fact,

$$\left(H - i\frac{d}{dt_{\boldsymbol{r}_T}}\right)\xi_i^+ = W_i\xi_i^+ = -\boldsymbol{\nabla}_{\boldsymbol{r}_P}D_{-\boldsymbol{v}}^+\cdot\boldsymbol{\nabla}_{\boldsymbol{r}_T}\Phi_i , \tag{52.12}$$

and

$$\left(H - i\frac{d}{dt_{\boldsymbol{r}_T}}\right)\xi_f^- = W_f\xi_f^-$$
$$= -e^{i\boldsymbol{v}\cdot\boldsymbol{r}_T - i\frac{v^2}{2}t}\nabla_{\boldsymbol{r}_T}D_{\boldsymbol{v}}^-\cdot\nabla_{\boldsymbol{r}_P}\phi_f . \tag{52.13}$$

The CDW transition amplitude is written as

$$A_{if} = -i\int_{-\infty}^{+\infty} dt\left\langle\xi_f^-\left|T_{CDW}\right|\xi_i^+\right\rangle . \tag{52.14}$$

A perturbative expansion via the distorted wave Lippmann–Schwinger equation can be made for T_{CDW}, either in the post form

$$T_{\mathrm{CDW}}^+ = W_f^\dagger (1 + G_V W_i) + T_{\mathrm{CDW}}^+ G_i V G_V W_i \,, \tag{52.15}$$

or in the prior form

$$T_{\mathrm{CDW}}^- = \left(1 + W_f^\dagger G_V\right) W_i + W_f^\dagger G_V V G_f T_{\mathrm{CDW}}^- \,, \tag{52.16}$$

where the Green functions are given by

$$G_{i,f} = \left(\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t_{\boldsymbol{r}_\mathrm{T}}} - H + W_{i,f} + \mathrm{i}\epsilon\right)^{-1} \,, \tag{52.17}$$

$$G_V = \left(\mathrm{i}\frac{\mathrm{d}}{\mathrm{d}t_{\boldsymbol{r}_\mathrm{T}}} - H + V + \mathrm{i}\epsilon\right)^{-1} \,, \tag{52.18}$$

and V is any potential which ensures that the kernels of the integral equations for T_{CDW} are continuous [52.13].

By taking the first term in the expansions (52.15) and (52.16), we get the post and prior forms of the CDW1 amplitude as used by Cheshire. When calculating these amplitudes, the separable nature of the CDW wave function is best exploited by using Fourier transforms to move to the time-independent wave picture. A similar transformation is not suitable in the coupled channel approach discussed in Sect. 52.1.3.

Crothers [52.13], working in the wave treatment, has calculated the second order CDW2 amplitude using various approximations for the Green functions, and has shown that the CDW perturbation series has converged very well to first-order in most parts of the differential cross section. This is in contrast to the standard Born or Brinkman–Kramers approximations which do not start to converge until expanded to second-order. CDW1 is the only first-order perturbation theory, apart from asymmetric hybrid models derived from it, which produces a Thomas peak. Unfortunately, due to the accidental cancellation of the leading order terms, CDW1 has an extreme dip at the Thomas angle, a defect removed in CDW2 [52.14]. This is illustrated in Fig. 52.1 which also includes both folded and unfolded versions of the asymmetric target CDW (TCDW) theory discussed below, as well as experimental data [52.12].

Further work in this area has included the development of the Thomas double-scattering electron capture at asymptotically high velocity within the third-order continuum distorted-wave perturbation theory for 1s–1s transitions in proton hydrogen collisions. It has been shown [52.15] that at the critical proton scattering angles, namely the forward peak, Thomas double

encounter peak, small angles, and the interference minimum, the CDW series has converged at second order. Moreover, it is proven that the third-order correction makes no contribution to the velocity dependent v^{-11} and v^{-12} behavior of the Thomas double-scattering total cross section at the leading angles. In contrast, it may be seen in [52.15] that the Oppenheimer–Brinkman–Kramers (OBK) travelling atomic orbital theory (which in general suffers from a common phase factor which embraces intermediate elastic divergences [52.16] in the first and higher-order terms) has not converged at second order. It remains an open question as to whether fourth-order terms or higher in the OBK approximation contribute to various differential cross-sections. It is concluded that the CDW model gives a superior description of the Thomas double-scattering mechanism when compared with the OBK model.

Anomalously large cross sections are obtained at low energies if the CDW wave function is not normalized at all times throughout the collision [52.11]. This is best demonstrated by the presence of the $N(\zeta)$ terms in

$$\lim_{t\to+\infty} \xi_i^+ = N(\zeta_\mathrm{P}) \Phi_i(\boldsymbol{r}_\mathrm{T}, t)$$
$$\times \exp\left[\mathrm{i}\frac{Z_\mathrm{P} Z_\mathrm{T}}{v} \ln(vR - v^2 t)\right] \tag{52.19}$$
Fig. 52.1 Differential cross sections for electron capture in the collision $\mathrm{H}^+ + \mathrm{H}(1s) \to \mathrm{H}(1s) + \mathrm{H}^+$ as a function of laboratory scattering angle (θ_{lab}) for impact energy of 5 MeV: *solid line* TCDW, folded over the experimental resolution of *Vogt* et al. [52.12]. Unfolded theoretical results: *dashed line* TCDW; *dotted line* CDW1. Experimental data; *circles*, *Vogt* et al. [52.12]

and

$$\lim_{t \to -\infty} \xi_f^- = N^*(\zeta_T) \Phi_f(\boldsymbol{r}_P, t) \exp\left(i\boldsymbol{v} \cdot \boldsymbol{r}_T - i\frac{v^2 t}{2} \right)$$
$$\times \exp\left[-i\frac{Z_T Z_P}{v} \ln(vR + v^2 t) \right] .$$
(52.20)

Using

$$\lim_{v \to 0} | N(Z/v)|^2 \sim \frac{2\pi Z}{v}$$
(52.21)

it is clear that the problem gets worse as v decreases. It can be corrected by defining

$$\hat{\xi}_{i,f}^\pm = \xi_{i,f}^\pm \left\langle \xi_{i,f}^\pm \middle| \xi_{i,f}^\pm \right\rangle^{-1/2} .$$
(52.22)

Simpler distorted wave models can be generated through further approximations. Two of the most popular are Target CDW [$D_{-\boldsymbol{v}}(\boldsymbol{r}_P) \to 1$] and Projectile CDW [$D_{\boldsymbol{v}}(\boldsymbol{r}_T) \to 1$]. These approximations are justified when $Z_T > Z_P$ and $Z_P > Z_T$, respectively, and are particularly simple to calculate when the simple Born-like residual interaction is used rather than the full CDW form.

The asymptotic forms of the CDW wave functions can be used throughout the collision, ensuring normalization, and this leads to the eikonal or symmetric eikonal models.

52.1.2 Relativistic Continuum–Distorted Waves

The CDW model can be naturally extended to the two-center time-dependent Dirac equation, so that a Lorentz invariant theory is obtained. When the electron orbital velocity $\alpha Z c$, or the collision velocity v, approaches the speed of light c, the kinematics are modified by time dilation. In addition, the particle interactions change because of retardation and the fact that spin-orbit effects are now important. Moreover, vacuum interactions such as radiative emissions and electron–positron pair production begin to play a role. A comprehensive account of atomic processes in relativistic heavy-particle collisions can be found in two recent books [52.17, 18]. At high collision energies, $\gamma \equiv \left(1 - v^2/c^2\right)^{-1/2} \gg 1$, and high-charge states of the ions, the Dirac sea of negative energy states becomes energetically accessible and strongly coupled. The process of electron capture, for example, may be mediated by spin-flip transitions [52.19], or spontaneous X-ray emission (radiative electron capture) [52.20] and even electron capture via pair production [52.21, 22]. Although the importance of vacuum processes diminishes with energy, these mechanisms

dominate in the extreme relativistic regime. Indeed the last of these processes was used to produce antihydrogen in the laboratory [52.23] at GeV u^{-1} energies.

At relativistic energies, the principal inelastic process is collisional ionization [52.17, 18]. The extensions of the distorted-wave theory to accommodate Lorentz invariance has been developed by *Rivarola* and *Deco* [52.24, 25] and *Crothers* and coworkers [52.19] following work on the Born series [52.26] and impulse approximation [52.27]. In practical applications to electron capture cross sections, the symmetric semi-relativistic CDW theory of *Glass* et al. [52.19] was found to be in very good agreement with experiments in the GeV u^{-1} energy range with charges $Z_{P,T} \sim 6$–80. For non-radiative electron capture, it was found that second-order retardation dominates at extreme relativistic velocities so that $\sigma \sim \gamma^{-1}(\ln\gamma)^2$ [52.28]. However, the momentum transfer kinematics for this process are unfavorable, and a more efficient mechanism based on electron–positron pair production with capture of the created electron is more strongly coupled. Theoretical estimates of this process using relativistic CDW [52.29] compared with experiments [52.30] are in very good agreement.

The same model has been applied to estimate yields of antihydrogen following antiproton impact with neutral high-Z atoms [52.23] following experiments at CERN and Fermilab. The virtual photon model of *Baur* [52.30] gives cross sections that agree well with the limited data [52.23]. However, these estimates are roughly ten times larger than the relativistic CDW results [52.17] and one hundred times the first-Born estimate [52.31]. It appears that additional studies, both experimental and theoretical, would be worthwhile in order to understand this process more fully.

52.1.3 Variational CDW

As the ratio of v/v_b decreases, perturbation theory starts to fail. This is due to the effective interaction time between the projectile and target atoms being long enough for strong three-body coupling. In this environment variational methods have proved successful. This procedure ensures both gauge invariance and unitarity – two fundamental attributes perturbation theory usually cannot guarantee. Continuing in the IPP, we use the Sil variational principle, which gives

$$\delta \int_{-\infty}^{+\infty} dt \langle \Psi | H - i\frac{d}{dt_{\boldsymbol{r}_T}} |\Psi\rangle = 0 .$$
(52.23)

In the two-state CDW approximation we may assume

$$\Psi_{\text{CDW}} = c_0(t)\xi_i^+ + c_1(t)\xi_f^- \tag{52.24}$$

subject to the boundary conditions $c_0(-\infty) = 1$ and $c_1(-\infty) = 0$. Variation of c_0^* and c_1^* gives the standard coupled equations

$$\text{i}N_{00}\dot{c}_0 + \text{i}N_{01}\dot{c}_1 = H_{00}c_0 + H_{01}c_1 , \tag{52.25}$$

$$\text{i}N_{10}\dot{c}_0 + \text{i}N_{11}\dot{c}_1 = H_{10}c_0 + H_{11}c_1 , \tag{52.26}$$

where

$$N_{00} = \left\langle \xi_i^+ \middle| \xi_i^+ \right\rangle ,$$

$$N_{11} = \left\langle \xi_f^- \middle| \xi_f^- \right\rangle ,$$

$$N_{01} = \left\langle \xi_i^+ \middle| \xi_f^- \right\rangle = N_{10}^* ,$$

and

$$H_{00} = \left\langle \xi_i^+ \middle| H - \text{i}\frac{\text{d}}{\text{d}t_{\boldsymbol{r}_\text{T}}} \middle| \xi_i^+ \right\rangle ,$$

$$H_{01} = \left\langle \xi_i^+ \middle| H - \text{i}\frac{\text{d}}{\text{d}t_{\boldsymbol{r}_\text{T}}} \middle| \xi_f^- \right\rangle ,$$

$$H_{10} = \left\langle \xi_f^- \middle| H - \text{i}\frac{\text{d}}{\text{d}t_{\boldsymbol{r}_\text{T}}} \middle| \xi_i^+ \right\rangle ,$$

$$H_{11} = \left\langle \xi_f^- \middle| H - \text{i}\frac{\text{d}}{\text{d}t_{\boldsymbol{r}_\text{T}}} \middle| \xi_f^- \right\rangle .$$

Equations (52.25) and (52.26) can clearly be written as a matrix equation,

$$\text{i}\boldsymbol{N}\dot{\boldsymbol{c}} = \boldsymbol{H}\boldsymbol{c} , \tag{52.27}$$

which is then easily generalized for larger expansions of Ψ. By using an orthogonalized basis set of normalized functions in the manner of *Löwdin* [52.32,33], the $\boldsymbol{N}$ matrix reduces to the unit matrix. This will be understood when considering expansions for Ψ from now on.

Another interesting, but potentially ruinous, result of the asymptotic forms (52.19) and (52.20) is their failure to obey the correct long-range Coulomb boundary conditions; compare this with their expressions at the opposite time extreme in (52.10) and (52.11). This has no consequence until second-order VCDW is calculated in which divergent integrals arise as a direct result of this feature of the wave functions. These terms are analogous to the well-known intermediate elastic divergences which occur in Born-type expansions which do not have the correct Coulomb phases.

A novel way to avoid this problem [52.34, 35] is to split the time plane into two parts, allowing the well-behaved set $\{\xi^+\}$ to be used exclusively for $t \le 0$, while the set $\{\xi^-\}$ forms the basis for $t \ge 0$. This phase integral halfway house VCDW is based on the factorization of the scattering matrix $\boldsymbol{S}$ into a product of two Møller matrices,

$$\boldsymbol{S} = \boldsymbol{\Omega}_-^\dagger \boldsymbol{\Omega}_+ , \tag{52.28}$$

where $\boldsymbol{\Omega}_-^\dagger$ represents the propagation of the initial state from $t = -\infty$ to $t = 0_-$, while $\boldsymbol{\Omega}_+$ represents the propagation of the final state from $t = +\infty$ to $t = 0_+$.

The total wave function is similarly split into two expansions over an orthogonal basis ψ, with

$$\boldsymbol{\Psi}^- = \boldsymbol{c}^- \psi^+ , \quad t < 0 , \tag{52.29}$$

$$\boldsymbol{\Psi}^+ = \boldsymbol{c}^+ \psi^- , \quad t > 0 , \tag{52.30}$$

where the superscripts on the $\boldsymbol{\Psi}$ correspond to the respective heavy-particle motion. This in turn divides the coupled equations into two sets

$$\text{i}\dot{\boldsymbol{c}}^- = \boldsymbol{H}^{++}\boldsymbol{c}^- , \quad t < 0 , \tag{52.31}$$

$$\text{i}\dot{\boldsymbol{c}}^+ = \boldsymbol{H}^{--}\boldsymbol{c}^+ , \quad t > 0 , \tag{52.32}$$

where

$$\boldsymbol{H}^{\pm\pm} = \langle \boldsymbol{\Psi}^\pm | H - \text{i}\frac{\text{d}}{\text{d}t_{\boldsymbol{r}_\text{T}}} | \boldsymbol{\Psi}^\pm \rangle . \tag{52.33}$$

The coefficients $c^\pm$ then have to be matched over a local discontinuity in the total wave function at $t = 0$, such that $\boldsymbol{c}^+(0) = \boldsymbol{c}^-(0)$. Halfway house VCDW has all the appealing attributes of a variational theory but, by explicitly satisfying the long-range Coulomb boundary conditions, it is divergence free.

52.1.4 Ionization

CDW, by treating the Coulomb interactions to such a high degree, has obvious attractions for modelling the ionization process. Single ionization of an electron from an atom by a high-energy projectile is a perturbative process and the Born approximation will match experimental total cross sections rather well. However CDW-like representations of the initial and final states generate better results at lower energies, as well as producing features in the differential cross sections which are beyond the reach of the first Born approximation.

In full CDW ionization theory, the initial state is given by the usual charge transfer wave function ξ_i

(52.5), while the final state takes the form

$$
\xi_f^- = (2\pi)^{-2/3} \exp\left(\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_\mathrm{T} - \mathrm{i}\frac{k^2}{2}t\right)
$$
$$
\times \exp\left[-\mathrm{i}\frac{Z_\mathrm{T}Z_\mathrm{P}}{v}\ln(vR + \boldsymbol{v}\cdot\boldsymbol{R})\right]
$$
$$
\times N^*(Z_\mathrm{T}/k)_1F_1
$$
$$
\times (-\mathrm{i}Z_\mathrm{T}/k;\ 1;\ -\mathrm{i}\boldsymbol{k}\cdot\boldsymbol{r}_\mathrm{T} - \mathrm{i}kr_\mathrm{T})
$$
$$
\times N^*(Z_\mathrm{P}/p)_1F_1
$$
$$
\times (-\mathrm{i}Z_\mathrm{P}/p;\ 1;\ -\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{r}_\mathrm{P} - \mathrm{i}pr_\mathrm{P}),\qquad (52.34)
$$

where $\boldsymbol{k}$ ($\boldsymbol{p} = \boldsymbol{k} - \boldsymbol{v}$) is the momentum of the electron relative to the target (projectile) nucleus.

CDW ionization theories presented prior to 1982 produced spuriously large results due to the unnormalized initial state. Since the matrix element $\langle \xi_i^+ \mid \xi_i^+ \rangle$ is computationally expensive to calculate as a function of $\boldsymbol{b}$ and t, a very successful alternative is to take the initial state as an eikonal distorted state [52.36], thus ensuring normalization. The initial state in this CDW-EIS theory is taken to be

$$
\xi_i^{\mathrm{EIS}} = \hat{D}_{-\boldsymbol{v}}^+(\boldsymbol{r}_\mathrm{P})\Phi_i(\boldsymbol{r}_\mathrm{T}, t)C(\boldsymbol{R}, t),\qquad (52.35)
$$

where now

$$
\hat{D}_{-\boldsymbol{v}}^+(\boldsymbol{r}_\mathrm{P}) = \exp\left[-\mathrm{i}\frac{Z_\mathrm{P}}{v}\ln(vr_\mathrm{P} + \boldsymbol{v}\cdot\boldsymbol{r}_\mathrm{P})\right].\qquad (52.36)
$$

The final state remains as in (52.34).

The CDW final state is most effective when differential cross sections are studied. The most interesting features are in the forward $\theta = 0$ ejection angle; i. e., the soft collision peak ($k \simeq 0$), the electron capture to the continuum peak ECC ($k \simeq v$) and the binary encounter peak ($k \simeq 2v$). CDW theories are especially suited to the description of the ECC peak which results theoretically from the presence of the $N(Z_\mathrm{P}/p)$ factor in the wave function. This peak can be analyzed in detail via a multipole expansion and much theoretical work has centered on the dipole parameter β. A negative β is strongly suggested by both experiment and physical intuition. CDW, CDW-EIS and halfway house VCDW all predict different values for β with the last theory being the only one which gives a high energy limit which remains negative [52.37].

Magnetically quantized continuum distorted wave theory also has been considered [52.1] in the description of ionization in ion–atom collisions. This generalizes the CDW-EIS theory of *Crothers* and *McCann* [52.2] to incorporate the azimuthal angle dependence of each CDW in the final state wave function. This is accomplished by the analytic continuation of hydrogenic-like wave functions from below to above threshold, using parabolic coordinates and quantum numbers, including magnetic quantum numbers, thus providing a more complete set of states. The continuation applies to excitation, charge transfer, ionization, and double and hybrid events for both light- and heavy-particle collisions. It has successfully been applied to the calculation of double differential cross sections for the single ionization of the hydrogen atom and for a hydrogen molecule by a proton for electrons ejected in the forward direction at a collision energy of 50 keV and 100 keV, respectively.

It is well known that the CDW-EIS models are the best suited to the intermediate and high energy regions. Recent results for proton-argon total ionization cross sections [52.38] highlight large discrepancies between CDW-EIS theory and experiment for energies below 80 keV. This problem has recently been addressed [52.3]. Here, following the theory of [52.39] the authors in [52.3] use a Born initial state wave function. In the final channel, the usual product of two continuum distorted wave functions each associated with a distinct electron–nucleus interaction is used. In their treatment the target is considered as a one-electron atom and the interactions between this active electron and remaining target electrons are treated by a model potential including both short- and long-range effects. The success of this new theory for low energies is shown in Fig. 52.2. Here it is clear that the calculation in [52.3] gives good agreement for the total cross sections in the energy range 10–300 keV with the measurements of *Rudd* et al. [52.40].

Double ionization in general remains an extremely difficult area for theoretical models based on perturbative expansions – even those with explicit distortions built in. In this process, the explicit correlation between the electrons in the target atom is vitally important. However, one example where CDW theory can overcome these problems is in the bound state wave function of *Pluvinage* [52.41]. This very successful treatment, which also includes a variationally determined parameter, is just the CDW analogy in bound state theory, although this appeared well before Cheshire's paper on scattering. The Pluvinage wave function for the ground state of a two-electron atom is given by

$$
\phi = c(\kappa)\left(\frac{Z_\mathrm{T}^3}{\pi}\right)\exp\left[-Z_\mathrm{T}(r_1 + r_2) + \mathrm{i}\kappa r_{12}\right]
$$
$$
\times {}_1F_1\left(1 + \frac{1}{2\mathrm{i}\kappa};\ 2;\ 2\mathrm{i}\kappa r_{12}\right),\qquad (52.37)
$$
Fig. 52.2 Total ionization cross section for the proton-impact single ionization of Ar: *solid line* theoretical results of [52.3], *dashed line* theoretical results of OPM [52.38] and *dotted line* HFS [52.38]. Experimental data; *circles*, *Rudd* et al. [52.40]

The constant κ is variationally determined to be 0.41, giving the normalization constant $c = (0.364\,05)^{1/2}$.

An analogous wave function for two electrons in the target continuum was derived [52.11] and implemented later in a successful CDW treatment of ionization by electrons and positrons [52.42]. This BBK theory, so named in deference to the authors, demonstrates the high resolution CDW final states obtained, right down to triply differential cross sections. However, this model suffers from the low-energy normalization problems associated with CDW, and is also unable to describe the threshold effects which are in the domain of Wannier theory.

where $r_{1,2}$ are the distances of the two electrons from the target nucleus, and r_{12} is the inter-electron separation.

52.2 Wannier Method

52.2.1 The Wannier Threshold Law

In 1953, *Wannier* [52.43] deduced the relationship between the cross section at the threshold of a reaction, and the excess-of-threshold energy of the incident particle for a three-body ionization problem, where the final state consists of a residual unit positive charge and two electrons, with each body moving in the continuum of the other two. This extended to three bodies the earlier two-body threshold law derived by *Wigner* [52.44] (see Sect. 60.2.1).

For final states with $L = 0$, Wannier employed hyperspherical coordinates $(\rho, \alpha, \theta_{12})$, where

$$\rho^2 = r_1^2 + r_2^2 , \quad \alpha = \tan^{-1}\left(\frac{r_2}{r_1}\right) ,$$
$$\theta_{12} = \cos^{-1}(\hat{\boldsymbol{r}}_1 \cdot \hat{\boldsymbol{r}}_2) . \tag{52.38}$$

Here we assume that the residual ion is infinitely massive and at rest with respect to the two electrons. By converting the two-electron problem to the case of motion of a single point in six-dimensional space, we can take the hyperradius ρ as the 'size' of the hypersphere, α as the radial correlation of the electrons and θ_{12} as their angular correlation. This allows the Schrödinger equation for the final state to be written

(in a.u.) as

$$\left(h_0 - \frac{l^2(\hat{\boldsymbol{r}}_1)}{\rho^2 \cos^2 \alpha} - \frac{l^2(\hat{\boldsymbol{r}}_2)}{\rho^2 \sin^2 \alpha} + 2E \right.$$
$$\left. + \frac{2Z(\alpha, \theta_{12})}{\rho}\right)\Psi(\boldsymbol{r}_1, \boldsymbol{r}_2) = 0 , \tag{52.39}$$

where

$$h_0 = \frac{1}{\rho^5}\frac{\partial}{\partial \rho}\left(\rho^5 \frac{\partial}{\partial \rho}\right) + \frac{1}{\rho^2 \sin^2 \alpha \cos^2 \alpha}\frac{\partial}{\partial \alpha}$$
$$\times \left(\sin^2 \alpha \cos^2 \alpha \frac{\partial}{\partial \alpha}\right) \tag{52.40}$$

and

$$Z(\alpha, \theta_{12}) = \frac{1}{\cos \alpha} + \frac{1}{\sin \alpha} - \frac{1}{(1 - \cos \theta_{12} \sin 2\alpha)^{\frac{1}{2}}} \tag{52.41}$$

is the potential surface on which the particle is moving [52.45].

The most likely configuration of the electrons leading to double escape at threshold corresponds to the region $\boldsymbol{r}_1 = -\boldsymbol{r}_2$, i.e., the two electrons escape in opposite directions from the reaction zone, corresponding to the saddle point of the potential surface $Z(\alpha, \theta_{12})$, and defined as the Wannier ridge. Also, dynamic screening

between the two electrons means there would be equal partitioning of the available energy for the two particles, and so they would have equal but opposite velocities on escape. In hyperspherical coordinates, the most important region for double escape is, therefore, $\alpha = \pi/4$, and $\theta_{12} = \pi$.

The main conclusion of Wannier's theory is that the total cross section for electron impact single ionization scales as

$$\sigma = kE^{m_{12}} , \tag{52.42}$$

where E is the excess-of-threshold energy,

$$m_{12} = -\frac{1}{4} + \frac{1}{4}\left(\frac{100Z - 9}{4Z - 1}\right)^{\frac{1}{2}} , \tag{52.43}$$

and Z the residual charge; m_{12} is 1.127 for unit residual charge, with $m_{12} \to 1$ as $Z \to \infty$.

52.2.2 Peterkop's Semiclassical Theory

The Wannier threshold law has been verified both semiclassically [52.46] and quantum mechanically [52.47]. *Peterkop* [52.46] adopted a semiclassical JWKB approach to the problem, by using the three-dimensional WKB ansatz

$$\Psi_0 = P^{\frac{1}{2}} \exp\left(\frac{iS}{\hbar}\right) , \tag{52.44}$$

for the final-state wave function, where S and P are, respectively, the solutions of the Hamilton–Jacobi equation,

$$(\nabla_1 S)^2 + (\nabla_2 S)^2 = 2(E - V) , \tag{52.45}$$

and the continuity equation,

$$\nabla_1(P\nabla_1 S) + \nabla_2(P\nabla_2 S) = 0 . \tag{52.46}$$

In hyperspherical coordinates, these equations become

$$\left(\frac{\partial S}{\partial \rho}\right)^2 + \frac{1}{\rho^2}\left(\frac{\partial S}{\partial \alpha}\right)^2 + \frac{4}{\rho^2 \sin^2 2\alpha}\left(\frac{\partial S}{\partial \theta_{12}}\right)^2$$
$$= 2E + \frac{2Z}{\rho} \tag{52.47}$$

and

$$D_0\left(P\frac{\partial S}{\partial \rho}\right) + \frac{1}{\rho^2}$$
$$\times \left[D_1\left(P\frac{\partial S}{\partial \alpha}\right) + D_2\left(\frac{\partial S}{\partial \theta_{12}}\right)\right] = 0 , \tag{52.48}$$

where

$$D_0 f = \frac{1}{\rho^5}\frac{\partial}{\partial \rho}(\rho^5 f) , \tag{52.49}$$

$$D_1 f = \frac{1}{\sin^2 2\alpha}\frac{\partial}{\partial \alpha}\left(f \sin^2 2\alpha\right) , \tag{52.50}$$

$$D_2 f = \frac{4}{\sin^2 2\alpha}\frac{1}{\sin \theta_{12}}\frac{\partial}{\partial \theta_{12}}(f \sin \theta_{12}) . \tag{52.51}$$

Following Wannier's hypothesis, solutions of these equations are found in the region $\alpha = \pi/4, \theta_{12} = \pi$. Taking the Taylor expansion for $Z(\alpha, \theta_{12})$ as

$$Z(\alpha, \theta_{12}) = Z_0 + \frac{1}{2}Z_1(\Delta\alpha)^2 + \frac{1}{8}Z_2(\Delta\theta_{12})^2 + \cdots , \tag{52.52}$$

where $\Delta\alpha = \alpha - \pi/4$ and $\Delta\theta_{12} = \theta_{12} - \pi$, it follows from (52.41) that

$$Z_0 = \frac{3}{\sqrt{2}}, Z_1 = \frac{11}{\sqrt{2}}, Z_2 = -\frac{1}{\sqrt{2}} . \tag{52.53}$$

Similarly, taking the solution of (52.47) in the form

$$S = S_0(\rho) + \frac{1}{2}S_1(\rho)(\Delta\alpha)^2 + \frac{1}{8}S_2(\rho)(\Delta\theta_{12})^2 + \cdots \tag{52.54}$$

gives

$$\frac{dS_0}{d\rho} = \omega , \tag{52.55}$$

$$\omega\frac{dS_i}{d\rho} + \frac{S_i^2}{\rho^2} = \frac{Z_i}{\rho} , \quad i = 1, 2 , \tag{52.56}$$

where $\omega = (2E + 2Z_0/\rho)^{\frac{1}{2}}$. The solutions are

$$S_0 = \rho\omega + \frac{Z_0}{\chi}\ln\frac{\rho(\chi + \omega)^2}{2Z_0} , \tag{52.57}$$

$$S_i = \rho^2\omega\frac{1}{u_i}\frac{du_i}{d\rho} , \quad i = 1, 2 , \tag{52.58}$$

where $\chi = (2E)^{\frac{1}{2}}$ and

$$u_i = C_{i1}u_{i1} + C_{i2}u_{i2} , \tag{52.59}$$

$$u_{ij} = \rho^{m_{ij}} {}_2F_1\left(m_{ij}, m_{ij} + 1; 2m_{ij} + \frac{3}{2}; \frac{-E\rho}{Z_0}\right) , \tag{52.60}$$

$$m_{i1} = -\frac{1}{4} - \frac{1}{2}\mu_i, m_{i2} = -\frac{1}{4} + \frac{1}{2}\mu_i , \tag{52.61}$$

$$\mu_i = \frac{1}{2}\left(1 + \frac{8Z_i}{Z_0}\right)^{\frac{1}{2}} . \tag{52.62}$$

where, for $i = 2$, the principal branch is understood.

Expanding P in the same form as S, and restricting the solution to finding P_0, gives

$$P_0 = \frac{C}{\rho^5 \omega u_1 u_2^2} , \qquad (52.63)$$

where $C \sim C_{12} E^{1-m_{12}}$. By solving these equations, Peterkop extracted the Wannier cross section behavior by matching the exact wave function with an approximate one for which the energy dependence is known at some arbitrarily finite value r_0 of ρ, giving the total cross section as

$$\sigma_{\text{tot}} \sim E^{1.127} , \qquad (52.64)$$

as required. However, neither this method of Peterkop nor the quantum mechanical approach of [52.47] were able to deduce the constant of proportionality.

52.2.3 The Quantal Semiclassical Approximation

As can be seen from the form of (52.63) for P_0, u_2 vanishes in the double limit $\rho \to +\infty$, $E \to 0$, and so, the semiclassical theory breaks down at the very configuration of importance. To avoid this problem, *Crothers* [52.8] adopted a change of the dependent variable to obtain a uniform JWKB approximation. Taking $\alpha = \pi/4$, (i. e., $\Delta\alpha = 0$) as the natural barrier, he set the final-state wave function as

$$\Psi^{-*} = \frac{x |\sin(\alpha - \pi/4)|^{1/2}}{\rho^{5/2} \sin\alpha \cos\alpha (\sin\theta_{12})^{1/2}} , \qquad (52.65)$$

so that

$$\left[\frac{\partial^2}{\partial\rho^2} + \frac{1}{\rho^2 \sin|\Delta\alpha|} \frac{\partial}{\partial\alpha} \left(\sin|\Delta\alpha| \frac{\partial}{\partial\alpha} \right) \right.$$
$$+ \frac{1}{\rho^2 \sin^2\alpha \cos^2\alpha} \frac{\partial^2}{\partial\theta_{12}^2} + 2E + \frac{2Z}{\rho}$$
$$\left. + \frac{(\frac{1}{4} + \frac{1}{4}\csc^2\Delta\theta_{12})}{\rho^2 \sin^2\alpha \cos^2\alpha} - \frac{\csc^2|\Delta\alpha|}{4\rho^2} \right] x = 0 , \qquad (52.66)$$

where $|\Delta\alpha|$ and θ_{12} are, respectively, the polar and azimuthal angles. Near $\theta_{12} = \pi$ and $\alpha = \pi/4$, (i. e., at $\Delta\theta_{12} = \Delta\alpha = 0$), the term $(4\rho^2)^{-1}$ is negligible compared with $\csc^2\theta_{12}/(4\rho^2)$. Also the θ_{12} pseudopotential is clearly attractive while the α potential is repulsive, and both potentials are large just at the region of importance, i. e., at $\Delta\alpha = 0 = \Delta\theta_{12}$.

Again, following the method of Peterkop, the final state wave function is written in the form (52.44),

(52.47) and (52.48), where now the action perturbation expression S must be generalized to

$$S = s_0 \ln|\Delta\alpha| + s_1 \ln(\Delta\theta_{12}) + S_0(\rho)$$
$$+ \frac{1}{2} S_1(\rho)(\Delta\alpha)^2 + \frac{1}{8} S_2(\rho)(\Delta\theta_{12})^2 + \dots , \qquad (52.67)$$

where the extra logarithmic phases indicate long-range Coulomb potentials. By applying the Kohn variational principle perturbatively, and invoking the Jeffreys' [52.48] connection formula on the Wannier ridge with $\rho = 0$ as the classical turning point, the final state wave function is [52.8]

$$\Psi_f^{-*} = \frac{c^{1/2} E^{m_{12}/2} \rho^{m_{12}/2+1/4} r(2Z_0)^{1/4} (-\chi/2\pi)^{1/2}}{(2Z_0/\rho)^{1/4} \rho^{5/2} \sin\alpha \cos\alpha}$$
$$\times \delta(\hat{\boldsymbol{k}}_1 - \hat{\boldsymbol{r}}_1) \delta(\hat{\boldsymbol{k}}_2 - \hat{\boldsymbol{r}}_2)$$
$$\times \exp\left[4i(8Z_0\rho)^{-1/2}(\Delta\theta_{12})^{-2} \right]$$
$$\times \left\{ \exp\left[-i(8Z_0\rho)^{1/2} - \frac{1}{2}i(\Delta\alpha)^2 \right.\right.$$
$$\times (2Z_0\rho)^{1/2} m_{12} - \frac{1}{8}i(\Delta\theta_{12})^2$$
$$\left.\left. \times (2Z_0\rho)^{1/2} m_{21} - \frac{1}{4}i\pi \right] - \text{c.c} \right\} , \qquad (52.68)$$

where $\chi = 2\pi \text{Im}(m_{21})$.

Taking the total cross section for distinguishable particles as

$$\sigma = \frac{\pi^2 a_0^2}{k_0} \int \int d\hat{\boldsymbol{k}}_1 d\hat{\boldsymbol{k}}_2 \frac{\pi Z_2 \tanh\chi}{(2E)^{1/2}} \left| f(\hat{\boldsymbol{k}}_1, \hat{\boldsymbol{k}}_2) \right|^2$$
$$\times \exp\left[\frac{-Z_2}{4(2E)^{1/2}}(\Delta\Theta_{12})^2 \pi \tanh\chi \right] , \qquad (52.69)$$

where f is the scattering amplitude, then the corresponding triple-differential cross section is

$$\frac{d^3\sigma}{d\hat{\boldsymbol{k}}_1 d\hat{\boldsymbol{k}}_2 d\left(\frac{1}{2}k_1^2\right)}$$
$$= \frac{2\pi^2 a_0^2}{k_0} \frac{d}{dE} \frac{\pi Z_2 \tanh\chi}{(2E)^{1/2}}$$
$$\times \exp\left[\frac{-Z_2}{4(2E)^{1/2}}(\Theta_{12} - R\pi)^2 \pi \tanh\chi \right]$$
$$\times \left| f\left(\hat{\boldsymbol{k}}_1, \hat{\boldsymbol{k}}_2\right) \right|^2 . \qquad (52.70)$$

Assuming the contribution from triplet states is negligible, $|f|^2$ can be written as

$$\frac{1}{4} \left| f(\hat{\boldsymbol{k}}_1, \hat{\boldsymbol{k}}_2) + f(\hat{\boldsymbol{k}}_2, \hat{\boldsymbol{k}}_1) \right|^2 , \qquad (52.71)$$

where $f(\hat{k}_1, \hat{k}_2)$ (and by permutation $f(\hat{k}_2, \hat{k}_1)$, hereafter referred to as f and g respectively) is given by

$$f \simeq \frac{2i}{\pi} \int d\mathbf{r}_1 d\mathbf{r}_2 d\mathbf{r}_3 \Psi_f^{-*} \phi_f(2, \mathbf{r}_3)$$
$$\times (H - E) \exp(i\mathbf{k}_0 \cdot \mathbf{r}_1) \psi_i(\mathbf{r}_2, \mathbf{r}_3) . \quad (52.72)$$

As a test of the above formulation for the process $e^- + He \rightarrow He^+ + 2e^-$ near the ionization threshold, *Crothers* [52.8] used an independent-electron open-shell wave function for the initial bound state helium target, written as

$$\psi_i(\mathbf{r}_2, \mathbf{r}_3) = \frac{\phi(\mathbf{r}_2, z_0)\phi(\mathbf{r}_3, \beta) + \phi(\mathbf{r}_3, z_0)\phi(\mathbf{r}_2, \beta)}{[2(1+S)]^{1/2}} , \quad (52.73)$$

where

$$\phi(\mathbf{r}, z_0) = z_0^{3/2} \pi^{-1/2} \exp(-z_0 r) , \quad (52.74)$$

$$S = \left[\int \phi(\mathbf{r}, z_0)\phi(\mathbf{r}, \beta) d\mathbf{r} \right]^2$$
$$= \left(\frac{4z_0\beta}{(z_0 + \beta)^2} \right)^3 , \quad (52.75)$$

and z_0 and β take the physical values $z_0 = 1.8072^{1/2}$ and $\beta = 2$. The total singlet cross section was found to be (in atomic units)

$$\sigma = 2.37 E^{m_{12}} a_0^2 , \quad (52.76)$$

in line with Wannier's threshold law, and with experiment [52.49], while the corresponding absolute triple differential cross sections (TDCS) were expressed as

$$\frac{d^3\sigma}{d\hat{k}_1 d\hat{k}_2 d\left(\frac{1}{2}k_1^2\right)} = \frac{70cz_0^2 2^{1/2} \chi \tanh \chi}{\pi R_\infty Z_0^{1/2} m_{12}} |f + g|^2$$
$$\times \left[\frac{d}{dE} E^{m_{12}-1/2} \exp\left(\frac{-Z_2(\Theta_{12} - \pi)^2 \pi \tanh \chi}{4(2E)^{1/2}} \right) \right] \quad (52.77)$$

in units of 10^{-19} cm^2 sr^{-2} eV^{-1}, where

$$c = \frac{\Gamma(m_{12} + 3/2) \Gamma(m_{12} + 1)}{2\pi Z_0^{m_{12}} \Gamma(2m_{12} + 3/2)} , \quad (52.78)$$

and where f (and similarly g for Θ_2) is given by

$$f = \int_0^\infty d\rho \rho^{3/2 + m_{21}/2 + 1/4} \sum_{L=0}^{L_{\max}} i^L (2L+1) j_L \left(\frac{\rho z_0}{2^{1/2}} \right)$$
$$\times P_L(\cos \Theta_1) \exp \left\{ \frac{1}{8} \right.$$
$$\times \text{Im} \left[m_{21}(\Theta_{12} - \pi)^2 (2Z_0\rho)^{1/2} \right] \right\}$$
$$\times 2 \cos \left\{ (8Z_0\rho)^{1/2} + \frac{1}{8} \right.$$
$$\times \text{Re} \left[m_{21}(\Theta_{12} - \pi)^2 (2Z_0\rho)^{1/2} \right] \right\}$$
$$\times r(\rho, \Theta_{12}) \quad (52.79)$$

with

$$(1+S)^{1/2} r(\rho, \Theta_{12})$$
$$= \exp\left(-\frac{\rho z_0}{2^{1/2}} \right) \left(2^{1/2} z_0 - \frac{1}{(1 - \cos \Theta_{12})^{1/2}} \right)$$
$$+ \exp(-2^{1/2}\rho) \left[\frac{64(2)^{1/2}(z_0 - 1)}{(z_0 + 2)^3} \right.$$
$$+ \frac{32}{(z_0 + 2)^3} [2(2)^{1/2}$$
$$+ (z_0 + 2)\rho] \exp\left(\frac{-\rho(z_0 + 2)}{2^{1/2}} \right) \right] . \quad (52.80)$$

These results have been found to compare favorably with both the relative experimental results of [52.50] and the absolute experimental results of [52.51]. The Crothers quantal semiclassical approximation has been successfully applied to other threshold (e, 2e) and (photon, 2e) collisions, namely two-electron photodetachment from H$^-$ [52.52], He$(^4P_{5/2}^0)$ [52.53] and K$^-$ [52.54]. Further investigations of the TDCS for helium at threshold have since been carried out. The $^3P^0$ triplet contribution to the TDCS was studied in [52.55], where small but notable improvements in the comparison with experimental results [52.50] and [52.51] were achieved for most configurations of the angles θ_1 and θ_2. The inclusion of contributions from $^3D^{e,0}$ or $^3F^0$ to the absolute TDCS were found to be negligible in comparison with the effect of the $^3P^0$ [52.56], although the admittedly non-Wannier effective-charge investigation of $\theta_{12} = \pi$ by *Pan* and *Starace* [52.57] suggests that $^3F^0$ may be important at $\theta_1 = \pi/6$ or $5\pi/6$, in line with the experiment of *Rösel* et al. [52.51]. Another aspect which is thought to contribute to the TDCS is explicit correlation in the initial bound state wave

function for the helium target, in which the interelectronic distance r_{23} is explicitly contained. Absolute singlet triple-differential cross sections have been obtained [52.58], using a helium ground state wave function developed by *Le Sech* [52.59]. Again, excellent agreement with the singlet results of [52.8] has been achieved, and, in most configurations, notable improvements with the corresponding experimental data are obtained, as shown in Fig. 52.3 for scattering angle $\theta_1 = 60°$ (a) and 90° (b), indicating that electron correlation should also be considered if a full picture of threshold ionization is to be achieved.

The last eight years has seen significant new developments and contributions to the Wannier theory. One notable achievement has been the analytical continuation of the uniform semi-classical wave function [52.8] to below the energy threshold to calculate the complex eigenenergies for doubly excited states of helium using a complex Bohr–Sommerfeld quantization rule with at least one complex transition point [52.4, 5]. The real parts of the eigenvalues were found to be in good agreement with the experimental results of *Buckman* et al. [52.60, 61] for the resonance positions while the imaginary parts

give the explicit widths of the resonances from which the intensities have been estimated. The theory in [52.4] was considered initially for the inaugural case of $L = 0$. Further investigation [52.5–7] has extended the theory to include resonant states for $L = 1$ and $L = 2$. In the case of $L = 1$, an irrational quantum number was obtained and attosecond lifetimes were obtained. Excellent results were obtained for the resonance positions, lifetimes, intensities, and scaling rules in comparison with the experimental data [52.60]. This success persuaded *Deb* and *Crothers* [52.62] to re-visit the problem of quantal near-threshold ionization of He by electron impact. In particular they re-examined the problem of above threshold ionization of He by electron impact by retaining the term $2L(L+1)/\rho^2$ in the hyperspherical equation

$$
\left(\frac{1}{\rho^5} \frac{\partial}{\partial \rho} \rho^5 \frac{\partial}{\partial \rho} + \frac{1}{\rho^2 \sin^2 2\alpha} \frac{\partial}{\partial \alpha} \sin^2 2\alpha \frac{\partial}{\partial \alpha} \right.
$$
$$
+ \frac{4}{\rho^2 \sin \theta_{12}} \frac{\partial}{\partial \theta_{12}} \sin \theta_{12} \frac{\partial}{\partial \theta_{12}} + 2E
$$
$$
\left. + \frac{2\zeta(\alpha, \theta_{12})}{\rho} \frac{2L(L+1)}{\rho^2} \right) \Psi = 0 \, . \tag{52.81}
$$

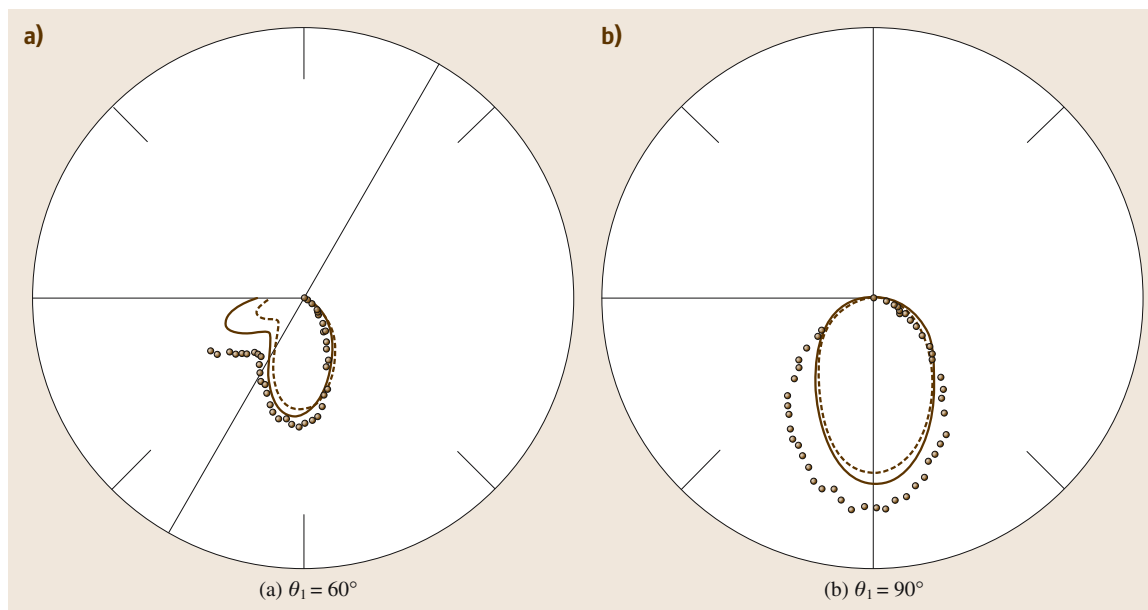
(a) $\theta_1 = 60°$ (b) $\theta_1 = 90°$


Fig. 52.3a,b Helium triply differential ionization cross section for coplanar geometry, $E_1 = E_2 = 1$ eV and $E = 2$ eV, calculated (*full curve*) TDCS of *Copeland* and *Crothers* [52.58] in polar coordinates, with polar coordinates as θ_2, for scattering angles $\theta_1 = 60°$ (**a**) and $\theta_1 = 90°$ (**b**), in comparison with absolute experimental (*circles*) data of *Rösel* et al. [52.44], and theoretical results (*broken curve*) of *Crothers* [52.40]. The radius of each circle is 1.0×10^{-19} cm^{2}sr^{-2}eV^{-1}

Following the procedure of *Crothers* [52.8], they obtained

$$\Psi_f^{-*} = \frac{c^{1/2}E^{m_{12}/2}u_1^{1/2}}{\tilde{\omega}^{1/2}\rho^{5/2}\sin\alpha\cos\alpha}\delta(\hat{\boldsymbol{k}}_1 - \hat{\boldsymbol{r}}_1)$$
$$\times \delta(\hat{\boldsymbol{k}}_2 - \hat{\boldsymbol{r}}2)\exp\left[4\mathrm{i}(8Z_0\rho)^{-1/2}(\Delta\theta_{12})^{-2}\right]$$
$$\times \exp\left\{-\mathrm{i}\left[S_0 + \frac{1}{2}S_1(\Delta\alpha)^2\right.\right.$$
$$\left.\left. + \frac{1}{8}S_2(\Delta\theta_{12})^2 + \frac{\pi}{4}\right] - \text{conjugate}\right\}, \tag{52.82}$$

where the classical action variables are given by

$$S_0 = \int\limits_0^\rho \mathrm{d}\tilde{\rho}\,\tilde{\omega}\,, \tag{52.83}$$

$$S_i = \rho^2\omega(\ln u_i)'\,, \quad i = 1,2 \tag{52.84}$$

with

$$\tilde{\omega} = \left[\omega^2 - \omega\,(\ln_{u_2} - \mathrm{i}\ln u_1)'\right]^{1/2}\,, \tag{52.85}$$

$$\omega^2 = 2E + 2Z_0/\rho - 2L(L+1)/\rho^2\,. \tag{52.86}$$

The primes in (52.84) and (52.85) denote derivatives with respect to ρ and $\tilde{\rho}$ respectively. It is to be noted here that the original work used the approximated form of ω by dropping the L-dependent term in (52.86). The inclusion of this angular momentum term moves the classical turning point from the origin to ρ_+, where

$$\rho_+ = \frac{-Z_0 + \sqrt{Z_0^2 + 4EL(L+1)}}{2E}\,. \tag{52.87}$$

As a result, the lower limit of ρ integration will be replaced by ρ_+. The classical action variables S_1 and S_2 are now evaluated without introducing the limit $E\rho \to 0$. Using the final state wave function in (52.82) we have calculated first the direct ionization amplitude. The exchange ionization amplitudes for the two indistinguishable atomic electrons were then obtained by interchanging the angles θ_1 and θ_2 in the direct amplitude. Singlet and triplet contributions are then accounted for in the usual ratio of 1:3.

Equation (52.82) is a more accurate variant of (52.68) used in the original theory of *Crothers* [52.8]. Using this refinement of the wave function, all partial wave contributions for singlets and triplets are accounted for up to $L = 6$ for the case of He by electron impact at an excess of 2 eV above threshold. It has been found that within the co-planar geometry, both the symmetric and asymmetric triple differential cross sections, peaking at and near the Wannier ridge, are greatly improved when compared with experiment [52.63]. However, far away from the Wannier ridge the triple differential cross sections tend to show qualitative differences from measurement [52.63].

The improved theory [52.62] has also successfully been applied to the calculation of total cross sections of positron impact ionization of helium for energies 0.5–10 eV above threshold [52.64]. Excellent agreement with available experimental data [52.65] was obtained for the absolute theoretical calculation of positron impact ionization [52.64].

Finally this recent work has answered some questions concerning near-threshold processes, a large and interesting area of study and we firmly believe that further development of this powerful theory will answer many more.

53. Ionization in High Energy Ion–Atom Collisions

Atomic species moving at high velocities form an important component of ionizing radiation. When these species interact with matter, they effect chemical and biological changes which originate with primary collision processes, usually the ejection of electrons. This chapter gives an overview of this primary process that has emerged from studies of the energy and angular distribution of electrons ejected by the impact of atomic or ionic projectiles on atomic targets. It seeks to highlight those features which are most

ubiquitous [53.1, 2]. Atomic units [53.3] are used, although e, m, and $\hbar$ are sometimes exhibited explicitly to show the connection with standard treatments of the first Born approximation [53.1].

When high-velocity projectiles strike atomic targets, electrons are ejected from the target atoms, and, if the projectiles have some electrons, from the projectile ions also. For partially ionized projectiles, there are two groups of electrons, one from the target and one from the projectile. In principle, these two groups of electrons cannot be separately identified, but in practice each group often predominates in separate energy and angular regions, and can be identified with the help of computed distributions. These disstributions are expressed in terms of doubly differential cross sections

(DDCS). Two somewhat different cross sections are used. The Galilean invariant cross sections are differential in the wave vectors k of the Schrödinger waves for the ejected electrons and are denoted by $d^3\sigma/dk^3$. The wave vectors k refer to the laboratory or target frame. The Galilean invariant cross sections take the same form in any reference frame, including the projectile frame. In this frame the electron wave vectors are denoted by primes, k'. The DDCS is given in terms of an alternative expression in Sect. 53.1, (53.9).

53.1 Born Approximation

The first Born approximation, often referred to as FBA or B1, provides an excellent framework to understand qualitatively most of the prominent features observed in fast ion–atom collisions. For a bare ion projectile of charge Z_P impinging upon a neutral atom target of nuclear charge Z_T, the Hamiltonian of the system is written as

$$H = H_0 + H_1 \,, \tag{53.1}$$

where

$$H_0 = \frac{P_P^2}{2\mu} + \sum_{j=1}^{Z_T} \left(\frac{p_j^2}{2m} - \frac{Z_T e^2}{r_j} + \sum_{i>j}^{Z_T} \frac{e^2}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} \right) \,,$$

$$H_1 = \frac{Z_P Z_T e^2}{R} - \sum_{j=1}^{Z_T} \frac{Z_P^2}{|\boldsymbol{R} - \boldsymbol{r}_j|} \,, \tag{53.2}$$

and where μ is the projectile reduced mass, m the electron mass, $\boldsymbol{R}$ the position vector of the projectile with respect to the target nucleus, $\boldsymbol{P}_P$ the corresponding momentum operator, $\boldsymbol{r}_j$ the position vector of the ith target electron and $\boldsymbol{p}_j$ the corresponding momentum operator. The first Born approximation consists of breaking H as in (53.1): the wave functions employed are antisymmetric products of the target eigenfunctions of H_0 and a plane wave of relative motion for the target and projectile. Transitions are induced by the interaction term H_1. For an inelastic collision, the target wave function is orthogonal to the initial state wave function and the matrix element of the first term in H_1, $Z_P Z_T e^2/R$, vanishes. Using Bethe's

integral

$$\int \frac{e^{i\boldsymbol{q}\cdot\boldsymbol{R}}}{|\boldsymbol{R}-\boldsymbol{r}|}\,d^3r = \frac{4\pi}{q^2}\,e^{i\boldsymbol{q}\cdot\boldsymbol{R}}\,, \tag{53.3}$$

the inelastic cross section becomes [53.4]

$$\sigma_{if} = \frac{4\mu^2 e^4}{\hbar^4}\frac{K_f}{K_i}\int d\Omega_{K_f}\frac{Z_P^2}{q^4} \\ \times |\langle\Phi_f|\sum_j \exp(i\boldsymbol{q}\cdot\boldsymbol{r}_j)|\Phi_i\rangle|^2\,, \tag{53.4}$$

where $\hbar K_i$ and $\hbar K_f$ are the initial and final momenta of the projectile, $\hbar\boldsymbol{q} = \hbar(\boldsymbol{K}_f - \boldsymbol{K}_i)$ is the momentum transferred from the projectile to the target, $\Phi_{(f,i)}$ represents the wave functions for the final (f) and initial (i) states of the target electrons, Ω_{K_f} is the solid angle of the scattered projectile, j sums over all target electron coordinates $\boldsymbol{r}_j$, and an average over initial and sum over final states is assumed [53.4]. The integral over $d\Omega_{K_f}$ can be performed by making the change of variables

$$d\Omega_{K_f} \equiv \sin\theta_{K_f}\,d\theta_{K_f}\,d\phi_{K_f} = \frac{1}{K_iK_f}q\,dq\,d\phi_{K_f} \tag{53.5}$$

and substituting $\hbar K_i = \mu v_i$ to obtain

$$\sigma_{if} = \frac{8\pi a_0^2 Z_P^2}{(v_i/v_B)^2} \\ \times \int_{K_-}^{K_+}\frac{dq}{q}\frac{|\langle\Phi_f|\sum_{j=1}^{Z_T}\exp(i\boldsymbol{q}\cdot\boldsymbol{r}_j)|\Phi_i\rangle|^2}{(qa_0)^2}\,, \tag{53.6}$$

where v_i is the initial relative velocity and $v_B = \alpha c$ is the atomic unit of velocity. $(v_i/v_B)^2 = T/R$ in the notation of [53.4]. From the definition of $\boldsymbol{q}$, the limits of integration are $K_\pm = |K_i \pm K_f|$. The cross section is independent of the mass of the incident projectile.

The dimensionless generalized oscillator strength (GOS) is defined by [53.5]

$$f_{if}(q) \equiv \frac{\Delta E}{R_\infty}\frac{|\langle\Phi_f|\sum_j\exp(i\boldsymbol{q}\cdot\boldsymbol{r}_j)|\Phi_i\rangle|^2}{(qa_0)^2}\,, \tag{53.7}$$

where ΔE is the energy lost by the projectile in the collsion; again, an average over initial and sum over final magnetic substates is assumed. In terms of the GOS, the cross section becomes

$$\sigma_{if} = \frac{8\pi a_0^2 Z_P^2}{(v_i/v_B)^2}\int_{K_-}^{K_+}\frac{f_{if}(q)}{\Delta E/R_\infty}\frac{dq}{q}\,. \tag{53.8}$$

The DDCS, as defined, is related to the Galilean invariant cross section $d^3\sigma/dk^3$ by [53.6]

$$\frac{d^3\sigma_{if}}{dE_k\,d\Omega_k} = \left(\frac{m}{\hbar^2}\right)k\frac{d^3\sigma_{if}}{d^3k}\,, \tag{53.9}$$

but it is more useful for describing the low energy ejected electrons since it connects smoothly with cross sections for discrete excitations of the target. The first Born approximation for both excitation and ionization by a bare projectile scale as Z_P^2. The advantage of the GOS is that, in the limit $q \to 0$, it approaches the optical oscillator strength – a relationship that connects ionization in fast ion–atom collisions with photoionization [53.7].

For an ionization process where an electron of momentum $\hbar\boldsymbol{k}$ is ejected from the target, the DDCS, differential in ejected electron energy E_k and angle Ω_k, denoted by $d^3\sigma_{if}/dE_k\,d\Omega_k$, is also given by (53.4) with the proviso that the Φ_f becomes Φ_f^-, representing a target ion plus an ejected (continuum) electron with incoming wave boundary conditions [53.5], normalized on the energy scale [53.3], i. e.,

$$\langle\Phi_f^-(E)|\Phi_f^-(E')\rangle = \delta(E - E')\,. \tag{53.10}$$

If the energy is in Rydbergs, the asymptotic form of the radial part, $r \to \infty$, of the continuum wave function of angular momentum ℓ is given by [53.7]

$$\frac{1}{r}\left(\frac{1}{\pi k}\right)^{\frac{1}{2}}\sin\left(kr - \ell\pi/2 + k^{-1}\ln 2kr + \sigma_\ell + \delta_\ell\right)\,, \tag{53.11}$$

where $\sigma_\ell \equiv \arg\Gamma(\ell + 1 - i/k)$ is the Coulomb phase shift, and δ_ℓ is the non-Coulomb phase shift due to the short range part of the potential. For normalization on the energy scale, in atomic units (1 a.u. $= 2R_\infty$), this asymptotic form is multiplied by $\sqrt{2}$, and for normalization on the k-scale, (53.11) is multiplied by $\sqrt{2k}$ [53.3].

One can also obtain the single differential cross section (SDS), $d\sigma_{if}/dE_k$, by integrating over Ω_k. This cross section can be expressed in terms of the differential GOS density in the continuum [53.5],

$$\frac{df_{if}(q)}{dE_k} = \frac{\Delta E}{R_\infty}\frac{1}{(qa_0)^2} \\ \times \int|\langle\Phi_f^-|\sum_{j=1}^{Z_T}\exp(i\boldsymbol{q}\cdot\boldsymbol{r}_j)|\Phi_i\rangle|^2\,d\Omega_k\,, \tag{53.12}$$

as

$$\frac{d\sigma_{if}}{dE_{\boldsymbol{k}}} = \frac{8\pi a_0^2}{(v_i/v_B)^2} \int \frac{df_{if}(q)/dE_{\boldsymbol{k}}}{\Delta E/R} \frac{dq}{q} , \quad (53.13)$$

with $\Delta E = E_{\boldsymbol{k}} + I_T$, and I_T is the ionization energy of the target. Finally, the total ionization cross section is obtained by integration of $d\sigma_{if}/dE_{\boldsymbol{k}}$ over $E_{\boldsymbol{k}}$,

$$\sigma_{if} = \frac{8\pi a_0^2 Z_P^2}{(v_i/v_B)^2} \int Z_P^2 \frac{df_{if}(q)/dE_{\boldsymbol{k}}}{\Delta E/R} \frac{dq}{q} dE_{\boldsymbol{k}} . \quad (53.14)$$

Let us now consider a collision in which the projectile brings in its own N_P electrons. The Hamiltonian for the system becomes

$$H = H_0 + H_1$$

$$H_0 = \frac{p_P^2}{2\mu} + \sum_{j=1}^{Z_T} \left(\frac{p_j^2}{2m} - \frac{Z_T e^2}{r_j} + \sum_{i>j}^{Z_T} \frac{e^2}{|\boldsymbol{r}_i - \boldsymbol{r}_j|} \right)$$

$$+ \sum_{k=1}^{N_P} \left(\frac{p_k^2}{2m} - \frac{Z_P e^2}{r_k} + \sum_{i>k}^{N_P} \frac{e^2}{|\boldsymbol{r}_i - \boldsymbol{r}_k|} \right)$$

$$H_1 = \frac{Z_P Z_T e^2}{R} - \sum_{j=1}^{Z_T} \frac{Z_P e^2}{|\boldsymbol{R} - \boldsymbol{r}_j|} - \sum_{k=1}^{N_P} \frac{Z_T e^2}{|\boldsymbol{R} + \boldsymbol{r}_k|}$$

$$+ \sum_{j=1}^{Z_T} \sum_{k=1}^{N_P} \frac{e^2}{|\boldsymbol{R} + \boldsymbol{r}_k - \boldsymbol{r}_j|} \quad (53.15)$$

where $\boldsymbol{p}_k$ and $\boldsymbol{r}_k$ refer to projectile electrons. Under these conditions, the solutions of H_0 include the wave function of the projectile electrons in the antisymmetric product. For an inelastic collision, the matrix element of the first term of H_1 vanishes as before. However, there are two extra terms in H_1: the interaction of the projectile electrons with the target nucleus, and the interaction of the target electrons with projectile electrons. These projectile electrons open physically distinct, alternative possibilities for the ionization process [53.2]: (a) target ionization, projectile remains in initial state; (b) target ionization, projectile excited (including ionization); (c) projectile ionization, target remains in initial state; (d) projectile ionization, target excited (including ionization).

For process (a), evaluation of the first Born cross section gives (53.4) with the projectile charge Z_P^2 replaced by $|Z_P - F_{ii}(q)|^2$, where the elastic form factor $F_{ii}(q)$ is

given by

$$F_{ii}(q) = \left\langle \Phi_i^P \middle| \sum_{k=1}^{N_P} \exp(i\boldsymbol{q} \cdot r_k) \middle| \Phi_i^P \right\rangle, \quad (53.16)$$

and $\Phi_{(f,i)}^P$ represents the wave function for the final and initial electron state of the projectile. Thus, the effect of the projectile electrons on process (a) is to screen the projectile nucleus, and the dynamical screening depends upon the momentum transfer q. Clearly from (53.16), $F_{ii}(0) = N_P$ and $F_{ii}(\infty) = 0$. Thus, for small energy transfer, which implies small q (large impact parameter), $Z_P \to Z_P - N_P$, i.e., full screening of the projectile by its electrons. For large energy transfer, which implies q (small impact parameter), Z_P remains unmodified, i.e., no screening.
Fig. 53.1 Theoretical double differential cross sections (DDCS) for the ionization of He by equal velocity H^+, He^{++} and He^+ (target ionization with no projectile excitation only) as a function of ejected electron energy in Ry for an ejection angle of $60°$. The incident velocity corresponds to 0.5 MeV H^+ and 2.0 MeV He^+ and He^{++} which all have the same velocity as a 20 Ry (272 eV) electron

To illustrate this effect, a calculation of process (a) is presented in Fig. 53.1 for the DDCS for 2 MeV He$^+$ + He collisions, along with a DDCS calculation for equal velocity H$^+$ and He^{++} projectiles [53.8]. From these results it is seen that for small energy transfer, the He$^+$ projectile behaves almost like a heavy proton. With increasing ejected electron energy, however, it is seen to approach He^{++}-like behavior. Note that this result is process (a) alone.

Looking at process (b), the situation is rather different. Now two electrons change their state so that transition matrix elements of all terms except the electron–electron term in H_1 vanish. In this case, Z_P^2 in (53.4) is replaced by the square of the inelastic projectile form factor $|F_{fi}|^2$, where

$$F_{fi}(q) = \left\langle \Phi_f^P \Big| \sum_{k=1}^{N_P} \exp(\mathrm{i}\boldsymbol{q} \cdot r_k) \Big| \Phi_i^P \right\rangle . \qquad (53.17)$$

Owing to the orthogonality of initial and final projectile states, this form factor vanishes in both the limits, $q \to 0$ and $q \to \infty$. Thus, the total target DDCS is process (a) plus the sum over all of the possible projectile excitations (including projectile ionization) of process (b). Since there is an infinite number of projectile excitations, it is useful to have a method for summing over all of them. Using the closure relation, the sum over all projectile excitations at fixed q is given by [53.2]

$$\sum_{f \neq i} |F_{fi}(q)|^2 = N_P - |F_{ii}(q)|^2 + \left\langle \Phi_i^P \right|$$
$$\times \sum_{j, j', j \neq j'}^{N_P} \exp[\mathrm{i}\boldsymbol{q} \cdot (\boldsymbol{r}_j - \boldsymbol{r}_{j'})] \left| \Phi_i^P \right\rangle , \qquad (53.18)$$

where only the initial state wave function of the projectile electrons appears. While this sum rule is exact, it cannot be substituted exactly into (53.4) because of the transformation between $\cos\theta_{K_f}$ and q, and hence the limits of integration over q vary with the excitation energy of the final state of the projectile. Various ways of choosing approximate integration limits have been suggested [53.9].

Projectile ionization alone, and with target excitation, process (c) and (d) above, are handled exactly as (a) and (b), but in the projectile reference frame. Thus, ionization of the projectile by the target is calculated using the methodology detailed above, after which the results are transformed into the laboratory frame using the invariance of $\mathrm{d}^3\sigma_{if}/\mathrm{d}^3k$ and $\boldsymbol{k}_L = \boldsymbol{k}_P + \boldsymbol{K}_i/\mu$. The subscripts L and P refer to the laboratory and projectile frame, respectively.

53.2 Prominent Features

A plot of $\mathrm{d}^3\sigma/\mathrm{d}k^3$ superimposes electrons from the target and electrons from the projectile. To sort out the main features of the two groups of electrons, first consider impact of bare ions on neutral targets, where the DDCS exhibits only electrons ejected from the target. Figure 53.2 shows a computed cross section for protons on H. The wave vectors are resolved into two components: a component $\boldsymbol{k}_\parallel$, which is parallel to the wave vector $\boldsymbol{K}_i$ of the projectile in the laboratory frame, and a component $\boldsymbol{k}_\perp$ perpendicular to $\boldsymbol{K}_i$. In most cases, integration is over the direction of $\boldsymbol{K}_f$ so that $\boldsymbol{K}_i$ is an axis of symmetry. Then the DDCS is independent of the direction of $\boldsymbol{k}_\perp$. Because Fig. 53.2 was computed using an approximate theory described in Sect. 53.2.1, the details are not necessarily accurate, but these computations are qualitatively reliable over an electron energy and angular range which excludes very low electron energies, i. e., the region around $k = 0$.

53.2.1 Target Electrons

The Bethe Ridge

Figure 53.2 provides a useful starting point to examine electron energy and angular distributions. The most prominent feature is the semicircular ridge, called the Bethe ridge, surrounding a valley. The center of the semicircle is at $\boldsymbol{k} = \boldsymbol{v}$, where $\boldsymbol{v} = \boldsymbol{K}_i/M_P$ is the velocity of the projectile in the lab frame. In the projectile frame, where $\boldsymbol{k}' = \boldsymbol{k} - \boldsymbol{v}$, the center of the circle is at $\boldsymbol{k}' = 0$ and the ridge is at $\boldsymbol{k}' = \boldsymbol{v}$. This region corresponds to ionization events where the momentum $\boldsymbol{J} = \boldsymbol{q} - \boldsymbol{k}$ of the recoiling target ion vanishes. Momentum conservation implies that

$$\boldsymbol{K}_i = \boldsymbol{K}_f + \boldsymbol{k} + \boldsymbol{J} , \qquad (53.19)$$

while energy conservation is expressed as

$$\frac{K_i^2}{2M_P} + \varepsilon_i = \frac{K_f^2}{2M_P} + \frac{k^2}{2} + \frac{J^2}{2M_T} , \qquad (53.20)$$

where M_T is the mass of the ionized target. At the Bethe ridge, $\mathbf{J} \approx 0$ so that (53.19) and (53.20) combine to determine the value of $\mathbf{k}$ at this point, called $\mathbf{k}_B$;

$$[(1+m/M_P)\mathbf{k}_B - \mathbf{v}]^2 = v^2 + (1+m/M_P)\varepsilon_i \tag{53.21}$$

where ε_i is the initial electron eigenenergy. In the approximation that m/M_P is set equal to zero and the inital binding energy is small compared with $1/2v^2$, (53.21) shows that the prominent ridge seen in Fig. 53.2 at $k' = v$ corresponds to collisions where all of the momentum lost by the projectile is transferred to the ejected electron. This ridge extends from $E_k = 0$ up to electron energies of the order of $2v^2$. Generally, ejected electrons move in the combined field of both the target and the projectile. Electrons with momenta $k_\parallel$ in the region $0 < k_\parallel < vZ_P/(Z_P + Z_P)$ will be referred to as low energy electrons since they move in regions where the target potential is stronger than that of the projectile. For very fast projectiles, many more electrons are in the low energy region than at higher energies, thus this region is of special interest. Since the target potential influences the motion significantly, the ionization process in this region represents a continuation of excitation across the ionization threshold. To analyze this region, cross sections differential in E_k and angle Ω_k in the target frame are preferable since they connect smoothly with cross sections for exciting target states (53.4). Because the DDCS is independent of the azimuthal angle φ_k, the DDCS integrated over φ_k is often employed.

As the variables E_k, θ_k suggest, the main features of the low energy electrons emerge in plots of energy and angular distributions. For fixed energy, the Bethe ridge appears at an angle θ_B given by (53.21) and can be written as a relation between $\cos\theta_B$ and E_k as

$$\cos\theta_B = \left(\frac{E_k + \varepsilon_i}{\sqrt{2E_k}}\right)\frac{1}{v}. \tag{53.22}$$

For fixed $E_k \neq 0$, the DDCS maximizes at an angle that approaches 90° as $v \to \infty$; in particular this angle is obtained when $E_k = -\varepsilon_i$. Figure 53.3 shows the angular distribution of 13.6 eV electrons ejected from He by 5 MeV proton impact [53.10]. The cross section maximizes at, and is nearly symmetric about, 90°. This feature is understandable from the Born approximation.

For small deflection angles, (53.20) gives

$$q_\parallel \approx K_i - K_f \approx \frac{E_k + \varepsilon_i}{v}. \tag{53.23}$$
Fig. 53.2 Plot of the Galilean invariant DDCS for electrons ejected from atomic hydrogen by 1.5 keV proton impact computed in the distorted wave strong potential Born approximation (DSPB)

For electron energies E_k of the order of the initial binding energy $|\varepsilon_i|$ and large v, the parallel component of $\mathbf{q}$ is much smaller than the magnitude given by (53.19), so that $\mathbf{q}$ is predominantly perpendicular to the beam direction. From (53.4), electrons ejected
Fig. 53.3 Plot of the angular distribution of 13.6 eV electrons ejected from He by 5 keV proton impact [53.10]. The *solid curve* is the Born approximation and the *points* are the measured values

Part D | 53.2

from isotropic inital states are distributed symmetrically about this axis, i.e., about 90°, in first approximation. Because q is averaged over in forming the cross section, all directions contribute to some extent, and the distribution is not completely symmetric. The solid curve in Fig. 53.3 represents a distribution computed in the Bethe–Born approximation, and it is seen to peak at 90° but is somewhat asymmeteric about this angle, reflecting effects of averaging over the direction of q. Such distributions are well described by only a few partial waves for the outgoing electron. Indeed, the theoretical distribution is well described by a combination of s and p waves. The calculations fit the experimental data except in the forward direction where the experimental distribution increases sharply. Such sharp increases must reflect the presence of many partial waves not described by the Born approximation. Since the main disagreement between theory and experiment is confined to a small angular region near 0° which contributes only a small part to the total cross section, the Bethe–Born approximation represents a well-founded theoretical framework for interpreting features that appear in the low-electron-energy portion of the DDCS.

While the main contribution to total ionization cross sections comes from the low energy region, electrons in the high energy region ($v/2 < k$) carry more energy per electron, and therefore play a prominent role in processes initiated by fast electrons. The fast electrons on the Bethe ridge correspond to collisions where the momentum q lost by the incident projectile is transferred mainly to the ejected electron. Because the momentum k of the ejected electrons is much larger than the mean value of the electron momentum in the initial state, given by $\sqrt{2\varepsilon_i}$, this portion of the spectrum can be interpreted in terms of a binary collision between the incident projectile and the target electron treated as quasifree. By quasifree we understand that the electron has a nonzero binding energy ε_i, but is otherwise regarded as a free electron with an initial momentum s, distributed over a range of values centered around the mean value. In the projectile reference frame, the electron has the momentum $s - v$. The electron scatters elastically from the projectile and emerges with a final momentum $k' = k - v$. This simple picture is known as the *elastic scattering model*, and is often employed for processes involving weakly bound electrons [53.11]. There are several quantal versions of this picture, indeed any theory of ionization must reduce to the electron scattering model in the limit that the initial binding energy ε_i vanishes.

When the projectile P is a bare ion so that the binary scattering process is just Rutherford scattering, the Bethe–Born approximation is in accord with this picture. It works because the electrons are fast so that effects of the target potential in the final state are unimportant, and because a first-order computation of Rutherford scattering gives the same scattering cross section as the exact Rutherford amplitude. For that reason the domain of applicability of the first Born approximation includes the Bethe ridge, even in the high energy region.

The binary encounter peak shows new features when the projectile carries electrons. The target electrons scatter from a partially screened ion and the Bethe ridge reflects properties of the elastic scattering cross section for the complex projectile species. In contrast to the Rutherford cross section, elastic scattering cross sections for complex species may have maxima and minima as functions of the electron energy and angle. Such features have been identified in collisions of highly charged ions with neutral atomic targets [53.12].

The Continuum Electron Capture Cusp

Figure 53.2 shows a sharp cusp-like structure when the momentum of the ejected electron in the projectile frame k' vanishes. Then the ejected electron moves with a velocity exactly equal to the projectile velocity. For charged projectiles, it is virtually impossible to determine whether such electron states are Rydberg states of high principal quantum number n', or continuum states with $E_{k'} = \frac{1}{2}k'^2$ much less than ε_i. Indeed, the physical similarity of such atomic states implies that the cross section for electron capture to states of high n' differs from the ionization cross section near $k' = 0$ only by a density of states factor. This factor is just $dE_{k'}$ for ionization processes and $dE_{n'} = Z_P^2 n'^{-3}$ for capture. It follows that the cross section $d^3\sigma/dE_{k'} d\Omega_{k'}$ is a smooth function of $E_{k'}$ which is nonzero and finite at $E_{k'} = 0$. The Galilean invariant cross section of Fig. 53.2, however, is not smooth; rather it is given by

$$\frac{d^3\sigma}{dk^3} = \frac{d^3\sigma}{dk'^3} = \frac{1}{k'}\frac{d^3\sigma}{dE_{k'} d\Omega_{k'}}. \tag{53.24}$$

Since $d^3\sigma/dE_{k'} d\Omega_{k'}$ is nonzero at $k' = 0$, it follows that the DDCS has a k'^{-1} singularity at $k' = 0$. Experiments measure cross sections averaged over this singular factor. The averaging results in the cusp-shaped feature at $k' = 0$ seen in Fig. 53.2 [53.13–15].

The theoretical description of the cusp feature requires that the electron in the final state move mainly in the field of the projectile rather than that of the target. While the appropriate final state wave function can be introduced into (53.4), the result is quantitatively inaccurate. A more accurate amplitude emerges when the exact amplitude is expanded in powers the interaction potential V_T of the electron with the final state target ion [53.16], since V_T has a much smaller effect than the interaction V_P. Approximate evaluation of the ionization amplitude in an independent particle approximation gives [53.17]

$$T_{fi} = \int d^3 s \, \tilde{V}_T(\boldsymbol{J}+\boldsymbol{s}) \tilde{\varphi}_i(\boldsymbol{s})$$
$$\times \langle \psi_{\boldsymbol{k}'}^-(\boldsymbol{r}) | \exp[i(\boldsymbol{J}+\boldsymbol{s})] | \psi_{\boldsymbol{s}-\boldsymbol{v}}^-(\boldsymbol{r}) \rangle , \qquad (53.25)$$

and

$$\frac{d^3\sigma}{dE_{\boldsymbol{k}} d\Omega_{\boldsymbol{k}}} = (2\pi)^4 \mu^2 \int |T_{fi}|^2 \, d\Omega_{\boldsymbol{K}_f} \qquad (53.26)$$

where μ is the reduced mass given by

$$\mu = M_P(M_P+1)/(M_P+M_T+1) , \qquad (53.27)$$

and $\tilde{\varphi}_i(\boldsymbol{s})$ is the momentum space independent-particle orbital wave function for the active electron in the initial state, $\tilde{V}_T$ is the corresponding effective interaction potential, and the $\psi_{\boldsymbol{k}'}^{\pm}$ are normalized on the momentum scale.

Figure 53.4 gives a pictorial interpretation of this amplitude. The initial momentum distribtution of the electron is given by $\tilde{\varphi}_i(\boldsymbol{s})$. In the projectile frame, this electron has momentum $\boldsymbol{s}-\boldsymbol{v}$ and moves in a projectile continuum state represented by $\psi_{\boldsymbol{s}-\boldsymbol{v}}^+(\boldsymbol{r})$. Owing to the interaction with the target represented by $\exp[i(\boldsymbol{J}+\boldsymbol{s})] \, \tilde{V}_T(\boldsymbol{J}+\boldsymbol{s})$, a transition to the final projectile state $\psi_{\boldsymbol{k}'}^-$ occurs as illustrated in Fig. 53.4 (b). The final state $\psi_{\boldsymbol{k}'}^-$ has a $1/\sqrt{k'}$ normalization that gives rise to the cusp at $\boldsymbol{k}=\boldsymbol{v}$ seen in Fig. 53.2. This picture describes ionization in terms of the free–free transition, $\psi_{\boldsymbol{s}-\boldsymbol{v}}^- \to \psi_{\boldsymbol{k}'}^+$.

The amplitude in (53.25), known as the distorted wave strong potential Born amplitude (DSPB) [53.18], or the projectile impulse approximation amplitude [53.19], also describes binary encounter electrons. Thus the regions of applicability of (53.4) and (53.25) overlap considerably. In the binary encounter region, where $k_{\parallel} > v/2$ and $\boldsymbol{J} \approx 0$, the cross section given by (53.9) and (53.25) reduces to the elastic scattering model (ESM) [53.20], where the incident electron with projectile frame momentum $-\boldsymbol{J}-\boldsymbol{v}$ quasi-elastically scatters
Fig. 53.4a,b Free–free transition picture of ionization. (**a**) Schematic representation of a target electron with momentum $\boldsymbol{s}-\boldsymbol{v}$ in the projectile frame. (**b**) A free–free transition from the projectile eigenstate $\psi_{\boldsymbol{s}-\boldsymbol{v}}^-$ to the final eigenstate $\psi_{\boldsymbol{k}'}^+$ occurs with the target interaction as the transition operator

from the projectile into a final state with projectile frame momentum $\boldsymbol{k}'$. This quasi-elastic cross section is averaged over the initial momentum distribution of the electron $|\tilde{\varphi}_i(-\boldsymbol{J})|^2 \, d^3 J$ so that

$$d^5\sigma^{\text{ESM}} = \left[(2\pi)^4 \frac{k'}{v} |T^{\text{elas}}(\boldsymbol{k}', -\boldsymbol{J}-\boldsymbol{v})|^2 | d\Omega_{\boldsymbol{k}'} \right]$$
$$\times |\tilde{\varphi}_i(-\boldsymbol{J})|^2 \, d^3 J . \qquad (53.28)$$

The projectile frame cross section is recovered upon using the relation $d^3 J = \mu_f \mu_i v \, d\Omega_{\boldsymbol{K}_f} k'^2 \, dk'$ in (53.25).

The two approximations (53.4) and (53.25) describe all of the major features that emerge in the ionization of one-electron targets by fully ionized projectiles. Both theories also incorporate some multi-electron effects that appear when either the target or projectile (or both) have several electrons. Equation (53.28) is useful for describing effects of target ionization by multi-electron projectiles when the projectile electrons remain in their ground state since T^{elas} incorporates, in principle, the exact amplitude for electrons to scatter from the projectile in its ground state. Of course, the multi-electron projectile can also become excited or ionized owing to its interaction with the target electrons. These processes are not incorporated in the ESM cross section (53.28); rather the Born amplitude of (53.4) represents a more tractable theory to analyze these features.

53.2.2 Projectile Electrons

When the incident atomic species carries some attached electrons, these electrons may be removed in the collision with a target. Essentially all of the features that appear for the target electrons also appear for the projectile electrons; however the DDCS is shifted by the Galilean transformation to the projectile frame. The transformation from the laboratory frame to the projectile frame is an essential step for interpreting features of the projectile electrons. This transformation has the effect of spreading out the electron energy distribution since at $\theta_k = 0°$ a small energy interval ΔE_k in the lab frame relates to a small energy interval $\Delta E'_k$ in the projectile frame according to

$$\Delta E_k = \Delta E'_k \left(1 + \frac{v}{\sqrt{2vE_{k'}}} \right) . \tag{53.29}$$

For example, when the projectile energy is 1.5 MeV/au, a projectile frame electron energy interval $0 < E'_k < 0.1\,\mathrm{eV}$ maps into an interval of $\pm 8.3\,\mathrm{eV}$ centered at $E_k = 817\,\mathrm{eV}$. This amplification of both the electron energy and the electron energy interval proves useful for measuring features of projectile species with high resolution [53.21].

53.3 Recent Developments

Added by Mark M. Cassar. The theoretical study of ionization processes in atomic collisions remains an active research field. At present, there are three main quantum mechanical approaches to the simplest colliding systems with one active electron. The first approach is to solve directly the time-dependent Schrödinger equation by taking advantage of modern-day computing power. The accuracy of these calculations, however, is still insufficient, and further computational and technological advancements are necessary. The second approach expands the total wave function in atomic or molecular bases; satisfactory agreement with experimental results is obtained, but at the expense of having to include a large number of basis set members in the expansions. The third approach involves the use of Sturmian expansions, along with a specific scaling and transformation of the wave functions. This technique overcomes many of the difficulties that others suffer from, and at the same time provides the best agreement with experimental data over a broad range of energies.

Problems in our understanding of the ionization process remain, even for the simplest colliding system H^+-H, and extensions and refinements of the present theoretical and experimental methods are needed. The reader is referred to the in-depth review by *Macek* et al. [53.22].

54. Electron–Ion and Ion–Ion Recombination

Electron–ion and ion–ion recombination processes are of key importance in understanding the properties of plasmas, whether they are in the upper atmosphere, the solar corona, or industrial reactors on earth. This is a collection of formulae, expressions, and specific equations that cover the various aspects, approximations, and approaches to electron-ion and ion-ion recombination processes.

54.1 Recombination Processes

54.1.1 Electron−Ion Recombination

This proceeds via the following four processes:
(a) radiative recombination (RR)

$$e^- + A^+(i) \rightarrow A(n\ell) + h\nu \,, \tag{54.1}$$
(b) three-body collisional-radiative recombination

$$e^- + A^+ + e^- \rightarrow A + e^- \,, \tag{54.2a}$$
$$e^- + A^+ + M \rightarrow A + M \,, \tag{54.2b}$$
where the third body can be an electron or a neutral gas.
(c) dielectronic recombination (DLR)

$$e^- + A^{Z+}(i) \rightleftharpoons \left[A^{Z+}(k) - e^- \right]_{n\ell}$$
$$\rightarrow A_{n'\ell'}^{(Z-1)+}(f) + h\nu \,, \tag{54.3}$$
(d) dissociative recombination (DR)

$$e^- + AB^+ \rightarrow A + B^* \,. \tag{54.4}$$

Electron recombination with bare ions can proceed only via (a) and (b), while (c) and (d) provide additional pathways for ions with at least one electron initially or for molecular ions AB^+. Electron radiative capture denotes the combined effect of RR and DLR.

54.1.2 Positive−Ion Negative−Ion Recombination

This proceeds via the following three processes:
(e) mutual neutralization

$$A^+ + B^- \rightarrow A + B^* \,, \tag{54.5}$$

(f) three-body (termolecular) recombination

$$A^+ + B^- + M \rightarrow AB + M \,, \tag{54.6}$$
(g) tidal recombination

$$AB^+ + C^- + M \rightarrow AC + B + M \tag{54.7a}$$
$$\rightarrow BC + A + M \,, \tag{54.7b}$$
where M is some third species (atomic, molecular or ionic). Although (e) always occurs when no gas M is present, it is greatly enhanced by coupling to (f). The dependence of the rate $\hat{\alpha}$ on density N of background gas M is different for all three cases, (e)–(g).

Processes (a), (c), (d) and (e) are elementary processes in that microscopic detailed balance (proper balance) exists with their true inverses, i. e., with photoionization (both with and without autoionization) as in (c) and (a), associative ionization and ion-pair formation as in (d) and (e), respectively. Processes (b), (f) and (g) in general involve a complex sequence of elementary energy-changing mechanisms as collisional and radiative cascade and their overall rates are determined by an input-output continuity equation involving microscopic continuum-bound and bound–bound collisional and radiative rates.

54.1.3 Balances

Proper Balances

Proper balances are detailed microscopic balances between forward and reverse mechanisms that are direct inverses of one another, as in

(a) Maxwellian: $e^-(v_1) + e^-(v_2) \rightleftharpoons e^-(v_1') + e^-(v_2')$,

$$\tag{54.8}$$
where the kinetic energy of the particles is redistributed;

(b) Saha: $e^- + H(n\ell) \rightleftharpoons e^- + H^+ + e^-$ $\qquad$ (54.9)
between direct ionization from and direct recombination into a given level $n\ell$;

(c) Boltzmann: $e^- + H(n\ell) \rightleftharpoons e^- + H(n', \ell')$ $\quad$ (54.10)
between excitation and de-excitation among bound levels;

(d) Planck: $e^- + H^+ \rightleftharpoons H(n\ell) + h\nu$, $\qquad$ (54.11)
which involves interaction between radiation and atoms in photoionization/recombination to a given level $n\ell$.

Improper Balances

Improper balances maintain constant densities via production and destruction mechanisms that are not pure inverses of each other. They are associated with flux activity on a macroscopic level as in the transport of particles into the system for recombination and net production and transport of particles (i. e. e^-, A^+) for ionization. Improper balances can then exist between dissimilar elementary production–depletion processes as in (a) coronal balance between electron-excitation into and radiative decay out of level n. (b) radiative

balance between radiative capture into and radiative cascade out of level n. (c) excitation saturation balance between upward collisional excitations $n-1 \to n \to n+$ 1 between adjacent levels. (d) de-excitation saturation balance between downward collisional de-excitations $n+1 \to n \to n-1$ into and out of level n.

54.2 Collisional–Radiative Recombination

Radiative Recombination

Process (54.1) involves a free-bound electronic transition with radiation spread over the recombination continuum. It is the inverse of photoionization without autoionization and favors high energy gaps with transitions to low $n \approx 1, 2, 3$ and low angular momentum states $\ell \approx 0, 1, 2$ at higher electron energies.

Three–Body Electron–Ion Recombination

Processes (54.2a,b) favor free-bound collisional transitions to high levels n, within a few $k_B T$ of the ionization limit of $A(n)$ and collisional transitions across small energy gaps. Recombination becomes stabilized by collisional-radiative cascade through the lower bound levels of A. Collisions of the $e^- - A^+$ pair with third bodies becomes more important for higher levels n and radiative emission is important down to and among the lower levels n. In optically thin plasmas this radiation is lost, while in optically thick plasmas it may be re-absorbed. At low electron densities radiative recombination dominates with predominant transitions taking place to the ground level. For process (54.2a) at high electron densities, three-body collisions into high Rydberg levels dominate, followed by cascade which is collision dominated at low electron temperatures T_e and radiation dominated at high T_e. For process (54.2b) at low gas densities N, the recombination is collisionally-radiatively controlled while, at high N, it eventually becomes controlled by the rate of diffusional drift (54.61) through the gas M.

Collisional–Radiative Recombination

Here the cascade collisions and radiation are coupled via the continuity equation. The population n_i of an individual excited level i of energy E_i is determined by the rate equations

$$\frac{dn_i}{dt} = \frac{\partial n_i}{\partial t} + \nabla \cdot (n_i \boldsymbol{v}_i) \tag{54.12}$$

$$= \sum_{i \neq f} \left[n_f v_{fi} - n_i v_{if} \right] = P_i - n_i D_i , \tag{54.13}$$

which involve temporal and spatial relaxation in (54.12) and collisional-radiative production rates P_i and destruction frequencies D_i of the elementary processes included in (54.13). The total collisional and radiative transition frequency between levels i and f is v_{if} and the f-sum is taken over all discrete and continuous (c) states of the recombining species. The transition frequency v_{if} includes all contributing elementary processes that directly link states i and f, e.g., collisional excitation and de-excitation, ionization ($i \to c$) and recombination ($c \to i$) by electrons and heavy particles, radiative recombination ($c \to i$), radiative decay ($i \to f$), possibly radiative absorption for optically thick plasmas, autoionization and dielectronic recombination.

Production Rates and Processes

The production rate for a level i is

$$P_i = \sum_{f \neq i} n_e n_f K_{fi}^c + n_e^2 N^+ k_{ci}^R$$
$$+ \sum_{f > i} n_f \left(A_{fi} + B_{fi} \rho_v \right)$$
$$+ n_e N^+ \left(\hat{\alpha}_i^{RR} + \beta_i \rho_v \right) , \tag{54.14}$$

where the terms in the above order represent (1) collisional excitation and de-excitation by $e^- - A(f)$ collisions, (2) three-body $e^- - A^+$ collisional recombination into level i, (3) spontaneous and stimulated radiative cascade, and (4) spontaneous and stimulated radiative recombination.

Destruction Rates and Processes

The destruction rate for a level i is

$$n_i D_i = n_e n_i \sum_{f \neq i} K_{if}^c + n_e n_i S_i$$
$$+ n_i \sum_{f < i} \left(A_{if} + B_{if} \rho_v \right)$$
$$+ n_i \sum_{f > i} B_{if} \rho_v + n_i B_{ic} \rho_v , \tag{54.15}$$

where the terms in the above order represent (1) collisional destruction, (2) collisional ionization,

(3) spontantaneous and stimulated emission, (4) photo-excitation, and (5) photoionization.

54.2.1 Saha and Boltzmann Distributions

Collisions of $A(n)$ with third bodies such as e^- and M are more rapid than radiative decay above a certain excited level n^*. Since each collision process is accompanied by its exact inverse the principle of detailed balance determines the population of levels $i > n^*$.

Saha Distribution
This connects equilibrium densities $\tilde{n}_i$, $\tilde{n}_e$ and $\tilde{N}^+$ of bound levels i, of free electrons at temperature T_e and of ions by

$$\frac{\tilde{n}_i}{\tilde{n}_e \tilde{N}^+} = \left(\frac{g(i)}{g_e g_A^+}\right) \frac{h^3}{(2\pi m_e k T_e)^{3/2}} \exp(I_i/k_B T_e) ,$$
(54.16)

where the electronic statistical weights of the free electron, the ion of charge $Z+1$ and the recombined $e^- - A^+$ species of net charge Z and ionization potential I_i are $g_e = 2$, g_A^+ and $g(i)$, respectively. Since $n_i \leq \tilde{n}_i$ for all i, then the Saha–Boltzmann distributions imply that $n_1 \gg n_i$ and $n_e \gg n_i$ for $i \neq 1, 2$, where $i = 1$ is the ground state.

Boltzmann Distribution
This connects the equilibrium populations of bound levels i of energy E_i by

$$\tilde{n}_i/\tilde{n}_j = [g(i)/g(j)] \exp\left[-(E_i - E_j)/k_B T_e\right] .$$
(54.17)

54.2.2 Quasi–Steady State Distributions

The reciprocal lifetime of level i is the sum of radiative and collisional components and is therefore shorter than the pure radiative lifetime $\tau_R \approx 10^{-7} Z^{-4}$ s. The lifetime τ_1 for the ground level is collisionally controlled, is dependent upon n_e, and generally is within the range of 10^2 and 10^4 s for most laboratory plasmas and the solar atmosphere. The excited level lifetimes τ_i are then much shorter than τ_1. The (spatial) diffusion or plasma decay (recombination) time is then much longer than τ_i and the total number of recombined species is much smaller than the ground-state population n_1. The recombination proceeds on a timescale much longer than the time for population/destruction of the excited levels. The condition for quasisteady state, or

QSS-condition, $dn_i/dt = 0$ for the bound levels $i \neq 1$, therefore holds. The QSS distributions n_i therefore satisfy $P_i = n_i D_i$.

54.2.3 Ionization and Recombination Coefficients

Under QSS, the continuity equation (54.13) then reduces to a finite set of simultaneous equations $P_i = n_i D_i$. This gives a matrix equation which is solved numerically for $n_i(i \neq 1) \leq \tilde{n}_i$ in terms of n_1 and n_e. The net ground-state population frequency per unit volume (cm^{-3} s^{-1}) can then be expressed as

$$\frac{dn_1}{dt} = n_e N^+ \hat{\alpha}_{CR} - n_e n_1 S_{CR} ,$$
(54.18)

where $\hat{\alpha}_{CR}$ and S_{CR}, respectively, are the overall rate coefficients for recombination and ionization via the collisional-radiative sequence. The determined $\hat{\alpha}_{CR}$ equals the direct $(c \to 1)$ recombination to the ground level supplemented by the net collisional-radiative cascade from that portion of bound-state population which originated from the continuum. The determined S_{CR} equals direct depletion (excitation and ionization) of the ground state reduced by the de-excitation collisional radiative cascade from that portion of the bound levels accessed originally from the ground level. At low n_e, $\hat{\alpha}_{CR}$ and S_{CR} reduce, respectively, to the radiative recombination coefficient summed over all levels and to the collisional ionization coefficient for the ground level.

$\mathcal{C}$, $\mathcal{E}$ and $\mathcal{S}$ Blocks of Energy Levels
For the recombination processes (54.2a), (54.2b) and (54.6) which involve a sequence of elementary reactions, the $e^- - A^+$ or $A^+ - B^-$ continuum levels and the ground $A(n = 1)$ or the lowest vibrational levels of AB are therefore treated as two large particle reservoirs of reactants and products. These two reservoirs act as reactant and as sink blocks $\mathcal{C}$ and $\mathcal{S}$ which are, respectively, drained and filled at the same rate via a conduit of highly excited levels which comprise an intermediate block of levels $\mathcal{E}$. This $\mathcal{C}$ draining and $\mathcal{S}$ filling proceeds, via block $\mathcal{E}$, on a timescale large compared with the short time for a small amount from the reservoirs to be re-distributed within block $\mathcal{E}$. This forms the basis of QSS.

54.2.4 Working Rate Formulae

For electron–atomic–ion collisional-radiative recombination (54.2a), detailed QSS calculations can be fitted by

the rate [54.1]

$$\hat{\alpha}_{\mathrm{CR}} = \left(3.8 \times 10^{-9} T_{\mathrm{e}}^{-4.5} n_{\mathrm{e}} + 1.55 \times 10^{-10} T_{\mathrm{e}}^{-0.63} \right.$$
$$\left. + 6 \times 10^{-9} T_{\mathrm{e}}^{-2.18} n_{\mathrm{e}}^{0.37} \right) \mathrm{cm^3\, s^{-1}} \qquad (54.19)$$

agrees with experiment for a Lyman α optically thick plasma with n_{e} and T_{e} in the range $10^9\,\mathrm{cm^{-3}} \le n_{\mathrm{e}} \le 10^{13}\,\mathrm{cm^{-3}}$ and $2.5\,\mathrm{K} \le T_{\mathrm{e}} \le 4000\,\mathrm{K}$. The first term is the pure collisional rate (54.49), the second term is the radiative cascade contribution, and the third term arises from collisional-radiative coupling.

For $(\mathrm{e^-} - \mathrm{He_2^+})$ recombination in a high (5–100 Torr) pressure helium afterglow the rate for (54.2b) is [54.2]

$$\hat{\alpha}_{\mathrm{CR}} = \left[(4 \pm 0.5) \times 10^{-20} n_{\mathrm{e}}\right] (T_{\mathrm{e}}/293)^{-(4 \pm 0.5)}$$
$$+ \left[(5 \pm 1) \times 10^{-27} n(\mathrm{He})\right.$$
$$\left. + (2.5 \pm 2.5) \times 10^{-10}\right]$$
$$\times (T_{\mathrm{e}}/293)^{-(1 \pm 1)}\,\mathrm{cm^3/s}. \qquad (54.20)$$

The first two terms are in accord with the purely collisional rates (54.49) and (54.52b), respectively.

54.3 Macroscopic Methods

54.3.1 Resonant Capture–Stabilization Model: Dissociative and Dielectronic Recombination

The electron is captured dielectronically (54.41) into an energy-resonant long-lived intermediate collision complex of super-excited states d which can autoionize or be stabilized irreversibly into the final product channel f either by molecular fragmentation

$$\mathrm{e^-} + AB^+(i) \underset{v_a}{\overset{k_\mathrm{c}}{\rightleftharpoons}} AB^{**} \overset{v_\mathrm{s}}{\rightarrow} A + B^* , \qquad (54.21)$$
as in direct dissociative recombination (DR), or by emission of radiation as in dielectronic recombination (DLR)

$$\mathrm{e^-} + A^{Z+}(i) \underset{v_a}{\overset{k_\mathrm{c}}{\rightleftharpoons}} \left[A^{Z+}(k) - \mathrm{e^-}\right]_{n\ell}$$
$$\overset{v_\mathrm{s}}{\rightarrow} A_{n'\ell'}^{(Z-1)+}(f) + h\nu . \qquad (54.22)$$
Production Rate of Super-Excited States d

$$\frac{\mathrm{d}n_d^*}{\mathrm{d}t} = n_{\mathrm{e}} N^+ k_\mathrm{c}(d) - n_d^* \left[v_A(d) + v_\mathrm{S}(d)\right] ; \quad (54.23)$$

$$v_A(d) = \sum_{i'} v_a(d \rightarrow i') , \qquad (54.24a)$$

$$v_\mathrm{S}(d) = \sum_{f'} v_\mathrm{s}(d \rightarrow f') . \qquad (54.24b)$$

Steady-State Distribution

For a steady-state distribution, the capture volume is

$$\frac{n_d^*}{n_{\mathrm{e}} N^+} = \frac{k_\mathrm{c}(d)}{v_A(d) + v_\mathrm{S}(d)} . \qquad (54.25)$$

Recombination Rate and Stabilization Probability

The recombination rate to channel f is

$$\hat{\alpha}_f = \sum_d \left(\frac{k_\mathrm{c}(d) v_\mathrm{s}(d \rightarrow f)}{v_A(d) + v_\mathrm{S}(d)}\right) , \qquad (54.26a)$$

and the rate to all product channels is

$$\hat{\alpha} = \sum_d \frac{k_\mathrm{c}(d) v_\mathrm{S}(d)}{v_A(d) + v_\mathrm{S}(d)} . \qquad (54.26b)$$

In the above, the quantities

$$P_f^{\mathrm{S}}(d) = v_\mathrm{s}(d \rightarrow f) / \left[v_A(d) + v_\mathrm{S}(d)\right] , \qquad (54.27)$$

$$P^{\mathrm{S}}(d) = v_\mathrm{S}(d) / \left[v_A(d) + v_\mathrm{S}(d)\right] , \qquad (54.28)$$

represent the corresponding stabilization probabilities.

Macroscopic Detailed Balance and Saha Distribution

$$K_{di}(T) = \frac{\tilde{n}_d^*}{\tilde{n}_{\mathrm{e}} \tilde{N}^+} = \frac{k_\mathrm{c}(d)}{v_a(d \rightarrow i)} = k_\mathrm{c}(d) \tau_a(d \rightarrow i) \qquad (54.29a)$$

$$= \frac{h^3}{(2\pi m_{\mathrm{e}} k_\mathrm{B} T)^{3/2}} \left(\frac{\omega(d)}{2\omega^+}\right)$$
$$\times \exp\left(-E_{di}^*/k_\mathrm{B} T\right) , \qquad (54.29b)$$

where E_{di}^* is the energy of super-excited neutral levels AB^{**} above that for ion level $AB^+(i)$, and ω are the corresponding statistical weights.

Alternative Rate Formula

$$\hat{\alpha}_f = \sum_d K_{di} \left(\frac{v_a(d \rightarrow i) v_\mathrm{s}(d \rightarrow f)}{v_A(d) + v_\mathrm{S}(d)}\right) . \qquad (54.30)$$

Normalized Excited State Distributions

$$\rho_d = n_d^*/\tilde{n}_d^* = \frac{\nu_a(d \to i)}{[\nu_A(d) + \nu_S(d)]} , \qquad (54.31)$$

$$\hat{\alpha} = \sum_d k_c(d) P^S(d) = \sum_d K_{di} \rho_d \nu_S(d) \qquad (54.32a)$$

$$= \sum_d k_c(d) [\rho_d \nu_S(d) \tau_a(d \to i)] . \qquad (54.32b)$$

Although equivalent, (54.26a) and (54.30) are normally invoked for (54.21) and (54.22), respectively, since $P^S \leq 1$ for DR so that $\hat{\alpha}_{DR} \to k_c$; and $\nu_A \gg \nu_S$ for DLR with $n \ll 50$ so that $\hat{\alpha} \to K_{di} \nu_S$. For $n \gg 50$, $\nu_S \gg \nu_A$ and $\hat{\alpha} \to k_c$. The above results (54.26a) and (54.30) can also be derived from microscopic Breit–Wigner scattering theory for isolated (nonoverlapping) resonances.

54.3.2 Reactive Sphere Model: Three-Body Electron–Ion and Ion–Ion Recombination

Since the Coulomb attraction cannot support quasibound levels, three body electron–ion and ion–ion recombination do not in general proceed via time-delayed resonances, but rather by reactive (energy-reducing) collisions with the third body M. This is particularly effective for A–B separations $R \leq R_0$, as in the sequence

$$A + B \underset{\nu_d}{\overset{k_c}{\rightleftharpoons}} AB^*(R \leq R_0) , \qquad (54.33a)$$

$$AB^*(R \leq R_0) + M \underset{\nu_{-s}}{\overset{\nu_s}{\rightleftharpoons}} AB + M . \qquad (54.33b)$$
In contrast to (54.21) and (54.22) where the stabilization is irreversible, the forward step in (54.33b) is reversible. The sequence (54.33a) and (54.33b) represents a closed system where thermodynamic equilibrium is eventually established.

Steady State Distribution of AB* Complex

$$n^* = \left(\frac{k_c}{\nu_s + \nu_d}\right) n_A(t) n_B(t) + \left(\frac{\nu_{-s}}{\nu_s + \nu_d}\right) n_s(t) . \qquad (54.34)$$

Saha and Boltzmann balances:

Saha: $\tilde{n}_A \tilde{n}_B k_c = \tilde{n}^* \nu_d$,

Boltzmann: $\tilde{n}_s \nu_{-s} = \tilde{n}^* \nu_s$. $\qquad (54.35)$

$\tilde{n}^*$ is in Saha balance with reactant block $\mathcal{C}$ and in Boltzmann balance with product block $\mathcal{S}$.

Normalized Distributions

$$\rho^* = \frac{n^*}{\tilde{n}^*} = P^D \gamma_c(t) + P^S \gamma_s(t) , \qquad (54.36a)$$

$$\gamma_c(t) = \frac{n_A(t) n_B(t)}{\tilde{n}_A \tilde{n}_B} , \qquad \gamma_s(t) = \frac{n_s(t)}{\tilde{n}_s} . \qquad (54.36b)$$

Stabilization and Dissociation Probabilities

$$P^S = \frac{\nu_s}{(\nu_s + \nu_d)} , \qquad P^D = \frac{\nu_d}{(\nu_s + \nu_d)} . \qquad (54.37)$$

Time Dependent Equations

$$\frac{dn_c}{dt} = -k_c P^S \tilde{n}_A \tilde{n}_B [\gamma_c(t) - \gamma_s(t)] , \qquad (54.38a)$$

$$\frac{dn_s}{dt} = -\nu_{-s} P^D \tilde{n}_s [\gamma_s(t) - \gamma_c(t)] , \qquad (54.38b)$$

$$\frac{dn_c}{dt} = -\hat{\alpha}_3 n_A(t) n_B(t) + k_d n_s(t) . \qquad (54.39)$$

where the recombination rate coefficient (cm^3/s) and dissociation frequency are, respectively,

$$\hat{\alpha}_3 = k_c P^S = \frac{k_c \nu_s}{(\nu_s + \nu_d)} , \qquad (54.40)$$

$$k_d = \nu_{-s} P^D = \frac{\nu_{-s} \nu_d}{(\nu_s + \nu_d)} , \qquad (54.41)$$

which also satisfy the macroscopic detailed balance relation

$$\hat{\alpha}_3 \tilde{n}_A \tilde{n}_B = k_d \tilde{n}_s . \qquad (54.42)$$

Time Independent Treatment

The rate $\hat{\alpha}_3$ given by the time dependent treatment can also be deduced by viewing the recombination process as a source block $\mathcal{C}$ kept fully filled with dissociated species A and B maintained at equilibrium concentrations $\tilde{n}_A, \tilde{n}_B$ (i.e. $\gamma_c = 1$) and draining at the rate $\hat{\alpha}_3 \tilde{n}_A \tilde{n}_B$ through a steady-state intermediate block $\mathcal{E}$ of excited levels into a fully absorbing sink block $\mathcal{S}$ of fully associated species AB kept fully depleted with $\gamma_s = 0$ so that there is no backward re-dissociation from block $\mathcal{S}$. The frequency k_d is deduced as if the reverse scenario, $\gamma_s = 1$ and $\gamma_c = 0$, holds. This picture uncouples $\hat{\alpha}$ and k_d, and allows each coefficient to be calculated independently. Both dissociation (or ionization) and association (recombination) occur within block $\mathcal{E}$.

If $\gamma_c = 1$ and $\gamma_s = 0$, then

$$\rho^* = n^*/\tilde{n}^* = \nu_d/(\nu_s + \nu_d) , \qquad (54.43a)$$

$$K = \tilde{n}^*/\tilde{n}_A \tilde{n}_B = k_c/\nu_d = k_c \tau_d , \qquad (54.43b)$$

$$P^S = \nu_s/(\nu_s + \nu_d) = \rho^* \nu_s \tau_s , \qquad (54.43c)$$

and the recombination coefficient is

$$\hat{\alpha} = k_c P^S = k_c \left(\rho^* \nu_s \tau_d \right) = K \rho^* \nu_s . \quad (54.44)$$

Microscopic Generalization

From (54.167), the microscopic generalizations of rate (54.40) and probability (54.43c) are, respectively,

$$\hat{\alpha} = \overline{v} \int_0^\infty \varepsilon e^{-\varepsilon} d\varepsilon \int_0^{b_0} 2\pi b \, db P^S(\varepsilon, b; R_0) , \quad (54.45a)$$

$$P^S(\varepsilon, b; R_0) = \oint_{R_i}^{R_0} \rho_i(R) \nu_i^b(R) \, dt \equiv \langle \rho \nu_s \rangle \tau_d , \quad (54.45b)$$

where $\rho_i(R) = n(\varepsilon, b; R)/\tilde{n}(\varepsilon, b; R)$; $\nu_i^{(b)}$ is the frequency (54.164a) of $(A-B)-M$ continuum-bound collisional transitions at fixed $A-B$ separation R, R_i is the pericenter of the orbit, $|i\rangle \equiv |\varepsilon, b\rangle$, and

$$b_0^2 = R_0^2 [1 - V(R)/E] , \quad \varepsilon = E/k_B T , \quad (54.45c)$$

$$\hat{\alpha} \equiv k_c \left\langle P^S \right\rangle_{\varepsilon, b} , \quad \overline{v} = (8k_B T/\pi M_{AB})^{1/2} , \quad (54.45d)$$

$$k_c = \left\{ \pi R_0^2 [1 - V(R_0)/k_B T] \, \overline{v} \right\} . \quad (54.45e)$$

where M_{AB} is the reduced mass of A and B.

Low Gas Densities

Here $\rho_i(R) = 1$ for $E > 0$,

$$P^S(\varepsilon, b; R_0) = \oint_{R_i}^{R_0} \nu(t) \, dt = \oint_{R_i}^{R_0} ds/\lambda_i . \quad (54.46)$$

$\lambda_i = (N\sigma)^{-1}$ is the microscopic path length towards the $(A-B)-M$ reactive collision with frequency $\nu = N\nu\sigma$. For λ_i constant, the rate (54.45a) reduces at low N to

$$\hat{\alpha} = (v\sigma_0 N) \int_0^{R_0} \left(1 - \frac{V(R)}{k_B T} \right) 4\pi R^2 \, dR \quad (54.47)$$

which is linear in the gas density N.

54.3.3 Working Formulae for Three−Body Collisional Recombination at Low Density

For three-body ion–ion collisional recombination of the form $A^+ + B^- + M$ in a gas at low density N, set $V(R) = -e^2/R$. Then (54.47) yields

$$\hat{\alpha}^c(T) = \left(\frac{8k_B T}{\pi M_{AB}} \right)^{1/2} \frac{4}{3} \pi R_0^3 \left(1 + \frac{3}{2} \frac{R_e}{R_0} \right) (\sigma_0 N) , \quad (54.48)$$

where $R_e = e^2/k_B T$, and the trapping radius R_0, determined by the classical variational method, is $0.41 R_e$, in agreement with detailed calculation. The special cases are:

(a) $e^- + A^+ + e^-$

Here, $\sigma_0 = \frac{1}{9}\pi R_e^2$ for $(e^- - e^-)$ collisions for scattering angles $\theta \geq \pi/2$ so that

$$\hat{\alpha}_{ee}^c(T) = 2.7 \times 10^{-20} \left(\frac{300}{T} \right)^{4.5} n_e \text{ cm}^3 \text{ s}^{-1} \quad (54.49)$$

in agreement with *Mansbach* and *Keck* [54.3].

(b) $A^+ + B^- + M$

Here, $\sigma_0 \overline{v} \approx 10^{-9} \text{ cm}^3 \text{ s}^{-1}$, which is independent of T for polarization attraction. Then

$$\hat{\alpha}_3(T) = 2 \times 10^{-25} \left(\frac{300}{T} \right)^{2.5} N \text{ cm}^3 \text{ s}^{-1} . \quad (54.50)$$

(c) $e^- + A^+ + M$

Only a small fraction $\delta = 2m/M$ of the electron's energy is lost upon $(e^- - M)$ collision so that (54.45a) for constant λ is modified to

$$\hat{\alpha}_{eM} = \sigma_0 N \int_0^{R_0} 4\pi R^2 \, dR \int_0^{E_m} \tilde{n}(R, E) v \, dE \quad (54.51a)$$

$$= \overline{v}_e \sigma_0 N \int_0^{R_0} 4\pi R^2 \, dR \int_0^{\varepsilon_m} \left(1 - \frac{V(R)}{E} \right) \varepsilon e^{-\varepsilon} \, d\varepsilon \quad (54.51b)$$

where $\varepsilon = E/k_B T$, and $E_m = \delta e^2/R = \varepsilon_m k_B T$ is the maximum energy for collisional trapping. Hence,

$$\hat{\alpha}_{eM}(T_e) = 4\pi\delta \left(\frac{8k_B T_e}{\pi m_e} \right)^{1/2} R_e^2 R_0 [\sigma_0 N] \quad (54.52a)$$

$$\approx \frac{10^{-26}}{M} \left(\frac{300}{T} \right)^{2.5} N \text{cm}^3 \text{ s}^{-1} , \quad (54.52b)$$

where the mass M of the gas atom is now in u. This result agrees with the energy diffusion result of *Pitaevskiĭ* [54.4] when R_0 is taken as the Thomson radius $R_T = \frac{2}{3} R_e$.

54.3.4 Recombination Influenced by Diffusional Drift at High Gas Densities

Diffusional–Drift Current

The drift current of A^+ towards B^- in a gas under an A^+–B^- attractive potential $V(R)$ is

$$\boldsymbol{J}(R) = -D\nabla n(R) - \left[\frac{K}{e}\nabla V(R)\right] n(R) \quad (54.53a)$$

$$= -\left(D\tilde{N}_A\tilde{N}_B\,e^{-V(R)/k_BT}\frac{\partial\rho}{\partial R}\right)\hat{\boldsymbol{R}}. \quad (54.53b)$$

Relative Diffusion and Mobility Coefficients

$$D = D_A + D_B\,,$$
$$K = K_A + K_B\,, \quad De = K(k_BT)\,, \quad (54.54)$$

where the D_i and K_i are, respectively, the diffusion and mobility coefficients of species i in gas M.

Normalized Ion–Pair R–Distribution

$$\rho(R) = \frac{n(R)}{\tilde{N}_A\tilde{N}_B\exp\left[-V(R)/k_BT\right]}\,. \quad (54.55)$$

Continuity Equations for Currents and Rates

$$\frac{\partial n}{\partial t} + \nabla\cdot\boldsymbol{J} = 0\,, \quad R \geq R_0 \quad (54.56a)$$

$$\hat{\alpha}_{RN}(R_0)\rho(R_0) = \hat{\alpha}\rho(\infty) \quad (54.56b)$$

The rate of reaction for ion-pairs with separations $R \leq R_0$ is $\alpha_{RN}(R_0)$. This is the recombination rate that would be obtained for a thermodynamic equilibrium distribution of ion pairs with $R \geq R_0$, i.e. for $\rho(R \geq R_0) = 1$.

Steady–State Rate of Recombination

$$\hat{\alpha}\tilde{N}_A\tilde{N}_B = \int\limits_{R_0}^{\infty}\left(\frac{\partial n}{\partial t}\right)\,\mathrm{d}\boldsymbol{R} = -4\pi R_0^2 J(R_0)\,. \quad (54.57)$$

Steady–State Solution

$$\rho(R) = \rho(\infty)\left(1 - \frac{\hat{\alpha}}{\hat{\alpha}_{TR}(R)}\right)\,, \quad R \geq R_0$$
$$(54.58a)$$

$$\rho(R_0) = \rho(\infty)\left[\hat{\alpha}/\hat{\alpha}_{RN}(R_0)\right]\,. \quad (54.58b)$$

Recombination Rate

$$\hat{\alpha} = \frac{\hat{\alpha}_{RN}(R_0)\hat{\alpha}_{TR}(R_0)}{\hat{\alpha}_{RN}(R_0) + \hat{\alpha}_{TR}(R_0)} \quad (54.59a)$$

$$\rightarrow \begin{cases} \hat{\alpha}_{RN}, & N \rightarrow 0 \\ \hat{\alpha}_{TR}, & N \rightarrow \infty\,. \end{cases} \quad (54.59b)$$

Diffusional–Drift Transport Rate

$$\hat{\alpha}_{TR}(R_0) = 4\pi D\left(\int\limits_{R_0}^{\infty}\frac{e^{V(R)/k_BT}}{R^2}\,\mathrm{d}R\right)^{-1}. \quad (54.60)$$

With $V(R) = -e^2/R$,

$$\hat{\alpha}_{TR}(R_0) = 4\pi Ke\left[1 - \exp(-R_e/R_0)\right]^{-1}\,, \quad (54.61)$$

where $R_e = e^2/k_BT$ provides a natural unit of length.

Langevin Rate

For $R_0 \ll R_e$, the transport rate

$$\hat{\alpha}_{TR} \rightarrow \hat{\alpha}_L = 4\pi Ke\,, \quad (54.62)$$

tends to the Langevin rate which varies as N^{-1}.

Reaction Rate

When R_0 is large enough that R_0-pairs are in (E, L^2) equilibrium (54.167),

$$\hat{\alpha}_{RN}(R_0) = \bar{v}\int\limits_0^{\infty}\varepsilon\,e^{-\varepsilon}\,\mathrm{d}\varepsilon\int\limits_0^{b_0}2\pi b\,\mathrm{d}b\,P^S(\varepsilon, b; R_0)$$
$$(54.63a)$$

$$\equiv \bar{v}\int\limits_0^{\infty}\varepsilon\,e^{-\varepsilon}\,\mathrm{d}\varepsilon\left[\pi b_0^2 P^S(\varepsilon; R_0)\right] \quad (54.63b)$$

$$\equiv \bar{v}\pi b_{max}^2 P^S(R_0)\,, \quad (54.63c)$$

where

$$b_0^2 = R_0^2\left[1 - V(R_0)/E\right]\,, \quad \varepsilon = E/k_BT\,, \quad (54.64a)$$

$$\bar{v} = (8kT/\pi M_{AB})^{1/2}\,, \quad (54.64b)$$

$$b_{max}^2 = R_0^2\left(1 - \frac{V(R_0)}{k_BT}\right)\,. \quad (54.64c)$$

The probability P^S and its averages over b and (b, E) for reaction between pairs with $R \leq R_0$ is determined in (54.63a–c) from solutions of coupled master equations. P^S increases linearly with N initially and tends to unity

at high N. The recombination rate (54.59a) with (54.63a) and (54.61) therefore increases linearly with N initially, reaches a maximum when $\hat{\alpha}_{TR} \approx \hat{\alpha}_{RN}$ and then decreases eventually as N^{-1}, in accord with (i).

Reaction Probability

The classical absorption solution of (54.157) is

$$P^S(E, b; R_0) = 1 - \exp\left(-\oint_{R_i}^{R_0} \frac{ds_i}{\lambda_i}\right).$$ (54.65)

With the binary decomposition $\lambda_i^{-1} = \lambda_{iA}^{-1} + \lambda_{iB}^{-1}$,

$$P^S = P_A + P_B - P_A\,P_B.$$ (54.66)

Exact b^2–Averaged Probability

With $V_c = -e^2/R$ for the A^+–B^- interaction in (54.63b), and at low gas densities N,

$$P_{A,B}(E, R_0) = \frac{\frac{4R_0}{3\lambda_{A,B}}\left(1 - \frac{3V_c(R_0)}{2E_i}\right)}{[1 - V_c(R_0)/E_i]}$$ (54.67)

appropriate for constant mean free path λ_i.

(E, b^2)–Averaged Probability

$P^S(R_0)$ in (54.63c) at low gas density is

$$P_{A,B}(R_0) = P_{A,B}(E = k_B T, R_0).$$ (54.68)

Thomson Trapping Distance

When the kinetic energy gained from Coulomb attraction is assumed lost upon collision with third bodies,

then bound $A - B$ pairs are formed with $R \le R_T$. Since $E = \frac{3}{2}k_B T - e^2/R$, then

$$R_T = \frac{2}{3}\left(\frac{e^2}{k_B T}\right) = \frac{2}{3}R_e.$$ (54.69)

Thomson Straight–Line Probability

The $E \to \infty$ limit of (54.65) is

$$P_{A,B}^T(b; R_T) = 1 - \exp\left[-2(R_T^2 - b^2)/\lambda_{A,B}\right].$$ (54.70)

The b^2-average is the Thomson probability

$$P_{A,B}^T(R_T) = 1 - \frac{1}{2X^2}\left[1 - e^{-2X}(1 + 2X)\right]$$ (54.71a)

for reaction of $(A - B)$ pairs with $R \le R_T$. As $N \to 0$

$$P_{A,B}^T(R_T) \to \frac{4}{3}X\left(1 - \frac{3}{4}X + \frac{2}{5}X^2 - \frac{1}{6}X^3 + \cdots\right)$$ (54.71b)

and tends to unity at high N. $X = R_T/\lambda_{A,B} = N(\sigma_0 R_T)$. These probabilites have been generalized [54.5] to include hyperbolic and general trajectories.

Thomson Reaction Rate

$$\hat{\alpha}_T = \pi R_T^2 \bar{v}\left(P_A^T + P_B^T - P_A^T P_B^T\right)$$

$$\to \begin{cases} \frac{4}{3}\pi R_T^3(\lambda_A^{-1} + \lambda_B^{-1}), & N \to 0 \\ \pi R_T^2 \bar{v}, & N \to \infty. \end{cases}$$ (54.72)

54.4 Dissociative Recombination

54.4.1 Curve-Crossing Mechanisms

Direct Process.

Dissociative recombination (DR) for diatomic ions can occur via a crossing at R_X between the bound and repulsive potential energy curves $V^+(R)$ and $V_d(R)$ for AB^+ and AB^{**}, respectively. Here, DR involves the two-stage sequence

$$e^- + AB^+(v_i) \underset{v_a}{\overset{k_c}{\rightleftharpoons}} (AB^{**})_R \xrightarrow{v_d} A + B^*. \quad (54.73)$$
The first stage is dielectronic capture whereby the free electron of energy $\varepsilon = V_d(R) - V^+(R)$ excites an electron of the diatomic ion AB^+ with internal separation R and is then resonantly captured by the ion, at rate k_c, to

form a repulsive state d of the doubly excited molecule AB^{**}, which in turn can either autoionize at probability frequency v_a, or else in the second stage predissociate into various channels at probability frequency v_d. This competition continues until the (electronically excited) neutral fragments accelerate past the crossing at R_X. Beyond R_X the increasing energy of relative separation reduces the total electronic energy to such an extent that autoionization is essentially precluded and the neutralization is then rendered permanent past the stabilization point R_X. This interpretation [54.6] has remained intact and robust in the current light of ab initio quantum chemistry and quantal scattering calculations for the simple diatomics $\left(O_2^+, N_2^+, Ne_2^+, \text{etc.}\right)$. Mechanism (54.73) is termed the direct process which, in terms

of the macroscopic frequencies in (54.73), proceeds at the rate

$$\hat{\alpha} = k_c P_S = k_c \left[v_d / (v_a + v_d) \right] , \qquad (54.74)$$

where P_S is probability for $A - B^*$ survival against autoionization from the initial capture at R_c to the crossing point R_X. Configuration mixing theories of this direct process are available in the quantal [54.7] and semiclassical-classical path formulations [54.8].

Indirect Process

In the three-stage sequence

$$e^- + AB^+(v_i^+) \rightarrow \left[AB^+(v_f) - e^- \right]_n \rightarrow (AB^{**})_d$$
$$\rightarrow A + B^* \qquad (54.75)$$
the so-called indirect process [54.7] might contribute. Here the accelerating electron loses energy by vibrational excitation $(v_i^+ \rightarrow v_f)$ of the ion and is then resonantly captured into a Rydberg orbital of the bound molecule AB^* in vibrational level v_f, which then interacts one way (via configuration mixing) with the doubly excited repulsive molecule AB^{**}. The capture initially proceeds via a small effect – vibronic coupling (the matrix element of the nuclear kinetic energy) induced by the breakdown of the Born-Oppenheimer approximation – at certain resonance energies $\varepsilon_n = E(v_f) - E(v_i^+)$ and, in the absence of the direct channel (54.73), would therefore be manifest by a series of characteristic very narrow Lorentz profiles in the cross section. Uncoupled from (54.73) the indirect process would augment the rate. Vibronic capture proceeds more easily when $v_f = v_i^+ + 1$ so that Rydberg states with $n \approx 7 - 9$ would be involved $\left[\text{for } H_2^+ (v_i^+ = 0) \right]$ so that the resulting longer periods of the Rydberg electron would permit changes in nuclear motion to compete with the electronic dissociation. Recombination then proceeds as in the second stage of (54.73), i.e., by electronic coupling to the dissociative state d at the crossing point. A multichannel quantum defect theory [54.9] has combined the direct and indirect mechanisms

Interrupted Recombination

The process

$$e^- + AB^+(v_i) \underset{v_a}{\overset{k_c}{\rightleftharpoons}} (AB^{**})_d \overset{v_d}{\rightarrow} A + B^*$$

$$v_{nd} \upharpoonleft\downharpoonright v_{dn}$$

$$\left[AB^+(v) - e^- \right]_n \qquad (54.76)$$
proceeds via the first (dielectronic capture) stage of (54.73) followed by a two-way electronic transition

with frequency v_{dn} and v_{nd} between the d and n states. All (n, v) Rydberg states can be populated, particularly those in low n and high v since the electronic $d - n$ interaction varies as $n^{-1.5}$ with broad structure. Although the dissociation process proceeds here via a second order effect (v_{dn} and v_{nd}), the electronic coupling may dominate the indirect vibronic capture and interrupt the recombination, in contrast to (54.75) which, as written in the one-way direction, feeds the recombination. Both dip and spike structure has been observed [54.10].

54.4.2 Quantal Cross Section

The cross section for direct dissociative recombination

$$e^- + AB^+\left(v_i^+\right) \rightleftharpoons \left(AB^{**}\right)_r \longrightarrow A + B^* \qquad (54.77)$$
of electrons of energy ε, wavenumber k_e and spin statistical weight 2, for a molecular ion $AB^+(v_i^+)$ of electronic statistical weight ω_{AB}^+ in vibrational level v_i^+ is

$$\sigma_{DR}(\varepsilon) = \frac{\pi}{k_e^2} \left(\frac{\omega_{AB}^*}{2\omega^+} \right) \left| a_Q \right|^2$$
$$= \left(\frac{h^2}{8\pi m_e \varepsilon} \right) \left(\frac{\omega_{AB}^*}{2\omega^+} \right) \left| a_Q \right|^2 . \qquad (54.78)$$

Here ω_{AB}^* is the electronic statistical weight of the dissociative neutral state of AB^* whose potential energy curve V_d crosses the corresponding potential energy curve V^+ of the ionic state. The transition T-matrix element for autoionization of AB^* embedded in the (moving) electronic continuum of $AB^+ + e^-$ is the quantal probability amplitude

$$a_Q(v) = 2\pi \int\limits_0^\infty V_{d\varepsilon}^*(R) \left[\psi_v^{+*}(R) \psi_d(R) \right] \, \mathrm{d}R \qquad (54.79)$$

for autoionization. Here ψ_v^+ and ψ_d are the nuclear bound and continuum vibrational wave functions for AB^+ and AB^*, respectively, while

$$V_{d\varepsilon}(R) = \langle \phi_d | \mathcal{H}_{el}(r, R(t)) | \phi_\varepsilon(r, R) \rangle_{r, \hat{\varepsilon}}$$
$$= V_{\varepsilon d}^*(R) \qquad (54.80)$$

are the bound-continuum electronic matrix elements coupling the diabatic electronic bound state wave functions $\psi_d(r, R)$ for AB^* with the electronic continuum state wave functions $\phi_\varepsilon(r, R)$ for $AB^+ + e^-$. The matrix element is an average over electronic coordinates r and

all directions $\hat{\epsilon}$ of the continuum electron. Both continuum electronic and vibrational wave functions are energy normalized (Sect. 54.8.3), and

$$\Gamma(R) = 2\pi \left| V_{d\varepsilon}^*(R) \right|^2 \tag{54.81}$$

is the energy width for autoionization at a given nuclear separation R. Given $\Gamma(R)$ from quantum chemistry codes, the problem reduces to evaluation of continuum vibrational wave functions in the presence of autoionization. The rate associated with a Maxwellian distribution of electrons at temperature T is

$$\hat{\alpha} = \overline{v}_e \int \varepsilon\, \sigma_{DR}(\varepsilon)\, e^{-\varepsilon/k_B T}\, d\varepsilon/(k_B T)^2 \tag{54.82}$$

where $\overline{v}_e$ is the mean speed (Sect. 54.9).

Maximum Cross Section and Rate
Since the probability for recombination must remain less than unity, $\left|a_Q\right|^2 \le 1$ so that the maximum cross section and rates are

$$\sigma_{DR}^{max}(\varepsilon) = \frac{\pi}{k_e^2}\left(\frac{\omega_{AB}^*}{2\omega^+}\right) = \left(\frac{h^2}{8\pi m_e \varepsilon}\right)(2\ell + 1), \tag{54.83}$$

where ω_{AB}^* has been replaced by $2(2\ell + 1)\omega^+$ under the assumption that the captured electron is bound in a high level Rydberg state of angular momentum ℓ, and

$$\hat{\alpha}_{max}(T) = \overline{v}_e\, \sigma_{DR}^{max}(\varepsilon = k_B T) \tag{54.84a}$$

$$\approx 5 \times 10^{-7} \left(\frac{300}{T}\right)^{1/2} (2\ell + 1)\ \mathrm{cm}^3/\mathrm{s}\,. \tag{54.84b}$$

Cross section maxima of $5(2\ell+1)(300/T) \times 10^{-14}\ \mathrm{cm}^2$ are therefore possible, being consistent with the rate (54.84b).

First–Order Quantal Approximation
When the effect of autoionization on the continuum vibrational wave function $\psi_d(R)$ for AB^* is ignored, then a first-order undistorted approximation to the quantal amplitude (54.79) is

$$T_B(v^+) = 2\pi \int_0^\infty V_{d\varepsilon}^*(R) \left[\psi_v^{+*}(R)\psi_d^{(0)}(R)\right] dR \tag{54.85}$$

where $\psi_d^{(0)}$ is ψ_d in the absence of the back reaction of autoionization. Under this assumption, (54.78) reduces to

$$\sigma_c(\varepsilon, v^+) = \frac{\pi}{k_e^2}\left(\frac{\omega_{AB}^*}{2\omega^+}\right)\left|T_B(v^+)\right|^2\,, \tag{54.86}$$

which is then the cross section for initial electron capture since autoionization has been precluded. Although the Born T-matrix (54.85) violates unitarity, the capture cross section (54.86) must remain less then the maximum value

$$\sigma_c^{max} = \frac{\pi}{k_e^2}\left(\frac{\omega_{AB}^*}{2\omega^+}\right) = \left(\frac{h^2}{8\pi m_e \varepsilon}\right)\left(\frac{\omega_{AB}^*}{2\omega^+}\right), \tag{54.87}$$

since $\left|a_Q\right|^2 \le 1$. So as to acknowledge after the fact the effect of autoionization, assumed small, and neglected by (54.85), the DR cross section can be approximated as

$$\sigma_{DR}(\varepsilon, v^+) = \sigma_c(\varepsilon, v^+) P_S\,, \tag{54.88}$$

where P_S is the probability of survival against autoionization on the V_d curve until stabilization takes place at some crossing point R_X.

Approximate Capture Cross Section
With the energy-normalized Winans–Stückelberg vibrational wave function

$$\psi_d^{(0)}(R) = \left|V_d'(R)\right|^{-1/2}\delta(R - R_c)\,, \tag{54.89}$$

where R_c is the classical turning point for $(A - B^*)$ relative motion, (54.86) reduces to

$$\sigma_c(\varepsilon, v^+) = \frac{\pi}{k_e^2}\left(\frac{\omega_{AB}^*}{2\omega^+}\right)\left[2\pi\Gamma(R_c)\right]\left\{\frac{\left|\psi_v^+(R_c)\right|^2}{\left|V_d'(R_c)\right|}\right\} \tag{54.90}$$

where the term inside the braces in (54.90) is the effective Franck–Condon factor.

Six Approximate Stabilization Probabilities
(1) A unitarized T-matrix is

$$T = \frac{T_B}{1 + \left|\frac{1}{2}T_B\right|^2}\,, \tag{54.91}$$

so that $P_S = |T|^2 / |T_B|^2$ to give

$$P_S(\text{low } \varepsilon)$$

$$= \left(1 + \frac{1}{4}|T_B|^2\right)^{-2}$$

$$= \left\{1 + \pi^2 \left|\int_0^\infty V_{d\varepsilon}^*(R)\left[\psi_v^{+*}(R)\psi_d^{(0)}(R)\right] dr\right|^2\right\}^{-2} \tag{54.92a}$$

which is valid at low ε when only one vibrational level v^+, i.e., the initial level of the ion is repopulated by autoionization.

(2) At higher ε, when population of many other ionic levels v_f^+ occurs, then

$$P_S(\varepsilon) = \left[1 + \frac{1}{4} \sum_f \left| T_B\left(v_f^+\right) \right|^2 \right]^{-2} , \qquad (54.92b)$$

where the summation is over all the open vibrational levels v_f^+ of the ion. When no intermediate Rydberg $AB^*(v)$ states are energy resonant with the initial $e^- + AB^+(v^+)$ state, i.e., coupling with the indirect mechanism is neglected, then (54.88) with (54.92b) is the direct DR cross section normally calculated.

(3) In the high-ε limit when an infinite number of v_f^+ levels are populated following autoionization, the survival probability, with the aid of closure, is then

$$P_S = \left[1 + \pi^2 \int_{R_c}^{R_X} \left| V_{d\varepsilon}^*(R) \right|^2 \left| \psi_d^{(0)}(R) \right|^2 dR \right]^{-2} . \qquad (54.93)$$

(4) On adopting in (54.93) the JWKB semiclassical wave function for $\psi_d^{(0)}$, then

$$P_S(\text{high } \varepsilon) = \left[1 + \frac{1}{2\hbar} \int_{R_c}^{R_X} \frac{\Gamma(R)}{v(R)} dR \right]^{-2}$$

$$= \left[1 + \frac{1}{2} \int_{t_c}^{t_X} v_a(t) dt \right]^{-2} , \qquad (54.94)$$

where $v(R)$ is the local radial speed of $A - B$ relative motion, and where the frequency $v_a(t)$ of autoionization is $\Gamma/\hbar$.

54.5 Mutual Neutralization

$$A^+ + B^- \rightarrow A + B . \qquad (54.99)$$

Diabatic Potentials
$V_i^{(0)}(R)$ and $V_f^{(0)}(R)$ for initial (ionic) and final (covalent) states are diagonal elements of

$$V_{if}(R) = \langle \Psi_i(\boldsymbol{r}, \boldsymbol{R}) | \mathcal{H}_{el}(\boldsymbol{r}, \boldsymbol{R}) | \Psi_f(\boldsymbol{r}, \boldsymbol{R}) \rangle_{\boldsymbol{r}} , \qquad (54.100)$$

where $\Psi_{i,f}$ are diabatic states and $\mathcal{H}_{el}$ is the electronic Hamiltonian at fixed internuclear distance R.

(5) A classical path local approximation for P_S yields

$$P_S = \exp\left(-\int_{t_c}^{t_X} v_a(t) dt \right) , \qquad (54.95)$$

which agrees to first-order for small v with the expansion of (54.94).

(6) A partitioning of (54.73) yields

$$P_S = v_d/(v_a + v_d) = (1 + v_a \tau_d)^{-1} , \qquad (54.96)$$

on adopting macroscopic averaged frequencies v_i and associated lifetimes $\tau_i = v_i^{-1}$. The six survival probabilities in (54.92a,b), (54.93–54.96) are all suitable for use in the DR cross section (54.88).

54.4.3 Noncrossing Mechanism

The dissociative recombination (DR) processes

$$e^- + H_3^+ \rightarrow H_2 + H$$
$$\rightarrow H + H + H \qquad (54.97)$$

at low electron energy ε, and

$$e^- + HeH^+ \rightarrow He + H(n=2) \qquad (54.98)$$
have spurred renewed theoretical interest because they both proceed at respective rates of $\left(2 \times 10^{-7} \text{ to } 2 \times 10^{-8}\right)$ cm^3 s^{-1} and 10^{-8} cm^3 s^{-1} at 300 K. Such rates are generally associated with the direct DR, which involves favorable curve crossings between the potential energy surfaces, $V^+(R)$ and $V_d(R)$ for the ion AB^+ and neutral dissociative AB^{**} states. The difficulty with (54.97) and (54.98) is that there are no such curve crossings, except at $\varepsilon \geq 8$ eV for (54.97). In this instance, the previous standard theories would support only extremely small rates when electronic resonant conditions do not prevail at thermal energies. Theories [54.11, 12] are currently being developed for application to processes such as (54.97).

Adiabatic Potentials for a Two–State System

$$V^\pm(R) = V_0(R) \pm \left[\Delta^2(R) + \left| V_{if}(R) \right|^2 \right]^{1/2} , \qquad (54.101a)$$

$$V_0(R) = \frac{1}{2} \left[V_i^{(0)}(R) + V_f^{(0)}(R) \right] , \qquad (54.101b)$$

$$\Delta(R) = \left[V_i^{(0)}(R) - V_f^{(0)}(R) \right] . \qquad (54.101c)$$

For a single crossing of diabatic potentials at R_X then $V_i^{(0)}(R_X) = V_f^{(0)}(R_X)$ and the adiabatic potentials at R_X are,

$$V^{\pm}(R_X) = V_i^{(0)}(R_X) \pm V_{if}(R_X) \qquad (54.102)$$

with energy separation $2V_{if}(R_X)$.

54.5.1 Landau–Zener Probability for Single Crossing at R_X

On assuming $\Delta(R) = (R - R_X)\Delta'(R_X)$, where $\Delta'(R) = d\Delta(R)/dR$, the probability for single crossing is

$$P_{if}(R_X) = \exp\left[\eta(R_X)/v_X(b)\right] \qquad (54.103a)$$

$$\eta(R_X) = \left(\frac{2\pi}{\hbar}\right) \frac{|V_{if}(R_X)|^2}{\Delta'(R_X)} \qquad (54.103b)$$

$$v_X(b) = \left[1 - V_i^{(0)}(R_X)/E - b^2/R_X^2\right]^{1/2} . \qquad (54.103c)$$

Overall Charge-Transfer Probability

From the incoming and outgoing legs of the trajectory,

$$P^X(E) = 2P_{if}(1 - P_{if}) . \qquad (54.104)$$

54.5.2 Cross Section and Rate Coefficient for Mutual Neutralization

$$\sigma_M(E) = 4\pi \int_0^{b_X} P_{if}(1 - P_{if})b \, db$$

$$= \pi b_X^2 P_M , \qquad (54.105a)$$

$$\pi b_X^2 = \pi \left(1 - \frac{V_i^{(0)}(R_X)}{E}\right) R_X^2$$

$$= \pi \left(1 + \frac{14.4}{R_X(\text{Å})E(\text{eV})}\right) R_X^2 . \qquad (54.105b)$$

P_M is the b^2-averaged probability (54.104) for charge-transfer reaction within a sphere of radius R_X.

The rate is

$$\hat{\alpha}_M = (8k_B T/\pi M_{AB})^{1/2} \int_0^{\infty} \epsilon \sigma_M(\epsilon) e^{-\epsilon} d\epsilon \qquad (54.106)$$

where $\epsilon = E/k_B T$.

54.6 One-Way Microscopic Equilibrium Current, Flux, and Pair-Distributions

Notation:

M	reduced mass $M_A M_B/(M_A + M_B)$
R	internal separation of $A - B$
E	orbital energy $\frac{1}{2}Mv^2 + V(R)$
L	orbital angular momentum
L^2	$2MEb^2$ for $E > 0$
v_R	radial speed $|\dot{R}|$
$\overline{v}$	mean relative speed $(8kT/\pi M_{AB})^{1/2}$
ε	normalized energy $E/k_B T$
n_i	pair distribution function $n_i^+ + n_i^-$
$n_i^{\pm}$	component of n_i with $\dot{R} > 0$ (+) and $\dot{R} < 0$ (−).

All quantities on the RHS in the expressions (a)–(e) below are to be multiplied by $\tilde{N}_A \tilde{N}_B [\omega_{AB}/\omega_A \omega_B]$ where the ω_i denote the statistical weights of species i which are not included by the density of states associated with the E, L^2 orbital degrees of freedom.

Case (a). $|i\rangle \equiv \left|R, E, L^2\right\rangle$.

Current: $j_i^{\pm}(R) = n^{\pm}(R, E, L^2)v_R \equiv n_i^{\pm} v_R$

Flux: $4\pi R^2 j_i^{\pm}(R) \, dE \, dL^2 = \dfrac{4\pi^2 e^{-E/k_B T}}{(2\pi M k_B T)^{3/2}} \, dE \, dL^2 .$
$$\qquad (54.107)$$

This flux is independent of R. For dissociated pairs $E > 0$,

$$4\pi R^2 j_i^{\pm}(R) \, dE \, dL^2 = \left[\overline{v}\varepsilon e^{-\varepsilon} d\varepsilon\right] [2\pi b \, db] . \qquad (54.108)$$

$\left(R, E, L^2\right)$-Distribution:

$$n\left(R, E, L^2\right) dR \, dE \, dL^2$$
$$= \frac{(8\pi^2/v_R) e^{-E/k_B T}}{(2\pi M k_B T)^{3/2}} \left(\frac{dR}{4\pi R^2}\right) dE \, dL^2 . \qquad (54.109)$$

Case (b). $|i\rangle \equiv |\boldsymbol{R}, E\rangle$; L^2-integrated quantities.

Current: $j_i^{\pm}(R) = \dfrac{1}{2} v n^{\pm}(\boldsymbol{R}, E) \equiv \dfrac{1}{2} v n_i^{\pm}$,   (54.110)

Flux: $4\pi R^2 j_i^{\pm}(R)\, dE = \left[\overline{v}\varepsilon\, e^{-\varepsilon}\, d\varepsilon\right] \pi b_0^2$,
(54.111a)

$\pi b_0^2 = \pi R^2 \left[1 - V(R)/E\right]$,   (54.111b)

$(\boldsymbol{R}, E)$-Distribution:

$n(\boldsymbol{R}, E)\, d\boldsymbol{R}\, dE$

$\quad = \dfrac{2}{\sqrt{\pi}} \left[\dfrac{E - V(R)}{k_B T}\right]^{1/2} e^{-\varepsilon}\, d\varepsilon\, d\boldsymbol{R}$

$\quad \equiv G_{MB}(E, R)\, d\boldsymbol{R}$,   (54.112)

which defines the Maxwell–Boltzmann velocity vistribution G_{MB} in the presence of the field $V(R)$.

Case (c). $\left(E, L^2\right)$-integrated quantities.

Current: $j^{\pm}(R) = \dfrac{1}{4} \overline{v}\, e^{-V(R)/k_B T}$,   (54.113)

Flux: $4\pi R^2 j^{\pm}(R) = \pi R^2 \overline{v}\, e^{-V(R)/k_B T}$,   (54.114)

Distribution: $n(R) = e^{-V(R)/k_B T}$.   (54.115)

When E-integration is only over dissociated states $(E > 0)$, the above quantities are

$j_d^{\pm}(R) = \dfrac{1}{4} \overline{v} \left[1 - V(R)/k_B T\right]$,   (54.116)

$4\pi R^2 j_d^{\pm}(R) = \pi R^2 \left(1 - \dfrac{V(R)}{k_B T}\right) \overline{v} \equiv \pi b_{\max}^2 \overline{v}$,
(54.117)

$n(R) = \left[1 - V(R)/k_B T\right]$.   (54.118)

Case (d). $\left(E, L^2\right)$-distribution. For Bound Levels

$n(E, L^2)\, dE\, dL^2 = \dfrac{4\pi^2 \tau_R(E, L)}{(2\pi M k_B T)^{3/2}} e^{-E/k_B T} dE\, dL^2$,
(54.119)

where $\tau_R = \oint dt = (\partial J_R/\partial E)$ is the period for bounded radial motion of energy E and radial action $J_R(E, L) = M \oint v_R\, dR$.

Case (e). E-distribution. For bound levels

$n(E)\, dE = \dfrac{2\, e^{-\varepsilon}}{\sqrt{\pi}}\, d\varepsilon \displaystyle\int_0^{R_A} \left(\dfrac{E - V}{k_B T}\right)^{1/2} d\boldsymbol{R}$,   (54.120)

where R_A is the turning point $E = V(R_A)$.

Example. For electron–ion bounded motion, $V(R) = -Ze^2/R$, $R_A = Ze^2/|E|$, $R_e = Ze^2/k_B T$, $\varepsilon = E/k_B T$. Then $\tau_R = 2\pi (m/Ze^2)^{1/2} (R_A/2)^{3/2}$,

$\displaystyle\int_0^{R_A} \left(\dfrac{R_e}{R} - |\varepsilon|\right)^{1/2} d\boldsymbol{R} = \dfrac{\pi^2}{4} R_A^{5/2} R_e^{1/2}$,   (54.121)

and

$n^s(E)\, dE = \left(\dfrac{2\, e^{-\varepsilon}}{\sqrt{\pi}}\, d\varepsilon\right) \dfrac{\pi^2}{4} R_A^{5/2} R_e^{1/2}$ (54.122)

$\qquad = \left(\dfrac{2\, e^{-\varepsilon}}{\sqrt{\pi}}\, d\varepsilon\right) \left(\dfrac{\pi^2 R_e^3}{4\, |\varepsilon|^{5/2}}\right)$.   (54.123)

For closely spaced levels in a hydrogenic $e^- - A^{Z+}$ system,

$n^s(p, \ell) = n(E, L^2) \left(\dfrac{dE}{dp}\right) \left(\dfrac{dL^2}{d\ell}\right)$ (54.124a)

$n^s(p) = n(E) \left(\dfrac{dE}{dp}\right)$.   (54.124b)

Using $E = -(2p^2)^{-1}(Z^2 e^2/a_0)$ and $L^2 = (\ell + 1/2)^2 \hbar^2$ for level (p, ℓ) then

$\tau_R(E, L) \dfrac{dE}{dp} \left(\dfrac{dL^2}{d\ell}\right) = \left(\dfrac{dJ_R}{dp}\right) \left(\dfrac{dL^2}{d\ell}\right)$ (54.125)

$\qquad\qquad = h\left((2\ell + 1)\hbar^2\right)$ (54.126)

$\dfrac{n^s(p, \ell)}{n_e N^+} = \dfrac{2(2\ell + 1)}{2\omega_A^+} \dfrac{h^3}{(2\pi m_e k_B T)^{3/2}} e^{I_p/k_B T}$,
(54.127a)

$\dfrac{n^s(p)}{n_e N^+} = \dfrac{2p^2}{2\omega_A^+} \dfrac{h^3}{(2\pi m_e k_B T)^{3/2}} e^{I_p/k_B T}$,   (54.127b)

in agreement with the Saha ionization formula (54.16) where N^+ is the equilibrium concentration of A^{Z+} ions in their ground electronic states. The spin statistical weights are $\omega_{eA} = \omega_e = 2$.

54.7 Microscopic Methods for Termolecular Ion–Ion Recombination

At low gas density, the basic process

$A^+ + B^- + M \rightarrow AB + M$ (54.128)
is characterized by nonequilibrium with respect to E. Dissociated and bound A^+–B^- ion pairs are in equilibrium with respect to their separation R, but bound pairs

are not in E-equilibrium with each other. L^2-equilibrium can be assumed for ion–ion recombination but not for ion–atom association reactions.

At higher gas densities N, there is nonequilibrium in the ion-pair distributions with respect to R, E and L^2. In the limit of high N, there is only nonequilibrium with respect to R. See [54.13] and the appropriate reference list for full details of theory.

54.7.1 Time Dependent Method: Low Gas Density

Energy levels E_i of A^+–B^- pairs are so close that they form a quasicontinuum with a nonequilibrium distribution over E_i determined by the master equation

$$\frac{\mathrm{d}n_i(t)}{\mathrm{d}t} = \int_{-D}^{\infty} \left(n_i v_{if} - n_f v_{fi} \right) \mathrm{d}E_f , \quad (54.129)$$

where $n_i \, \mathrm{d}E_i$ is the number density of pairs in the interval $\mathrm{d}E_i$ about E_i, and $v_{if} \, \mathrm{d}E_f$ is the frequency of i-pair collisions with M that change the i-pair orbital energy from E_i to between E_f and $E_f + \mathrm{d}E_f$. The greatest binding energy of the A^+–B^- pair is D.

Association Rate

$$R^A(t) = \int_{-D}^{\infty} P_i^{\mathrm{S}} \left(\frac{\mathrm{d}n_i}{\mathrm{d}t} \right) \mathrm{d}E_i \quad (54.130a)$$

$$= \hat{\alpha} N_A(t) N_B(t) - k n_{\mathrm{s}}(t) , \quad (54.130b)$$

where P_i^{S} is the probability for collisional stabilization (recombination) of i-pairs via a sequence of energy changing collisions with M. The coefficients for $\mathcal{C} \to \mathcal{S}$ recombination out of the $\mathcal{C}$-block with ion concentrations $N_A(t)$, $N_B(t)$ (in cm^{-3}) into the $\mathcal{S}$ block of total ion-pair concentrations $n_{\mathrm{s}}(t)$ and for $\mathcal{S} \to \mathcal{C}$ dissociation are $\hat{\alpha} \left(\mathrm{cm}^3 \, \mathrm{s}^{-1} \right)$ and $k \left(\mathrm{s}^{-1} \right)$, respectively.

One-Way Equilibrium Collisional Rate and Detailed Balance

$$C_{if} = \tilde{n}_i v_{if} = \tilde{n}_f v_{fi} = C_{fi} , \quad (54.131)$$

where the tilde denotes equilibrium (Saha) distributions.

Normalized Distribution Functions

$$\gamma_i(t) = n_i(t)/\tilde{n}_i^{\mathrm{S}} , \quad \gamma_{\mathrm{s}}(t) = n_{\mathrm{s}}(t)/\tilde{n}_{\mathrm{s}}^B(t) , \quad (54.132)$$

$$\gamma_{\mathrm{c}}(t) = N_A(t) N_B(t)/\tilde{N}_A \tilde{N}_B , \quad (54.133)$$

where $\tilde{n}_i^{\mathrm{S}}$ and $\tilde{n}^B$ are the Saha and Boltzmann distributions.

Master Equation for $\gamma_i(t)$

$$\frac{\mathrm{d}\gamma_i(t)}{\mathrm{d}t} = -\int_{-D}^{\infty} \left[\gamma_i(t) - \gamma_f(t) \right] v_{if} \, \mathrm{d}E_f . \quad (54.134)$$

Quasi–Steady State (QSS) Reduction

Set

$$\gamma_i(t) = P_i^{\mathrm{D}} \gamma_{\mathrm{c}}(t) + P_i^{\mathrm{S}} \gamma_{\mathrm{s}}(t) \overset{t \to \infty}{\longrightarrow} 1 \quad (54.135)$$

where P_i^{D} and P_i^{S} are the respective time-independent portions of the normalized distribution γ_i which originate, respectively, from blocks $\mathcal{C}$ and $\mathcal{S}$. The energy separation between the $\mathcal{C}$ and $\mathcal{S}$ blocks is so large that $P_i^{\mathrm{S}} = 0$ ($E_i \geq 0$, $\mathcal{C}$ block), $P_i^{\mathrm{S}} \leq 1$ ($0 > E_i \geq -S$, $\mathcal{E}$ block), $P_i^{\mathrm{S}} = 1$ ($-S \geq E_i \geq -D$, $\mathcal{S}$ block). Since $P_i^{\mathrm{S}} + P_i^{\mathrm{D}} = 1$, then

$$\frac{\mathrm{d}\gamma_i(t)}{\mathrm{d}t} = -\left[\gamma_{\mathrm{c}}(t) - \gamma_{\mathrm{s}}(t) \right] \int_{-D}^{\infty} \left(P_i^{\mathrm{D}} - P_f^{\mathrm{D}} \right) C_{if} \, \mathrm{d}E_f . \quad (54.136)$$

Recombination and Dissociation Coefficients

Equation (54.135) in (54.130a) enables the recombination rate in (54.130b) to be written as

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{-D}^{\infty} P_i^{\mathrm{D}} \, \mathrm{d}E_i \int_{-D}^{\infty} \left(P_i^{\mathrm{D}} - P_f^{\mathrm{D}} \right) C_{if} \, \mathrm{d}E_f . \quad (54.137)$$

The QSS condition ($\mathrm{d}n_i/\mathrm{d}t = 0$ in block $\mathcal{E}$) is then

$$P_i^{\mathrm{D}} \int_{-D}^{\infty} v_{if} \, \mathrm{d}E_f = \int_{-D}^{E} v_{if} P_f^{\mathrm{D}} \, \mathrm{d}E_f , \quad (54.138)$$

which involves only time independent quantities. Under QSS, (54.137) reduces to the net downward current across bound level $-E$,

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int_{-E}^{\infty} \mathrm{d}E_i \int_{-D}^{-E} \left(P_i^{\mathrm{D}} - P_f^{\mathrm{D}} \right) C_{if} \, \mathrm{d}E_f , \quad (54.139)$$

which is independent of the energy level ($-E$) in the range $0 \geq -E \geq -S$ of block $\mathcal{E}$.

The dissociation frequency k in (54.130b) is

$$k \tilde{n}_{\mathrm{s}} = \int_{-D}^{-E} \mathrm{d}E_i \int_{-E}^{\infty} \left(P_i^{\mathrm{S}} - P_f^{\mathrm{S}} \right) C_{if} \, \mathrm{d}E_f , \quad (54.140)$$

and macroscopic detailed balance $\hat{\alpha}\tilde{N}_A\tilde{N}_B = k\tilde{n}_s$ is automatically satisfied. $\hat{\alpha}$ is the direct ($\mathcal{C} \to \mathcal{S}$) collisional contribution (small) plus the (much larger) net collisional cascade downward contribution from that fraction of bound levels which originated in the continuum $\mathcal{C}$. k_d is the direct dissociation frequency (small) plus the net collisional cascade upward contribution from that fraction of bound levels which originated in block $\mathcal{S}$.

54.7.2 Time Independent Methods: Low Gas Density

QSS–Rate. Since recombination and dissociation (ionization) involve only that fraction of the bound state population which originated from the $\mathcal{C}$ and $\mathcal{S}$ blocks, respectivel,y recombination can be viewed as time independent with

$$N_A N_B = \tilde{N}_A \tilde{N}_B, \quad n_s(t) = 0, \tag{54.141a}$$

$$\rho_i = n_i/\tilde{n}_i \equiv P_i^D \tag{54.141b}$$

$$\hat{\alpha}\tilde{N}_A\tilde{N}_B = \int\limits_{-E}^{\infty} dE_i \int\limits_{-D}^{-E} (\rho_i - \rho_f)\, C_{if}\, dE_f . \tag{54.141c}$$

QSS Integral Equation.

$$\rho_i \int\limits_{-D}^{\infty} v_{if}\, dE_f = \int\limits_{-S}^{\infty} \rho_f v_{if}\, dE_f \tag{54.142}$$

is solved subject to the boundary condition

$$\rho_i = 1 (E_i \geq 0), \quad \rho_i = 0 (-S \geq E_i \geq -D) . \tag{54.143}$$

Collisional Energy–Change Moments.

$$D^{(m)}(E_i) = \frac{1}{m!} \int\limits_{-D}^{\infty} (E_f - E_i)^m C_{if}\, dE_f , \tag{54.144}$$

$$D_i^{(m)} = \frac{1}{m!} \frac{d}{dt} \langle (\Delta E)^m \rangle . \tag{54.145}$$

Averaged Energy–Change Frequency. For an equilibrium distribution $\tilde{n}_i$ of E_i-pairs per unit interval dE_i per second,

$$D_i^{(1)} = \frac{d}{dt} \langle \Delta E \rangle .$$

Averaged Energy–Change per Collision.

$$\langle \Delta E \rangle = D_i^{(1)}/D_i^{(0)} .$$

Time Independent Dissociation. The time independent picture corresponds to

$$n_s(t) = \tilde{n}_s, \quad \gamma_c(t) = 0, \quad \rho_i = n_i/\tilde{n}_i \equiv P_i^S , \tag{54.146}$$

in analogy to the macroscopic reduction of (54.38a,b).

Variational Principle

The QSS-condition (54.135) implies that the fraction P_i^D of bound levels i with precursor $\mathcal{C}$ are so distributed over i that (54.137) for $\hat{\alpha}$ is a minimum. Hence P_i^D or ρ_i are obtained either from the solution of (54.142) or from minimizing the variational functional

$$\hat{\alpha}\tilde{N}_A\tilde{N}_B = \int\limits_{-D}^{\infty} n_i\, dE_i \int\limits_{-D}^{\infty} (\rho_i - \rho_f)\, v_{if}\, dE_f \tag{54.147a}$$

$$= \frac{1}{2} \int\limits_{-D}^{\infty} dE_i \int\limits_{-D}^{\infty} (\rho_i - \rho_f)^2\, C_{if}\, dE_f \tag{54.147b}$$

with respect to variational parameters contained in a trial analytic expression for ρ_i. Minimization of the quadratic functional (54.147b) has an analogy with the principle of least dissipation in the theory of electrical networks.

Diffusion–in–Energy–Space Method

Integral Equation (54.142) can be expanded in terms of energy-change moments, via a Fokker–Planck analysis to yield the differential equation

$$\frac{\partial}{\partial E_i} \left(D_i^{(2)} \frac{\partial \rho_i}{\partial E_i} \right) = 0 , \tag{54.148}$$

with the QSS analytical solution

$$\rho_i(E_i) = \left(\int\limits_{E_i}^{0} \frac{dE}{D^{(2)}(E)} \right) \left(\int\limits_{-S}^{0} \frac{dE}{D^{(2)}(E)} \right)^{-1} \tag{54.149}$$

of *Pitaevskiĭ* [54.4] for $(e^- + A^+ + M)$ recombination where collisional energy changes are small. This distribution does not satisfy the exact QSS condition (54.142). When inserted in the exact non-QSS rate (54.147b), highly accurate $\hat{\alpha}$ for heavy-particle recombination are obtained.

Bottleneck Method

The one-way equilibrium rate $\left(\text{cm}^{-3}\,\text{s}^{-1}\right)$ across $-E$, i.e., (54.141c) with $\rho_i = 1$ and $\rho_f = 0$, is

$$\hat{\alpha}(-E)\tilde{N}_A\tilde{N}_B = \int\limits_{-E}^{\infty} \text{d}E_i \int\limits_{-D}^{-E} C_{if}\,\text{d}E_f \,. \qquad (54.150)$$

This is an upper limit to (54.141c) and exhibits a minimum at $-E^*$, the bottleneck location. The least upper limit to $\hat{\alpha}$ is then $\hat{\alpha}(-E^*)$.

Trapping Radius Method

Assume that pairs with internal separation $R \leq R_\text{T}$ recombine with unit probability so that the one-way equilibrium rate across the dissociation limit at $E = 0$ for these pairs is

$$\hat{\alpha}(R_\text{T})\tilde{N}_A\tilde{N}_B = \int\limits_{0}^{R_\text{T}} \text{d}\boldsymbol{R} \int\limits_{V(R)}^{0} C_{if}(R)\,\text{d}E_f \,, \qquad (54.151)$$

where $V(R) = -e^2/R$, and $C_{if}(R) = \tilde{n}_i(R)v_{if}(R)$ is the rate per unit interval $(\text{d}\boldsymbol{R}\,\text{d}E_i)\,\text{d}E_f$ for the $E_i \to E_f$ collisional transitions at fixed R in

$$\left(A^+ - B^-\right)_{E_i, R} + M \to \left(A^+ - B^-\right)_{E_f, R} + M \,. \qquad (54.152)$$
The concentration $\left(\text{cm}^{-3}\right)$ of pairs with internal separation R and orbital energy E_i in the interval $\text{d}\boldsymbol{R}\,\text{d}E_i$ about $(\boldsymbol{R}, E_i)$ is $\tilde{n}_i(R)\,\text{d}\boldsymbol{R}\,\text{d}E_i$. Agreement with the exact treatment [54.13] is found by assigning $R_\text{T} = (0.48 - 0.55)\left(e^2/k_\text{B}T\right)$ for the recombination of equal mass ions in an equal mass gas for various ion–neutral interactions. For further details on the above methods, see the appropriate references on termolecular recombination in the general references on page 825.

54.7.3 Recombination at Higher Gas Densities

As the density N of the gas M is raised, the recombination rate $\hat{\alpha}$ increases initially as N to such an extent that there are increasingly more pairs $n_i^-(R, E)$ in a state of contraction in R than there are those $n_i^+(R, E)$ in a state of expansion; i.e., the ion-pair distribution densities $n_i^\pm(R, E)$ per unit interval $\text{d}E\,\text{d}R$ are not in equilibrium with respect to R in blocks $\mathcal{C}$ and $\mathcal{E}$. Those in the highly excited block $\mathcal{E}$ in addition are not in equilibrium with respect to energy E. Basic sets of coupled master equations have been developed [54.13] for the microscopic nonequilibrium distributions $n^\pm\left(R, E, L^2\right)$

and $n^\pm(R, E)$ of expanding $(+)$ and contracting $(-)$ pairs with respect to A–B separation R, orbital energy E and orbital angular momentum L^2. With $n\left(\boldsymbol{R}, E_i, L_i^2\right) \equiv n_i(R)$, and using the notation defined at the beginning of Sect. 54.6, the distinct regimes for the master equations discussed in Sect. 54.7.4 are:

Low N	Equilibrium in R, but not in E, L^2 $\to$ master equation for $n\left(E, L^2\right)$.
Pure Coulomb attraction	Equilibrium in L^2 $\to$ master equation for $n(E)$.
High N	Nonequilibrium in R, E, L^2 $\to$ master equation for $n_i^\pm(R)$.
Highest N	Equilibrium in $\left(E, L^2\right)$ but not in R $\to$ macroscopic transport equation (54.56a) in $n(R)$.

Normalized Distributions

For a state $|i\rangle \equiv \left|E, L^2\right\rangle$,

$$\rho_i(R) = \frac{n_i(R)}{\tilde{n}_i(R)}, \qquad \rho_i^\pm(R) = \frac{n_i^\pm(R)}{\tilde{n}_i^\pm(R)} \,,$$

$$\rho_i(R) = \frac{1}{2}\left(\rho_i^+ + \rho_i^-\right) \,. \qquad (54.153)$$

Orbital Energy and Angular Momentum

$$E_i = \frac{1}{2}M_{AB}v^2 + V(R) \,, \qquad (54.154a)$$

$$E_i = \frac{1}{2}M_{AB}v_\text{R}^2 + V_i(R) \,, \qquad (54.154b)$$

$$V_i(R) = V(R) + \frac{L_i^2}{2M_{AB}R^2} \,, \qquad (54.154c)$$

$$L_i = |\boldsymbol{R} \times M_{AB}\boldsymbol{v}| \,,$$

$$L_i^2 = (2M_{AB}E_i)b^2, \ E_i > 0 \,. \qquad (54.154d)$$

Maximum Orbital Angular Momenta

(1) A specified separation R can be accessed by all orbits of energy E_i with L_i^2 between 0 and

$$L_{im}^2(E_i, R) = 2M_{AB}R^2\left[E_i - V(R)\right] \,. \qquad (54.155a)$$

(2) Bounded orbits of energy $E_i < 0$ can have L_i^2 between 0 and

$$L_{ic}^2(E_i) = 2M_{AB}R_\text{c}^2\left[E_i - V(R_\text{c})\right] \,, \qquad (54.155b)$$

where R_c is the radius of the circular orbit determined by $\partial V_i/\partial R = 0$, i.e., by $E_i = V(R_\text{c}) + \frac{1}{2}R_\text{c}(\partial V/\partial R)_{R_\text{c}}$.

54.7.4 Master Equations

Master Equation for $n_i^\pm(R)^\pm(\boldsymbol{R}, E_i, L_i^2)$ [54.13]

$$\pm \frac{1}{R^2} \frac{\partial}{\partial R} \left[R^2 n_i^\pm(R) \, |v_R| \right]_{E_i, L_i^2}$$

$$= -\int\limits_{V(R)}^{\infty} dE_f \int\limits_{0}^{L_{fm}^2} dL_f^2 \Big[n_i^\pm(R) v_{if}(R)$$

$$- n_f^\pm(R) v_{fi}(R) \Big] . \tag{54.156}$$

The set of master equations [54.13] for n_i^+ is coupled to the n_i^- set by the boundary conditions $n_i^-\left(R_i^\mp\right) = n_i^+\left(R_i^\mp\right)$ at the pericenter R_i^- for all E_i and apocenter R_i^+ for $E_i < 0$ of the E_i, L_i^2-orbit.

Master Equations for Normalized Distributions [54.13]

$$\pm |v_R| \frac{\partial \rho_i^\pm}{\partial R} = -\int\limits_{V(R)}^{\infty} dE_f \int\limits_{0}^{L_{fm}^2} dL_f^2 \tag{54.157}$$

$$\times \left[\rho_i^\pm(R) - \rho_f^\pm(R) \right] v_{if}(R) .$$

Corresponding Master equations for the L^2 integrated distributions $n^\pm(R, E)$ and $\rho^\pm(R, E)$ have been derived [54.13].

Continuity Equations

$$J_i = \left[n_i^+(R) - n_i^-(R) \right] |v_R| = \left(\rho_i^+ - \rho_i^- \right) \tilde{j}_i^\pm \tag{54.158}$$

$$\frac{1}{R^2} \frac{\partial}{\partial R} (R^2 J_i) = -\int\limits_{V(R)}^{\infty} dE_f \int\limits_{0}^{L_{fm}^2} dL_f^2$$

$$\times \left[n_i(R) v_{if}(R) - n_f(R) v_{fi}(R) \right] , \tag{54.159}$$

$$\frac{1}{2} |v_R| \frac{\partial \left[\rho_i^+(R) - \rho_i^-(R) \right]}{\partial R}$$

$$= -\int\limits_{V(R)}^{\infty} dE_f \int\limits_{0}^{L_{fm}^2} dL_f^2 \left[\rho_i(R) - \rho_f(R) \right] v_{if}(R) . \tag{54.160}$$

54.7.5 Recombination Rate

Flux Representation
The $R_0 \to \infty$ limit of

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = -4\pi R_0^2 J(R_0) \tag{54.161}$$

has the microscopic generalization

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int\limits_{V(R_0)}^{\infty} dE_i \int\limits_{0}^{L_{ic}^2} dL_i^2 \left[4\pi R_0^2 \tilde{j}_i^\pm(R_0) \right]$$

$$\times \left[\rho_i^-(R_0) - \rho_i^+(R_0) \right] , \tag{54.162}$$

where L_{ic}^2 is given by (54.155b) with $R_c = R_0$ for bound states and is infinite for dissociated states, and where

$$\rho_i^-(R_0) - \rho_i^+(R_0) = \oint\limits_{R_i}^{R_0} \rho_i(R) \left[v_i^b(R) + v_i^c(R) \right] dt , \tag{54.163}$$

with

$$\rho_i(R) v_i^b(R) = \int\limits_{V(R)}^{V(R_0)} dE_f \int\limits_{0}^{L_{fm}^2} dL_f^2 \left[\rho_i(R) - \rho_f(R) \right]$$

$$\times v_{if}(R) , \tag{54.164a}$$

$$\rho_i(R) v_i^c(R) = \int\limits_{V(R_0)}^{\infty} dE_f \int\limits_{0}^{L_{fm}^2} dL_f^2 \left[\rho_i(R) - \rho_f(R) \right]$$

$$\times v_{if}(R) . \tag{54.164b}$$

Collisional Representation

$$\hat{\alpha} \tilde{N}_A \tilde{N}_B = \int\limits_{V(R_0)}^{\infty} dE_i \int\limits_{0}^{L_{ic}^2} dL_i^2 \int\limits_{R_i}^{R_0} \tilde{n}_i(R) \, d\boldsymbol{R}$$

$$\times \left[\rho_i(R) v_i^b(R) \right] , \tag{54.165}$$

which is the microscopic generalization of the macroscopic result $\hat{\alpha} = K \rho^* v_s = \alpha_{RN}(R_0) \rho(R_0)$.

The flux for dissociated pairs $E_i > 0$ is

$$4\pi R^2 |v_R| \tilde{n}_i^\pm(R) \, dE \, dL^2$$

$$= \left[\bar{v} \varepsilon e^{-\varepsilon} \, d\varepsilon \right] \left[2\pi b \, db \right] \tilde{N}_A \tilde{N}_B , \tag{54.166}$$

so the rate (54.165) as $R_0 \to \infty$ is

$$\hat{\alpha} = \bar{v} \int\limits_{0}^{\infty} \varepsilon e^{-\varepsilon} \, d\varepsilon \int\limits_{0}^{b_0} 2\pi b \, db \oint\limits_{R_i}^{R_0} \rho_i(R) v_i^b(R) \, dt , \tag{54.167}$$

which is the microscopic generalization (54.45) of the macroscopic result $\hat{\alpha} = k_c P^S$ of (54.44).

Reaction Rate $\alpha_{RN}(R_0)$

On solving (54.157) subject to $\rho(R_0) = 1$, then according to (54.56b), $\hat{\alpha}$ determined by (54.162) is the rate $\hat{\alpha}_{RN}$ of recombination within the $(A - B)$ sphere of radius R_0. The overall rate of recombination $\hat{\alpha}$ is then given by the full diffusional-drift reaction rate (54.59b) where the rate of transport to R_0 is determined uniquely by (54.60).

For development of theory [54.13] and computer simulations, see the reference list on Termolecular Ion–Ion Recombination: Theory, and Simulations, respectively.

54.8 Radiative Recombination

In the radiative recombination (RR) process

$$\mathrm{e}^-(E, \ell') + A^{Z+}(c) \rightarrow A^{(Z-1)+}(c, n\ell) + h\nu \,, \tag{54.168}$$
the accelerating electron e^- with energy and angular momentum (E, ℓ') is captured, via coupling with the weak quantum electrodynamical interaction $(e/m_e c)\mathbf{A} \cdot \mathbf{p}$ associated with the electromagnetic field of the moving ion, into an excited state $n\ell$ with binding energy $I_{n\ell}$ about the parent ion A^{Z+} (initially in an electronic state c). The simultaneously emitted photon carries away the excess energy $h\nu = E + I_{n\ell}$ and angular momentum difference between the initial and final electronic states. The cross section $\sigma_R^{n\ell}(E)$ for RR is calculated (a) from the Einstein A coefficient for free–bound transitions or (b) from the cross section $\sigma_I^{n\ell}(h\nu)$ for photoionization (PI) via the detailed balance (DB) relationship appropriate to (54.168).

The rates $\langle v_e \sigma_R \rangle$ and averaged cross sections $\langle \sigma_R \rangle$ for a Maxwellian distribution of electron speeds v_e are then determined from either

$$\hat{\alpha}_R^{n\ell}(T_e) = \overline{v}_e \int_0^\infty \varepsilon \sigma_R^{n\ell}(\varepsilon) \exp(-\varepsilon) \, \mathrm{d}\varepsilon$$

$$= \overline{v}_e \left\langle \sigma_R^{n\ell}(T_e) \right\rangle \,, \tag{54.169}$$

where $\varepsilon = E/k_B T_e$, or from the Milne DB relation (54.243) between the forward and reverse macroscopic rates of (54.168). Using the hydrogenic semiclassical σ_I^n of *Kramers* [54.5], together with an asymptotic expansion [54.14] for the g-factor of *Gaunt* [54.15], the quantal/semiclassical cross section ratio in (54.249), Seaton [54.16] calculated $\hat{\alpha}_R^{n\ell}$.

The rate of electron energy loss in RR is

$$\left\langle \frac{\mathrm{d}E}{\mathrm{d}t} \right\rangle_{n\ell} = n_e \overline{v}_e (k_B T_e) \int_0^\infty \varepsilon^2 \sigma_R^{n\ell}(\varepsilon) \, \mathrm{e}^{-\varepsilon} \, \mathrm{d}\varepsilon \,, \tag{54.170}$$

and the radiated power produced in RR is

$$\left\langle \frac{\mathrm{d}(h\nu)}{\mathrm{d}t} \right\rangle_{n\ell} = n_e \overline{v}_e \int_0^\infty \varepsilon h\nu \sigma_R^{n\ell}(\varepsilon) \, \mathrm{e}^{-\varepsilon} \, \mathrm{d}\varepsilon \,. \tag{54.171}$$

Standard Conversions

$$E = p_e^2/2m_e = \hbar^2 k_e^2/2m_e = k_e^2 a_0^2 \left(e^2/2a_0 \right) \tag{54.172a}$$

$$= \kappa^2 \left(Z^2 e^2/2a_0 \right) = \varepsilon \left(Z^2 e^2/2a_0 \right) \,, \tag{54.172b}$$

$$E_\nu = h\nu = \hbar\omega = \hbar k_\nu c = (I_n + E) \tag{54.172c}$$

$$\equiv \left(1 + n^2\varepsilon \right) \left(Z^2 e^2/2n^2 a_0 \right) \,, \tag{54.172d}$$

$$h\nu/I_n = 1 + n^2\varepsilon \,, \quad k_e^2 a_0^2 = 2E/\left(e^2/a_0 \right) \,, \tag{54.172e}$$

$$k_\nu a_0 = (h\nu)\alpha/\left(e^2/a_0 \right) \,, \tag{54.172f}$$

$$k_\nu^2/k_e^2 = (h\nu)^2/\left(2Em_e c^2 \right) \tag{54.172g}$$

$$= \alpha^2 (h\nu)^2/\left[2E\left(e^2/a_0 \right) \right] \,, \tag{54.172h}$$

$$I_H = e^2/2a_0 \,, \quad \alpha = e^2/\hbar c = 1/137.035\,9895 \,,$$

$$\alpha^{-2} = m_e c^2/\left(e^2/a_0 \right) \,, \quad I_n = \left(Z^2/n^2 \right) I_H \,. \tag{54.172i}$$

The electron and photon wavenumbers are k_e and k_ν, respectively.

54.8.1 Detailed Balance and Recombination–Ionization Cross Sections

Cross sections $\sigma_R^{n\ell}(E)$ and $\sigma_I^{n\ell}(h\nu)$ for radiative recombination (RR) into and photoionization (PI) out of level $n\ell$ of atom A are interrelated by the detailed balance relation

$$g_e g_A^+ k_e^2 \sigma_R^{n\ell}(E) = g_\nu g_A \, k_\nu^2 \sigma_I^{n\ell}(h\nu) \,, \tag{54.173}$$

where $g_e = g_\nu = 2$. Electronic statistical weights of A and A^+ are g_A and g_A^+, respectively. Thus, using

(54.172g) for k_v^2/k_e^2,

$$\sigma_R^{n\ell}(E) = \left(\frac{g_A}{2g_A^+}\right)\left(\frac{(h\nu)^2}{Em_ec^2}\right)\sigma_I^{n\ell}(h\nu) \,. \qquad (54.174)$$

The statistical factors are:
(a) For $(A^+ + e^-)$ state $c[S_c, L_c; \varepsilon, \ell', m']$:
$$g_A^+ = (2S_c + 1)(2L_c + 1).$$

(b) For $A(n\ell)$ state $b[S_c, L_c; n, \ell]SL$:
$$g_A = (2S + 1)(2L + 1).$$

(c) For $n\ell$ electron outside a closed shell:
$$g_A^+ = 1, \, g_A = 2(2\ell + 1).$$

Cross sections are averaged over initial and summed over final degenerate states. For case (c),

$$\sigma_I^n = \frac{1}{n^2}\sum_{\ell=0}^{n-1}(2\ell+1)\sigma_I^{n\ell} \,; \qquad (54.175a)$$

$$\sigma_R^n = \sum_{\ell=0}^{n-1}2(2\ell+1)\sigma_R^{n\ell} \,. \qquad (54.175b)$$

54.8.2 Kramers Cross Sections, Rates, Electron Energy–Loss Rates and Radiated Power for Hydrogenic Systems

These are all calculated from application of detailed balance (54.173) to the original $\sigma_I^n(h\nu)$ of *Kramers* [54.5].

Semiclassical (Kramers) Cross Sections
For hydrogenic systems,

$$I_n = \frac{Z^2e^2}{2n^2a_0}, \qquad h\nu = I_n + E \,. \qquad (54.176)$$

The results below are expressed in terms of the quantities

$$b_n = \frac{I_n}{k_BT_e} \,, \qquad (54.177)$$

$$\sigma_{I0}^n = \frac{64\pi a_0^2\alpha}{3\sqrt{3}}\left(\frac{n}{Z^2}\right)$$
$$= 7.907\,071\times10^{-18}(n/Z^2)\,\mathrm{cm}^2 \,, \qquad (54.178)$$

$$\sigma_{R0}(E) = \left(\frac{8\pi a_0^2\alpha^3}{3\sqrt{3}}\right)\frac{(Z^2e^2/a_0)}{E} \,, \qquad (54.179)$$

$$\hat{\alpha}_0(T_e) = \bar{v}_e\left(\frac{8\pi a_0^2\alpha^3}{3\sqrt{3}}\right)\frac{(Z^2e^2/a_0)}{k_BT_e} \qquad (54.180)$$

PI and RR Cross Sections for Level n. In the Kramer (K) semiclassical approximation,

$$_K\sigma_I^n(h\nu) = \left(\frac{I_n}{h\nu}\right)^3\sigma_{I0}^n = {}_K\sigma_I^{n\ell}(h\nu) \,, \qquad (54.181)$$

$$_K\sigma_R^n(E) = \sigma_{R0}(E)\left(\frac{2}{n}\right)\left(\frac{I_n}{I_n + E}\right) \qquad (54.182)$$
$$= 3.897\times10^{-20}$$
$$\times\left[n\varepsilon\left(13.606 + n^2\varepsilon^2\right)\right]^{-1}\mathrm{cm}^2 \,,$$

where ε is in units of eV and is given by

$$\varepsilon = E/Z^2 \equiv \left(2.585\times10^{-2}/Z^2\right)(T_e/300) \,. \qquad (54.183)$$

Equation (54.182) illustrates that RR into low n at low E is favored.

Cross Section for RR into Level $n\ell$.

$$_K\sigma_R^{n\ell} = \left[(2\ell+1)/n^2\right]{}_K\sigma_R^n \,. \qquad (54.184)$$

Rate for RR into Level n.

$$\hat{\alpha}_R^n(T_e) = \hat{\alpha}_0(T_e)\,(2/n)\,b_n\,e^{b_n}E_1(b_n) \,, \qquad (54.185a)$$

which tends for large b_n (i. e., $k_BT_e \ll I_n$) to

$$\hat{\alpha}_R^n(T_e \to 0) = \hat{\alpha}_0(T_e)\,(2/n)$$
$$\times\left(1 - b_n^{-1} + 2b_n^{-2} - 6b_n^{-3} + \cdots\right) \,. \qquad (54.185b)$$

The Kramers cross section for photoionization at threshold is σ_{I0}^n and

$$\sigma_{R0}^n = 2\sigma_{R0}/n; \qquad \hat{\alpha}_0^n = 2\hat{\alpha}_0/n \qquad (54.186)$$

provide the corresponding Kramers cross section and rate for recombination as $E \to 0$ and $T_e \to 0$, respectively.

RR Cross Sections and Rates into All Levels $n \geq n_f$.

$$\sigma_R^T(E) = \int_{n_f}^{\infty}\sigma_R^n(E)\,\mathrm{d}n$$
$$= \sigma_{R0}(E)\ln(1 + I_f/E) \,, \qquad (54.187a)$$

$$\hat{\alpha}_R^T(T_e) = \hat{\alpha}_0(T_e)\left[\gamma + \ln b_f + e^{b_f}E_1(b_f)\right] \qquad (54.187b)$$

Useful Integrals.

$$\int_0^\infty e^{-x} \ln x \, dx = \gamma \,, \tag{54.188a}$$

$$\int_b^\infty x^{-1} e^{-x} \, dx = E_1(b) \,, \tag{54.188b}$$

$$\int_0^b e^x E_1(x) \, dx = \gamma + \ln b + e^b E_1(b) \,, \tag{54.188c}$$

$$\int_0^b \left[1 - x e^x E_1(x) \right] dx$$

$$= \gamma + \ln b + e^b (1 - b) E_1(b) \,, \tag{54.188d}$$

where $\gamma = 0.5772157$ is Euler's constant, and $E_1(b)$ is the first exponential integral such that

$$b e^b E_1(b)$$

$$\xrightarrow{b \gg 1} 1 - b^{-1} + 2b^{-2} - 6b^{-3} + 24b^{-4} + \cdots \,.$$

Electron Energy Loss Rate
Energy Loss Rate for RR into Level n.

$$\left\langle \frac{dE}{dt} \right\rangle_n = n_e \hat{\alpha}_R^n (T_e) k_B T_e \left(\frac{1 - b_n e^{b_n} E_1(b_n)}{e^{b_n} E_1(b_n)} \right) \,, \tag{54.189a}$$

which for large b_n (i.e. $(k_B T_e) \ll I_n$) tends to

$$n_e \hat{\alpha}_R^n (T_e) k_B T_e \left(1 - b_n^{-1} + 3b_n^{-2} - 13b_n^{-3} + \cdots \right) \tag{54.189b}$$

with (54.185a) for $\hat{\alpha}_R^n$.

Energy Loss Rate for RR into All Levels $n \geq n_f$.

$$\left\langle \frac{dE}{dt} \right\rangle$$

$$= n_e k_B T_e \hat{\alpha}_0(T_e) \left[\gamma + \ln b_f + e^{b_f} E_1(b_f)(1 - b_f) \right] \tag{54.190a}$$

$$= n_e (k_B T_e) \left[\hat{\alpha}_R^T(T_e) - \hat{\alpha}_0(T_e) b_f e^{b_f} E_1(b_f) \right] \tag{54.190b}$$

with (54.187b) and (54.180) for $\hat{\alpha}_R^T$ and $\hat{\alpha}_0$.

Radiated Power
Radiated Power for RR into Level n.

$$\left\langle \frac{d(h\nu)}{dt} \right\rangle_n = n_e \hat{\alpha}_R^n (T_e) I_n \left[b_n e^{b_n} E_1(b_n) \right]^{-1} \,, \tag{54.191a}$$

which for large b_n (i.e. $(k_B T_e) \ll I_n$) tends to

$$n_e \hat{\alpha}_R^n (T_e) I_n \left(1 + b_n^{-1} - b_n^{-2} + 3b_n^{-3} + \cdots \right) \,. \tag{54.191b}$$

Radiated Power for RR into All Levels $n \geq n_f$.

$$\left\langle \frac{d(h\nu)}{dt} \right\rangle = n_e \hat{\alpha}_0(T_e) I_f \,. \tag{54.192}$$

To allow n-summation, rather than integration as in (54.187a), to each of the above expressions is added $1/2 \sigma_R^{n_f}$, $1/2 \hat{\alpha}_R^{n_f}$, $1/2 \langle dE/dt \rangle_{n_f}$ and $1/2 \langle d(h\nu)/dt \rangle_{n_f}$, respectively. The expressions valid for bare nuclei of charge Z are also fairly accurate for recombination to a core of charge Z_c and atomic number Z_A, provided that Z is identified as $1/2(Z_A + Z_c)$.

Differential Cross Sections for Coulomb Elastic Scattering.

$$\sigma_c(E, \theta) = \frac{b_0^2}{4 \sin^4 \frac{1}{2}\theta} \,, \quad b_0^2 = (Ze^2/2E)^2 \,. \tag{54.193}$$

The integral cross section for Coulomb scattering by $\theta \geq \pi/2$ at energy $E = (3/2)k_B T$ is

$$\sigma_c(E) = \pi b_0^2 = \frac{1}{9} \pi R_e^2, \quad R_e = e^2/k_B T \,. \tag{54.194}$$

Photon Emission Probability.

$$P_\nu = \sigma_R^n(E)/\sigma_c(E) \,. \tag{54.195a}$$

This is small and increases with decreasing n as

$$P_\nu(E) = \left(\frac{8\alpha^3}{3\sqrt{3}} \right) \frac{8}{n} \frac{E}{(e^2/a_0)} \left(\frac{I_n}{h\nu} \right) \,. \tag{54.195b}$$

54.8.3 Basic Formulae for Quantal Cross Sections

Radiative Recombination and Photoionization Cross Sections

The cross section $\sigma_R^{n\ell}$ for recombination follows from the continuum–bound transition probability P_{if} per unit

time. It is also provided by the detailed balance relation (54.173) in terms of $\sigma_I^{n\ell}$ which follows from P_{fi}. The number of radiative transitions per second is

$$\left[g_e g_A^+ \rho(E) \, dE \, d\hat{\boldsymbol{k}}_e \right] P_{if} \left[\rho(E_\nu) \, dE_\nu \, d\hat{\boldsymbol{k}}_\nu \right]$$

$$= g_e g_A^+ v_e \frac{d\boldsymbol{p}_e}{(2\pi\hbar)^3} \sigma_R(\boldsymbol{k}_e) = g_\nu g_A \, c \frac{d\boldsymbol{k}_\nu}{(2\pi)^3} \sigma_I(\boldsymbol{k}_\nu) \,,$$

(54.196)

where the electron current $(\text{cm}^{-2}\,\text{s}^{-1})$ is

$$\frac{v_e \, d\boldsymbol{p}_e}{(2\pi\hbar)^3} = \left(\frac{2mE}{h^3} \right) dE \, d\hat{\boldsymbol{k}}_e \,,$$

(54.197)

and the photon current $(\text{cm}^{-2}\,\text{s}^{-1})$ is

$$c \frac{d\boldsymbol{k}_\nu}{(2\pi)^3} = c \frac{(h\nu)^2}{(2\pi\hbar c)^3} \, dE_\nu \, d\hat{\boldsymbol{k}}_\nu \,.$$

(54.198)

Time Dependent Quantum Electrodynamical Interaction.

$$V(\boldsymbol{r},t) = \frac{e}{mc} \boldsymbol{A} \cdot \boldsymbol{p} = ie \left(\frac{2\pi h\nu}{\mathcal{V}} \right)^{1/2} (\hat{\boldsymbol{\epsilon}} \cdot \boldsymbol{r}) e^{-i(\boldsymbol{k}_\nu \cdot \boldsymbol{r} - \omega t)}$$

$$\equiv V(\boldsymbol{r}) e^{i\omega t} \,.$$

(54.199)

In the dipole approximation, $e^{-i\boldsymbol{k}_\nu \cdot \boldsymbol{r}} \approx 1$.

Continuum–Bound State-to-State Probability.

$$P_{if} = \frac{2\pi}{\hbar} \left| V_{fi} \right|^2 \delta\left[E_\nu - (E + I_n) \right]$$

$$V_{fi} = \langle \Psi_{n\ell m}(\boldsymbol{r}) | V(\boldsymbol{r}) | \Psi_i(\boldsymbol{r}, \boldsymbol{k}_e) \rangle \,.$$

(54.200)

Number of Photon States in Volume $\mathcal{V}$.

$$\rho\left(E_\nu, \hat{\boldsymbol{k}}_\nu\right) dE_\nu \, d\hat{\boldsymbol{k}}_\nu = \mathcal{V}(h\nu)^2/(2\pi\hbar c)^3 \, dE_\nu \, d\hat{\boldsymbol{k}}_\nu$$

(54.201a)

$$= \mathcal{V} \left[\omega^2/(2\pi c)^3 \right] d\omega \, d\hat{\boldsymbol{k}}_\nu \,.$$

(54.201b)

Continuum–Bound Transition Rate. On summing over the two directions $(g_\nu = 2)$ of polarization, the rate for transitions into all final photon states is

$$A_{n\ell m}\left(E, \hat{\boldsymbol{k}}_e\right) = \int P_{if} \rho(E_\nu) \, dE_\nu \, d\hat{\boldsymbol{k}}_\nu$$

$$= \frac{4e^2}{3\hbar} \frac{(h\nu)^3}{(3\hbar c)^3} \left| \langle \Psi_{n\ell m} | \boldsymbol{r} | \Psi_i(\boldsymbol{k}_e) \rangle \right|^2 \,.$$

(54.202)

Transition Frequency: Alternative Formula.

$$A_{n\ell m}\left(E, \hat{\boldsymbol{k}}_e\right) = (2\pi/\hbar) \left| D_{fi} \right|^2 \,,$$

(54.203)

where the dipole atom–radiation interaction coupling is

$$D_{fi}(\boldsymbol{k}_e) = \left(\frac{2\omega^3}{3\pi c^3} \right)^{1/2} \langle \Psi_{n\ell m} | e\boldsymbol{r} | \Psi_i(\boldsymbol{k}_e) \rangle \,.$$

(54.204)

RR Cross Section into Level $(n\ell m)$.

$$\sigma_R^{n\ell m}(E) = \frac{1}{4\pi} \int \sigma_R^{n\ell m}(\boldsymbol{k}_e) \, d\hat{\boldsymbol{k}}_e$$

$$= \frac{h^3 \rho(E)}{8\pi m_e E} \int A_{n\ell m}\left(E, \hat{\boldsymbol{k}}_e\right) d\hat{\boldsymbol{k}}_e \,.$$

(54.205)

RR Cross Section into Level $(n\ell)$.

$$\sigma_R^{n\ell}(E) = \frac{8\pi^2}{3} \left(\frac{(\alpha h\nu)^3}{2(e^2/a_0)E} \right) \rho(E) R_I^{n\ell}(E)$$

$$R_I^{n\ell}(E) = \int d\hat{\boldsymbol{k}}_e \sum_m \left| \langle \Psi_{n\ell m} | \boldsymbol{r} | \Psi_i(\boldsymbol{k}_e) \rangle \right|^2 \,.$$

(54.206)

Transition T–Matrix for RR.

$$\sigma_R^{n\ell}(E) = \frac{\pi a_0^2}{(k a_0)^2} \left| T_R \right|^2 \rho(E) \,,$$

(54.207)

$$\left| T_R \right|^2 = 4\pi^2 \int \sum_m \left| D_{fi} \right|^2 d\hat{\boldsymbol{k}}_e \,.$$

(54.208)

Photoionization Cross Section. From detailed balance in (54.196), $\sigma_I^{n\ell}$ is

$$\sigma_I^{n\ell}(h\nu) = \left(\frac{8\pi^2}{3} \right) \alpha h\nu \left(\frac{g_A^+}{g_A} \right) \rho(E) R_I^{n\ell}(E) \,.$$

(54.209)

Continuum Wave Function Expansion.

$$\Psi_i(\boldsymbol{k}_e, \boldsymbol{r}) = \sum_{\ell'm'} i^{\ell'} e^{i\eta_{\ell'}} R_{E\ell'}(r) Y_{\ell'm'}\left(\hat{\boldsymbol{k}}_e\right) Y_{\ell'm'}(\hat{\boldsymbol{r}}) \,.$$

(54.210)

Energy Normalization. With $\rho(E) = 1$,

$$\int \Psi_i(\boldsymbol{k}_e; \boldsymbol{r}) \Psi_i^*\left(\boldsymbol{k}_e'; \boldsymbol{r}\right) d\boldsymbol{r} = \delta\left(E - E'\right) \delta\left(\hat{\boldsymbol{k}}_e - \hat{\boldsymbol{k}}_e'\right) \,.$$

(54.211)

Plane Wave Expansion.

$$e^{i\boldsymbol{k}\cdot\boldsymbol{r}} = 4\pi \sum_{\ell=0}^{\infty} i^\ell j_\ell(kr) Y_{\ell m}^*\left(\hat{\boldsymbol{k}}\right) Y_{\ell m}(\hat{\boldsymbol{r}})$$

(54.212)

$$j_\ell(kr) \sim \sin\left(kr - \frac{1}{2}\ell\pi \right)/(kr) \,.$$

(54.213)

For bound states,

$$\Psi_{n\ell m}(\boldsymbol{r}) = R_{n\ell}(r) Y_{\ell m}(\hat{\boldsymbol{r}}) \,.$$

(54.214)

RR and PI Cross Sections and Radial Integrals.

$$\sigma_R^{n\ell}(E) = \frac{8\pi^2}{3} \left(\frac{(\alpha h\nu)^3}{2(e^2/a_0)E} \right) \rho(E) R_I(E; n\ell) \,.$$

(54.215)

For an electron outside a closed core,

$$g_A^+ = 1, \quad g_A = 2(2\ell + 1)$$

$$\sigma_{\mathrm{I}}^{n\ell}(h\nu) = \frac{4\pi^2 \alpha h\nu \rho(E)}{3(2\ell + 1)} R_{\mathrm{I}}(E; n\ell) , \qquad (54.216a)$$

$$R_{n\ell}^{\varepsilon, \ell'} = \int_0^\infty (R_{\varepsilon\ell'} \, r \, R_{n\ell}) \, r^2 \, \mathrm{d}r , \qquad (54.216b)$$

$$R_{\mathrm{I}}(E; n\ell) = \ell \left| R_{n\ell}^{\varepsilon, \ell-1} \right|^2 + (\ell + 1) \left| R_{n\ell}^{\varepsilon, \ell+1} \right|^2 . \qquad (54.216c)$$

For an electron outside an unfilled core (c) in the process $(A^+ + \mathrm{e}^-) \rightarrow A(n\ell)$, the weights are
State i: $[S_{\mathrm{c}}, L_{\mathrm{c}}; \varepsilon]$, $g_A^+ = (2S_{\mathrm{c}} + 1)(2L_{\mathrm{c}} + 1)$
State f: $[(S_{\mathrm{c}}, L_{\mathrm{c}}; n\ell)S, L]$, $g_A = (2S + 1)(2L + 1)$.

$$R_{\mathrm{I}}(E; n\ell) = \frac{(2L + 1)}{(2L_{\mathrm{c}} + 1)}$$

$$\times \sum_{\ell' = \ell \pm 1} \sum_{L'} (2L' + 1) \left\{ \begin{matrix} \ell & L & L_{\mathrm{c}} \\ L' & \ell' & 1 \end{matrix} \right\}^2$$

$$\times \ell_{\max} \left| \int_0^\infty (R_{\varepsilon\ell'} \, r \, R_{n\ell}) \, r^2 \, \mathrm{d}r \right|^2 . \qquad (54.217)$$

This reduces to (54.216c) when the radial functions $R_{i,f}$ do not depend on $(S_{\mathrm{c}}, L_{\mathrm{c}}, S, L)$.

Cross Section for Dielectronic Recombination

$$\sigma_{\mathrm{DLR}}^{n\ell}(E) = \frac{\pi a_0^2}{(ka_0)^2} |T_{\mathrm{DLR}}(E)|^2 \rho(E) , \qquad (54.218)$$

$$|T_{\mathrm{DLR}}(E)|^2 = 4\pi^2 \int \mathrm{d}\hat{\boldsymbol{k}}_{\mathrm{e}}$$

$$\times \sum_j \left| \frac{\langle \Psi_f | D | \Psi_j \rangle \langle \Psi_j | V | \Psi_i(\boldsymbol{k}_{\mathrm{e}}) \rangle}{(E - \varepsilon_j + \mathrm{i}\Gamma_j/2)} \right|^2 , \qquad (54.219)$$

which is the generalization of the T-matrix (54.208) to include the effect of intermediate doubly-excited autoionizing states $|\Psi_j\rangle$ in energy resonance to within width Γ_j of the initial continuum state Ψ_i. The electrostatic interaction $V = e^2 \sum_{i=1}^N (\boldsymbol{r}_i - \boldsymbol{r}_{N+1})^{-1}$ initially produces dielectronic capture by coupling the initial state i with the resonant states j which become stabilized by coupling via the dipole radiation field interaction $\boldsymbol{D} = (2\omega^3/3\pi c^3)^{1/2} \sum_{i=1}^{N+1} (e\boldsymbol{r}_i)$ to the final stabilized state f. The above cross section for (54.3) is valid for isolated, nonoverlapping resonances.

Continuum Wave Normalization and Density of States

The basic formulae (54.206) for $\sigma_{\mathrm{R}}^{n\ell}$ depends on the density of states $\rho(E)$ which in turn varies according to the particular normalization constant N adopted for the continuum radial wave,

$$R_{E\ell}(r) \sim N \sin\left(kr - \frac{1}{2}\ell\pi + \eta_\ell\right) \bigg/ r , \qquad (54.220)$$

in (54.210) where the phase is

$$\eta_\ell = \arg \Gamma(\ell + 1 + \mathrm{i}\beta) - \beta \ln 2kr + \delta_\ell . \qquad (54.221)$$

The phase corresponding to the Hartree–Fock short-range interaction is δ_ℓ. The Coulomb phase shift for electron motion under $(-Ze^2/r)$ is $(\eta_\ell - \delta_\ell)$ with $\beta = Z/(ka_0)$.

For a plane wave $\phi_{\boldsymbol{k}}(\boldsymbol{r}) = N' \exp(\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r})$,

$$\langle \phi_{\boldsymbol{k}}(\boldsymbol{r}) | \phi_{\vec{k}}(\boldsymbol{r}) \rangle \, \mathrm{d}\boldsymbol{k} = (2\pi)^3 |N'|^2 \rho(\boldsymbol{k}) \, \mathrm{d}\boldsymbol{k} \, \delta(\boldsymbol{k} - \boldsymbol{k}')$$

$$\equiv \left(\frac{h^3}{mp}\right) |N'|^2 \rho(E, \hat{\boldsymbol{k}}) \, \mathrm{d}E \, \mathrm{d}\hat{\boldsymbol{k}} \, \delta(E - E')\delta(\hat{\boldsymbol{k}} - \hat{\boldsymbol{k}}') . \qquad (54.222)$$

On integrating (54.222) over all E and $\hat{\boldsymbol{k}}$ for a single particle distributed over all $|E, \hat{\boldsymbol{k}}\rangle$ states, N' and ρ are then interrelated by

$$|N'|^2 \rho(E, \hat{\boldsymbol{k}}) = mp/h^3 . \qquad (54.223)$$

The incident current is

$$j \, \mathrm{d}E \, \mathrm{d}\hat{\boldsymbol{k}}_{\mathrm{e}} = v |N'|^2 \rho(E, \hat{\boldsymbol{k}}) \, \mathrm{d}E \, \mathrm{d}\hat{\boldsymbol{k}}_{\mathrm{e}} \qquad (54.224a)$$

$$= (2mE/h^3) \, \mathrm{d}E \, \mathrm{d}\hat{\boldsymbol{k}}_{\mathrm{e}} = v \, \mathrm{d}\boldsymbol{p}_{\mathrm{e}}/h^3 . \qquad (54.224b)$$

Radial Wave Connection. From (54.210) and (54.212), $N = (4\pi N'/k)$, so that the connection between N of (54.220) and $\rho(E)$ is

$$|N|^2 \rho(E, \hat{\boldsymbol{k}}) = \frac{(2m/\hbar^2)}{\pi k} = \frac{(2/\pi)}{ka_0 e^2} . \qquad (54.225)$$

RR Cross Sections for Common Normalization Factors of Continuum Radial Functions

(a) $N = 1$; $\quad \rho(E) = \dfrac{(2m/\hbar^2)}{\pi k} = \dfrac{(2/\pi)}{(ka_0)e^2}$, $\qquad (54.226)$

$$\sigma_{\mathrm{R}}^{n\ell}(E) = \frac{8\pi^2 a_0^2}{(ka_0)^3} \int \sum_m |D_{fi}|^2 \, \mathrm{d}\hat{\boldsymbol{k}}_{\mathrm{e}} , \qquad (54.227)$$

where D_{fi} of (54.204) is dimensionless.

(b) $N = k^{-1}$; $\rho(E) = (2m/\hbar^2)(k/\pi)$,   (54.228)

$$\sigma_R^{n\ell}(E) = \frac{16\pi a_0^2}{3\sqrt{2}} \left(\frac{\alpha h\nu}{e^2/a_0}\right)^3 \sqrt{\frac{(e^2/a_0)}{E}} \left(\frac{R_I}{a_0^5}\right) ,$$
(54.229)

where (54.216b) and (54.216c) for R_I has dimension $[L^5]$.

(c) $N = k^{-1/2}$; $\rho(E) = \frac{(2m/\hbar^2)}{\pi}$,   (54.230)

$$\sigma_R^{n\ell}(E) = \frac{8\pi a_0^2}{3} \left(\frac{\alpha^3 (h\nu)^3}{(e^2/a_0)^2 E}\right) \left(\frac{R_I}{a_0^4}\right) ,$$
(54.231)

where R_I has dimensions of $[L^4]$.

(d) $N = (2m/\hbar^2\pi^2 E)^{1/4}$; $\rho(E) = 1$,   (54.232)

$$\sigma_R^{n\ell}(E) = \frac{4(\pi a_0)^2}{3} \left(\frac{\alpha^3 (h\nu)^3}{(e^2/a_0)^2 E}\right) \left(\frac{R_I}{e^2 a_0}\right) ,$$
(54.233)

where R_I has dimensions of $[L^2 E^{-1}]$.

54.8.4 Bound–Free Oscillator Strengths

For a transition $n\ell \to E$ to $E + dE$,
$$\frac{d f_{n\ell}}{dE} = \frac{2}{3} \frac{(h\nu)}{(e^2/a_0)} \frac{1}{(2\ell+1)} \sum_m \sum_{\ell'm'} \left| r_{n\ell m}^{\varepsilon\ell'm'} \right|^2 ,$$
(54.234)

$$R_I(\varepsilon; n\ell) = \int d\hat{k}_e \sum_m |\langle \Psi_{n\ell m} | r | \Psi_i(k_e) \rangle E|^2$$
$$= \sum_{m,\ell',m'} \left| r_{n\ell m}^{\varepsilon\ell'm'} \right|^2 ,$$
(54.235)

$$\sigma_R^{n\ell}(E) = 2\pi^2 \alpha a_0^2 g_A \left(\frac{k_\nu^2}{k_e^2}\right) \left(\frac{e^2}{a_0}\right) \frac{d f_{n\ell}}{dE} ,$$
(54.236a)

$$\sigma_I^{n\ell}(h\nu) = 2\pi^2 \alpha a_0^2 g_A^+ \left(\frac{e^2}{a_0}\right) \frac{d f_{n\ell}}{dE} .$$
(54.236b)

Semiclassical Hydrogenic Systems

$$g_A = g_{n\ell} = 2(2\ell+1) , \quad g_A^+ = 1 ,$$

$$\sigma_R^n(E) = \sum_{\ell=0}^{n-1} \sigma_R^{n\ell}(E) = 2\pi^2 \alpha a_0^2 \left(\frac{k_\nu^2}{k_e^2}\right) \frac{d F_n}{dE} ,$$
(54.237)

$$\frac{d F_n}{dE} = \sum_{\ell=0}^{n-1} g_{n\ell} \frac{d f_{n\ell}}{dE} = 2 \sum_{\ell,m} \frac{d f_{n\ell m}}{dE} .$$
(54.238)

Bound–Bound Absorption Oscillator Strength. For a transition $n \to n'$,

$$F_{nn'} = 2 \sum_{\ell m} \sum_{\ell'm'} f_{n\ell m}^{n'\ell'm'}$$
(54.239a)

$$= \frac{2^6}{3\sqrt{3}\pi} \left[\left(\frac{1}{n^2} - \frac{1}{n'^2}\right)^{-3}\right] \frac{1}{n^3} \frac{1}{n'^3} ,$$
(54.239b)

$$\frac{d F_n}{dE} = \frac{2^5}{3\sqrt{3}\pi} n \frac{I_n^2}{(h\nu)^3} = 2n^2 \frac{d f_{n\ell}}{dE} ,$$
(54.239c)

$$\sigma_R^n(E) = \frac{2^5 \alpha^3}{3\sqrt{3}} \left(\frac{n I_n^2}{E(h\nu)}\right) \pi a_0^2 ,$$
(54.239d)

$$\sigma_I^{n\ell}(h\nu) = \frac{2^6 \alpha}{3\sqrt{3}} \frac{n}{Z^2} \left(\frac{I_n}{h\nu}\right)^3 \pi a_0^2 ,$$
(54.239e)

$$= 7.907\,071 \left(\frac{n}{Z^2}\right) \left(\frac{I_n}{h\nu}\right)^3 \text{Mb} .$$
(54.239f)

This semiclassical analysis yields exactly Kramers PI and associated RR cross sections in Sect. 54.8.2.

54.8.5 Radiative Recombination Rate

$$\hat{\alpha}_R^{n\ell}(T_e) = \overline{v}_e \int_0^\infty \varepsilon \, \sigma_R^{n\ell}(\varepsilon) \, e^{-\varepsilon} \, d\varepsilon$$
(54.240a)

$$\equiv \overline{v}_e \left\langle \sigma_R^{n\ell}(T_e) \right\rangle ,$$
(54.240b)

where $\varepsilon = E/k_B T$ and $\left\langle \sigma_R^{n\ell}(T_e) \right\rangle$ is the Maxwellian-averaged cross section for radiative recombination.

In terms of the continuum-bound $A_{n\ell}(E)$,

$$\hat{\alpha}_R^{n\ell}(T_e) = \frac{h^3}{(2\pi m_e k_B T)^{3/2}} \int_0^\infty \left(\frac{d A_{n\ell}}{d\varepsilon}\right) e^{-\varepsilon} \, d\varepsilon ,$$
(54.241)

$$\frac{d A_{n\ell}}{dE} = \rho(E) \sum_m \int A_{n\ell m}(E, \hat{k}_e) \, d\hat{k}_e .$$
(54.242)

Milne Detailed Balance Relation
In terms of $\sigma_I^{n\ell}(h\nu)$,

$$\hat{\alpha}_R^{n\ell}(T_e)$$
$$= \overline{v}_e \left(\frac{g_A}{2g_A^+}\right) \left(\frac{k_B T_e}{mc^2}\right) \left(\frac{I_n}{k_B T_e}\right)^2 \left\langle \sigma_I^{n\ell}(T_e) \right\rangle ,$$
(54.243)

where, in reduced units $\omega = h\nu/I_n$, $T = k_B T_e/I_n = b_n^{-1}$, the averaged PI cross section corresponding to (54.174)

is

$$\left\langle \sigma_{\mathrm{I}}^{n\ell}(T) \right\rangle = \frac{\mathrm{e}^{1/T}}{T} \int\limits_{1}^{\infty} \omega^2 \sigma_{\mathrm{I}}^{n\ell}(\omega)\, \mathrm{e}^{-\omega/T}\, \mathrm{d}\omega \;. \quad (54.244)$$

When $\sigma_{\mathrm{I}}^{n\ell}(\omega)$ is expressed in Mb $(10^{-18}\,\mathrm{cm}^2)$,

$$\hat{\alpha}_{\mathrm{R}}^{n\ell}(T_{\mathrm{e}}) = 1.508 \times 10^{-13} \left(\frac{300}{T_{\mathrm{e}}} \right)^{1/2} \left(\frac{I_n}{I_{\mathrm{H}}} \right)^2 \left(\frac{g_A}{2g_A^+} \right)$$
$$\times \left\langle \sigma_{\mathrm{I}}^{n\ell}(T) \right\rangle \mathrm{cm}^3\,\mathrm{s}^{-1} \;. \quad (54.245)$$

When σ_{I} can be expressed in terms of the threshold cross section σ_0^n (54.178) as

$$\sigma_{\mathrm{I}}^{n\ell}(h\nu) = (I_n/h\nu)^p \sigma_0(n); \; (p = 0, 1, 2, 3) \;, \quad (54.246)$$

then $\left\langle \sigma_{\mathrm{I}}^{n\ell}(T) \right\rangle = S_p(T)\sigma_0(n)$, where

$$S_0(T) = 1 + 2T + 2T^2 \;, \quad S_1(T) = 1 + T \;, \quad (54.247a)$$

$$S_2(T) = 1 \;, \quad (54.247b)$$

$$S_3(T) = \left(\mathrm{e}^{1/T}/T \right) E_1(1/T) \quad (54.247c)$$

$$\overset{T \ll 1}{\sim} 1 - T + 2T^2 - 6T^3 \;. \quad (54.247d)$$

The case $p = 3$ corresponds to Kramers PI cross section (54.181) so that

$$_{\mathrm{K}}\hat{\alpha}_{\mathrm{R}}^{n\ell}(T_{\mathrm{e}}) = \frac{(2\ell + 1)}{n^2} \frac{2}{n} \hat{\alpha}_0(T_{\mathrm{e}}) S_3(T) \quad (54.248a)$$

$$\equiv {}_{\mathrm{K}}\hat{\alpha}_{\mathrm{R}}^{n\ell}(T_{\mathrm{e}} \to 0) S_3(T) \;, \quad (54.248b)$$

such that $_{\mathrm{K}}\hat{\alpha}_{\mathrm{R}}^{n\ell} \sim Z^2 / \left(n^3 T_{\mathrm{e}}^{1/2} \right)$ as $T = (k_{\mathrm{B}} T_{\mathrm{e}}/I_n) \to 0$.

54.8.6 Gaunt Factor, Cross Sections and Rates for Hydrogenic Systems

The Gaunt factor $G_{n\ell}$ is the ratio of the quantal to Kramers (K) semiclassical PI cross section such that

$$\sigma_{\mathrm{I}}^{n\ell}(h\nu) = {}_{\mathrm{K}}\sigma_{\mathrm{I}}^n(h\nu) G_{n\ell}(\omega) \;; \quad (54.249)$$

$$\omega = h\nu/I_n = 1 + E/I_n \;.$$

(a) Radiative Recombination Cross Section

$$\sigma_{\mathrm{R}}^{n\ell}(E) = \left(\frac{g_A}{g_A^+} \right) \left(\frac{\alpha^2 (h\nu)^2}{2E(e^2/a_0)} \right) G_{n\ell}(\omega) {}_{\mathrm{K}}\sigma_{\mathrm{I}}^n(h\nu)$$
$$\quad (54.250a)$$

$$= G_{n\ell}(\omega) {}_{\mathrm{K}}\sigma_{\mathrm{R}}^{n\ell}(E) \quad (54.250b)$$

$$= \left[\frac{(2\ell + 1)}{n^2} G_{n\ell}(\omega) \right]_{\mathrm{K}} \sigma_{\mathrm{R}}^n(E) \;, \quad (54.250c)$$

$$\sigma_{\mathrm{R}}^n(E) = G_n(\omega) {}_{\mathrm{K}}\sigma_{\mathrm{R}}^n(E) \quad (54.250d)$$

where the quantum mechanical correction, or Gaunt factor, to the semiclassical cross sections

$$G_{n\ell}(\omega) \to \begin{cases} 1, & \omega \to 1 \\ \omega^{-(\ell+1/2)}, & \omega \to \infty \end{cases} \quad (54.251)$$

favors low $n\ell$ states. The ℓ-averaged Gaunt factor is

$$G_n(\omega) = (1/n^2) \sum_{\ell=0}^{n-1} (2\ell + 1) G_{n\ell}(\omega) \;. \quad (54.252)$$

Approximations for G_n: as ε increases from zero,

$$G_n(\varepsilon) = \left[1 + \frac{4}{3}(a_n + b_n) + \frac{28}{18} a_n^2 \right]^{-3/4} \quad (54.253a)$$

$$\simeq 1 - (a_n + b_n) + \frac{7}{3} a_n b_n + \frac{7}{6} b_n^2 \quad (54.253b)$$

where $E = \varepsilon \left(Z^2 e^2 / 2a_0 \right)$, $\omega = 1 + n^2 \varepsilon$, and

$$a_n(\varepsilon) = 0.172\,825 \left(1 - n^2 \varepsilon \right) c_n(\varepsilon) \;, \quad (54.254a)$$

$$b_n(\varepsilon) = 0.049\,59 \left(1 + \frac{4}{3} n^2 \varepsilon + n^4 \varepsilon^2 \right) c_n^2(\varepsilon) \;, \quad (54.254b)$$

$$c_n(\varepsilon) = n^{-2/3} \left(1 + n^2 \varepsilon \right)^{-2/3} \;. \quad (54.254c)$$

Radiative Recombination Rate

$$\hat{\alpha}_{\mathrm{R}}^{n\ell}(T_{\mathrm{e}}) = {}_{\mathrm{K}}\hat{\alpha}_{\mathrm{R}}^{n\ell}(T_{\mathrm{e}} \to 0) F_{n\ell}(T) \;, \quad (54.255)$$

$$\hat{\alpha}_{\mathrm{R}}^{n\ell}(T_{\mathrm{e}} \to 0) = \frac{(2\ell + 1)}{n^2} \left(\frac{2}{n} \right) \hat{\alpha}_0(T_{\mathrm{e}}) \;, \quad (54.256)$$

in accordance with (54.185b).

$$F_{n\ell}(T) = \frac{\mathrm{e}^{1/T}}{T} \int\limits_{1}^{\infty} \frac{G_{n\ell}(\omega)}{\omega}\, \mathrm{e}^{-\omega/T}\, \mathrm{d}\omega \;. \quad (54.257)$$

The multiplicative factors F and G convert the semiclassical (Kramers) $T_{\mathrm{e}} \to 0$ rate and cross section to their quantal values. Departures from the scaling rule $\left(Z^2 / n^3 T_{\mathrm{e}}^{1/2} \right)$ for RR rates is measured by $F_{n\ell}(T)$.

54.8.7 Exact Universal Rate Scaling Law and Results for Hydrogenic Systems

$$\hat{\alpha}_{\mathrm{R}}^{n\ell}(Z, T_{\mathrm{e}}) = Z \hat{\alpha}_{\mathrm{R}}^{n\ell} \left(1, T_{\mathrm{e}}/Z^2 \right) \quad (54.258)$$

as exhibited by (54.243) with (54.239e) and (54.244).

Recombination rates are greatest into low n levels and the $\omega^{-\ell-1/2}$ variation of $G_{n\ell}$ preferentially populates states with low $\ell \approx 2$–5. Highly accurate analytical

fits for $G_{n\ell}(\omega)$ have been obtained for $n \leq 20$ so that (54.249) can be expressed in terms of known functions of fit parameters [54.17]. This procedure (which does not violate the S_2 sum rule) has been extended to nonhydrogenic systems of neon-like Fe XVII, where $\sigma_I^{n\ell}(\omega)$ is a monotonically decreasing function of ω.

The variation of the ℓ-averaged values

$$n^{-2} \sum_{\ell=0}^{n-1} (2\ell+1) F_{n\ell}(T)$$

is close in both shape and magnitude to the corresponding semiclassical function $S_3(T)$, given by (54.257) with $G_{n\ell}(\omega) = 1$. Hence the ℓ-averaged recombination rate is

$$\hat{\alpha}_R^n(Z, T) = (300/T)^{1/2} (Z^2/n) F_n(T)$$
$$\times 1.1932 \times 10^{-12} \, \text{cm}^3 \, \text{s}^{-1} \,,$$

where F_n can be calculated directly from (54.257) or be approximated as $G_n(1)S(T)$. A computer program based on a three-term expansion of G_n is also available [54.18]. From a three-term expansion for G, the rate of radiative recombination into all levels of a hydrogenic system is

$$\hat{\alpha}(Z, T) = 5.2 \times 10^{-14} Z \lambda^{1/2}$$
$$\times \left(0.43 + \frac{1}{2} \ln \lambda + 0.47/\lambda^{1/2} \right) ,$$
(54.259)

where $\lambda = 1.58 \times 10^5 Z^2/T$ and $[\hat{\alpha}] = \text{cm}^3/\text{s}$. Tables [54.19] exist for the effective rate

$$\hat{\alpha}_E^{n\ell}(T) = \sum_{n'=n}^{\infty} \sum_{\ell'=0}^{n'-1} \hat{\alpha}_R^{n'\ell'} C_{n'\ell',n\ell}$$
(54.260)

of populating a given level $n\ell$ of H via radiative recombination into all levels $n' \geq n$ with subsequent radiative cascade ($i \to f$) with probability $C_{i,f}$ via all possible intermediate paths. Tables [54.19] also exist for the full rate

$$\hat{\alpha}_F^N(T) = \sum_{n=N}^{\infty} \sum_{\ell=0}^{n-1} \hat{\alpha}_R^{n\ell}$$
(54.261)

of recombination, into all levels above $N = 1, 2, 3, 4$, of hydrogen. They are useful in deducing time scales of radiative recombination and rates for complex ions.

54.9 Useful Quantities

(a) Mean Speed

$$\bar{v}_e = \left(\frac{8k_B T}{\pi m_e} \right)^{1/2} = 1.076\,042 \times 10^7 \left(\frac{T}{300} \right)^{1/2} \text{cm/s}$$
$$= 6.692\,38 \times 10^7 T_{eV}^{1/2} \text{cm/s}$$
$$\bar{v}_i = 2.511\,16 \times 10^5 \left(\frac{T}{300} \right)^{1/2} (m_p/m_i)^{1/2} \text{cm/s}$$

where $(m_p/m_e)^{1/2} = 42.850\,352$, and $T = 11\,604.45\,T_{eV}$ relates the temperature in K and in eV.

(b) Natural Radius
$|V(R_e)| = e^2/R_e = k_B T$.

$$R_e = \frac{e^2}{k_B T} = 557 \left(\frac{300}{T} \right) \text{Å} = \left(\frac{14.4}{T_{eV}} \right) \text{Å} \,.$$

(c) Boltzmann Average Momentum

$$\langle p \rangle = \int_{-\infty}^{\infty} e^{-p^2/2mk_B T} \, dp = (2\pi m_e k_B T)^{1/2} \,.$$

(d) De Broglie Wavelength

$$\lambda_{dB} = \frac{h}{\langle p \rangle} = \frac{h}{(2\pi m_e k_B T)^{1/2}}$$
$$= \frac{7.453\,818 \times 10^{-6}}{T_e^{1/2}} \text{ cm}$$
$$= 43.035 \left(\frac{300}{T_e} \right)^{1/2} \text{Å} = \frac{6.9194}{T_{eV}^{1/2}} \text{ Å} \,.$$

55. Dielectronic Recombination

Dielectronic recombination (DR) is a two-step process that greatly increases the effciency for electrons and ions to recombine in a plasma. The process therefore plays an important role in the theoretical modeling of plasmas, whether in the laboratory or in astrophysical sources such as the solar corona. The purpose of this chapter is to present the theoretical formulation for DR, and the principal methods for calculating rate coefficients. The results are compared with experiment over a broad range of low–Z ions and high–Z ions where relativistic effects become important.

Electron–ion recombination into a particular final recombined state may be schematically represented as

$$e^- + A_i^{q+} \rightarrow A_f^{(q-1)+} + \hbar\omega \,, \tag{55.1}$$

and

$$e^- + A_i^{q+} \rightarrow \left[A_j^{(q-1)+} \right] \rightarrow A_f^{(q-1)+} + \hbar\omega \,, \tag{55.2}$$
where q is the charge on the atomic ion A, ω is the frequency of the emitted light, and the brackets in (55.2) indicate a doubly-excited resonance state. The first process is called radiative recombination (RR), while the second is called dielectronic recombination (DR). Both recombination mechanisms are the inverse of photoionization. At sufficiently high electron density, three-body recombination becomes possible. The three-body mechanism is the inverse of electron impact ionization.

The review article by *Seaton* and *Storey* [55.1] includes an interesting history of the theoretical work on dielectronic recombination. The process was first referred to as dielectronic recombination by *Massey* and *Bates* [55.2], after a suggestion of its possible importance in the ionosphere by Sayers in 1939. However, estimates of the rate coefficient for this process indicated that DR is not an important process in the ionosphere, where the temperatures are too low to excite anything but the lower energy resonance states.

In 1961, Unsold, in a letter to Seaton, suggested that DR might account for a well-known temperature discrepancy in the solar corona. Seaton initially concluded that DR would not significantly increase recombination in the solar corona. However, he had only included the lower energy resonance states in his analysis; *Burgess* [55.3] showed that when one includes the higher members of the Rydberg series of resonance states that are populated at coronal temperatures, DR can indeed explain this discrepancy.

Dielectronic recombination has since received much theoretical attention due, in part, to its importance in modeling high temperature plasmas. Various approaches to the theory are discussed in a review by *Hahn* [55.4] and in [55.5]. Recently, there have been various projects aimed at the generation of large quantities of DR data for use in astrophysical and fusion plasma modeling. One such project is based on the results of the AUTOSTRUCTURE code, with both the total and partial (i. e., resolved by recombined level) DR rate coefficients being archived. The methodology is outlined in *Badnell* et al. [55.6]. Data are calculated for all members of an isoelectronic sequence from H to Ar, along with various ions relevant to astrophysics or fusion, namely Ca, Ti, Cr, Fe, Ni, Zn, Kr, Mo, and Xe. Work has been completed for the oxygen [55.7], beryllium [55.8], carbon [55.9], lithium [55.10], boron [55.11], neon [55.12] and nitrogen [55.13] isoelectronic sequences. There has also been

a large quantity of data generated using a fully relativistic Dirac–Fock code [55.14]. This data includes calculations of Na-like ions [55.15] and H-like through to Ne-like [55.16] ions of certain astrophysically important elements.

Interest in dielectronic recombination has increased dramatically in the last twenty years. *Mitchell* et al. [55.17] published the DR cross section for C^+ using a merged electron–ion beams apparatus, and *Belic* et al. [55.18] reported on a crossed beams measurement of the DR cross section for Mg^+. Also, *Dittner* et al. [55.19] published merged beams measurements of the DR cross section for the multiply charged ions

B^{2+} and C^{3+}. Since that time, atomic physics experiments carried out using heavy-ion traps, accelerators, and storage-cooler rings have produced high-resolution mappings of the resonance structures associated with electron-ion recombination. The experiments have been carried out using a wide range of facilities and technologies, such as the test storage ring (TSR) at Heidelberg, the experimental storage ring (ESR) at Darmstadt, the accelerator-cooler ring facility at Aarhus, the electron beam ion trap (EBIT) at Livermore, and the electron beam ion source (EBIS) at Kansas State. A good review of the dramatic experimental progress in DR measurements is again found in the NATO proceedings [55.5].

55.1 Theoretical Formulation

In the independent-processes approximation, the two paths for recombination are summed incoherently. The radiative recombination cross section for (55.1), in lowest-order of perturbation theory, is given by

$$\sigma_{RR} = \frac{8\pi^2}{k^3}$$

$$\times \sum_{\ell j} \sum_{JM} \sum_{M_0} \frac{1}{2g_1} \left| \langle \alpha_0 J_0 M_0 | D | \alpha_1 J_1 \ell j JM \rangle \right|^2 .$$

(55.3)

The set $(\alpha_1 J_1)$ represents the quantum numbers for the N-electron target ion state, $(\alpha_0 J_0 M_0)$ represents the
Fig. 55.1 Dielectronic Recombination for O^{5+}. Calculations were performed for fields of $0\,V/cm$ (*dotted curve*), $3\,V/cm$ (*dashed curve*), $5\,V/cm$ (*chain curve*), and $7\,V/cm$ (*solid curve*)

quantum numbers for the $(N+1)$-electron recombined ion state, $(k\ell j)$ represents the quantum numbers for the continuum electron state, (JM) represents the quantum numbers for the $(N+1)$-electron system of target plus free electron state, and g_1 is the statistical weight of a J_1 level. The dipole radiation field operator is given by

$$D = \sqrt{\frac{2\omega^3}{3\pi c^3}} \sum_{s=1}^{N+1} r_s .$$

(55.4)

Continuum normalization is chosen as one times a sine function, and atomic units ($e = \hbar = m = 1$) are used. In the isolated-resonance approximation, the dielectronic recombination cross section for (55.2), in lowest-order perturbation theory, is given by

$$\sigma_{DR} = \frac{8\pi^2}{k^3} \sum_{\ell j} \sum_{JM} \sum_{M_0} \frac{1}{2g_1}$$

$$\times \sum_{\alpha_i J_i M_i} \left| \frac{\langle \alpha_0 J_0 M_0 | D | \alpha_i J_i M_i \rangle \langle \alpha_i J_i M_i | V | \alpha_1 J_1 \ell j JM \rangle}{E_0 - E_i + i\Gamma_i/2} \right|^2 ,$$

(55.5)

where the set $(\alpha_i J_i M_i)$ represents the quantum numbers for a resonance state with energy E_i and total width Γ_i, and the electrostatic interaction between electrons is given by

$$V = \sum_{s=1}^{N} |r_s - r_{N+1}|^{-1} .$$

(55.6)

By the principle of detailed balance, σ_{RR} of (55.3) is proportional to the photoionization cross section from

the bound state, while the energy-averaged σ_{DR} may be written as

$$\langle \sigma_{\mathrm{DR}} \rangle = \frac{2\pi^2}{\Delta \epsilon k^2} \sum_{\alpha_i J_i M_i} \frac{1}{2g_1} \frac{A_{\mathrm{a}} A_{\mathrm{r}}}{\Gamma_i} \,, \qquad (55.7)$$

where the autoionization decay rate A_{a} is given by

$$A_{\mathrm{a}} = \frac{4}{k} \sum_{\ell j} \sum_{JM} |\langle \alpha_1 J_1 \ell j JM | V | \alpha_i J_i M_i \rangle|^2 \,, \quad (55.8)$$

the radiative decay rate A_{r} is given by

$$A_{\mathrm{r}} = 2\pi \sum_{M_0} |\langle \alpha_0 J_0 M_0 | D | \alpha_i J_i M_i \rangle|^2 \,, \qquad (55.9)$$

and $\Delta \epsilon$ is the energy bin width. Each resonance level in (55.7) makes a contribution at a fixed continuum energy $k^2/2$; thus $\langle \sigma_{\mathrm{DR}} \rangle$ plotted as a function of energy is a histogram.

55.2 Comparisons with Experiment

55.2.1 Low−Z Ions

For the most part, the agreement between the recent high-resolution measurements and theoretical calculations based on the independent-processes and isolated-resonance (IPIR) approximations is quite good [55.20–38]. We illustrate the agreement with experiment obtained by calculations employing the IPIR approximations with three examples from the Li isoelectronic sequence. The pathways for dielectronic capture, in terms of specific levels, are given by

$$\mathrm{e}^- + A^{q+}(2\mathrm{s}_{1/2}) \rightarrow \left[A^{(q-1)+}(2\mathrm{p}_{1/2}nlj) \right]$$
$$\searrow$$
$$\left[A^{(q-1)+}(2\mathrm{p}_{3/2}nlj) \right] \,, \quad (55.10)$$
where a $1\mathrm{s}^2$ core is assumed to be present. Both Rydberg series autoionize by the reverse of the paths in (55.10), while for sufficiently high n, the $2\mathrm{p}_{3/2}\,nlj$ levels may autoionize to the $2\mathrm{p}_{1/2}$ continuum. Both series radiatively stabilize by either a $2\mathrm{p} \rightarrow 2\mathrm{s}$ core orbital transition, or by a $nlj \rightarrow n'l'j'$ valence orbital transition, where $2\mathrm{p}_j\,n'l'\,j'$ with $j = \frac{1}{2}, \frac{3}{2}$ is a bound level.

Dielectronic recombination cross section calculations [55.28] in the IPIR approximation for O^{5+} are compared with experiment in Fig. 55.1. Fine-structure splitting of the two series of (55.10) is minimal for this light ion, so there appears only one Rydberg series. The $2\mathrm{p}\,6\ell$ resonances are located at $2.5\,\mathrm{eV}$, the $2\mathrm{p}\,7\ell$ at $5.0\,\mathrm{eV}$, and so on; accumulating at the series limit around $11.3\,\mathrm{eV}$. Electric field effects on the high-n resonances are strong in O^{5+}, so that calculations were done for fields of 0, 3, 5, and $7\,\mathrm{V/cm}$. Since the precise electric field strength in the experiment is not known, the accuracy of an electric field dependent theory, in this case, has yet to be determined. However, the effects of state mixing by extrinsic fields in the collision region for the dielectronic recombination of Mg^+

have been investigated both experimentally [55.39] and theoretically [55.40].

There have been a significant number of recent experiments on low-Z ions. These experiments, in general, show good agreement with theory, see *Fogle* et al. [55.37] and *Schnell* et al. [55.38]. However, it is also clear that discrepancies remain between theory and experiment for certain low energy resonances, due to the difficulty in calculating the energy positions of such resonances. As has been pointed out in *Savin* et al. [55.41] and *Schippers* et al. [55.42], this can lead to significant uncertainties in low temperature DR rate coefficients. Calculating such low energy resonances to sufficient accuracy for low temperature DR rate coefficients remains a significant challenge for theory. Some success in this area has been achieved using relativistic many-body perturbation theory, obtaining very good agreement with low energy resonance positions for a range of systems, see, for example, *Lindroth* et al. [55.43], *Fogle* et al. [55.44], and *Tokman* et al. [55.45].

55.2.2 High−Z Ions and Relativistic Effects

Dielectronic recombination cross section calculations [55.31] in the IPIR approximation for Cu^{26+} are compared with experiment in Fig. 55.2. The two fine-structure Rydberg series are now clearly resolved; the fine-structure splitting is about $27\,\mathrm{eV}$ for Cu^{26+}. The $2\mathrm{p}_{1/2}\,13\ell$ resonances are just above threshold, while the $2\mathrm{p}_{3/2}\,11\ell$ resonances are found around $5.0\,\mathrm{eV}$. Electric fields in the range 0–$50\,\mathrm{V/cm}$ have little effect on the Cu^{26+} spectrum. Overall, the agreement between theory and experiment is excellent.

Electron-ion recombination cross section calculations [55.32] in the IPIR approximation for low-lying resonances in Au^{76+} are compared with experiment in Fig. 55.3. The $2\mathrm{p}_{1/2}\,nlj$ series limit is at $217\,\mathrm{eV}$, while the $2\mathrm{p}_{3/2}\,nlj$ series limit is at $2.24\,\mathrm{keV}$; yielding a fine
Fig. 55.2 Dielectronic Recombination for Cu^{26+}

Fig. 55.3a–c Dielectronic recombination for Au^{76+}. The curves show (**a**) perturbative relativistic, (**b**) semirelativistic, and (**c**) fully relativistic calculations for the dielectronic recombination cross section

structure splitting of 2.03 keV. QED effects alone shift the $2p_{3/2}\,nlj$ series limit by 22.0 eV. Thus accurate atomic structure calculations must be made to locate the $2p_{3/2}\,6lj$ resonances in the 0–50 eV energy range of the experiment. The figure shows that the perturbative relativistic, semirelativistic, and fully relativistic calculations for the dielectronic recombination cross section ride on top of a strong radiative recombination background. In principle, the fully relativistic theory contains the most physics, and thus it is comforting that on the whole it is in good agreement with the experiment. It is instructive, however, to see how well the computationally simpler perturbative relativistic and semirelativistic theories do for such a highly charged ion.

There have been several recent experimental measurements on high-Z ions, in particular, for astrophysically abundant species. In general, there is good agreement between theory and experiment. Examples of high-Z element DR studies include those done on Fe XXI and Fe XXII by *Savin* et al. [55.41], and on Fe XX by *Savin* et al. [55.46].

55.3 Radiative–Dielectronic Recombination Interference

There has been a great deal of effort in recent years to develop a more general theory of electron-ion recombi-

nation which would go beyond the IPIR approximation to include radiative–dielectronic recombination inter-

ference and overlapping (and interacting) resonance structures [55.47–54]. In almost all cases, the interference between a dielectronic recombination resonance and the radiative recombination background is quite small and difficult to observe. The best possibility for observation of RR-DR interference appears to be in highly charged atomic ions. In the cases studied to date, the combination of electron and photon continuum coupling selection rules and the requirement of near energy degeneracy make the overlapping (and interacting) resonance effects small and difficult to observe. Heavy ions in relatively low stages of ionization are the best place to look, since there are resonance series attached to the large numbers of LS terms or fine structure levels.

The distorted wave approximation (Chapt. 52) has been so successful in describing dielectronic recombination cross sections for most atomic ions because, for low charged ions, the DR cross section is proportional to the radiative rate, while for highly charged ions the DR cross section is proportional to the autoionization rate. Thus the weakness of the distorted wave method in calculating accurate autoionization rates for low charged ions is masked by a DR cross section that is highly dependent on radiative atomic structure. As one moves to more highly charged ions, the DR cross section becomes more sensitive to the autoionization rates, but at the same time, the distorted-wave method becomes increasingly more accurate.

55.4 Dielectronic Recombination

Dielectronic recombination is an important atomic process that is included in the theoretical modeling of the ionization state and emission of radiating ions, which is fundamental to the interpretation of spectral emission from both fusion and astrophysical plasmas (Chapts. 82, 86, and 87). The dielectronic recombination rate coefficient, into a particular final recombined state, is given by

$$\alpha_{DR} = \sqrt{\frac{2}{\pi T^3}} k^2 \Delta\epsilon \, \langle \sigma_{DR}(i \rightarrow f) \rangle \exp\left(\frac{-k^2}{2T}\right),$$

(55.11)

where T is the electron temperature. Dielectronic recombination rate coefficients, from the ground and metastable states of a target ion into fully resolved low-lying states and bundled high-lying states of a recombined ion, are required for a generalized collisional radiative treatment [55.55, 56] of highly populated metastable states, the influence of finite plasma density on excited state populations, and of ionization in dynamic plasmas.

56. Rydberg Collisions: Binary Encounter, Born and Impulse Approximations

Rydberg collisions are collisions of electrons, ions and neutral particles with atomic or molecular targets which are in highly excited Rydberg states characterized by large principal quantum numbers ($n \gg 1$). Rydberg collisions of atoms and molecules with neutral and charged particles include the study of collision−induced transitions both to and from Rydberg states and transitions among Rydberg levels. The basic quantum mechanical structural properties of Rydberg states are given in Chapt. 14. This Chapter collects together many of the equations used to study theoretically the collisional properties of both charged and neutral particles with atoms and molecules in Rydberg states or orbitals. The primary theoretical scattering approximations enumerated in this Chapter are the impulse approximation, binary encounter approximation and the Born approximation. The theoretical techniques used to study Rydberg collisions complement and supplement the eigenfunction expansion approximations used for collisions with target atoms and molecules in their ground ($n = 1$) or first few excited states ($n > 1$), as discussed in Chapt. 47. Direct application of eigenfunction expansion techniques to Rydberg collisions, wherein the target particle can be in a Rydberg orbital with principal quantum number in the range $n \geq 100$, is prohibitively difficult due to the need to compute numerically and store wave functions with n^3 nodes. For $n = 100$ this amounts to $\sim 10^6$ nodes for each of the wave functions represented in the eigenfunction expansion. Therefore, a variety of approximate scattering theories have been developed to deal specifically with the pecularities of Rydberg collisions.

56.1 Rydberg Collision Processes

(A) State-Changing Collisions

Quasi-elastic ℓ-mixing collisions:

$$A^*(n\ell) + B \rightarrow A^*(n\ell') + B \,. \tag{56.1}$$

Quasi-elastic J-mixing collisions: Fine structure transitions with $J = |\ell \pm 1/2| \rightarrow J' = |\ell \pm 1/2|$ are

$$A^*(n\ell J) + B \rightarrow A^*(n\ell J') + B \,. \tag{56.2}$$

Energy transfer n-changing collisions:

$$A^*(n) + B(\beta) \rightarrow A^*(n') + B(\beta') \,, \tag{56.3}$$

where, if B is a molecule, the transition $\beta \rightarrow \beta'$ represents an inelastic energy transfer to the rotational-vibrational degrees of freedom of the molecule B from the Rydberg atom A^*.

Elastic scattering:

$$A^*(\gamma) + B \rightarrow A^*(\gamma) + B \,, \tag{56.4}$$

where the label γ denotes the set of quantum numbers n, ℓ or n, ℓ, J used.

Depolarization collisions:

$$A^*(n\ell m) + B \rightarrow A^*(n\ell m') + B \,, \tag{56.5a}$$
$$A^*(n\ell JM) + B \rightarrow A^*(n\ell JM') + B \,. \tag{56.5b}$$

(B) Ionizing Collisions

Direct and associative ionization:

$$A^*(\gamma) + B(\beta) \rightarrow \begin{cases} A^+ + B(\beta') + e^- \\ BA^+ + e^- \,. \end{cases} \tag{56.6}$$

Penning ionization:

$$A^*(\gamma) + B \rightarrow A + B^+ + e^- \,. \tag{56.7}$$

Ion pair formation:

$$A^*(\gamma) + B \rightarrow A^+ + B^- \,. \tag{56.8}$$

Dissociative attachment:

$$A^*(\gamma) + BC \rightarrow A^+ B^- + C \,. \tag{56.9}$$

56.2 General Properties of Rydberg States

Table 56.1 displays the general n-dependence of a number of key properties of Rydberg states and some specific representative values for hydrogen.

56.2.1 Dipole Moments

Definition. $\boldsymbol{D}_{i \rightarrow f} = -e\boldsymbol{X}_{i \rightarrow f}$ where

$$\boldsymbol{X}_{i \rightarrow f} = \langle \phi_f | \sum_j \mathrm{e}^{\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{r}_j} \boldsymbol{r}_j | \phi_i \rangle \,. \tag{56.10}$$

Hydrogenic Dipole Moments. See *Bethe* and *Salpeter* [56.1] and the references by *Khandelwal* and co-workers [56.2–5] for details and tables.

Exact Expressions. In the limit $|\boldsymbol{k}| \rightarrow 0$, the dipole allowed transitions summed over final states are

$$\left| X_{1s \rightarrow n} \right|^2 = \frac{2^8}{3} n^7 \frac{(n-1)^{2n-5}}{(n+1)^{2n+5}} \,, \tag{56.11a}$$

$$\left| X_{2s \rightarrow n} \right|^2 = \frac{2^5}{3n^3} \frac{\left(\frac{1}{2} - 1n\right)^{2n-7}}{\left(\frac{1}{2} + 1n\right)^{2n+7}} \left(\frac{1}{4} - \frac{1}{n^2}\right)\left(1 - \frac{1}{n^2}\right) \,, \tag{56.11b}$$

$$\left| X_{2p \rightarrow n} \right|^2 = \frac{2^5}{144} \frac{1}{n^3} \frac{\left(\frac{1}{2} - \frac{1}{n}\right)^{2n-7}}{\left(\frac{1}{2} + \frac{1}{n}\right)^{2n+7}} \left(11 - \frac{12}{n^2}\right) \,. \tag{56.11c}$$

Asymptotic Expressions. For $n \gg 1$,

$$n^3 \left| X_{1s \rightarrow n} \right|^2 \approx 1.563 + \frac{5.731}{n^2} + \frac{13.163}{n^4} + \frac{24.295}{n^6} + \frac{39.426}{n^8} + \frac{58.808}{n^{10}} \,, \tag{56.12a}$$

$$n^3 \left| X_{2s \rightarrow n} \right|^2 \approx 14.658 + \frac{180.785}{n^2} + \frac{1435.854}{n^4} + \frac{9341.634}{n^6} + \frac{54\,208.306}{n^8} + \frac{292\,202.232}{n^{10}} \,, \tag{56.12b}$$

$$n^3 \left| X_{2p \rightarrow n} \right|^2 \approx 13.437 + \frac{218.245}{n^2} + \frac{2172.891}{n^4} + \frac{17\,118.786}{n^6} + \frac{117\,251.682}{n^8} + \frac{731427.003}{n^{10}} \,. \tag{56.12c}$$

Table 56.1 General n-dependence of characteristic properties of Rydberg states. After [56.6]

Property	$n-$dependence	$n = 10$	$n = 100$	$n = 500$	$n = 1000$
Radius (cm)	$n^2 a_0 / Z$	5.3×10^{-7}	5.3×10^{-5}	1.3×10^{-3}	5.3×10^{-3}
Velocity (cm/s)	$v_B Z / n$	2.18×10^7	2.18×10^6	4.4×10^5	2.18×10^5
Area (cm^2)	$\pi a_0^2 n^4 / Z^2$	8.8×10^{-13}	8.8×10^{-9}	5.5×10^{-6}	8.8×10^{-5}
Ionization potential (eV)	$Z^2 R_\infty / n^2$	1.36×10^{-1}	1.36×10^{-3}	5.44×10^{-5}	1.36×10^{-6}
Radiative lifetime (s)[a]	$n^5 (3 \ln n - \frac{1}{4}) / (A_0 Z^4)$	8.4×10^{-5}	17	7.3×10^4	7.22 hours
Period of classical motion (s)	$2\pi / \omega_{n,n\pm 1} = h n^3 / (2 Z^2 R_\infty)$	1.5×10^{-13}	1.5×10^{-10}	1.9×10^{-8}	1.5×10^{-7}

56.2.2 Radial Integrals

Definition.

$$R_{n\ell}^{n'\ell'} \equiv \int_0^\infty R_{n\ell}(r) r R_{n'\ell'}(r) r^2 \, dr , \qquad (56.13)$$

where $R_{n\ell}(r)$ are solutions to the radial Schrödinger equation. See Chapt. 9 for specific representations of $R_{n\ell}$ for hydrogen.

Exact Results for Hydrogen. For $\ell' = \ell - 1$ and $n \neq n'$ [56.7],

$$R_{n\ell}^{n'\ell-1} = \frac{a_0}{Z} \frac{(-1)^{n'-\ell} (4nn')^{\ell+1} (n-n')^{n+n'-2\ell-2}}{4(2\ell-1)!(n+n')^{n+n'}}$$
$$\times \left[\frac{(n+\ell)!(n'+\ell-1)!}{(n'+\ell')!(n-\ell-1)!} \right]^{1/2}$$
$$\times \left\{ {}_2F_1(-n+\ell+1, -n'+\ell; 2\ell; Y) \right.$$
$$\left. - \left(\frac{n-n'}{n+n'} \right)^2 {}_2F_1(-n+\ell-1, -n'+\ell; 2\ell; Y) \right\} , \qquad (56.14)$$

where $Y = -4nn'/(n-n')^2$. For $n = n'$,

$$R_{n\ell}^{n\ell-1} = \left(\frac{a_0}{Z} \right) \frac{3}{2} n \sqrt{n^2 - \ell^2} . \qquad (56.15)$$

Semiclassical Quantum Defect Representation [56.8].

$$\left| R_{n\ell}^{n'\ell'} \right|^2 = \left(\frac{a_0}{Z} \right)^2 \frac{n_c^2}{2\Delta} \left[\left(1 - \frac{\Delta\ell \, \ell_>}{n_c} \right) J_{\Delta-1}(-x) \right.$$
$$- \left(1 + \frac{\Delta\ell \, \ell_>}{n_c} \right) J_{\Delta+1}(-x)$$
$$\left. + \frac{2}{\pi} \sin(\pi\Delta)(1-e) \right]^2 , \qquad (56.16)$$

where

$$n_c = 2n^* n^{*\prime} / (n^* + n^{*\prime}) , \qquad (56.17a)$$
$$\Delta = n^{*\prime} - n^* , \qquad (56.17b)$$
$$\Delta\ell = \ell' - \ell, \ \ell_> = \max(\ell, \ell') , \qquad (56.17c)$$
$$x = e\Delta, e = \sqrt{1 - (\ell_> / n_c)^2} , \qquad (56.17d)$$

and $J_n(y)$ is the Anger function.

The energies of the states $n\ell$ and $n'\ell'$ are given in terms of the quantum defects by

$$E_{n\ell} = -Z^2 R_\infty / n^{*2}, n^* = n - \delta_\ell , \qquad (56.18a)$$
$$E_{n'\ell'} = -Z^2 R_\infty / n^{*\prime 2}, n^{*\prime} = n' - \delta_{\ell'} . \qquad (56.18b)$$

Sum Rule. For hydrogen

$$\sum_{n'} \left| R_{n\ell}^{n'\ell-1} \right|^2 = \sum_{n'} \left| R_{n\ell}^{n'\ell+1} \right|^2 \qquad (56.19a)$$
$$= \frac{n^2 a_0^2}{2 Z^2} \left[5n^2 + 1 - 3\ell(\ell+1) \right] . \qquad (56.19b)$$

See §61 of [56.1] for additional sum rules.

56.2.3 Line Strengths

Definition.

$$S(n'\ell', n\ell) = e^2 (2\ell+1) \left| \mathbf{r}_{n'\ell',n\ell} \right|^2 \qquad (56.20a)$$
$$= e^2 \max(\ell, \ell') \left| R_{n\ell}^{n'\ell'} \right|^2 , \qquad (56.20b)$$

where $\ell' = \ell \pm 1$. For hydrogen

$$S(n', n) = 32 \left(\frac{ea_0}{Z} \right)^2 (nn')^6 \frac{(n-n')^{2(n+n')-3}}{(n+n')^{2(n+n')+4}}$$
$$\times \left\{ \left[{}_2F_1(-n', -n+1; 1; Y) \right]^2 \right.$$
$$\left. - \left[{}_2F_1(-n'+1, -n; 1; Y) \right]^2 \right\} , \quad (56.21)$$

where $Y = -4nn'/(n-n')^2$.

Semiclassical Representation [56.9].

$$S(n', n) = \frac{32}{\pi\sqrt{3}} \left(\frac{ea_0}{Z}\right)^2 \frac{(\varepsilon\varepsilon')^{3/2}}{(\varepsilon - \varepsilon')^4} G(\Delta n) , \quad (56.22)$$

where $\varepsilon = 1/n^2$, $\varepsilon' = 1/n'^2$, and the Gaunt factor $G(\Delta n)$ is given by

$$G(\Delta n) = \pi\sqrt{3}|\Delta n| J_{\Delta n}(\Delta n) J'_{\Delta n}(\Delta n) , \quad (56.23)$$

where the prime on the Anger function denotes differentiation with respect to the argument Δn. Equation (56.23) can be approximated to within 2% by the expression

$$1 - \frac{1}{4|\Delta n|} . \quad (56.24)$$

Relation to Oscillator Strength.

$$S(n', n) = \sum_{\ell, \ell'} S(n'\ell', n\ell)$$
$$= 3e^2 a_0^2 \frac{R_\infty}{\hbar\omega} \sum_{\ell, \ell'} f_{n'\ell', n\ell} . \quad (56.25)$$

Connection with Radial Integral.

$$-f_{n'\ell', n\ell} = \frac{\hbar\omega}{3R_\infty} \frac{\max(\ell, \ell')}{(2\ell + 1)} |R_{n\ell}^{n'\ell'}| . \quad (56.26)$$

Density of Line Strengths.
For bound-free $n\ell \to E\ell'$ transitions in a Coulomb field, the semiclassical representation [56.6] is

$$\frac{d}{dE} S(n\ell, E) = 2n(2\ell + 1) \left(\frac{R_\infty}{\hbar\omega}\right)^2$$
$$\times \left[J'_\Delta(e\Delta)^2 + \left(1 - \frac{1}{e^2}\right) J_\Delta(e\Delta)^2\right] \frac{e^2 a_0^2}{R_\infty} , \quad (56.27)$$

where $\Delta = \hbar\omega n^3/2R_\infty$ and $e = \sqrt{1 - \left(\ell + \frac{1}{2}\right)^2/n^2}$. Asymptotic expression for $\Delta \gg 1$:

$$\frac{d}{dE} S(n\ell, E) = \frac{2(2\ell + 1)}{3\pi^2} \left(\frac{R_\infty}{\hbar\omega}\right)^2 \frac{\left(\ell + \frac{1}{2}\right)^4}{n^3}$$
$$\times \left[K_{1/3}^2(\eta) + K_{2/3}^2(\eta)\right] \frac{e^2 a_0^2}{R_\infty} , \quad (56.28)$$

where $\eta = (E/R_\infty)(\ell + 1/2)^3/6$ and the $K_\nu(x)$ are Bessel functions of the third kind.

Line Strength of Line n.

$$S_n \equiv S(n) = \sum_{k \neq 0} S(n+k, n) \frac{1}{k^3} . \quad (56.29)$$

Born Approximation to Line Strength S_n [56.6].

$$S_n^B = \frac{Z^2 R_\infty}{E} \left[\frac{1}{2} \ln(1 + \varepsilon_e/\varepsilon) \sum_{k \neq 0} \left(1 - \frac{1}{4k}\right) \frac{1}{k^4}\right.$$
$$\left. + \frac{4}{3} \frac{\varepsilon_e}{\varepsilon + \varepsilon_e} \sum_{k \neq 0} \left(1 - \frac{0.60}{k}\right) \frac{1}{k^3}\right]$$
$$= \frac{Z^2 R_\infty}{E} \left[0.82 \ln\left(1 + \frac{\varepsilon_e}{\varepsilon}\right) + \frac{1.47\varepsilon_e}{\varepsilon + \varepsilon_e}\right], \quad (56.30)$$

where $\varepsilon = |E_n|Z^2/R_\infty$ and $\varepsilon_e = \varepsilon/Z^2 R_\infty$.

56.2.4 Form Factors

$$F_{n'n}(Q) = \sum_{\ell, m} \sum_{\ell', m'} |\langle n\ell m|e^{iQ\cdot r}|n'\ell'm'\rangle|^2 . \quad (56.31)$$

Connection with Generalized Oscillator Strengths.

$$f_{n'n}(Q) = \frac{Z^2 \Delta E}{n^2 Q^2 a_0^2} F_{n'n}(Q) . \quad (56.32)$$

Semiclassical Limit.

$$\lim_{Q \to 0} f_{n'n}(Q) = \frac{32}{3n^2} \left(\frac{nn'}{\Delta n(n+n')}\right)^3$$
$$\times \Delta n J_{\Delta n}(\Delta n) J'_{\Delta n}(\Delta n) , \quad (56.33)$$

where $J_m(y)$ denotes the Bessel function.

Representation as Microcanonical Distribution.

$$F_{n',n\ell}(Q) = (2\ell + 1) \frac{2Z^2 R_\infty}{n'^3} \int d\mathbf{p}|g_{n\ell}(p)|^2$$
$$\times \delta\left(\frac{(\mathbf{p} - \hbar\mathbf{Q})^2}{2m} - \frac{p^2}{2m} - E_{n'} - E_{n\ell}\right) , \quad (56.34)$$

$$F_{n',n}(Q) = \frac{4Z^2 R_\infty^2}{(nn')^3} \int \frac{d\mathbf{p}\,d\mathbf{r}}{(2\pi\hbar)^3} \delta\left(\frac{p^2}{2m} - \frac{Ze^2}{r} - E_n\right)$$
$$\times \delta\left(\frac{(\mathbf{p} - \hbar\mathbf{Q})^2}{2m} - \frac{Ze^2}{r} - E_{n'}\right) , \quad (56.35)$$

$$= \frac{2^9}{3\pi(nn')^3} \frac{\kappa^5}{(\kappa^2 + \kappa_+^2)^3(\kappa^2 + \kappa_-^2)^3} , \quad (56.36)$$

where $\kappa = Qa_0/Z$ and $\kappa_\pm = |1/n \pm 1/n'|$.

56.2.5 Impact Broadening

The total broadening cross section of a level n is

$$\sigma_n = \left(\pi a_0^2/Z^4\right) n^4 S_n \ . \tag{56.37}$$

The width of a line $n \to n+k$ is [56.10]

$$\gamma_{n,n+k} = n_e \left[\langle v\sigma_n\rangle + \langle v\sigma_{n+k}\rangle\right] \ , \tag{56.38}$$

where n_e is the number density of electrons, and

$$\langle v\sigma_n\rangle = \sum_{k\neq 0}\langle v\sigma_{n+k,n}\rangle = \frac{n^4}{Z^3}K_n \tag{56.39a}$$

$$= \frac{n^4\pi a_0^2 v_B}{Z^3\theta^{3/2}} \int\limits_0^\infty e^{-E/k_B T} S_n \frac{E\,dE}{(Z^2 R_\infty)^2} \ , \tag{56.39b}$$

where $\theta = k_B T/Z^2 R_\infty$. See Chapt. 59 for collisional line broadening.

56.3 Correspondence Principles

Correspondence principles are used to connect quantum mechanical observables with the corresponding classical quantities in the limit of large n. See [56.11] for details on the equations in this section.

56.3.1 Bohr–Sommerfeld Quantization

$$A_i = J_i\Delta w_i \oint p_i\,dq_i = 2\pi\hbar(n_i + \alpha_i) \ , \tag{56.40}$$

where $n_i = 0, 1, 2, \ldots$ and $\alpha_i = 0$ if the generalized coordinate q_i represents rotation, and $\alpha_i = 1/2$ if q_i represents a libration.

56.3.2 Bohr Correspondence Principle

$$E_{n+s} - E_n = h\nu_{n+s,n} \sim s\hbar\omega_n, \ s = 1, 2, \ldots \ll n \ , \tag{56.41}$$

where $\nu_{n+s,n}$ is the line emission frequency and ω_n is the angular frequency of classical orbital motion. The number of states with quantum numbers in the range Δn is

$$\Delta N = \prod_{i=1}^{D}\Delta n = \prod_{i=1}^{D}\left(\Delta J_i\Delta w_i\right)/(2\pi\hbar)^D$$

$$= \prod_{i=1}^{D}(\Delta p_i\Delta q_i)/(2\pi\hbar)^D \ , \tag{56.42}$$

for systems with D degrees of freedom, and the mean value $\bar{F}$ of a physical quantity $F(q)$ in the quantum state Ψ is

$$\bar{F} = \langle\Psi|F(q)|\Psi\rangle = \sum_{n,m} a_m^* a_n F_{mn}^{(q)} e^{i\omega_{mn}t} \ , \tag{56.43}$$

where the $F_{mn}^{(q)}$ are the quantal matrix elements between time independent states.

The first order S-matrix is

$$S_{fi} = -\frac{i\omega}{2\pi\hbar}\int\limits_{-\infty}^{\infty} dt \int\limits_0^{2\pi/\omega} V[R(t), r(t_1)]\,e^{is\omega(t_1-t)}\,dt_1 \ , \tag{56.44}$$

where R denotes the classical path of the projectile and r the orbital of the Rydberg electron.

56.3.3 Heisenberg Correspondence Principle

For one degree of freedom [56.11],

$$F_{mn}^{(q)}(R) = \int\limits_0^\infty \phi_m^*(r)F(r, R)\phi_n(r)\,dr \tag{56.45}$$

$$= \frac{\omega}{2\pi}\int\limits_0^{2\pi/\omega} F^{(c)}[r(t)]\,e^{is\omega t}\,dt \ . \tag{56.46}$$

The three-dimensional generalization is [56.11]

$$F_{n,n'}^{(q)} \sim F_s^{(c)}(J) = \frac{1}{8\pi^3}\int F^c[r(J, w)]\,e^{is\cdot w}\,dw \ , \tag{56.47}$$

where n, n' denotes the triple of quantum numbers (n, ℓ, m), (n', ℓ', m'), respectively, and $s = n - n'$.

The correspondence between the three dimensional quantal and classical matrix elements in (56.47) follows from the general Fourier expansion for any classical function $F^{(c)}(r)$ periodic in r,

$$F^{(c)}[r(t)] = \sum_s F_s^{(c)}(J)\exp(-is\cdot w) \ , \tag{56.48}$$

where J, w denotes the action-angle conjugate variables for the motion. For the three dimensional Coulomb

problem, the action-angle variables are

$$J_n = n\hbar , \qquad w_n = \left(\frac{\partial E}{\partial J_n}\right) t + \delta ,$$

$$J_\ell = \left(\ell + \frac{1}{2}\right)\hbar , \qquad w_\ell = \psi_E ,$$

$$J_m = m\hbar , \qquad w_m = \phi_E , \qquad (56.49)$$

where ψ_E is the Euler angle between the line of nodes and a direction in the plane of the orbit (usually taken to be the direction of the perihelion or perigee), and is constant for a Coulomb potential. The Euler angle ϕ_E is the angle between the line of nodes and the fixed x-axis. See [56.11] for details.

The first order S-matrix is

$$S_{fi} = -\frac{\mathrm{i}\omega}{2\pi\hbar} \int_0^{2\pi/\omega} \mathrm{d}t_e \int_{-\infty}^{\infty} \mathrm{d}t \, V\big[\boldsymbol{R}(t), r(t+t_e)\big] \mathrm{e}^{\mathrm{i}s\omega t_e} , \tag{56.50}$$

with $s = i - f$, $\boldsymbol{R}$ is the classical path of the projectile, and $r(t_e)$ is the classical internal motion of the Rydberg electron.

56.3.4 Strong Coupling Correspondence Principle

The S-matrix is

$$S_{fi} = \frac{\omega}{2\pi} \int_0^{2\pi/\omega} \mathrm{d}t_e \exp\Big\{\mathrm{i}(s\omega t_e)$$

$$- \frac{\mathrm{i}}{\hbar} \int_{-\infty}^{\infty} V\big[\boldsymbol{R}(t), r(t+t_e)\big] \mathrm{d}t\Big\} . \tag{56.51}$$

See [56.11–14] for additional details.

56.3.5 Equivalent Oscillator Theorem

$$\sum_n a_n(t) V_{fn}(t)\, \mathrm{e}^{\mathrm{i}\omega_{fn}t} = \sum_{d=-f} a_{d+f}(t) V_d(t)\, \mathrm{e}^{-\mathrm{i}d\omega t} . \tag{56.52}$$

The S-matrix is

$$S_{\boldsymbol{n}',\boldsymbol{n}} = a_{\boldsymbol{n}'}(t \to \infty) \tag{56.53}$$

$$= \int_0^{2\pi} \frac{\mathrm{d}\boldsymbol{w}}{8\pi^3} \exp\Big[\mathrm{i}s\cdot\boldsymbol{w} - \frac{\mathrm{i}}{\hbar} \int_{-\infty}^{\infty} V(\boldsymbol{w}+\omega t, t)\, \mathrm{d}t\Big] .$$

56.4 Distribution Functions

The function $W_\alpha(x)\,\mathrm{d}x$ characterizes the probability (distribution) of finding an electron in a Rydberg orbital α within a volume $\mathrm{d}x$ centered at the point x in phase space. Integration of the distribution function W_α over all phase space volumes $\mathrm{d}x$ yields, depending upon the normalization chosen, either unity or the density of states appropriate to the orbital α.

56.4.1 Spatial Distributions

Distribution over n, ℓ, m [56.6]:

$$W_{n\ell m}(r,\theta)r^2 \sin\theta\, \mathrm{d}r\, \mathrm{d}\theta \tag{56.54}$$

$$= \frac{r^2 \sin\theta\, \mathrm{d}r\, \mathrm{d}\theta}{\pi^2 a^2 r\big\{\big[\mathrm{e}^2 - (1-r/a)^2\big]\big[\sin^2\theta - (m/\ell)^2\big]\big\}^{1/2}} ,$$

where $a = Ze^2/2|E| = n^2\hbar^2/mZe^2\hbar^2$ is the semimajor axis, and $\mathrm{e}^2 = 1 - (\ell/n)^2$ is the eccentricity.

Distribution over n, ℓ:

$$W_{n\ell}(r,\theta)r^2 \sin\theta\, \mathrm{d}r\, \mathrm{d}\theta$$

$$= g(n\ell) \frac{r^2 \sin\theta\, \mathrm{d}r\, \mathrm{d}\theta}{2\pi a^2 r\big[\mathrm{e}^2 - (1-r/a)^2\big]^{1/2}} , \tag{56.55}$$

where $g(n\ell) = 2\ell$.

Distribution over n:

$$W_n(r)r^2\, \mathrm{d}r = g(n) \frac{2}{\pi}\left[1 - \left(1-\frac{r}{a}\right)^2\right]^{1/2} \frac{r\, \mathrm{d}r}{a^2} , \tag{56.56}$$

with $g(n) = n^2$.

56.4.2 Momentum Distributions

Distribution over n, ℓ [56.6]:

$$W_{n\ell}(p)p^2\, \mathrm{d}p = g(n\ell) \frac{4}{\pi} \frac{\mathrm{d}x}{\left(1+x^2\right)^2} , \tag{56.57}$$

where $x = p/p_n$ and $p_n^2 = 2m|E|$.

Distribution over n:

$$W_n(p)p^2\, \mathrm{d}p = g(n) \frac{32}{\pi} \frac{x^2\, \mathrm{d}x}{\left(1+x^2\right)^4} . \tag{56.58}$$

Sum Rules.

$$\frac{1}{n^2} \sum_{\ell,m} \big|G_{n\ell m}(\boldsymbol{k})\big|^2 = \left(\frac{na_0}{Z}\right)^3 \frac{8}{\pi^2\left(x^2+1\right)^4} , \tag{56.59a}$$

$$\frac{1}{n^2} \sum_{\ell=0}^{n-1} (2\ell+1)\left|g_{n\ell}(k)\right|^2 k^2 = \frac{32 n a_0 x^2}{\pi Z \left(x^2+1\right)^4} \, ,$$

(56.59b)

where $x = n k a_0/Z$, and

$$G_{n\ell m}(\boldsymbol{k}) = g_{n\ell}(k) Y_{\ell m}(\hat{\boldsymbol{k}}) \, ,$$ (56.60a)

$$g_{n\ell}(k) = \left(\frac{2}{\pi} \frac{(n-\ell-1)!}{(n+\ell)!}\right)^{1/2} \left(\frac{a_0}{Z}\right)^{3/2} 2^{2(\ell+1)} n^2 \ell!$$
$$\times \frac{(-ix)^\ell}{\left(x^2+1\right)^{\ell+2}} C_{n-\ell-1}^{(\ell+1)} \left(\frac{x^2-1}{x^2+1}\right) \, ,$$

(56.60b)

where $C_i^{(j)}(y)$ is the associated Gegenbauer polynomial. See Chapt. 9 for additional details on hydrogenic wave functions.

Quantum Defect Representation [56.15].

$$g_{n\ell}(k) = -\left(\frac{2}{\pi} \frac{\Gamma(n^*-1)}{\Gamma(n^*+\ell+1)}\right)^{1/2} n^* (a_0/Z)^{3/2} 2^{2(\ell+1)}$$
$$\times \frac{(\ell+1)!(-ix)^\ell}{\left(x^2+1\right)^{\ell+2}} \mathcal{J}(n^*, \ell+1; X) \, ,$$

(56.61)

where $n^* = n - \delta$, δ being the quantum defect, and $x = n^* k a_0/Z$. The function $\mathcal{J}$ is given by the recurrence relation

$$\mathcal{J}(n^*, \ell+1; X) = -\frac{1}{2(2\ell+2)} \frac{\partial}{\partial X} \mathcal{J}(n^*, \ell; X) \, ,$$

(56.62)

$$\mathcal{J}(n^*, 0; X) = -\frac{n^* \sin\left[n^*(\beta-\pi)\right]}{\sin(\beta-\pi)}$$
$$-\frac{\sin n^*\pi}{\pi} \int_0^1 \frac{\left(1-s^2\right) s^{n^*}}{\left(1-2Xs+s^2\right)} \, \mathrm{d}s \, ,$$

(56.63)

where $X = (x^2-1)/(x^2+1)$, and $\beta = \cos^{-1} X$. In the limit $\ell \ll n^*$, (56.61) becomes

$$|g_{n\ell}(k)|^2 = 4\left(\frac{n^* a_0}{Z}\right)^3 \frac{1-(-1)^\ell \cos\left[2n^*(\beta-\pi)\right]}{\pi x^2 (x^2+1)^2} \, .$$

(56.64)

Classical Density of States.

$$\rho(E) = \int \delta\left[E - H(\boldsymbol{p}, \boldsymbol{r})\right] \frac{\mathrm{d}\boldsymbol{p}\,\mathrm{d}\boldsymbol{r}}{(2\pi\hbar)^3} = \frac{n^5 \hbar^2}{m Z^2 e^4} \, .$$

(56.65)

56.5 Classical Theory

The classical cross section for energy transfer ΔE between two particles, with arbitrary masses m_1, m_2 and charges Z_1, Z_2, is given by [56.16]

$$\sigma_{\Delta E}(\boldsymbol{v}_1, \boldsymbol{v}_2) = \frac{2\pi (Z_1 Z_2 e^2 V)^2}{v^2 |\Delta E|^3}$$
$$\times \left(1 + \cos^2 \bar{\theta} + \frac{\Delta E}{\mu v V} \cos \bar{\theta}\right) \, ,$$

(56.66)

valid for $-1 \le \cos\bar{\theta} - \Delta E/(\mu v V) \le 1$, and $\sigma_{\Delta E}(\boldsymbol{v}_1, \boldsymbol{v}_2) = 0$ otherwise, where

$$\boldsymbol{v} = \boldsymbol{v}_1 - \boldsymbol{v}_2 \, ,$$ (56.67a)

$$\boldsymbol{V} = (m_1 \boldsymbol{v}_1 + m_2 \boldsymbol{v}_2)/M \, ,$$ (56.67b)

$$\cos\bar{\theta} = \frac{1}{vV} \boldsymbol{v} \cdot \boldsymbol{V} \, ,$$ (56.67c)

and $\mu = m_1 m_2/M$, $M = m_1 + m_2$. If particle 2 has an isotropic velocity distribution in the lab frame, the effective cross section averaged over the direction $\hat{\boldsymbol{n}}_2$ of $\boldsymbol{v}_2$ is

$$v_1 \sigma_{\Delta E}^{(\text{eff})}(\boldsymbol{v}_1, \boldsymbol{v}_2) = \frac{1}{4\pi} \int \mathrm{d}\hat{\boldsymbol{n}}_2 |\boldsymbol{v}_1 - v_2 \hat{\boldsymbol{n}}_2| \sigma_{\Delta E}(\boldsymbol{v}_1, \boldsymbol{v}_2) \, .$$

(56.68)

If $\boldsymbol{v}_1$ is also isotropic, then the average of (56.68), together with (56.66), gives for the special case of a Coulomb potential

$$\sigma_{\Delta E}^{(\text{eff})}(\boldsymbol{v}_1, \boldsymbol{v}_2)$$
$$= \frac{\pi \left(Z_1 Z_2 e^2\right)^2}{4|\Delta E| 3 v_1^2 v_2^2} \left[\left(v_1^2 - v_2^2\right)\left(v_2'^2 - v_1'^2\right)\left(v_l^{-1} - v_u^{-1}\right)\right.$$
$$\left. + \left(v_1^2 + v_2^2 + v_1'^2 + v_2'^2\right)(v_u - v_\ell) - \frac{1}{3}\left(v_u^3 - v_l^3\right)\right] \, ,$$

(56.69)

where

$$v_1' = \left(v_1^2 - 2\Delta E/m_1\right)^{1/2} \, ,$$ (56.70)

$$v_2' = \left(v_2^2 + 2\Delta E/m_2\right)^{1/2} , \tag{56.71}$$

and v_u, v_l are defined below for cases 1.–4. With the definitions

$$\Delta\varepsilon_{12} = 4m_1 m_2 (E_1 - E_2)/M^2 , \quad \Delta m_{12} = |m_1 - m_2| ,$$

$$\Delta\tilde{\varepsilon}_{12} = \frac{4m_1 m_2}{M^2}\left(E_1\frac{v_2}{v_1} - E_2\frac{v_1}{v_2}\right) ,$$

the four cases are

1. $\Delta E \geq \Delta\varepsilon_{12} + |\Delta\tilde{\varepsilon}_{12}| \geq 0$, and $2m_2 v_2 \geq \Delta m_{12} v_1$:

$$v_l = v_2' - v_1' , \quad v_u = v_1' + v_2' , \quad \Delta E \geq 0 ; \tag{56.72a}$$

$$v_l = v_2 - v_1 , \quad v_u = v_1 + v_2 , \quad \Delta E \leq 0 . \tag{56.72b}$$

If $2m_2 v_2 < \Delta m_{12} v_1$, then $\sigma_{\Delta E}^{\mathrm{eff}}(v_1, v_2) = 0$,

2. $\Delta\varepsilon_{12} - \Delta\tilde{\varepsilon}_{12} \leq \Delta E \leq \Delta\varepsilon_{12} + \Delta\tilde{\varepsilon}_{12}$, and $m_1 > m_2$:

$$v_l = v_2' - v_1' , \quad v_u = v_1 + v_2 , \quad \Delta E \geq 0 ; \tag{56.72c}$$

$$v_l = v_2 - v_1 , \quad v_u = v_1' + v_2' , \quad \Delta E \leq 0 \tag{56.72d}$$

3. $\Delta E \leq \Delta\varepsilon_{12} - |\Delta\tilde{\varepsilon}_{12}| \leq 0$, and $2m_1 v_1 \geq \Delta m_{12} v_2$:

$$v_l = v_1 - v_2 , \quad v_u = v_1 + v_2 , \quad \Delta E \geq 0 ; \tag{56.72e}$$

$$v_l = v_1' - v_2' , \quad v_u = v_1' + v_2' , \quad \Delta E \leq 0 . \tag{56.72f}$$

If $2m_1 v_1 < \Delta m_{12} v_2$, then $\sigma_{\Delta E}^{\mathrm{eff}}(v_1, v_2) = 0$,

4. $\Delta\varepsilon_{12} + \Delta\tilde{\varepsilon}_{12} \leq \Delta E \leq \Delta\varepsilon_{12} - \Delta\tilde{\varepsilon}_{12}$, and $m_1 < m_2$:

$$v_l = v_1 - v_2 , \quad v_u = v_1' + v_2' , \quad \Delta E \geq 0 ; \tag{56.72g}$$

$$v_l = v_1' - v_2' , \quad v_u = v_1 + v_2 , \quad \Delta E \leq 0 . \tag{56.72h}$$

If $2m_1 v_1 < \Delta m_{12} v_2$, then $\sigma_{\Delta E}^{\mathrm{eff}}(v_1, v_2) = 0$.

Since v_1' and v_2', given by (56.70) and (56.71) respectively, must be real, $\sigma_{\Delta E}(\boldsymbol{v}_1, \boldsymbol{v}_2) = 0$ for ΔE outside the range

$$-\frac{1}{2}m_2 v_2^2 \leq \Delta E \leq \frac{1}{2}m_1 v_1^2 , \tag{56.73}$$

which simply expresses the fact that the particle losing energy in the collision cannot lose more than its initial kinetic energy.

The cross section (56.69) must be integrated over the classically allowed range of energy transfer ΔE and averaged over a prescribed speed distribution $W(v_2)$ before comparison with experiment can be made. See [56.16, 17] for details.

Classical Removal Cross Section [56.18]. The cross section for removal of an electron from a shell is given by

$$\sigma_{\mathrm{r}}(V) = \int\limits_0^\infty f(v)\sigma_{\Delta E}(\boldsymbol{v}_1, \boldsymbol{v}_2)\,\mathrm{d}v . \tag{56.74}$$

Total Removal Cross Section [56.18]. In an independent electron model,

$$\sigma_{\mathrm{r}}^{\mathrm{total}}(V) = N_{\mathrm{shell}}\sigma_{\mathrm{r}}(V) , \tag{56.75}$$

where N_{shell} is the number of equivalent electrons in a shell. In a shielding model,

$$\sigma_{\mathrm{r}}^{\mathrm{total}}(V) = \left[1 - \frac{(N_{\mathrm{shell}} - 1)}{4\pi\bar{r}^2}\sigma_{\mathrm{r}}(V)\right]N_{\mathrm{shell}}\sigma_{\mathrm{r}}(V) , \tag{56.76}$$

where $\bar{r}^2$ is the root mean square distance between electrons within a shell. Experiment [56.19] favors (56.76) over (56.75). See Fig. 4a–e of [56.18] for details.

Classical trajectory and Monte-Carlo methods are covered in Chapt. 58.

56.6 Working Formulae for Rydberg Collisions

56.6.1 Inelastic n,ℓ-Changing Transitions

$$A^*(n\ell) + B \rightarrow A^*(n') + B + \Delta E_{n',n\ell} , \tag{56.77}$$

where $\Delta E_{n',n\ell} = E_{n'} - E_{n\ell}$ is the energy defect. The cross section for (56.77) in the quasifree electron

model [56.20] is

$$\sigma_{n',n\ell}(V) = \frac{2\pi a_{\mathrm{s}}^2}{\left(V/v_{\mathrm{B}}\right)^2 n'^3}f_{n',n\ell}(\lambda) , \quad \ell \ll n , \tag{56.78}$$

where a_{s} is the scattering length for $e^- + B$ scattering, $\lambda = n^* a_0 \omega_{n',n\ell}/V$, $\omega_{n',n\ell} = |\Delta E_{n',n\ell}|/\hbar$,

$E_{n'} = -R_\infty/n'^2$,   and $E_{n\ell} = -R_\infty/n^{*2}$,   with $n^* = n - \delta_\ell$. Also, v_B is the atomic unit of velocity (see Chapt. 1), and

$$f_{n',n\ell}(\lambda) = \frac{2}{\pi}\left[\tan^{-1}\left(\frac{2}{\lambda}\right) - \frac{\lambda}{2}\ln\left(1 + \frac{4}{\lambda^2}\right)\right].$$
(56.79)

Limiting cases: $f_{n',n\ell}(\lambda) \to 1$ as $\lambda \to 0$, and $f_{n',n\ell}(\lambda) \sim 8/\left(3\pi\lambda^3\right)$ for $\lambda \gg 1$. Then

$$\sigma_{n',n\ell} \sim \begin{cases} \dfrac{2\pi a_s^2}{(V/v_B)^2 n'^3}, & \lambda \to 0, \\[2ex] \dfrac{16 a_s^2 V n^3}{3 v_B |\delta_\ell + \Delta n|^3}, & \lambda \gg 1. \end{cases}$$
(56.80)

Rate Coefficients.

$$\langle \sigma_{n',n\ell}(V) \rangle \equiv \langle V\sigma_{n',n\ell}(V)\rangle / \langle V \rangle$$
(56.81a)

$$= \frac{2\pi a_s^2}{\left(V_T/v_B\right)^2 n'^3}\varphi_{n',n\ell}(\lambda_T),$$
(56.81b)

where $V_T = \sqrt{2k_B T/\mu}$, $\lambda_T = n^* a_0 \omega_{n',n\ell}/V_T$, $\Delta n = n' - n$, and μ is the reduced mass of A–B. The function $\varphi_{n',n\ell}(\lambda_T)$ in (56.81b) is given by

$$\varphi_{n',n\ell}(\lambda_T) = e^{\lambda_T^2/4}\text{erfc}\left(\frac{1}{2}\lambda_T\right)$$
(56.82a)

$$- \frac{\lambda_T}{\pi}\int_0^\infty \frac{du}{\sqrt{u}}e^{-u}\ln\left(1 + \frac{4}{\lambda_T^2}\right)$$

$$= \begin{cases} 1 - \dfrac{\lambda_T}{\sqrt{\pi}}\ln\left(1/\lambda_T^2\right), & \lambda_T \to 0 \\[2ex] 2/\left(\sqrt{\pi}\lambda_T^3\right), & \lambda_T \gg 1 \end{cases}$$
(56.82b)

and erfc (x) is the complementary error function.

56.6.2 Inelastic $n \to n'$ Transitions

$$A^*(n) + B \to A^*(n') + B + \Delta E_{n'n}.$$
(56.83)

(A) Cross Sections.

$$\sigma_{n'n} = \sum_{\ell\ell'}\frac{(2\ell+1)}{n^2}\sigma_{n'\ell',n\ell},$$
(56.84)

$$\sigma_{n',n}(V) = \frac{2\pi a_s^2}{(V/v_B)^2 n'^3}F_{n'n}(\lambda),$$
(56.85)

where $\lambda = n a_0 \omega_{n'n}/V = |\Delta n| v_B/(n^2 V)$, and

$$F_{n'n}(\lambda) = \frac{2}{\pi}\left[\tan^{-1}\left(\frac{2}{\lambda}\right) - \frac{2\lambda\left(3\lambda^2 + 20\right)}{3\left(4 + \lambda^2\right)^2}\right].$$
(56.86)

Limiting cases:

$$\sigma_{n'n} \sim \begin{cases} \dfrac{2\pi a_s^2}{\left(V/v_B^2 n'^3\right)}, & \lambda \ll 1, \\[2ex] \dfrac{256\sigma_{e^--B}^{\text{elastic}}\,(V/v_B)^3\,n^7}{15\pi|\Delta n|5}, & \lambda \gg 1, \end{cases}$$
(56.87)

where $\sigma_e^- - B^{\text{elastic}}$ is the elastic cross section for $e^- + B$ scattering.

(B) Rate Coefficients.

$$K_{n'\ell',n\ell}(T) = \langle V\sigma_{n'\ell',n\ell}\rangle,$$
(56.88a)

$$K_{n'n}(T) = \sum_{\ell,\ell'}\frac{(2\ell+1)}{n^2}K_{n'\ell',n\ell},$$
(56.88b)

$$K_{n'n}(T) = \frac{v_B\sigma_{e^--B}^{\text{elastic}}}{\sqrt{\pi}n^3\left(V_T/v_B\right)}\Phi_{n'n}(\lambda_T),$$
(56.88c)

where

$$\Phi_{n'n}(\lambda_T) = e^{\lambda_T^2/8}\left[e^{\lambda_T^2/8}\text{erfc}\left(\frac{1}{2}\lambda_T\right) - \frac{\lambda_T^2}{\sqrt{2\pi}}D_{-3}\left(\frac{\lambda_T}{2}\right)\right.$$

$$\left. - \frac{5\lambda_T}{\sqrt{\pi}}D_{-4}\left(\frac{\lambda_T}{\sqrt{2}}\right)\right]$$
(56.89a)

$$\sim \begin{cases} 1 - 8\lambda_T/3\sqrt{\pi}, & \lambda_T \ll 1 \\[2ex] 2^6/\left(\sqrt{\pi}\lambda_T^5\right), & \lambda_T \gg 1 \end{cases},$$
(56.89b)

where $D_{-\nu}(y)$ denotes the parabolic cylinder function. Limiting cases:

$$K_{n'n}(T) \sim \begin{cases} \left(\dfrac{\mu R_\infty}{\pi m_e k_B T}\right)^{1/2}\dfrac{v_B\sigma_{e^--B}^{\text{elastic}}}{n^3}, & \lambda_T \to 0, \\[2ex] \dfrac{2^6 v_B\sigma_{e-B}^{\text{elastic}}n^7}{\pi|\Delta n|5}\left(\dfrac{2k_B T}{\mu v_B^2}\right)^2, & \lambda_T \gg 1. \end{cases}$$
(56.90)

Born Results:

$$\sigma_{n'n} = \frac{8\pi}{k^2}\frac{1}{n^2}\int_{|k-k'|}^{k+k'}F_{n'n}(Q)\frac{d(Qa_0)}{(Qa_0)^3}.$$
(56.91)

(A) Electron–Rydberg Atom Collision.

$$\sigma_{n'n} = \frac{8\pi a_0^2 R_\infty}{Z^2 E n^2}\left[\left(1 - \frac{1}{4\Delta n}\right)\frac{(\varepsilon\varepsilon')^{3/2}}{(\Delta\varepsilon)^4}\ln\left(1 + \varepsilon_e/\varepsilon\right)\right.$$

$$\left. + \left(1 - \frac{0.6}{\Delta n}\right)\frac{\varepsilon_e}{\varepsilon + \varepsilon_e}\frac{(\varepsilon')^{3/2}}{(\Delta\varepsilon)^2}\left(\frac{4}{3\Delta n} + \frac{1}{\varepsilon}\right)\right]$$
(56.92)

for $n' > n$, where $\varepsilon_e = E/(Z^2 R_\infty)$, $\varepsilon = 1/n^2$, $\varepsilon' = 1/n'^2$, and $\Delta\varepsilon = \varepsilon - \varepsilon'$.

(B) Heavy Particle–Rydberg Atom Collision.

$$\sigma_{n'n} = \frac{8\pi a_0^2 \mathcal{Z}^2}{Z^4 n^2 \varepsilon_e} \left[\left(1 - \frac{1}{4\Delta n}\right) \frac{(\varepsilon\varepsilon')^{3/2}}{(\Delta\varepsilon)^4} \ln(1 + \varepsilon_e/\varepsilon) \right. $$
$$\left. + \left(1 - \frac{0.6}{\Delta n}\right) \varepsilon_{\frac{e}{\varepsilon + \varepsilon_e}} \frac{(\varepsilon')^{3/2}}{(\Delta\varepsilon)^2} \left(\frac{4}{3\Delta n} + \frac{1}{\varepsilon}\right) \right] ,$$
(56.93)

where $\varepsilon_e = m\varepsilon/M\mathcal{Z}^2 R_\infty$ with heavy particle mass and charge denoted above by M and $\mathcal{Z}$, respectively, and all other terms retain their meaning as in (56.92).

56.6.3 Quasi-Elastic ℓ-Mixing Transitions

$$\sigma_{n\ell}^{(\ell-\text{mixing})} \equiv \sum_{\ell' \neq \ell} \sigma_{n'\ell', n\ell} \qquad (56.94a)$$

$$\sim \begin{cases} \sigma_{\text{geo}} = 4\pi a_0^2 n^4 , & n \ll n_{\max} , \\ 2\pi a_s^2 v_B^2 / V^2 n^3 , & n \gg n_{\max} . \end{cases}$$
(56.94b)

The two limits correspond to strong (close) coupling for $n \ll n_{\max}$, and weak coupling for $n \gg n_{\max}$, and expressions (56.94b) are valid when the quantum defect δ_ℓ of the initial Rydberg orbital $n\ell$ is small. $n_{\max}$ is the principal quantum number, where the ℓ-mixing cross section reaches a maximum [56.21],

$$n_{\max} \sim \left(\frac{v_B |a_s|}{V a_0}\right)^{2/7} . \qquad (56.95)$$

For Rydberg atom–noble gas atom scattering, $n_{\max} = 8$ to 20, while for Rydberg atom–alkali atom scattering $n_{\max} = 15$ to 30.

56.6.4 Elastic $n \ell \rightarrow n \ell'$ Transitions

$$A^*(n\ell) + B \rightarrow A^*(n\ell') + B . \qquad (56.96)$$

(A) Cross Sections.

$$\sigma_{ns}^{\text{elastic}}(V) = \frac{2\pi C_{ss} a_s^2}{(V/v_B)^2 n^{*4}} , \qquad (56.97)$$

valid for $n^* \gg [v_B |a_s|/(4 V a_0)]^{1/4}$ with

$$C_{ss} = \frac{8}{\pi^2} \int_0^{1/\sqrt{2}} [K(k)]^2 \, dk , \qquad (56.98)$$

where $K(k)$ denotes the complete elliptic integral of the first kind.

(B) Rate Coefficients [56.22] (Three Cases). With the definitions

$$v_B = v_B/v_{\text{rms}} , \quad v_{\text{rms}} = \sqrt{(8k_B T)/\mu\pi} , \qquad (56.99)$$

$$f(y) = y^{-1/2}\left(1 - (1-y)e^{-y}\right) + y^{3/2}\text{Ei}(y) , \qquad (56.100)$$

$$y = (v_B a_s)^2 / \left(4\pi a_0^2 n^{*8}\right) , \qquad (56.101)$$

$$n_1 = (|a_s| v_B/4 a_0)^{1/4} , \qquad (56.102)$$

$$n_2 = 0.7 \left[|a_s| v_B^{5/6} / \left(\alpha_d a_0^3\right)^{1/6}\right]^{1/3} , \qquad (56.103)$$

where α_d is the dipole polarizability of A^*, then

$$\left\langle \sigma_{ns}^{\text{el}} \right\rangle \sim \begin{cases} 8\pi a_0^2 n^{*4} , & n^* \leq n_1 , \\ 4\pi^{1/2} a_0 |a_s| v_B f(y) , & n_1 \leq n^* \leq n_2 , \\ 7(\alpha_d v_B)^{2/3} + \dfrac{4 a_s^2 v_B^2}{n^{*4}} \\ \quad - \dfrac{2.7 a_s^2 v_B^2 (\alpha_d v_B)^{1/3}}{a_0 n^{*6}} , & n^* \geq n_2 . \end{cases}$$
(56.104)

56.6.5 Fine Structure $n \ell J \rightarrow n \ell J'$ Transitions

$$A^*(n\ell J) + B \rightarrow A^*(n\ell J') + B + \Delta E_{J'J} . \quad (56.105)$$

(A) Cross Sections (Two Cases).

$$\sigma_{n\ell J}^{n\ell J'}(V) = \frac{2J' + 1}{2(2\ell + 1)} c_{\text{norm}} 4\pi a_0^2 n^{*4} , \qquad (56.106)$$

valid for $n^* \leq n_0(V)$, and

$$\sigma_{n\ell J}^{n\ell J'}(V) = \frac{2\pi C_{J'J}^{(\ell)} a_s^2 v_B^2}{V^2 n^{*4}} \varphi_{J'J}^{(\ell)}(v_{J'J}) \left(1 - \frac{n_0^8(V)}{2n^{*8}}\right) ,$$
(56.107)

valid for $n^* \geq n_0(V)$, where the quantity $n_0(V)$ is the effective principal quantum number such that the impact parameter ρ_0 of B (moving with relative velocity V) equals the radius $2n^{*2}a_0$ of the Rydberg atom A^*. $n_0(V)$ is given by the solution to the following transcendental equation

$$n_0^8(V) = \frac{(2\ell + 1)C_{J'J}^{(\ell)}}{2(2J' + 1)c_{\text{norm}}} \left(\frac{v_B a_s}{V a_0}\right)^2 \varphi_{J'J}^{(\ell)}(v_{J'J}[n_0(V)]) .$$
(56.108)

The constant c_{norm} in (56.106) is equal to 5/8 if $\sigma_{\text{geo}} = \pi \langle r^2 \rangle_{n\ell}$, or 1 if $\sigma_{\text{geo}} = 4\pi a_0^2 n^{*4}$. The function $\varphi_{J'J}^{(\ell)}(v_{J'J})$ in (56.107) is given in general by [56.23, 24]

$$\varphi_{J'J}^{(\ell)}(v_{J'J}) = \xi_{J'J}^{(\ell)}(v_{J'J}) / \xi_{J'J}^{(\ell)}(0) , \quad (56.109a)$$

$$\xi_{J'J}^{(\ell)}(v_{J'J}) = \sum_{s=0}^{\ell} A_{\ell J', \ell J}^{(2s)} \int_{v_{J'J}}^{\infty} j_s^2(z) J_s^2(z) z \, dz , \quad (56.109b)$$

$$v_{J'J} = |\delta_{\ell J'} - \delta_{\ell J}| \frac{v_B}{V n^*} , \quad (56.109c)$$

where $j_s(z)$ is the spherical Bessel function and the coefficients $C_{J'J}^{(\ell)}$ and $A_{\ell J', \ell J}^{(2s)}$ in (56.107) and (56.109b), respectively, are given in table 5.1 of *Beigman* and *Lebedev* [56.6]. The quantum defect of Rydberg state $n\ell J$ is $\delta_{\ell J}$. For elastic scattering, $v_{JJ} = 0$, and $\varphi_{JJ}^{(\ell)}(0) = 1$.

Symmetry relation:

$$\xi_{JJ'}^{(\ell)}(v_{J'J}) = \frac{2J+1}{2J'+1} \xi_{J'J}^{(\ell)}(v_{J'J}) . \quad (56.110)$$

(B) Rate Coefficients.

$$\langle \sigma_{n\ell J}^{n\ell J'} \rangle = \left(\frac{c_{\text{norm}}(2J'+1)C_{J'J}^{(\ell)}}{2(2\ell+1)} \right)^{1/2}$$

$$\times \pi a_0^2 F(\zeta) \left(\frac{v_B |a_s|}{V_T a_0} \right) , \quad (56.111)$$

where $\zeta = n_0^8(V_T)/n^{*8}$, and

$$F(\zeta) \equiv \sqrt{\zeta} \left[E_2(\zeta) + \frac{1}{\zeta}(1 - e^{-\zeta}) \right] , \quad (56.112)$$

where $E_2(x)$ is an exponential integral.

Limiting cases:

$$\left\langle \sigma_{n\ell J}^{n\ell J'} \right\rangle = \begin{cases} \dfrac{2J'+1}{2(2\ell+1)} c_{\text{norm}} 4\pi a_0^2 n^{*4} , & n^* \ll n_{\text{max}}^* , \\[2ex] \dfrac{2\pi C_{J'J}^{(\ell)} a_s^2 v_B^2}{V_T^2 n^{*4}} , & n^* \gg n_{\text{max}}^* , \end{cases} \quad (56.113)$$

where $n_{\text{max}}^* = (3/2)^{1/8} n_0(V)$ if $v_{J'J} \ll 1$.

56.7 Impulse Approximation

56.7.1 Quantal Impulse Approximation

Basic Formulation [56.25]

Consider a Rydberg collision between a projectile (1) of charge Z_1 and a target with a valence electron (3) in orbital ψ_i bound to a core (2). The full three-body wave function for the system of projectile + target is denoted by Ψ_i. The relative distance between 1 and the center-of-mass of $2-3$ is denoted by $\boldsymbol{\sigma}$, while the separation of 2 from the center-of-mass of $1-3$ is $\boldsymbol{\rho}$.

Formal Scattering Theory.

$$\Psi_i^{(+)} = \Omega^{(+)} \psi_i , \quad (56.114)$$

where the Möller scattering operator $\Omega^{(+)} = 1 + G^+ V_i$, and $V_i = V_{12} + V_{13}$.

Let χ_m be a complete set of free-particle wave functions satisfying

$$(H_0 - E_m)\chi_m = 0 , \quad (56.115)$$

and define operators $\omega_{ij}^+(m)$ by

$$\omega_{ij}^+(m)\chi_m = \left(1 + \frac{1}{E_m - H_0 - V_{ij} + i\epsilon} V_{ij} \right) \chi_m , \quad (56.116)$$

where V_{ij} denotes the pairwise interaction potential between particles i and j ($i, j = 1, 2, 3$). Then the action of the full Green's function G^+ on the two-body potential V_{ij} is

$$G^+ V_{ij} = \left[\omega_{ij}^+(m) - 1 \right]$$
$$+ G^+ \left[(E_m - E) + V_{12} + V_{13} + V_{23} - V_{ij} \right]$$
$$\times \left[\omega_{ij}^+(m) - 1 \right] . \quad (56.117)$$

Projection Operators.

$$b_{ij}^+(m) = \omega_{ij}^+(m) - 1 , \quad (56.118a)$$

$$b_{ij}^+ = \sum_m b_{ij}^+(m) |\chi_m\rangle\langle\chi_m| , \quad \omega_{ij}^+ = b_{ij}^+ + 1 . \quad (56.118b)$$

$$G^+ V_{ij} |\psi_i\rangle = \sum_m G^+ V_{ij} |\chi_m\rangle\langle\chi_m|\psi_i\rangle \quad (56.119a)$$

$$= \left[b_{ij}^+ + G^+ \left[V_{23}, b_{ij}^+ \right] \right.$$
$$+ G^+ \left[V_{12} + V_{13} - V_{ij} \right] b_{ij}^+(m) \Big] |\psi_i\rangle . \quad (56.119b)$$

Möller Scattering Operator.

$$\Omega^+ = \left(\omega_{13}^+ + \omega_{12}^+ - 1\right) + G^+\left[V_{23}, \left(b_{13}^+ + b_{12}^+\right)\right]$$
$$+ G^+\left(V_{13}b_{12}^+ + V_{12}b_{13}^+\right) . \tag{56.120}$$

Exact T–Matrix.

$$T_{if} = \left\langle \psi_f \middle| V_f \middle| \left(\omega_{13}^+ + \omega_{12}^+ - 1\right)\psi_i \right\rangle$$
$$+ \left\langle \psi_f \middle| V_f \middle| G^+\left[V_{23}, \left(b_{13}^+ + b_{12}^+\right)\right]\psi_i \right\rangle$$
$$+ \left\langle \psi_f \middle| V_f \middle| G^+\left(V_{13}b_{12}^+ + V_{12}b_{13}^+\right)\psi_i \right\rangle . \tag{56.121}$$

The impulse approximation to the exact T-matrix element (56.121) is obtained by ignoring the second term involving the commutator of V_{23}.

$$\Psi_i \longrightarrow \Psi_i^{\mathrm{imp}} = \left(\omega_{13}^+ + \omega_{12}^+ - 1\right)\psi_i . \tag{56.122}$$

Impulse Approximation: Post Form.

$$T_{if}^{\mathrm{imp}} = \left\langle \psi_f \middle| V_f \middle| \left(\omega_{13}^+ + \omega_{12}^+ - 1\right)\psi_i \right\rangle . \tag{56.123}$$

The impulse approximation can also be expressed using incoming-wave boundary conditions by making use of the prior operators

$$\omega_{ij}^-(m)\chi_m = \left(1 + \frac{1}{E_m - H_0 - V_{ij} - i\epsilon}V_{ij}\right)\chi_m , \tag{56.124a}$$

$$\omega_{ij}^- = \sum_m \omega_{ij}^-(m)|\chi_m\rangle\langle\chi_m| . \tag{56.124b}$$

The impulse approximation (56.123) is exact if V_{23} is a constant since the commutator of V_{23} vanishes in that case.

Applications [56.25]

(1) Electron Capture. $X^+ + \mathrm{H}(i) \to X(f) + \mathrm{H}^+$.

$$T_{if}^{\mathrm{imp}} = \left\langle \psi_f \middle| V_{12} + V_{23}\left(\omega_{12}^+ + \omega_{13}^+ - 1\right)\psi_i \right\rangle . \tag{56.125}$$

Wave functions: $\psi_i = e^{i\boldsymbol{k}_i \cdot \boldsymbol{\sigma}}\varphi_i(\boldsymbol{r})$, $\psi_f = e^{i\boldsymbol{k}_f \cdot \boldsymbol{\rho}}\varphi_f(\boldsymbol{x})$, $\chi_m = (2\pi)^{-3}\exp\left[i(\boldsymbol{K} \cdot \boldsymbol{x} + \boldsymbol{k} \cdot \boldsymbol{\rho})\right]$, where the φ_n are hydrogenic wave functions.

If X above is a heavy particle, the V_{12} term in (56.125) may be omitted due to the difference in mass between the projectile 1 and the bound Rydberg electron 3. See [56.25] and references therein for details.

With the definitions

$$z = \frac{4\alpha\delta^2}{(T - 2\delta)(T - 2\alpha\delta)} , \qquad T = \beta^2 + P^2 ,$$

$$\delta = i\beta K - \boldsymbol{p} \cdot \boldsymbol{K} , \qquad \nu = aZ_1/K ,$$

$$\boldsymbol{t}_1 = \boldsymbol{K}/a + \boldsymbol{v} , \qquad N(\nu) = e^{\pi\nu/2}\Gamma(1 - i\nu) ,$$

$$a = \frac{M_1}{M_1 + m_e} , \qquad b = \frac{M_2}{M_2 + m_e} ,$$

$$\boldsymbol{k} = a\boldsymbol{k}_2 - (1-a)\boldsymbol{k}_f , \qquad \boldsymbol{K} = a\boldsymbol{k}_1 - (1-a)\boldsymbol{k}_i ,$$

$$\boldsymbol{t} = (\boldsymbol{K} - \boldsymbol{p})/a , \qquad \boldsymbol{p} = a\boldsymbol{k}_f - \boldsymbol{k}_i ,$$

$$\beta = aZ_1/n ,$$

and n is the principal quantum number, the impulse approximation to the T-matrix becomes, in this case,

$$T_{if}^{\mathrm{imp}} \sim \left\langle \psi_f \middle| V_{23} \middle| \omega_{13}^+ \psi_i \right\rangle \tag{56.126}$$

$$= \frac{-1}{2\pi^2 a^3} \int \frac{\mathrm{d}\boldsymbol{K}}{t^2} N(\nu) g_i(\boldsymbol{t}_1)\mathcal{F}(f, \boldsymbol{K}, \boldsymbol{p}) , \tag{56.127}$$

where, for a general final s-state,

$$\mathcal{F}(f, \boldsymbol{K}, \boldsymbol{p}) = \int \varphi_f^*(\boldsymbol{x}) e^{i\boldsymbol{p} \cdot \boldsymbol{x}} {}_1F_1\left[i\nu, 1; i(Kx - \boldsymbol{K} \cdot \boldsymbol{x})\right]\mathrm{d}\boldsymbol{x} , \tag{56.128}$$

and $g_i(\boldsymbol{t}_1)$ denotes the Fourier transform of the initial state. The normalization of the Fourier transform is chosen such that momentum and coordinate space hydrogenic wave functions are related by $\varphi_n(\boldsymbol{r}) = (2\pi)^{-3}\int \exp(i\boldsymbol{t}_1 \cdot \boldsymbol{r})g_n(\boldsymbol{t}_1)\,\mathrm{d}\boldsymbol{t}_1$. For the case $f = 1s$,

$$\mathcal{F}(1s, \boldsymbol{K}, \boldsymbol{p}) = -\frac{\beta^{3/2}}{\sqrt{\pi}}\frac{\partial}{\partial\beta}\mathscr{l}(\nu, 0, \beta, -\boldsymbol{K}, \boldsymbol{p})$$

$$= 8\sqrt{\pi}\beta^{3/2}\left[\frac{(1-i\nu)\beta}{T^2}\right.$$

$$\left. + \frac{i\nu(\beta - iK)}{T(T - 2\delta)}\left(\frac{T}{T - 2\delta}\right)^{i\nu}\right] \tag{56.129}$$

evaluated at $\beta = aZ_1$. For the case $f = 2s$,

$$\mathcal{F}(2s, \boldsymbol{K}, \boldsymbol{p}) = -\frac{\beta^{3/2}}{\sqrt{\pi}}\left[\left(\frac{\partial}{\partial\beta} + \beta\frac{\partial^2}{\partial\beta^2}\right)\right.$$

$$\left. \times \mathscr{l}(\nu, 0, \beta, -\boldsymbol{K}, \boldsymbol{p})\right] \tag{56.130}$$

evaluated at $\beta = aZ_1/2$. For a general final ns-state f,

$$\mathscr{l}(\nu, \alpha, \beta, \boldsymbol{K}, \boldsymbol{p}) = \frac{4\sqrt{\pi}}{T}\left(\frac{T - 2\alpha\delta}{T - 2\delta}\right)^{i\nu} \tag{56.131}$$

$$\times (U\cosh\pi\nu \pm iV\sinh\pi\nu) ,$$

where the complex quantity $U + iV$ is

$$U + iV = (4z)^{i\nu} \frac{\Gamma\left(\frac{1}{2} + i\nu\right)}{\Gamma(1 + i\nu)}$$
$$\times {}_2F_1(-i\nu, -i\nu; 1 - 2i\nu; 1/z) . \quad (56.132)$$

(2) Electron Impact Excitation.

$$e^- + H(i) \rightarrow e^- + H(f) . \quad (56.133)$$

Neglecting V_{12} and exchange yields the approximate T-matrix element

$$T_{if}^{\text{imp}} \sim \langle \psi_f | V_{13} | \omega_{13}^+ \psi_i \rangle$$
$$= \frac{-Z_1}{(2\pi a)^3} \int d\mathbf{x} \int d\mathbf{r} \, e^{i\mathbf{q} \cdot \boldsymbol{\sigma}} \varphi_f^*(\mathbf{r}) \frac{1}{x}$$
$$\times \int d\mathbf{K} \, N(\nu) g_i(t_1) e^{it_1 \cdot \mathbf{r}} {}_1F_1(i\nu, 1; iKx - i\mathbf{K} \cdot \mathbf{x})$$
$$\quad (56.134)$$

$$= \frac{-Z_1}{(2\pi a)^3} \int d\mathbf{K} \, N(\nu) g_i(t_1) g_f^*(t_2)$$
$$\times \mathcal{I}(\nu, 0, 0, -\mathbf{K}, -\mathbf{q}) , \quad (56.135)$$

where

$$\mathcal{I}(\nu, 0, 0, -\mathbf{K}, -\mathbf{q})$$
$$= \lim_{\beta \to 0} \frac{4\pi}{\beta^2 + q^2} \left(\frac{\beta^2 + q^2}{\beta^2 + q^2 + 2\mathbf{q} \cdot \mathbf{K} - 2i\beta K} \right)^{i\nu}$$
$$\quad (56.136)$$

$$= \frac{4\pi}{q^2} \left| 1 + \frac{2K}{q} \cos\theta \right|^{-i\nu} A(\cos\theta) , \quad (56.137)$$

with

$$A(\cos\theta) = \begin{cases} 1 , & \cos\theta > -q/2K , \\ e^{-\pi\nu} , & \cos\theta < -q/2K , \end{cases} \quad (56.138)$$

and $\cos\theta = \hat{\mathbf{K}} \cdot \hat{\mathbf{q}}$, $t_2 = t_1 + bq$ and $\mathbf{q} = \mathbf{k}_i - \mathbf{k}_f$.

(3) Heavy Particle Excitation [56.26].

$$H^+ + H(1s) \rightarrow H^+ + H(2s) . \quad (56.139)$$

$$T_{if}^{\text{imp}} = -\frac{Z_1 2^{15/2} b^5}{\pi a^3 q^2} \int\limits_0^\infty d K \, N(K) K^2 \int\limits_{-1}^1 d(\cos\theta)$$
$$\times \left| 1 + \frac{2K}{q} \cos\theta \right|^{-i\nu} \widetilde{A}(\cos\theta) , \quad (56.140)$$

where

$$\widetilde{A}(\cos\theta) = \frac{2\pi}{D^4} \left(\frac{\alpha D (D - 2b^2)}{(\alpha^2 - \beta^2)^{3/2}} + \frac{8 (3b^2 - D)}{(\alpha^2 - \beta^2)^{1/2}} \right.$$
$$- \frac{48\gamma^2 D^2 b^2}{(\gamma^2 - \delta^2)^{5/2}} + \frac{16D[\gamma D - (3\gamma + 4\alpha) b^2]}{(\gamma^2 - \delta^2)^{3/2}}$$
$$\left. + \frac{32 (D - 3b^2)}{(\gamma^2 - \delta^2)^{1/2}} \right) A(\cos\theta) , \quad (56.141)$$

with $A(\cos\theta)$ given by (56.138), and

$$\alpha = b^2 + v^2 + \frac{K^2}{a^2} + \frac{K}{aq} \left(\frac{q^2}{\mu} + \Delta E \right) \cos\theta ,$$
$$\quad (56.142a)$$

$$\beta = \frac{K}{aq} \sin\theta \left[4v^2 q^2 - \left(\frac{q^2}{\mu} + \Delta E \right)^2 \right]^{1/2} , \quad (56.142b)$$

$$\delta = 4\beta , \quad \gamma = 4\alpha + D , \quad (56.142c)$$

$$D = \frac{4bq}{a} (q + 2K \cos\theta) , \quad (56.142d)$$

while ν and $N(\nu)$ retain their meaning from (56.127).

(4) Ionization. $e^- + H(i) \rightarrow e^- + H^+ + e^-$.

$$T_{if}^{\text{imp}} \sim -\frac{4\pi}{q^2} N(\nu) g_i(\mathbf{k} - b\mathbf{q}) \left(\frac{q^2}{q^2 - 2\mathbf{q} \cdot \mathbf{K}} \right)^{i\nu} , \quad (56.143)$$

where $\mathbf{K} = a(\mathbf{k} - b\mathbf{q} - \mathbf{v})$ and $\mathbf{q} = \mathbf{k}_i - \mathbf{k}_f$ and exchange and V_{12} are neglected.

(5) Rydberg Atom Collisions [56.11, 27].

$$A + B(n) \rightarrow A + B(n') \quad (56.144)$$
$$\rightarrow A + B^+ + e^- . \quad (56.145)$$

Consider a Rydberg collision between a projectile (3) and a target with an electron (1) bound in a Rydberg orbital to a core (2) [56.11, 27].

Full T-matrix element:

$$T_{fi}(\mathbf{k}_3, \mathbf{k}_3') \quad (56.146)$$
$$= \langle \phi_f(\mathbf{r}_1) e^{i\mathbf{k}_3' \cdot \mathbf{r}_3} | V(\mathbf{r}_1, \mathbf{r}_3) | \Psi_i^{(+)}(\mathbf{r}_1, \mathbf{r}_3; \mathbf{k}_3) \rangle ,$$

with primes denoting quantities after the collision, and where the potential V is

$$V(\mathbf{r}_1, \mathbf{r}_3) = V_{13}(\mathbf{r}) + V_{3C}(\mathbf{r}_3 + a\mathbf{r}_1) , \quad \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_3 , \quad (56.147)$$

with $a = M_1/(M_1 + M_2)$, while the subscript C labels the core. The impulse approximation to the full, outgoing

wave function $\Psi_i^{(+)}$ is written

$$\Psi_i^{\text{imp}} = (2\pi)^{3/2} \int g_i(\mathbf{k}_1) \Phi(\mathbf{k}_1, \mathbf{k}_3; \mathbf{r}_1, \mathbf{r}_3) \, d\mathbf{k}_1 , \tag{56.148}$$

$$g_i(\mathbf{k}_1) = \frac{1}{(2\pi)^{3/2}} \int \phi_i(\mathbf{r}_1) e^{-i\mathbf{k}_1 \cdot \mathbf{r}_1} \, d\mathbf{r}_1 . \tag{56.149}$$

Impulse approximation:

$$T_{fi}^{\text{imp}}(\mathbf{k}_3, \mathbf{k}_3') = \int d\mathbf{k}_1 \int d\mathbf{k}_1' \, g_f^*(\mathbf{k}_1') g_i(\mathbf{k}_1) T_{13}(\mathbf{k}, \mathbf{k}')$$
$$\times \delta \left[\mathbf{P} - (\mathbf{k}_1' - \mathbf{k}_1) \right] , \tag{56.150}$$

where T_{13} is the exact off-shell T-matrix for 1–3 scattering,

$$T_{13}(\mathbf{k}, \mathbf{k}') = \langle \exp(i\mathbf{k}' \cdot \mathbf{r}) | V_{13}(\mathbf{r}) | \psi(\mathbf{k}, \mathbf{r}) \rangle . \tag{56.151}$$

The delta function in (56.150) ensures linear momentum, $\mathbf{K} = \mathbf{k}_1 + \mathbf{k}_3 = \mathbf{k}_1' + \mathbf{k}_3'$, is conserved in 1–3 collisions, with

$$\mathbf{k}_1' = \mathbf{k}_1 + (\mathbf{k}_3 - \mathbf{k}_3') \equiv \mathbf{k}_1 + \mathbf{P} , \tag{56.152a}$$

$$\mathbf{k}' = \frac{M_3}{M_1 + M_3}(\mathbf{k}_1 + \mathbf{k}_3) - \mathbf{k}_3' = \mathbf{k} + \mathbf{P} . \tag{56.152b}$$

Elastic scattering:

$$T_{ii}(\mathbf{k}_3, \mathbf{k}_3) = \int g_f^*(\mathbf{k}_1) g_i(\mathbf{k}_1) T_{13}(\mathbf{k}, \mathbf{k}) \, d\mathbf{k}_1 , \tag{56.153}$$

where $\mathbf{k} = (M_3/M)\mathbf{k}_1 + (M_1/M)\mathbf{k}_3$ and $M = M_1 + M_3$.

Integral cross section: for 3–(1,2) scattering,

$$\sigma_{if}(\mathbf{k}_3) = \left(\frac{M_{AB}}{M_{13}} \right)^2 \frac{k_3'}{k_3} \int \left| \langle g_f(\mathbf{k}_1 + \mathbf{P}) \right|$$
$$\times f_{13}(\mathbf{k}, \mathbf{k}') g_i(\mathbf{k}_1) \rangle \right|^2 \, d\hat{\mathbf{k}}_3' , \tag{56.154}$$

where M_{AB} is the reduced mass of the 3–(1,2) system, M_{13} the reduced mass of 1–3. The 1–3 scattering amplitude f_{13} is given by

$$f_{13}(\mathbf{k}, \mathbf{k}') = -\frac{1}{4\pi} \left(\frac{2M_{13}}{\hbar^2} \right) T_{13}(\mathbf{k}, \mathbf{k}') . \tag{56.155}$$

Six Approximations to (56.150)

(1) Optical Theorem.

$$\sigma_{\text{tot}}(\mathbf{k}_3) = \frac{1}{k_3} \frac{2M_{AB}}{\hbar^2} T_{ii}(\mathbf{k}_3, \mathbf{k}_3')$$
$$= \frac{1}{v_3} \int \left| g_i(\mathbf{k}_1) \right|^2 \left[v_{13} \sigma_{13}^{\text{T}}(v_{13}) \right] \, d\mathbf{k}_1 , \tag{56.156}$$

where σ_{13}^{T} is the total cross section for 1–3 scattering at relative speed v_{13}. The resultant cross section (56.156) is an upper limit and contains no interference terms.

(2) Plane–Wave Final State.

$$\phi_f(\mathbf{r}_1) = (2\pi)^{-3/2} \exp(i\mathbf{\kappa}_1' \cdot \mathbf{r}_1) , \tag{56.157}$$

$$g_f(\mathbf{k}_1') = \delta(\mathbf{k}_1' - \mathbf{\kappa}_1') , \tag{56.158}$$

$$T_{fi}(\mathbf{k}_3, \mathbf{k}_3') = g_i(\mathbf{k}_1) T_{13}(\mathbf{k}, \mathbf{k}') , \quad \mathbf{k}_1 = \mathbf{\kappa}_1 - \mathbf{P} , \tag{56.159}$$

$$\frac{d\sigma_{if}}{d\hat{\mathbf{k}}_3' \, d\mathbf{k}_1'} = \left(\frac{M_{AB}}{M_{13}} \right)^2 \frac{k_3'}{k_3} \left| g_i(\mathbf{k}_1) \right|^2 \left| f_{13}(\mathbf{k}, \mathbf{k}') \right|^2 . \tag{56.160}$$

(3) Closure.

$$\sum_f g_f(\mathbf{k}_1') g_f^*(\mathbf{k}_1'') = \delta(\mathbf{k}_1' - \mathbf{k}_1'') , \tag{56.161}$$

$$\frac{d\sigma_i^T}{d\hat{\mathbf{k}}_3'} = \frac{\bar{k}_3'}{k_3} \left(\frac{M_{AB}}{M_{13}} \right)^2 \int \left| g_i(\mathbf{k}_1) \right|^2 \left| f_{13}(\mathbf{k}, \mathbf{k}') \right|^2 \, d\mathbf{k}_1 , \tag{56.162}$$

where $\mathbf{k}_1' = (M_3/M)(\mathbf{k}_1 + \mathbf{k}_3) - \mathbf{k}_3'$.

Conditions for validity of (56.162): (a) k_3 is high enough to excite all atomic bound and continuum states, and (b) $k_3'^2 = (k_3^2 - 2\varepsilon_{fi}/M_{AB})$ can be approximated by k_3, or by an averaged wavenumber $\bar{k}_3' = (k_3^2 - 2\bar{\varepsilon}_{fi}/M_{AB})^{1/2}$, where the averaged excitation energy is

$$\bar{\varepsilon}_{fi} = \ln\langle \varepsilon_{fi} \rangle = \sum_j f_{ij} \ln \varepsilon_{ij} \left(\sum_j f_{ij} \right)^{-1} , \tag{56.163}$$

and the f_{ij} are the oscillator strengths.

(4) Peaking Approximation.

$$T_{fi}^{\text{peak}}(\mathbf{k}_3, \mathbf{k}_3') = F_{fi}(\mathbf{P}) T_{13}(\mathbf{k}, \mathbf{k}') , \tag{56.164}$$

where F_{fi} is the inelastic form factor

$$F_{fi}(\mathbf{P}) = \int g_f^*(\mathbf{k}_1 + \mathbf{P}) g_i(\mathbf{k}_1) \, d\mathbf{k}_1 \tag{56.165}$$

$$= \langle \psi_f(\mathbf{r}) | \exp(i\mathbf{P} \cdot \mathbf{r}) | \psi_i(\mathbf{r}) \rangle . \tag{56.166}$$

(5) $T_{13} = T_{13}(\mathbf{P})$.

$$T_{fi}(\mathbf{k}_3, \mathbf{k}_3') = T_{13}(\mathbf{P}) F_{fi}(\mathbf{P}) . \tag{56.167}$$

(6) $T_{13} = $ *constant.* $f_{13} \equiv a_s = $ constant scattering length.

$$\sigma_{if}(k_3) = \frac{2\pi a_s^2}{k_3^2}\left(\frac{M_{AB}}{M_{13}}\right)^2 \int\limits_{k_3-k_3'}^{k_3+k_3'} |F_{fi}(\boldsymbol{P})|^2 P\,dP ,$$
(56.168)

$$\sigma_{\text{tot}}(k_3) = \begin{cases} 4\pi a_s^2 , & v_3 \gg v_1 \\ \langle v_1\rangle 4\pi a_s^2/v_3 , & v_3 \ll v_1 . \end{cases}$$
(56.169)

Validity Criteria

(A) Intuitive Formulation [56.27]. (i) Particle 3 scatters separately from 1 and 2, i.e., $r_{12} \gg A_{1,2}$; the relative separation of (1,2) $\gg$ the scattering lengths of 1 and 2. (ii) $\lambda_{13} \ll r_{12}$, i.e., the reduced wavelength for $1-3$ relative motion $\ll r_{12}$. Interference effects of 1 and 2 can be ignored and $1, 2$ treated as *independent* scattering centers.
(iii) $2-3$ collisions do not contribute to inelastic $1-3$ scattering.
(iv) Momentum impulsively transferred to 1 during collision (time τ_{coll}) with 3 $\gg$ momentum transferred to 1 due to V_{12}, i.e.,

$$P \gg \langle\psi_{n\ell}| - \nabla V_{12}|\psi_{n\ell}\rangle\tau_{\text{coll}} .$$
(56.170)

For a precise formulation of validity criteria based upon the two-potential formula see the Appendix of [56.27].

Two classes of interaction in $A-B(n)$ Rydberg collisions justify use of the impulse approximation for the T-matrix for $1-3$ collisions: (i) quasiclassical binding with $V_{\text{core}} = $ const., and (ii) weak binding with

$$E_3 \gg \Delta E_c \sim \langle\psi_n(r)|V_{1C}(r)|\psi_n(r)\rangle ,$$
(56.171a)

$$\langle\psi_n(\boldsymbol{r}_1)| - \frac{\hbar^2}{2M_{12}}\nabla_1^2|\psi_n(\boldsymbol{r}_1)\rangle \sim |\varepsilon_n| ,$$
(56.171b)

where E_3 is the kinetic energy of relative motion of 3, and ΔE_c is the energy shift in the core. The fractional error is [56.28]

$$\frac{f_{13}}{\lambda}\frac{\Delta E_c}{\hbar}\left(\frac{\hbar}{E_3} + \tau_{\text{delay}}\right) \ll 1 ,$$
(56.172)

where $\lambda \sim k_3^{-1}$ is the reduced wavelength of 3, f_{13} is the scattering amplitude for $1-3$ collisions and τ_{delay} is the time delay associated with $1-3$ collisions.

Special Case: for nonresonant scattering with $\tau_{\text{delay}} = 0$

$$\frac{f_{13}}{\lambda}\frac{|\varepsilon_n|}{E_3} \ll 1 ,$$
(56.173)

which follows from (56.172) upon identifying the shift in the core energy ΔE_c with the binding energy $|\varepsilon|$.

Condition (56.173) is less restrictive than (56.171a) or (56.171b) since f_{13} can be either less than or greater than λ.

56.7.2 Classical Impulse Approximation

(A) Ionization. For electron impact on heavy particles [56.29], the cross section for ionization of a particle moving with velocity t by a projectile with velocity s is

$$Q(s,t) = \frac{1}{u^2}\frac{2s}{m_2}\int\limits_1^{s^2} \frac{dz}{z^2}\left[\frac{A(z)}{z} + B(z)\right] ,$$
(56.174)

where

$$A(z) = \frac{1}{2st^3}\left[\frac{1}{3}\left(x_{02}^{3/2} - x_{01}^{3/2}\right)\right.$$
$$\left. - 2\left(s^2 + t^2\right)\left(x_{02}^{1/2} - x_{01}^{1/2}\right)\right]$$
$$- \frac{(s^2 - t^2)^2}{2ts^3}\left(x_{02}^{-1/2} - x_{01}^{-1/2}\right) ,$$
(56.175a)

$$B(z) = \frac{1}{2m_2st^3}\left[(m_1 + m_2)\left(s^2 - t^2\right)\left(x_{02}^{-1/2} - x_{01}^{-1/2}\right)\right.$$
$$\left. - (m_2 - m_1)\left(x_{02}^{1/2} - x_{01}^{1/2}\right)\right] .$$
(56.175b)

For electron impact, (56.175b) is evaluated at $m_1 = 1$. The remaining terms above are given by

$$s^2 = v_2^2/v_0^2 , \quad t^2 = v_1^2/v_0^2 = E_1/u ,$$
$$E_2 = m_2 v_2^2 ,$$
$$u = v_0^2 = \text{Ionization potential of target} ,$$
$$x_{0i} = (s^2 + t^2 - 2st\cos\theta_i) , \quad i = 1, 2 ,$$
$$\cos\theta_i = \begin{cases} \kappa_0 \pm \kappa_1 , & |\kappa_0 \pm \kappa_1| \leq 1 \\ 1 , & \kappa_0 \pm \kappa_1 > 1 \\ -1 , & \kappa_0 \pm \kappa_1 < -1 \end{cases} ,$$
$$\kappa_0 \pm \kappa_1 = -\frac{1}{2}\left(1 - \frac{m_1}{m_2}\right)\frac{z}{st} \pm \sqrt{\left(1 + \frac{z}{t^2}\right)\left(1 - \frac{z}{s^2}\right)} .$$

Equal Mass Case: $(m_1 = m_2)$

$$Q(s,t) = \begin{cases} \dfrac{4}{3s^2}\dfrac{1}{u^2}\dfrac{2(s^2-1)^{3/2}}{t} , & 1 \leq s^2 \leq t^2 + 1 , \\ \dfrac{4}{3s^2}\dfrac{1}{u^2}\left(2t^2 + 3 - \dfrac{3}{s^2 - t^2}\right) , & s^2 \geq t^2 + 1 . \end{cases}$$
(56.176)

Integrating over the speed distribution (Sect. 56.4),

$$Q(s) = \frac{32}{\pi} \frac{1}{u^2} \int_0^\infty \frac{Q(s,t)t^2 \, dt}{(t^2+1)^4} , \tag{56.177}$$

which is then numerically evaluated. For electrons, the integral can be done analytically with the result

$$Q(y) = \frac{8}{3\pi y^2 (y+1)^4}$$

$$\times \left[\left(5y^4 + 15y^3 - 3y^2 - 7y + 6 \right) (y-1)^{1/2} \right.$$

$$+ \left(5y^5 + 17y^4 + 15y^3 - 25y^2 + 20y \right)$$

$$\times \tan^{-1}(y-1)^{1/2}$$

$$\left. - 24 y^{3/2} \ln \left| \frac{\sqrt{y} + \sqrt{y-1}}{\sqrt{y} - \sqrt{y-1}} \right| \right] , \tag{56.178}$$

with $y = s^2$.

Thomson's Result:

$$Q_T(y) = \frac{4}{y} \frac{1}{u^2} \left(1 - \frac{1}{y} \right) . \tag{56.179}$$

(B) Electron Loss Cross Section [56.18].

$$A(V) + B(u) \rightarrow A^+ + e^- + B(f) , \tag{56.180}$$

where $B(f)$ denotes that the target B is left in any state (either bound or free) after the collision with the projectile A. The initial velocity of the projectile is V while the velocity of the Rydberg electron relative to the core is u, and the ionization potential of the target B is I.

$$\sigma_{\text{loss}} = \frac{1}{3\pi v^2} \int_{\tau/4v}^\infty dx \, \sigma_T(x\bar{u}) \left(\frac{8vx - 1 - (v-x)^2 - 2\tau}{\left[1 + (v-x)^2 \right]^3} \right.$$

$$\left. + \frac{1}{\left[1 + (v+x)^2 - \tau \right]^2} \right) , \tag{56.181}$$

where $v = V/\bar{u}$, $\tau = I/\frac{1}{2}m_e\bar{u}^2$, $\bar{u} = \sqrt{2I/m_e}$, and σ_T is the total electron scattering cross section at speed $x\bar{u}$. The cross section (56.181) is valid only for particles being stripped (or lost from the projectile) which are not strongly bound. See [56.18, 30, 31] for details and numerous results.

(C) Capture Cross Section from Shell i [56.18].

$$\sigma_{\text{capture}}^i(V)$$

$$= \frac{2^{5/2} N_i \pi}{3V^7} \int_0^{r_i} dr \int_{\mathcal{C}(-1)}^{\mathcal{C}(+1)} d(\cos \eta') \, [P_i(r)]^2$$

$$\times \frac{\sqrt{1+y^2} \left[4\varepsilon^2 - (\varepsilon^2 - y^2)(1+\varepsilon^2 + a^2 - y^2) \right]}{r^{3/2} \varepsilon^{9/2} (1+a^2)^3 \sqrt{y^2 - a^2}} , \tag{56.182}$$

where $\mathcal{C}$ denotes that the integration range $[-1, +1]$ is restricted such that the integrand is real and positive and that $|1 - \varepsilon| < \sqrt{y^2 - a^2}$. The dimensionless variables a and y above are defined as

$$y^2 = \frac{2}{m_e} |V(R)| V^2 , \quad a^2 = \frac{2}{m_e} I_i V^2 , \tag{56.183}$$

and with $P_i(r)/r$ representing the Hartree–Fock–Slater radial wave function for shell i, with normalization

$$\int_0^{r_i} [P_i(r)]^2 \, dr = 1 . \tag{56.184}$$

The ionization potential and number of electrons in shell i are denoted above, respectively, by I_i and N_i.

(D) Total Capture Cross Section [56.18].

$$\sigma_{\text{capture}}^{\text{total}}(V) = \sum_i \sigma_{\text{capture}}^i . \tag{56.185}$$

(E) Universal Capture Cross Section [56.18].
A universal curve independent of projectile mass M and charge Z is obtained from the above expressions for the capture cross section by plotting the scaled cross section

$$\widetilde{\sigma}_{\text{capture}}^{\text{total}} = \frac{E^{11/4}}{M^{11/4} Z^{7/2} \lambda^{3/4}} \sigma_{\text{capture}}^{\text{total}} \tag{56.186}$$

versus the scaled energy

$$\widetilde{E} = \frac{m_e}{M} \frac{E}{I} , \tag{56.187}$$

where m_e is the mass of the particle captured, which is usually taken to be a single electron, and I is the ionization potential of the target. The term λ in (56.186) is the coupling constant in the target potential, $V(R) = m_e \lambda / R^2$, which the electron being captured experiences during the collision. See Fig. 11 of [56.18] for details.

56.7.3 Semiquantal Impulse Approximation

Basic Expression [56.27, 32, 33].

$$\frac{d\sigma}{d\varepsilon\,dP\,dk_1\,dk\,d\phi_1} = \frac{k_1'^2}{J_{55}}\frac{k_3'}{k_3}\left(\frac{M_3}{M_{13}}\right)^2 |g_i(\mathbf{k}_1)|^2$$
$$\times |f_{13}(\mathbf{k},\mathbf{k}')|^2 . \qquad (56.188)$$

J_{55} is the 5-dimensional Jacobian of the transformation

$$(P, \varepsilon, k_1, k, \phi_1) \rightarrow (\hat{\mathbf{k}}_3', \mathbf{k}_1') , \qquad (56.189a)$$

$$J_{55} = \frac{\partial\,(P, \varepsilon, k_1, k, \phi_1)}{\partial\left(\cos\theta_3'\phi_3', k_1', \cos\theta_1', \phi_1'\right)} . \qquad (56.189b)$$

Expression for Elemental Cross Section [56.27]. In the $(P, \varepsilon, k_1, k, \phi_1)$ representation,

$$d\sigma = \frac{d\varepsilon\,dP}{M_{13}^2 v_3^2}\left[\frac{|g_i(\mathbf{k}_1)|^2 k_1^2\,dk_1\,d\phi_1}{v_1}\right]$$
$$\times \frac{|f_{13}(\mathbf{k},\mathbf{k}')|^2\,dg^2}{\sqrt{\left(g_+^2 - g^2\right)\left(g^2 - g_-^2\right)}} , \qquad (56.190)$$

where $g_\pm^2 = \frac{1}{2}B \pm \sqrt{\frac{1}{4}B^2 - C}$, and

$$B = B(\varepsilon, P, v_1; v_3)$$
$$= \frac{a}{(1+a)^2}\frac{P^2}{M_{13}^2} + \left(v_1^2 + v_1'^2 + v_3^2 + v_3'^2 + \frac{2\Delta_3}{M_{13}}\right)$$
$$- \frac{4\varepsilon(\varepsilon + \Delta_3)}{P^2} ,$$

$$C = C(\varepsilon, P, v_1; v_3)$$
$$= \frac{v_1^2 + av_3^2}{1+a}\frac{P^2}{M_{13}^2} + \left(v_1^2 - v_3^2\right)\left(v_1'^2 - v_3'^2\right)$$
$$+ \frac{2\Delta_3}{M_{13}}\left(v_1^2 + v_3^2\right) + \frac{4\Delta_3}{P^2}\left[v_1^2(\varepsilon + \Delta_3) - \varepsilon v_3^2\right] ,$$

$$a = \frac{M_2 M_3}{M_1(M_1 + M_2 + M_3)} ,$$

$$\widetilde{M}_1 = M_1(1 + M_1/M_2) ,$$

$$v_1'^2 = v_1^2 + \frac{2\varepsilon}{\widetilde{M}_1} , \qquad v_3'^2 = v_3^2 - \frac{2(\varepsilon + \Delta_3)}{M_{AB}} ,$$

and Δ_3 is the change in internal energy of particle 3, while ε denotes the energy change in the target $1 - 2$.

Hydrogenic Systems $g_i(\mathbf{k}_1) = g_{n'}(k_1)Y_{\ell m}(\theta_1, \phi_1)$. The $g_{n\ell}$ are the hydrogenic wave functions in momentum space. See Chapt. 9 for details on hydrogenic wave functions.

Elemental Cross Sections (m–Averaged and ϕ_1-Integrated).

$$d\sigma = \frac{d\varepsilon\,dP}{M_{13}^2 v_3^2}\frac{W_{n\ell}(v_1)\,dv_1}{2v_1}\frac{|f_{13}(P,g)|^2\,dg^2}{\sqrt{\left(g_+^2 - g^2\right)\left(g^2 - g_-^2\right)}} , \qquad (56.191)$$

where the speed distribution $W_{n\ell}$ is given by (56.57).

Two Representations for 1–3 Scattering Amplitude [56.27]. (i) $f_{13} = f_{13}(P, g)$ is a function of momentum transferred and relative speed. Then

$$\sigma(v_3) = \frac{1}{M_{13}^2 v_3^2}\int_{\varepsilon_1}^{\varepsilon_2} d\varepsilon \int_{v_{10}}^{\infty}\frac{W_{n\ell}(v_1)\,dv_1}{v_1}\int_{P^-}^{P^+} dP$$
$$\times \int_{g_-}^{g_+}\frac{|f_{13}(P,g)|^2\,dg^2}{\sqrt{\left(g_+^2 - g^2\right)\left(g^2 - g_-^2\right)}} , \qquad (56.192)$$

where $v_{10}^2(\varepsilon) = \max\left[0, (2\varepsilon/M)\right]$, and the limits to the P integral are

$$P^+ = P^+(\varepsilon, v_1; v_3)$$
$$= \min\left[M(v_1' + v_1), M_{AB}(v_3' + v_3)\right] , \qquad (56.193a)$$

$$P^- = P^-(\varepsilon, v_1; v_3)$$
$$= \max\left[M|v_1' - v_1|, M_{AB}|v_3' - v_3|\right] , \qquad (56.193b)$$

and unless $P^+ > P^-$, the P integral is zero.
(ii) $f_{13} = f_{13}(g, \psi)$ is a function of relative speed and scattering angle. Then

$$\sigma(v_3) = \frac{1}{v_3^2}\int_{\varepsilon_1}^{\varepsilon_2} d\varepsilon \int_{v_{10}}^{\infty}\frac{W_{n\ell}(v_1)\,dv_1}{v_1}\int_{g_-}^{g_+}\frac{g\,dg}{S(v_1, g; v_3)}$$
$$\times \int_{\psi^-}^{\psi^+}\frac{|f_{13}(g,\psi)|^2\,d(\cos\psi)}{\sqrt{\left(\cos\psi^+ - \cos\psi\right)\left(\cos\psi - \cos\psi^-\right)}} , \qquad (56.194)$$

where

$$S(v_1, g; v_3) = \frac{M_{13}}{1+a}\left[(1+a)\left(v_1^2 + av_3^2\right) - ag^2\right]^{1/2} .$$

Scattering angle ψ-limits,

$$\cos\psi^\pm = \cos\psi^\pm(\varepsilon, v_1, g; v_3) \qquad (56.195)$$
$$= \frac{g}{g'}\frac{1}{\alpha^2 + \beta^2}\left\{\alpha(\alpha + \tilde{\varepsilon}) \pm \beta\left[\omega^2\left(\alpha^2 + \beta^2\right)\right.\right.$$
$$\left.\left. - (\alpha + \tilde{\varepsilon})^2\right]^{1/2}\right\} , \qquad (56.196)$$

where

$$\alpha = \alpha(v_1, g; v_3)$$

$$= \frac{1}{2} M_{13} \left[v_1^2 - v_3^2 + \left(\frac{1-a}{1+a} \right) g^2 \right] ,$$

$$\beta = \beta(v_1, g; v_3)$$

$$= \frac{1}{2} M_{13} \left[\left(2v_1^2 + 2v_3^2 - g^2 \right) g^2 - \left(v_1^2 - v_3^2 \right)^2 \right]^{1/2} ,$$

$$\omega = g'/g , \quad \tilde{\varepsilon} = \varepsilon + \frac{a}{1+a} \Delta_3 .$$

Special Case: $f_{13} = f_{13}(P)$.

$$\sigma(v_3) = \frac{\pi}{M_{13}^2 v_3^2} \int_{\varepsilon_1}^{\varepsilon_2} \mathrm{d}\varepsilon \int_{v_{10}}^{\infty} \frac{W_{n\ell}(v_1) \, \mathrm{d}v_1}{v_1}$$

$$\times \int_{P^-}^{P^+} |f_{13}(P)|^2 \, \mathrm{d}P . \tag{56.197}$$

56.8 Binary Encounter Approximation

The basic assumption of the binary encounter approximation is that an excitation or ionization process is caused solely by the interaction of the incoming charged or neutral projectile with the Rydberg electron bound to its parent ion. If, for example, the cross section depends only on the momentum transfer P to the Rydberg electron (as in the Born approximation), then the total cross section is obtained by integrating σ_P over the momentum distribution of the Rydberg electron. The basic cross sections required are given in the following section. For further details see [56.34] and references therein.

56.8.1 Differential Cross Sections

Cross Section per Unit Momentum Transfer

Let the masses, velocities and charges of the particles be $(m_1, \boldsymbol{v}_1, Z_1, e)$ and $(m_2, \boldsymbol{v}_2, Z_2, e)$, with $v = |\boldsymbol{v}_1 - \boldsymbol{v}_2|$ denoting the relative velocity and quantities *after* the collision are denoted by primes. Then for distinguishable particles,

$$\sigma_P = \frac{8\pi Z_1^2 Z_2^2 \mathrm{e}^4 P}{v^2} \left| \frac{\exp(\mathrm{i}\eta_P)}{P^2} \right|^2 , \tag{56.198}$$

where the phase shift η_P is

$$\eta_P = -2\gamma \ln(P/2\mu v) + 2\eta_0 + \pi , \tag{56.199}$$

and with

$$\mu = \frac{m_1 m_2}{m_1 + m_2} , \quad \gamma = \frac{Z_1 Z_2 e^2}{\hbar v} , \quad e^{2\mathrm{i}\eta_0} = \frac{\Gamma(1 + \mathrm{i}\gamma)}{\Gamma(1 - \mathrm{i}\gamma)} . \tag{56.200}$$

For identical particles,

$$\sigma_P^\pm = \frac{8\pi Z_1^2 Z_2^2 \mathrm{e}^4 P}{v^2} \left| \frac{\mathrm{e}^{\mathrm{i}\eta_P}}{P^2} \pm \frac{\mathrm{e}^{\mathrm{i}\eta_S}}{S^2} \right|^2 , \tag{56.201}$$

where η_P is given by (56.199) and η_S is

$$\eta_S = -2\gamma \ln(S/2\mu v) + 2\eta_0 + \pi , \tag{56.202}$$

while η_0 is given by (56.200). The momenta $\boldsymbol{P}$ and $\boldsymbol{S}$ transferred by direct and exchange collisions, respectively, are given by

$$\boldsymbol{P} = m_1(\boldsymbol{v}_1 - \boldsymbol{v}_1') = m_2(\boldsymbol{v}_1 - \boldsymbol{v}_2') , \tag{56.203a}$$

$$\boldsymbol{S} = m_1(\boldsymbol{v}_1 - \boldsymbol{v}_2') = m_2(\boldsymbol{v}_1' - \boldsymbol{v}_2) . \tag{56.203b}$$

The collision rates (in cm^3/s) are

$$\hat{\alpha}_P = v_1 \sigma_P , \quad \hat{\alpha}_P^\pm = v_1 \sigma_P^\pm . \tag{56.204}$$

Cross Section per Unit Momentum Transferred per Unit Steradian

Differential relationships:

$$\alpha_{E,P} = \frac{\mathrm{d}^2\alpha}{\mathrm{d}P \, \mathrm{d}E} = \frac{\mathrm{d}^2\alpha}{\mathrm{d}P \, \mathrm{d}\varphi} \frac{\mathrm{d}\varphi}{\mathrm{d}E} = \alpha_{P,\varphi} \frac{\mathrm{d}\varphi}{\mathrm{d}E} . \tag{56.205}$$

For distinguishable particles,

$$\alpha_P = 2\pi v_1 \sigma_{P,\varphi} = 2\pi \alpha_{P,\varphi} , \tag{56.206a}$$

$$\alpha_{P,\varphi} = \frac{4 Z_1^2 Z_2^2 e^4 P}{v} \left| \frac{\mathrm{e}^{\mathrm{i}\eta_P}}{P^2} \right|^2 , \tag{56.206b}$$

$$\alpha_{E,P} = v_1 \sigma_{E,P} = \frac{8 Z_1^2 Z_2^2 e^4}{v_1 v_2 \sqrt{X}} \left| \frac{\mathrm{e}^{\mathrm{i}\eta_P}}{P^2} \right|^2 . \tag{56.206c}$$

For identical particles,

$$\alpha_{P,\varphi}^\pm = \frac{4 Z_1^2 Z_2^2 e^4 P}{v} \left| \frac{\mathrm{e}^{\mathrm{i}\eta_P}}{P^2} \pm \frac{\mathrm{e}^{\mathrm{i}\eta_S}}{S^2} \right|^2 , \tag{56.207a}$$

$$\alpha_{E,P}^\pm = v_1 \sigma_{E,P}^\pm = \frac{8 Z_1^2 Z_2^2 e^4}{v_1 v_2 \sqrt{X}} \left| \frac{\mathrm{e}^{\mathrm{i}\eta_P}}{P^2} \pm \frac{\mathrm{e}^{\mathrm{i}\eta_S}}{S^2} \right|^2 , \tag{56.207b}$$

where

$$X = -\cos^2\phi + 2(\hat{\boldsymbol{v}}_{\boldsymbol{I}}\cdot\hat{\boldsymbol{P}})(\hat{\boldsymbol{v}}_{\boldsymbol{2}}\cdot\hat{\boldsymbol{P}})\cos\phi + 1$$
$$\qquad - (\hat{\boldsymbol{v}}_{\boldsymbol{I}}\cdot\hat{\boldsymbol{P}})^2 - (\hat{\boldsymbol{v}}_{\boldsymbol{2}}\cdot\hat{\boldsymbol{P}})^2 \tag{56.208a}$$
$$\qquad = (\cos\phi_{\min} - \cos\phi)(\cos\phi - \cos\phi_{\max}) \tag{56.208b}$$
$$\qquad = \left(\frac{v}{v_1 v_2 P}\right)^2 (E_{\max} - E)(E - E_{\min}) , \tag{56.208c}$$

with ϕ being the angle between the velocity vectors $\boldsymbol{v}_1$ and $\boldsymbol{v}_2$.

For the special case of electron impact, $M_2 = m_{\rm e}$, $Z_2 = -1$, and

$$\sigma_{E,P}(\phi) = \frac{8Z_1^2 e^4}{v_1^2 v_2 P^4 \sqrt{X}} , \tag{56.209}$$

$$\sigma_{E,P}^{\pm}(\phi) = 8e^4 v_1^2 v_2 \sqrt{X}$$
$$\qquad \times \left(\frac{1}{P^4} + \frac{1}{S^4} \frac{2\cos(\eta_P - \eta_S)}{P^2 S^2}\right) , \tag{56.210}$$

where $\eta_P - \eta_S = -2\gamma \ln(P/S) = (2e^2/\hbar v)\ln(S/P)$, and X is given by (56.208b).

Integrated Cross Sections

For incident heavy particles:

$$\sigma_{E,P} = \int_0^\pi \sigma_{E,P}(\phi) \frac{1}{2} \sin\phi \, {\rm d}\phi = \frac{4\pi Z_1^2 e^4}{v_1^2 v_2 P^4} . \tag{56.211}$$

For incident electrons:

$$\sigma_{E,P}^{\pm} = \int_0^\pi \sigma_{E,P}^{\pm}(\phi) \frac{1}{2} \sin\phi \, {\rm d}\phi \tag{56.212a}$$
$$= \frac{4\pi e^4}{v_1^2 v_2} \left(\frac{1}{P^4} + \frac{v_1^2 + v_2^2 - P^2/2m_{\rm e}^2 - 2E^2/P^2}{m_{\rm e}^4 |v_1^2 - v_2^2 - 2E/m_{\rm e}|^3}\right.$$
$$\qquad \left. \pm \frac{2\Phi}{m_{\rm e}^2 P^2 |v_1^2 - v_2^2 - 2E/m_{\rm e}|}\right) , \tag{56.212b}$$

where Φ can be approximated [56.35] by

$$\Phi \sim \cos\left(\left|\frac{R_\infty}{E_3 - E_2}\right|^{1/2} \ln\left|\frac{E}{E_3 - E_2 - E}\right|\right) . \tag{56.213}$$

and E_3 is defined in [56.35].

Cross Sections per Unit Energy

For incident heavy particles (three cases):

$$\sigma_E = \frac{2\pi Z_1^2 e^4}{m_{\rm e} v_1^2}\left(\frac{1}{E^2} + \frac{2m_{\rm e} v_2^2}{3E^2}\right) , \tag{56.214}$$

which is valid for $2v_1 \geq v_2 + v_2'$, $E \leq 2m_{\rm e} v_1(v_1 - v_2)$, or

$$\sigma_E = \frac{\pi Z_1^2 e^4}{3v_1^2 v_2 E^3}\left(4v_1^3 - \frac{1}{2}(v_2' - v_2)^2\right) , \tag{56.215}$$

which is valid for $v_2' - v_2 \leq 2v_1 \leq v_2' + v_2$, $2m_{\rm e} v_1 (v_1 - v_2) \leq E \leq 2m_{\rm e} v_1(v_1 + v_2)$, or otherwise, $\sigma_E = 0$ for $E \geq m_{\rm e} v_1(v_2' + v_2)$.

For incident electrons (two cases):

$$\sigma_E^{\pm} = \frac{2\pi e^4}{m_{\rm e} v_1^2}\left(\frac{1}{E^2} + \frac{2m_{\rm e} v_2^2}{3E^3} + \frac{1}{D^2} + \frac{2m_{\rm e} v_2^2}{3D^3} \pm \frac{2\Phi}{ED}\right) , \tag{56.216}$$

which is valid for $m_{\rm e}(v_2 - v_2') \leq m_{\rm e}(v_1' - v_1)$, $m_{\rm e}(v_2' + v_2) \leq m_{\rm e}(v_1 + v_1')$, $D \geq 0$, or

$$\sigma_E = \frac{2\pi e^4}{m_{\rm e} v_1^2}\left(\frac{1}{E^2} + \frac{2m_{\rm e} v_1'^2}{3E^3} + \frac{1}{D^2}\right.$$
$$\qquad \left. + \frac{2m_{\rm e} v_1'^2}{3|D|^3} \pm \frac{2\Phi}{E|D|}\right)\frac{v_1'}{v_1} , \tag{56.217}$$

which is valid for $m_{\rm e}(v_2' - v_2) \leq m(v_1 - v_1')$, $m_{\rm e}(v_1 + v_1') \leq m_{\rm e}(v_2' + v_2)$, $D \leq 0$. In the expressions above, the exchange energy D transferred during the collision is

$$D = \frac{1}{2}m_{\rm e} v_1^2 - \frac{1}{2}m_{\rm e} v_2'^2 = \frac{1}{2}m_{\rm e} v_1^2 - \frac{1}{2}m_{\rm e} v_2^2 - E . \tag{56.218}$$

56.8.2 Integral Cross Sections

$$e^-(T) + A(E_2) \to e^-(E) + A^+ + e^- , \tag{56.219}$$

where T is the initial kinetic energy of the projectile electron, while the Rydberg electron, initially bound in potential U_i to the core A^+, has kinetic energy E_2. The cross section per unit energy E is denoted below by $\sigma_{\rm E}$. See the review by *Vriens* [56.34] for details.

For electron impact, there are two collision models: the *unsymmetrical collision model* of Thomson and Gryzinski assumes that the incident electron has zero potential energy, and the *symmetrical collision model* of Thomas and Burgess assumes that the incident electron is accelerated initially by the target (and thereby gains kinetic energy) while losing an equal amount of potential energy.

Unsymmetrical model (two cases):

$$\sigma_{\rm E} = \frac{\pi e^4}{T}\left(\frac{1}{E^2} + \frac{4E_2}{3E^3} + \frac{1}{D^2} + \frac{4E_2}{3D^3} - \frac{\Phi}{ED}\right) , \tag{56.220}$$

which is valid for $D = T - E_2 - E \geq 0$ or,

$$
\sigma_E = \frac{\pi e^4}{T} \left(\frac{1}{E^2} + \frac{4T'}{3E^3} + \frac{1}{D^2} + \frac{4T'}{3|D|^3} - \frac{\Phi}{E|D|} \right)
$$
$$
\times \left(\frac{T'}{E_2} \right)^{1/2}
$$
(56.221)

which is valid for $D \leq 0$ and $T \geq E$; and where $T' \equiv T - E$.

Symmetrical model (two cases):

$$
\sigma_E = \frac{\pi e^4}{T_i} \left(\frac{1}{E^2} + \frac{4E_2}{3E^3} + \frac{1}{X_i^2} + \frac{4E_2}{3X_i^3} - \frac{\Phi}{EX_i} \right) ,
$$
(56.222)

which is valid for $X_i \equiv T + U_i - E \geq 0$, with $T_i \equiv T + U_i + E_2$, and

$$
\sigma_E = \frac{\pi e^4}{T_i} \left(\frac{1}{E^2} + \frac{4T_i'}{3E^3} + \frac{1}{X_i^2} + \frac{4T_i'}{3|X_i|^3} - \frac{\Phi}{E|X_i|} \right)
$$
$$
\times \left(\frac{T_i'}{E_2} \right)^{1/2}
$$
(56.223)

which is valid for $0 \leq T_i' \leq E_2$, $T \geq 0$, with $T_i' \equiv T_i - E$, and where Φ is given by (56.213).

For incident heavy particles, the unsymmetrical model (56.220) should be used.

Single Particle Ionization

The total ionization cross section per atomic electron for incident heavy particles is

$$
Q_i = \frac{2\pi Z_1^2 e^4}{m_e v_1^2} \left(\frac{1}{U_i} + \frac{m_e v_2^2}{3U_i^2} - \frac{1}{2m_e (v_1^2 - v_2^2)} \right) ,
$$
(56.224)

which is valid for $U_i \leq 2m_e v_1 (v_1 - v_2)$, or

$$
Q_i = \frac{\pi Z_1^2 e^4}{m_e v_1^2} \Bigg\{ \frac{1}{2m_e v_2 (v_1 + v_2)} + \frac{1}{U_i}
$$
$$
+ \frac{m_e}{3 v_2 U_i^2} \left[2v_1^3 + v_2^3 - (2U_i/m_e + v_2^2)^{3/2} \right] \Bigg\} ,
$$
(56.225)

which is valid for $2m_e v_1 (v_1 - v_2) \leq U_i \leq 2m_e v_1 (v_1 + v_2)$, or otherwise $Q_i = 0$ for $U_i \geq 2m_e v_1 (v_1 + v_2)$.

For electron impact,

$$
Q_i = \frac{1}{2} \left(Q_i^{\mathrm{dir}} + Q_i^{\mathrm{ex}} + Q_i^{\mathrm{int}} \right) .
$$
(56.226)

In the unsymmetrical model, Q_i^{ex} diverges, hence the exchange and interference terms above are omitted in the unsymmetrical model for electrons to obtain

$$
Q_i^{\mathrm{dir}} = \frac{\pi e^4}{T} \left(\frac{1}{U_i} + \frac{2E_2}{3U_i^2} - \frac{1}{T - E_2} \right) ,
$$
(56.227)

which is valid for $T \geq E_2 + U_i$, or

$$
Q_i^{\mathrm{dir}} = \frac{2\pi e^4}{3T} \frac{(T - U_i)^{3/2}}{U_i^2 \sqrt{E_2}} ,
$$
(56.228)

which is valid for $U_i \leq T \leq E_2 + U_i$.

In the symmetrical model,

$$
Q_i^{\mathrm{dir}} = Q_i^{\mathrm{ex}}
$$
$$
= \frac{\pi e^4}{T_i} \left[\frac{1}{U_i} - \frac{1}{T} + \frac{2}{3} \left(\frac{E_2}{U_i^2} - \frac{E_2}{T^2} \right) \right] ,
$$
(56.229)

$$
Q_i^{\mathrm{int}} = -\frac{\pi e^4}{T_i} \left(\frac{2\Phi'}{T + U_i} \ln \frac{T}{U_i} \right) ,
$$
(56.230)

where Φ' can be approximated by [56.35]

$$
\Phi' = \cos \left[\left(\frac{R_\infty}{E_1 + U_i} \right)^{1/2} \ln \frac{E_1}{U_i} \right] .
$$
(56.231)

and E_1 is defined in [56.35].

The sum of (56.229) and (56.230) yields

$$
Q_i = \frac{\pi e^4}{T_i} \left[\frac{1}{U_i} - \frac{1}{T} + \frac{2}{3} \left(\frac{E_2}{U_i} - \frac{E_2}{T^2} \right) \right.
$$
$$
\left. - \frac{\Phi'}{T + U_i} \ln \frac{T}{U_i} \right] ,
$$
(56.232)

which is also obtained by integrating the expression (56.223) for σ_E,

$$
Q_i = \int_{U_i}^{\frac{1}{2}(T + U_i)} \sigma_E \, dE .
$$
(56.233)

Ionization Rate Coefficients. For heavy particle impact [56.29],

$$
\langle Q \rangle = \frac{a_0^2}{\kappa^2} \Bigg\{ \frac{128}{9} \left(\kappa^3 b^3 - b^{3/2} \right)
$$
$$
+ \frac{1}{3} \lambda b \left(35 - \frac{58}{3} b \frac{8}{3} b^2 \right)
$$
$$
+ \frac{2}{3} \kappa a b \left[\left(5 - 4\kappa^2 \right) \left(3a^2 + \frac{3}{2} ab + b^2 \right) \right.
$$
$$
\left. - \lambda \kappa \left(\frac{15}{2} + 9a + 5b \right) \right] - 16\kappa a^4 \ln \left(4\kappa^2 1 \right)
$$
$$
+ \theta \left[\frac{35}{6} - \kappa^2 a \left(\frac{5}{2} + 3a + 4a^2 + 8a^3 \right) \right] \Bigg\} ,
$$
(56.234)

where

$$\kappa = v_1/v_0 \,,$$
$$\lambda = \kappa - (4\kappa)^{-1} \,,$$
$$\theta = \pi + 2\tan^{-1}\lambda \,,$$
$$a = (1+\kappa^2)^{-1} \,,$$
$$b = (1+\lambda^2)^{-1} \,.$$

$$\langle \sigma_{E,P}\, dP\, dE \rangle = \frac{64 e^4 v_0^5}{3 v_1^2 P^4}$$
$$\times \left(\left| \frac{E}{P} - \frac{P}{2m_e} \right|^2 v_0^2 \right)^{-3} dP\, dE \,,$$

(56.235)

where $\frac{1}{2}m_e v_0^2$ is the ionization energy of H(1s).

Scaling Laws. Given the binary encounter cross section for ionization by protons of energy E_1 of an atom with binding energy u_a, the cross section for ionization of an atom with different binding energy u_b and scaled proton energy E_1' can be determined to be [56.18]

$$\sigma_{\text{ion}}\left(E_1', u_b\right) = \left(\frac{u_a^2}{u_b^2}\right)\sigma_{\text{ion}}(E_1, u_a) \,,$$ (56.236)

$$E_1' = (u_b/u_a)E_1 \,,$$ (56.237)

where $\sigma_{\text{ion}}(E, u)$ is the ionization cross section for removal of a single electron from an atom with binding energy u by impact with a proton with initial energy E.

Double Ionization. See [56.36] for binary encounter cross section formulae for the direct double ionization of two-electron atoms by electron impact.

Excitation. Excitation is generally less violent than ionization and hence binary encounter theory is less applicable. Binary encounter theory can be applied to exchange excitation transitions, e.g., $\text{e}^- + \text{He}(n^1 L) \rightarrow \text{e}^- + \text{He}(n'^3 L)$, with the restriction of large incident electron velocities. The cross section is

$$Q_e^{\text{ex}} = \int_{U_n}^{U_{n+1}} \sigma_{E,\text{ex}}\, dE$$
$$= \frac{\pi e^4}{T_i}\left[\frac{1}{\mathcal{T}_{n+1}} - \frac{1}{\mathcal{T}_n} + \frac{2}{3}\left(\frac{E_2}{\mathcal{T}_{n+1}^2} - \frac{E_2}{\mathcal{T}_n^2}\right)\right] \,,$$

(56.238)

valid for $T \geq U_{n+1}$, with $\mathcal{T}_n \equiv T + U_i - U_n$ and $\mathcal{T}_{n+1} \equiv T + U_i + U_{n+1}$, or

$$Q_e^{\text{ex}} = \int_{U_n}^{T} \sigma_{E,\text{ex}}\, dE$$ (56.239)

$$= \frac{\pi e^4}{T_i}\left[\frac{1}{U_i} - \frac{1}{\mathcal{T}_n} + \frac{2}{3}\left(\frac{E_2}{U_i^2} - \frac{E_2}{\mathcal{T}_n^2}\right)\right] \,,$$

valid for $U_n \leq T \leq U_{n+1}$. U_n and U_{n+1} denote the excitation energies for levels n and $n+1$, respectively.

56.8.3 Classical Ionization Cross Section

Applying the classical energy-change cross section result (56.69) of *Gerjuoy* [56.16] to the case of electron-impact ionization yields the four cases [56.17]

$$\sigma_{\text{ion}}(v_1, v_2) \sim \int_{\Delta E_\ell}^{\Delta E_u} \sigma_{\Delta E}^{\text{eff}}(v_1, v_2; m_1/m_2)\, d(\Delta E)$$

$$= \frac{\pi\left(Z_1 Z_2 e^2\right)^2}{3 v_1^2 v_2}\left(\frac{-2 v_2^3}{(\Delta E)^2} - \frac{6 v_2}{m_2 \Delta E}\right) \,,$$

(56.240)

which is valid for $0 < \Delta E < b$, or

$$\sigma_{\text{ion}}(v_1, v_2) = \frac{\pi\left(Z_1 Z_2 e^2\right)^2}{3 v_1^2 v_2}$$
$$\times \left(\frac{4\left(v_1 - 2v_1'\right)}{m_1^2\left(v_1 - v_1'\right)^2} + \frac{4\left(v_2 - 2v_2'\right)}{m_2^2\left(v_2 - v_2'\right)^2}\right) \,,$$

(56.241)

which is valid for $b < \Delta E < a$, or

$$\sigma_{\text{ion}}(v_1, v_2) = \frac{\pi(Z_1 Z_2 e^2)^2}{3 v_1^2 v_2}\left(\frac{-2 v_1'^3}{(\Delta E)^2}\right) \,,$$ (56.242)

which is valid for $\Delta E > a$, $2m_2 v_2 > |m_1 - m_2| v_1$, or otherwise is zero for $\Delta E > a$, $2m_2 v_2 < |m_1 - m_2| v_1$.

The limits $\Delta E_{\ell,u}$ to the ΔE integration in each of the four cases is indicated in the appropriate validity conditions. The constants a and b above are given by

$$a = \frac{4 m_1 m_2}{(m_1 + m_2)^2}\left[E_1 - E_2 + \frac{1}{2}v_1 v_2(m_1 - m_2)\right] \,,$$
$$b = \frac{4 m_1 m_2}{(m_1 + m_2)^2}\left[E_1 - E_2 - \frac{1}{2}v_1 v_2(m_1 - m_2)\right] \,.$$

The expressions above for $\sigma_{\text{ion}}(v_1, v_2)$ must be averaged over the speed distribution of v_2 before comparison with experiment. See [56.17] for explicit formulae for the case of a delta function speed distribution.

56.8.4 Classical Charge Transfer Cross Section

Applying the classical energy-change cross section result (56.69) of *Gerjuoy* [56.16] to the case of charge-transfer yields the four cases [56.17]

$$\sigma_{\mathrm{CX}}(v_1, v_2) \sim \int_{\Delta E_\ell}^{\Delta E_u} \sigma_{\Delta E}^{(\mathrm{eff})}(\boldsymbol{v}_1, \boldsymbol{v}_2)\, \mathrm{d}\Delta E$$

$$= \frac{\pi e^4}{3 v_1^2 v_2}\left(-\frac{2 v_2^3}{(\Delta E)^2} - \frac{6 v_2/m_2}{\Delta E}\right),$$

(56.243)

which is valid for $0 < \Delta E < b$, or

$$\sigma_{\mathrm{CX}}(v_1, v_2) = \frac{\pi e^4}{3 v_1^2 v_2}\left(3\frac{v_1/m_1 - v_2/m_2}{\Delta E}\right.$$

$$\left. + \frac{(v_2'^3 - v_2^3) - (v_1'^3 + v_1^3)}{(\Delta E)^2}\right),$$

(56.244)

which is valid for $b < \Delta E < a$, or

$$\sigma_{\mathrm{CX}}(v_1, v_2) = \frac{\pi e^4}{3 v_1^2 v_2}\left(-\frac{2 v_1'^2}{(\Delta E)^2}\right),$$

(56.245)

which is valid for $\Delta E > a$, $m_{\mathrm{e}} v_2 > (m_1 - m_{\mathrm{e}}) v_1$, or otherwise $\sigma_{\mathrm{CX}} = 0$ when $\Delta E > a, m_{\mathrm{e}} v_2 < (m_1 - m_{\mathrm{e}}) v_1$. The above expressions for $\sigma_{\mathrm{CX}}(v_1, v_2)$ must be averaged over the speed distribution $W(v_2)$ before comparison with experiment. See [56.17] for details. The constants a and b above are as defined in Sect. 56.8.3, and the limits $\Delta E_{\ell, u}$ are given by

$$\Delta E_\ell = \frac{1}{2} m_{\mathrm{e}} v_1^2 + U_A - U_B ,$$

(56.246a)

$$\Delta E_u = \frac{1}{2} m_{\mathrm{e}} v_1^2 + U_A + U_B ,$$

(56.246b)

$$v_2 = \sqrt{2 U_A/m_{\mathrm{e}}} ,$$

(56.246c)

where $U_{A,B}$ are the binding energies of atoms A and B. The expressions above for σ_{CX} diverge for some $v_1 > 0$ if $U_A < U_B$. If $U_A = U_B$ then σ_{CX} diverges at $v_1 = 0$. To avoid the divergence, employ Gerjuoy's modification, $\Delta E_\ell = \frac{1}{2} m_{\mathrm{e}} v_1^2 + U_A$.

56.9 Born Approximation

See reviews [56.37,38], as well as any standard textbook on scattering theory, for background details on the Born approximation, and [56.39–42] for extensive tables of Born cross sections.

56.9.1 Form Factors

The basic formulation of the first Born approximation for high energy heavy particle scattering is discussed in Sect. 53.1. For the general atom–atom or ion–atom scattering process

$$A(i) + B(i') \rightarrow A(f) + B(f') ,$$

(56.247)

with nuclear charges Z_A and Z_B respectively, let $\hbar \boldsymbol{K}_i$ and $\hbar \boldsymbol{K}_f$ be the initial and final momenta of the projectile A, and $\hbar \boldsymbol{q} = \hbar \boldsymbol{K}_f - \hbar \boldsymbol{K}_i$ be the momentum transferred to the target. Then (53.6) can be written in the generalized form

$$\sigma_{if}^{i'f'} = \frac{8 \pi a_0^2}{s^2} \int_{t_-}^{t_+} \frac{\mathrm{d}t}{t^3} \left| Z_A \delta_{if} - F_{if}^A(t) \right|^2$$

$$\times \left| Z_B \delta_{i'f'} - F_{i'f'}^B(t) \right|^2 ,$$

(56.248)

where the momentum transfer is $t = q a_0$, and $s = v/v_{\mathrm{B}}$ is the initial relative velocity in units of v_{B}. The form factors are

$$F_{if}^A(t) = \left\langle \Phi_f^A \,\Big|\, \sum_{k=1}^{N_A} \exp(\mathrm{i}\boldsymbol{t} \cdot \boldsymbol{r}_a/a_0) \,\Big|\, \Phi_i^A \right\rangle, \quad (56.249)$$

where N_A is the number of electrons associated with atom A, and similarly for $F_{if}^B(t)$. The limits of integration are $t_\pm = |K_f \pm K_i| a_0$. For heavy particle collisions, $t_+ \sim \infty$ and

$$t_- = (K_i - K_f) a_0$$

$$\simeq \frac{\Delta E_{if}}{2s}\left(1 + \frac{m_{\mathrm{e}} \Delta E_{if}}{4 M s^2}\right) ,$$

(56.250)

where $M = M_A M_B/(M_A + M_B)$.

Limiting Cases. As discussed in Sect. 53.1, for the case $i = f$, $F_{if}^A(t) \rightarrow N_A$ as $t \rightarrow 0$, so that $Z_A - F_{if}^A(t) \rightarrow Z_A - N_A$. For the case $i \neq f$, $F_{if}^A(t) \rightarrow 0$ as $t \rightarrow 0$ and $t \rightarrow \infty$.

56.9.2 Hydrogenic Form Factors

Bound–Bound Transitions. In terms of $\tau = t/Z$,

$$|F_{1s,1s}| = \frac{16}{\left(4 + \tau^2\right)^2} ,$$

(56.251a)

$$|F_{1s,2s}| = 2^{17/2} \frac{\tau^2}{(4\tau^2+9)^3} , \tag{56.251b}$$

$$|F_{1s,2p}| = 2^{15/2} \frac{3\tau}{(4\tau^2+9)^3} , \tag{56.251c}$$

$$|F_{1s,3s}| = 2^4 3^{7/2} \frac{(27\tau^2+16)\tau^2}{(9\tau^2+16)^4} , \tag{56.251d}$$

$$|F_{1s,3p}| = 2^{11/2} 3^3 \frac{(27\tau^2+16)\tau}{(9\tau^2+16)^4} , \tag{56.251e}$$

$$|F_{1s,3d}| = 2^{17/2} 3^{7/2} \frac{\tau^2}{(9\tau^2+16)^4} . \tag{56.251f}$$

Bound–Continuum Transitions. In terms of the scaled wave vector $\kappa = ka_0/Z$ for the ejected electron,

$$|F_{1s,\kappa}|^2 = \frac{2^8 \kappa \tau^2 (1+3\tau^2+\kappa^2) \exp(-2\theta/\kappa)}{3[1+(\tau-\kappa)^2]^3 [1+(\tau+\kappa)^2]^3 (1-e^{-2\pi/\kappa})} \tag{56.252}$$

where $\theta = \tan^{-1}[2\kappa/(1+\tau^2-\kappa^2)]$. Expressions for the bound–continuum Form Factors for the L-shell $(2\ell \to \kappa)$ and M-shell $(3\ell \to \kappa)$ transitions can be found in [56.43] and [56.44], respectively. See also §4 of [56.45] for further details.

General Expressions and Trends
For final ns states

$$|F_{1s,ns}|^2 = \frac{2^4 n [(n-1)^2+n^2\tau^2]^{n-1}}{\tau^2 [(n+1)^2+n^2\tau^2]^{n+1}}$$
$$\times \sin^2(n\tan^{-1}x + \tan^{-1}y) , \tag{56.253}$$

where

$$x = \frac{2\tau}{n(\tau^2+1-n^{-2})} , \quad y = \frac{2\tau}{\tau^2-1+n^{-2}} . \tag{56.254}$$

For final $n\ell$ states [56.46]

$$F_{1s,n\ell}(\tau)$$
$$= (i\tau)^\ell 2^{3(\ell+1)} \sqrt{2\ell+1}(\ell+1)! \left(\frac{(n-\ell-1)!}{(n+\ell)!}\right)^{1/2}$$
$$\times n^{\ell+1} \frac{[(n-1)^2+n^2\tau^2]^{(n-\ell-3)/2}}{[(n+1)^2+n^2\tau^2]^{(n+\ell+3)/2}} \left[a_{n\ell} C_{n-\ell-1}^{(\ell+2)}(x) \right.$$
$$\left. - b_{n\ell} C_{n-\ell-2}^{(\ell+2)}(x) + c_{n\ell} C_{n-\ell-3}^{(\ell+2)}(x) \right] , \tag{56.255}$$

with coefficients $a_{n\ell}$, $b_{n\ell}$ and $c_{n\ell}$ given by

$$a_{n\ell} = (n+1)\left[(n-1)^2+n^2\tau^2\right] ,$$
$$b_{n\ell} = 2n\sqrt{\left[(n-1)^2+n^2\tau^2\right]\left[(n+1)^2+n^2\tau^2\right]} ,$$
$$c_{n\ell} = (n-1)\left[(n+1)^2+n^2\tau^2\right] ,$$

and argument

$$x = \frac{n^2-1+n^2\tau^2}{\sqrt{\left[(n+1)^2+n^2\tau^2\right]\left[(n-1)^2+n^2\tau^2\right]}} .$$

Summation over final ℓ states:

$$|F_{1s,n}|^2 = \sum_\ell |F_{1s,n\ell}|^2$$
$$= 2^8 n^7 \tau^2 \left[\frac{1}{3}\left(n^2-1\right)+n^2\tau^2\right]$$
$$\times \frac{[(n-1)^2+n^2\tau^2]^{n-3}}{[(n+1)^2+n^2\tau^2]^{n+3}} . \tag{56.256}$$

which becomes for large n,

$$|F_{1s,n}|^2 \sim \frac{2^8 \tau^2 (3\tau^2+1)}{3n^3 (\tau^2+1)^6} \exp\left(\frac{-4}{(\tau^2+1)}\right) . \tag{56.257}$$

For initial $2s$ and $2p$ states,

$$|F_{2s,n}|^2 = 2^4 n^7 \tau^2 \left[-\frac{1}{3}+\frac{1}{2}n^2-\frac{3}{16}n^4+\frac{1}{48}n^6 \right.$$
$$+n^2\tau^2\left(\frac{1}{3}-\frac{2}{3}n^2+\frac{19}{48}n^4\right)$$
$$\left. +n^4\tau^4\left(\frac{5}{3}-\frac{7}{6}n^2\right)+n^6\tau^6\right]$$
$$\times \frac{[(\frac{1}{2}n-1)^2+n^2\tau^2]^{n-4}}{[(\frac{1}{2}n+1)^2+n^2\tau^2]^{n+4}} , \tag{56.258}$$

$$|F_{2p,n}|^2 = \frac{2^4 n^9 \tau^2}{3}\left[\frac{1}{4}-\frac{7}{24}n^2+\frac{11}{192}n^4 \right.$$
$$\left. -n^2\tau^2\left(\frac{5}{6}-\frac{23}{24}n^2\right)+\frac{1}{4}n^4\tau^4\right]$$
$$\times \frac{[(\frac{1}{2}n-1)^2+n^2\tau^2]^{n-4}}{[(\frac{1}{2}n+1)^2+n^2\tau^2]^{n+4}} . \tag{56.259}$$

Power Series Expansion. $\tau^2 \ll 1$ [56.3]

$$|F_{1s,ns}(\tau)|^2 = A(n)\tau^4 + B(n)\tau^6 + C(n)\tau^8 + \cdots ,$$
$$(56.260)$$

where

$$A(n) = \frac{2^8 n^9 (n-1)^{2n-6}}{3^2 (n+1)^{2n+6}} ,$$

$$B(n) = -\frac{2^9 n^{11} (n^2+11) (n-1)^{2n-8}}{3^2 5 (n+1)^{2n+8}} ,$$

$$C(n) = -\frac{2^8 n^{13} (313n^4 - 1654n^2 - 2067)}{3^2 5^2 7 (n+1)^{2n+10}}$$
$$\times (n-1)^{2n-10} .$$

For analytical expressions for $A(n)$, $B(n)$ and $C(n)$ for final np and nd states see [56.47, 48].

General Trends in Hydrogenic Form Factors [56.49].
The inelastic form factor $|F_{n\ell \to n'\ell'}|$ oscillates with ℓ' on an increasing background until the value

$$\ell'_{max} = \min \left((n'-1), n \left(\frac{2(n+3)}{(n+1)} \right)^{1/2} - \frac{1}{2} \right)$$
$$(56.261)$$

is reached, after which a rapid decline for $\ell > \ell'_{max}$ occurs. See [56.49] for illustrative graphs.

56.9.3 Excitation Cross Sections

Atom–Atom Collisions [56.50, 51]
Single Excitation. For the process

$$A(i) + B \to A(f) + B ,$$
$$(56.262)$$

(56.248) reduces to

$$\sigma_{if} = \frac{8\pi a_0^2}{s^2} \int_{t_-}^{\infty} \frac{dt}{t^3} |F_{if}^A|^2 |Z_B - F_{i'i'}^B|^2 .$$
$$(56.263)$$

Double Excitation. For the process

$$H(1s) + H(1s) \to H(n\ell) + H(n'\ell') ,$$
$$(56.264)$$
$$\sigma_{1s,n\ell}^{1s,n'l'} = \frac{8\pi a_0^2}{s^2} \int_{t_-}^{\infty} \frac{dt}{t^3} |F_{1s,n\ell}|^2 |F_{1s,n'\ell'}|^2 .$$
$$(56.265)$$

Special cases are [56.52]

$$\sigma_{1s,2s}^{1s,2s} = \frac{2^{30} \pi a_0^2 (880t_-^4 + 396t_-^2 + 81)}{495 s^2 (4t_-^2 + 9)^{11}} ,$$
$$(56.266a)$$

$$\sigma_{1s,2p}^{1s,2p} = \frac{2^{30} 3^4 \pi a_0^2}{11 s^2 (4t_-^2 + 9)^{11}} ,$$
$$(56.266b)$$

$$\sigma_{1s,2s}^{1s,2p} = \frac{2^{29} 3^2 (44t_-^2 + 9)}{55 s^2 (4t_-^2 + 9)^{11}} ,$$
$$(56.266c)$$

with $t_-^2 = [9/(16s^2)][1 + 3m_e/(4Ms^2) + \cdots]$.

Ion–Atom Collisions. For the proton impact process

$$H^+ + H(1s) \to H^+ + H(n\ell) ,$$
$$(56.267)$$
(56.248) reduces to

$$\sigma_{1s,n\ell} = \frac{8\pi a_0^2}{s^2} \int_{t_-}^{\infty} \frac{dt}{t^3} |F_{1s,n\ell}(t)|^2 ,$$
$$(56.268)$$

with $t_- = (1 - n^{-2})/(2s)$.

Asymptotic Expansions

$$\sigma_{1s,ns} = \frac{4\pi a_0^2 (n^2-1) |X_{1s \to ns}|^2}{24 s^2 n^2} \left[C_s(n) - \frac{1}{s^2} \right.$$
$$\left. + \frac{n^2+11}{20n^2 s^4} + \frac{313n^4 - 1654n^2 - 2067}{8400 n^4 s^6} \right] ,$$
$$(56.269)$$

$$\sigma_{1s,np} = \frac{2^{10} \pi a_0^2 n^7 (n-1)^{2n-5}}{3 s^2 (n+1)^{2n+5}} \left[C_p(n) + \ln s^2 \right.$$
$$\left. + \frac{n^2+11}{10n^2 s^2} + \frac{313n^4 - 1654n^2 - 2067}{5600 n^4 s^4} \right] ,$$
$$(56.270)$$

$$\sigma_{1s,nd} = \frac{2^{11} \pi a_0^2 (n^2-4) n^5 (n^2-1)^2 (n-1)^{2n-7}}{3^2 5 s^2 (n+1)^{2n+7}}$$
$$\times \left[C_d(n) - \frac{1}{s^2} + \frac{11n^2+13}{28n^2 s^4} \right] ,$$
$$(56.271)$$

where $C_s(2) = 16/5$, $C_s(3) = 117/32$, $C_s(4) \approx 3.386$, and

$$\gamma_n C_p(n) = \frac{1.3026}{n^3} + \frac{1.7433}{n^5} + \frac{16.918}{n^7} ,$$
$$(56.272)$$

$$\gamma_n C_d(n) = \frac{2.0502}{n^3} + \frac{7.6125}{n^5} ,$$
$$(56.273)$$

with

$$\gamma_n \equiv \frac{2^8 n^7 (n-1)^{(2n-5)}}{3(n+1)^{(2n+5)}} .$$
$$(56.274)$$

Further asymptotic expansion results can be found in [56.2–5].

A general expression for Born excitation and ionization cross sections for hydrogenic systems in terms of a parabolic coordinate representation (Chapt. 9) is given in [56.53].

Number of Independent Transitions $\mathcal{N}_i$ Between Levels n and n'. [56.53]

$$\mathcal{N}_i = n^2 \left[n' - \left(\frac{n}{3} \right) \right] + \left(\frac{n}{3} \right) . \qquad (56.275)$$

Validity Criterion.
The Born approximation is valid provided that [56.54]

$$nE \gg \ln \left(\frac{4E}{J_n} \right) \qquad (56.276)$$

for transitions $n \to n'$ when $n, n' \gg 1$ and $|n - n'| \sim 1$. The constant J_n is undetermined (see [56.54] for details) but is generally taken to be the ionization potential of level n.

56.9.4 Ionization Cross Sections

$$e^-(k) + H \to e^-(k') + H^+ + e^-(\kappa) . \qquad (56.277)$$

The general expression for the Born differential ionization cross section can be evaluated in closed form using screened hydrogenic wave functions. The differential cross section per incident electron scattered into solid angle $d\Omega_{k'}$, integrated over directions κ for the ejected electron (treated as distinguishable) is [56.55–57]

$$I(\theta, \phi) \, d\Omega_{k'} \, d\kappa' = \frac{4k'}{kq^4 a_0 \tilde{Z}_B^4} \left| F_{n\ell,\kappa'} \right|^2 (q) \, d\Omega_{k'} \, d\kappa' , \qquad (56.278)$$

where the form factor is given by (56.253)) for the case $n\ell = 1s$, with the ejected electron wavenumber κ and momentum transferred q in the collision, $\kappa' = \kappa a_0 / \tilde{Z}_B$, $q = (k' - k)a_0 / \tilde{Z}_B$, being scaled by the screened nuclear charge $\tilde{Z}_B$ appropriate to the $n\ell$-shell from which the electron is ejected. The total Born ionization cross section per electron is

$$\sigma_{\text{ion}}^{\text{B}} = \int_0^{\kappa_{\text{max}}} d\kappa' \int_{k-k'}^{k+k'} I(q, \kappa') \, dq , \qquad (56.279)$$

which is generally evaluated numerically.

56.9.5 Capture Cross Sections

Electron Capture.

$$A^+ + B(n\ell) \to A(n'\ell') + B^+ . \qquad (56.280)$$

In the Oppenheimer–Brinkman–Kramers (OBK) approximation [56.58],

$$\sigma_{n\ell,n'\ell'} = \frac{M^2}{2\pi\hbar^3} \frac{v_f}{v_i} \int_{-1}^{1} d(\cos\theta) \left| F_{n\ell \to n'\ell'} \right|^2 , \qquad (56.281)$$

where $\boldsymbol{v}_i = v_i \hat{\boldsymbol{n}}_i$, $\boldsymbol{v}_f = v_f \hat{\boldsymbol{n}}_f$, θ is the angle between $\hat{\boldsymbol{n}}_i$ and $\hat{\boldsymbol{n}}_f$, $M = M_A M_B / (M_A + M_B)$, and

$$\left| F_{n\ell,n'\ell'} \right| = \iint d\boldsymbol{r} \, d\boldsymbol{s} \, \varphi_i(\boldsymbol{r}) \varphi_f^*(\boldsymbol{s}) \left(\frac{Z_A e^2}{r} \right) \\ \times e^{i(\boldsymbol{\alpha}\cdot\boldsymbol{r} + \boldsymbol{\beta}\cdot\boldsymbol{s})} , \qquad (56.282)$$

with

$$\boldsymbol{\alpha} = k_f \hat{\boldsymbol{n}}_f + k_i \hat{\boldsymbol{n}}_i \frac{M_A}{M_A + m_e} ,$$

$$\boldsymbol{\beta} = -k_i \hat{\boldsymbol{n}}_i - k_f \hat{\boldsymbol{n}}_f \frac{M_B}{M_B + m_e} ,$$

$$k_i = \frac{v_f}{\hbar} \frac{M_B(M_A + m_e)}{(M_A + M_B + m_e)} ,$$

$$k_f = \frac{v_f}{\hbar} \frac{(M_B + m_e)M_A}{(M_A + M_B + m_e)} .$$

The Jackson–Schiff correction factor [56.59] is

$$\gamma_{\text{JS}} = \frac{1}{192} \left(127 + \frac{56}{p^2} + \frac{32}{p^4} \right) \\ - \frac{\tan^{-1} \frac{1}{2}p}{48p} \left(83 + \frac{60}{p^2} + \frac{32}{p^4} \right) \\ + \frac{\left(\tan^{-1} \frac{1}{2}p \right)^2}{24p^2} \left(31 + \frac{32}{p^2} + \frac{16}{p^4} \right) , \qquad (56.283)$$

and the capture cross section is

$$\sigma(n_i \ell_i, n_f \ell_f) = \frac{\gamma_{\text{JS}} \pi a_0^2}{p^2} C(n_i \ell_i, n_f \ell_f) \\ \times \int_x^\infty F(n_i \ell_i, n_f \ell_f; x) \, dx , \qquad (56.284)$$

with

$$p = \frac{m v_i}{\hbar} , \quad a = \frac{Z_A}{n_i} , \quad b = \frac{Z_B}{n_f} ,$$

$$x = \left[p^2 + (a+b)^2 \right] \left[p^2 + (a-b)^2 \right] \Big/ 4p^2 .$$

Table 56.2 Coefficients $C(n_i \ell_i \to n_f \ell_f)$ in the Born capture cross section formula (56.284)

$n_f \ell_f$	$C(1s \to n_f \ell_f)$
$1s$	$2^8 Z_A^5 Z_B^5$
$2s$	$2^5 Z_A^5 Z_B^5$
$2p$	$2^5 Z_A^5 Z_B^7$
$3s$	$2^8 Z_A^5 Z_B^5/3^3$
$3p$	$2^{13} Z_A^5 Z_B^7/3^6$
$3d$	$2^{15} Z_A^5 Z_B^9/3^9$
$4s$	$2^2 Z_A^5 Z_B^5$
$4p$	$5 Z_A^5 Z_B^7$
$4d$	$Z_A^5 Z_B^9$
$4f$	$Z_A^5 Z_B^{11}/20$
$C(2s \to n_f \ell_f) = C(1s \to n_f \ell_f)/8$	
$C(2p \to n_f \ell_f) = C(1s \to n_f \ell_f)/24$	

Table 56.3 Functions $F(n_i \ell_i \to n_f \ell_f; x)$ in the Born capture cross section formula (56.284)

$n_f \ell_f$	$F(n_i \ell_i, n_f \ell_f; x)$
$1s$	x^{-6}
$2s$	$(x - 2b^2)^2 x^{-8}$
$2p$	$(x - b^2) x^{-8}$
$3s$	$(x^2 - \frac{16}{3} b^2 x + \frac{16}{3} b^4)^2 x^{-10}$
$3p$	$(x - b^2)(x - 2b^2)^2 x^{-10}$
$3d$	$(x - b^2)^2 x^{-10}$
$4s$	$(x - 2b^2)^2 (x^2 - 8b^2 x + 8b^4)^2 x^{-12}$
$4p$	$(x - b^2)(x^2 - \frac{24}{5} b^2 x + \frac{24}{5} b^4)^2 x^{-12}$
$4d$	$(x - b^2)^2 (x - 2b^2)^2 x^{-12}$
$4f$	$(x - b^2)^3 x^{-12}$
$F(2s, n_f \ell_f; x) = (x - 2a^2)^2 x^{-2} F(1s, n_f \ell_f; x)$	
$F(2p, n_f \ell_f; x) = (x - a^2) x^{-2} F(1s, n_f \ell_f; x)$	

The coefficients C in (56.284) are given in Table 56.2, while the functions F are given in Table 56.3 [56.58]. In Table 56.3, the appropriate value of a and b is indicated by the quantum numbers n_i, ℓ_i and n_f, ℓ_f.

57. Mass Transfer at High Energies: Thomas Peak

Thomas peaks correspond to singular second-order quantum effects whose location may be determined by classical two step kinematics. The widths of these peaks (or ridges) may be estimated using the uncertainty principle. A second-order quantum calculation is required to obtain the magnitude of these peaks. Thomas peaks and ridges have been observed in various reactions in atomic and molecular collisions involving mass transfer and also ionization.

Transfer of mass is a quasiforbidden process. Simple transfer of a stationary mass M_2 to a moving mass M_1 is forbidden by conservation of energy and momentum. If $M_1 < M_2$ then M_1 rebounds, if $M_1 = M_2$ then M_1 stops and M_2 continues on, and if $M_1 > M_2$ then M_2 leaves faster than M_1. In none of these cases do M_1 and M_2 leave together. *Thomas* [57.1] understood this in 1927 and further realized that transfer of mass occurs only when a third mass is present and all three masses interact. The simplest allowable process is a two-step process now called a Thomas process [57.2, 3].

Quantum mechanically [57.4], the second Born term at high energies is the largest Born term and corresponds to the simplest allowed classical process, namely the Thomas process. While the classically forbidden first Born term is not zero (saved by the uncertainty principle), the first Born cross section varies at high v as v^{-12}, in contrast to the second Born cross section which varies as v^{-11}, thus dominating. Higher Born terms correspond to multistep processes that are unlikely in fast collisions where there is not enough time for complicated processes. The higher Born terms ($n > 2$) are also smaller than the second Born term.

57.1 The Classical Thomas Process

The basic Thomas process is shown in Fig. 57.1. Here, the entire collision is coplanar since particles 1 and 2 go off together (that is what is meant by mass transfer). We assume that all the masses and the incident velocities v are known. Thus, there are six unknowns, v', v_f and v_3, each with two components. Conservation of momentum gives two equations of constraint for each collision. Conservation of overall energy gives a fifth constraint, and conservation of energy in the intermediate state (which only holds classically) gives a sixth constraint. With six equations of constraint, all six unknowns may be completely determined. The allowed values of v', v_f and v_3 depend on the masses M_1, M_2 and M_3. For example, in the case of the transfer of an electron from atomic hydrogen to a proton, i.e., $p^+ = H \rightarrow H + p^+$, it is easily verified that the angles are $\alpha = (M_2/M_1) \sin 60°$, $\beta = 60°$ and $\gamma = 120°$, where $m' = M_2 = m_e$ and $M_1 = M_3 = M_p = 1836 \, m_e$. For the case $e^+ + H \rightarrow Ps + p^+$, it may be verified that $\alpha = 45°$, $\beta = 45°$ and $\gamma = 90°$.

Fig. 57.1 Diagram for mass transfer via a Thomas two-step process

Fig. 57.2 Lieber diagram for mass transfer

In general, the intermediate mass m' may be equal to M_1, M_2 or M_3. We shall regard these as different Thomas processes, and label them B, A, and C respectively. The standard Thomas process (the one actually considered by Thomas in 1927) is case A, and corresponds to the first example given above. Lieber diagrams for the Thomas processes A, B, and C [57.5] are illustrated in Fig. 57.2. In the Lieber diagram, mass regions in which solutions exist for processes A, B, and C are shown. (An equivalent diagram was given earlier by

Detmann and *Liebfried* [57.3].) There are some regions in which two-step processes are forbidden. In these regions the theory of mass transfer is not fully understood at present.

57.2 Quantum Description

57.2.1 Uncertainty Effects

In quantum mechanics, energy conservation in the intermediate states may be violated within the limits of the uncertainty principle, $\Delta E \geq \hbar/\Delta t$, where Δt is the uncertainty in time of mass transfer. It is not possible to determine if mass transfer actually occurs at the beginning, in the middle, or at the end of the collision. Thus, we choose $\Delta t = \bar{r}/\bar{v}$, where $\bar{r}$ is the size of the collision region and $\bar{v}$ is the mean collision velocity. Taking $\bar{r} \approx a_0/Z_{\text{target}}$ and $\bar{v} \approx v$, the projectile velocity, we have

$$\Delta E \approx \frac{\hbar}{\Delta t} = \frac{\hbar \bar{v}}{\bar{r}} = \frac{\hbar v}{a_0/Z_{\text{target}}} = \frac{\hbar Z_{\text{target}}}{a_0} \ . \quad (57.1)$$

Here, a_0 is the Bohr radius and Z_{target} is the nuclear charge of the target in units of the electron charge. Within this range of energy ΔE, the constraint of energy conservation in the intermediate state does not apply.

57.2.2 Conservation of Overall Energy and Momentum

Conservation of overall energy and momentum then gives three equations of constraint on the four unknowns $\boldsymbol{v}_f$ and $\boldsymbol{v}_3$ [57.6], namely,

$$M_1 \boldsymbol{v} = \left(M_f + \tilde{M}_f\right) \boldsymbol{v}_f + M_3 \boldsymbol{v}_3 \ , \quad (57.2)$$

$$M_1 v^2 = \left(M_f + \tilde{M}_f\right) v_f^2 + M_3 v_3^2 \ , \quad (57.3)$$

where M_f $\left(\tilde{M}_f\right)$ is the mass of the upper (lower) particle in the final state of the bound system shown in Fig. 57.1, in which m' is the mass of the intermediate particle M_1, M_2 or M_3. From (57.2) and (57.3) it may be shown that the velocity of the recoil particle is constrained by the condition

$$2\boldsymbol{v}_3 \cdot \hat{\boldsymbol{v}} = 2\cos\gamma = \frac{M_1 + M_2 + M_3}{M_1} \frac{v_3}{v} - \frac{M_2}{M_3} \frac{v}{v_3} \ . \quad (57.4)$$

Thus, the magnitude and the direction of $\boldsymbol{v}_3$ are not independent. Specifying either v_3 or $\hat{\boldsymbol{v}}_3$ is sufficient, to-

gether with the equations of constraint, to determine the energies and directions of all particles in the final state. Similarly, one may express the equations of constraint in terms of v_f and $\hat{\boldsymbol{v}}_f$.

57.2.3 Conservation of Intermediate Energy

In a classical two-step process, the projectile hits a particle in the target, and the intermediate mass m' then propagates and subsequently undergoes a second collision. Quantum mechanically, this corresponds to a second-Born term represented by $V_1 G_0 V_2$, where V represents an interaction and G_0 is the propagator of the intermediate state, namely,

$$G_0 = (E - H_0 + i\epsilon)^{-1}$$
$$= -i\pi\delta(E - H_0) + \wp \frac{1}{E - H_0} , \qquad (57.5)$$

where $\wp$ is the Cauchy principal value of G_0 which excludes the singularity at $E = H_0$. This singularity corresponds to conservation of energy in the intermediate state. It is this singularity which gives rise to the weaker secondary ridge in Fig. 57.3 at $v_3 = v$. The width of the secondary ridge is given approximately by $\Delta E = \hbar/\Delta t$, as discussed above. The intersection of the ridges is the Thomas peak. At very high collision velocities, the Thomas peak dominates the total cross section for mass transfer.
Fig. 57.3 Counting rate (or cross section) on the *vertical axis* versus recoil speed v_3 and recoil angle γ for a Thomas process in which a proton (projectile) picks up an electron from helium (target). The captured electron bounces off the second target electron

The constraint imposed by conservation of intermediate energy may be expressed by replacing the speed of the recoil particle v_3 by the scaled variable $K = M_3 v_3 / m' v$. Then it may be shown that the conservation of intermediate energy may be expressed in the form [57.6]:

$$\left(\frac{M_3 v_3}{m' v} \right)^2 \equiv K^2 = 1 . \qquad (57.6)$$

The constraints of conservation of overall energy and momentum, i.e., (57.4), may be easily written in terms of K as

$$2 \cos \gamma = r \frac{m'}{M_2} K - \frac{M_2}{m'} \frac{1}{K} , \qquad (57.7)$$

where $r = (M_1 + M_2 + M_3) M_2 / (M_1 M_3)$.

57.2.4 Example: Proton–Helium Scattering

The effect of the constraints of conservation of overall energy and momentum may be seen in Fig. 57.3, where a sharp ridge is evident in the reaction

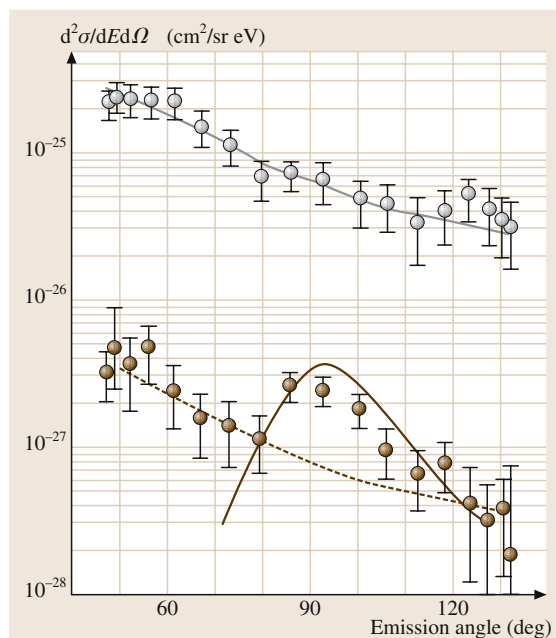
$$p^+ + He \rightarrow H + He^{++} + e^- , \qquad (57.8)$$
and $M_1 = M_p$, $M_2 = M_3 = m_e$. Here v_3 is the speed of the recoiling ionized target electron, and the target nucleus is not directly involved in the reaction. The width


Fig. 57.4 Observation of a slice of the Thomas ridge structure in $p^+ + He \rightarrow H + He^{++} + e^-$ at 1 MeV by *Palinkas* et al. [57.7]

of the sharp ridge is due to the momentum spread of the electrons in helium and may be regarded as being caused by the uncertainty principle since this momentum (or velocity) spread corresponds to $\Delta p = \hbar / \Delta r$ where Δr is taken as the radius of the helium atom.

The locus of the sharp ridge in Fig. 57.3, corresponding to conservation of overall energy and momentum, is given by (57.8). The locus of the weaker ridge, corresponding to the conservation of energy in the intermediate state, is given by (57.7). The intersection of these two loci gives the unique classical result suggested

by Thomas. The width of these ridges may be estimated from the uncertainty principle as described above.

Experimental evidence for the double ridge structure has been reported by *Palinkas* et al. [57.7] corresponding to the calculations given in Fig. 57.3, but at a collision energy of 1 MeV, as shown below.

The data in Fig. 57.4 corresponds to a slice across the sharp ridge of Fig. 57.3 at $v = v_3$. The solid line is a second Born calculation [57.8, 9] at 1 MeV. The bump of data above a smooth backgroud is the indication of the ridge structure.

57.3 Off–Energy–Shell Effects

In (57.6), the Green's function G_0 contains an energy-conserving term $i\pi\delta(E - H_0)$ which is imaginary, and a real energy-nonconserving term $\wp[1/(E - H_0)]$. The latter does not occur classically; it is permitted by the uncertainty principle and represents the contribution of virtual (off-the-energy-shell or energy-nonconserving) states within $\pm\Delta E = \hbar / \Delta t$ about the classical value $E = H_0$. This quantum term also represents the effect of time-ordering in the second Born amplitude [57.10]. In plane wave second-Born calculations, the off-energy-shell term gives the real part of the scattering amplitude f_2, while the on-shell (energy conserving) term gives the imaginary part of f_2. These two contributions are shown in Fig. 57.5.

Half of the Thomas peak comes from energy-nonconserving contributions which are not included in a classical description. Also, the energy-nonconserving contribution plays a significant role in determining the shape of the standard Thomas peak, which has been observed [57.11].

Fig. 57.5 Energy-conserving (on-shell) and energy-nonconserving contributions to the second Born scattering amplitude

57.4 Dispersion Relations

Because of the form of the Green's function of (57.6), the second Born contribution f_2 to the scattering amplitude has a single pole in the lower half of the complex plane. Consequently it obeys the dispersion relation

$$\mathrm{Re}[f_2(\lambda)] = -\frac{1}{\pi}\wp \int\limits_{-\infty}^{+\infty} \frac{\mathrm{Im}[f_2(\lambda')]}{\lambda - \lambda'}\,\mathrm{d}\lambda'\,,$$

$$\mathrm{Im}[f_2(\lambda)] = \frac{1}{\pi}\wp \int\limits_{-\infty}^{+\infty} \frac{\mathrm{Re}[f_2(\lambda')]}{\lambda - \lambda'}\,\mathrm{d}\lambda'\,. \qquad (57.9)$$

where $\mathrm{Re}\,f_2$ and $\mathrm{Im}\,f_2$ denote the real and imaginary parts of f_2. Thus the energy-nonconserving part of f_2 is related to an integral over the energy-conserving part and vice versa. In the case of the dielectric constant it is well known that the real and imaginary parts of ϵ are also related by a dispersion relation, namely the Kramers–Kronig relatio [57.12].

Resonances are usually a function of energy E. The width of a resonance gives the lifetime τ of the resonance. Classically, τ is how long the projectile orbits the target before it leaves, corresponding to a delay or shift in time of the projectile during the interac-

tion. If the width of the resonance is ΔE, then the lifetime is $\tau = \hbar/\Delta E$. E and τ are conjugate variables. The Thomas peak is an overdamped resonance in scattering angle, corresponding to a shift in the impact parameter of the scattering event [57.13]. However, unlike energy resonances, our Thomas resonance in the scattering angle seems to have no classical analog [57.14].

57.5 Destructive Interference of Amplitudes

It has already been noted that the location of the Thomas peaks depends on the mass of the collision partners. For the process

$$p^+ + \text{Atom} \rightarrow \text{Atom} + H \,, \tag{57.10}$$

there are two separate Thomas peaks [57.2, 15] corresponding to cases A and B in the Lieber diagram (Fig. 57.2). Experimental evidence exists for both peaks. The standard Thomas peak occurs at small forward angles [57.11], while the second peak [57.16] occurs at about 60°. If the mass of the projectile is reduced, the positions of these Thomas peaks move toward one another [57.17] as illustrated in Fig. 57.6.

When $M_1 = M_2$, then both Thomas peaks occur at 45°. This occurs in positronium formation where $M_1 = M_2 = m_e$, i.e.,

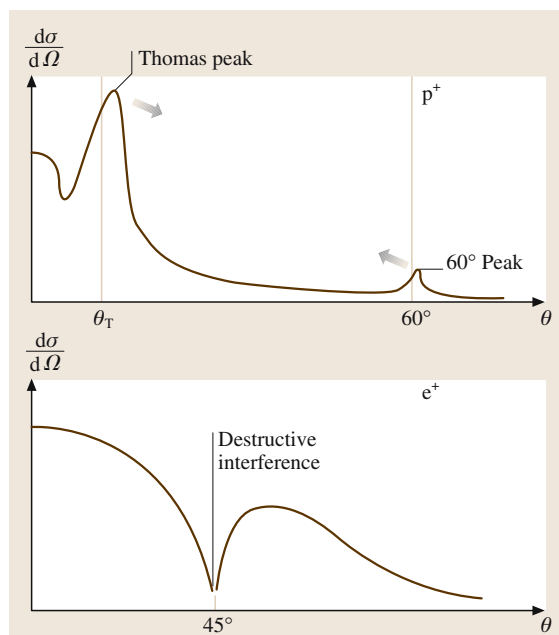
$$e^+ + \text{He} \rightarrow \text{Ps} + \text{He}^{++} + e^- \,. \tag{57.11}$$
In cases A and B of Fig. 57.2, the two $V_1 G_0 V_2$ second Born terms are of opposite sign because V_2 is of opposite sign in diagrams A and B. This leads to destructive interference for 1s − 1s electron capture (which is dominant at high velocities) as was first discussed by *Shakeshaft* and *Wadehra* [57.17]. Consequently, the observed Thomas peak structure is expected [57.18, 19] to be quite different for e^+ impact than for impact of p^+ or other projectiles heavier than an electron. The double ridge structure for transfer ionization of helium by e^+ is expected to differ significantly from


Fig. 57.6 Change of position and nature of the Thomas peaks with decreasing projectile mass

the structure shown in Fig. 57.3. Understanding such destructive interference between resonant amplitudes may give deeper insight into the physical nature of the intermediate states in this special few-body collision system.

57.6 Recent Developments

In the late 1990's observations [57.20] of the Thomas peak in the case of transfer ionization (where one electron is ionized and another is transferred) differential in the momentum of the ejected electron provided new specific detail on the kinematics of the two step process [57.21]. In 2001 the Thomas peak was discussed [57.22] in the context of quantum time ordering.

In this case time ordering surprisingly is not significant at the center of the peak, in contradiction to the classical picture that there is a definite order in the two step process for transfer ionization. However, time ordering does contribute to the shape of the Thomas peak. In 2002 the Stockholm group [57.23] reported that at very high velocities, the ratio of trans-

fer ionization to total transfer approaches the same asymptotic limit as in double to single ionization in (non-Compton) photoionization, namely 1.66%. This

was interpreted in terms of a common shake process occurring when the wavefunction collapses after a sudden collision.

58. Classical Trajectory and Monte Carlo Techniques

The classical trajectory Monte Carlo (CTMC) method originated with Hirschfelder, who studied the H + D$_2$ exchange reaction using a mechanical calculator [58.1]. With the availability of computers, the CTMC method was actively applied to a large number of chemical systems to determine reaction rates, and final state vibrational and rotational populations (see, e.g., *Karplus* et al. [58.2]). For atomic physics problems, a major step was introduced by *Abrines* and *Percival* [58.3] who employed Kepler's equations and the Bohr–Sommerfield model for atomic hydrogen to investigate electron capture and ionization for intermediate velocity collisions of H$^+$ + H. An excellent description is given by *Percival* and *Richards* [58.4]. The CTMC method has a wide range of applicability to strongly-coupled systems, such as collisions by multiply-charged ions [58.5]. In such systems, perturbation methods fail, and basis set limitations of coupled-channel molecular- and atomic-orbital techniques have difficulty in representing the multitude of active

excitation, electron capture, and ionization channels. Vector- and parallel-processors now allow increasingly detailed study of the dynamics of the heavy projectile and target, along with the active electrons.

58.1 Theoretical Background

58.1.1 Hydrogenic Targets

For a simple three-body collision system comprised of a fully-stripped projectile (a), a bare target nucleus (b), and an active electron (c), one begins with the classical Hamiltonian for the system,

$$H = p_a^2/2m_a + p_b^2/2m_b + p_c^2/2m_c \\ + Z_a Z_b/r_{ab} + Z_a Z_c/r_{ac} + Z_b Z_c/r_{bc} , \quad (58.1)$$

where p_i are the momenta and $Z_i Z_f/r_{if}$ are the Coulomb potentials between the individual particles. From (58.1), one obtains a set of 18 coupled, first-order differential equations arising from the necessity to determine the time evolution of the Cartesian coordinates of each particle,

$$\mathrm{d}q_i/\mathrm{d}t = \partial H/\partial p_i , \quad (58.2)$$

and their corresponding momenta,

$$\mathrm{d}p_i/\mathrm{d}t = -\partial H/\partial q_i . \quad (58.3)$$

Five random numbers, constrained by Kepler's equation, are then used to initialize the plane and eccentricity of the electron's orbit, and another is used to determine the impact parameter within the range of interaction [58.4, 5]. A fourth-order Runge–Kutta integration method is suitable because of its ease of use and its ability to vary the time step-size. This latter requirement is essential since it is not uncommon for the time step to vary by three orders of magnitude during a single trajectory.

In essence, the CTMC method is a computer experiment. Total cross sections for a particular process are determined by

$$\sigma_R = (N_R/N)\pi b_{\max}^2 , \quad (58.4)$$

where N is the total number of trajectories run within a given maximum impact parameter b_{max}, and N_R is the number of positive tests for a reaction, such as electron capture or ionization. Angle and energy differential cross sections are easily generalized from the above. As in an experiment, the cross section given by (58.4) has a standard deviation of

$$\Delta \sigma_R = \sigma [(N - N_R)/NN_R]^{1/2} , \qquad (58.5)$$

which for large N is proportional to $1/N_R^{1/2}$. Here lies one of the major difficulties associated with the CTMC method: it takes considerable computation time to determine minor or highly differential cross sections. Present day desktop workstations can provide a partial remedy of this statistics problem. To decrease the statistical error of a cross section by a factor of two, four times as many trajectories must be evaluated.

58.1.2 Nonhydrogenic One–Electron Models

For many-electron target atoms, it is sometimes adequate to treat the problem within a one-electron model and employ the independent electron approximation to approximate atomic shell structure [58.6]. For an accurate calculation, it is necessary to use an interaction potential that simulates the screening of the target nucleus by the electrons. One can simply apply a Coulomb potential with an effective charge Z_{eff} obtained from, for example, Slater's rules. Then, the computational procedure is the same as for the hydrogenic case. However, the boundary conditions for the long- and short-range interactions are poorly satisfied.

To improve the electronic representation of the target, potentials derived from quantum mechanical calculations are now routinely used. Here, the simple solution of Kepler's equation cannot be applied. However, *Peach* et al. [58.7] and *Reinhold* and *Falcón* [58.8] have provided the appropriate methods that yield a target representation that is correct under the microcanonical distribution. The method of Reinhold and Falcón is popular because of its ease of use and generalizability. For the effective interaction potential, *Garvey* et al. [58.9] have performed a large set of Hartree–Fock calculations, and have parametrized their results in the form

$$V(R) = -[Z - NS(R)]/R , \qquad (58.6)$$

with the screening of the core given by

$$S(R) = 1 - \{(\eta/\xi)[\exp(\xi R) - 1] + 1\}^{-1/2} , \qquad (58.7)$$

where Z and N denote the nuclear charge and number of nonactive electrons in the target core, and η and ξ are screening parameters. Screening parameters are given in [58.9] for all ions and atoms with $Z \leq 54$. This potential can also be used for the representation of partially-stripped projectile ions.

58.1.3 Multiply–Charged Projectiles and Many–Electron Targets

Multiple ionization and electron capture mechanisms in energetic collisions between multiply-charged ions and many-electron atoms is poorly understood because major approximations must be made to solve a many-electron problem associated with transitions between two centers. For a representative collision system such as

$$A^{q+} + B \rightarrow A^{(q-j)+} + B^{i+} + (i-j)e^- , \qquad (58.8)$$
it is essential that the theoretical method be able to predict simultaneously the various charge states of the projectile and recoil ions, and also the energy and angular spectra of the ejected electrons. Theoretical methods based on the independent electron model fail because the varying ionization energies of the electrons are not well represented by a constant value, especially for outer shells. To present, only the nCTMC method, which is a direct extension of the hydrogenic CTMC method to an n-electron system, has been able to make reasonable predictions of the cross sections and scattering dynamics of such strongly-coupled systems [58.10]. As such, the number of coupled equations rises to $6n + 12$, where n is the number of electrons included in the calculation. However, computing time does not increase linearly, since modern vector-processors become very efficient with coupled equations for multiples of 64.

In the nCTMC technique, all interactions of the projectile and target nuclei with each other and the electrons are implicitly included in the calculations. The inclusion of all the particles then allows a direct determination of their angular scattering, along with an estimate of the energy deposition to electrons and heavy particles. Post collision interactions are included between projectile and recoil ions with the electrons; however, electron–electron interactions are introduced only in the bound initial state via a screening factor in a central-field approximation. This theoretical model has been very successful in predicting the single and double differential cross sections for the ionized electron spectra. Moreover, since a fixed target nucleus approximation is not used, this method has been the only one available to help understand and predict the results for the new field of recoil-ion momentum spectroscopy [58.11].

Only a modest amount of work has been completed on molecular targets. At present, only an H_2 target has been formulated for application to the CTMC method [58.12]. For H_2, a fixed internuclear axis is assumed which is then randomly orientated for each trajectory. The electrons are initialized in terms of two one-electron microcanonical distributions constructed from the quantum mechanical wave function for the ground state of H_2. Total cross sections for a variety of projectiles are in reasonable accord with experiment. The effect of the orientation of the molecular axis on the cross sections was also investigated, along with tests as to the validity of assuming that the cross sections for H_2 are simply the product of twice the H values.

58.2 Region of Validity

The CTMC method has a demonstrated region of applicability for ion–atom collisions in the intermediate velocity regime, particularly in the elucidation of both heavy-particle and electron collision dynamics. The method can be termed a semiclassical method in that the initial conditions for the electron orbits are determined by quantum mechanically determined interaction potentials with the parent nucleus. Since the method is most applicable to strongly-coupled systems, it has been applied successfully to a variety of intermediate energy multiply-charged ion collisions. Figure 58.1 describes pictorially the regions of validity of theoretical models. Both the atomic orbital (AO) and molecular orbital (MO) basis set expansion methods (Chapt. 50) work well until ionization strongly mediates the collision, since the theoretical description of the ionization continuum is not well-founded and relies on pseudostates to span all ejected electron energies and angles. We have arbitrarily limited these methods to a projectile charge to target charge ratio of, $Z_P/Z_T \simeq 8$, since above this value the number of terms in the basis set becomes prohibitively large. The CTMC method does not include molecular effects, and thus it is restricted from low velocities, except in the case of high-charge-state projectiles that capture electrons into high-lying Rydberg states which are well-described classically. Likewise, at high velocities the method is inapplicable in the perturbation regime where quantum tunneling is important, and thus is restricted to strongly cou-
Fig. 58.1 Approximate regions of validity of various theoretical methods. Z_P/Z_T is the ratio of the projectile charge to the target charge, and v/v_e is the ratio of the collision velocity to the velocity of the active target electron. Theoretical methods: molecular orbital (MO), atomic orbital (AO), classical trajectory Monte Carlo (CTMC), continuum distorted wave (CDW), and first-order perturbation theory (BORN)

pled systems. The continuum distorted wave (CDW) method (Chapt. 52) greatly extends the region of applicability of first-order perturbation methods and has demonstrated validity in high-charge state ionization collisions.

58.3 Applications

58.3.1 Hydrogenic Atom Targets

The original application of the CTMC method to atomic physics collisions were done on the $H^+ + H$ system [58.3]. Here, the electron capture and ionization total cross sections were found to be in very good accord with experiment. The Abrines and Percival procedure casts the coupled equations into the c.m. coordinate system to reduce the three-body problem to 12 coupled equations. However, this reduction complicates exten-

sions of the code to laser processes and collisions in electric fields or with many electrons.

An ideal application for the CTMC method is for collisions involving excited targets. Such processes are well-described classically, and basis set expansion methods show limited applicability due to computer memory constraints. Considerable early work has been done on Rydberg atom collisions which includes state-selective electron capture, ionization, and electric fields [58.13–15]. Presently, there is a resurgence of work on Rydberg atom collisions because new crossed-field experimental techniques allow the production of these atoms with specific spatial orientations and eccentricities [58.16].

For hydrogenic ion–ion collision processes, one must be careful to apply the CTMC method only for projectile charges $Z_P \geq Z_T$ because after the initialization of the active electron's orbit and energy, there is no classical constraint on the orbital energy of a captured electron. For a low-charge-state ion colliding with a ground state highly charged ion, one will obtain unphysical results because a captured electron will tend to preserve its original binding energy. Thus, excess probability will be calculated for electron orbits that lead to unrealistic deeply bound states of the projectile.

58.3.2 Pseudo One–Electron Targets

Collisions involving alkali atoms are of interest because of their relevance to applied programs, such as plasma diagnostics in tokamak nuclear fusion reactors. They are also a testing ground for theoretical methods since experimental benchmarks are difficult to realize with hydrogenic targets, but are amenable for such cases as alkali atoms. In such collisions, it is essential that a theoretical formalism be used that correctly simulates the screening of the nucleus by the core electrons (Sect. 58.1.2), since a simple $-Z_{\mathrm{eff}}/R$ Coulomb potential is inadequate for both large and small R.

One can also apply the methods of Sect. 58.1.2 to partially or completely filled atomic shells. This works reasonably well for collisions with a low charge state ion such as a proton, but fails for strong collisions involving multiply-charged ions. The reason is that the independent electron approximation [58.6] must be applied to the calculated transition probabilities in order to simulate the shell structure. This latter method can only maintain its validity if the transition probability is low. Otherwise, it will greatly overestimate the multiple elec-

tron removal processes since the first ionization potential is inherently assumed for each subsequent electron that is removed from the shell, leading to an underestimate of the energy deposition.

58.3.3 State–Selective Electron Capture

One of the powers of the CTMC method is that it can be applied to electron capture and excitation of high-lying states that are not accessible with basis set expansion techniques [58.17]. For the $C^{4+} + Li$ system, where AO calculations and experimental data exist, the CTMC method agrees quite favorably with both [58.18].

The procedure is first to define a classical number n_c related to the calculated binding energy E of the active electron to either the projectile (electron capture) or target nucleus (excitation) as

$$E = -Z^2/(2n_c^2) . \tag{58.9}$$

Then, n_c is related to the principal quantum number n of the final state by the condition [58.19]

$$\left[n\left(n-\frac{1}{2}\right)(n-1)\right]^{1/3} < n_c \leq \left[n\left(n+\frac{1}{2}\right)(n+1)\right]^{1/3} . \tag{58.10}$$

From the electron's normalized classical angular momentum $l_c = (n/n_c)(\mathbf{r} \times \mathbf{k})$, l_c is related to the orbital quantum number l of the final state by

$$l < l_c \leq l+1 . \tag{58.11}$$

The magnetic quantum number m_l is then obtained from

$$\frac{2m_l - 1}{2l + 1} \leq \frac{l_z}{l_c} < \frac{2m_l + 1}{2l + 1} , \tag{58.12}$$

where l_z is the z-projection of the angular momentum obtained from calculations [58.20]. In principle, it is also possible to analyze the final-state distributions from the effective quantum number

$$n^* = n - \delta_l , \tag{58.13}$$

where δ_l is the quantum defect. In this latter case, it is necessary to sort the angular momentum quantum numbers first, and then sort the principal quantum numbers.

The CTMC method has been widely applied to collisions of multiply-charged ions and hydrogen targets in the nuclear fusion program. Here, the calculated nl

charge exchange cross sections are used to predict the resulting visible and UV line emissions arising after electron capture to high principle quantum numbers. These line emission cross sections are routinely used as a diagnostic for tokamak fusion plasmas [58.21]. Likewise, for low energy collisions, CTMC results have been used to provide an explanation for the X-ray emission discovered from comets as they orbit through our solar system [58.22, 23].

58.3.4 Exotic Projectiles

The study of collisions involving antimatter projectiles, such as positrons and antiprotons, is a rapidly growing field which is being spurred on by recent experimental advances. Such scattering processes are of basic interest, and they also contribute to a better understanding of normal matter-atom collisions. Antimatter-atom studies highlight the underlying differences in the dynamics of the collision, as well as on the partitioning of the overall scattering. In the Born approximation, ionization cross sections depend on the square of the projectile's charge and are independent of its mass. Thus, the comparison of the cross sections for electron, positron, proton and antiproton scattering from a specific target gives a direct indication of higher-order corrections to scattering theories.

Early work using the CTMC method concentrated on the spectra of ionized electrons for antimatter projectiles [58.24]. Later work focused on the angular scattering of the projectiles during electron removal collisions, such as positronium formation, on ratios of the electron removal cross sections, and on ejected electron 'cusp' and 'anticusp' formation. A recent review that compares various theoretical results and available experiments is given in [58.25].

58.3.5 Heavy Particle Dynamics

A major attribute of the CTMC method is that it inherently includes the motion of the heavy particles after the collision. A straight-line trajectory for the projectile is not assumed, nor is the target nucleus constrained to be fixed. This allows one to compute easily the differential cross sections for projectile scattering or the recoil momenta of the target nucleus. As a computational note, the angular scattering of the projectile should be computed from the momentum components, not the position coordinates after the collision, since faster convergence of the cross sections using the projectile momenta is obtained. For recoil ion momentum transfer studies, one must ini-

tialize the target atom such that the c.m. of the nucleus plus its electrons has zero momentum so that there is no initial momentum associated with the target. A common error is to initialize only the target nucleus momenta to zero. Then the target atom after a collision has an artificial residual momentum that is associated with the Compton profile of the electrons because target–electron interactions are included in the calculations. Examples of recoil and projectile scattering cross sections are given in [58.10, 11].

The field of recoil ion momentum spectroscopy is rapidly expanding and the CTMC theoretical method has impacted the interpretation and understanding of experimental results because the method inherently provides a kinematically complete description of the collision products. For the studied systems, primarily He targets because of experimental constraints, it is necessary that a theoretical method be able to follow all ejected electrons and the heavy particles after a collision. As an example, it has been possible to observe the backward recoil of the target nucleus in electron capture reactions, which is due to conservation of momentum when the active electron is transferred from the target's to the projectile's frame of [58.26]. Theoretical methods are being tested further with the recent development of magneto-optical-taps (MOT) that provide frozen alkali metal atomic targets ($T \ll 1$ mK) from which to perform recoil ion studies [58.27].

For three- and four-body systems, it is now possible to measure the momenta of all collision products. These observations provide a severe test of theory, since all projectile and target interactions must be included in calculations. The CTMC method includes all projectile interactions with the target nucleus and electrons. Thus, it is possible to calculate fully differential cross sections. It is of interest that recent triply differential cross sections calculated using the CTMC method compare very favorably with sophisticated continuum distorted wave methods [58.28].

The CTMC technique allows one to incorporate electrons on both the projectile and target nuclear centers. All interactions between centers are included. The only interaction that needs to be approximated is the electron–electron interactions on a given center. Here, simple screening parameters derived from Hartree–Fock calculations are employed to eliminate nonphysical autoionization. Within this many-electron model, the signatures of the electron–electron and electron–nuclear interactions on the dynamics of the collisions have been observed [58.29, 30]. Further, projectile ionization studies can be undertaken [58.31].

58.4 Conclusions

In many ways it is surprising that a classical model can be successful in a quantum mechanical world, especially since the classical radial distribution for the hydrogen atom is described so poorly. However, hydrogen's classical momentum distribution is exactly equivalent to the quantum one, and since collision processes are primarily determined by velocity matching between projectile and electron, reasonable results can be expected. Moreover, the CTMC method pre-serves conservation of flux, energy, and momentum; and Coulomb scattering is the same in both quantal and classical frameworks.

Of significant importance is that the CTMC method is not restricted to one-electron systems and can easily be extended to more complicated systems involving electrons on both projectile and target. For these latter cases, multiple electron capture and ionization reactions can be investigated.

59. Collisional Broadening of Spectral Lines

One-photon processes only are discussed and aspects of line broadening directly related to collisions between the emitting (or absorbing) atom and one perturber are considered. Molecular lines and bands are not considered here. Pointers to other aspects are included and a comprehensive bibliography of work on atomic line shapes, widths, and shifts already exists [59.1–7]. The perturber may be an electron, a neutral atom or an atomic ion and can interact weakly or strongly with the emitter. The emitter is either a hydrogenic or nonhydrogenic atom that is either neutral or ionized. In general, transitions in nonhydrogenic atoms can be treated as isolated, that is the separation between neighboring lines is much greater than the width of an individual line. When the emitter is hydrogen or a hydrogenic ion, the additional degeneracy of the energy levels with respect to orbital angular momentum quantum number means that lines overlap and are coupled.

   Pressure broadening is a general term that describes any broadening and shift of a spectral line produced by fields generated by a background gas or plasma. The term Stark broadening implies that the perturbers are atomic ions and/or electrons, and collisional broadening implies that the 'collision' model is appropriate; this term is often used to describe an isolated line perturbed by electrons. Neutral atom broadening indicates neutral atomic perturbers; this implies short-range emitter–perturber interactions which in turn influence the approximations made.

General reviews of the theory of pressure broadening have been given [59.8–10], and Chapt. 2, Chapt. 10, Chapt. 14, Chapt. 19, Chapt. 45, Chapt. 47, and Chapt. 86 discuss topics relevant to the theory of collisional broadening of spectral lines. The International Conference on Spectral Line Shapes (ICSLS) is devoted exclusively to this subject.

59.1 Impact Approximation

If the perturbers are rapidly moving, the broadening and shift of the line arise from a series of binary collisions between the atom and one of the perturbers. The theory assumes that although weak collisions may occur simultaneously, strong collisions are relatively rare and only occur one at a time. The impact approximation is valid if

$$w\tau \ll 1 , \quad \bar{V}\tau/\hbar \ll 1 , \tag{59.1}$$

where w is the half width at half maximum, τ is the average time of collision and $\bar{V}$ is the average emitter-

perturber interaction. It is not only widely applicable to electron and neutral atom broadening, but also, for certain plasma conditions, to broadening by atomic ions. The power radiated per unit time and per unit interval in circular frequency ω, in terms of the line profile $I(\omega)$, is

$$P(\omega) = \frac{4}{3} \frac{\omega^4}{c^3} I(\omega) \ . \tag{59.2}$$

For an isolated line produced by a transition from an upper energy level i to a lower level f, the line profile is Lorentzian with a shift d:

$$I(\omega) = \frac{1}{\pi} \langle\!\langle i f^* | \boldsymbol{\Delta} | i f^* \rangle\!\rangle \frac{w}{(\omega - \omega_{if} - d)^2 + w^2} \ , \tag{59.3}$$

and if the profile is for a transition between an upper set of levels i, i' and a lower set f, f' with quantum numbers $J_i M_i$, $J_{i'} M_{i'}$, $J_f M_f$, and $J_{f'} M_{f'}$, then

$$I(\omega) = \frac{1}{\pi} \operatorname{Re} \left(\sum_{ii'ff'} \langle\!\langle i f^* | \boldsymbol{\Delta} | i' f'^* \rangle\!\rangle \tag{59.4} \right.$$
$$\left. \times \langle\!\langle i' f'^* \big| [\boldsymbol{w} + \mathrm{i}\boldsymbol{d} - \mathrm{i}(\omega - \omega_{if})\boldsymbol{I}]^{-1} \big| i f^* \rangle\!\rangle \right),$$

where $\boldsymbol{I}$ is the unit operator and $\boldsymbol{w}$ and $\boldsymbol{d}$ are width and shift operators. In (59.4) $\boldsymbol{\Delta}$ is an operator corresponding to the dipole line strength defined by

$$\langle\!\langle i f^* | \boldsymbol{\Delta} | i' f'^* \rangle\!\rangle \equiv q^2 \langle i | \boldsymbol{r} | f \rangle \cdot \langle i' | \boldsymbol{r} | f' \rangle \ , \tag{59.5}$$

where $\boldsymbol{r}$ represents the internal emitter coordinates, $q^2 = e^2/(4\pi\epsilon_0)$ is the square of the electronic charge, and ϵ_0 is the permittivity of vacuum in SI units of J m. On taking the average over all degenerate magnetic sublevels,

$$I(\omega) = \frac{1}{\pi} \operatorname{Re} \left(\sum_{ii'ff'} \langle\!\langle i f^* \| \boldsymbol{\Delta} \| i' f'^* \rangle\!\rangle \tag{59.6} \right.$$
$$\left. \times \langle\!\langle i' f'^* \big\| [\boldsymbol{w} + \mathrm{i}\boldsymbol{d} - \mathrm{i}(\omega - \omega_{if})\boldsymbol{I}]^{-1} \big\| i f^* \rangle\!\rangle \right)$$

in terms of reduced matrix elements that are independent of magnetic quantum numbers. They are defined by

$$\langle\!\langle i f^* | \boldsymbol{\Delta} | i' f'^* \rangle\!\rangle = D_{i f i' f'} \langle\!\langle i f^* \| \boldsymbol{\Delta} \| i' f'^* \rangle\!\rangle \ , \tag{59.7}$$

where

$$D_{i f i' f'} = \sum_{\mu} (-1)^{J_i + J_{i'} - M_i - M_{i'}}$$
$$\times \begin{pmatrix} J_i & 1 & J_f \\ -M_i & \mu & M_f \end{pmatrix} \begin{pmatrix} J_{i'} & 1 & J_{f'} \\ -M_{i'} & \mu & M_{f'} \end{pmatrix} , \tag{59.8}$$

$$\langle\!\langle i' f'^* \big\| [\boldsymbol{w} + \mathrm{i}\boldsymbol{d} - \mathrm{i}(\omega - \omega_{if})\boldsymbol{I}]^s \big\| i f^* \rangle\!\rangle$$
$$= \sum_{M_i, M_{i'}, M_f, M_{f'}} D_{i f i' f'}$$
$$\times \langle\!\langle i' f'^* \big| [\boldsymbol{w} + \mathrm{i}\boldsymbol{d} - \mathrm{i}(\omega - \omega_{if})\boldsymbol{I}]^s \big| i f^* \rangle\!\rangle \tag{59.9}$$

with $s = -1, 1$. For the line profile (59.3), the width and each have a single matrix element:

$$\gamma = 2w = \langle\!\langle i f^* \| 2\boldsymbol{w} \| i f^* \rangle\!\rangle , \quad d = \langle\!\langle i f^* \| \boldsymbol{d} \| i f^* \rangle\!\rangle , \tag{59.10}$$

where γ is the full width at half maximum.

Throughout the rest of this article it will be assumed that collisions only connect the set of upper levels i, i' or the set of lower levels f, f' which is valid when $w \ll \omega$; pressure broadening of spectral lines is also assumed to be independent of Doppler broadening. However, for microwave spectra of molecules, w can be of the order of ω and collisions connecting the upper to the lower levels become important; for further details see *Ben-Reuven* [59.11, 12]. Also for microwave spectra, pressure broadening and Doppler broadening cannot be considered to be independent effects and a generalized theory has been developed by *Ciuryło* and *Pine* [59.13].

59.2 Isolated Lines

59.2.1 Semiclassical Theory

The motion of the perturber relative to the emitter is treated classically and is assumed to be independent of the internal states of the emitter and perturber. This common trajectory is specified by an emitter–perturber separation

$$\boldsymbol{R} \equiv \boldsymbol{R}(\boldsymbol{b}, \boldsymbol{v}, t) , \quad \boldsymbol{b} \cdot \boldsymbol{v} = 0 , \tag{59.11}$$

where $\boldsymbol{v}$ is the relative velocity and $\boldsymbol{b}$ is the impact parameter. The time-dependent wave equation for the emitter-perturber system is

$$\mathrm{i}\hbar \frac{\mathrm{d}\Psi}{\mathrm{d}t} = H\Psi \tag{59.12}$$

and the eigenfunctions ψ_i for the unperturbed emitter obey

$$H_0 \psi_i = E_i \psi_i , \quad i = 0, 1, 2, \ldots \ . \tag{59.13}$$

If $\Psi(\mathbf{r}, \mathbf{R})$ is expanded in the form

$$\Psi(\mathbf{r}, \mathbf{R}) = \sum_j a_{ji}(t) \psi_j(\mathbf{r}) \exp(-iE_j t/\hbar) , \quad (59.14)$$

where initially at time $t = -\infty$

$$a_{ji}(-\infty) = \delta_{ji} , \quad (59.15)$$

and (59.12)–(59.14) give

$$i\hbar \frac{da_{ji}}{dt} = \sum_k a_{ki} V_{jk} \exp(i\omega_{jk}t) ,$$

$$i, j, k = 0, 1, 2, \dots , \quad (59.16)$$

where

$$V_{jk}(\mathbf{R}) = \int \psi_j^*(\mathbf{r}) V(\mathbf{r}, \mathbf{R}) \psi_k(\mathbf{r}) \, d\mathbf{r} \quad (59.17)$$

in which $V(\mathbf{r}, \mathbf{R})$ is the emitter-perturber interaction and

$$\hbar\omega_{jk} = E_j - E_k . \quad (59.18)$$

Integration of equations (59.16) for $-\infty \leq t \leq \infty$ gives the unitary scattering matrix $\mathbf{S}$, with elements

$$S_{ji}(\mathbf{b}, \mathbf{v}) \equiv a_{ji}(\infty) , \quad i, j = 0, 1, 2, \dots . \quad (59.19)$$

Then

$$w + id = 2\pi N \int_0^\infty v f(v) \, dv$$

$$\times \int_0^\infty \left[\delta_{i'i} \delta_{f'f} - S_{i'i}(\mathbf{b}, \mathbf{v}) S_{f'f}^*(\mathbf{b}, \mathbf{v}) \right]_{\text{av}} b \, db ,$$

$$(59.20)$$

where $J_{i'} = J_i$ and $J_{f'} = J_f$, N is the perturber density and $[\cdots]_{\text{av}}$ denotes an average over all orientations of the collision and over the magnetic sublevels [see Eq. (59.9)]. In (59.20), $f(v)$ is the Maxwell velocity distribution at temperature T for an emitter-perturber system of reduced mass μ:

$$f(v) = 4\pi v^2 \left(\frac{\mu}{2\pi k_B T} \right)^{3/2} \exp\left(-\frac{\mu v^2}{2k_B T} \right) ,$$

$$\int_0^\infty f(v) \, dv = 1 . \quad (59.21)$$

59.2.2 Simple Formulae

These are useful for making quick estimates, but in individual cases may give results in error by a factor of two

or more. If it is assumed in (59.17) that

$$V_{ij}(\mathbf{R}) = V_{jj}(\mathbf{R}) \delta_{ij} , \quad (59.22)$$

where $V_{jj}(\mathbf{R})$ is a simple central potential

$$V_{jj}(\mathbf{R}) = \hbar C_j R^{-p} , \quad j = i, f , \quad (59.23)$$

and C_j depends only on the state j of the emitter, and if the relative motion is along the straight line

$$\mathbf{R} = \mathbf{b} + \mathbf{v}t , \quad (59.24)$$

then

$$\left[S_{i'i}(\mathbf{b}, \mathbf{v}) S_{f'f}^*(\mathbf{b}, \mathbf{v}) \right]_{\text{av}} = \exp\left[2i(\eta_i - \eta_f) \right] , \quad (59.25)$$

where the phase shifts are

$$\eta_j(b, v) = -\frac{1}{2\hbar} \int_{-\infty}^{\infty} V_{jj}(R) \, dt , \quad j = i, f . \quad (59.26)$$

Equations (59.20)–(59.26) give

$$w + id = \pi N \bar{v} \left(\frac{\beta_p |C_p|}{\bar{v}} \right)^{2/(p-1)}$$

$$\times \Gamma\left(\frac{p-3}{p-1} \right) \exp\left(\pm \frac{i\pi}{p-1} \right) \alpha_p , \quad (59.27)$$

where

$$\alpha_p = \Gamma\left(\frac{2p-3}{p-1} \right) \left(\frac{\pi}{4} \right)^{-1/(p-1)} ,$$

$$\beta_p = \sqrt{\pi} \frac{\Gamma\left(\frac{1}{2}(p-1) \right)}{\Gamma\left(\frac{1}{2}p \right)} ,$$

$$C_p = C_i - C_f ,$$

$$\bar{v} = \int_0^\infty v f(v) \, dv = \left(\frac{8k_B T}{\pi \mu} \right)^{1/2} . \quad (59.28)$$

In (59.27) the $\pm$ sign indicates the sign of C_p, $\alpha_p \simeq 1$ for $p \geq 3$, and $\Gamma(\cdots)$ is the gamma function.

The cases $p = 3, 4$, and 6 correspond to resonance, quadratic Stark and van der Waals broadening, respectively. This approximation is invalid for the dipole case ($p = 2$) for which (59.27) is not finite. The dipole–dipole interaction ($p = 3$) occurs when emitter and perturber are identical atoms (apart from isotopic differences). If the level i is connected to the ground state by a strong allowed transition with

absorption oscillator strength f_{gi}, and the perturbation of the level f can be neglected by comparison, then

$$C_3 = c_d \frac{q^2 f_{gi}}{2m_e |\omega_{gi}|} ,$$

$$c_d = 1 + \frac{1}{2\sqrt{3}} \ln \left(2 + \sqrt{3}\right) = 1.380\,173 . \quad (59.29)$$

Also, if g_j is the statistical weight of level j, the constant c_d may be replaced by an empirical value

$$c_d = \frac{4}{\pi} \left(\frac{g_g}{g_i}\right)^{1/2} , \quad (59.30)$$

and this gives a width correct to about 10% [59.14]. Equation (59.27) does not predict a finite shift. Quadratic Stark broadening occurs when a nonhydrogenic emitter is polarized by electron perturbers. Then

$$C_4 = -\frac{q^2}{2\hbar} \left(\alpha_i - \alpha_f\right) , \quad (59.31)$$

where α_i and α_f are the dipole polarizabilities of states i and f, respectively. Van der Waals broadening occurs when the emitter and perturber are nonidentical neutral atoms. If energy level separations of importance in the perturbing atom are much greater than those of the emitter (e.g., alkali spectra broadened by noble gases), C_6 is given by

$$C_6 = -\frac{q^2}{\hbar} \alpha_d \left(\overline{r_i^2} - \overline{r_f^2}\right) , \quad (59.32)$$

where α_d is the dipole polarizability of the perturber. The mean square radii can be calculated from the normalized radial wave functions $\frac{1}{r} P_{n_j^* l_j} (r)$ or estimated from

$$\overline{r_j^2} = \int_0^\infty P_{n_j^* l_j}^2 (r) r^2 \, dr$$

$$\simeq \frac{n_j^{*2} a_0^2}{2z^2} \left[5n_j^{*2} + 1 - 3l_j \left(l_j + 1\right)\right] ,$$

$$j = i, f \quad (59.33)$$

in which the effective principal quantum numbers n_j^* are given by

$$E_j \equiv -\frac{z^2}{n_j^{*2}} I_h , \quad z = Z_e + 1 , \quad (59.34)$$

where $I_h = hcR_\infty$ is the Rydberg energy, Z_e is the charge on the emitter and $z = 1$ in this case.

59.2.3 Perturbation Theory

An approximate solution of (59.16) is given by [59.8–10, 15, 16]

$$S_{ji} (\boldsymbol{b}, \boldsymbol{v}) = \delta_{ji} - \frac{i}{\hbar} \int_{-\infty}^{\infty} V_{ji} (t) \exp \left(i\omega_{ji}t\right) \, dt$$

$$- \frac{1}{\hbar^2} \sum_k \left[\int_{-\infty}^{\infty} V_{jk} (t) \exp \left(i\omega_{jk}t\right) \, dt \right.$$

$$\left. \times \int_{-\infty}^{t} V_{ki} (t') \exp \left(i\omega_{ki}t'\right) \, dt' \right] . \quad (59.35)$$

This gives a cross section for the collisional transition $i \to j$:

$$\sigma_{ij} (v) = 2\pi \int_0^\infty \left[P_{ij} (\boldsymbol{b}, \boldsymbol{v})\right]_{av} b \, db ,$$

$$i, j = 0, 1, 2, \dots , \quad (59.36)$$

where

$$P_{ij} (\boldsymbol{b}, \boldsymbol{v}) = \left|\delta_{ji} - S_{ji} (\boldsymbol{b}, \boldsymbol{v})\right|^2 , \quad (59.37)$$

$$2 \, \mathrm{Re} \left[1 - S_{ii} (\boldsymbol{b}, \boldsymbol{v})\right] = \sum_j P_{ij} (\boldsymbol{b}, \boldsymbol{v}) , \quad (59.38)$$

correct to second-order in $V (\boldsymbol{r}, \boldsymbol{R})$ on both sides. Using (59.10), (59.20) and (59.36)–(59.38), the full width is

$$\gamma = N \int_0^\infty v f (v) \, dv$$

$$\times \left[\sum_{j \neq i} \sigma_{ij} (v) + \sum_{j \neq f} \sigma_{fj} (v) + \widetilde{\sigma}_{if} (v) \right] ,$$

$$\quad (59.39)$$

where the sums are taken over all energy-changing transitions, the tilde indicates an interference term, and

$$\widetilde{\sigma}_{if} (v) = 2\pi \int_0^\infty \left[\widetilde{P}_{if} (\boldsymbol{b}, \boldsymbol{v})\right]_{av} b \, db , \quad (59.40)$$

in which

$$\widetilde{P}_{if} (\boldsymbol{b}, \boldsymbol{v}) = \left| \frac{1}{\hbar} \int_{-\infty}^{\infty} \left[V_{ii} (t) - V_{ff} (t)\right] \, dt \right|^2 . \quad (59.41)$$

59.2.4 Broadening by Charged Particles

The total emitter-perturber interaction is

$$\frac{zZ_\mathrm{p}q^2}{R} - \frac{Z_\mathrm{p}q^2}{|\boldsymbol{R}-\boldsymbol{r}|} \simeq V_0(R) + V(\boldsymbol{r}, \boldsymbol{R}) , \qquad (59.42)$$

where Z_p is the charge on the perturber and

$$V_0(R) = \frac{Z_\mathrm{e}Z_\mathrm{p}q^2}{R} , \quad V(\boldsymbol{r}, \boldsymbol{R}) = -Z_\mathrm{p}q^2\frac{\boldsymbol{r}\cdot\boldsymbol{R}}{R^3} . \qquad (59.43)$$

If $Z_\mathrm{e} = 0$, the relative motion is described by (59.24), but if $Z_\mathrm{e} \neq 0$, the trajectory is hyperbolic and is given by

$$\mu\frac{\mathrm{d}^2\boldsymbol{R}}{\mathrm{d}t^2} = -\nabla V_0 = \frac{Z_\mathrm{e}Z_\mathrm{p}q^2}{R^3}\boldsymbol{R} , \qquad (59.44)$$

with the resulting hyperbola characterized by a semi-major axis a and an eccentricity ϵ, where

$$b^2 = a^2\left(\epsilon^2 - 1\right) , \quad a = \frac{|Z_\mathrm{e}Z_\mathrm{p}|q^2}{\mu v^2} . \qquad (59.45)$$

On using (59.17), (59.20), (59.36)–(59.41) and (59.43),

$$V_{ii}(t) = 0 , \quad \widetilde{P}_{if}(\boldsymbol{b}, \boldsymbol{v}) = 0 , \quad \widetilde{\sigma}_{if}(v) = 0 , \qquad (59.46)$$

and

$$w + \mathrm{i}d = 2\pi N \int_0^\infty v f(v)\,\mathrm{d}v$$
$$\times \left[\int_0^\infty \sum_{j\neq i} Q_{ij}(b, v) + \sum_{j\neq f} Q_{fj}(b, v)\right] b\,\mathrm{d}b , \qquad (59.47)$$

where

$$Q_{ij}(v) = \frac{4Z_p^2 I_h^2 a_0^2}{\hbar m_\mathrm{e}|\omega_{ij}|}\frac{f_{ij}}{b^2 v^2}[A(\beta, \xi) + \mathrm{i}B(\beta, \xi)] ,$$
$$2\,\mathrm{Re}[Q_{ij}(v)] = [P_{ij}(\boldsymbol{b}, \boldsymbol{v})]_\mathrm{av} . \qquad (59.48)$$

If

$$\xi \equiv \frac{a|\omega_{ij}|}{v} , \quad \beta \equiv \xi\epsilon , \quad \delta \equiv \frac{\epsilon^2 - 1}{\epsilon^2} , \qquad (59.49)$$

the functions $A(\beta, \xi)$ and $B(\beta, \xi)$ in (59.48) are given by

$$A(\beta, \xi) = \delta\exp(\mp\pi\xi)\,\beta^2$$
$$\times \left[\left|K'_{i\xi}(\beta)\right|^2 + \delta\left|K_{i\xi}(\beta)\right|^2\right] \qquad (59.50)$$

$$B(\beta, \xi) = \frac{2\beta}{\pi}\wp\int_0^\infty \frac{A(\beta', \xi)\,\mathrm{d}\beta'}{(\beta^2 - \beta'^2)} , \qquad (59.51)$$

where $K_{i\xi}(\beta)$ is a modified Bessel function. In (59.50), the $\mp$ sign corresponds to $Z_\mathrm{e}Z_\mathrm{p} = \pm|Z_\mathrm{e}Z_\mathrm{p}|$, and in (59.51), $\wp$ indicates the Cauchy principal value. If $Z_\mathrm{e} = 0$, then

$$\xi = 0 , \quad \beta = b\frac{|\omega_{ij}|}{v} , \quad \delta = 1 \qquad (59.52)$$

in (59.50) and (59.51).

Approximation (59.48) breaks down at small values of b because of assumption (59.43) and the lack of unitarity of S as given by (59.35). This problem is discussed elsewhere [59.8, 15, 16], and all methods used involve choosing a cutoff at $b = b_0$, where $b_0^2 \gtrsim r_f^2$, and using (59.48) only for $b > b_0$. For $b \leq b_0$, an effective constant probability is introduced and the method works well as long as the contribution from $b \leq b_0$ is small. For $b > b_0$ (or $\beta > \beta_0$), the contribution to $\sigma_{ij}(v)$ in (59.39) is evaluated using (59.47)–(59.50) and (59.52), where

$$\int_{b_0}^\infty A(\beta, \xi)\,\frac{\mathrm{d}b}{b} = -\mathrm{e}^{\mp\pi\xi}\beta_0 K'_{i\xi}(\beta_0)\,K_{i\xi}(\beta_0) . \qquad (59.53)$$

A similar treatment exists for the quadrupole contribution to $V(\boldsymbol{r}, \boldsymbol{R})$ in (59.43) [59.8, 15, 16].

59.2.5 Empirical Formulae

An empirical formula based on the theory of Sect. 59.2.4 for the width of an atomic line Stark broadened by electrons has been developed [59.17]. *Konjević* [59.18] has reviewed the data available for nonhydrogenic lines and has provided simple analytical representations of the experimental results for widths and shifts.

The full half-width is given by (59.39), where $\widetilde{\sigma}_{if} = 0$ and

$$\int_0^\infty v f_\mathrm{e}(v) \sum_{k\neq j} \sigma_{jk}(v)\,\mathrm{d}v = \frac{8\pi^2}{3\sqrt{3}}\left(\frac{\hbar}{m_\mathrm{e}}\right)^2 \overline{v^{-1}}$$
$$\times \left[T_j g(x_j) + \sum_{l_{j'}=l_j\pm1} \widetilde{T}_{jj'}\widetilde{g}(x_{jj'})\right] , \quad j = i, f , \qquad (59.54)$$

where

$$\overline{v^{-1}} = \int_0^\infty v^{-1} f_e(v) \, dv = \left(\frac{2m_e}{\pi k_B T}\right)^{1/2} , \quad (59.55)$$

and $f_e(v) = f(v)$ with $\mu = m_e$. In (59.54),

$$T_j = \left(\frac{3n_j^*}{2z}\right)^2 \frac{1}{9} \left[n_j^{*2} + 3l_j(l_j+1) + 11\right] , \quad (59.56)$$

$$\widetilde{T}_{jj'} = \frac{l_>}{(2l_j+1)} R_{jj'}^2(n_{l_>}^*, n_{l_<}^*, l_>) , \quad (59.57)$$

$$l_< = \min(l_j, l_{j'}) , \quad l_> = \max(l_j, l_{j'}) ,$$

with

$$R_{jj'}(n_{l_>}^*, n_{l_<}^*, l_>) \equiv a_0^{-1} \int_0^\infty P_{n_{l_>}^* l_>}(r) \, r P_{n_{l_<}^* l_<}(r) \, dr .$$
$$(59.58)$$

The radial matrix element (59.58) can be written as

$$R_{jj'}(n_{l_>}^*, n_{l_<}^*, l_>)$$
$$= \widetilde{R}_{jj'}(n_{l_>}^*, l_>) \, \phi(n_{l_>}^*, n_{l_<}^*, l_>)$$
$$\equiv \frac{3n_{l_>}^*}{2z}\left(n_{l_>}^{*2} - l_>^2\right)^{1/2} \phi(n_{l_>}^*, n_{l_<}^*, l_>) \quad (59.59)$$

and $\phi(n_{l_>}^*, n_{l_<}^*, l_>)$ is tabulated elsewhere [59.19]. The effective principal quantum numbers $n_{l_>}^*$ and $n_{l_<}^*$ of the states j and j' in (59.57)–(59.59) both correspond to principal quantum number n_j and $\phi \simeq 1$ for

$(n_{l_>}^* - n_{l_<}^*) \ll 1$. The effective Gaunt factors $g(x)$ and $\widetilde{g}(x)$ are given by

$$\widetilde{g}(x) = 0.7 - 1.1/z + g(x) , \quad x = \frac{3k_B T}{2\Delta E} , \quad (59.60)$$

where

x	≤ 2	3	5	10	30	100
$g(x)$	0.20	0.24	0.33	0.56	0.98	1.33

is used for $x < 50$, and for $x > 50$

$$\widetilde{g}(x) = g(x) = \frac{\sqrt{3}}{\pi}\left[\frac{1}{2} + \ln\left(\frac{4}{3z}\frac{|E|}{I_h}x\right)\right] , \quad (59.61)$$

with (59.60) and (59.61) joined smoothly near $x = 50$. The energy $E = E_j$ is given by (59.34) and x_j and $x_{jj'}$ in (59.54) are evaluated using

$$\Delta E_j = \frac{2z^2}{n_j^{*3}} I_h , \quad \Delta E_{jj'} = |E_j - E_{j'}| . \quad (59.62)$$

For $Z_e = 2$ and 3, (59.54) is generally accurate to within $\pm 30\%$ and $\pm 50\%$. For $Z_e \geq 4$, (59.54) is less accurate, as relativistic effects and resonances become more important. Accuracy increases for transitions to higher Rydberg levels as long as the line remains isolated.

Tables in appendices IV and V of [59.8] give widths for atoms with $Z_e = 0, 1$ and other semi-empirical formulas based on detailed calculations have been developed by Seaton [59.20, 21] for use in the Opacity Project where simple estimates of many thousands of line widths are required.

59.3 Overlapping Lines

59.3.1 Transitions in Hydrogen and Hydrogenic Ions

The most important case is that of lines of hydrogenic systems emitted by a plasma with overall electrical neutrality, broadened by perturbing electrons and atomic ions. The line profile is given by (59.4)–(59.9) in which (59.20) is generalized to give

$$\langle\!\langle i' f'^* \| \boldsymbol{w} + i\boldsymbol{d} \| i f^* \rangle\!\rangle = 2\pi N \int_0^\infty v f(v) \, dv$$

$$\times \int_0^\infty \left[\delta_{i'i}\delta_{f'f} - S_{i'i}(\boldsymbol{b}, \boldsymbol{v}) S_{f'f}^*(\boldsymbol{b}, \boldsymbol{v})\right]_{av} b \, db .$$
$$(59.63)$$

The superscripts and suffices e and i will be used to denote electron and ion quantities, and em indicates that averaging over magnetic quantum numbers has not been carried out. In the impact approximation, electron and ion contributions evaluated using (59.63) are additive and the matrix to be inverted is of order $n_i n_f$. However, under typical conditions in a laboratory plasma, e.g., a hydrogen plasma with $N_e = N_i = 10^{22}$ m^{-3}, perturbing atomic ions cannot be treated using the impact approximation. The ions collectively generate a static field at the emitter which produces first-order Stark splitting of the upper and lower levels. The ions are randomly distributed around the emitter and the field distribution $W(\boldsymbol{F})$ used assumes that each ion is Debye screened by electrons; allowance is made for these heavy composite perturbers interacting with each other as well as with the emitter. If the ion field has a slow

time variation, ion dynamic effects on the line are produced [59.8, 9, 22].

The shift produced by electron perturbers is very small and the usual model adopted is to assume that the ions split the line into its Stark components, and that each component is broadened by electron impact. In both cases, only the dipole interactions in (59.43) are included and the profile is symmetric. Then (59.4) takes the form

$$
I(\omega) = \frac{1}{\pi} \operatorname{Re} \int W(\boldsymbol{F}) \, \mathrm{d}\boldsymbol{F} \sum_{ii'ff'} \langle\!\langle if^* | \boldsymbol{\Delta} | i'f'^* \rangle\!\rangle
$$
$$
\times \langle\!\langle i'f'^* \left| \left[\boldsymbol{w} + \mathrm{i}\boldsymbol{d} - \mathrm{i}\left(\omega - \omega_{if}\right)\boldsymbol{I}\right]^{-1} \right| if^* \rangle\!\rangle \,,
$$
(59.64)

and the destruction of the degeneracy by the ion field means that the matrix to be inverted in (59.64) is of order $\left(n_i n_f\right)^2$. Inclusion of higher multipoles in $V(\boldsymbol{r}, \boldsymbol{R})$ in (59.43) introduces small asymmetries. The Stark representation for the hydrogenic wave functions is often used because it diagonalizes the shift matrix in (59.64). The transformation is given by (see Sect. 9.1.2 and 13.4.2)

$$
\left|n_j K_j m_j\right\rangle = \sum_{l_j=|m_j|}^{n_j-1} (-1)^K \left(2l_j+1\right)^{1/2}
$$
$$
\times \begin{pmatrix} N & N & l_j \\ M_1 & M_2 & -m_j \end{pmatrix} \left|n_j l_j m_j\right\rangle \,,
$$
$$
j = i, i', f, f' \,,
$$
(59.65)

where quantum number K_j replaces l_j and

$$
n_j = K_j + K'_j + |m_j| + 1 \,, \quad N = \frac{1}{2}\left(n_j - 1\right) \,,
$$
$$
K = \frac{1}{2}\left(2K'_j + |m_j| + m_j\right) + 1 \,,
$$
$$
0 \le K_j \le \left(n_j - 1\right) \,,
$$
$$
M_1 = \frac{1}{2}\left(m_j + K'_j - K_j\right) \,,
$$
$$
M_2 = \frac{1}{2}\left(m_j + K_j - K'_j\right) \,.
$$
(59.66)

For the electron impact broadening, it is convenient to separate the energy-changing and the zero energy-change transitions, so that (59.39) is generalized to give

$$
\gamma_{em} = \gamma_{em}^0 + \tilde{\gamma}_{em} \equiv \langle\!\langle i'f'^* | 2\boldsymbol{w}_e | if^* \rangle\!\rangle \,,
$$
(59.67)

where

$$
\gamma_{em}^0 \equiv \langle\!\langle i'f'^* \left| 2\boldsymbol{w}_e^0 \right| if^* \rangle\!\rangle = N_e \int_0^\infty v f_e(v) \, \mathrm{d}v
$$
$$
\times \left[\sum_{j\neq i} \sigma_{ij}^{em}(v) + \sum_{j\neq f} \sigma_{fj}^{em}(v) \right] \delta_{ii'} \delta_{ff'} \,,
$$
(59.68)

$$
\tilde{\gamma}_{em} \equiv \langle\!\langle i'f'^* | 2\widetilde{\boldsymbol{w}}_e | if^* \rangle\!\rangle
$$
$$
= N_e \int_0^\infty v f_e(v) \, \mathrm{d}v \, \tilde{\sigma}_{i'f'if}^{em}(v) \,.
$$
(59.69)

In (59.68), $\left|n_i - n_j\right| \neq 0$ and $\left|n_f - n_j\right| \neq 0$ in the first and second terms, respectively, and in (59.69) $(n_{i'} - n_i) = \left(n_{f'} - n_f\right) = 0$. The matrix element (59.68) can be evaluated using (59.36), (59.48), (59.50), and (59.52) as before. In (59.68),

$$
\sigma_{ij}^{em}(v) = 2\pi \int_0^\infty \left[P_{ij}^e(\boldsymbol{b}, v) \right]_{\mathrm{av}_0} b \, \mathrm{d}b \,,
$$
$$
i, j = 0, 1, 2, \ldots \,,
$$
(59.70)

and in (59.69)

$$
\tilde{\sigma}_{i'f'if}^{em}(v) = 2\pi \int_0^\infty \left[\tilde{P}_{i'f'if}^e(\boldsymbol{b}, v) \right]_{\mathrm{av}_0} b \, \mathrm{d}b
$$
(59.71)

by analogy with (59.36) and (59.40), where av_0 indicates an average over all orientations of the collision only. On using (59.48)–(59.50), (59.59) and (59.8) with $j_i = l_i$, $j_{i'} = l_{i'}$, $j_f = l_f$, and $j_{f'} = l_{f'}$,

$$
\left[\tilde{P}_{i'f'if}^e(\boldsymbol{b}, v) \right]_{\mathrm{av}_0} = \frac{8 I_h a_0^2}{3 m_e b^2 v^2} D_{if i'f'} \tilde{R}_{i'f'if} A(0,0) \,,
$$
(59.72)

where

$$
\tilde{R}_{i'f'if}
$$
$$
\equiv \left[\sum_{l_j=l_i\pm 1} \tilde{R}_{ij}^2\left(n_i, l_{i>}\right) + \sum_{l_j=l_f\pm 1} \tilde{R}_{fj}^2\left(n_f, l_{f>}\right) \right]
$$
$$
\times \delta_{l_{i'}l_i} \delta_{l_{f'}l_f}
$$
$$
- 2\tilde{R}_{i'i}(n_i, l_{i>}) \tilde{R}_{f'f}\left(n_f, l_{f>}\right) \delta_{l_{i'}l_i\pm 1} \delta_{l_{f'}l_f\pm 1} \,.
$$
(59.73)

From (59.45) and (59.49)–(59.53)

$$
A(0,0) = \delta \,,
$$

$$\int_{b_0}^{b_1} A(0,0) \frac{db}{b} = \begin{cases} \ln(\epsilon_1/\epsilon_0) \,, & Z_e \neq 0 \,, \\ \ln(b_1/b_0) \,, & Z_e = 0 \,. \end{cases} \quad (59.74)$$

(59.53). The impact approximation neglects electron–electron correlations and the finite duration of collisions, so the long-range dipole interaction leads to a logarithmic divergence at large impact parameters in (59.74). Therefore, a second cutoff parameter is introduced which is chosen to be the smaller of the Debye length b_D and $v\tau$:

$$b_1 = \min\left[b_D \equiv \left(\frac{k_B T}{4\pi q^2 N_e}\right)^{1/2}, v\tau\right], \quad (59.75)$$

but estimating τ in this case is not straightforward; it depends on the splitting of the Stark components [59.8].

59.3.2 Infrared and Radio Lines

If the density N_i is low enough, the impact approximation becomes valid for the perturbing atomic ions, and since impact shifts are unimportant, (59.6) gives

$$I(\omega) = \frac{1}{\pi} \operatorname{Re} \sum_{ii'ff'} \langle\!\langle if^* \| \Delta \| i'f'^* \rangle\!\rangle$$
$$\times \langle\!\langle i'f'^* \| \left[w_e + w_i - \mathrm{i}\left(\omega - \omega_{if}\right) I \right]^{-1} \| if^* \rangle\!\rangle$$
$$(59.76)$$

where in (59.76)

$$\gamma_{e,i} = \gamma_{e,i}^0 + \tilde{\gamma}_{e,i} \equiv \langle\!\langle i'f'^* \| 2w_{e,i} \| if^* \rangle\!\rangle \,, \quad (59.77)$$

$$\gamma_{e,i}^0 \equiv \langle\!\langle i'f'^* \| 2w_{e,i}^0 \| if^* \rangle\!\rangle = N_{e,i} \int_0^\infty v f_{e,i}(v) \, \mathrm{d}v$$
$$\times \left[\sum_{j\neq i} \sigma_{ij}^{e,i}(v) + \sum_{j\neq f} \sigma_{fj}^{e,i}(v)\right] \delta_{i'i}\delta_{f'f} \,, \quad (59.78)$$

$$\tilde{\gamma}_{e,i} \equiv \langle\!\langle i'f'^* \| 2\tilde{w}_{e,i} \| if^* \rangle\!\rangle$$
$$= N_{e,i} \int_0^\infty v f_{e,i}(v) \, \mathrm{d}v \, \tilde{\sigma}_{i'f'if}^{e,i}(v) \,. \quad (59.79)$$

In general, cross sections for electron and heavy-particle impact are roughly comparable for the same velocity and hence different impact energies. Therefore, using (59.78) and (59.79),

$$\gamma_e^0 \gg \gamma_i^0 \,, \quad \tilde{\gamma}_e \ll \tilde{\gamma}_i \,, \quad (59.80)$$

and this result is consistent with approximation (59.64) for high density plasmas. If $(n_i - n_f) = 1, 2$, say, as n_f increases, the relative contributions from (59.78) and (59.79) decrease because there is increasing coherence, and hence cancellation in $\tilde{\sigma}_{i'f'if}^e(v)$ and $\tilde{\sigma}_{i'f'if}^1(v)$ between the effects of levels i, i' and f, f'.

Radio lines of hydrogen are observed in galactic HII regions where principal quantum numbers are of the order of $n_f \simeq 100$, temperatures are $T_e = T_i \simeq 10^4$ K, and densities are $N_e = N_i \simeq 10^9$ m^{-3}. If γ is the full-half width and $\tilde{\gamma}$ is the full-half width when only contributions (59.79) are retained, the effect of cancellation is illustrated by

$n_i - n_f = 1$	electrons	protons + electrons
n_f	$\tilde{\gamma}/\gamma$	$\tilde{\gamma}/\gamma$
5	0.81	0.99
10	0.44	0.95
15	0.21	0.87
20	0.11	0.75
25	0.06	0.61
50	0.00	0.32
100	0.00	0.16

59.4 Quantum–Mechanical Theory

59.4.1 Impact Approximation

The scattering amplitude for a collisional transition $i \to j$ is given in terms of elements of the transition matrix $T = 1 - S$ by

$$f(k_j, k_i) \equiv f(\chi_j M_j k_j, \chi_i M_i k_i)$$
$$= \frac{2\pi\mathrm{i}}{(k_i k_j)^{1/2}} \sum_{lml'm'} \mathrm{i}^{l-l'} Y_{lm}^*\left(\hat{k}_i\right) Y_{l'm'}\left(\hat{k}_j\right)$$
$$\times T\left(\chi_j M_j l'm'; \chi_i M_i lm\right) \,, \quad (59.81)$$

where the quantities $k_i lm$ and $k_j l'm'$ refer to the motion of the perturber relative to the emitter before and after the collision, and χ_i and χ_j represent all nonmagnetic quantum numbers associated with the unperturbed states i and j of the emitter. The total energy of the emitter-perturber system is given by

$$E_J = E_j + \varepsilon_j \,, \quad \varepsilon_j = \frac{\hbar^2}{2\mu} k_j^2 \,,$$
$$(J, j) = (I, i), \ (F, f) \,, \quad (59.82)$$

and for an isolated line, γ is given by (59.39), where

$$
\sigma_{ij}(v) = \frac{k_j}{k_i} \frac{1}{4\pi g_i}
$$

$$
\times \sum_{M_i M_j} \int \left| f\left(\chi_j M_j \boldsymbol{k}_j, \chi_i M_i \boldsymbol{k}_i\right) \right|^2 \, \mathrm{d}\hat{\boldsymbol{k}}_i \, \mathrm{d}\hat{\boldsymbol{k}}_j ,
$$

$$
k_i = \mu v / \hbar , \tag{59.83}
$$

and the interference term $\tilde{\sigma}_{if}(v) \equiv \tilde{\sigma}_{ifif}(v)$ is given by

$$
\tilde{\sigma}_{if}(v) = \frac{1}{4\pi} \sum_{\substack{M_i M_{i'} \\ M_f M_{f'}}} D_{ifi'f'} \int \left| f(\chi_i M_{i'} \boldsymbol{k}', \chi_i M_i \boldsymbol{k}) \right.
$$

$$
\left. - f(\chi_f M_{f'} \boldsymbol{k}', \chi_f M_f \boldsymbol{k}) \right|^2 \, \mathrm{d}\hat{\boldsymbol{k}} \, \mathrm{d}\hat{\boldsymbol{k}}' , \tag{59.84}
$$

with $k = k' = \mu v / \hbar$. From (59.8) and (59.20),

$$
w + \mathrm{i}d = \pi \left(\frac{\hbar}{\mu}\right)^2 N \int_0^\infty \frac{1}{v} f(v) \, \mathrm{d}v
$$

$$
\times \sum_{l=0}^\infty (2l+1) \left[1 - S_{ii}(l, v) S_{ff}^*(l, v) \right] , \tag{59.85}
$$

where

$$
(\mu v b)^2 \Longrightarrow \hbar^2 l (l+1) \tag{59.86}
$$

and the integral over b has been replaced by a summation over l. In (59.85)), $S_{ii}(l, v) S_{ff}^*(l, v)$ is given by

$$
S_{ii}(l, v) S_{ff}^*(l, v)
$$

$$
= \frac{1}{(2l+1)} \sum_{\substack{M_i M_i' M_f M_f' \\ m m'}} D_{ifi'f'} S_I\left(\chi_{i'} M_{i'} l m'; \chi_i M_i l m\right)
$$

$$
\times S_F^*\left(\chi_{f'} M_{f'} l m'; \chi_f M_f l m\right) \tag{59.87}
$$

and subscripts I and F are introduced to emphasize that the S-matrix elements correspond to different total energies E_I and E_F defined by (59.82). If scattering by the emitter in a state j is treated using a central potential, the amplitude for elastic scattering is

$$
f\left(k', k\right) = \frac{\mathrm{i}}{2k} \sum_{l=0}^\infty (2l+1) \, T_{jj}(l, v) \, P_l\left(\hat{\boldsymbol{k}}' \cdot \hat{\boldsymbol{k}}\right) , \tag{59.88}
$$

where

$$
1 - T_{jj}(l, v) = S_{jj}(l, v) = \exp\left[2\mathrm{i}\eta_j(l, k)\right] ,
$$

$$
j = i, f , \tag{59.89}
$$

[cf. (59.23), (59.25), and (59.26)]. For the case of overlapping lines, (59.63) becomes

$$
\langle\!\langle i' f'^* \| \boldsymbol{w} + \mathrm{i}\boldsymbol{d} \| i f^* \rangle\!\rangle = \pi \left(\frac{\hbar}{\mu}\right)^2 N \int_0^\infty \frac{1}{v} f(v) \, \mathrm{d}v
$$

$$
\times \sum_{l=0}^\infty (2l+1) \left[\delta_{i'i} \delta_{f'f} - S_{i'i}(l, v) S_{f'f}^*(l, v) \right] \tag{59.90}
$$

on generalizing (59.85) and using (59.87). Formulae (59.85) and (59.90) have been obtained by assuming that a collision produces no change in the angular momentum of the relative emitter-perturber motion. This corresponds to the assumption of a common trajectory in semiclassical theory, and means that the total angular momentum of the emitter-perturber system is not conserved. This assumption is removed in the derivation of the more general expressions given in the following sections.

59.4.2 Broadening by Electrons

Different coupling schemes can be used to describe the emitter-perturber collision. For LS coupling,

$$
\chi_j M_j \Rightarrow \chi_j^0 L_j M_j S M_S , \quad j = i, i', f, f' , \tag{59.91}
$$

in (59.81), where χ_j^0 denotes all other quantum numbers required to describe state j that do not change during the collision. Then

$$
\left| L_j M_j S M_S l m \frac{1}{2} m_s \right\rangle = \sum_{L_j^T M_j^T S^T M_S} C_{M_j m M_S^T}^{L_j l L_j^T} C_{M_S m_s M_S^T}^{S \frac{1}{2} S^T}
$$

$$
\times \left| L_j S l \frac{1}{2} L_j^T M_j^T S^T M_S^T \right\rangle , \tag{59.92}
$$

where $C_{m_1 m_2 m_3}^{j_1 j_2 j_3}$ is a vector coupling coefficient, the superscript T denotes quantum numbers of the emitter-perturber system, and $\frac{1}{2}$, m_s are the spin quantum numbers of the scattered electron. On using (59.92),

(59.90) is replaced by

$$
\begin{aligned}
\langle\!\langle i'f'^* \,\|\, \boldsymbol{w}+\mathrm{i}\boldsymbol{d} \,\|\, if^*\rangle\!\rangle &= \pi\,(\hbar/m_{\mathrm e})^2 N \\
&\times \sum_{L_i^T L_f^T S^T ll'} (-1)^{L_i+L_{i'}+l+l'}\left(2L_i^T+1\right)\left(2L_f^T+1\right) \\
&\times \frac{(2S^T+1)}{2\,(2S+1)}\left\{\begin{array}{ccc} L_f^T & L_i^T & 1 \\ L_i & L_f & l \end{array}\right\}\left\{\begin{array}{ccc} L_f^T & L_i^T & 1 \\ L_{i'} & L_{f'} & l' \end{array}\right\} \\
&\times \int_0^\infty \frac{1}{v} f_{\mathrm e}(v)\,\mathrm dv\Big[\delta_{l'l}\delta_{L_{i'}L_i}\delta_{L_{f'}L_f} \\
&- S_I\left(L_{i'}Sl'\tfrac{1}{2}L_i^T S^T; L_i Sl\tfrac{1}{2}L_i^T S^T\right) \\
&\times S_F^*\left(L_{f'}Sl'\tfrac{1}{2}L_f^T S^T; L_f Sl\tfrac{1}{2}L_f^T S^T\right)\Big]\,,
\end{aligned}
$$
(59.93)

where, for an isolated line, the width and shift are given by (59.93) with $L_{i'}=L_i$ and $L_{f'}=L_f$. For hydrogenic systems, where states i, i' and f, f' with different angular momenta are degenerate, a logarithmic divergence occurs for large values of l and l' [cf. Eq. (59.74)], and must be removed by using (59.75) and (59.86).

If a jj coupling scheme is used $\chi_j M_j \Rightarrow \chi_j^0 J_j M_j$, $j=i, i', f, f'$ in (59.81), and

$$
\left|J_j M_j l m\tfrac{1}{2}m_s\right\rangle = \sum_{J_j^T M_j^T jm'} C_{M_j m' M_j^T}^{J_j j J_j^T} C_{mm_s m'}^{l\frac{1}{2}j}\left|J_j lj J_j^T M_j^T\right\rangle\,,
$$
(59.94)

then (59.93) becomes

$$
\begin{aligned}
\langle\!\langle i'f'^* \,\|\, \boldsymbol{w}+\mathrm{i}\boldsymbol{d} \,\|\, if^*\rangle\!\rangle &= \pi\,(\hbar/m_{\mathrm e})^2 N \\
&\times \sum_{J_i^T J_f^T jj'll'} (-1)^{J_i+J_{i'}+2J_f^T+j+j'}\tfrac{1}{2}(2J_i^T+1)(2J_f^T+1) \\
&\times\left\{\begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_i & J_f & j \end{array}\right\}\left\{\begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_{i'} & J_{f'} & j' \end{array}\right\} \\
&\times \int_0^\infty \frac{1}{v} f_{\mathrm e}(v)\,\mathrm dv\Big[\delta_{l'l}\delta_{j'j}\delta_{J_{i'}J_i}\delta_{J_{f'}J_f} \\
&- S_I(J_{i'}l'j'J_i^T; J_i ljJ_i^T)\,S_F^*(J_{f'}l'j'J_f^T; J_f ljJ_f^T)\Big]\,,
\end{aligned}
$$
(59.95)

where $J_{i'}=J_i$ and $J_{f'}=J_f$ for an isolated line. If the spectrum of the emitter is classified using LS coupling,

it is often sufficient to use energies defined by

$$
E_{L_j S} = \sum_{J_j} \frac{(2J_j+1)}{(2L_j+1)(2S_j+1)} E_{L_j S J_j}\,,
$$
(59.96)

and obtain the S-matrix elements in an LS coupling scheme. They are then transformed to jj coupling by using the algebraic transformation

$$
\begin{aligned}
S&\left(J_{j'}l'j'J_j^T; J_j ljJ_j^T\right) \\
&= [(2J_j+1)(2J_{j'}+1)(2j+1)(2j'+1)]^{1/2} \\
&\times \sum_{L_j^T S^T} (2L_j^T+1)(2S^T+1) \\
&\times\left\{\begin{array}{ccc} L_j & l & L_j^T \\ S & \frac{1}{2} & S^T \\ J_j & j & J_j^T \end{array}\right\}\left\{\begin{array}{ccc} L_{j'} & l' & L_j^T \\ S & \frac{1}{2} & S^T \\ J_{j'} & j' & J_j^T \end{array}\right\} \\
&\times S\left(L_{j'}Sl'\tfrac{1}{2}L_j^T S^T; L_j Sl\tfrac{1}{2}L_j^T S^T\right)\,,
\end{aligned}
$$
(59.97)

and introducing the splitting of the fine structure components in (59.4) or (59.6). If in LS coupling the line is isolated, but nevertheless the broadened fine structure components overlap significantly, then the interference terms in (59.6) must be included.

59.4.3 Broadening by Atoms

The formal result is very similar to (59.95), but in this case, the relative motion only gives rise to orbital angular momentum. Thus

$$
\begin{aligned}
\langle\!\langle i'f'^* \,\|\, \boldsymbol{w}+\mathrm{i}\boldsymbol{d} \,\|\, if^*\rangle\!\rangle &= \pi\,(\hbar/\mu)^2 N \\
&\times \sum_{J_i^T J_f^T ll'} (-1)^{J_i+J_{i'}+2J_f^T+l+l'}(2J_i^T+1)(2J_f^T+1) \\
&\times\left\{\begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_i & J_f & l \end{array}\right\}\left\{\begin{array}{ccc} J_f^T & J_i^T & 1 \\ J_{i'} & J_{f'} & l' \end{array}\right\} \\
&\times \int_0^\infty \frac{1}{v} f(v)\,dv\Big[\delta_{l'l}\delta_{J_{i'}J_i}\delta_{J_{f'}J_f} \\
&- S_I\left(J_{i'}l'J_i^T; J_i lJ_i^T\right) S_F^*\left(J_{f'}l'J_f^T; J_f lJ_f^T\right)\Big]\,.
\end{aligned}
$$
(59.98)

For many cases of practical interest, transitions of type $J_i \to J_f$ are isolated and so have line profiles given by (59.3), (59.10), and (59.98), where $J_i=J_{i'}$ and $J_f=J_{f'}$ [59.14]. In order to obtain the S-matrix elements in

(59.98), it is usually sufficient to use adiabatic potentials for the emitter-perturber system that have been calculated neglecting fine structure. Since T is typically a few hundred degrees, only coupling between adiabatic states that tend to the appropriate separated-atom limit are retained in the scattering problem. The coupled scattering equations are then solved with fine structure introduced by applying an algebraic transformation to the adiabatic potentials, and using the observed splittings of the energy levels. The Born–Oppenheimer approximation is valid, and details are given in [59.23].

59.5 One–Perturber Approximation

59.5.1 General Approach and Utility

If only one perturber is effective in producing broadening, $I(\omega)$ can be obtained by considering a dipole transition between initial and final states I and F of the emitter-perturber system. Then $P(\omega)$ is given by (59.2), where

$$I(\omega) = \left[\delta(\omega - \omega_{IF}) \langle\!\langle IF^* | \boldsymbol{\Delta} | IF^* \rangle\!\rangle \right]_{av} ,$$
$$\hbar\omega_{IF} = E_I - E_F , \tag{59.99}$$

and av denotes an average over states I and a sum over states F [59.9]. Wave functions Ψ_J are given by

$$\Psi_J(\boldsymbol{r}, \boldsymbol{R}) = \mathcal{O} \sum_j \psi_j(\boldsymbol{r}) \phi(\boldsymbol{k}_j, \boldsymbol{k}_{j_0}; \boldsymbol{R}) , \tag{59.100}$$

where $J = I, F$, and $\mathcal{O}$ is an operator that takes account of any symmetry properties of the emitter-perturber system. The energies E_I and E_F are given by (59.82). The perturber wave functions for initial state j_0 and final state j are expanded in the form

$$\phi(\boldsymbol{k}_j, \boldsymbol{k}_{j_0}; \boldsymbol{R}) = 2\pi i \sum_{l_{j_0} m_{j_0} l_j m_j} i^{l_{j_0}} k_{j_0}^{-1/2} Y_{l_{j_0} m_{j_0}}^* (\hat{\boldsymbol{k}}_{j_0})$$
$$\times Y_{l_j m_j}(\hat{\boldsymbol{R}}) \frac{1}{R} F(\Gamma_j, \Gamma_{j_0}; R) \tag{59.101}$$

where Γ_j denotes a channel characterized by

$$\Gamma_j = \chi_j M_j l_j m_j , \quad j = 0, 1, 2, \dots , \tag{59.102}$$

[see Eq. (59.81)]. In (59.101), the radial perturber wave function has the limiting forms

$$F(\Gamma_j, \Gamma_{j_0}; R) \overset{R \to 0}{\underset{\sim}{}} R^{l_j + 1}$$
$$\overset{R \to \infty}{\underset{\sim}{}} k_j^{-1/2} \left[\delta_{\Gamma_j \Gamma_{j_0}} \exp(-i\theta_j) - S_J(\Gamma_j; \Gamma_{j_0}) \exp(i\theta_j) \right] , \tag{59.103}$$

with

$$\theta_j = k_j R - \frac{1}{2} l_j \pi - \frac{z}{k_i} \ln(2k_j R)$$
$$+ \arg \Gamma\left(l_j + 1 + i\frac{z}{k_j} \right) ,$$
$$z = \frac{\mu q^2}{\hbar^2} Z_e Z_p . \tag{59.104}$$

The coupled equations obtained by using (59.12), (59.13), (59.100), and (59.101), where

$$\Psi(\boldsymbol{r}, \boldsymbol{R}, t) = \Psi_J(\boldsymbol{r}, \boldsymbol{R}) \exp(-iE_J t/\hbar) , \tag{59.105}$$

are integrated to give functions $F(\Gamma_j, \Gamma_{j_0}; R)$. Using (59.100) and (59.101), (59.99) becomes

$$I(\omega) = \frac{1}{2} N \sum_{\Gamma_{i_0} \Gamma_i \Gamma_{i'} \Gamma_{f_0} \Gamma_f \Gamma_{f'}} u_{i_0} \langle\!\langle \Gamma_i \Gamma_f^* | \boldsymbol{\Delta} | \Gamma_{i'} \Gamma_{f'}^* \rangle\!\rangle$$
$$\times \int_0^\infty \frac{1}{v} f(v) \, dv \, \mathcal{F}(\Gamma, v) , \tag{59.106}$$

where

$$\mathcal{F}(\Gamma, v) = \int_0^\infty F^*(\Gamma_i, \Gamma_{i_0}; R) F(\Gamma_f, \Gamma_{f_0}; R) \, dR$$
$$\times \int_0^\infty F(\Gamma_{i'}, \Gamma_{i_0}; R) F^*(\Gamma_{f'}, \Gamma_{f_0}; R) \, dR , \tag{59.107}$$

$$u_{i_0} = g_{i_0} \bigg/ \sum_{i'_0} g_{i'_0} , \quad v = \frac{\hbar k_{i_0}}{\mu} . \tag{59.108}$$

The one-perturber approximation is valid when

$$\Delta\omega \equiv |\omega - \omega_{if}| \gg w ; \quad V \gg \bar{V} , \tag{59.109}$$

where V is the effective interaction potential required to produce a shift $\Delta\omega$. In the center of the line, many-body effects are always important and the one-perturber approximation diverges as $\Delta\omega \to 0$. In many cases, there

is a region of overlap where criteria (59.1) and (59.109) are all valid, but when $\Delta\omega\tau \gg 1$, (59.99) is a static approximation, since the average time between collisions is $\Delta\omega^{-1}$.

59.5.2 Broadening by Electrons

If LS coupling is used, definition of channel Γ_j in (59.104) is replaced by

$$\Gamma_j = L_j S l_j \frac{1}{2} L_j^T S^T , \quad j = i_0, i, i', f_0, f, f' , \tag{59.110}$$

[cf. (59.91) and (59.92)]. Then assuming that the weights u_{i_0} of all the levels i_0 that effectively contribute to the line are the same, (59.106) becomes

$$
I(\omega) = \frac{1}{2} N_e \sum_{\substack{\Gamma_{i_0}\Gamma_i\Gamma_{i'} \\ \Gamma_{f_0}\Gamma_f\Gamma_{f'}}} \langle\!\langle L_i S\left(L_f S\right)^* \|\mathbf{\Delta}\| L_{i'} S\left(L_{f'} S\right)^* \rangle\!\rangle
$$

$$
\times \delta_{l_i l_f}\delta_{l_{i'} l_{f'}}\delta_{L_{i_0}^T L_i^T}\delta_{L_{f_0}^T L_f^T}\delta_{L_{i_0}^T L_{i'}^T}\delta_{L_{f_0}^T L_{f'}^T}
$$

$$
\times (-1)^{L_i+L_{i'}+l_i+l_{i'}} \frac{(2S^T+1)}{2(2S+1)}
$$

$$
\times \left(2L_i^T+1\right)\left(2L_f^T+1\right)
$$

$$
\times \begin{Bmatrix} L_f^T & L_i^T & 1 \\ L_i & L_f & l \end{Bmatrix}\begin{Bmatrix} L_f^T & L_i^T & 1 \\ L_{i'} & L_{f'} & l_{i'} \end{Bmatrix}
$$

$$
\times \int_0^\infty \frac{1}{v} f_e(v)\, \mathrm{d}v\, \mathcal{F}\left(\Gamma, v\right) , \tag{59.111}
$$

where $\mathcal{F}\left(\Gamma, v\right)$ is defined by (59.107) and (59.111). If the functions $F\left(\Gamma_{j'}, \Gamma_{j_0}; R\right)$ in (59.107) are replaced by their asymptotic forms (59.103), then

$$
\mathcal{F}\left(\Gamma, v\right) \simeq \Delta\omega^{-2}\left(\hbar/m_e\right)^2
$$

$$
\times \left[\delta_{\Gamma_{i_0}\Gamma_i}\delta_{\Gamma_{f_0}\Gamma_f} - S_I\left(\Gamma_i; \Gamma_{i_0}\right)S_F^*\left(\Gamma_f; \Gamma_{f_0}\right)\right]
$$

$$
\times \left[\delta_{\Gamma_{i_0}\Gamma_{i'}}\delta_{\Gamma_{f_0}\Gamma_{f'}} - S_I^*\left(\Gamma_{i'}; \Gamma_{i_0}\right)S_F\left(\Gamma_{f'}; \Gamma_{f_0}\right)\right] . \tag{59.112}
$$

On substituting (59.112) into (59.111), summing over Γ_{i_0} and Γ_{f_0} and using the unitary property of the S-matrix,

$$
I(\omega)
$$
$$
= \frac{1}{\pi\Delta\omega^2}\sum_{L_i^T L_f^T S^T ll'} \langle\!\langle L_i S\left(L_f S\right)^* \|\mathbf{\Delta}\| L_{i'} S\left(L_{f'} S\right)^* \rangle\!\rangle
$$

$$
\times \langle\!\langle i'f'^* \|\mathbf{w}\| if^* \rangle\!\rangle , \tag{59.113}
$$

where $\langle\!\langle i'f'^* \|\mathbf{w}\| if^* \rangle\!\rangle$ is given by (59.93). Line shape (59.113) is identical to that obtained from (59.6) when $\Delta\omega \gg w$. If the jj coupling scheme specified by (59.94) is used, and channel Γ_j is defined by

$$\Gamma_j = J_j l_j j_j J_j^T , \quad j = i_0, i, i', f_0, f, f' , \tag{59.114}$$

Equation (59.106) becomes [cf. (59.95)]

$$
I(\omega)
$$
$$
= \frac{1}{2} N_e \sum_{\substack{\Gamma_{i_0}\Gamma_i\Gamma_{i'} \\ \Gamma_{f_0}\Gamma_f\Gamma_{f'}}} \langle\!\langle J_i\left(J_f\right)^* \|\mathbf{\Delta}\| J_{i'}\left(J_{f'}\right)^* \rangle\!\rangle
$$

$$
\times \delta_{l_i l_f}\delta_{l_{i'} l_{f'}}\delta_{j_i j_f}\delta_{j_{i'} j_{f'}}\delta_{J_{i_0}^T J_i^T}\delta_{J_{f_0}^T J_f^T}\delta_{J_{i_0}^T J_{i'}^T}\delta_{J_{f_0}^T J_{f'}^T}
$$

$$
\times (-1)^{J_i+J_{i'}+2J_f^T+j_i+j_{i'}}
$$

$$
\times \frac{1}{2}\left(2J_i^T+1\right)\left(2J_f^T+1\right)
$$

$$
\times \begin{Bmatrix} J_f^T & J_i^T & 1 \\ J_i & J_f & j_i \end{Bmatrix}\begin{Bmatrix} J_f^T & J_i^T & 1 \\ J_{i'} & J_{f'} & j_{i'} \end{Bmatrix}
$$

$$
\times \int_0^\infty \frac{1}{v} f_e(v)\, \mathrm{d}v\, \mathcal{F}\left(\Gamma, v\right) , \tag{59.115}
$$

where $\mathcal{F}\left(\Gamma, v\right)$ is given by (59.107) and (59.114).

59.5.3 Broadening by Atoms

In the wings of a line where $\hbar|\Delta\omega| \simeq \left|E_{J_i} - E_{J_{i'}}\right|$, $j = i_0, i, i', f_0, f, f'$, coupling between the fine structure levels is important. If channel Γ_j is defined by

$$\Gamma_j = J_j l_j J_j^T , \quad j = i_0, i, i', f_0, f, f' , \tag{59.116}$$

Equation (59.106) becomes [cf. (59.115)]

$$
I(\omega) = \frac{1}{2} N \sum_{\substack{\Gamma_{i_0}\Gamma_i\Gamma_{i'} \\ \Gamma_{f_0}\Gamma_f\Gamma_{f'}}} \langle\!\langle J_i\left(J_f\right)^* \|\mathbf{\Delta}\| J_{i'}\left(J_{f'}\right)^* \rangle\!\rangle
$$

$$
\times \delta_{l_i l_f}\delta_{l_{i'} l_{f'}}\delta_{J_{i_0}^T J_i^T}\delta_{J_{f_0}^T J_f^T}\delta_{J_{i_0}^T J_{i'}^T}\delta_{J_{f_0}^T J_{f'}^T}
$$

$$
\times (-1)^{J_i+J_{i'}+2J_f^T+l_i+l_{i'}}\left(2J_i^T+1\right)\left(2J_f^T+1\right)
$$

$$
\times \begin{Bmatrix} J_f^T & J_i^T & 1 \\ J_i & J_f & l_i \end{Bmatrix}\begin{Bmatrix} J_f^T & J_i^T & 1 \\ J_{i'} & J_{f'} & l_{i'} \end{Bmatrix}
$$

$$
\times \int_0^\infty \frac{1}{v} f(v)\, \mathrm{d}v\, \mathcal{F}\left(\Gamma, v\right) , \tag{59.117}
$$

where $\mathcal{F}\left(\Gamma, v\right)$ is given by (59.107) and (59.116). In the far wings, where $\hbar|\Delta\omega| \gg \left|E_{J_i} - E_{J_{i'}}\right|$, $j = i_0, i, i', f_0, f, f'$, an adiabatic approximation is valid.

Adiabatic states of the diatomic molecule formed by the emitter-perturber system are considered in which the total spin is assumed to be decoupled from the total orbital angular momentum of the electrons. The coupling between rotational and electronic angular momentum can also be neglected, because typically, contributions to the line profile come from $0 \leq l_j \lesssim 400$, whereas $\Lambda_j \lesssim 2$. Therefore, transitions take place between channels defined by

$$\Gamma_j = \Lambda_j L_j S L_j , \quad j = i, f , \tag{59.118}$$

where the unperturbed emitter in state j has quantum numbers $L_j S$, the quantum number Λ_j represents the projection of the orbital angular momentum on the internuclear axis, and (59.100) is replaced by

$$\Psi_J (\mathbf{r}, \mathbf{R}) = \mathcal{O} \sum_j \psi_j (\mathbf{r}; \mathbf{R}) \, \phi \left(k_j, k_{j_0}; \mathbf{R} \right) , \tag{59.119}$$

where $k_j = k_{j_0}$ and $\psi_j (\mathbf{r}; R)$ is the wave function for molecular state Λ_j. In (59.119), the only molecular states retained are those that correlate with emitter states i and f. The scattering is described by

$$\left[\frac{d^2}{dR^2} - \frac{l_j (l_j + 1)}{R^2} - \frac{2z}{R} - \frac{2\mu}{\hbar^2} V_{\Lambda_j} (R) + k_j^2 \right]$$
$$\times F_j (R) = 0 , \tag{59.120}$$

where $k_j = k_{j_0}$ and

$$F_j (R) = P_{v_j l_j} (R) \text{ or}$$
$$F_j (R) \equiv F \left(\Gamma_j, \Gamma_j; R \right) = F_{k_i l_i} (R) \tag{59.121}$$

for vibrational or free states, respectively, and $V_{\Lambda_j} (R)$ is the potential energy of state Λ_j. Free–free transitions always contribute to the line profile, but bound-free and free-bound transitions only contribute on the red and blue wings, respectively. On using (59.82), (59.99), and (59.109), $\hbar \Delta \omega = \varepsilon_i - \varepsilon_f$, and ε_j becomes the energy of bound state j with vibrational quantum number v_j when $\varepsilon_j < 0$. If

$$\mathcal{G} \left(\Gamma, \varepsilon_i, \varepsilon_f \right) \equiv \left| \int_0^\infty F_i^* (R) \, \bar{\Delta} (R) \, F_f (R) \, dR \right|^2 \tag{59.122}$$

[*cf.* (59.107)], where

$$\bar{\Delta} (R) = -q \int \psi_i^* (\mathbf{r}; \mathbf{R}) \, \mathbf{r} \, \psi_f (\mathbf{r}; \mathbf{R}) \, d\mathbf{r} \tag{59.123}$$

is the dipole moment, then using (59.119)), the free–free contribution is given by

$$I_0 (\omega) = \frac{N}{2} \sum_{\Gamma_i \Gamma_f} u_{\Lambda_i} \delta_{l_i l_f} (2l_i + 1)$$
$$\times \int_0^\infty \frac{f(v)}{v} \, dv \, \mathcal{G}(\Gamma, \varepsilon_i, \varepsilon_f) , \tag{59.124}$$

where $\varepsilon_i = \frac{1}{2} \mu v^2$, and u_{Λ_i} is the relative weight of state Λ_i [*cf.* Eqs. (59.106)–(59.108)]. The bound-free contribution is

$$I_1 (\omega) = \frac{N}{2} \sum_{\Gamma_i \Gamma_f} u_{\Lambda_i} \delta_{l_i l_f} (2l_i + 1)$$
$$\times \sum_i g (\varepsilon_i) \, \mathcal{G} \left(\Gamma, \varepsilon_i, \varepsilon_f \right) \tag{59.125}$$

and the free–bound contribution is

$$I_2 (\omega) = \frac{1}{2} N \sum_{\Gamma_i \Gamma_f} u_{\Lambda_i} \delta_{l_i l_f} (2l_i + 1) \exp \left(-\frac{\hbar \Delta \omega}{k_B T} \right)$$
$$\times \sum_f g (\varepsilon_f) \, \mathcal{G} \left(\Gamma, \varepsilon_i, \varepsilon_f \right) , \tag{59.126}$$

where

$$g(\varepsilon) = 2\pi \left(\frac{\hbar}{\mu} \right)^2 \frac{f(v)}{v^2}$$
$$= 8\pi^2 \left(\frac{\hbar}{\mu} \right)^2 \left(\frac{\mu}{2\pi k_B T} \right)^{3/2} \exp \left(-\frac{\varepsilon}{k_B T} \right) , \tag{59.127}$$

on using (59.21) with $\varepsilon = \frac{1}{2} \mu v^2$. The full line profile is then given by (59.124)–(59.126), so that

$$I (\omega) = \sum_{j=0}^2 I_j (\omega) . \tag{59.128}$$

The satellite features that are often seen in line wings arise because turning points in the difference potential $\left[V_{\Lambda_i} (R) - V_{\Lambda_f} (R) \right]$ produce a phenomenon analogous to the formation of rainbows in scattering theory. The JWKB approximation is often used for the functions $F_{k_j l_j} (R)$, and can be shown to lead to the correct static limit in which transitions take place at fixed values of R called 'Condon points', i.e., the Franck–Condon principle is valid. Further details are given in [59.9, 10, 24–26].

59.6 Unified Theories and Conclusions

The pressure broadening of spectral lines is in general a time-dependent many-body problem and as such cannot be solved exactly. After all, even the problem of two free electrons scattered by a proton is still a subject of active research. There is no practical theory that leads to the full static profile in the limit of high density (or low temperature) and to the full impact profile in the limit of low density (or high temperature). As with so many problems in physics, it is the intermediate problem that is intractable because no particular feature can be singled out as providing a weak perturbation on a known physical situation. However, much progress has been made over the last thirty years in developing theories that take into account many of the key features of the intermediate problem and they are often successful in predicting line profiles for practical applications [59.8–10, 24–26].

More recently, time-dependent many-body problems have been tackled using computer-oriented approaches that invoke Monte Carlo and other simulation methods to study line broadening in dense, high-temperature plasmas, see for example [59.27]. In this chapter, the emphasis has been on aspects of the subject that relate directly to electron-atom and low-energy atom–atom scattering. Many experts in the fields of electron–atom and atom–atom collisions are still not exploiting the direct applicability of their work to line broadening. It is hoped that this contribution will encourage more research workers to study these fascinating problems that not only provide links with plasma physics and in particular with the physics of fusion plasmas, but also with a quite distinct body of laboratory-based experimental data.

Scattering

Part E

Part E Scattering Experiments

60. Photodetachment

Investigations of photon–ion interactions have grown rapidly over the past few decades due primarily to the increased availability of laser and synchrotron light sources. At photon energies below about 1 keV the dominant radiative process is the electric dipole induced photoelectric effect. In the gaseous phase the photoelectric effect is referred to as either photoionization (atoms and positive ions) or photodetachment (negative ions). This chapter reviews developments in the field of photodetachment that have taken place over the past decade. The focus will be on accelerator-based investigations of the photodetachment of atomic negative ions. The monographs of *Massey* [60.1] and *Smirnov* [60.2] offer a good introduction to the subject of negative ions. Recent reviews of negative ions and photodetachment include those of *Bates* [60.3], *Buckman* and *Clark* [60.4], *Blondel* [60.5], *An-*

dersen [60.6], *Andersen* et al. [60.7] and *Bilodeau* and *Haugen* [60.8].

60.1 Negative Ions

Interest in negative ions stems from the fact that their structure and dynamics are qualitatively different from those of isoelectronic atoms and positive ions. This can be traced to the nature of the force that binds the outermost electron. In the case of atoms and positive ions, the outermost electron moves asymptotically in the long range Coulomb field of the positively charged core. The relatively strong $1/r$ potential is able to support an infinite spectrum of bound states that converge on the ionization limit. In contrast, the outermost electron in a negative ion experiences the short-range induced-dipole field of the atomic core. The relatively weak $1/r^4$ polarization potential is shallow and typically can only support a single bound state. The weakness of the binding is reflected in the magnitudes of electron affinities of atoms, which are numerically equal to the binding energies of the outermost electron in the corresponding negative ion. Electron affinities are typically an order of magnitude smaller than the ionization energies of

atoms. Excited bound states of negative ions are rare. With the possible exception of Os^-, all such states that exist have the same configuration, and therefore parity, as the ground state. A rich spectrum of unbound excited states, however, are associated with most ions. These discrete states are embedded in the continua lying above the first detachment limit.

Electron correlation plays an important role in determining the structure and dynamics of many-electron systems [60.9]. Weakly bound systems such as negative ions are ideally suited for investigations of the effects of correlation. As a result of the more efficient shielding of the nucleus by the atomic core, the electron–electron interactions become relatively more important than the electron-nucleus interaction in negative ions. The goal of photodetachment experiments is to measure, in high resolution, correlation-sensitive quantities such as electron affinities and the energies and widths of resonant states. These quantities

provide sensitive tests of the ability of theorists to incorporate electron correlation into their calculations. The stimulating interplay between experiment and

theory continues to help elucidate the role of many-electron effects in the structure and dynamics of atomic systems.

60.2 Photodetachment

Essentially all information about the structure and dynamics of negative ions comes from controlled experiments in which electrons are detached from the ions when they interact with photons or other particles. Photodetachment is the preferred method of studying negative ion structure and dynamics since the energy resolution associated with such measurements is typically much higher than that attainable in any particle-induced detachment process. Generally, one or more electrons are detached from a negative ion following the absorption of one or more photons in the photodetachment process. Most measurements to date, however, involve the simplest process of single electron detachment following single photon absorption. Cross sections for this process start at zero at threshold, rise to a maximum a few eV above threshold and then decrease monotonically. Photodetachment cross sections at their maximum have a typical magnitude of ≈ 10–100 Mb. Threshold behavior and resonance structure in detachment cross sections are of particular interest since they both involve a high degree of correlation between the electrons.

60.2.1 Threshold Behavior

Cross sections for photodetachment are zero at threshold, in contrast to the finite value characteristic of photoionization cross sections. The threshold behavior is determined by the dynamics of two particles in the final continuum state. The Wigner law [60.10] governs the energy dependence of the near-threshold cross section for the photodetachment of a single electron from an atomic negative ion. The Wigner law can be written as

$$\sigma = Ak^{2l+1} = B(E - E_t)^{l+1/2} , \qquad (60.1)$$

where k represents the wavenumber of the detached electron, $(E - E_t)$ is the excess energy of the electron above threshold and l is the smallest value of the orbital angular momentum quantum number. As a result of the electric dipole selection rules, the detached electron is represented, in general, by two

partial waves with $l = l_0 + 1$ and $l_0 - 1$, where l_0 is the angular momentum of the bound electron in the negative ion prior to detachment. Wigner demonstrated that for a two-body final state the near-threshold cross section depends only on the dominant long-range interaction between the two product particles. In the case of photodetachment involving electrons with $l > 0$, this contribution arises from the centrifugal force. Shorter-range interactions, such as the polarization force, will not change the form of the threshold behavior but they will limit the range of validity of the Wigner law. There is no a priori way of determining the range of validity of the Wigner law in any particular experiment. It depends on the strengths of short-range interactions. Measured threshold data is usually fit to the Wigner law in order to determine the threshold energy. In principle, it is possible to extend the range of the fit beyond that of the Wigner law. *O'Malley* [60.11], for example, considered the effects of multipole forces on threshold behavior. O'Malley's formalism, however, does not treat polarization explicitly. This is, however, accounted for in the modified effective range theory of *Watanabe* and *Greene* [60.12]. Recently, *Sandstroem* et al. [60.13] have used a modified effective range theory to fit photodetachment data taken at excited state thresholds of the alkali-metal atoms, Li and K. In these cases the dipole polarizability is very high and consequently the range of validity of the Wigner law is correspondingly small.

60.2.2 Resonance Structure

Negative ion resonances correspond to states in which an electron and an atom are transiently associated. Such states are the subject of a review by *Buckman* and *Clark* [60.4]. In photodetachment they arise when more than one electron, or a core electron, is excited. These unbound discrete states are embedded in the continua above the first detachment limit and are therefore subject to decay via the spontaneous process of autodetachment. The allowed autodetachment process is induced by the relatively strong electrostatic interaction

between the outermost electrons. This process causes discrete continuum states to be very short lived. If the selection rules on the allowed Coulomb-induced autodetachment process are violated, however, the state may live much longer. Metastable states eventually decay via autodetachment processes induced by the weaker magnetic interactions. The He^- ion is the prototypical metastable negative ion. It is formed in the spin-aligned $1s2s2p\ ^4P^0$ state when an electron attaches itself to a He atom in the metastable $1s2s\ ^3S$. It is bound by 77.516 meV [60.14]. The decay of a discrete state in the continuum by autodetachment is manifested as a resonance structure in the detachment cross section. The shape of a resonance is determined by the interference between the two pathways for reaching the same final continuum state: direct detachment and detachment via the discrete state embedded in the continuum. A resonance can be parametrized by fitting it to a *Fano* [60.15] or *Shore* profile [60.16]. The energy and width of the discrete continuum state are extracted from the fit.

60.3 Experimental Procedures

60.3.1 Production of Negative Ions

Negative ions are created in exoergic attachment processes when an electron is captured by an atom or molecule. These quantum systems are weakly bound with diffuse outer orbitals. As a consequence, they are easily destroyed in collisions with other particles. Due to their fragility they are rarely observed in bulk matter. The production of negative ions with a density sufficiently high for spectroscopic studies poses a challenge to the experimentalist since processes involved in their creation must compete with more probable destruction processes. The most versatile source of production of negative ions for accelerator-based experiments is the Cs sputter ion source [60.19]. This source has been used to generate a wide variety of atomic, molecular, and cluster negative ions.

Negative ions can be produced and maintained in ion traps [60.20]. In this case, the ions are produced inside the trap by electron-induced dissociative attachment collisions and photodetachment is investigated by monitoring the depletion of the negative ions. The most commonly used source for spectroscopic studies of negative ions is, however, a beam produced by an accelerator. In an accelerator-based apparatus the ions

60.2.3 Higher Order Processes

With the advent of high power, pulsed lasers it became possible to observe multiphoton detachment. In this process a single electron is ejected following the absorption of two or more photons. Early work in this area has been reviewed by *Crance* [60.17], *Davidson* [60.18] and *Blondel* [60.5]. More recently, Haugen and coworkers have used two photon E1 transitions to determine fine structure splittings in the ground state of negative ions and to measure the binding energies of excited states of negative ions that have the same parity as the ground state. *Bilodeau* and *Haugen* [60.8] have reviewed these measurements.

Multielectron detachment involves the detachment of two or more electrons following the absorption of a single photon. This process, which appears to be initiated by the detachment of an inner shell electron, requires photons with energies higher than can be generated by lasers. Such measurements can be performed at synchrotron radiation sites.

are extracted from the ion source and focused to form a collimated beam that is accelerated to a desired energy, typically 1–10 keV. Mass analysis of the ions is used to produce an elementally and isotopically pure beam that is essentially mono–energetic and unidirectional. The directed particles then drift to the interaction region through a beam line that is maintained at low pressure to minimize destructive collisions between the ions and the residual gas. Recently, negative ions have been injected into storage rings. In this case the ions make repeated passes through the interaction region. The enhanced luminosity associated with multiple-pass experiments makes it possible to investigate relatively rare processes that would be impossible in single-pass experiments.

60.3.2 Interacting Beams

The well-defined spatial dimensions of an ion beam readily permit an efficient overlap with a beam of photons. The two interacting beams are most often mated in either crossed or collinear beam geometries. The choice of geometry is typically determined by the types of particles to be detected, the detection geometry to be used, and the level of sensitivity and resolution required in

the experiment. The crossed beam arrangement is best suited for spectroscopic studies of the photoelectrons ejected following photodetachment, since the electrons can most easily be collected from a spatially well defined interaction region. In a collinear beam arrangement it is better to detect the residual heavy particles produced in the photodetachment process since they all travel in the same direction, the direction of motion of the ion beam, and can be collected with high efficiency. Both the sensitivity and energy resolution attainable using a collinear beam apparatus are typically much higher than for a crossed beam apparatus. Nowadays, most experiments employ an apparatus in which the photon and ions are collinearly merged and the present chapter will focus on this arrangement. Figure 60.1 shows a typical collinear beam apparatus that was designed by *Hanstorp* [60.21]. The signal is enhanced when the photon and ion beams are collinearly merged due to the extended interaction region and the high collection and detection efficiencies of the heavy residual particles. The major source of background noise in collinear beam experiments is associated with the production of atoms or positive ions by collisions of the beam ions with the atoms or molecules of the residual gas in the vacuum chamber. By maintaining a high vacuum, typically 10^{-9} mTorr or better, one can keep the background contribution to a tolerable level. In interacting beam experiments involving the detection of the heavy residual particles, the energy resolution that is attainable is usually limited by kinematic broadening. The amount of broadening is determined by the properties of the ion and photon beams and how they are overlapped. The longitudinal velocity distribution of the ions in a beam is compressed when the ions undergo acceleration after leaving the ion source [60.22]. If the photon beam is merged collinearly with the "cooled" ion beam, the photons sample the narrowed velocity distribution, thus significantly reducing the contribution from Doppler broadening. If kinematic broadening is rendered negligible, the energy resolution is usually determined by the bandwidth of the light source.

60.3.3 Light Sources

Since the particle density in the ion beam is typically low, it is important to have a light source that generates an intense beam of photons. In addition, the output of the light source must be tunable. Pulsed lasers are most often used in photodetachment experiments. Their time structure is often used to advantage in time-of-flight schemes to enhance the signal-to-background
Fig. 60.1 A schematic of a collinear laser-negative ion beam apparatus. The quadrupole deflector is used to merge the laser and ion beam in the interaction region. The first laser is used to photodetach electrons from the ions. A second laser beam is directed along the common path of the first laser beam and the ion beam. This laser is used in the state-selective detection scheme based on resonance ionization. The positive ions produced in the sequential interaction of the negative ions with both laser beams and the external electric field are detected in a channel electron multiplier. The directions of the laser beams can be reversed

ratio. The large peak powers characteristic of pulsed lasers are required in multiphoton experiments. Lasers or laser-based sources used in photodetachment experiments span the wavelength range from the ultraviolet to the infrared. Second harmonic generation in a nonlinear crystal is the conventional method of producing UV radiation. The generation of tunable infrared radiation with wavelengths of a few μm has proven to be more difficult. Recently, however, Haugen and coworkers have performed experiments using infrared radiation produced in a laser-pumped Raman conversion cell [60.8]. Commercial optical parametric oscillators are also becoming more readily available. In order to investigate inner shell excitation and detachment pro-

cesses it is necessary to access the VUV or X-ray region. These regions are currently outside the limits of lasers and can only be accessed at synchrotron radiation facilities.

60.3.4 Detection Schemes

Photodetachment events can be monitored by either measuring the attenuation of the negative ions or by detecting the particles (electrons, atoms or positive ions) produced in the breakup of the ion. In accelerator-based measurements the ion beam is too tenuous to be able to monitor attenuation and particle detection must be employed. The heavy residual particles, atoms or positive ions, are usually detected in experiments that employ collinearly merged beams of photons and negative ions. The selectivity and sensitivity of a measurement is improved significantly if the residual particles are state-selectively detected. In the case of residual excited atoms, the method most often employed is based on the use of a second laser to excite the atoms to a state near the ionization limit. This resonance step is followed by electric field ionization. The resulting positive ions constitute the signal.

60.4 Results

There have been several new developments in accelerator-based photodetachment measurements during the past decade. Tunable infrared radiation has been used in single photon and multiphoton experiments. State-selective detection schemes based on resonance ionization have been successfully employed in measurements of thresholds and resonances. The lifetimes of long-lived negative ions have been determined by the use of magnetic storage rings. Synchrotron radiation sources have been instrumental in the pioneering studies of inner shell processes in negative ions.

60.4.1 Threshold Measurements

A measurement of a threshold energy using photodetachment allows one to determine the binding energy of the extra electron in the negative ion or, equivalently, the electron affinity of the parent atom. *Andersen* et al. [60.7] have recently published a review of the methods currently used to measure the binding energies of atomic negative ions. The article includes an up-to-date compilation of recommended electron affinities. The simplest, and potentially the most accurate, method of determining binding energies is the laser photodetachment threshold (LPT) method. In this technique, the normalized yield of residual atoms is recorded as a function of the photon energy in the near-threshold region of the cross section. In most cases, the Wigner law can be fitted to the data and the threshold energy is determined by extrapolation. The Wigner law demonstrates that not all thresholds have the same energy dependence. The most accurate measurements to date involve detachment into an s-wave continuum. In the case of $l = 0$, the threshold energy dependence of $E^{1/2}$ is more pronounced than for cases with $l > 0$. S-wave photodetachment requires that a p-orbital electron be ejected. Haugen and coworkers have used tunable infrared spectroscopy to measure the binding energies of negative ions with open p-shells [60.23–25]. In these experiments the detachment process left the residual atom in its ground state so that state-selective detection was not needed.

Considerable experimental and theoretical effort have gone into investigating the negative ions of the alkaline earth elements since the experimental discovery [60.26] and subsequent theoretical confirmation [60.27] of the existence of a stable Ca^- ion in 1987. Prior to this time it was generally accepted that the closed s-shell configurations of the alkaline earth atoms would inhibit the production of stable negative ions. *Andersen* et al. [60.28] have reviewed progress in this field. *Andersen* and coworkers used the LPT method combined with state-selective detection to determine the binding energies of the negative ions of the heavier alkaline earths Ca^-, Sr^- and Ba^- [60.29–31]. No stable negative ions of Be and Mg have been found, but the Be^- ion is known to be metastable. These heavier ions are weakly bound but tunable infrared sources were not available at the time to detach them into the ground state of the parent atom. Instead, UV radiation was used to access an excited state threshold. In the case of Ca^- the $4s5s\ ^3S$ threshold was used since it allowed access to an s-wave continuum. In order to suppress the background noise in the experiment, the Ca atoms left in this excited state following detachment were selectively detected by a method based on resonance ionization. Before the excited Ca atom could radiatively decay, a second laser was used to induce a transition from the excited state to a high lying Rydberg state. The Rydberg atoms were efficiently

ionized in an electrostatic field applied to the beam. The Ca^+ ion thus produced were used as the signal that, once normalized, was proportional to the photodetachment cross section. The structures of the heavy alkaline earths are very difficult to calculate. Three relatively loosely bound electrons move in the field of a highly polarizable core. Electron correlation and relativistic effects must be included in a theoretical description of their structure. As calculations became more sophisticated it became clear that correlations between the core electrons and between the valence and core electrons had to be taken into account in addition to the correlations between the valence electrons [60.32].

The negative ions of the alkali-metal elements have a closed s-shell configuration. In this case it is necessary to access an excited state threshold in order to detach into an s-wave continuum. Hanstorp and coworkers have used the LPT method combined with state-selective detection to measure the electron affinities of Li [60.33] and K [60.34]. Since accelerator-based measurements involve the use of fast and unidirectional beams of ions, one must take into account Doppler shifts in accurate measurements of threshold energies. In the K^- experiment [60.34], two separate sets of data were accumulated, one with the laser and ion beams co-propagating and the other with them counter-propagating. The Doppler shift can be eliminated to all orders by taking the geometric mean of the measured red-shifted and blue-shifted threshold energies [60.35].

LPT measurements can be used to selectively suppress one isotope relative to other isotopes of the same element, thereby changing the relative abundances from their natural values. This technique could be applied, for example, to the problem of sensitivity enhancement in mass spectrometry by suppressing unwanted isotopic interferences. *Sandstroem* et al. [60.36] recently performed a proof-of-principle experiment using the ^{34}S and ^{32}S isotopes. The goal of the experiment was to enrich the ^{34}S isotope relative to the more abundant ^{32}S isotope. Due to the large differential Doppler shifts associated with the fast moving ions of the two isotopes of different masses, it was possible to selectively photodetach one isotope and leave the other untouched. In this feasibility experiment, the $^{34}S/^{32}S$ ration was enhanced by a factor of > 50 over its natural value. With a better vacuum and the selection of a more suitable laser, it is predicted that the enhancement ratio could be significantly improved. The application of LPT to mass spectrometry clearly has the potential for enhancing the sensitivity in measurements of the abundances of rare and ultra-rare isotopes.

60.4.2 Resonance Parameters

The simplest negative ion is the two-electron H^- ion. This three-body Coulomb system is fundamentally important in our understanding of the role played by electron correlation in atomic structure. The pioneering measurements of the photodetachment of one and two electrons from the H^- ion were performed by *Bryant* and coworkers [60.37–39] several decades ago. The ASTRID (Aarhus storage ring Denmark) heavy ion storage ring has been used in two new measurements of the resonance structure in the vicinity of the $H(n = 2)$ threshold [60.40, 41]. The energy resolution of these storage ring experiments was much higher than that attained in previous experiments. As a consequence, *Andersen* et al. [60.41] were able to observe, for the first time, a second resonance below the $H(n = 2)$ threshold. In principle, the $1/r^2$ dipolar potential should support an infinite series of resonances below each excited state of the H atom [60.42]. Calculations, however, indicate that the series will be truncated after the third member by relativistic and radiative interactions [60.43].

Detachment continua contain a wealth of structure and many measurements of Feshbach resonances in non-hydrogenic negative ions have been reported during the past decade. The dipole polarizability of an atom increases with the degree of excitation, making it easier for electrons to attach to the excited parent atom. Series of Feshbach resonances containing several members are often found below excited state thresholds. Resonances in the photodetachment spectra of the metastable He^- ion [60.44] and the alkali-metal negative ions [60.45–49] have been studied extensively by Hanstorp and coworkers using the collinear beam apparatus shown in Fig. 60.1. R-matrix calculations [60.50–53] have generally been successful in predicting the energies and widths of most of the resonances observed in the experiments. There has been keen interest in the similarities and differences between the photodetachment spectra of Li^- and H^-.

The He^- ion is a metastable negative ion but it is sufficiently long lived to pass from the ion source to the interaction region with relatively little attenuation via autodetachment. Electric dipole selection rules limit photon-induced transitions from the $1s2s2p$ $^4P^0$ ground state to excited states with ^4S, ^4P and ^4D symmetry. The spectra of Feshbach resonances that lie below the $He(n = 3, 4, 5)$ thresholds have been investigated using the collinear beam apparatus shown in Fig. 60.1 [60.44, 54, 55]. Resonance ionization was used to state selectively detect the residual excited He atoms.

Figure 60.2 shows a high resolution spectrum of the resonance structure in the range 3.7–4.0 eV, a range that encompasses the H($n = 4$) thresholds. In this relatively small energy range *Kiyan* et al. [60.44] found many resonances exhibiting a variety of different shapes. The resonances labeled a,c,e are members of the ^{4}P series with dominant configurations of 1s4pnp ($n = 4, 5, 6$). The resonances labeled b,d appear to be the $n = 5, 6$ members of the 1s4sns ^{4}S series.

Recent studies using synchrotron radiation have revealed resonances in photodetachment cross sections in the X-ray and VUV regions that can be associated with the excitation of inner shell electrons. Resonances arising from K-shell excitation in the Li$^-$ ion have been reported by *Kjeldsen* et al. [60.56] and *Berrah* et al. [60.57]. Similarly, resonances were found in a study of He$^-$ [60.58] and C$^-$ [60.59]. Resonances associated with L-shell excitation of the Na$^-$ ion were observed by *Covington* et al. [60.60]. Figure 60.3 shows

Fig. 60.3 Total cross section for the photodetachment of Na$^-$ over the range 30–51 eV. Thresholds are indicated by vertical lines. The peaks are resonances associated with the excitation of a 2p core electron accompanied, in most cases, by the excitation of a 3s valence electron

part of the spectrum in which the dominant feature is a resonance at ≈ 36 eV that arises from the excitation of a pair of electrons – a 2p core electron and a 3s valence electron. Absolute cross sections were measured in most of the experiments. *R*-matrix calculations of the cross sections at energies corresponding to K-shell excitation have successfully accounted for most of the observations [60.61–63].

60.4.3 Lifetimes of Metastable Negative Ions

Heavy ion storage rings are well suited for studies of the radiative or autodetaching decay of long lived excited states of negative ions. They have also been used to investigate the effect of blackbody radiation on weakly bound stable negative ions [60.64]. Andersen and coworkers have used the ASTRID facility to measure the lifetimes of the metastable negative ions Be$^-$ [60.65] and He$^-$ [60.66] against autodetaching decay. The decay rate was measured by simply detecting the neutral atoms produced in the ring as a function of time after injection. The range of autodetaching lifetimes that can be measured in a storage ring depends on the size of the ring and on the destruction rate of the ions by collisional detachment with the residual gas in

Fig. 60.2 Partial cross section for the photodetachment of He$^-$ via the He(1s3p ^{3}P)+e(kp) continuum channel in the energy range 3.73–4.00 eV. The *open circles* represent the measured data. The fits to the sum of Shore profiles are shown by the *solid lines*. The energies of the resonances obtained from the fits are shown as *short vertical lines*. The *inset* shows the region near the He(1s4p ^{3}P) threshold in finer detail

the ring. More recently, *Ellman* et al. [60.67] have used the CRYRING facility (at the Manne Siegbahn Laboratory in Stockholm) to measure the radiative lifetime of a bound excited state of a negative ion. In this proof-of-principle experiment, the lifetime of the $5p^5\,^2P_{1/2}$ level of Te^- was measured to be 0.42(5) s. This value is in excellent agreement with the result of a multi-configuration Dirac Hartree-Fock (MCDHF) calculation. The $J = 1/2$ level radiatively decays to the $J = 3/2$ ground level, primarily via M1 transitions. The idea of the experiment was to monitor the population of the $J = 1/2$ level as a function of time after injection of the Te^- into the ring. This was accomplished by selectively photodetaching ions in the $J = 1/2$ level as the Te^- ions repeatedly passed through the field of a laser beam situated along one arm of the ring. The neutral Te atoms thus produced were used as the signal. Corrections were made for collisionally-induced detachment and repopulation. Data was taken at four different ring pressures. A linear fit to this data yielded the zero-pressure radiative lifetime of the excited $J = 1/2$ level.

60.4.4 Multielectron Detachment

Synchrotron radiation has been used over the past few years in order to study how negative ions respond to the absorption of high-energy photons. Photons in the VUV and X-ray regions will excite and/or detach inner shell electrons. Multiple electron detachment appears to be initiated by the detachment of a core electron. This process triggers the ejection of one or more valence electrons either by shake off or by interactions of the detached core electron with the valence electrons as it leaves the atom. The ALS (Advanced Light Source) has been used to investigate multiple electron detachment. Measurements of the absolute cross sections for the detachment of two electrons from the closed shell ions Cl^- [60.68] and F^- [60.69] have been reported.

61. Photon–Atom Interactions: Low Energy

Theoretical and experimental aspects of the atomic photoelectric effect at photon energies up to about 1 keV are presented. Relevant formulae and interpretations are given for the various excitation and decay processes. Techniques and results of photoelectron spectrometry in conjunction with synchrotron radiation are emphasized.

61.1 Theoretical Concepts

Scattering of low-energy photons proceeds predominantly through the photoelectric effect. In this process a photon γ of energy $h\nu$, angular momentum $j_\gamma = 1$, and parity $\pi_\gamma = -1$ interacts with a free atom or molecule A, having total energy E_i, angular momentum J_i, and parity π_i to produce an electron of energy ε, spin $s = 1/2$, orbital angular momentum ℓ, total angular momentum j, and parity $\pi_e = (-1)^\ell$ and an ion A^+ with final total energy E_f, angular momentum J_f, and parity π_f. This process can be written as the reaction

$$\gamma(h\nu, j_\gamma = 1, \pi_\gamma = -1) + A(E_i, J_i, \pi_i)$$
$$\rightarrow A^+(E_f, J_f, \pi_f) + e^-[\varepsilon, \ell s j, \pi_e = (-1)^\ell].$$
$$(61.1)$$
Conservation laws require that

$$h\nu + E_i = \varepsilon + E_f,$$
$$\boldsymbol{J}_i + \boldsymbol{j}_\gamma = \boldsymbol{J}_f + \boldsymbol{s} + \boldsymbol{\ell},$$
$$\pi_i \cdot \pi_\gamma = \pi_f \cdot \pi_e = (-1)^\ell \cdot \pi_f. \qquad (61.2)$$

Since $E_f - E_i$ becomes quite large for inner shells or deep core levels, scattering of low-energy photons involves the removal of an electron from a valence or shallow core level. In the low-energy regime, from the first ionization threshold to $h\nu \approx 1$ keV, the photoelectric effect accounts for more than 99.6% of the photon interactions in the elements, with elastic scattering contributing the remainder [61.1, 2]. Ionization by inelastic scattering, the Compton effect, assumes increasing importance with the higher photon energies and the lower Z elements. Above the first ionization potential, the

total photoabsorption cross section and the photoionization cross section are essentially equivalent at the lower photon energies.

The cross section σ_{if} for producing a given final ionic state in the photoionization process is given by

$$\sigma_{if} = \frac{4\pi^2 \alpha^2}{k} \sum |\langle \Psi_f \,|\, \hat{T} \,|\, \Psi_i \rangle|^2, \qquad (61.3)$$

where k is the photon momentum, $\hat{T}$ is the transition operator, Ψ_i and Ψ_f are the wave functions of the initial and final states, and the summation includes an average over all initial states and a summation over all the unobserved variables in the final state. A detailed derivation of this expression, including the different forms for $\hat{T}$, is given in the articles by *Fano* and *Cooper* [61.3] and *Starace* [61.4] and in Chapt. 24. The total cross section is given by the sum of all these different partial cross sections, σ_{if}.

61.1.1 Differential Analysis

Detailed information about the photoionization process can be obtained most directly in emission measurements, especially those involving the photoelectron. The resulting photoelectron spectrum yields the energy and intensity for a given interaction. Further differentiation is obtained by varying the angle of observation and by a spin analysis of the photoelectron. Hence, electron emission analysis can reveal all energetically allowed photoprocesses connecting an initial atomic state i to a final ionic state f and yield their dynamic prop-

erties. When averaged over the spin, the differential cross section $d\sigma_{if}/d\Omega$ is given in terms of the partial cross section σ_{if} and an expression involving an expansion in Legendre polynomials of order n with the coefficients B_n:

$$\frac{d\sigma_{if}}{d\Omega} = \left(\frac{\sigma_{if}}{4\pi}\right) \sum_n B_n P_n(\cos\theta) , \qquad (61.4)$$

where the angle θ is measured between the direction of the emitted electron and the unpolarized incoming photon beam. In the *dipole* approximation, which describes the dominant process at low energy, only the terms containing P_0 and P_2 contribute. Then (61.4) reduces, for a photon beam with linear polarization p, to

$$\frac{d\sigma_{if}}{d\Omega} = \left(\frac{\sigma_{if}}{4\pi}\right)\left[1 + \frac{\beta_{if}}{4}(1 + 3p\cos 2\theta)\right] , \quad (61.5)$$

where the angle θ lies in the plane perpendicular to the direction of propagation and is measured with respect to the major axis of the polarization ellipse [61.5]. Then, the differential cross section, or photoelectron angular distribution, is characterized by the single angular distribution or anisotropy parameter β_{if} for a particular process $i \to f$. For observation at the so-called pseudomagic angle θ_m, defined as

$$\theta_m = \frac{1}{2}\cos^{-1}\left(\frac{-1}{3p}\right) , \qquad (61.6)$$

the differential cross section $d\sigma_{if}/d\Omega$ becomes proportional to the angle-integrated, or partial, cross section σ_{if}.

In the absence of correlation effects, the partial cross section σ_{if} for the production of an individual final state and the corresponding anisotropy parameter β_{if} are given by simple expressions derived from a single-particle model [61.1, 4]. For the central field potential,

$$\sigma_{if} = \frac{4\pi^2\alpha}{3}a_0^2 N_{n\ell}h\nu$$
$$\times \left[\left(\frac{\ell}{2\ell+1}\right)R_-^2 + \left(\frac{\ell+1}{2\ell+1}\right)R_+^2\right] , \quad (61.7)$$

where $N_{n\ell}$ is the occupation number of the subshell, and

$$\beta_{if} = \frac{\ell(\ell-1)R_-^2 + (\ell+1)(\ell+2)R_+^2}{(2\ell+1)\left[\ell R_-^2 + (\ell+1)R_+^2\right]}$$
$$- \frac{6\ell(\ell+1)R_+R_-\cos\Delta}{(2\ell+1)\left[\ell R_-^2 + (\ell+1)R_+^2\right]} . \qquad (61.8)$$

The subscripts $+$ and $-$ refer to the $(\ell+1)$ and $(\ell-1)$ channels respectively, and $\Delta = \delta_+ - \delta_-$ is the difference in phase shift between these two allowed outgoing waves. The parameter $R_\pm$ is the radial dipole matrix element connecting the electron in the bound orbital with orbital angular momentum ℓ with the outgoing wave having orbital angular momentum $\ell \pm 1$.

Effects of the electron correlation on the direct photoionization process can result in values for β which are not reproduced by the Cooper–Zare expression (61.8) [61.4]. The contribution of the different partial waves to the outgoing wave function can, however, be ascertained through the angular momentum transfer formalism developed by *Fano* and *Dill* [61.6]. In this approach, one defines the angular momentum transferred from the photon to the unobserved variables j_t as

$$j_t = j_\gamma - \boldsymbol{\ell} = \boldsymbol{J}_f + \boldsymbol{s} - \boldsymbol{J}_i , \qquad (61.9)$$

where the second portion of the equality results from the conservation of angular momentum. For each allowed value of j_t the associated transfer can be defined as either parity favored or parity unfavored according to whether the product $\pi_i\pi_f$ is equal to $+(-1)^{j_t}$ or $-(-1)^{j_t}$ respectively. (All symbols have the same definition as in (61.1).) Calculation of the partial cross section for the production of a given final state characterized by the values $\boldsymbol{J}_f$ and $\boldsymbol{s}$ is then determined from the cross section corresponding to each angular momentum transfer according to

$$\sigma_{if} = \sum_{j_t} \sigma(j_t) . \qquad (61.10)$$

The associated anisotropy parameter β_{if} is derived from a similar sum:

$$\sigma_{if}\beta_{if} = \sum_{j_t=\text{fav}} \sigma(j_t)_{\text{fav}}\,\beta(j_t)_{\text{fav}} - \sum_{j_t=\text{unfav}} \sigma(j_t)_{\text{unfav}} .$$
$$(61.11)$$

The second equation derives from the fact that $\beta(j_t)$ for each parity-favored value must be calculated separately, whereas for the parity-unfavored case $\beta(j_t) = -1$ always.

The physical effect described by the angular momentum transfer approach is the interaction between an electron and the anisotropic distribution of the other electrons in the atom. Thus, it becomes most useful in the case of ionization from an open-shell atom having an extra electron or a hole in a shell with $\ell \neq 0$. An illustrative example is the 3s ionization of chlorine. Here $\beta_{if} = 2$ identically in (61.8) because only the single

value $\ell = 1$ is allowed in the single-particle model. However, the three possible values, $j_t = 0,\ 1,\ 2$ are allowed, of which only the first corresponds to the Cooper–Zare or single-particle, central field result [61.4]. That $\beta \neq 2$ for 3s ionization of atomic chlorine has been demonstrated experimentally [61.7].

It is generally the case for ionization of elements which are found naturally in the atomic state that there is an equal population in all the fine-structure components of the initial state. This is because of the relatively small energies associated with the fine-structure splitting. (This does not necessarily apply to atomic species generated through a process of molecular dissociation or high-temperature metal vaporization.) Thus, the determination of all cross sections and angular distributions involves an average over these fine-structure components. However, it is possible to generate atoms in which one of the fine-structure components is preferentially populated. In this case there can also be a preferential ionization to a particular J-component of the final ionic state even in the limit in which the electron correlation is neglected, i.e., the geometrical limit. The partial intensities for the production of a given ionic state characterized by the angular momenta $L_f S_f J_f$ by removal of an electron from an orbital ℓ of a state characterized by $L_i S_i J_i$ are given by

$$
R_\ell^{L_f S_f J_f} = \frac{[J_f][L_f][S_f]}{[1/2][\ell]} g(\ell, L_i, S_i, L_f, S_f)
$$
$$
\times \sum_{j=\ell-1/2}^{j=\ell+1/2} [j] \left\{ \begin{array}{ccc} \ell & 1/2 & j \\ L_i & S_i & J_i \\ L_f & S_f & J_f \end{array} \right\}^2 . \quad (61.12)
$$

Here the term in curly brackets is a 9–j symbol, and the notation $[J] = 2J + 1$ is used. The quantities $g(\ell, L_i, S_i, L_f, S_f)$ are weighting factors determined solely by the initial-state wave function. For the case in which ℓ represents a closed shell, these factors are equal to unity [61.8].

In situations in which the target atoms possess an initial orientation, i.e., have an average value $\langle J_z \rangle \neq 0$, or if the ionization is performed with circularly polarized radiation, the electrons which are produced have a net spin [61.9, 10]. It is also possible that unpolarized atoms which are ionized by unpolarized photons can have a net spin, provided that the detection is carried out at a specific angle, and the ionization is from a given fine-structure component of the initial state to a given fine-structure component of the final state. In the latter case, the transverse spin polarization is given by

$$
P = \frac{-2\xi \sin\theta \cos\theta}{1 + \beta P_2(\cos\theta)} , \quad (61.13)
$$

for linearly polarized radiation, and by

$$
P = \frac{2\xi \sin\theta \cos\theta}{2 - \beta P_2(\cos\theta)} , \quad (61.14)
$$

for unpolarized radiation [61.11, 12]. The angle θ is the same as in the angular distribution measurement; the parameter ξ is the spin parameter analogous to β; and $P_2(\cos\theta)$ is the Legendre polynomial of order 2.

Yet another parameter which describes the differentiation inherent in the photoionization process is the alignment A, which reflects an anisotropy in the quadrupole distribution of the angular momentum J_f of the ion [61.12]. For the cylindrically symmetric coordinate system appropriate to dipole photon excitation, only one moment A_0 of the distribution is nonzero. This is defined by

$$
A_0 = \frac{\sum_{m_j} \left[3m_j^2 - J_f(J_f+1) \right] \sigma(m_j)}{J_f(J_f+1) \sum_{m_j} \sigma(m_j)} , \quad (61.15)
$$

where $\sigma(m_j)$ is the partial cross section for production of a given m_j component of J_f. A very useful approach to the interpretation of the alignment can be obtained through the angular-momentum-transfer formalism [61.13]. In this approach the angular momentum transfer j_t is defined as

$$
\mathbf{j}_t = \mathbf{j}_\gamma - \mathbf{J}_f . \quad (61.16)
$$

In contrast to the case of the electron angular distribution, it is possible to derive an alignment for each value of j_t as a function of the angular momentum J_f of the ion. The net alignment is then the incoherent sum of the contributions corresponding to each:

$$
A_0 = \sum_{j_t} A_0(j_t)\sigma(j_t) \bigg/ \sum_{j_t} \sigma(j_t) \quad (61.17)
$$

If the photoionization produces an ion in an excited state which decays by photoemission, the parameter A_0 is reflected either in the angular distribution of the fluorescence photons $I(\theta)$ or the linear polarization P measured at one angle, typically 90°, according to

$$
I(\theta) = I_0 \bigg[1 - \frac{1}{2} h^{(2)} A_0 P_2(\cos\theta)
$$
$$
+ \frac{3}{4} h^{(2)} A_0 \sin^2\theta \cos(2\chi) \cos(2\eta) \bigg] \quad (61.18)
$$

or, for $\theta = \pi/2$ and $\chi = 0$,

$$P = \frac{I(\eta=0) - I(\eta=\pi/2)}{I(\eta=0) + I(\eta=\pi/2)} = \frac{3h^{(2)}A_0}{4 + h^{(2)}A_0} ,$$

(61.19)

respectively. The angle θ is the angle at which the fluorescence is determined, and the angle χ is measured between the axis of the polarization selected by the detector and the quantization axis. The polarization of the fluorescence is given by $\zeta = (\cos\eta,\ i\sin\eta,\ 0)$. The quantity $h^{(2)}$ is a ratio of 6–j symbols depending on the angular momenta J_f of the intermediate ion and the final state J_f':

$$h^{(2)} = (-1)^{J_f - J_f'}$$

$$\times \begin{Bmatrix} J_f & J_f & 2 \\ 1 & 1 & J_f' \end{Bmatrix} \Big/ \begin{Bmatrix} J_f & J_f & 2 \\ 1 & 1 & J_f \end{Bmatrix} .$$

(61.20)

When it is energetically allowed, a hole in a shallow inner-shell will preferentially undergo Auger decay, emitting an electron with an energy ε_A determined by the energy difference between the energy E_f of the ion and E_f' of the state of the doubly-charged ion to which the decay occurs. Angular analysis of the Auger electrons reflects the alignment of the intermediate ionic state, which is different from, and does not bear a one-to-one relationship to, the angular distribution parameter β of the photoelectrons. Normally, Auger decay is regarded as a two-step process in which the first step is the production of the hole and the release of the primary photoelectron, followed by the decay and the release of the second electron. Within this approximation [61.14], the angular distribution of the Auger electrons takes on the simple form

$$I(\theta) = \left(\frac{I_0}{4\pi}\right) [1 + \alpha_2 A_0 P_2(\cos\theta)] .$$

(61.21)

Here $P_2(\cos\theta)$ is the second-order Legendre polynomial, and α_2 is the matrix element corresponding to the Auger decay. For the specific case in which the Auger decay is to a final ionic state of $^1S_0$ symmetry, α_2 is purely geometric, and a measurement of the angular distribution leads directly to a determination of the alignment. Correspondingly, if the alignment of a specific state can be determined through such a decay, then analysis of the angular distribution of the decay to other states provides a value for α_2.

61.1.2 Electron Correlation Effects

The primary focus of advanced studies in photoionization is to determine the role played by electron correlation in the structure and dynamics of electron motion above the lowest ionization threshold. Because the form of the interaction potential for the Coulomb interaction is very well known, theory can focus on the many-body aspects of the process (Chapt. 23). Electron correlation manifests itself in many ways. Most prominent are the appearance of autoionization structure due to the excitation of one or two electrons, the production of correlation satellites due primarily to the ionization of one electron accompanied by the excitation of another, and the creation of two continuum electrons in a double ionization process.

Autoionization resonances are perhaps the oldest known features associated with electron correlation (Chapt. 25). These features arise when the absorption of a photon creates a localized state which lies in energy above at least one ionization limit. This state is then degenerate in energy with a state of an electron in the continuum, and the interaction between these states results in the decay of the quasi-localized state into the continuum. Such resonance states appear in an absorption spectrum in the form of strong, localized variations over an energy range characteristic of the width Γ of the feature, which is in turn related to the lifetime τ of the state by

$$\Gamma = \hbar/\tau .$$

(61.22)

In contrast to absorption features between bound states, autoionization resonances are characterized by having an asymmetric line shape. When only one localized state and one continuum are involved, these line shapes can be derived analytically, as first shown by *Fano* [61.15] and later by *Shore* [61.16], resulting in simple parametrized forms which are suitable for numerical calculation of overlap integrals for determining widths. For the Fano profile

$$\sigma(\epsilon) = \sigma_a \frac{(\epsilon + q)^2}{\epsilon^2 + 1} + \sigma_b ,$$

(61.23)

with

$$\epsilon = \frac{E - E_r}{(\Gamma/2)} ,$$

(61.24)

the parameter q describes the asymmetry of the line, E_r is the resonance position, and Γ is the width of the line. The parameters σ_a and σ_b reflect the relative contributions to states in the continuum which do and do not interact with

the autoionizing state respectively. The energy E_r does not correspond to the peak energy E_m of the resonance feature but is related to the maximum through

$$E_m = E_r + \frac{\Gamma}{2q} \, . \tag{61.25}$$

The Shore profile,

$$\sigma(\epsilon) = C(\epsilon) + \frac{A\epsilon + B}{\epsilon^2 + 1} \, , \tag{61.26}$$

describes the same phenomenon except that the interpretation of the parameters A and B is different. In this case, they represent products of dipole and Coulomb matrix elements. $C(\epsilon)$ is the continuum contribution.

From an experimental point of view, the parametrized forms for the Fano and Shore profiles are very useful as a basis for fitting autoionization spectra. However, they both have the limitation that they only describe the interaction of an isolated state with the continuum. While they can be extended to include several continuua [61.4], they do not allow for an interaction among two or more localized states [61.17, 18]. Nevertheless, it is possible to use these functions to achieve often good fits of states which do interact with each other, as these functions are mathematical representations of localized resonances in a continuous spectral distribution. If this is done, the parameters no longer have the physical meaning which they have for the noninteracting case.

Mixing of discrete ionization channels with competing continuum channels adds complexity to the photoionization process, not just in the classical autoionization regime but also in the vicinity of inner shells [61.19–21]. In a rigorous application of the Mies formalism [61.17], feasible with modern computer power, even complex experimental spectra can now be satisfactorily interpreted and reproduced. A case in point is the excitation spectrum from the 2p level of the open-shell chlorine atom [61.19].

The process of autoionization is discussed in more detail in Chapt. 25. In Fig. 61.1 an example is shown of the set of $2s^2 p^3 (^4S) \rightarrow 2s2p^3 np$, $n \geq 3$ autoionization resonances which decay into the ^3P ground state of the N^+ ion [61.22]. The energies E_n of these resonances are related to the ionization limit E_∞ of the series by the Rydberg formula

$$E_n = E_\infty - R_\infty/(n - \mu_s)^2 \tag{61.27}$$

where n is the principal quantum number and μ_s is the quantum defect characteristic of a given series and reflecting the short-range electrostatic interactions of the

electron with the ion core. Values of μ_s for s, p, d, and f electrons have been calculated for atoms and ions up to $Z = 50$ [61.23]. For high precision work, the reduced Rydberg constant

$$R_M = \frac{R_\infty}{1 + 5.485\,799 \times 10^{-4}/(M_A - m_e)} \tag{61.28}$$

should be used instead of the value R_∞ for infinite nuclear mass (Chapt. 1). The atomic mass M_A and the electron mass m_e are in a.u.

A process closely related to the autoionization phenomenon is resonant Auger decay. This process differs from the ordinary Auger process [61.24] in that an electron from an inner shell is not ionized but excited to either a partially filled or an empty subshell. It may be viewed either as an Auger process or as autoionization. Such an inner-shell excited state of a neutral atom (molecule) lies above one or more of the ionization limits of the singly ionized species and consequently must decay by electron emission unless the decay is forbidden by selection rules. As a result, resonance structure will appear superimposed on the continua of direct photoionization from the various subshells. From a most general point of view, the resonant Auger process can be considered as resonances in the continua of single photoionization, while the ordinary Auger process can be regarded as resonances in the continua of double photoionization. If excitation proceeds to a partially filled subshell *within* a principal shell, as, for example, Mn 3p $\rightarrow$ 3d [61.20], interference between the direct photoionization channels and the indirect resonance channel may be strong, and the lineshapes are
Fig. 61.1 Autoionization resonances $2s^2 2p^3 (^4S) \rightarrow 2s2p^3 np$ in atomic nitrogen

given by (61.23) with arbitrary q values and σ_a/σ_b ratios. If, however, the excitation proceeds to an empty shell, as, for example, Mg 2p $\rightarrow$ ns or nd, $n \geq 4$, interference with the direct channels is likely to be negligible, and the resulting resonances are distinguished by essentially Lorentzian line shapes (as for normal Auger lines) with $q \gg 1$ and $\sigma_a/\sigma_b \gg 1$ in (61.23). For a given excitation state a number of resonance peaks may arise because more than one ionization channel is usually available and, in addition, the excited electron can change its orbital from n to $n' = n \pm 1, 2, \ldots$ in a shakeup or shakedown process [61.25].

As a consequence of the electron–electron interactions which occur simultaneously with the electron–photon interaction, ions are produced in states which do not correspond to those which would be expected based on an interpretation using an independent particle model, which allows for only a single-electron transition (Chapt. 24). Evidence for these states appears as correlation satellites in the photoelectron spectrum, the Auger electron spectrum or the X-ray spectrum [61.26]. Figure 61.2 [61.27] presents as an example the photoelectron spectrum of argon produced by photons with $h\nu$ =60.6 eV. In addition to the 3s main line of single electron photoionization (and the 3p main lines not shown) numerous satellite lines are seen as the manifestation of two-electron transitions involving ionization-with-excitation correlations. It is convenient to categorize the satellites in a photoelectron spectrum according to various electron correlations, as, for example, initial state interactions which mix dif-ferent configurations into the initial state, and final state interactions, which include core relaxation and electron–electron interactions in the final ionic state, electron–continuum, and continuum–continuum interactions. While initial-state correlations are essentially independent of the photon energy, final-state correlations depend on the energy of the photon through the interactions with the continuum channels. However, the heuristic value of placing correlation effects into a strict classification scheme is limited by the fact that their relative strengths depend on the basis set used in a particular theoretical model and its expansion into a "fully correlated" system within a given gauge [61.3, 4, 28, 29] (see also Chapt. 24).

Another manifestation of double-electron processes is the simultaneous excitation of two electrons to bound states. These states may decay by electron or photon emission and are seen as resonance structures above the thresholds of inner-shell ionization or near autoionizing members of Rydberg series. As single or double ionization continua are usually strong in the spectral range of the double excitations, interference occurs, and the lineshapes can display dispersion forms. Typically, the cross section for the sum of all correlation processes is between 10 and 30% of that for single photoionization, but may exceed this range considerably in special cases.

Photon scattering near thresholds is complex because of the possibility of strong interactions between the various particles created and the different modes of deexcitation (Chapt. 62). In the case of ionization-with-excitation processes, the threshold cross section is finite, as it is for single electron photoionization, in accord with Wigner's theorem [61.30] (Sect. 60.2.1). In the case of double photoionization, the cross section is zero at threshold and then rises according to Wannier's law [61.31] (Chapt. 52). For the motion of two electrons with essentially zero kinetic energies in the field of the ionic core,

$$\sigma \propto E^{(2\mu-1)/4} , \tag{61.29}$$

where μ depends on the value of the nuclear charge Z through

$$\mu = \frac{1}{2}\left(\frac{(100Z-9)}{(4Z-1)}\right)^{\frac{1}{2}} . \tag{61.30}$$

For $Z = 1$ the Wannier exponent has the value 1.127.

In the case of Auger decay following ionization at threshold, interaction between the two electrons results in a shift in the energy of the Auger
Fig. 61.2 Photoelectron spectrum (PES) of 3s, 3p satellites in argon at a photon energy of 60.6 eV. Note the reduced intensity of the satellites compared to the 3s main line

electron and a corresponding shift in that of the photoelectron (to conserve energy), as well as an asymmetry in the shape of the Auger electron peak and a corresponding asymmetry in the photoelectron peak shape. In this so-called post-collision interaction (Chapt. 62), the lineshape, averaged over angles, has the form [61.32]

$$K(\varepsilon) = \frac{(\Gamma/2\pi)}{(\varepsilon - \varepsilon_A)^2 + (\Gamma/2)^2} f(\varepsilon) \qquad (61.31)$$

with

$$f(\varepsilon) = \frac{\pi\psi}{\sinh(\pi\psi)} \exp\left[2\psi \tan^{-1}\left(\frac{\varepsilon - \varepsilon_A}{(\Gamma/2)}\right)\right].$$
$$(61.32)$$

In the above equations, ε is the energy of the Auger line, ε_A is the nominal Auger energy, Γ is the initial hole-state width, and the parameter $\psi = 1/\sqrt{2\varepsilon_e} - 1/\sqrt{2\varepsilon_A}$, with ε_e being the energy of the photoelectron, and $\varepsilon_A \geq \varepsilon_e$.

61.2 Experimental Methods

An overview of the experimental approaches to the study of photon interactions at low energies is given in Fig. 61.3. The sketch emphasizes the interaction of a polarized photon beam with a small static or particle-beam target of atoms, ions, molecules, or clusters, and the detection of the reaction products at various angles in a plane perpendicular to the direction of propagation of the photon beam, where the general equation (61.5) is valid. Emission products, such as electrons, ions, or photons, may be studied by way of the total
Fig. 61.3 Generic arrangement for detection of particles in an emission measurement. The incoming radiation is assumed to be linearly polarized along the z-axis

yields, which can be related to the total photoionization cross section, or by differential analysis in a spectrometer according to energy, intensity, emission angle, and polarization. The various particles may be measured independently, simultaneously, or in coincidence. The photon monitor provides the information for normalization of the data with regard to flux and polarization. The photon monitor can also be used for a measurement of the total photoionization cross section, equivalent to the photoabsorption or photoattenuation coefficient at low photon energies. For this purpose, the size of the target source is advantageously increased in the direction of the photon beam. While experimental apparatus differs, sometimes drastically, for the photon sources as well as for the spectrometry of electrons, ions, and fluorescence photons, many features are common, and the relationships of the measured quantities to basic properties of the atoms and the photon–atom interaction are similar. Thus, the following will place emphasis only on the roles of the synchrotron radiation source and photoelectron spectrometry, whereas specific references to other methods can be found elsewhere [61.5, 33–38].

61.2.1 Synchrotron Radiation Source

The primary source of photons over a broad energy range for experiments in the VUV and soft X-ray region of the spectrum is the synchrotron radiation source [61.39, 40]. In a synchrotron or electron storage ring, radiation is produced as the electrons are bent to maintain the closed orbit. Such bending magnet radiation is emitted in a broad continuous spectrum which begins in the infra-red and ends sharply at a critical photon energy given by $h\nu_c = \kappa E_e^2$, where E_e is the energy of the electrons in the ring and κ is a constant characteristic of the ring. Synchrotron radiation can also be generated by introducing additional magnetic field structures [61.41]

into the ring, such as undulators or wigglers, which produce a deviation of the electron motion from a straight path in a well-defined manner. Wiggler radiation has the same spectrum as a bending magnet, except that the critical energy is generally much higher because the effective magnetic fields can be larger than those of the bending magnet. Undulator radiation is very different in that it consists of a sharp spiked profile of about a 1% bandwidth at energies determined by the magnetic field within the undulator and by the electron beam energy in the storage ring.

Synchrotron radiation, no matter what the magnetic field structure of the source, requires monochromatization before it can be used for experiments. For the wavelengths of interest in low-energy photon scattering, this can be achieved by using grating instruments with a metallic coating on the grating surface. The highest resolution possible is obtained through the use of a normal incidence monochromator (NIM) with a plane grating set at normal incidence. However, because the reflectivity of the metallic coating at normal beam incidence decreases drastically as the photon energy increases, use of a NIM has an upper limit of about 40 eV. At energies above this, up to about 1 keV, gratings can still be used but must be mounted at grazing incidence. There is a number of functional designs for these grazing-incidence instruments which vary in the shape of the grating – spherical, toroidal, or plane surfaces (SGM, TGM, PGM) – and the associated optics. Above 1 keV, gratings are no longer suitable, and crystal diffraction must be used. While the radiation emerging from a beamline which couples the monochromator to a bending magnet, wiggler, or undulator has a high degree of linear polarization, varying from 80 to 99% in the plane of the electron orbit, a useful flux of circularly polarized radiation can be derived from out-of-plane radiation [61.33], by the use of multiple reflection optics, or from a helical undulator.

61.2.2 Photoelectron Spectrometry

The primary particle emitted in photoionization is the photoelectron. Hence, a photoelectron spectrum provides a detailed view of the photon interaction by (a) specifying the individual processes from an initial state i to a final state f by way of the electron energy, (b) determining their differential and partial cross sections by recording the number of electrons as a function of emission angle, and (c) measuring the polarization of the electrons by a spin analysis (spin polarimetry). The experimental approach is governed largely by the relations (61.3), (61.5), and (61.6). The number of electrons $N_{if}(e)$ detected per unit time at an angle θ within an energy interval $d\varepsilon$ and within a solid angle $d\Omega$ is given by

$$N_{if}(e) = GN(h\nu)N(A)f(h\nu)f(\varepsilon)\frac{d\sigma_{if}}{d\Omega}d\varepsilon \quad (61.33)$$

where G is a geometry factor, which includes the source dimensions, $N(h\nu)$ the number of photons, $N(A)$ the number of atoms in the source, $f(h\nu)$ and $f(\varepsilon)$ efficiency factors depending, respectively, on photon and electron kinetic energies, and $d\sigma_{if}/d\Omega$ is the differential cross section for a particular transition $i \rightarrow f$. Equation (61.33) assumes that $d\Omega$ and $d\varepsilon$ are sufficiently small that integration over the pertinent parameters is not needed. Since $N_{if} \propto d\sigma_{if}/d\Omega$, a measurement at two angles, e.g., $\theta = 0°$ and $90°$, yields the electron angular distribution parameter β_{if} according to (61.5), and a measurement at θ_m (61.6) yields the partial cross section σ_{if}. In the case of closed-shell atoms, $n\ell j$ notation is sufficient to designate single ionization to an $\varepsilon\ell$ continuum, e.g., $3p_{1/2,3/2} \rightarrow \varepsilon s$ or εd in argon, but for open-shell atoms LSJ notation is required, e.g., $3p^5(^2P^o_{3/2}) \rightarrow 3p^4(^3P^e_{2,1,0}, {}^1D^e_2, {}^1S^e_0)\varepsilon\ell(^2D^e, {}^2P^e, {}^2S^e)$ in chlorine. Similarly, for ionization-with-excitation transitions, the final state requires an open-shell designation.

The sum of the partial cross sections is equal to the total photoionization or absorption cross section

$$\sigma_{\text{tot}} = \sum_{i,f} \sigma_{if} \quad (61.34)$$

where the σ_{if} encompass (a) single ionization events in all energetically accessible subshells $n\ell j$, or the LSJ multiplet components, (b) ionization-with-excitation events (shakeup or shakedown), and (c) double ionization events (shakeoff). All σ_{if} can be determined from a photoelectron spectrum from its discrete peaks (cf. Fig. 61.2) and from the continuum distribution of multiple ionization. However, the latter process is measured more readily by observing the multiply charged ions in a mass spectrometer.

The differentiation afforded by measuring the various partial cross sections, and the associated β parameters, can be augmented by differentiating the continuum channels according to the spin using a spin polarimeter [61.33]. In closed-shell atoms, this allows for an experimental determination of the relevant matrix elements and phase shifts, and hence for a direct comparison with theory at the most basic level [61.34, 35]. In a more global measurement, the cross section σ_{tot} is

obtained by ion or mass spectrometry from

$$\sigma_{\text{tot}} = \sigma(A^+) + \sigma(A^{2+}) + \sigma(A^{3+}) + \cdots . \quad (61.35)$$

Generally, the charge states can be correlated with the various initial photoionization processes if allowance is made for Auger transitions and the fluorescence yield upon exceeding the binding energies of core levels.

If the charge states are not distinguished, as in a total ion yield measurement, σ_{tot} is obtained directly. Similarly, a direct measurement of the global quantity σ_{tot} is obtained by the total electron yield, although care must be exercised to avoid discrimination by angular distribution effects. At photon energies below about 1 keV, ionization, absorption, and attenuation are virtually equivalent, and σ_{tot} can also be determined in an ion chamber setup [61.36] or in a photoabsorption measurement in which the number of photons ΔN absorbed in a source of length d and having an atom density n is given by

$$\Delta N = N(\text{ph})[1 - \exp(-\sigma_{\text{tot}} nd)] \quad (61.36)$$

with $N(\text{ph})$ being the flux of incident photons. As a rule, in all experiments employing the relation (61.5), the total, partial, or differential cross sections are determined on a relative rather than an absolute scale because it is very difficult to know accurately such factors as the geometry of the source volume and the number density. However, once a single absolute value of σ_{tot} or any σ_{if} is available, all relative values of the other quantities can be converted to absolute values.

An electron spectrometric experiment can be carried out in three different operational modes, as defined in Fig. 61.4. In the most conventional mode, PES, the photon energy is fixed, and a scan of the electron kinetic energy reveals all the electron-emission processes possible and yields their properties. The CIS (constant ionic state) mode is especially suited to follow continuously a selected process as a function of photon energy by locking onto a given state $E_f - E_i$ (denoted by E_B) which requires a strict synchronization of the photon energy ($h\nu$) and electron kinetic energy (ε) during a scan. This mode is particularly advantageous to elucidate resonance features, such as autoionization resonances. Finally, a CKE (constant kinetic energy) scan allows one to access various processes sequentially or, most importantly, follow a process of fixed energy, such as an Auger transition, as a function of photon energy. This description also includes the technique of zero-

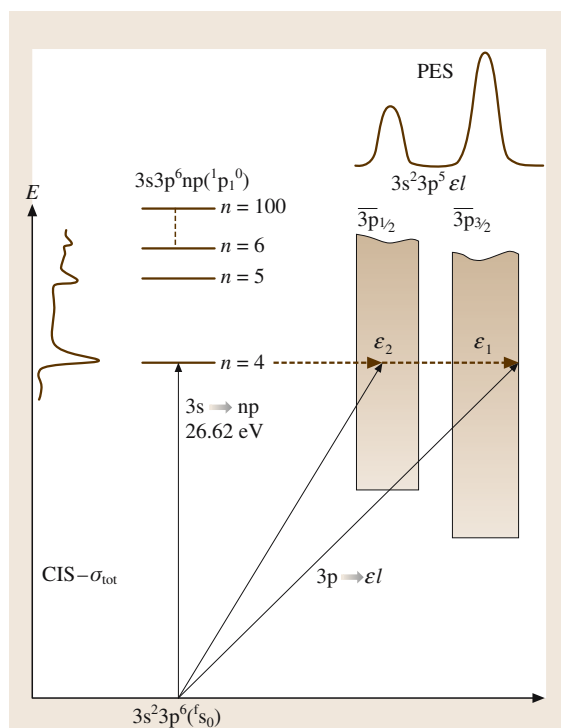
Fig. 61.4 Energy relationship among the three different operational modes of the technique of photoelectron spectrometry. E_B is the binding energy of the level


Fig. 61.5 Connection between the PES and CIS techniques as illustrated by the $3s \rightarrow np$ autoionization resonances in argon

kinetic-energy measurements. Most frequently, the PES and CIS modes are employed, and Fig. 61.5 gives a self-explanatory example of an actual experiment directed at the characterization of the argon $3s \to np$ autoionizing resonances. It should be stressed that the cross section σ_{tot} can be partitioned into its components by CIS scans that differentiate between the $3p_{1/2}$ and $3p_{3/2}$ doublet states.

Energy analysis can be performed either by electrostatic energy analyzers or by time-of-flight techniques. The latter is well-suited to those electrons which have very low kinetic energy, including threshold electrons with $\varepsilon \approx 0 \, \mathrm{eV}$. Of the electrostatic energy analyzers now in use, two designs are prevalent, the cylindrical mirror analyzer (CMA) and the hemispherical analyzer, where the latter readily lends itself to the application of multichannel detectors.

61.2.3 Resolution and Natural Width

The details that can be gleaned from an experiment using photons depend on the resolution achievable with the particular photon source and spectrometry used, the particular excitation or analysis modes and the target conditions chosen, and, ultimately, on the natural width of either the levels or transitions examined as well as any fine structure present. Generally, the instrumental and operational resolution should approach, but need not exceed by much, the natural width inherent in the photoprocess under scrutiny. The demands are most severe for processes involving outer levels because of their typically very narrow widths, and are relatively mild for processes involving inner levels [61.5, 35]. It is desirable that in the former case the resolving power (the inverse of the resolution) of the instrument exceed 10^5, while in the latter case 10^4 may suffice. If the target atoms move randomly, a resolution limit is set by the thermal motion, namely

$$\Delta\varepsilon = 0.723 \, (\varepsilon T/M)^{1/2} \ (\mathrm{meV}) \,, \tag{61.37}$$

where, in an experiment involving photoelectron spectrometry, ε is the kinetic energy of the photoelectron in eV, T the temperature in K, and M the mass in a.u. of the target atom. This contribution can be limited in first order by employing a suitably directed atomic beam.

The experimental peak-width and shape generally contain the natural width; the extent to which instrumental factors enter depends on the specific experiment. In a measurement of the total or partial photoionization

cross section in which either the fluorescence photons, the electrons, or the ions are monitored, the resolution of the photon source (often called the bandpass) is the only instrumental contributor. This applies specifically to the CIS mode of electron spectrometry, in which features are scanned in photon energy and the electron serves solely as a monitor. However, in such a CIS study, or a corresponding fluorescence study, the resolution of the electron or fluorescence spectrometer must be adequate to be able to distinguish adjacent processes. For the example of Fig. 61.5, the $3p_{3/2}$ and $3p_{1/2}$ levels of Ar need to be separated if the partial photoionization cross sections are to be determined across the resonances. In such a case of more than one open ionization channel, the natural widths of the features will be identical in all channels [61.4], but the shapes may be different. In emission processes subsequent to initial photoionization, namely electron (Auger) decay or photon (X-ray) emission, the resolution of only the spectrometer performing the detection counts on the instrumental side. In the PES mode (Fig. 61.4) the observed lines contain contributions from all sources, the photon source or photon monochromator, the electron analyzer, thermal broadening, and the natural level width. In the special case of photoprocesses near inner thresholds, the post-collision interaction influences the position and shape of photoelectron and Auger lines (Chapt. 62).

Excluding threshold regions and the resonant Raman effect, the line profile observed in the various experiments is given by the Voigt function

$$V(\omega, \omega_0) = \int L(\omega' - \omega) G(\omega' - \omega_0) \, d\omega' \,. \tag{61.38}$$

In this the Lorentzian function L represents the natural level or transition profile, and the Gaussian function G is representative of the window functions of the dispersive apparatus. Although the integral representing the Voigt profile has no analytic form, it can be represented for practical purposes by the analytic Pearson-7 function [61.42]

$$P_7(\varepsilon) = A \left(1 + \frac{(\varepsilon - \varepsilon_0)^2}{B^2 C} \right)^{-C} \,, \tag{61.39}$$

where A is the peak height, ε_0 the peak position, B the nominal half-width-half-maximum of the peak, and C the shape of the peak. In the limit in which $C = 1$, this function is identically a Lorentzian; in the limit $C \to \infty$, the function is essentially Gaussian. Use of this function allows one to fit the resulting photoelectron spectrum using standard numerical techniques. If the width of

the feature is the only quantity of interest, the simple approximate expression

$$\frac{\Gamma_{\mathrm{L}}}{\Gamma_{\mathrm{V}}} = 1 - \left(\frac{\Gamma_{\mathrm{G}}}{\Gamma_{\mathrm{V}}}\right)^2 \tag{61.40}$$

which relates the Voigt width Γ_{V} with the Lorentzian width Γ_{L} and the Gaussian width Γ_{G} can be used to determine either Γ_{L} or Γ_{G} from the measured Γ_{V} [61.5]. Often the observed feature exhibits a dispersive shape given by the Fano or Shore profile. In this instance the instrumental function must be convoluted with the resonance profiles given by (61.23) or (61.26) in order to fit the data and to extract the parameters [61.43].

For the special case of resonant Auger decay in which the bandpass of the exciting radiation is very narrow compared with the natural width of the excited state, the experimental linewidth is governed by the width of the exciting radiation, and will be more narrow than the natural width of the line. The resulting lineshape in this resonant Raman effect is then the simple product [61.24]

$$L'(\omega, \omega_0) = L(\omega)G(\omega - \omega_0) , \tag{61.41}$$

where $L(\omega)$ is the line profile as determined by the natural width, typically Lorentzian for resonant Auger decay, and $G(\omega - \omega_0)$ is the, usually, Gaussian function representing the bandpass of the exciting radiation.

61.3 Additional Considerations

Although low-energy photon interactions are well described nonrelativistically in the dipole approximation, relativistic and higher multipole effects which become increasingly important at higher energies cannot be ignored even below 1 keV. Spin-orbit effects [61.44] and relativistic effects [61.45] are of special significance even at low energies in Cooper minima, where one of the transition matrix elements becomes zero. Moreover, the use of intermediate coupling, which includes both the spin-orbit and electrostatic interactions [61.46], is required in open-shell systems, as exemplified for the halogen atoms and atomic oxygen [61.47]. Level energies of heavy elements also require a relativistic treatment [61.48] (Chapt. 22), and it is natural to employ relativistic formulations for calculating the spin parameters appearing in photoionization [61.49].

Although low energy photon scattering is dominated by the dipole contribution, experiments and theory have shown higher multipole effects to be present at $h\nu < 1$ keV [61.50–57]. As a result, measurements that take the dipole formulations as a basis (61.5) and (61.6) can incur a discernible error in both the differential cross sections $d\sigma_{if}/d\Omega$ and the partial cross sections σ_{if}. A more accurate determination of $d\sigma_{if}/d\Omega$ can be made [61.51, 55, 56] on the basis of the equation

$$\frac{d\sigma_{if}}{d\Omega} = \left(\frac{\sigma_{if}}{4\pi}\right)\left[1 + \beta P_2(\cos\theta)\right.$$
$$\left. + (\delta + \gamma \cos^2\theta)\,\sin\theta\,\cos\phi\right] , \tag{61.42}$$

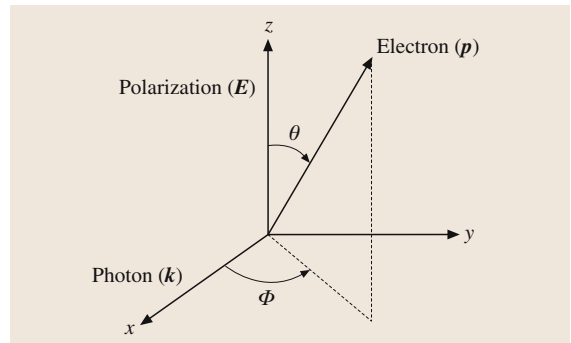
using linearly polarized radiation, where $P_2(\cos\theta)$ is the second-order Legendre polynomial, θ is the angle between the electron emission direction and the electric vector, ϕ is the angle between the electron and photon directions, β is the angular distribution parameter related to B_2, and the parameters δ and γ are related to B_1 and B_3 in (61.4). Figure 61.6 shows the geometry for the relationship between the photoelectron momentum vector, the polarization vector, and the photon propagation vector as used in (61.42). It serves as the template for the arrangement and motion of the electron detector, or, for added efficiency and accuracy, several detectors [61.51–53, 56]. The parameters β, δ, and γ have been calculated for most subshells of the noble gases for photoelectron energies between 100 eV and 5 keV [61.55]


Fig. 61.6 Geometry of the relationship between the photoelectron momentum p, the polarization vector E, and the photon momentum k. (Courtesy of O. Hemmers)

and 20 eV to 5 keV [61.57]. Generally, the electric quadrupole (E2) and magnetic dipole (M1) photoionization channels are the most important beyond the dipole (E1) photoionization channel. Similar to the dipole angular distribution parameter β, the parameter γ may also be subject to interchannel coupling and relativistic effects, as demonstrated for xenon 5s photoionization [61.51].

62. Photon–Atom Interactions: Intermediate Energies

The main photon–atom interaction processes in the energy range from $\approx 1\,\mathrm{keV}$ to $\approx 1\,\mathrm{MeV}$ are outlined. The atomic response to inelastic photon scattering is discussed; essential aspects of radiative and radiationless transitions are described, including hole-state widths and fluorescence yields, in the two-step approximation which applies well above threshold where atomic de-excitation is nearly independent of the excitation process. Multi-electron photoexcitation that transcends the independent-electron model is briefly considered.

Threshold phenomena that arise when the two-step model breaks down, so that excitation and de-excitation must be treated as a single second-order quantum process are described. The time-independent resonant scattering approach that leads to a unified description of photoexcitation, ionization, and Auger electron or X-Ray emission is outlined. In terms of this theory, Raman processes and post-collision interaction are described.

62.1 Overview

62.1.1 Photon–Atom Processes

It is convenient to divide photon-atom interactions into elastic and inelastic processes, depending on whether or not the photon energy changes in the c.m. frame. This separation, while useful, is somewhat arbitrary [62.1]: the radiative corrections of quantum electrodynamics (Chapt. 27) and the possibility of emitting very soft photons, as well as target recoil, make all processes in fact inelastic, while experimental comparison of incident and scattered photon energies is limited by source bandwidth and detector resolution.

Elastic photon-atom interactions (Chapt. 45) include scattering from bound electrons (Rayleigh scattering) with transition amplitude A^{R} and nuclear Thomson scattering, Delbrück scattering, and nuclear resonance scattering, with amplitudes A^{NT}, A^{D}, and A^{NR}, respectively. These amplitudes are coherent, i.e., not physically distinguishable: they add, retaining relative phase information, in the total atom elastic scattering amplitude A [62.1]. In the commonly used approximation, that is however "neither unique nor exact" [62.2], we have

$$A = A^{\mathrm{R}} + A^{\mathrm{NT}} + A^{\mathrm{D}} + A^{\mathrm{NR}} . \qquad (62.1)$$

The total atom elastic cross section is proportional to A^2.

Inelastic photon-atom interactions are photoexcitation (including ionization) (Chapt. 24), Compton scattering, and pair production. The pair production threshold at $2m_{\mathrm{e}}c^2$ lies above the energy region considered here (Chapt. 27). Inelastic scattering processes are generally incoherent, e.g., ejected Compton electrons originating from different orbitals can be distinguished [62.1]. However, coherence can enter even between photoionization and Compton scattering in the infrared-divergence limit [62.1, 3–5].

Fig. 62.1 Contributions of the photoeffect, elastic, and inelastic scattering to the total photon interaction cross section of copper. (After [62.6], by permission, University of California, Lawrence Livermore National Laboratory; work performed under the auspices of the U.S. Department of Energy)

The cross sections for the main elastic and inelastic photon-atom processes comprising the photoeffect are illustrated in Fig. 62.1 for Cu [62.6] in which, however, resonant pieces of the inelastic (Compton) cross section are omitted. Elastic exceeds inelastic scattering up to well above the K edge; this is true for all atomic numbers. The total cross section is dominated by the photoeffect up to photon energies that increase with atomic number, from ≈ 6 keV for He [62.5] to ≈ 25 keV for C and ≈ 700 keV for U [62.6–8]. (See also Sect. 24.2.2 and Sect. 92.3.2). For a summary of some current developments in the field see [62.9]
62.2 Elastic Photon–Atom Scattering

62.2.1 Rayleigh Scattering

The term Rayleigh scattering is applied to elastic photon scattering from bound atomic electrons (Sect. 68.6.1). The Rayleigh scattering amplitude for neutral atoms dominates the total atom elastic scattering amplitude, at all angles, for photon energies below ≈ 1 MeV and dominates forward scattering at higher energies [62.1]. At angles other than 0°, Rayleigh scattering occurs increasingly from inner atomic shells as the photon energy is raised. Depending on the energy, the process can thus sensitively probe atomic structure in distinct regions [62.1].

Rayleigh scattering has been reviewed by *Henke* [62.10], *Gavrila* [62.11], *Kissel* and *Pratt* [62.1], and *Kane* et al. [62.12]. The process has commonly been estimated in a simple *form-factor approximation*, which represents scattering from a free charge distribution; this underlies comprehensive tabulations of elastic scattering cross sections and attenuation coefficients [62.7, 8]. The form factor relates cross sections to classical theory, and has been derived from both nonrelativistic and relativistic quantum mechanics. It is attractive because of calculational simplicity [62.2, 13].

The form factor $f(q)$ for a spherically symmetric charge number density $\rho(r)$ is the Fourier transform of

the charge density:

$$f(q) \equiv \int \rho(\boldsymbol{r})\, e^{i\boldsymbol{q}\cdot\boldsymbol{r}}\, d\boldsymbol{r} = \int_0^\infty \rho(r) \frac{\sin(qr)}{qr} r^2\, dr \,,$$

(62.2)

where

$$\hbar q = (2\hbar\omega/c)\sin(\theta/2)$$

(62.3)

is the momentum transfer, and θ the scattering angle. In elastic photon scattering, $f(q)$ corrects the Thomson point charge scattering cross section for scattering from an extended charge distribution. In the form factor approximation, the differential Rayleigh scattering cross section (neglecting other coherent processes) for unpolarized photons, averaged over final polarization, is

$$\frac{d\sigma}{d\Omega} = \frac{1}{2}r_e^2\left(1 + \cos^2\theta\right)|f(q)|^2 \,,$$

(62.4)

where $r_e = e^2/(m_e c^2)$ is the classical electron radius and the terms multiplying $|f(q)|^2$ are the Thomson cross section.

Even with modifications and corrections [62.1, 2], the range of validity for the form factor approximation for elastic photon scattering is limited [62.13]. Predictions based on this approach are often wrong in quantitative detail, although they lend insight into

qualitative features of the Rayleigh amplitude [62.2] Fig. 62.2.

The shortcomings of the form factor approximation arise from the absence of binding effects in the Thomson cross section, which pertains to photon scattering from a free charged particle. Specifically, accurate Rayleigh amplitudes must include the interaction of the electron with the atomic potential in the initial, intermediate, and final states [62.1]. The form factor approximation fails, especially for photons of low energy compared with the electron binding energy, and for large scattering angles (high momentum transfer), but $\mathcal{O}\left(Z\alpha^2\right)$ discrepancies remain at all energies and angles [62.2].

Substantial progress in the understanding of elastic photon-atom scattering was made with the advent of numerical calculations of the amplitudes based on the second-order S-matrix of quantum electrodynamics and relativistic wave functions [62.2, 14]. These numerical partial wave calculations include binding effects in the intermediate state exactly to all orders. They constitute an approach that leads to amplitudes with errors of $\mathcal{O}(1\%)$. However, some limitations do exist: (1) great computer time requirements make it necessary to employ simpler (e.g., modified form factor) methods for outer shell contributions, (2) only lowest-order terms of the S-matrix expansion in powers of e are included, and (3) most electron-electron correlation effects are not taken into account [62.1].

Measurements of Rayleigh scattering in the energy range here considered are rather scarce [62.12]. Gamma rays from radioactive sources have been used in most experiments, but discrimination from inelastic contributions has been a problem [62.15]. Comparison of measurements on medium- and high-Z targets with theory, albeit incomplete, has however been encouraging [62.1, 12, 15].

62.2.2 Nuclear Scattering

The nucleus contributes to the total atom elastic scattering amplitude through nuclear Thomson, Delbrück, and nuclear resonance scattering. Only the first two of these processes are important in the energy range considered here.

Nuclear Thomson Scattering

Photon scattering by the nuclear charge can be approximated by treating the nucleus as a rigid, spinless sphere of charge Ze, mass M, and radius r_N. In the simplest point-charge form factor approximation, nuclear Thomson scattering is included by replacing $|f(q)|$ in
Fig. 62.2 Differential elastic photon-atom scattering cross section (in b/atom) for neutral lead in form factor approximation. The contribution of nuclear Thomson scattering (see Sect. 62.2.2) to the amplitude is included (After [62.1])

(62.4) by $\left|f(q) + Z^2(m_e/M)\right|$. If the finite nuclear radius r_N is taken into account, the nuclear form factor is approximately [62.1]

$$f_N \approx Z^2 \left(1 - \frac{\omega^2}{3c^2} \langle r_N^2 \rangle \right) . \tag{62.5}$$

The nuclear Thomson scattering cross section is

$$\frac{\mathrm{d}\sigma^{NT}}{\mathrm{d}\Omega} = \frac{r_e^2}{2} \left| \frac{m_e}{M} f_N \right|^2 (1 + \cos^2 \theta) \tag{62.6}$$

if other coherent processes can be neglected. For some energies, scattering angles, and target atoms, the nuclear Thomson scattering contribution to elastic scattering can dominate. A few measurements exist that confirm the preceding predictions with $f_N \cong Z^2$ [62.1].

Delbrück Scattering

Scattering of photons by virtual electron-positron pairs created in the screened nuclear Coulomb potential is called Delbrück scattering [62.1, 16]. The imaginary part of the amplitude describes photon absorption due

to pair production; it vanishes for $\hbar\omega \leq 2m_e c^2$. The real part of the amplitude, which adds coherently to the Rayleigh and nuclear Thomson amplitudes, arises from vacuum polarization. Together with photon-photon scattering, photon splitting and coalescence in an external field, Delbrück scattering belongs to the nonlinear effects of quantum electrodynamics that have no classical analog (Sect. 27.2) [62.17]. In the photon energy range $0.1-1\,\text{MeV}$, the Delbrück amplitude can be significant at intermediate scattering angles for high-Z targets [62.1]. Theory and experiment have been reviewed by *Papatzacos* and *Mork* [62.16] and more recently by *Kissel* and *Pratt* [62.1] and by *Milstein*

and *Schumacher* [62.18]. Lowest-order Born approximation calculations of the Delbrück amplitude scale as $\alpha(Z\alpha^2)$. Experiments to verify the process have been performed since 1933, but only recently has the necessary accuracy been attained [62.18]; a major obstacle in the interpretation was the lack of accurate predictions of the Rayleigh amplitude, a problem that is now being solved to a considerable extent (Sect. 62.2.1). Recent measurements agree with the Born approximation predictions to a few percent below $Z = 60$; but for heavier targets, Coulomb corections appear to play a significant role that have only recently been calculated [62.19].

62.3 Inelastic Photon–Atom Interactions

62.3.1 Photoionization

Photoexcitation and ionization are important processes for the investigation of atomic structure and dynamics (Chapt. 61). Early reviews of the theory of the atomic photoelectric effect are by *Fano* and *Cooper* [62.20] (low photon energy) and by *Pratt* et al. [62.21] ($\hbar\omega > 10\,\text{keV}$). See also recent comprehensive monographs by *Starace* [62.22] and *Amusia* [62.23]. In the present volume, the theory of atomic photoionization for photon energies below $1\,\text{keV}$ is summarized in Chapt. 24. Experimental aspects have been reviewed, e.g., by *Samson* [62.22, 24] and by *Siegbahn* and *Karlsson* [62.25].

An extensive compilation of measured X-ray attenuation coefficients or total absorption cross sections, as well as calculated photoelectric cross sections (computed with relativistic Hartree-Slater wave functions), has been published by *Saloman* et al. [62.26]. Based on the National Bureau of Standards (now the National Institute of Standards and Technology) data base, this work covers the photon energy range from $0.1-100\,\text{keV}$ and includes all elements with atomic numbers $1 \leq Z \leq 92$; an extensive bibliography is included. Very useful tables of theoretical subshell photoionization cross sections covering all elements and the photon energy range $1-1500\,\text{keV}$ have been computed by *Scofield* [62.27]; the atomic electrons are treated relativistically as moving in a Hartree-Slater central potential, and all relevant multipoles as well as retardation effects are included. Accuracy of the results is borne out by systematic comparisons with experiment and detailed tests [62.28]. A useful energy range for applications in electron spectrometry is covered by a tabulation of subshell cross

sections calculated by *Yeh* and *Lindau* [62.29] in the dipole approximation with nonrelativistic Hartree-Fock-Slater wave functions. Because they were obtained in a frozen-core model, these cross sections like those of *Scofield* [62.27] automatically include all multiple excitations [62.30]. Such multi-electron processes (Sect. 62.4.4) can make substantial contributions, e.g., $\approx 40\%$ of the $1s$ photoionization in the threshold region of Kr [62.31]. A very useful family of codes being developed by I Grant's Oxford group is "GRASP – A General Purpose Relativistic Atomic Structure Program", several versions of which are being distributed through the *Computer Physics Communications Program Library* (Elsevier Science).

The usefulness of photoexcitation and ionization for experimental studies of atomic structure and processes has been greatly enhanced by the advent of *synchrotron radiation sources* beginning in the 1960's [62.1, 32, 33]. At first, experiments were performed mostly "parasitically". Later, they were done with dedicated sources, taking advantage of the high brightness, narrow bandwidth and wide tunability of the radiation (with suitable monochromators, from the visible to the hard X-ray regime), its high degree of polarization and sharp time structure [62.34]. In the 1990's, "third-generation" sources are being commissioned in which radiation is primarily derived from insertion devices, wigglers and undulators [62.35], entailing further increase of the power of this experimental tool. There is a growing literature on research applications of synchrotron radiation in atomic and molecular physics, including handbooks [62.36–38], proceedings of the series of conferences on X-ray and atomic inner-shell physics [62.39], and mono-

graphs [62.40–43]. Much of the physics described in the remainder of this chapter is being explored with synchrotron radiation.

62.3.2 Compton Scattering

Compton scattering denotes the scattering of photons from free electrons. The term is also used for inelastic photon scattering from bound electrons, which approaches the free electron case when the photon energy greatly exceeds the electron binding energy [62.1]. The theory of the process is discussed in standard textbooks [62.17, 44, 45]. Photon scattering from a free electron at rest is expressed, within lowest-order relativistic quantum electrodynamics, by the Klein–Nishina formula. A low energy approximation to the Klein–Nishina cross section is

$$\sigma^{KN} = \sigma^T \left(1 + \frac{2\hbar\omega}{m_e c^2} + \cdots \right) , \quad \hbar\omega \ll m_e c^2 , \tag{62.7}$$

where σ^T is the classical total Thomson cross section,

$$\sigma^T = (8\pi/3) r_e^2 . \tag{62.8}$$

The energy $\hbar\omega'$ of a photon scattered through an angle θ is related to the incident photon energy $\hbar\omega$ by the Compton relation

$$\hbar\omega' = \frac{\hbar\omega}{1 + \left(\hbar\omega/m_e c^2\right)\left(1 - \cos\theta\right)} . \tag{62.9}$$

The differential cross section for Compton scattering from free electrons, averaged over initial and summed over final photon and electron polarizations, is

$$\frac{d\sigma^{KN}}{d\Omega} = \frac{r_e^2}{2} \left(\frac{\omega'}{\omega} \right)^2 \left(\frac{\omega}{\omega'} + \frac{\omega'}{\omega} - \sin^2\theta \right) . \tag{62.10}$$

In the limit $\omega' \to \omega$, this reduces to the Thomson differential cross section,

$$\frac{d\sigma^T}{d\Omega} = \frac{r_e^2}{2} \left(1 + \cos^2\theta \right) \tag{62.11}$$

contained in (62.4).

Compton scattering from bound electrons has extensive applications in the study of electron momentum distributions in atoms and solids [62.46]. An exact second-order S-matrix code for the relativistic numerical calculation of cross sections for Compton scattering of photons by bound electrons within the independent particle approximation has been developed [62.47].

A systematic treatment of elastic and inelastic photon scattering, starting from many-body formalism, has been described by *Pratt*, *Kissel*, and *Bergstrom* [62.48].

62.4 Atomic Response to Inelastic Photon–Atom Interactions

62.4.1 Auger Transitions

Atomic inner shell vacancy states tend to decay predominantly through radiationless or Auger transitions, which are autoionization processes (see also Chapt. 25 and Chapt. 61) that arise from the Coulomb interaction between electrons [62.1,1,22,49–55]. Radiationless transitions dominate over radiative ones, except for 1s vacancies in atoms with atomic numbers $Z < 30$, primarily because of the magnitude of the matrix elements and because far fewer channels are allowed by electric dipole X-ray emission selection rules (Sect. 62.4.2, 62.4.3) than by the selection rules for Auger transitions, which in pure LS coupling are

$$\Delta L = \Delta S = \Delta M_L = \Delta M_S = 0 ,$$
$$\Delta J = \Delta M = 0 , \quad \Pi_i = \Pi_f . \tag{62.12}$$

Thus, for example, 2784 electron-electron interaction matrix elements can contribute to the radiationless decay of a $2p_{3/2}$ hole state in Hg.

In the simplest approach, ionization and subsequent Auger decay are treated as two distinct steps. This approximation is valid if the electron which is ejected in the ionization process is sufficiently energetic so that it does not interact significantly with the Auger electron, and the interaction of the core hole state with the Auger continuum is weak. Then the hole state can be considered to be quasi-stationary and the decay rate can be expressed according to Wentzel's ansatz, formulated in 1927 and later known as Fermi's Golden Rule No. 2 of time dependent perturbation theory [62.49]. In the independent-electron central-field approximation, this leads to the following nonrelativistic matrix element for a direct Auger transition:

$$D = \int\int \psi_{n''\ell''f''}^*(1)\psi_{\infty\ell_A j_A}^*(2) \left| \frac{e^2}{r_1 - r_2} \right|$$
$$\times \psi_{n\ell j}(1)\psi_{n'\ell' j'}(2)\, d\tau_1\, d\tau_2 , \tag{62.13}$$

where the quantum numbers n, ℓ, j characterize electrons that are identified schematically in Fig. 62.3. The
Fig. 62.3 Energy levels involved in the direct (D) and exchange (E) Auger processes, and notation for the principal, orbital angular momentum, and total angular momentum quantum numbers that characterize the pertinent electron states

state of the continuum (Auger) electron is labeled by $\infty \ell_A j_A$. In the physically indistinguishable exchange process, described by a matrix element E, the roles of electrons $n\ell j$ and $n'\ell' j'$ are interchanged (Fig. 62.3). The radiationless transition probability per unit time is

$$w_{fi} = \frac{2\pi}{\hbar}|D - E|^2 \rho(E_f) \,, \qquad (62.14)$$

where $\rho(E_f)$ is the density of final states for the energy E_f that satisfies energy conservation. With the continuum wave function normalized to one electron ejected per unit time, we have $\rho(E_f) = (2\pi\hbar)^{-1}$ ([62.22, 52], Appendix E).

The matrix elements D and E in (62.14) can be separated into radial and angular factors. Evaluation of the angular factors depends upon the choice of an appropriate angular momentum coupling scheme [62.1, 51, 53], ranging from the ($LSJM$) representation of Russell-Saunders coupling for the lightest atoms in which the spin-orbit interaction can be neglected, through intermediate coupling, to $j-j$ coupling in the high-Z limit. The coupling scheme particularly affects intensity ratios among multiplet components of Auger spectra, which can vary by more than an order of magnitude depending upon its choice. Furthermore, realistic calculations of Auger energies and rates call for the use of relativistic wave functions and inclusion of correlation and relaxation effects [62.1, 54]. It is this extreme sensitivity of Auger transitions to the details of the atomic model that makes them an exceedingly useful probe of atomic structure (see also Chapt. 23 and Chapt. 61).

Classification of Auger transitions in the central field model is conventionally based on the nomenclature summarized in Table 62.1.

The spectroscopic notation s, p, d, f, ... is employed for orbital angular momentum quantum numbers

Table 62.1 Nomenclature for vacancy states. The subscripts in the column headings are the values of $j = l \pm s$, and n is the principal quantum number

n	$s_{1/2}$	$p_{1/2}$	$p_{3/2}$	$d_{3/2}$	$d_{5/2}$	$f_{5/2}$	$f_{7/2}$
1	K						
2	L_1	L_2	L_3				
3	M_1	M_2	M_3	M_4	M_5		
4	N_1	N_2	N_3	N_4	N_5	N_6	N_7

$\ell = 0, 1, 2, 3, \ldots$, and shells with principal quantum numbers $n = 1, 2, 3, \ldots$ are denoted by $K, L, M, \ldots$. Let an inner shell vacancy be created initially in a subshell X_ν and consider a radiationless transition in which an electron from subshell Y_μ fills that vacancy and a Z_ξ-electron is ejected, in the direct process. This transition is denoted by X_ν-$Y_\mu Z_\xi$, which stands for $(n''\ell'' j'')$ -$(n\ell j)(n'\ell' j')$ in terms of the vacancies indicated in Fig. 62.3

Coster–Kronig transitions are a subclass of Auger transitions in which a vacancy "bubbles up" among subshells of the same shell, i.e., X_ν-$X_\mu Y_\xi$. These are exceptionally fast because the low energy of the ejected electron tends to prevent cancellations of its wave function overlap with the other factors in the matrix element (62.13) and the overlap of the bound state wave functions can be large owing to their similarity. Coster–Kronig transitions can therefore lead to hole-state widths in excess of $10\,\text{eV}$ (lifetimes $< 10^{-16}\,\text{s}$) for the $L_{1,2}$ subshells of the heaviest elements, for example. McGuire has coined the name super-Coster–Kronig transitions for the (even faster) type X_ν-$X_\mu X_\xi$ [62.50]. Here the initial state can no longer be considered quasi-stationary, the width becomes energy-dependent and the two-step model breaks down.

The Auger transition energy or kinetic energy of the ejected electron is, within the central field model,

$$E_A = E_{n''\ell'' j''} - E_{n\ell j, n'\ell' j'} \,, \qquad (62.15)$$

where, in the notation of Fig. 62.3, $E_{n''\ell'' j''}$ is the absolute value of the energy of the atom with an $n''\ell'' j''$ vacancy, with reference to the neutral atom energy, and $E_{n\ell j, n'\ell' j'}$ is the energy of the atom with *two* vacancies in the states indicated by the subscripts. This latter energy can be approximated by a mean of measured single-ionization energies of the atom under consideration and that with the next higher atomic number (the "$Z+1$ rule" [62.49]); with present-day computers it is readily calculated through one of the nonrelativistic [62.56, 57] or relativistic [62.58] self-consistent-field codes.

Photoionization and, even more so, ionization by charged particle impact, often produces more than one vacancy in the target atom (see Sect. 61.1.2 and Sect. 62.4.4). The ensuing Auger spectrum can then exhibit satellite lines shifted in energy, due to the presence of spectator vacancies and electrons, with respect to the diagram lines that arise from the decay of a singly ionized atom [62.1, 50, 53].

62.4.2 X–Ray Emission

The emission of X-rays by atoms ionized in inner shells was studied long before the discovery of the much more probable radiationless transitions, and has played a crucial role in the investigation of atomic structure and interactions with the environment [62.59]. At present, X-ray spectrometry is providing important insights into the structure of highly ionized species produced, e.g., in electron beam ion traps [62.60] or plasmas [62.61], and for the very precise experimental evaluation of inner-vacancy level energies [62.1, 62].

A classical treatment of multipole radiation by atomic and nuclear systems is given by Jackson [62.44], who shows by a simple argument that for atoms the electric dipole transition rate is $\approx (137/Z_{eff})^2$ times more intense than electric quadrupole or magnetic dipole emission, where Z_{eff} is the effective (screened) nuclear charge. The quantum theory of atomic radiation is presented in the treatises by *Sakurai* [62.63], *Mizushima* [62.64], *Berestetskii* et al. [62.17], and *Sobel'man* [62.65], for example. X-ray emission has been reviewed by *Scofield* [62.50, 66] and, with emphasis on relativistic effects, by *Chen* [62.1, 54, 60, 67]. In the present volume, radiative transitions are treated in Chapt. 33 to which the reader is referred for details.

62.4.3 Widths and Fluorescence Yields

The energy profile of an atomic hole state that decays exponentially with time is found to be the same from quantum as from classical theory [62.68]; it has the resonance or Lorentz shape

$$I(\omega)\,d\omega = \frac{I_0(\Gamma/2\pi)\,d(\hbar\omega)}{(\hbar\omega - \hbar\omega_0)^2 + \frac{1}{4}\Gamma^2} \ . \tag{62.16}$$

The full width Γ at half maximum of this energy distribution is proportional to the total decay rate τ^{-1} of the state, in accordance with Heisenberg's uncertainty principle $\Gamma\tau = \hbar$.

The decay rate $\tau^{-1} = \Gamma/\hbar$ of an atomic hole state is commonly given in units of eV/$\hbar$ or in atomic units (a.u.) of inverse time, with the corresponding level width Γ in eV or a.u. Thus, for the decay rate,

$$\frac{1}{\tau} = 1\,\text{a.u.} = 4.134\,14 \times 10^{16}\,\text{s}^{-1} = 27.2116\,\frac{\text{eV}}{\hbar} \ . \tag{62.17}$$

K-level (1s hole-state) widths increase monotonically with atomic number, from 0.24 eV for Ne to 96 eV for U, closely following the approximate relation [62.49]

$$\Gamma(1\,\text{s}) = 1.73\,Z^{3.93} \times 10^{-6}\,\text{eV} \ . \tag{62.18}$$

L-subshell widths, as functions of atomic number, exhibit sharp discontinuities that correspond to energetic cutoffs and onsets of intense Coster–Kronig channels (Sect. 62.4.1) [62.69].

If there are several decay channels, their partial widths Γ_i add:

$$\Gamma = \sum_i \Gamma_i \ . \tag{62.19}$$

The main decay channels for inner shell hole states are radiative, with a partial width Γ_R, and radiationless or Auger, with a partial width Γ_A.

The fluorescence yield ω_i of a hole state i is defined as the relative probability that the state decays radiatively:

$$\omega_i \equiv \Gamma_R(i)/\Gamma(i) \ . \tag{62.20}$$

Macroscopically, for example, the K-shell fluorescence yield ω_K is the number of characteristic K X-ray photons emitted from a sample divided by the number of primary K-shell vacancies created in the sample. This ratio rises from 0.04 for Al to 0.97 for U [62.49]. The definition of fluorescence yields of shells above the K-shell is more complicated because the higher shells consist of several subshells and Coster–Kronig transitions (Sect. 62.4.1) can shift primary vacancies to higher subshells before they are filled radiatively.

The concept of fluorescence yields is useful in many applications, particularly where the transport of radiant energy through matter is an issue, as in space sciences, medical radiology, and some fields of engineering as well as in physics. Tables of fluorescence yields can be found in the review by *Bambynek* et al. [62.49] and in the compilations by *Krause* [62.70] and *Hubbell* et al. [62.71]. Considerable uncertainty persists in the fluorescence yields of higher shells.

62.4.4 Multi-Electron Excitations

In atomic inner-shell photoionization, more than one electron can be excited with significant probability. Final states are thus produced that can be described approximately by removal of a core electron and excitation of additional electrons to higher bound states (shakeup) or to the continuum (shakeoff). These multiple excitation processes exhibit themselves through satellites in photoelectron spectra (Sect. 61.1.2) and in the Auger and X-ray spectra emitted when the excited states decay, as well as in some cases by features in absorption spectra [62.72]. As the photon-electron interaction is described by a one-electron operator, the frozen-core, central field model does not predict changes of state under photon impact by more than one electron. Direct multiple excitation processes are thus a result of electron-electron correlation (Chapt. 23, Sect. 61.1.2).

Cross sections for photoexcitation and ionization of two inner shell electrons have been evaluated [62.72] by the multichannel multiconfiguration Dirac–Fock (MMCDF) method [62.73]. Within this model, the correlation effects that cause direct two-electron processes are (i) relaxation or core rearrangement, (ii) initial state configuration interaction, (iii) final ionic state configuration interaction, and (iv) final continuum state configuration, or final state channel interaction.

Mechanisms that contribute to two-electron photoionization of the outermost shells of noble gas atoms have been separated within many-body perturbation theory [62.74]. In first order of the combined perturbations by the photon field and electron correlations, the important contributions are core rearrangement, initial state correlations, virtual Auger transitions, and "direct collisions" by the photoelectron with another orbital electron. If treated nonperturbatively, these mechanisms belong within the MMCDF scheme to categories (i)–(iv) described above. The different mechanisms have been found to be of varying importance, depending on the photon energy relative to the double ionization threshold energy, the orbitals which are ionized, and the relative final state energies of the active electrons. Interest in the theory [62.75, 76] has been enhanced by experiments with synchrotron radiation on the double ionization of He [62.77], a process that epitomizes the problem. Above $\approx 5\,\mathrm{keV}$ photon energy, the double ionization of He has been shown to be dominated by Compton scattering, not photoeffect [62.78].

62.4.5 Momentum Spectroscopy

We close with a few examples of fruitful recent advances in approaches to the study of electron-atom interactions. A step-function advance in viewing atomic collision dynamics, including photon-electron interactions, arose from the development (first in the University of Frankfurt by Schmidt-Böcking and his group) of Cold-Target Recoil-Ion Momentum Spectroscopy (COLTRIMS), a "momentum microscope" to view the dynamics of photon-atom collisions [62.79–81]. This novel momentum space imaging technique allows the investigation of the dynamics of ion, electron, or photon impact reactions with atoms or molecules. Studies performed with this technique yield kinematically complete pictures of the fragments of atomic and molecular breakup processes, unprecedented in resolution, detail and completeness. The multiple-dimensional momentum-space images often directly unveil the physical mechanism underlying the many-particle transitions that are being investigated [62.82]. Important applications are being developed [62.83, 84].

62.4.6 Ultrashort Light Pulses

Advances in laser technology have made it possible to obtain high-intensity (up to $10^{14}\,\mathrm{W/cm^2}$), short (5 fs) pulses, making laser-atom [62.85] and laser-molecule interactions [62.86–89] amenable to experimental study. In the latter category, nonlinear phenomena such as above-threshold ionization and laser-induced molecular potentials have already been explained theoretically [62.90–92].

Ultrashort light pulses make it possible to follow ultrafast relaxation processes on never-before-accessed time scales and to study light-matter interactions at unprecedented intensity levels [62.85, 93].

Ultrafast optics has permitted the generation of light wave packets comprising only a few oscillation cycles of the electric and magnetic fields. The spatial extension of these wave packets along the direction of their propagation is limited to a few times the wavelength of the radiation. The pulses can be focused to a spot size comparable to the wavelength. Radiation can thus be temporarily confined to a few cubic micrometers, forming a "light bullet". The extreme temporal and spatial confinement allows moderate pulse energies of the order of one microjoule to result in peak intensities higher than $10^{15}\,\mathrm{W/cm^2}$. These field strengths exceed those of the static field seen by outer-shell electrons in atoms. The laser field consequently is strong enough to suppress the

binding Coulomb potential in atoms and triggers optical field ionization [62.94, 95].

Attosecond $(10^{-18}\,\text{s})$ trains from high-harmonic generation have been discovered [62.90–92]. High harmonics, generated in a gas jet by a femtosecond laser pulse, have a well-defined phase relation with respect to each other. The relative phases result in strong amplitude beating between the various harmonics. The emerging radiation thus consists of attosecond pulses.

The process of harmonic generation can be thought of as consisting of three steps [62.92]: a (rate-limiting) field ionization of the atom at times near the electric field maxima, followed by acceleration of the free electron which, due to the ac character of the driving light, eventually makes the electron recollide at high energy with its parent ion. Radiative recapture of this fast electron into the ground state, strongly favored due to the remaining coherence between the two parts of what was initially the same wave function, completes the harmonic generation process without any change to the atom.

In summary, intense few-cycle light pulses open up never yet accessed parameters in high-field physics [62.85]. Strong-field processes induced by few-cycle laser fields may permit access to the phase of the carrier wave and hence to the light fields for the first time. Phase-controlled light pulses may allow control of high-intensity light-matter interaction on a subcycle time scale. The search for laser-driven ultrafast X-ray sources is also drawing benefits from this research area. Substantial major progress can be anticipated in this new field.

62.4.7 Nondipolar Interactions

A powerful tool for exploring photon-atom interactions has been photoionization of atoms and molecules [62.96]. Analysis of photoelectron angular distribution measurements was routinely performed in the electric-dipole approximation, in which all higher-order multipoles are neglected [62.97]. While breakdown of the dipole approximation at higher photon energies (above 5 keV) was known, so that a proper description requires inclusion of many multipoles [62.98], experimental limitations appeared to make such extension unnecessary. A notable exception was a hint found by Krause, who noticed deviations from the dipole approximation in measurements on rare gases using unpolarized X-rays [62.99].

Only when more sophisticated radiation sources became available, notably synchrotron radiation, and advances in detector technology took place, did it become possible to gain data on nondipolar photoionization [62.98]. Intense experimental and theoretical work ensued.

Photoelectron angular distributions depend upon dynamical parameters of the target atoms and upon the polarization of the photon beam. Peshkin developed a systematic analysis of the restrictions imposed by symmetry, through a geometric description of polarization that is easily visualized and has been found useful in planning experiments [62.100].

Earlier theories predicted nondipolar asymmetries of 1s photoelectron distributions in the point-Coulomb potential. More recently, photoionization amplitudes are calculated in screened potentials, predicting richer Z-dependent and subshell-dependent energy variations of nondipole asymmetries [62.97]. A full relativistic multipole expansion, incuding screening effects, in the independent-particle approximation was discussed by *Tseng* et al. [62.97]. In addition, leading correction terms to the dipole approximation can be included by adopting the "retardation expansion" of the exponential factor $\exp(\mathbf{i k} \cdot \mathbf{r})$ [62.101, 102] which, unlike the multipole expansion, includes a finite number of multipoles within the long-wavelength limit [62.103]. A lucid summary of the development of the subject can be found in the paper by *Krässig* et al.on nondipole asymmetries of Kr 1s photoelectrons [62.104]. Extending the subject, experiments and theory on electric-octupole and pure-electric-quadruple effects on soft-X-ray photoemission have been described by *Derevianko* et al. [62.105].

62.5 Threshold Phenomena

During the creation of a core vacancy by photoexcitation or ionization, the escape of the photoelectron from an inner shell involves complex dynamics of electron excitations with multiple correlational aspects. The entire process of inner shell photoionization and subsequent de-excitation has drastically different characteristics near threshold from that in the high energy limit. In the latter case, discussed in the preceding sections, if an X-ray photon promotes an inner shell electron to an energetic continuum state, the atom first relaxes in

its excited (hole) state. In a practically distinct second step, the hole is then filled—most often by a radiationless transition, under emission of an Auger electron with *diagram* energy that can readily be calculated from the wave function of the stationary, real intermediate state [62.1, 53].

On the other hand, in the vicinity of core-level energy thresholds, atomic photoexcitation and the ensuing X-ray or Auger electron emission occur in a single second-order quantum process, the resonant Raman effect. Here, the intermediate states are virtual and there is no relaxation phase. The resonant Raman regime, comprising the energy region just below threshold, is linked by the post-collision interaction regime (Sect. 62.5.2) above threshold to the (asymptotically) two-step regime.

The primary process of photoionization and Auger electron emission can be viewed as resonant double photoionization mediated by a complete set of intermediate states; these correspond to an intermediate virtual inner shell hole and an electron in excited bound or continuum states. A unified treatment of the process, as well as of resonant X-ray Raman scattering, has been developed within the framework of relativistic time independent resonant scattering theory [62.48, 106–108]. As the energy of the incoming photons is increased,

Fig. 62.4 Energy of the Xe L_3–M_4M_5 ($^1G_4$) Auger electron peak, as a function of exciting photon energy. Near threshold Auger satellites, caused by the spectator photoelectron in bound orbits, exhibit linear Raman dispersion. The post-collision interaction shift (*right-hand scale*) vanishes only in the asymptotic limit (After [62.83])

sweeping through an inner shell threshold, continuous asymmetric electron distributions associated with different two-hole multiplets evolve into Auger-electron lines with characteristic energies. The shapes and energies of the characteristic lines continue to change until the energy of the photoelectron exceeds that of the Auger electron. The nonresonant two-electron emission amplitude is usually negligible in this region, compared with the resonant amplitude.

62.5.1 Raman Processes

Resonant Raman transitions to bound final states are the inelastic analog of resonance fluorescence [62.68], with which they share two characteristic features: (1) the emitted radiation can have a narrower bandwidth than the natural lifetime width of the corresponding diagram line, and (2) the energy of the emitted radiation exhibits linear dispersion with excitation energy. Radiative resonant Raman scattering was first observed by *Sparks* in 1974 [62.109] and subsequently explored with synchrotron radiation by *Eisenberger* et al.(see [62.48, 48, 108, 110]). Radiationless resonant Raman scattering was identified by *Brown* et al. [62.111] and in subsequent studies [62.112] of the deformation of Auger-electron lines near threshold (Fig. 62.4). The connection between resonant Raman and Compton scattering has been pointed out by *Bergstrom* et al. [62.47].

According to a generalization of time independent resonant scattering theory [62.106, 107], a transition matrix element can be constructed that accounts for photoexcitation and either radiative or radiationless deexcitation, including resonance structure [62.48, 108]. The wave functions represent both the atomic and photon fields and include all electrons throughout the process. The conventional two-step model of X-ray fluorescence and Auger electron emission is but a special case of the transition amplitude

$$T_{\beta\alpha} = \left\langle \psi_{\beta\varepsilon\varepsilon'}^- \left| V_\gamma + \sum_v \int d\tau \frac{(H-E)|\psi_{\tau v}\rangle\langle\psi_{\tau v}|V_\gamma}{E - E_{\tau v}(E)} \right| \psi_\alpha \right\rangle \tag{62.21}$$

where H is the total Hamiltonian, V_γ the photon-electron interaction operator, and $E = \hbar\omega_1 + E_\alpha$ is the total energy. The first term in $T_{\beta\alpha}$ represents direct nonresonant Raman scattering; the resonance behavior is embedded in the second amplitude. The complex eigenenergies $E_{\tau v}(E)$ satisfy a complicated secular equation that involves diagonal and nondiagonal matrix elements of the level shifts and widths [62.1, 3, 48, 108]. The initial state

wave function ψ_α is a direct product of the initial atomic state wave function and a one-photon state $|\mathbf{k}_1, \mathbf{e}_1\rangle$, where $\mathbf{k}_1$ is the wave vector and $\mathbf{e}_1$, the polarization vector. The final state scattering wave function $\psi^-_{\beta\varepsilon\varepsilon'}$ corresponds, in the radiative case, to a scattered photon in a definite state $|\mathbf{k}_2, \mathbf{e}_2\rangle$ and an electron plus ion in a given quantum state, which may involve the linear momentum $\hbar\mathbf{k}_e$ of the electron if the latter is in the continuum. In the radiationless case, there are an ion and two electrons, both of which may be in a continuum state $|\mathbf{k}_e, \mathbf{k}'_e\rangle$. The wave function $\psi^-_{\beta\varepsilon\varepsilon'}$ fulfills the ingoing-wave boundary condition with respect to the electron(s) and accounts for final state channel interaction effects.

Work on inner shell Raman processes is as yet in its infancy. Synchrotron radiation experiments, interpreted in light of the theory outlined above, promise to become a useful tool in atomic physics and materials science [62.113, 114].

62.5.2 Post-Collision Interaction

In the radiationless decay of an atom that has been photoionized near an inner shell threshold, the Coulomb field of the receding photoelectron perturbs the Auger electron energy and line shape. This post-collision interaction provides continuity in the energy evolution of inner shell dynamics between the Raman and asymptotic two-step regimes. In Auger decay, following photoionization, the Auger electron initially screens the ionic Coulomb field seen by the receding photoelectron. This screening subsides when the (usually fast) Auger electron passes the slow photoelectron. Distortion of the Auger line shape results, and the Auger energy is raised at the expense of the photoelectron energy (Fig. 62.4).

A semiclassical potential curve model of post-collision interaction leads to intuitive insight and surprisingly accurate predictions [62.115, 116]. In sim-

ple terms, the attractive potential well in which the slow photoelectron moves is deepened suddenly when the residual singly ionized atom undergoes Auger decay and its net charge changes from $+e$ to $+2e$. The photoelectron sinks down into this deeper well, there being no time for it to speed up, and the energy lost by the photoelectron is transferred to the Auger electron. The photoelectron slows down and may even be recaptured by the atom from which it was emitted [62.117].

Quantum theoretically, post-collision interaction can be treated from the point of view of resonant scattering theory (Sect. 62.5.1). A lowest-order line shape formula, corresponding to a shakedown mechanism, can be shown to emerge from approximations of the general multichannel transition matrix element [62.118]; the phenomenon thus arises as a consequence of a resonant rearrangement collision in which a photon and an atom in the initial channel turn into an ion and two electrons (one of which has nearly characteristic energy) in the final channel. In this lowest order, the results can be interpreted in terms of an analytic line shape formula based on asymptotic Coulomb wave functions [62.118]. The line shape depends only on the excess photon energy, the lifetime of the initial state of the Auger process, and the change of the ionic charge during Auger electron emission.

The interaction between the photoelectron and the Auger electron in the final state can be included by reinterpreting the ionic charge seen by the photoelectron on the basis of asymptotic properties of the continuum wave function pertaining to the two outgoing electrons [62.119, 120]. This results in a procedure which is consistent with semiclassical models that account for the time required for the Auger electron to overtake the photoelectron. Calculations based on this approach agree very well with measurements performed with synchrotron radiation [62.120].

63. Electron–Atom and Electron–Molecule Collisions

Electron–atom and electron–molecule collision processes play a prominent role in a variety of systems ranging from discharge or electron-beam lasers and plasma processing devices to aurorae and solar plasmas. Early studies of these interactions contributed significantly to the understanding of the quantum nature of matter. Experimental activities in this field, initiated by *Franck* and *Hertz* [63.1], flourished in the 1930s and, after a dormant period of about a quarter of a century, have had a renaissance in recent years.

When electrons collide with atomic or molecular targets, a large variety of reactions can take place (see Sect. 63.1.1). We limit our discussion to electron collisions with gaseous targets, where single collision conditions prevail. Furthermore, we discuss only low-energy (threshold to few hundred eV) impact processes where the interaction between the valence-shell electrons of the target and the free electron dominates.

Comprehensive discussions on electron–atom (molecule) collision physics can be found in the books of *Massey* et al. [63.2], *McDaniel* [63.3] and the volumes of Advances in Atomic and Molecular (since 1990 Atomic, Molecular and Optical) Physics. The latest developments are usually published in

Physical Review A, Journal of Physics B, Journal of Chemical Physics and Journal of Physical and Chemical Reference Data, and are presented at the biannual International Conference on Photonic, Electronic and Atomic Collisions (ICPEAC).

63.1 Basic Concepts

63.1.1 Electron Impact Processes

Lox energy electrons can very effectively interact with the valence-shell electrons of atoms and molecules, in part because they have similar speeds. In elastic scattering, the continuum electron changes direction and transfers momentum to the target. Inelastic collisions include also a transfer of kinetic energy to the target, such as excitation of valence electrons to discrete energy levels, to the ionization continuum, and, in the case of molecules, excitation of nuclear motion (rotational, vibrational) and excitation to states which dissociate into neutral or ionic fragments. Various combinations of these processes are also possible, e.g., dissociative attachment, excitation or ionization. Excitation of more than one valence electron at the same time, or excitation of electrons from intermediate and inner shells, may also occur but these processes are more likely at impact energies of a few keV. These excitations lie above the first ionization limit and lead, therefore, with high probability, to autoionization, except for heavy elements where X-ray emission is an important competing process.

63.1.2 Definition of Cross Sections

The parameters which characterize collision processes are the cross sections. Electron collision cross sections depend on impact energy E_0 and scattering polar angles θ and ϕ. The differential cross section, for a specific well-defined excitation process indicated by the index n is defined as

$$\frac{\mathrm{d}\sigma_n(E_0, \Omega)}{\mathrm{d}\Omega} = \frac{k_f}{k_i} |f_n(E_0, \Omega)|^2 , \qquad (63.1)$$

where Ω is the polar angle of detection, k_i and k_f are the initial and final electron momenta, and f_n is the complex scattering amplitude ($n = 0$ refers to elastic scattering). Integration over the energy-loss profile is assumed. If the energy-loss spectrum is broad, differentiation with respect to energy loss also has to be included. For certain processes it may be necessary to define differential cross sections with respect to angle and energy for both primary and secondary particles.

Integration over all scattering angles yields the integral cross sections

$$\sigma_n(E_0) = \int\limits_0^{2\pi} \int\limits_0^\pi \frac{\mathrm{d}\sigma_n(E_0, \Omega)}{\mathrm{d}\Omega} \sin\theta \, \mathrm{d}\theta \, \mathrm{d}\phi . \qquad (63.2)$$

In the case of elastic scattering, the momentum transfer cross section is defined as

$$\sigma_0^M(E_0) = \int\limits_0^{2\pi} \int\limits_0^\pi \frac{\mathrm{d}\sigma_0(E_0, \Omega)}{\mathrm{d}\Omega} (1 - \cos\theta) \sin\theta \, \mathrm{d}\theta \, \mathrm{d}\phi . \qquad (63.3)$$

The total electron scattering cross section is obtained by summing all integral cross sections:

$$\sigma_{\text{tot}}(E_0) = \sum_n \sigma_n(E_0) + \sum_m \sigma_m(E_0) , \qquad (63.4)$$

where σ_m are the cross sections for other possible channels. Experimental cross sections typically represent averages over indistinguishable processes (e.g., magnetic sublevels, hyperfine states, rotational states etc.). The cross section obtained this way corresponds to an average over initial and sum over final indistinguishable states with equal weight given to the initial states. (This may not always be true, as discussed later.) If the target molecules are randomly oriented, the cross section averaged over these orientations is independent of ϕ. In addition, there is

an averaging over the finite energy and angular resolution of the apparatus. It is important, therefore, to specify clearly the nature of the measured cross section, otherwise their utilization and comparison with other experimental and theoretical cross sections become meaningless. We denote the conventionally measured differential and integral cross sections by $D_n(E_0, \theta)$ and $Q_n(E_0)$, with the various averagings implied. Similarly, $Q^M(E_0)$ and $Q_{\text{tot}}(E_0)$ are the corresponding momentum transfer and total scattering cross sections.

The collision strength for a process $i \to j$, which is the particle equivalent of the oscillator strength, is defined by

$$\Omega_{ij}(E_0) = q_i E_0 \sigma_{ij}(E_0) , \qquad (63.5)$$

where q_i is the statistical weight of the initial state [$q_i = (2L_i + 1)(2J_i + 1)$], E_0 is in Rydbergs and σ_{ij} is in units of πa_0^2.

The rate for a specific collision process (e.g., excitation) for electrons of energy E_0 is given as

$$R_{ij}(E_0) = NI(E_0)\sigma_{ij}(E_0) , \qquad (63.6)$$

where N is the density of the target particles $\left(\mathrm{m}^{-3}\right)$, and $I(E_0)$ is the electron flux $\left(\mathrm{m}^{-2}\,\mathrm{s}^{-1}\right)$; σ_{ij} is in m^2, yielding R_{ij} in units of $\mathrm{m}^{-3}\,\mathrm{s}^{-1}$. For nonmonoenergetic electron beams, (63.6) must be integrated over E_0 to get the average rate.

63.1.3 Scattering Measurements

Most scattering experiments, are carried out in a beam–beam arrangement (Fig. 63.1). A beam of nearly
Fig. 63.1 A schematic diagram for electron scattering measurements

monoenergetic electrons is formed by extracting electrons from a hot filament and selecting a narrow segment of the thermal energy distribution. For the formation and control of the electron beam, electrostatic lenses are used and the energy selection is achieved with electrostatic energy selectors. A magnetic field may also be applied to obtain a magnetically collimated electron beam. The target beam is formed by letting the sample gas effuse from an orifice, tube or capillary array with various degrees of collimation. Target species which are in the condensed phase at room temperature need to be placed in a crucible and evaporated by heating. Extensive discussion of this technique has been given by *Scoles* [63.4]. The electron beam intersects the target beam at a 90° angle and electrons scattered into a specific direction, over a small solid angle $\left(\approx 10^{-3} \, \text{sr} \right)$, are detected. However the scattered electron is not necessarily the same as the incoming electron. Exchange with the target electrons may occur, and is required for spin-forbidden transitions in light elements. The detector system consists of electron lenses and energy analyzers similar to those used in the electron gun. The actual detector is an electron multiplier which generates a pulse for each electron. In the scattering process, secondary species (electrons, photons, ions, neutral fragments) may also be generated and can be detected individually or in various coincidence schemes. The experiments are carried out in a vacuum chamber and it is important to minimize stray electric and magnetic fields. More details about the apparatus and procedures can be found in a review by *Trajmar* and *Register* [63.5]. The primary information gained in these experiments is the energy and angular distribution of the scattered electrons.

There are several methods used to carry out scattering measurements. In the most commonly used energy-loss mode, the impact energy and scattering angle are fixed, and the scattering signal as a function of energy lost by the electron is measured by applying pulse counting and multichannel scaling techniques. The result of such an experiment is an energy-loss spectrum. The elastic scattering feature appears at zero energy loss; the other features correspond to various excitation processes and to ionization. Energy-loss spectra can also be generated in the constant residual energy mode. In this case, the detector is set to detect only electrons with a specific residual energy $E_R = E_0 - \Delta E$ at a fixed scattering angle, and E_0 and ΔE are simultaneously varied. Each feature in the energy-loss spectrum is obtained then at the same energy above its own threshold. An exam-
Fig. 63.2 Energy-loss spectrum of He at a constant residual energy of 1.2 eV and scattering angle of 90°. The inelastic features with the corresponding principal quantum numbers are shown. IE is the ionization potential of He (24.58 eV). No background is subtracted and true signal zero is indicated by a dotted line under the expand portion of the spectrum m. (Taken from *Allen* [63.6])

ple, taken from the work of *Allan* [63.6], ist shown in Fig. 63.2.

The energy loss spectrum becomes equivalent to the photoabsorption spectrum in the limit of small momentum transfer $\mathbf{K}$, where $\mathbf{K} = \mathbf{k}_f - \mathbf{k}_i$ (i. e., high impact energy, small scattering angle). The equivalence of electrons and photons in this limit follows from the Born approximation, and it can be used to obtain optical absorption and ionization cross sections. The correspondence is defined through the Limit Theorem

$$\lim_{\mathbf{K} \to 0} f_n^{\text{G}}(\mathbf{K}) = f_n^{\text{opt}} , \tag{63.7}$$

$$f_n^{\text{G}}(\mathbf{K}) = \frac{\Delta E}{2} \frac{\mathbf{k}_i}{\mathbf{k}_f} \mathbf{K}^2 \frac{\text{d}\sigma_n}{\text{d}\Omega}(\mathbf{k}) , \tag{63.8}$$

where f_n^{G} is the generalized oscillator strength for excitation process n, and f_n^{opt} is the corresponding optical f-value. Equation (63.7) was originally derived by *Bethe* [63.7] from the Born cross section. It was extended later by *Lassettre* et al. [63.8] to cases where the Born approximation does not hold. In this case, $f_n^{\text{G}}(\mathbf{K})$ is replaced by $f_n^{\text{app}}(\mathbf{K})$, the apparent generalized oscillator strength. The Limit Theorem implies that, in the limit of small K, optical selection rules apply to electron impact excitation. The practical problem is that the limit is nonphysical and the extrapolation to zero K involves some arbitrariness. When K is significantly different from zero,
Fig. 63.3 Variation of energy-loss spectra (and DCSs) with scattering angle for He at 40 eV impact energy. Spectra are shown at 5°, 50° and 125° scattering angles

Fig. 63.4 The 19.37 eV He resonance observed in the elastic channel at 90° scattering angle

optical-type selection rules do not apply to electron-impact excitation. As can be seen from Fig. 63.3, spin and/or symmetry forbidden transitions then readily occur and can be an efficient way of producing metastable species.

Selection rules for electron impact excitations can be derived from group theoretical arguments [63.9, 10]. For atoms, the selection rule $S_g \leftrightarrow S_u$ applies in general and scattering to 0° and 180° is forbidden if $(L_i + \Pi_i + L_f + \Pi_f)$ is odd. Here, L_i and L_f are the angular momenta and Π_i and Π_f are the parities. For molecules, selection rules can be derived under two special conditions: (a) rules concerning 0° and 180° scattering for arbitrary orientation of the molecule, and (b) rules concerning scattering to any angle but for specific orientation of the molecule. An important example of the first case is the $\Sigma^- \not\leftrightarrow \Sigma^+$ selection rule for linear molecules at 0° and 180° scattering angles.

The energy dependence of cross sections is obtained by fixing the energy-loss value (scattering channel) and studying the variation of scattering signal with impact energy at a given angle or integrated over all scattering angles. In general, cross sections associated with spin forbidden and optically allowed transitions peak near and at several times the threshold impact energy respectively, and they usually vary smoothly with impact energy. However, resonances may appear at certain specific impact energies. These sudden changes are associated with temporary electron capture and are the result of quantum mechanical interference between two indistinguishable paths. An example is shown in Fig. 63.4 for He in the elastic channel at 19.37 eV impact energy.

Integral cross sections can be obtained from extrapolation of the measured $D_n(E_0, \theta)$ to 0° and 180° scattering angles and integration over all angles. Recently, incorporation of an "angle-changing" device has enabled measurements to be extended over the whole range of scatering angles [63.11, 12]. In certain cases it is possible to measure integral cross sections directly by detecting secondary products such as photons and ions. These procedures and the resulting cross sections will be discussed in some detail in Sect. 63.2.

63.2 Collision Processes

In addition to the basic elastic and inelastic processes defined in Sect. 63.1.2, we now also explicitly include dissociation (to neutral and charged fragments) cross sections $Q_D(E_0)$; and ionization cross sections $Q_I(E_0)$. Each of these is now considered separately.

63.2.1 Total Scattering Cross Sections

Total electron scattering cross sections represent the sum of all integral cross sections:

$$Q_{\text{tot}}(E_0) = \sum_n Q_n(E_0) + Q_I(E_0) + Q_D(E_0) ,$$

(63.9)

$Q_{\text{tot}}(E_0)$ are useful for checking the validity of scattering theories, and the consistency of available data, for normalization of integral and differential cross sections, and as input to the Boltzmann equation. At low impact energies, elastic scattering dominates, while at intermediate and high impact energies, electronic excitations and ionization become major contributors to Q_{tot}. Figure 63.5 shows the various cross sections for electron–helium collisions. The data are from the recommended values of *Trajmar* and *Kanik* [63.13].

Two methods are commonly used for measuring $Q_{\text{tot}}(E_0)$: the transmission method and the target recoil method (for details see [63.5, 14]). Total scattering cross sections measured by these techniques are, in general, accurate to within a few percent. The extensive reviews by *Zecca* and co-workers [63.15–17] should be noted.

63.2.2 Elastic Scattering Cross Sections

Elastic scattering cross sections $Q_0(E_0)$ are not as readily available as $Q_{\text{tot}}(E_0)$. They are obtained from differential scattering experiments over limited angular ranges by extrapolation and integration of the measured values. Typical error limits are 5 to 20%. For molecular species rotational excitation is usually not resolved but is included in the $D_0(E_0, \theta)$ and $Q_0(E_0)$ values. In order to obtain the absolute $D_0(E_0, \theta)$ directly from the scattering signal, one has to know the electron flux, the number of scattering species, the scattering geometry and the overall response function of the apparatus. A direct measurement of these parameters can be made at high energies (> 100 eV). However, at low electron energies, this approach is not feasible. A number of methods have been devised to derive relative $D_0(E_0, \theta)$ from the measured scattering intensities and then to nor-
Fig. 63.5 Cross sections for various processes in the electron–helium collision (see text for data sources)

malize the $D_0(E_0, \theta)$ to the absolute scale. We briefly outline here only the most commonly used procedure.

The most practical and reliable method of obtaining the absolute $D_0(E_0, \theta)$ is the relative flow technique in which scattering signals for a known standard gas and an unknown test gas are compared at each energy and angle [63.5, 18–20]. The He elastic cross section is the natural choice of standard since it is known accurately over a wide energy and angular range, and He is experimentally easy to handle. Only the relative electron beam flux and molecular beam densities (and their distributions) need be known in the two measurements. The flow rate of the test gas is adjusted so that the flux and density distribution patterns of the two gases are identical, and all geometrical factors cancel in the scattering intensity ratios. The absolute $D_0(E_0, \theta)$ for the sample gas is obtained from the measured scattering intensity, target density, and electron beam intensity ratios and the standard $D_0(E_0, \theta)$ value. See [63.5, 20, 21] for a detailed discussion of this technique.

63.2.3 Momentum Transfer Cross Sections

$Q^M(E_0)$ can be obtained both from the elastic DCSs and from swarm measurements. At low electron-impact energies (from 0.05 to a few eV), where only a few collision channels are open, the electron swarm technique is the most accurate ($\approx 3\%$) way to determine the momentum transfer cross sections. Beam–beam experiments are mandatory at higher energies. A detailed

discussion of these techniques is given by *Trajmar* and *Register* [63.5].

63.2.4 Excitation Cross Sections

$D_n(E_0, \theta)$ and $Q_n(E_0)$ can be derived from energy-loss spectra obtained in beam–beam scattering experiments. The relative $D_n(E_0, \theta)$ is usually normalized to $D_0(E_0, \theta)$ which in turn is normalized to the helium $D_0(E_0, \theta)$ by the relative flow technique described in Sect. 63.2.2. There are, however, complications and uncertainties associated with this technique because of the sensitivity of the instrument response function to the residual energy of the scattered electrons. For more details, see *Trajmar* and *McConkey* [63.21]. Data obtained by this procedure are rather limited, partly due to experimental difficulties and partly due to the time required to carry out such measurements.

For cases where an excited state j is formed which can radiatively decay by means of a short-lived (dipole-allowed) transition to a lower lying state i, the intensity of the resultant radiation is directly related to the cross section for production of the excited state in the original collision process. An optical emission cross section, $Q_{ji}(E_0)$, is defined by

$$Q_{ji}(E_0) = \frac{N_j \Gamma_{ji}}{I n_0 \tau_j} , \qquad (63.10)$$

where N_j and n_0 are the densities in the excited and ground states, respectively, Γ_{ji} is the branching ratio for radiative decay from state j to state i, I is the electron beam flux, and τ_j is the natural radiative lifetime of state j. Since the excited state may be produced either by direct electron impact or by cascade from higher-lying states k, also formed in the collision process, we may define the direct excitation cross section $Q_j^d(E_0)$ by

$$Q_j^d(E_0) = \sum_i Q_{ji}(E_0) - \sum_k Q_{kj}(E_0) . \qquad (63.11)$$

The last term subtracts the cascade contribution from higher lying states. The quantity $Q_j^a(E_0) = \sum_i Q_{ji}(E_0)$ is known as the apparent excitation cross section for level j. Clearly, to obtain $Q_j^d(E_0)$ from $Q_j^a(E_0)$, the cascade contribution must be known.

In (63.10), $N_j \Gamma_{ji}/\tau_j$ gives the steady state number of $j \rightarrow i$ photons per unit time per unit volume emitted from the interaction region. Since observation is made in a particular direction care must be taken to correct for any anisotropy in the radiation pattern. Alternatively, if observation is made at the so-called "magic" angle

($54° 44'$) to the electron beam direction, the emission intensity per unit solid angle is equal to the average intensity per unit solid angle irrespective of the polarization of the emitted radiation. However, even at this magic angle, care must be taken to avoid problems with polarization sensitivity of the detection equipment [63.22, 23].

The phenomenon of radiation trapping is often a problem if the radiative decay channels of the excited state include a dipole allowed channel to the ground state. Repeated absorption and re-emission of the radiation can occur and can lead to a diffuse emitting region much larger than the original interaction region, and the polarization of the emitted light can also be altered. Often a study of the variation of the emitted intensity or polarization with the target gas pressure is sufficient to reveal the presence of radiation trapping or other secondary effects.

The emission cross sections of certain lines have been measured with great care and now serve as bench-marks for other work. Examples of these are the measurements of *van Zyl* et al. [63.24] on the n^1S levels of He in the visible spectral region or the measurements of the cross section for production of Lyman α from H_2 in the VUV region (see [63.25] for a full discussion of this including many references). Use of secondary standards is particularly important when crossed-beam measurements are being carried out because of the cancellation of geometrical and other effects which occur.

The Bethe–Born theory [63.26] provides a convenient calibration of the detection system for optically allowed transitions of known oscillator strength. At sufficiently high energies, the excitation cross section, Q_n, of level n is given by

$$Q_n = \frac{4\pi a_0^2}{E_0/R_\infty} \frac{f_n^{opt}}{\Delta E_n/R_\infty} \ln(4c_n E_0/R_\infty) . \quad (63.12)$$

Here ΔE_n is the excitation energy, and c_n is a constant dependent on the transition. A plot of $Q_n E_0$ versus $\ln E_0$ is a straight line with a slope proportional to f_n^{opt} and the intercept with the $\ln E_0$ axis yields an experimental value for c_n independent of the normalization. For example, the He n^1P–1^1S optical oscillator strengths are very accurately known, as are cascade contributions. Thus accurate normalization of the slope of the Bethe plot can be made, yielding accurate excitation cross sections.

As mentioned above, the excitation cross sections display characteristic shapes as a function of energy. For optically allowed transitions, the cross section rises relatively slowly from threshold to a broad maximum approximately five times the threshold energy. At higher energies the $(\ln E_0)/E_0$ dependence of the cross section

predicted by (63.12) is observed. For exchange processes, e.g., a triplet excited state from a singlet ground state, the cross section peaks sharply close to threshold and falls off at high energy as E^{-3}. If the excitation is spin allowed but optically forbidden, e.g., He n^1D from 1^1S, then the Bethe theory predicts an E^{-1} dependence of the cross section at high energies.

When excitation occurs to a long-lived (metastable or Rydberg) state following electron impact, it is often possible to detect the excited particle directly. Time-of-flight (T.O.F.) techniques are used to distinguish the long lived species from other products, e.g., photons, produced in the collisions.

63.2.5 Dissociation Cross Sections

Dissociation of a molecular target can result in fragments which may be excited or ionized. Such processes may be studied using the techniques discussed in the previous section or in the following section, where charged particle detection is considered. Because a repulsive state of the molecule is accessed, the fragments can leave the interaction region with considerable kinetic energy (several eV). If the fragment is in a long-lived metastable or Rydberg state, T.O.F. techniques may be used to distinguish the long-lived species from other products such as photons, and also to measure the energies of the excited fragments, and thus provide information on the repulsive states responsible for the dissociation. For further discussion see the reviews by *Compton* and *Bardsley* [63.27], *Freund* [63.28], and *Zipf* [63.29]. If the detector can be made sensitive to a particular excited species, its excitation can be isolated and studied. Examples are the work of *McConkey* and co-workers [63.30, 31] on O(^{1}S) and S(^{1}S$_0$) production from various molecules. The detection of unexcited neutral fragments is more challenging. One early method was to trap selectively the dissociation products using a getter and measure the resulting pressure decrease. In a more sophisticated approach, *Cosby* [63.32] produced a fast (≈ 1 keV) target molecular beam by resonant charge exchange and subjected it to electron impact dissociation. The fast dissociation products were detected by conventional particle detectors in a time correlated measurement. Laser techniques, such as laser-induced fluorescence or multiphoton ionization, have also been used recently to detect the dissociation products.

The Franck–Condon principle largely governs molecular dissociation. The principle states that if the excitation takes place on a time scale which is short compared with vibrational motion of the atomic nuclei the transition occurs vertically between potential energy curves. Since dissociation rapidly follows a vertical transition to the repulsive part of a potential energy curve, compared with the period of molecular rotation, the dissociation products tend to move in the direction of vibrational motion. Since the excitation probability depends on the relative orientation of the electron beam and the molecule, dissociation products often demonstrate pronounced anisotropic angular distributions. The angular distributions have been analyzed by *Dunn* [63.33] using symmetry considerations.

63.2.6 Ionization Cross Sections

Tate and *Smith* [63.34] some 60 years ago developed the basic techniques for measuring total ionization cross sections. These were later improved by *Rapp* and *Englander-Golden* [63.35]. Full details of the experimental methods are given in the reviews and books already cited. *Märk* and *Dunn* [63.36] reviewed the situation as it existed in the mid 1980s. In the basic "parallel plate" method, the electron beam is directed through a beam or a static target gas between collector plates which detect the resultant ions. Unstable species can be studied by the "fast neutral beam" technique [63.37], in which the neutral target species is formed by charge neutralization from a fast ion beam, and is subsequently ionized by a crossed electron beam. For the determination of partial ionization cross sections specific to a given ion species in a given ionization stage, mass spectroscopic (quadrupole mass spectrometer, electrostatic or magnetic charged particle analyzer or time of flight) methods are used. Fourier Transform Mass Spectrometry (FTMS) has also been used effectively to study fragmentation with formation of both positive and negative ions. Reference [63.38] is a recent example of this. Absolute total ionization cross sections have been measured for a large number of species with an accuracy of better than 10%. *Christophorou* and colleagues have presented helpful compilations of ionization and other data of particular relevance to the plasma processing industry, [63.39, and earlier references in this journal].

A large number of mechanisms can contribute to the ionization of atoms and molecules by electron impact. For targets with only a few atomic electrons, the dominant process is single ionization of the outer shell, with the resultant ion being left in its ground state. The process is direct and is characterized by large impact parameters b and small momentum transfers. The cross section varies with incident electron energy in a way very similar to the optically allowed

excitation processes discussed in Sect. 63.2.4. Processes involving ionization of more than one outer shell electron become more important as the size of the target increases. These events are associated with small b and electron–electron correlations are usually strong. Autoionization increases in significance for heavier targets. Here also, collisions with small b dominate and electron–electron correlations are strong. For heavier targets, inner shell effects, such as Auger electron or X-ray emission, become progressively more important. For molecular targets, dissociative ionization (either directly or through a highly excited intermediate state) and ion pair formation also play a significant role.

In addition to measurement of gross ion production, it is also possible to study the ionization process by monitoring the electron(s) ejected or scattered inelastically. Conventional electron spectroscopic techniques are used for this purpose. The addition of coincidence techniques (e–2e measurements) in which the momenta of all the electrons involved are completely specified has allowed many of the fine details of the ionization process to be extracted [63.40].

63.3 Coincidence and Superelastic Measurements

The cross section measurements described so far do not yield complete information on electron scattering processes. As mentioned in Sect. 63.1.2, these cross sections do not distinguish for magnetic sublevels, electron spin etc.and represent summation of cross sections over these experimentally indistinguishable processes (summation of the square moduli of the corresponding scattering amplitudes). The quantum mechanical description of a scattering process is given in terms of scattering amplitudes and under certain conditions requires summing up amplitudes and squaring the sum. This leads to interference terms which arise from the coherent nature of the scattering process. A complete characterization of a scattering process, therefore, requires knowledge of the complex scattering amplitudes.

Sophisticated experimental techniques have been developed in recent years, which go beyond the conventional scattering cross section measurements and yield information on magnetic sublevel specific scattering amplitudes and the polarization (alignment and orientation) of the excited atomic ensemble. The experimental techniques fall into two main categories: a) electron–photon coincidence measurements, and b) superelastic scattering measurements involving coherently excited species. (We still consider unpolarized electron beams in the description of these two techniques here and will address the question of spin polarization in the following section.)

In electron–photon coincidence measurements, the radiation pattern emitted by the excited atom is determined for a given direction of the scattered electron. A scattering plane is defined by k_i and k_f, and hence the symmetry is lowered from cylindrical (around the incident beam direction) to planar, (Fig. 63.6).

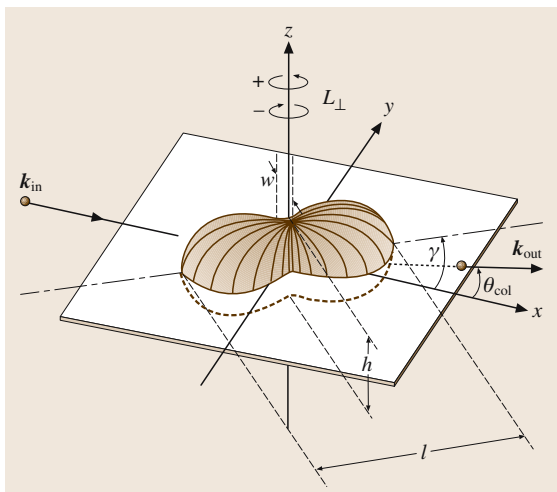
It is now possible to determine, at least in principle, both the atomic alignment (i. e., the shape of the excited state charge cloud and its alignment in space) and its orientation (i. e., the angular momentum transferred to the atom during the course of the collision). Complete sets of excitation amplitudes for the coherently excited atomic states and their relative phases have been measured in some cases. A comparison with theory can then be made at the most fundamental level. See [63.41] for full discussion and analysis.


Fig. 63.6 Schematic illustration of a collisionally induced charge cloud in a p-state atom. The scattering plane is fixed by the direction of incoming k_{in} and outgoing k_{out} momentum vectors of the electrons. The atom is characterized by the relative length (l), width (w), and height (h) of the charge cloud, by its alignment angle γ, and by its inherent angular momentum $L_\perp$. The coordinate frame is the natural frame with the z-axis perpendicular to the scattering plane and with the x- and y-axes defined as shown in the figure relative to k_{in} and k_{out}

The electron–photon coincidence measurements can be carried out in two ways: (1) measuring polarization correlations, and (2) measuring angular correlations. In (1), polarization analysis of the emitted photon in a given direction occurs, while in (2), the angular distribution of the emitted photons is determined without polarization analysis. We will describe here only method (1) in some detail.

Method (1) has the advantage that it measures directly the angular momentum (perpendicular to the scattering plane) transferred in the collision. For P-state excitation from a $^1S_0$ ground state, four parameters plus a cross section are needed to describe fully the collisionally excited P-state. The natural parameters introduced by *Andersen* et al. [63.41] are defined as follows (Fig. 63.6): γ is the alignment angle of the excited state charge cloud relative to the electron beam axis, P_ℓ^+ is the linear polarization in the scattering plane, $L_\perp^+$ is the orbital angular momentum perpendicular to the scattering plane that is transferred to the atom in the collision, and ρ_{00} is the relative height of the charge cloud perpendicular to the scattering plane at the point of origin. The $+$ superscript indicates positive reflection symmetry with respect to the scattering plane.

In polarization correlation experiments, one typically measures two linear (P_1, P_2) and one circular (P_3) polarization correlation parameters perpendicular to the scattering plane. One additional linear polarization correlation parameter P_4 is measured in the scattering plane. Each parameter is the result of two intensity measurements for different orientations of the polarization analyzer:

$$P_1 = \frac{I(0°) - I(90°)}{I(0°) + I(90°)}\beta^{-1},$$

$$P_2 = \frac{I(45°) - I(135°)}{I(45°) + I(135°)}\beta^{-1},$$

$$P_3 = \frac{I^R - I^L}{I^R + I^L}\beta^{-1},$$

$$P_4 = \frac{I(0°) - I(90°)}{I(0°) + I(90°)}\beta^{-1}. \tag{63.13}$$

Here $I(\alpha)$ denotes the photon intensity measured for a polarizer orientation α with respect to the electron beam axis, I^R and I^L refer to right- and left-handed circularly polarized light and β denotes the polarization sensitivity of the polarization analyzer. The relationships between the experimentally determined polarization correlation parameters and the natural parameters are given by

$$\gamma = \frac{1}{2}\tan^{-1}(P_2/P_1),$$

$$P_\ell^+ = \left(P_1^2 + P_2^2\right)^{1/2},$$
$$L_\perp^+ = -P_3,$$
$$\rho_{00} = \frac{(1+P_1)(1-P_4)}{4-(1-P_1)(1-P_4)}. \tag{63.14}$$

The total polarization P_{tot}^+, which is defined as

$$P_{\text{tot}}^+ = \left[\left(P_\ell^+\right)^2 + \left(L_\perp^+\right)^2\right]^{1/2}$$
$$= \left(P_1^2 + P_2^2 + P_3^2\right)^{1/2}, \tag{63.15}$$

is a measure for the degree of coherence in the excitation process. In the absence of atomic depolarizing effects due to, for example, fine and/or hyperfine interactions, a value of $P_{\text{tot}}^+ = +1$ for the emitted radiation indicates total coherence of the excitation process.

Much of the earlier work involved excitation of helium $n\,^1P$ state. Here the situation is simplified as $L-S$ coupling applies strictly: $P_4 = 1$ and ρ_{00} is zero. Excitation of the $2\,^1P$ state, for example, is fully coherent and hence the excitation is completely specified by just two parameters, γ and $L_\perp$ (or P_ℓ since $P_\ell = \left(1 - L_\perp^2\right)^{1/2}$). More recently, the techniques have been applied to heavier targets and more complicated excitation processes [63.42–46].

The superelastic scattering experiments could be looked at as time inverse electron–photon coincidence experiments (although this is not exactly the case). In these experiments, a laser beam is utilized to prepare a coherently excited, polarized ensemble of target atoms for the electron scattering measurement. The superelastic scattering intensity is then measured as a function of laser-beam polarization and/or angle with respect to a reference direction. Linearly polarized laser light produces an aligned target (uneven population in magnetic sublevels for quantum numbers of different $|M_J|$ value). Circularly polarized laser light produces oriented targets (uneven population in $M_J = +m$ and $M_J = -m$ magnetic sublevels). From these measurements the same electron impact coherence parameters can be deduced as from the coincidence experiments. This approach has been applied to atomic species (mainly metal atoms) which are conveniently excited with available lasers. Detailed descriptions of the experimental techniques, the underlying theoretical background, and the interpretation of the experimental data are given in [63.47–56].

It should be noted that electron scattering by coherently excited atoms can be utilized not only for obtaining electron impact coherence parameters for inelastic processes originating from ground state but for

elastic, inelastic, and superelastic transitions involving excited states. These measurements yield information on creation, destruction, and transfer of alignment and ori-entation in electron collision processes which is needed, e.g., in the application of plasma polarization spectroscopy [63.57].

63.4 Experiments with Polarized Electrons

So far we have considered the utilization of unpolarized electron beams which yield spin averaged cross sections. Little information on spin dependent interactions is gained from these experiments. However, these interactions can be studied using polarized electron beam techniques. Developments on both the production and detection of spin-polarized electron beams have resulted in a wide range of elegant experiments probing these effects. The theory is also highly developed. For a detailed discussion see the works of *Kessler* [63.58, 59], *Blum* and *Kleinpoppen* [63.60], *Hanne* [63.61–63] and *Andersen* et al. [63.44, 45] and the references therein. Some basic concepts are presented here.

The degree of polarization P of an electron beam is given by

$$P = \frac{N(\uparrow) - N(\downarrow)}{N(\uparrow) + N(\downarrow)} , \qquad (63.16)$$

where $N(\uparrow)$ and $N(\downarrow)$ are the numbers of electrons with spins respectively parallel and antiparallel to a particular quantization direction. Measurements of P both before and after the collision enable one to probe directly for specific spin dependent processes. For example, in elastic scattering from heavy spinless atoms any changes in the polarization of the electrons must be caused by spin–orbit interactions alone since, in this instance, it is not possible to alter the polarization of the electron beam by electron exchange. Measurements have been carried out for Hg and Xe and both direct (f) and spin-flip (g) scattering amplitudes, as well as their phase differences, have been determined [63.59].

The spin–orbit interaction for the continuum electron caused by the target nucleus leads to different scattering potentials and consequently to different cross sections for spin-up and spin-down electrons (called Mott scattering). Consequently, an initially unpolarized electron beam can become spin polarized after scattering by a specific angle according to

$$\boldsymbol{P}' = S_p(\theta)\hat{\boldsymbol{n}} , \qquad (63.17)$$

where $\boldsymbol{n}$ is the unit vector normal to the scattering plane, $S_p(\theta)$ is the polarization function and $\boldsymbol{P}'$ is the polarization of the scattered beam. For the same reasons, when a spin-polarized electron beam is scattered by an angle θ to the left and to the right, an asymmetry is found in the scattering cross sections. Furthermore, an existing polarization $\boldsymbol{P}'$ can be detected through the left–right asymmetry A in the differential cross section, which is given by

$$A \equiv \frac{\sigma_l(\theta) - \sigma_r(\theta)}{\sigma_l(\theta) + \sigma_r(\theta)} = S_{\mathrm{A}}(\theta)\boldsymbol{P}' \cdot \hat{\boldsymbol{n}} , \qquad (63.18)$$

where $\sigma_l(\theta)$ and $\sigma_r(\theta)$ are the differential cross sections for scattering at an angle θ relative to the incident beam axis to the left and to the right, respectively. For elastic scattering, the polarization function S_{P}, and the asymmetry function S_{A} are identical and are called the Sherman function.

When electron exchange is studied under conditions where other explicitly spin-dependent forces can be neglected, the cross sections for scattering of polarized electrons from polarized atoms depend on the relative orientation of the polarization vectors. According to [63.59]

$$\sigma(\theta) = \sigma_u(\theta)[1 - A_{\mathrm{ex}}(\theta)\boldsymbol{P}_e \cdot \boldsymbol{P}_A] , \qquad (63.19)$$

where $\boldsymbol{P}_e$ and $\boldsymbol{P}_A$ are the electron and atom polarization vectors, and $\sigma_u(\theta)$ is the cross section for unpolarized electrons. Hence, an "exchange asymmetry" $A_{\mathrm{ex}}(\theta)$ can be defined by

$$A_{\mathrm{ex}}(\theta)\,\boldsymbol{P}_e \cdot \boldsymbol{P}_A = \frac{\sigma_{\uparrow\downarrow}(\theta) - \sigma_{\uparrow\uparrow}(\theta)}{\sigma_{\uparrow\downarrow}(\theta) + \sigma_{\uparrow\uparrow}(\theta)} , \qquad (63.20)$$

where $\sigma_{\uparrow\uparrow}(\theta)$ and $\sigma_{\uparrow\downarrow}(\theta)$ denote the cross sections for parallel and antiparallel polarization vectors respectively. As *Bartschat* [63.64] points out, an asymmetry can occur even if the scattering angle is not defined. In this case the function $A_{\mathrm{ex}}(\theta)$ is averaged over all angles. Differential and integral measurements of this kind have been performed for elastic scattering, excitation and ionization.

For heavy target systems it is necessary to consider a combination of effects together with a description of the target states in the intermediate or fully coupled scheme. Consequently, the number of independent parameters can become very large and the "complete" experiments, which disentangle the various contributions to any observed asymmetry in the scattering, are rarely possible.

Even for very light target atoms, where conventional Mott scattering is negligible, *Hanne* [63.61] has shown that the "fine structure" effect, in which electron scattering from individual fine structure levels of a multiplet occurs, can lead to polarization effects. In fact it can be a dominating effect for inelastic collision processes.

For full details of these various mechanisms and how density matrix theory and other theoretical techniques have been applied to scattering involving polarization effects, the reader is referred to the review articles cited, particularly *Andersen* et al. [63.44].

In certain cases, experiments involving spin polarized electron beams coupled with coincidence (or superelastic) measurements allow one to extract the maximum possible information for a given process, and are termed as complete or perfect in the sense defined by *Bederson* [63.65–67].

63.5 Electron Collisions with Excited Species

There are many plasma systems where electron collisions with excited atoms and molecules play a prominent role, e.g., electron beam and discharge pumped lasers, planetary and astrophysical plasmas. Especially important are electron collisions with metastable species because of the long lifetime, large cross section and large amount of excitation energy associated with them. Electron collision studies and cross section data in this area are scarce mainly due to experimental difficulties associated with the production of target beams with sufficiently high densities of excited species. With the application of lasers for the preparation of the excited species this problem can be overcome. However, this approach has not yet been extensively exploited. Reviews of this field are given by *Lin* and *Anderson* [63.68], *Trajmar* and *Nickel* [63.69] and *Christophorou* and *Olthoff* [63.70].

Since electron collisions with excited species necessarily involve a method of preparation, they are two step processes. Excitation and ionization in these cases are frequently referred to as stepwise excitation and ionization. The target preparation leads to mixed beams containing both ground and excited atoms or molecules. Preparation of excited atoms is achieved by electron impact or photoabsorption. Fast metastable beams can be produced by near-resonance charge exchange. For more details see [63.69, 71, 72]. Electron impact excitation is simple and effective but highly nonspecific, and characterization of the composition of the mixture is difficult.

Laser excitation is more involved but very well defined. Specific fine and hyperfine levels of individual isotopes can be excited. When laser excitation is used in conjunction with superelastic electron scattering, an energy resolution of 10^{-8} eV is easily achieved, compared with the 10^{-2} eV resolution possible in conventional electron scattering.

Depending on the method of preparation, the population distribution in the magnetic sublevels of the target atoms may be uneven and some degree of polarization (alignment or orientation) may be present. The scattering will then be ϕ-dependent. For polarized target atoms the measured electron collision cross sections do not correspond to the conventional cross sections (which are summed over final and averaged over initial experimentally indistinguishable states, with equal populations in the initial states). One, therefore, has to characterize precisely the state of the target beam in order to be able to deduce a well defined, meaningful cross section. Polarization of atoms can be conveniently controlled, in the case of excitation with laser light, through the control of the laser light polarization (as discussed in Sect. 63.3). Since the atomic ensemble is coherently excited in this case, the scattering cross sections will depend on the azimuthal scattering angle ϕ. These considerations also come into play when one tries to relate measured inelastic and corresponding inverse superelastic cross sections by the principle of detailed balancing.

63.6 Electron Collisions in Traps

A technique which has recently begun to be exploited involves collisions with trapped atoms. Pioneered by *Lin* and colleagues [63.73, 74], using Rb targets the technique has many advantages over more conventional techniques, not least of which is the fact that the absolute number density of the target need not be known. Cross section data are obtained from measurements of trap loss and electron beam current density. Because up to half of the atoms in the trap can be in the excited state, it is possible to make measurements of cross sections involving excited states as well [63.75]. Measurements involving Cs targets have also been reported [63.76].

63.7 Future Developments

Electron-driven processes have been identified as being of fundamental importance in a wide range of environmentally and technologically significant areas [63.77]. *Boudaiffa* et al. [63.78] have shown that electron attachment is a significant process in bond-breaking in DNA. Electron-initiated dissociation of large molecules can act as a catalyst for reactive chemistry in environmentally sensitive situations. Developments in large scale computing have opened the door to calculations involving large molecules which could not even have been contemplated a few years ago. Electron collisions in intense laser field situations is an exciting new field which is rapidly expanding [63.79, 80]. Electron–cluster interactions allow one to probe how interactions change as one progresses from the gaseous to the solid phase.

64. Ion–Atom Scattering Experiments: Low Energy

This chapter outlines the physical principles and experimental methods used to investigate low energy ion–atom collisions. A low energy collision is here defined as one in which the initial ion–atom relative velocity is less than the mean orbital velocity $\langle v_e \rangle$ of the electrons affected by the collision. For outer or valence electrons, $\langle v_e \rangle \simeq v_B$, where $v_B = 2.1877 \times 10^8$ cm/s is the Bohr velocity. In terms of the energy of a projectile ion, v_B corresponds to 24.8 keV/N, where N is the projectile nuclear number (e.g., 16 for 0^+).

The theory and results of ion–atom scattering studies are further discussed in Chaps. 37, 38, and 47 to 51. The focus here is on the experimental techniques. Since several of these depend on the characteristics of a specific process, the following section presents a summary of the physics of low-energy ion–atom collisions. See Chaps. 50 and 51 for more detailed information.

64.1 Low Energy Ion–Atom Collision Processes

The most important and widely studied inelastic ion–atom collision process in the low energy region is electron capture (also referred to as charge exchange, charge transfer or electron transfer) represented by

$$A^{+q} + B \rightarrow A^{+q-k} + B^{k+} + Q \,, \qquad (64.1)$$
where Q is the potential energy difference between the initial and final states. For an exoergic process, $Q > 0$ and this energy appears as excess kinetic energy of the products after the collision. For an endoergic process, $Q < 0$ and must be provided by the initial kinetic energy of the reactants, so that the corresponding cross section is usually small at low collision energies. Cross sections for electron capture are appreciable even at very low energies if Q is zero or very small (resonant or near-resonant process). Electron capture by multiply charged ions from atoms is predominantly an exoergic process, for which cross sections may also be large at low energies. In this case, electrons are preferentially captured

into excited levels of A^{+q-k}. The typical cross section behavior for single electron capture ($k = 1$) by a multiply charged ion from atomic hydrogen is shown in Fig. 64.1. The initial ionic charge is the major determinant of the cross section at intermediate and high collision energies, whereas the cross section at low energies depends strongly on the structure of the transient quasimolecule formed during the collision.

Multiple electron capture ($k > 1$) from multielectron atoms occurs predominantly into multiply excited levels, which stabilize either radiatively, leading to stabilized or "true" double capture, or via autoionization. The latter process is usually referred to as transfer ionization,

$$A^{+q} + B \rightarrow A^{+q-k} + B^{m+} + (m-k)e^- + Q \,. \qquad (64.2)$$
At low energies, transfer ionization is particularly important in collisions of highly charged ions with multi-electron atoms.

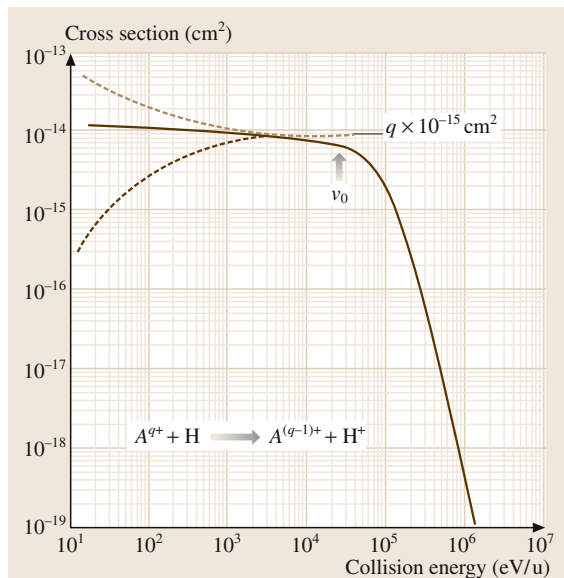
Part E | 64


Fig. 64.1 Typical cross section variation with collision energy for electron capture by a multiply charged ion from hydrogen. The low energy behavior depends on the structure of the quasimolecule formed during the collision

Adiabatic potential energy curves representing the collision of a multiply charged ion with a neutral atom are presented in Fig. 64.2. For such collisions, the Coulomb repulsion in the final state produces avoided crossings of the initial and final state potential curves, the positions of which are determined by the binding energy of the atomic electron and electronic energy level structure of the product ion. Generally, reaction channels that are moderately exoergic produce curve crossings at internuclear separations where there is sufficient overlap of the electron clouds for electron capture to be a likely process. The Landau–Zener curve-crossing model [64.1] (Chapt. 49), the classical over-barrier model for single capture [64.2] and the extended classical over-barrier model for multiple capture [64.3], are useful in predicting the important final product states, and in providing a semiquantitative interpretation. In the case of single electron capture by a bare multiply charged ion (of charge $q = Z$) from a hydrogen atom, the principal quantum number n_p of the most probable final ionic state is given in this model [64.2] by

$$n_p = \sqrt{\frac{2Z^{1/2}+1}{Z+2Z^{1/2}}} \,. \tag{64.3}$$
Fig. 64.2 Schematic representation of potential energy curves for the collision of a multiply charged ion A^{q+} with a multielectron atom B

The internuclear separation R_p at which the potential curves cross in this case is given by

$$R_p = \frac{2(Z-1)}{Z^2/n_p^2 - 1} \,. \tag{64.4}$$

There has been much discussion of the role of electron correlation in the multiple electron capture process. At issue is the relative importance of the mechanism whereby several electrons are transferred (in a correlated manner) at a single curve crossing compared with that whereby single electrons are transferred successively at different curve crossings. Experimental evidence exists for both mechanisms, with the relative importance depending on the electronic structure of the transient quasimolecule that is formed during the collision. Measurements of the distribution of final ion product electronic states provides the major insight into such collision mechanisms [64.4].

Other inelastic ion–atom collision processes, such as direct electronic excitation and ionization, are endothermic, with relatively small cross sections that fall off with decreasing energy below a few tens of keV/N. Exceptions are collisions involving Rydberg atoms and collisional excitation of fine structure transitions, for which the required energy transfer is relatively small. Relatively little experimental data are available for direct excitation and ionization processes at low collision energies.

64.2 Experimental Methods for Total Cross Section Measurements

In the present context, a total cross section measurement refers to an integration or summation over scattering angles, product kinetic energies and (frequently) electronic states. The total cross section is usually measured as a function of relative collision energy or velocity.

64.2.1 Gas Target Beam Attenuation Method

The attenuation of a collimated ion beam of incident intensity I_0 in a differentially pumped gas target cell or gas jet is related to the collision cross section σ by

$$I = I_0 \, e^{-\sigma N L} \, , \tag{64.5}$$

where I is the intensity after traversing an effective length L of the target gas, and N is the number density of target atoms. For a gas target cell with entrance and exit apertures of diameter d_1 and d_2 which are much less than the physical length z of the gas cell, L is given to a good approximation by $z + (d_1 + d_2)/2$. This is valid under molecular flow conditions, for which the mean free path between collisions of target atoms is much larger than the dimensions of the gas cell.

In designing the gas cell for measurements of total cross sections, d_2 and the beam detector must be large enough that elastic scattering may be eliminated as a contributor to the measured attenuation. Usually d_2 is made larger than d_1. Measurement of the gas pressure in a target cell is usually made using a capacitance manometer connected to the cell via a tube whose conductance is much larger than that of the gas cell apertures so that, to a good approximation, the pressure will be the same in both the manometer and the gas cell. For gas jet targets, the effective target thickness NL is usually determined by in situ normalization to some well-known cross section.

The quantity σ in (64.5) refers to an effective cross section for removing projectile ions from the incident beam, which is the sum of cross sections for all such processes. In many cases, a single process (e.g., electron capture) is dominant, and σ primarily describes that process. Whether a collision process removes a projectile ion from the reactant beam or not depends on the configuration of the experiment. For example, the projectile particle may remain physically in the beam after passing through the target, but with a changed charge due to a collision. This would be registered as an attenuation of the primary ion beam if the beam is charge analyzed after the reaction.

64.2.2 Gas Target Product Growth Method

The product growth method is similar to the beam attenuation method; the major difference that the growth of reaction products is measured rather than the loss of reactant projectiles. The products may be derived from either the projectile beam or the gas target, or both. The main advantage of this method is its higher degree of selectivity of a specific collision process. In addition, the reactants and products can usually be registered simultaneously, or in some cases in coincidence, eliminating the sensitivity of the measurement to temporal variation of ion beam intensity.

An important criterion is that the target gas density be low enough that single collision conditions prevail (i.e. that the likelihood of an ion passing through the gas target and interacting with more than one target atom is negligibly small). This must in general be satisfied in order for (64.5) to relate correctly the measured attenuation to the collision cross section of interest, and is critical to the product growth method [64.5]. In this case, under single collision conditions, one may set the number of products $I_p = I_0 - I$, and (64.5) then may be written as

$$\frac{I_p}{I_0} = 1 - e^{-\sigma N L} \approx \sigma N L \, . \tag{64.6}$$

The approximate expression is useful for $\sigma N L \ll 1$, which is a requirement for single collision conditions. It is also important that the products not be lost in a subsequent collision in the gas cell, so the magnitudes of cross sections for loss of products in the target gas must also be considered. The products in such an experiment may be derived from either the projectile beam or the target gas (e.g., collection of slow product ions in a gas cell), or from both in coincidence to enhance the specificity of the method. The method may in principle be used to determine either total or differential cross sections, depending on the degree of selectivity of collision products.

64.2.3 Crossed Ion and Thermal Beams Method

Replacement of the gas target cell by an effusive thermal beam is advantageous for studying collisions of ions with reactive species such as atomic hydrogen, as well as for collecting slow ion products. The use of accelerating electrodes or grids for slow charged products allows coincident detection of fast and slow products, permitting

measurement of ionization as well as electron-capture cross sections. Use of an effusive source or gas jet precludes accurate measurement of the effective target thickness, and in situ normalization to the cross section for some well known process is usually employed. A comprehensive discussion of such methods as applied to collisions of multiply charged ions with atomic hydrogen is given by *Gilbody* [64.6].

64.2.4 Fast Merged Beams Method

Cross sections for ion–atom collision processes at very low energies have been measured by merging fast beams of ions and neutral atoms [64.7], as in Fig. 64.3. In this case, σ is determined from experimental parameters by

$$\sigma = \frac{R}{\epsilon} \frac{e}{I_+ I_0} \frac{v_+ v_0}{|v_+ - v_0|} F , \qquad (64.7)$$

where R is the number of products detected per second, ϵ is the product detection efficiency, e is the electronic charge, I_+ is the ion current, I_0 is the flux of atoms, v_+ and v_0 are the laboratory velocities of the ion and atom beams, v_{rel} is their relative velocity, and F is the form factor that describes the spatial overlap of the two beams. If the z-axis is chosen to be the direction of propagation of the beams, the form factor has units of length and is given by

$$F = \frac{\iint I_+(x, y, z) \, dx \, dy \, \iint I_0(x, y, z) \, dx \, dy}{\iiint I_+(x, y, z) I_0(x, y, z) \, dx \, dy \, dz} . \qquad (64.8)$$

The two-dimensional integrals in the numerator represent the total intensities of the two beams, which are independent of z, so that F is also independent of z.
Fig. 64.3 Schematic of the merged beams arrangement used by *Havener* et al. [64.7] to study low energy electron capture collisions of multicharged ions with H atoms

The relative collision energy E_{rel} in eV/u is given by

$$\frac{E_{rel}}{\mu} = \frac{E_+}{m_+} + \frac{E_0}{m_0} - 2\sqrt{\frac{E_+}{m_+} \frac{E_0}{m_0}} \cos\theta , \qquad (64.9)$$

where E_+, m_+ and E_0, m_0 are the energies and masses of the ion and atom, respectively, and μ is their reduced mass. For collinear merged beams, $\theta = 0$, and E_{rel} can be reduced to zero by making the two beam velocities the same. In practice, the finite divergences of the beams place a lower limit on the energy and the energy resolution. The fast neutral atom beam is created by neutralizing an accelerated ion beam by electron capture by a positive ion beam in a gas, by electron detachment of a negative ion beam either in a gas, or using a laser beam. In gas collisions, a small fraction of the neutral beam is produced in excited n-levels (with an n^{-3} distribution), which may influence the measurements.

With fast colliding beams, the maximum effective beam densities are invariably much smaller than the background gas density, even under ultrahigh vacuum conditions. For example, a typical $10 \, \text{keV}$ proton beam with a circular cross section of diameter $3 \, \text{mm}$ and a current $I = 10 \, \mu\text{A}$ has an average effective density $n = I/(eAv) = 1.6 \times 10^6 \, \text{cm}^{-3}$ (A is the beam cross sectional area and v is its velocity). It is therefore necessary either to modulate the beams or to use coincidence techniques to separate signal events due to beam–beam collisions from background events produced by collisions of either beam with background gas. A typical two-beam modulation scheme is shown in Fig. 64.4. To eliminate the production of spurious signals, the detector gates are delayed for a short time after the beams are switched, and the beam modulation period is made much shorter than the pressure time constant of the vacuum system.

Absolute electron-capture cross sections have been measured for $O^{5+} + H$ collisions to energies below $1 \, \text{eV/N}$, where the attractive ion-induced-dipole (polarization) interaction is expected to play a role [64.7]. The inverse velocity dependence of the cross section in this region is suggestive of the classical Langevin orbiting model for ion–neutral collisions [64.8].

64.2.5 Trapped Ion Method

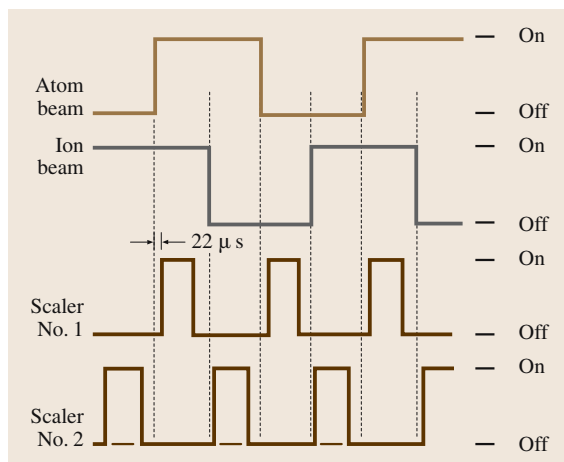
The trapped ion method is used to determine rate coefficients and effective cross sections for ion–atom collisions at near thermal energies. The technique involves storing ions in an electrostatic or electromagnetic


Fig. 64.4 Fast two-beam modulation scheme to separate the signal due to beam–beam collisions from events due to beam collisions with residual gas or surfaces [64.7]

trap, and measuring the rate of loss of ions from the trap after a small quantity of neutral gas is admitted [64.9]. Like the beam attenuation method, the trap technique cannot distinguish different processes that cause ions to be lost from the trap. The mean collision energy is estimated from an analysis of the ion dynamics in the trap.

64.2.6 Swarm Method

The swarm method, using the flowing afterglow, drift tube or selected-ion flow tube, has been used successfully to study ion–atom collisions at very low energies [64.10]. Ions are injected into a homogeneous electric field and drift through a suitable low-density buffer gas such as helium. The ions move as a swarm whose mean energy depends on the applied electric field and on collisions with the buffer gas, and can be varied from the near-thermal region to tens of eV. The method involves measuring the additional attenuation of the directed ion swarm by a known quantity of added reactant gas, and is the major technique that has been used for the study of ion–atom collisions at near-thermal energies [64.11]. As with ion beam attenuation and ion trap methods, the drift tube is not selective of the process that leads to attenuation of the ion swarm.

64.3 Methods for State and Angular Selective Measurements

Three principal methods have been developed and applied to the measurement of partial cross sections for population of specific product electronic states in ion–atom collisions involving electron capture [64.12]. These are based on spectroscopic measurements of photon emission, translational energy spectroscopy and electron emission in collisions of ion beams with gas targets.

64.3.1 Photon Emission Spectroscopy

Since electron capture from atoms by multiply charged ions populates excited levels, photon emission spectroscopy may be employed to determine state-selective partial cross sections [64.13]. An ion beam is directed through a gas cell or jet, and a photomultiplier or suitable detector registers photons analyzed by an optical filter, a grating or a crystal spectrometer. The measured photon signal at a given angle depends on the detection solid angle, the polarization of the emitted radiation, the absolute efficiencies of the dispersive device and detector, and (for emission by fast ions) the lifetime of the radiating state. Depending on the spectral region, the photon detection system may be absolutely cali-

brated using a standard photon source or detector, or by using a reference ion or electron beam and well established cross section data for photon emission [64.14]. Cascading from higher populated levels must also be considered whenever measured spectral line emission intensities are used to infer cross sections for populating specific energy levels. Successful state-selective cross section measurements have been made for transitions in the visible, VUV and X-ray spectral regions.

64.3.2 Translational Energy Spectroscopy

Translational energy loss or energy gain spectroscopy provides a convenient method to determine the distribution of final states in low energy ion–atom collisions that are either endoergic or exoergic ($Q \neq 0$). For example, this method has been used extensively by the Belfast group [64.15] to study the predominantly exoergic process of electron capture by multiply charged ions from hydrogen atoms. An ion beam with a well defined energy is directed through a gas target, and the energy of the product ion beam is energy analyzed after the collision. Since the energy gain or loss to be measured is only a very small fraction of the initial kinetic

energy, it is usually necessary to reduce the initial energy spread to a few tenths of an eV by decelerating the reactant ion beam prior to energy selection by an electrostatic analyzer. If the scattering angle of the ion is very small, its energy change is approximately equal to Q. Since the ion beam is attenuated by deceleration and energy analysis, cross sections for collisionally populating specific states are determined by normalizing the measured product-state distributions to total cross section data. The attainable state resolution is not as good as for photon emission spectroscopy.

64.3.3 Electron Emission Spectroscopy

As noted in Sect. 64.1, multiple electron capture by multiply charged ions from atoms at low energies occurs primarily into multiply excited states, which decay either radiatively or via autoionization (with a branching ratio) [64.4]. The latter decay pathway (transfer ionization) provides an experimental method to determine the product ionic states by ejected-electron spectroscopy. Analysis of electrons emitted into the forward (ion beam) direction (zero degree spectroscopy) offers significant advantages for analysis of low energy electrons with high resolution [64.16]. Since a gas jet is often employed and absolute electron collection and spectrometer efficiencies are difficult to determine, some normalization procedure is usually employed to determine state-selective cross sections by this method. Electrons and product projectile or recoil ions have also been detected in coincidence to increase the specificity of the method.

64.3.4 Angular Differential Measurements

The measurement of angular distributions of scattered ions in low energy ion–atom collisions has been facilitated by the availability of position-sensitive particle detectors consisting of a microchannel plate and a resistive or segmented anode [64.17]. The method for processes that have forward-peaked angular distributions involves directing a highly collimated ion beam through a gas target cell, and counting the scattered projectile ions on a position-sensitive particle detector. Product ions produced by electron capture can be selected by the use of electrostatic retarding grids mounted immediately in front of the detector, to reject the primary ion beam.

64.3.5 Recoil Ion Momentum Spectroscopy

Perhaps the most significant experimental development of the last decade, cold target recoil-ion momentum spectroscopy (COLTRIMS) [64.18] has been made possible by advances in position-sensitive particle detection. This technique, based on momentum imaging and also called a "reaction microscope", has yielded important new insights into the dynamics of ion–atom collision processes [64.19] as well as other types of interactions involving cold atoms and molecules. The method is particularly suited to studies of charge-changing and molecular fragmentation processes.

In this method, an ion beam intersects a cold supersonic atomic beam in an interaction volume within which small electric and magnetic fields are imposed in order to guide slow ions and ejected electrons to fast position-sensitive detectors. The charge and the transverse and longitudinal components of the momentum of the slow (recoil) ion are measured by a combination of position and time-of-flight measurements, permitting the Q-value of the collision and the final electronic states of the projectile and recoil ions to be uniquely determined. The position measurement additionally provides information about the angular scattering during the collision. Coincident measurement of the scattered projectile ion and determination of its charge state by electrostatic deflection, and/or time-of-flight measurements of ejected electrons have provided new insights into complex multielectron processes occurring in low-energy ion–atom collisions.

65. Ion–Atom Collisions – High Energy

This chapter deals with inelastic processes which occur in collisions between fast, often highly charged, ions and atoms. Fast collisions are here defined to be those for which $V/v_e \geq 1$, where V is the projectile velocity and v_e the orbital velocity of this electron. For processes involving outer shell target electrons, this implies $V \gtrsim 1\,\text{a.u.}$, or the projectile energy $\gtrsim 25\,\text{keV/a.m.u.}$ For inner shell electrons, typically, $V \gtrsim Z_2/n\,\text{a.u.}$, where Z_2 is the target nuclear charge and n the principal quantum number of the active electron. A useful relationship is $V = 6.35\sqrt{E/M}$, where V is in a.u., E is in MeV, and M is in a.m.u. Fast collisions involving outer shell processes can be studied using relatively small accelerators, while those involving inner shell processes require larger van de Graaffs, LINACs, etc. Because the motion of the inner shell electrons is dominated by the nuclear Coulomb field of the target, and because transitions involving these electrons take place rather independently of what transpires with the outer shell electrons, it has proven somewhat easier to understand one electron processes involving inner shell electrons. Thus, for a long time, a great deal of the work on fast ion–atom collisions has concentrated on inner shell processes involving heavy target atoms. However, more recently, new experimental techniques have led to a shift of this focus to

inelastic processes involving light target atoms. Furthermore, present investigations go beyond the one–electron picture to include the influence of the electron–electron interaction. The present chapter outlines some of the developments in this area over a very active past few decades. The literature is vast, and only a small sampling of references is given. Emphasis is on experimental results (for the theory see Chaps. 45–57)

65.1 Basic One–Electron Processes

65.1.1 Perturbative Processes

Inner Shell Ionization of Heavy Targets

For ion–atom collisions involving projectile and target nuclear charges Z_1 and Z_2 respectively, the parameters $\eta_1 = \left[\hbar V/(Z_1 e^2)\right]^2$ and $\eta_2 = \left[\hbar v_e/(Z_2 e^2)\right]^2$ are useful in characterizing the strength of the interaction between Z_1, Z_2, and the target electron. If $\eta_2 \ll \eta_1$, (i.e., $Z_1/Z_2 \ll V/v_e$), the effect of the projectile on the target wave function can be treated perturbatively. Perturbation treatments of inner shell ionization by lighter projectiles have been extensively studied and reviewed

[65.1–8]. Two well-known formulations have been used: the plane wave Born approximation (PWBA) [65.1–4], and the semiclassical approximation (SCA) [65.9, 10]. The former represents the nuclear motion with plane waves, while the latter is formulated in terms of the impact parameter b with the nuclear motion treated classically. For straight line motion of the nuclei, the results are equivalent [65.11]. The total cross section for ionizing the K-shell of a target of charge Z_2 by a projectile of charge Z_1 is given within the PWBA by

$$\sigma_i = \left(8\pi Z_1^2/Z_2^4 \eta_2\right) f(\theta_2, \eta_2)\, a_0^2 , \tag{65.1}$$

where $\theta_2 = 2u_k n^2/Z_2^2$ and u_k is the target binding energy. The function f rises rapidly for $V < v_e$, reaching a value near unity near $V = v_e$ and falling very slowly thereafter. Tables of f for K- and L-shell ionization are given in [65.3, 4]. Figure 65.1 shows a comparison of experimental data for K vacancy production by protons with PWBA calculations, and with a classical binary encounter approximation [65.12] for a large range of proton data [65.6]. For larger Z_1, corrections to the PWBA and SCA must be made for the effective increase of u_k due to the presence of the projectile during the ionization, for nuclear projectile deflection, for relativistic corrections, and for the polarization of the electron cloud, as reviewed in [65.13–17]. Total cross section measurements for inner shell vacancy production in the perturbative region are reviewed in [65.15, 16].

In the SCA treatment, the heavy particle motion is taken to be classical, and the evolution of the electronic wave function under the influence of the projectile field is calculated by time-dependent perturbation theory. The assumption of classical motion is valid if the
Bohr parameter $K = 2Z_1 Z_2 e^2/(\hbar V)$ is much larger than unity [65.18]. If this condition is satisfied, the projectile scattering angle can be associated with a particular b through a classical deflection function. For K-shell ionization, the action occurs typically at sufficiently small b that a screened Coulomb potential is sufficient for calculating the deflection. In the absence of screening, $\theta = r_0/b$, where $r_0 = Z_1 Z_2 e^2/E$ with θ and E expressed in either the laboratory or c.m. system. Calculations for K- and L-shell ionization have been carried out [65.10]. The typical ionization probability $P(b)$ for $V \sim v_e$ and $b = 0$ is $P(0) \sim (Z_1/Z_2)^2$. For $V < v_e$, $P(b)$ decreases with increasing b with a characteristic scale length of $r_{ad} = V/\omega$, the *adiabatic radius*, where ω is the transition energy. For $V > v_e$, $P(b)$ cuts off near the K-shell radius of the target. A more complete relativistic SCA program has been written [65.19], and is widely used for calculating $P(b)$, cross sections, and probabilities differential in final electron energy and angle. Experimentally, the probability $P(b)$ for inner shell ionization can be determined from

$$P(b) = \frac{1}{\epsilon \omega \Delta \Omega} \left(\frac{Y}{N[\theta(b)]} \right) , \qquad (65.2)$$

where Y is the coincidence yield for the scattering of $N(\theta)$ ions into a well-defined angle $\theta(b)$ accompanied by X-ray (or Auger electron) emission with fluorescence yield ω into a detector of efficiency ϵ and solid angle $\Delta \Omega$ [65.20]. The necessary ω can be obtained from calculations for neutral targets [65.21] (Chapt. 62). However, they must be corrected for changes due to extensive outer shell ionization during the collision. Such corrections are particularly important for targets with low fluorescence yields, for Z_2 below 30, and for collisions in which the L-shell is nearly depleted in the collision [65.15,16]. Values of $P(b)$ have been measured for many systems and generally show good agreement (better than 10%) with the SCA for fast light projectiles such as protons, with increasing deviation as higher Z_1 or slower V are used [65.22]. Examples of $P(b)$ for K vacancy production for several systems are shown in Fig. 65.2, showing the evolution away from the SCA as the collision becomes less perturbative.

Ionization of Light Target Atoms

Ionization of light target atoms by bare ion impact is a particularly suitable process to study the atomic few-body problem. In the case of an atomic hydrogen target the collision represents a three-body system, i.e., the simplest system for which the Schrödinger equation is not analytically solvable. However, because of the ex-

Fig. 65.1 Comparison of experimental cross sections for K-shell vacancy production with PWBA (*dashed*) and binary encounter (*solid*) theories. U_k is the target binding energy in keV and λ the projectile/electron mass ratio [65.6]
Fig. 65.2 $P(b)$ for K-shell vacancy production versus b/r_{ad} for several systems (see text). The ratio V/v_e is designated as "V" in this figure. For protons p, agreement with the SCA theory is found [65.10], while for higher Z_1/Z_2, $P(b)$ moves to larger impact parameters as one leaves the perturbative region [65.22]

perimental difficulties associated with atomic hydrogen, measurements with this target species are rare [65.23] and experimental studies have focused on helium targets. Here, the collision still constitutes a relatively simple four-body system. With regard to the few-body problem, studies of ionization processes have the important advantage that, in contrast to pure excitation and capture processes, the final state involves at least three independently moving particles.

Detailed information about the few-body dynamics in a collision can be extracted from multiply differential measurements. This can be accomplished by measuring the kinematic properties (e.g., energy, momentum, ejection angle) of one or more of the collision fragments. The first experimental multiply differential single ionization cross sections were obtained by studying the ionized electron spectra as a function of energy and ejection angle. Such studies were reviewed by

Rudd et al. [65.24] and are discussed in more detail in Sect. 65.3. More recently, complementary multiply differential data were obtained by measuring projectile energy-loss spectra as a function of scattering angle in p + He collisions [65.25, 26].

A comprehensive picture of ionizing collisions can be obtained from kinematically complete experiments. In such a study the momentum vectors of all collision fragments need to be determined. However, in the case of single ionization it is sufficient to directly measure the momentum vectors of any two particles in the final state; the third one is then readily determined by momentum conservation. For ionization by electron impact, this has been accomplished by momentum-analyzing the scattered and the ionized electrons (for a review see [65.27]). For ion impact, this approach is difficult because of the very small scattering angles and energy losses (relative to the initial collision energy) resulting from the large projectile mass. Consequently, the only kinematically complete experiments involving a direct projectile-momentum analysis were reported for light ions at relatively low projectile energies [65.28]. For heavy-ion impact at high projectile energies, in contrast, the complete determination of the final space state is only possible through a direct measurement of the ionized electron and recoil-ion momenta [65.29].

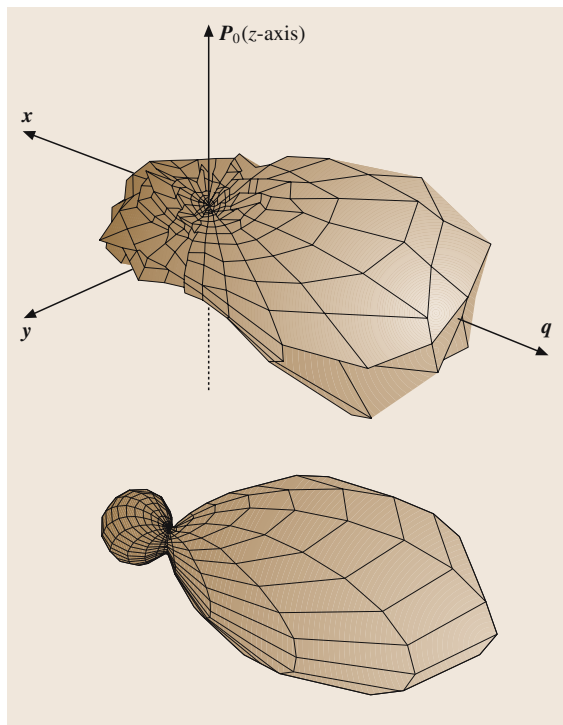
The technology to measure recoil-ion momenta with sufficient resolution, and therefore to perform kinematically complete experiments for heavy-ion impact, has only become available over the last decade (for reviews, see [65.30–32]). Figure 65.3 shows measured (top) and calculated (bottom) three-dimensional angular distributions of electrons ionized in 100 MeV/a.m.u. C^{6+} + He collisions for fully determined kinematic conditions [65.33]. The arrows labeled p_o and q indicate the direction of the initial projectile momentum and the momentum transfer defined as the difference between p_0 and the final projectile momentum p_f. This plot is rich in information about the dynamics of the ionization process. The main feature is a pronounced peak in the direction of q. It can be explained in terms of a binary interaction between the projectile and the electron, i.e., a first-order process, and is thus dubbed the "Binary Peak". A second, significantly smaller, structure is a contribution centered on the direction of $-q$ (called the "Recoil Peak"). This has been interpreted as a two-step mechanism where the electron is initially kicked by the projectile in the direction of q and then backscattered by the residual target ion by 180°. Although this process involves two interactions of the electron, it is nevertheless a first-order process in the projectile–target atom inter-


Fig. 65.3 Three-dimensional angular distribution for fully determined kinematic conditions of electrons ionized in $100\,\text{MeV/a.m.u.}\,C^{6+} + \text{He}$ collisions. *Top*, experimental data; *bottom*, CDW calculation (see text)

action. Therefore, as expected for this very large value of $\eta_1 = 100$ (in a.u.), the ionization cross sections are dominated by first-order contributions.

The basic features of the data in Fig. 65.3 are well reproduced even by the relatively simple first Born approximation (FBA). Furthermore, the calculation shown in the bottom of Fig. 65.3, which is based on the more sophisticated continuum distorted wave approach (CDW)([65.35–37] see also Chapt. 52), yields practically identical results to the FBA. In the CDW method, higher-order contributions are accounted for in the final-state scattering wavefunction. Apart from this good overall agreement, a closer inspection of the comparison between experiment and theory also reveals some significant discrepancies. While in the calculation the Binary and Recoil peaks are sharply separated by a minimum near the origin, in the data this minimum is almost completely filled up giving rise to a "ring-like" shape of the recoil peak. This was explained by a higher-order ionization mechanism involving an interaction between the projectile and the residual target

ion [65.33, 37, 38]. Although the contribution of this process to the total cross section is negligible, it is a very surprising result that for selected kinematic conditions higher-order processes can be important even at large projectile energies. A sobering conclusion of recent research on ionization of light target atoms is that even well inside the perturbative regime the atomic few-body problem is not nearly as well understood as was previously assumed based on studies for restricted collision geometries. At large perturbation, the lack of understanding is dramatic [65.39].

Excitation

Inner shell excitation can be treated within the same perturbative framework, which leads to a cross section given in terms of the generalized oscillator strength for the transition [65.40–42]. For inner shell vacancy production by light projectiles, the excitation is generally much smaller than the ionization, since the strongest oscillator strengths are to low-lying occupied orbitals, as reviewed by *Inokuti* [65.41]. Excitation cross sections can be deduced from photon production cross sections and from inelastic energy loss experiments. An example of the cross section for excitation of the $n = 2$ level of H by protons, measured by the latter technique, is shown in Fig. 65.4 [65.34].
Fig. 65.4 Energy loss spectrum for $50\,\text{keV}$ protons in atomic hydrogen, showing excitation to discrete states in H proceeding smoothly into ionization at the continuum limit [65.34]

Capture

As Z_1/Z_2 is raised, the probability for direct transfer of inner shell electrons from projectile to target becomes competitive with, and can even exceed, that for ionization of the target electron into the continuum. The first-order perturbation treatment for electron capture, given by *Oppenheimer* [65.43] and by *Brinkman* and *Kramers* [65.44] (OBK) ([65.11], p. 379) results in a cross section per atom

$$\sigma_{\text{OBK}} = 2^9 \pi (Z_1 Z_2)^5 / 5 \, V^2 v^5 n^3 \beta^5 \, a_0^2 \,, \tag{65.3}$$

from a filled shell v to all final states n, where

$$\beta = \frac{1}{4} V^2 \Big[V^4 + 2V^2 \big(Z_2^2/v^2 + Z_1^2/n^2 \big) \\ + \big(Z_2^2/v^2 - Z_1^2/n^2 \big)^2 \Big] \,. \tag{65.4}$$

Both the PWBA/SCA and the OBK cross sections maximize near the matching velocity, but the OBK falls off much more strongly with increasing V beyond this, eventually falling as V^{-12}, while the ionization cross section only falls as $V^{-2} \ln V$. The OBK amplitude for capture is simply the momentum space overlap of the initial wave function with the final state wave function, where the latter is simply a bound state on the projectile but moving at a velocity V relative to the initial bound state. The integral is done only over the transverse momentum, since the longitudinal momentum transfer is fixed by energy conservation [65.11]. This capture amplitude thus depends heavily on there being enough momentum present in the initial and/or final wave function to enable the transfer, and the loss of this match is what leads to the steep decrease in the OBK cross section above velocity matching. Cross sections for K-shell capture have been measured by detection of K Auger electrons and K X-rays in coincidence with charge capture by the projectiles [65.22, 45, 46]. On the basis of these and many other data on electron capture, the OBK is a factor of approximately three too large [65.45–48]. This factor comes from a fundamental failure of first-order perturbation theory for electron capture. As pointed out already in 1927 by *Thomas* [65.49], who proposed a classical two-collision mechanism for capture, it is essential that the electron interacts with both nuclei during the collision in order to be captured (Chapt. 57). In quantum theories, this corresponds to the fundamental need to include second-order terms (and higher) in the capture amplitude. In the limit of large V, the second-order cross section decreases more slowly than the OBK term, as V^{-10}, and thus is asymptotically larger than the first-order term [65.50]. At large V, the coefficient of the V^{-12} term, the dominant one at most experimentally reachable V, is 0.29 times the OBK cross section when the theory is carried out to second-order in the projectile potential [65.50, 51]. Roughly speaking, this provides an explanation for the factor of three. Much more sophisticated treatments of high velocity capture are now available [65.52–60]. The underlying role of the second-order scattering process was confirmed experimentally by the detection of the Thomas peak in the angular distribution of protons capturing electrons from He and H [65.61, 62] (Chapt. 57).

In spite of the basic importance of second-order amplitudes in perturbative capture, the OBK gives an excellent account of the relative contributions from and to different final shells over a large range of V above v_e, and is thus, when appropriately reduced, still useful as an estimate for perturbative capture cross sections between well defined v and n for large V.

For electron capture, as in the case of ionization (see previous section), the development of recoil-ion momentum spectroscopy (RIMS) has enabled much more detailed studies of the collision dynamics. The transverse (perpendicular to the beam direction) recoil-ion momentum component $p_\perp$ reflects the closeness of the collision both relative to the target nucleus and the electrons. The longitudinal (parallel to the beam direction) component p_z, on the other hand, is related to the internal energy transfer Q in the collision by (in a.u.)

$$p_z = -Q/V - nV/2 \,, \tag{65.5}$$

where n is the number of captured electrons. A measurement of p_z is therefore equivalent to a measurement of Q. The advantage over measuring Q from the projectile energy loss is that at large collision energies a much better energy resolution is achievable. A sample Q measurement with RIMS is shown in Fig. 65.5 [65.63]. Very recently, RIMS was applied to study capture processes in collisions with an atomic hydrogen target [65.64]. This could be an important breakthrough in advancing our understanding of the atomic few-body problem as it opens the possibility to perform kinematically complete experiments on the true three-body system $X^{Z+} + \text{H}$, where X can be any bare projectile.

65.1.2 Nonperturbative Processes

Fano–Lichten Model

When the collision becomes increasingly perturbative, either due to a decreased V or increased Z_1/Z_2, higher-order effects become generally more important. One approach to account for such contributions
Fig. 65.5 Longitudinal momentum spectrum of recoil ions from 0.25 MeV He^{2+} capturing a single electron from a cold He target, showing clear resolution of capture to $n = 1$ from that which leaves target or projectile excited [65.63]

Fig. 65.6 Schematic correlation diagram for the $Cl-Ar$ system, indicating the rotational coupling and radial couplings important for K vacancy production and the $4f\sigma$ orbital whose promotion leads to L vacancy production [65.66]

is the continuum distorted wave–eikonal initial state (CDW-EIS)model ([65.35, 36, 65], see also Chapt. 52 and Sect. 65.1.1). The range of validity of CDW-EIS is roughly given by $Z_1/V^2 \ll 1$ [65.35]. Therefore, if the perturbation is large due to the projectile charge, the collision may still be treated perturbatively provided that the collision energy is sufficiently large. Otherwise, the perturbation treatment is replaced by a molecular orbital treatment.

Fano and *Lichten* [65.67] pointed out that the ratio V/v_e can be small for inner orbitals even for V of several a.u., and thus an adiabatic picture of the collision holds. K vacancy production cross sections become much larger than the perturbation treatments above predict and extend to much larger b. In the molecular orbital picture, the collision system is described in terms of time-dependent molecular orbitals (MO) formed when the inner shells of the systems overlap. Vacancy production occurs due to rotational, radial, and potential coupling terms between these orbitals during the collision. The independent electron model is used, but the results in any specific collision are quite sensitive to the occupation numbers (or vacancies) in the initial orbitals. These are very difficult to control in ion–atom collisions in solids and even problematic in gases, since outer shell couplings can produce vacancies at large internuclear distances which then enable transfers at smaller distances. Numerous reviews of the subject are available, including [65.68–72]. The most famous MO ionization mechanism involves the

promotion of the $4f\sigma$ orbital in a symmetric collision (Fig. 65.6), which promotes both target and projectile L electrons to higher energies where they are easily lost to the continuum during the collision. There are now many treatments of inner shell vacancy production mechanisms based on MO expansions (Chapts. 50, 51). For the case of K vacancy production in quasisymmetric collisions, an important MO mechanism is the transfer of L vacancies in the projectile to the K-shell of the target through the rotational coupling between $2p\pi$ and $2p\sigma$ orbitals which correlate to the L- and K-shells respectively of the separated systems (Fig. 65.6) [65.73, 74]. The process can be dynamically altered by the sharing at large b between L vacancies of target and projectile through a radial coupling mechanism [65.75, 76]. This sharing mechanism can also give rise to the direct transfer of K vacancies from projectile to target (KK sharing). In symmetric systems, the KK sharing results in an oscillation of the K vacancy back and forth between target and projectile during the collision, and leads to an oscillatory behavior of the transfer prob-

ability with V and b [65.77, 78]. Both of the above vacancy production mechanisms are electron transfer processes rather than direct ionization processes, in that no inner shell electron need be liberated into the continuum. Between the perturbation region and the full MO region the importance of transfer increases relative to ionization. While the MO correlation diagrams and mechanisms are qualitatively useful, actual close coupling calculations for both inner and outer shell processes are often carried out using atomic orbitals instead of molecular orbitals, as well as other basis sets (Chaps. 50, 51).

65.2 Multi−Electron Processes

In a single collision between multi-electron partners, two or more electrons may be simultaneously excited or ionized. The electric fields created during a violent ion–atom collision are so large that the probability of such multi-electron processes can be of order unity. While there are many similarities between ion–atom collisions and the interaction of atoms with photons (X-rays or short laser pulses) or electrons, the dominance of multi-electron processes is very much less common in the photon and electron cases. As an example, when a K-shell electron is removed from a target atom by the passage of a fast highly charged ion through its heart, the probability that L-shell electrons will be removed at the same time can be large. This gives rise to target X-ray and Auger-electron spectra which are dominated by satellite structure [65.20]. For example, the spectrum of X-rays from Ti bombarded by 30 MeV oxygen shows that the production of the K vacancy is accompanied by multiple L vacancy production, and that the dominant K X-rays are those of systems which are missing several L electrons [65.79] (Fig. 65.7).

When a gas target is used, the recoil target ion is heavily ionized and/or excited electronically without receiving much translational kinetic energy. In the impulse approximation the transverse momentum $\Delta p_\perp$ received by the target from a projectile passing at impact parameter b is given in a.u. by $\Delta p_\perp = 2Z_1 Z_2 / bV$. This expression ignores the exchange of electronic translational momentum but gives a good estimate. The resulting recoil energies are typically quite small, ranging from thermal to a few eV. This subject has been reviewed in [65.63, 80]. These slow moving recoils have
Fig. 65.7 K X-ray spectrum of Ti for various projectiles, showing dominance of multi-electron transitions when K vacancies are collisionally produced by heavily ionizing projectiles (^{16}O beam) [65.79]

been used to provide information about the primary collision dynamics, and as secondary highly charged ions from a fast-beam-pumped ion source. Such an ion source has, for moderately charged ions, a high brightness and has been used extensively for energy-gain measurements. The primary recoil production process is difficult to treat without the independent electron model, and even in this model the nonperturbative nature of the collision makes the theory difficult. The most successful treatments have been the CTMC (see Chapt. 58) and a solution of the Vlasov equation [65.64].

Studies of many-electron transitions in collisions of bare projectiles with a He target are particularly suitable to investigate the role of electron–electron correlation effects because such collisions represent the simplest systems where the electron–electron interaction is present. Such studies have been performed extensively for a variety of processes, such as double ionization, transfer-ionization, double excitation, transfer-excitation, or double capture (for reviews see [65.82–84]). It is common to distinguish (somewhat artificially) between such correlations in the initial state, the final state, and during the transition (dynamic correlation). From a theoretical point of view, the biggest challenge is to describe electron–electron correlation effects and the dynamics of the two-center potential generated by the projectile and the target nucleus simultaneously with sufficient accuracy.

In the case of double ionization, an experimental method, based on the so-called correlation function [65.81], was developed to analyze electron–electron correlations independently of the collision dynamics. Here, a measured two-electron spectrum (for example the momentum difference spectrum of both ionized electrons) is normalized to the corresponding spectrum one would obtain for two independent electrons. An example of such a correlation function R is shown in Fig. 65.8 for three very different collision systems (η_1 ranging from 0.05 to 100 and η_2 from 0.01 to 0.5 in a.u.). The similarity in these three data sets illustrates that R is remarkably insensitive to the collision dynamics. Rather, the shape of R is determined predominantly by correlations in the final state [65.81, 85]. However, for selected kinematic conditions, R can also be sensitive to initial-state correlations [65.86]. Clear signatures of initial-state correlations were found in the recoil-ion momentum spectra for transfer-ionization [65.87].

Early attempts to identify dynamic correlations were based on measurements of the ratio of double to single ionization cross sections [65.88, 89]. From such studies, it was found that at small V double ionization
Fig. 65.8 Correlation function R for double ionization in the collisions indicated in the legend as a function of the momentum difference between the two electrons [65.81]. R is defined as $R = I_{exp}/I_{IEM} - 1$, where I_{exp} is the directly measured momentum spectrum and I_{IEM} the one obtained for independent electrons

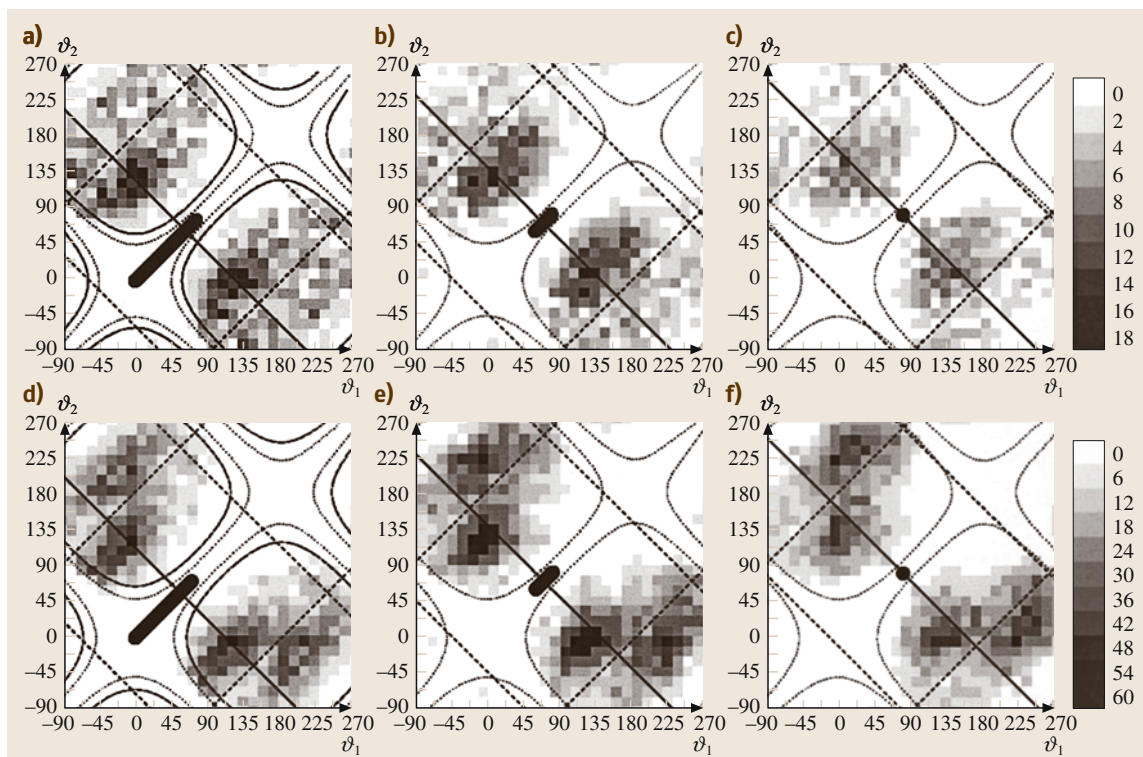
is dominated by an uncorrelated mechanism involving two independent interactions of the projectile with both electrons. In contrast, at large V the double to single ionization ratio asymptotically approaches a common value for all collision systems [65.90]. This is indicative of the dominance of first-order double ionization mechanisms, where the projectile interacts with only one electron and the second electron is ionized through an electron–electron correlation effect. This may either be a rearrangement process of the target atom adjusting to a new Hamiltonian (shake-off, an initial-state correlation), or a direct interaction with the first electron (i. e., dynamic correlation). However, a recent nearly kinematically complete experiment on double ionization in p + He collisions revealed that even at large V higher-order contributions are not negligible [65.91]. In Fig. 65.9 the ejection angles of both electrons are plotted against each other for almost completely determined kinematics. For comparison, the bottom part of Fig. 65.9 shows the corresponding spectra for electron impact at the same V [65.92]. For both projectiles, the basic features of these spectra are determined by the


Fig. 65.9a–f Differential double ionization cross sections in 6 MeV p + He (*top*) and 2 keV e⁻ + He (*bottom*) collisions as a function of the polar emission angle of both electrons, which are emitted into the scattering plane. The electrons have equal energy and data are shown for small (*left*), medium (*center*), and large momentum transfers (*right*) [65.91]

electric dipole selection rules, which again is indicative of dominating first-order contributions. However, a closer inspection of the comparison between the proton and electron impact data shows some non-negligible differences. Since in a first-order treatment the cross sections should be identical for both projectile species, this demonstrates that higher-order contributions cannot be ignored.

65.3 Electron Spectra in Ion−Atom Collisions

65.3.1 General Characteristics

An ionizing collision between a single ion and a neutral atom ejects electrons into the continuum via two major processes. Electrons ejected during the collision form broad features or continua, and are traditionally referred to as delta rays; electrons ejected after the collisions from the Auger decay of vacancies created during the collision form sharp lines in the spectra. The distributions of energy and angle of all electrons determine the electronic stopping power and characteristics of track formation of ions in matter (Chapt. 91), and the study of these distributions in the binary encounter of one ion with one atom form the basis of any detailed understanding of these averaged quantities. Figure 65.10 shows a typical electron spectrum from the collision of a fast O ion with O_2 [65.93, 94]. Electrons from the projectile can be identified in the cusp peak (electron loss, P) or ELC, and the O-K-Auger (P) peak. Electrons from the target include the soft (large b) collision electrons (T) which are ejected directly by Coulomb ionization by the projectile, the binary collision (or encounter) electrons coming from hard collisions between projectile and quasifree target electrons, and the target O-K-Auger (T)
Fig. 65.10 Electron spectrum from 30 MeV O on molecular oxygen. See text for explanation of features [65.93, 94]

electrons. The electron loss peak is widely called the *cusp* peak because the doubly differential cross section in the laboratory $d^2\sigma/dE\,d\Omega$ becomes infinite, in principle, if it is finite in the projectile frame. In general, this peak may also contain capture to the continuum. All of these features have been heavily studied; some reviews are [65.95, 96]. Capture to the continuum [65.96] is an extension of normal capture into the continuum of the projectile, and is not a weak process. Both it and ELC produce a heavy density of events in the electron momentum space centered on the projectile velocity vector, and thus appear strongly only at or near zero degrees in the laboratory and at $v_e \simeq V$.

The binary encounter electrons at forward angles occur at $v_e \cong 2V$. For relatively slow collisions it was found that the ELC and binary peaks are just part of a more general and complex structure of the electron spectra [65.98]. Additional peaks in the forward direction were found for $v_e \cong nV$, where n in principle can be any integer number. These structures reflect a "bouncing back and forth" (known as Fermi shuttle) between the projectile and the target core before the electron eventually gets ejected from the collision system.

In electron spectra for molecular targets, additional structures were found that were not observed for atomic targets [65.99]. These were initially interpreted as an interference effect. The electronic wavefunction has maxima at the atomic centers of the molecule. Since in the experiment it cannot be distinguished from which center the electron is ionized, both possibilities have to be treated coherently. However, more recent studies showed that at small electron energies the structures in the electron spectra reflect vibrational excitation of the molecule [65.100].

65.3.2 High Resolution Measurements

The Auger electron spectra provide detailed information about inner shell vacancy production mechanisms.

Fig. 65.11 High resolution Auger electron spectrum from H-like B on H_2, showing resolved lines from doubly excited projectile states lying on top of a continuum due to electron elastic scattering [65.97]. The *bottom part* shows an R-matrix calculation which does not account for the experimental resolution. The smooth line in the upper figure is the R-matrix calculation convoluted with the experimental spectrometer resolution
When coupled with fluorescence yields, Auger electron production probabilities and cross sections can be converted into the corresponding quantities for vacancy production [65.15, 95]. This is best done when sufficient resolution can be obtained to isolate individual Auger lines. The Auger spectra in ion–atom collisions are often completely different from those obtained from electron or photon bombardment because of the multiple outer shell ionization which attends the inner shell vacancy producing event, in close analogy to X-ray spectra (see previous section). Projectile Auger electron spectra suffer from kinematic broadening due to the finite solid angle of the spectrometer and velocity of the emitter, but at 0° to the beam this problem vanishes, and the resolution in the emitter frame is actually enhanced by the projectile motion, such that for electrons with eV energies in the projectile frame, resolutions in the meV region are possible [65.101, 102]. The highest resolution Auger lines from ion–atom collisions has been done on the projectiles. A sample spectrum is shown in Fig. 65.11. From such high resolution spectra, one-electron processes in which one electron is excited, captured or ionized can be distinguished from the configuration of the emitting state.

65.4 Quasi-Free Electron Processes in Ion–Atom Collisions

At sufficiently low V, those electrons not actively involved in a transition play only a passive role in screening the Coulomb potential between the nuclei, and thereby create a coherent effective potential for their motion. However, at high V the colliding electrons begin behaving as incoherent quasifree particles capable of inducing transitions directly via the electron–electron interaction. Such processes signal their presence through their free-particle kinematics, as if the parent nucleus were not present. For example, a projectile ionization process requiring energy U has a threshold at $\frac{1}{2} m_e V^2 \simeq U$, in collisions with light targets where the quasifree picture is meaningful. The threshold is not sharp, due to the momentum distribution or Compton profile of the target electrons. Within the impulse approximation, the cross section for any free electron process can be related to the corresponding cross section for the ion–atom process by folding the free electron cross section into the Compton profile [65.97, 103, 104].

65.4.1 Radiative Electron Capture

The first quasifree electron process to be observed was radiative electron capture (REC), the radiative capture of a free electron by an ion. Conservation of energy and momentum is achieved by the emission of a photon which carries away the binding energy. The cross section exceeds that for bound state capture at high V. Radiative electron capture was observed through the X-ray spectra from fast heavy projectiles for which the electrons of light targets appear to be 'quasi-free'. The corresponding free electron process was seen [65.105] and has recently been heavily studied in EBIT [65.106], cooler [65.107], and storage rings [65.108]. Total cross sections for REC have also been deduced from measured total capture cross sections at large V where REC dominates bound state capture [65.109]. At high velocities, the cross section for radiative capture to the K-shell of a bare projectile is given approximately by

$$\sigma_n = \left[n/\left(\kappa^{-2} + \kappa^{-4}\right)\right] \times 2.1 \times 10^{-22}\,\text{cm}^2 , \quad (65.6)$$

where [65.110] $\kappa = \sqrt{E_B/E_0}$, E_B is the binding energy of the captured electron, E_0 the energy of the initial electron in the ion frame and n the principal quantum number of the captured electron. The theory seems to be in good agreement with experiment for capture to all shells of fast bare projectiles, although a small unexplained discrepancy between theory and experiment exists for capture to the K-shell [65.108].

65.4.2 Resonant Transfer and Excitation

Dielectronic recombination in electron–ion collisions is the process whereby an incident electron excites one target electron and, having suffered a corresponding energy loss, drops into a bound state on the projectile (Chapt. 55). If the doubly excited state so populated decays radiatively, resonant radiative recombination is achieved (DR); if it Auger decays, resonant elastic scattering has occurred. The process has long been known to be important as a recombination process in hot plasmas [65.111], but was not observed in the laboratory until 1983 [65.112–114]. The corresponding ion–atom process, known as resonant transfer and excitation (RTE) was seen a bit earlier by *Tanis* et al. [65.115]. (See [65.116, 117] for reviews of both DR and RTE.)

65.4.3 Excitation and Ionization

Excitation and ionization of inner shells of fast projectile ions by the quasifree electrons of light targets (usually He or H_2) have been identified and studied. This process competes with excitation and ionization by the target nucleus [65.118–120], and special signatures must be sought to distinguish the processes. In the case of excitation, the e–e excitation populates states through the exchange part of the interaction which is excluded for the nuclear excitation, and this has been used to separate this mechanism [65.121]. For ionization, enhancements of the ionization cross section above the Born result for nuclear ionization [65.122], coincident charge exchange measurements [65.123], and

projectile [65.124] and recoil ion momentum spectroscopy [65.125, 126] have been used to distinguish the two processes. Rapid development in the production of good sources of beams of highly charged ions (EBIS/T, ECR; see [65.127]) have made these studies possible. Continued study of this field in heavy ion storage rings is now achieving resolutions of meV and opening broad new opportunities for data of unprecedented high quality for electron-ion collisions [65.128].

Recently, the first kinematically complete experiment on projectile ionization by quasifree electrons was reported [65.129]. The observed features are qualitatively similar to those found for ionization of neutral target atoms by free electron impact.

65.5 Some Exotic Processes

65.5.1 Molecular Orbital X–Rays

A typical time duration for an ion–atom encounter is $\sim 10^{-17}$ s, which is much shorter than Auger and X-ray lifetimes, so that hard characteristic radiation is emitted by the products long after the collision. There remains, however, a small but finite probabiltiy that X-rays or Auger electrons can be emitted during the collision, in which case the radiation proceeds between the time-dependent molecular orbitals formed in the collision and reflects the time evolution of the energies and transition strengths between the orbitals. Such molecular orbital X-radiation (MOX) has now been observed in many collision systems [65.130] and is reviewed in [65.131–133]. MOX spectra have been studied in total cross sections as well as a function of impact parameter. In the latter case, oscillating structures in the MOX spectra are seen [65.132, 134], due to the interference between amplitudes for the emission of X-rays with the same energy on the incoming and outgoing parts of the trajectory.

The formation of transient molecular orbitals in close collisions between highly charged ions provides opportunities for studying the electrodymamics of very highly charged systems [65.135]. For example, two uranium nuclei passing within one K-shell radius of each other form a transient molecule whose energy levels resemble those of an atom of charge 184.

65.5.2 Positron Production from Atomic Processes

Investigating the MOX interference patterns in such exotic systems offers the interesting prospect of performing spectroscopy on superheavy ions.

Reinhart et al. [65.136] predicted that, for such highly charged species, the binding energy of the united atom K-shell exceeds twice the rest mass energy of the electron, and that if a K vacancy is either brought into the collision or created during it, spontaneous electron-positron pair production occurs (the decay of the charged vacuum) with the electron filling the K-hole. However, further analysis showed that the dominant mechanism for positron production (other than those resulting from the decay of nuclear excitations) likely results from the dynamic time dependence of the fields during the collision [65.137]. Experiments showed evidence for such positron production in collisions at 6 MeV/u [65.138], but reported sharp lines in the positron spectra were later attributed to an error in the data analysis.

Present theories for the production of lepton pairs in the close collision of two highly charged systems predict that the cross section grows rapidly with collision energy. Electrons produced in such a process may end up in bound states on either collision partner, and thus represent a new charge changing mechanism. At highly relativistic velocities, the cross section for this process exceeds that for any other charge changing process. In a heavy ion collider, such as RHIC,

this process could limit the ultimate storage time for the counter-propagating beams, since charge-exchanged ions are lost. The cross section has been measured recently by *Vane* et al. [65.139], for 6.4 TeV S on several targets (the highest energy ion–atom collision experiment performed to date), and are in good agreement

with theory [65.140]. The bound state capture has been measured at lower energy by *Belkacem* et al. [65.141], with similarly good agreement. The extension of ion–atom collisions to such extreme velocities has opened the field for the study of processes not even imagined a short time ago.

66. Reactive Scattering

This chapter presents a résumé of the methods commonly employed in scattering experiments involving neutral molecules at chemical energies, i. e., less than about 10 eV. These experiments include the study of intermolecular potentials, the transfer of energy in molecular collisions, and elementary chemical reaction dynamics. Closely related material is presented in Chapts. 35, 37, and 38 as well as in other chapters on quantum optics.

66.1 Experimental Methods

66.1.1 Molecular Beam Sources

The development of molecular beam methods in the past two decades has transformed the study of chemical physics [66.1]. Supersonic molecular beam sources allow one to prepare reagents possessing a very narrow velocity distribution with very low internal energies, ideal for use in detailed studies of intermolecular interactions. Early experiments generally employed continuous beam sources, but in recent years intense pulsed beam sources have come into common usage [66.2]. The advantages of pulsed beams primarily arise from the lower gas loads associated with their use, hence reduced demands on the pumping system. If any component of the experiment is pulsed (pulsed laser detection, for example) then considerable advantage may be obtained by also pulsing the beam. Although the theoretical descriptions of pulsed and continuous expansions are essentially equivalent, in practice some care is required in employing pulsed beams because the temperature and

velocity distributions may change dramatically through the course of the pulse. Free jet expansions are supersonic because the dramatic drop in the local temperature in the beam is associated with a drop in the local speed of sound. A detailed description of the supersonic expansion may be found in [66.3–5]. In practice, many of the detailed features associated with a supersonic expansion may be ignored and one may assume an isentropic expansion into the vacuum. For an isentropic nozzle expansion of an ideal gas, the maximum terminal velocity is given by

$$v_{\max} = \sqrt{2\hat{C}_p T_0} \,, \tag{66.1}$$

where, for an ideal gas, the heat capacity is

$$\hat{C}_p = \left(\frac{\gamma}{\gamma - 1} \right) \frac{R}{m} \,, \tag{66.2}$$

R is the gas constant, m is the molar molecular mass, T_0 the temperature in the stagnation region, and γ the

heat capacity ratio. For ideal gas mixtures, and assuming C_p independent of temperature for the range encountered in the expansion, one may use

$$\bar{C}_p = \sum_i X_i C_{p_i} = \sum_i X_i \left(\frac{\gamma_i}{\gamma_i - 1} \right) R , \qquad (66.3)$$

and the average molar mass

$$\bar{m} = \sum_i X_i m_i , \qquad (66.4)$$

where X_i is the mole fraction of component i, to obtain an estimate of the maximum velocity for a mixture:

$$v_{\max} = \sqrt{2\bar{C}_p T_0/\bar{m}} . \qquad (66.5)$$

By seeding heavy species in light gases one may accelerate them to superthermal energies. Supersonic beams are characterized by the speed ratio, i. e., the mean velocity divided by the velocity spread:

$$S \equiv \frac{v}{\sqrt{2kT/m}} , \qquad (66.6)$$

where T is the local translational temperature, or by the Mach number

$$M \equiv \frac{v}{\sqrt{\gamma kT/m}} . \qquad (66.7)$$

For the purpose of order-of-magnitude calculations, the number density on axis far from the nozzle may be estimated as

$$n \approx n_0 \left(d/x \right)^2 , \qquad (66.8)$$

where n_0 is the number density in the stagnation region, d is the nozzle diameter, and x is the distance from the nozzle. The number density versus speed distribution of a nozzle beam is well described as a Gaussian characterized by the speed ratio S and a parameter $\alpha = v_0/S$, where v_0 is the most probable velocity:

$$n(v) = v^2 \exp\left[-(v/\alpha - S)^2 \right] . \qquad (66.9)$$

Cooling efficiencies for the various internal degrees of freedom correlate with the efficiency of coupling of these modes with translation, hence they vary widely. Coupling of modes A and B is expressed by the collision number Z_{A-B}:

$$Z_{A-B} \equiv Z\tau_{A-B} , \qquad (66.10)$$

where τ_{A-B} is the bulk relaxation time, and Z the collision frequency. This represents the number of collisions between effective inelastic events. Typical values are

Table 66.1 Collision numbers for coupling between different modes. V, R, T refer to vibrational, rotational, and translational energy, respectively. Each entry is the typical range of Z_{A-B}

	V	R	T
V	$10^{0.5-3}$	10^{3-4}	10^{5-6}
R		10^{0-1}	10^{2-3}

summarized in Table 66.1. R–T coupling is relatively efficient, while V–T coupling is quite inefficient, so that vibrational excitation may not be effectively cooled in the expansion.

66.1.2 Reagent Preparation

Molecular beam methods may be used in conjunction with a variety of other techniques to prepare atoms or molecules in excited or polarized initial states (Chapt. 46), to generate unstable molecules or radicals [66.6, 7] or to produce beams of refractory materials such as transition metals or carbon [66.8, 9]. Some of the common techniques are outlined below. Optical pumping of atoms to excited electronic states is a useful means of reagent preparation, and this topic is presented in detail in Chapt. 10. This technique further allows one, using polarized lasers, to explore the influence of angular momentum polarization in the reagents on the collision dynamics [66.10]. Most of these studies have been performed using alkali and alkaline earth metals since there exist strong electronic transitions and convenient narrow-band visible lasers suitable for use with these systems. Laser excitation may also be used to generate vibrationally excited molecules in their ground electronic states. The techniques employed include direct IR excitation using an HF chemical laser [66.11], population depletion methods [66.12] and various Raman techniques [66.13].

Metastable atoms may also be prepared by laser photolysis of a suitable precursor. $O(^1D)$ preparation is readily prepared by photolysis of ozone or N_2O, for example [66.14]. Alternatively, rf or microwave discharges may be used to produce metastable species or reactive atoms or radicals [66.15]. These techniques may also be used to prepare ground state atoms; for example, hot H atom beams are frequently produced by photolysis of HI or H_2S [66.16]. Such atomic or molecular radical beams may also be generated by pyrolysis in the nozzle. In this case care must be taken to minimize recombination through careful choice of the temperature, nozzle geometry, and transit time through the heated region.

Beams of refractory materials are now commonly generated using laser ablation sources [66.8, 9]. Typically these employ a rod or disk of the substrate of interest which is simultaneously rotated and translated to provide a fresh surface for ablation at each laser pulse. A laser beam is focused on the substrate and timed to fire just as a carrier gas pulse passes over. Laser power and wavelength must be optimized for a given substrate. Lasers operating in the IR, visible, and UV have all been employed. Aligned or oriented molecules have been prepared using multipole focussing [66.17, 18], and more recently using strong electric fields ("brute force") [66.19]. In the former case, specific quantum states are focused by the field. In the latter case, so called pendular states are prepared from the low rotational levels of molecules possessing large dipole moments and small rotational constants. The ability to orient these molecules can be estimated on the basis of the Stark parameter $\omega = \mu E/B$, where μ is the dipole moment, E the electric field strength, and B the rotational constant. Orientation is feasible for low rotational levels of molecules when the Stark parameter is on the order of 10 or higher [66.19].

66.1.3 Detection of Neutral Products

Broadly speaking, detection of neutral molecules is accomplished either by optical (spectroscopic) or nonoptical techniques. Nonoptical methods usually involve nonspecific ionization of neutral particles, most commonly by electron impact, followed by mass selection and ion counting. Thermal detectors such as cryogenic bolometers are also finding widespread application in molecular beam experiments owing to their remarkable sensitivity [66.20]. In general, optical methods may rely on resonant or nonresonant processes, hence they may or may not enjoy quantum state selectivity. Both photoionization and laser-induced fluorescence methods are now in common usage, usually in applications where quantum state resolved information is desired. The advantage of nonoptical methods is primarily one of generality: all neutral molecules may be detected, and branching into different channels readily measured. Quantum state resolution is more difficult to achieve using nonoptical detection methods, but both vibrationally- and rotationally-resolved measurements have been obtained by these means [66.21, 22].

The primary advantage of spectroscopic detection is the aforementioned possibility of quantum state specificity. Another unique opportunity afforded by spectroscopic probes is the measurement of product alignment and orientation. In addition, in some cases background interference may be reduced or eliminated using state-specific probes, thereby affording enhanced signal-to-noise ratios.

Nonoptical Techniques

Detectors based on nonspecific ionization remain the most commonly used in molecular beam experiments, owing to the ease of subsequent mass selection, and the convenience and sensitivity of ion detection. Surface ionization is a sensitive means of detecting alkali atoms and other species exhibiting low ionization potentials [66.23]. Surface ionization occurs when a neutral atom or molecule with a low ionization potential sticks on a surface with a high work function and is subsequently desorbed. Typically these detectors employ a hot platinum or oxidized tungsten wire or ribbon for formation and subsequent desorption of the ions, which is surrounded by an ion collector. They are very efficient for the detection of alkali atoms and molecules whose ionization potentials are $\lesssim 6\,\mathrm{eV}$.

All neutral gas molecules may be ionized by collision with energetic electrons, and electron beam ionizers may be produced that couple conveniently to quadrupole mass spectrometers [66.24]. Collision of a molecule with a $100-200\,\mathrm{eV}$ electron leads predominantly to formation of the positive ion and a secondary electron. Other processes also occur and can be very significant: doubly or triply charged ions may be formed and, importantly, molecules can fragment yielding many daughter ions in addition to the parent ion. These fragmentation patterns vary with different molecules, and may further show a strong dependence on molecular internal energy, so particular care must be taken to determine the role of these phenomena in each particular application. It is often necessary to record data for the parent ion and daughter ions for a given product channel and compare them to eliminate contributions arising from cracking of the parent molecule or other species [66.25]. Electron impact ionization probabilities for most species exhibit a similar dependence on electron energy, rising rapidly from the ionization potential to a peak at $80-100\,\mathrm{eV}$, then falling more slowly with increasing collision energy. The ionization cross section for different species scales with molecular polarizability according to a well-established empirical relation [66.26]:

$$\sigma_{\mathrm{ion}} = 36\sqrt{\alpha} - 18 , \tag{66.11}$$

where σ_{ion} is in $\mathrm{\AA}^2$ and α, the molecular polarizability, is in $\mathrm{\AA}^3$. This relation can be used to estimate branching ratios in the absence of any other means of calibrating

the relative contributions of two different channels. The ionization rate is given by

$$\frac{\mathrm{d}[M^+]}{\mathrm{d}t} = I_e \sigma [M] \, , \tag{66.12}$$

where I_e is the electron beam intensity, typically $10 \, \mathrm{mA/cm^2}$ or 6×10^{16} electrons/cm^2 s, and $[M]$ is the number density of molecules M in the ionizer. If one assumes an ionization cross section σ_{ion} of $10^{-16} \, \mathrm{cm^2}$ for collision with $150 \, \mathrm{eV}$ electrons (a typical value for a small molecule), the ionization probability for molecules residing in the ionizer is then

$$\frac{\mathrm{d}[M^+]}{\mathrm{d}t} \frac{1}{[M]} = I_e \sigma = 6 \times 10^{16} \times 10^{-16} = 6 \, \mathrm{s^{-1}} \, . \tag{66.13}$$

However, product molecules arriving in the detector are not stationary. Typically, product velocities are on the order of $500 \, \mathrm{m/s}$. If the ionization region has a length of $1 \, \mathrm{cm}$, the residence time τ of a product molecule is on the order of $2 \times 10^{-5} \, \mathrm{s}$. Consequently, the ionization probability of product molecules passing through the ionizer is

$$\frac{\mathrm{d}[M^+]}{\mathrm{d}t} \frac{\tau}{[M]} = 2 \times 10^{-5} \times 6 = 1.2 \times 10^{-4} \, . \tag{66.14}$$

Although this does not appear very efficient (indeed, it is 4 orders of magnitude less so than surface ionization), nevertheless, if the background count rate is sufficiently low, then good statistics may be obtained with signal levels as low as 1 Hz. Thus, for detection based on electron impact ionization, a key factor determining the sensitivity of the experiment is the background count rate at the masses of interest.

Spectroscopic Detection

Spectroscopic detection methods usually involve either laser-induced fluorescence (LIF) or resonant photoionization (REMPI) (Chapt. 44). Alternative techniques such as laser-induced grating methods and nonresonant VUV photoionization are also being applied to scattering experiments. Essential to the use of spectroscopic methods for reactive scattering studies is an understanding of the spectrum of the species of interest. This may be challenging for many reactive systems because the products may be produced in highly excited vibrational or electronic states that may not be well characterized. Additional spectroscopic data may be required. Franck–Condon factors are necessary to compare the intensities of different product vibrational states, while a calibration of the relative intensities of different electronic bands requires a measure of the electronic transition moments.

In some cases, one must include the specific dependence of the electronic transition moment on the internuclear distance by integrating over the vibrational wave function. Populations corresponding to different rotational lines may be compared after the appropriate correction, which is represented by the Hönl–London factors, only for isotropic irradiation and detection. This is certainly not the case for most laser-based experiments. Generally, the detailed dependence of the excitation and detection on the relevant magnetic sublevels must be considered [66.27–29]. Caution is required in using any spectroscopic method involving a level that is predissociated. This may lead to a dramatic decrease in the associated fluorescence or photoionization yield if the predissociation rate approaches or exceeds the rate of fluorescence or subsequent photoionization. An important question in any experiment based on spectroscopic detection is whether product flux or number density is probed. This question is considered in detail in several articles [66.13, 30]. It depends on the lifetime of the state that is probed, the relative time that the molecule is exposed to the probe laser field, and its residence time in the interaction region. Saturation phenomena are also important, yet not necessarily easily anticipated. Complete saturation does not readily occur because excitation in the wings of the laser beam profile becomes more significant as the region in the center of the beam becomes saturated [66.31].

LIF is currently the most widely used spectroscopic technique in inelastic and reactive scattering experiments [66.27, 32, 33]. It has been used to measure state-resolved total cross sections [66.34] and differential cross sections in electronic [66.35], vibrational and rotationally inelastic scattering [66.12] as well as reactive scattering [66.36].

With the development of high-power tunablebreak lasers and the discovery of useful photoionization schemes, REMPI is becoming a more general technique [66.37, 38]. REMPI has the advantages associated with ion detection, namely considerable convenience in mass selection and efficient detection, in addition to the capability for quantum state selectivity. Disadvantages associated with REMPI arise primarily from higher laser power employed compared with LIF. Caution is required in attempting to extract quantitative information from REMPI spectra if one or several of the steps involved in the ionization process are saturated. This is of particular concern at the high laser powers necessary for multiple photon transitions. An alternative to direct photoionization involves excitation of products to metastable Rydberg states, followed by field ionization

some distance from the interaction region. This technique has the advantage of very low background and is capable of extraordinary time-of-flight resolution. Remarkable results have recently been obtained for the reaction $D + H_2$ using this method [66.39]. Photoionization techniques are becoming more widely used in scattering experiments as the basis for product imaging detection schemes discussed below.

66.1.4 A Typical Signal Calculation

For a crossed-beam system in which a beam of atoms A collides with a beam of molecules B yielding products C and D, the rate of formation of C is given by

$$\frac{dN_C}{dt} = n_A n_B \sigma_r g \Delta V \,, \tag{66.15}$$

where n_A and n_B are the number densities of the respective reagents at the interaction region, σ_r is the reaction cross section, g the magnitude of the relative velocity between the reactants, and ΔV the volume of intersection of the beams. For a typical experiment employing continuous supersonic beams, the number densities of the atomic and molecular reactants are $\sim 10^{11}$–$10^{12}\,\text{cm}^{-3}$ and the scattering volume $10^{-2}\,\text{cm}^3$. For $g = 10^5\,\text{cm/s}$ and $\sigma_r = 10^{-15}\,\text{cm}^2$, the rate of product formation $dN_C/dt = 10^{11}$ molecules/s. The kinematics and energetics of the reaction then determines the range of laboratory angles into which the products scatter, and the magnitude of the scattered signal.

If the products scatter into $1\,\text{sr}$ of solid angle, and the detector aperture is $3 \times 10^{-3}\,\text{sr}$ (roughly 1 degree in both directions perpendicular to the detector axis), then the detector receives 3×10^7 product molecules/s.

Given the detection probability obtained above, 3600 product ions/s are detected. This is adequate to obtain very good statistics in a short time as long as the background count rate is not considerably higher.

For a nonspecific detection technique, such as electron bombardment ionization coupled with mass filtering, it is necessary to use ultrahigh vacuum $\left(10^{-10}\,\text{torr}\right)$ in the detector region to minimize interference from background gases. The residual gases are then primarily H_2 and CO, with number densities on the order of $10^6\,\text{cm}^3$. Differential pumping stages, each of which may reduce the background by 2 orders of magnitude, are generally used to lower the background from gases whose partial pressures are lower than the ultrahigh vacuum limit of the detector chamber. However, this differential pumping helps only for those molecules that do not follow a straight trajectory through the detector. The contribution from the latter is given by

$$n' = \frac{nA}{4\pi x^2} \,, \tag{66.16}$$

where n is the number density of molecules effusing from an orifice of area A, and n' is their number density at a distance x on axis downstream. For a distance of 30 cm and a main chamber pressure of 3×10^{-7} torr, this corresponds to a steady state density of 10^5 molecules/cm^3 at the ionizer, a reduction of 6 orders of magnitude. Three stages of differential pumping are thus the maximum useful under these conditions, since the primary source of background is then molecules following a straight trajectory from the main chamber. A liquid helium cooled surface opposite the detector entrance may then be useful to minimize scattering of background molecules into the ionizer.

66.2 Experimental Configurations

66.2.1 Crossed–Beam Rotatable Detector

The configuration illustrated in Fig. 66.1 represents a standard now widely used [66.24], usually with two continuous beams fixed at 90 degrees. The molecular beam sources are differentially pumped and collimated to yield an angular divergence of about 2 degrees. The beams cross as close as possible to the nozzles, with a typical interaction volume of $3\,\text{mm}^3$. Scattered products pass through an aperture on the front of the detector, thence through several stages of differential pumping before reaching the ionizer. Ions formed

by electron impact on the neutral products are then extracted into a quadrupole mass spectrometer with associated ion counter. A chopper wheel is generally used at the entrance to the detector to provide a time origin for recording time-of-flight spectra. Pseudorandom sequence chopper disks provide optimal counting statistics while maintaining a high duty cycle (50%) [66.40]. The detector may be rotated about the interaction region, typically through a range of 120° or so, allowing one to examine products scattered at a range of laboratory angles. In addition to time-of-flight detection, one of the beams may be gated on and off for background sub-
Fig. 66.1 Experimental arrangement for $F + D_2 \rightarrow DF + F$ reactive scattering. Pressure (in torr) indicated in each region. Components are (1) effusive F atom source; (2) velocity selector; (3) cold trap; (4) D_2 beam source; (5) heater; (6) liquid nitrogen feedline; (7) skimmer; (8) tuning fork chopper; (9) synchronous motor; (10) cross-correlation chopper; (11) ultrahigh vacuum differentially pumped mass spectrometer detector

traction and the detector moved to record the integrated signal at each laboratory angle.

Two kinds of measurements are typically made in these experiments: time-of-flight spectra and angular distributions. Usually one is interested in obtaining the complete product-flux vs. velocity contour map, since this contains full details of the scattering process. This is obtained by measuring a full angular distribution as well as time-of-flight data at many laboratory angles. The results are then simulated using a forward convolution fitting procedure to obtain the underlying contour map [66.41–43]. Because scattering of isotropic reagents exhibits cylindrical symmetry about the relative velocity vector, it is sufficient to measure products scattered in any plane containing this vector to determine the product distribution. This is not true for structured particles (e.g. involving atoms in P states); however, this azimuthal anisotropy has been used to explore the impact parameter dependence of the reaction dynamics [66.44].

In a typical reactive scattering experiment, $A + BC \rightarrow AB + C$, either of the two products may be detected. Conservation of linear momentum requires that the cm frame momenta of the two products must sum

to zero. It is thus only necessary to obtain the contour map for one of the products. The choice of detected product is usually dictated by kinematic considerations, although one may choose to detect a product that is kinematically disfavored if its partner happens to have a mass with a large natural background in the detector. Kinematic considerations can be critical in assessing the suitability of a given system for study. It is very important that one of the products be scattered entirely within the viewing range of the detector in order to obtain a complete picture of the reaction dynamics.

The advantages of crossed-beams employed in conjunction with an electron impact ionizer-mass spectrometer detector derive primarily from the universality of the detector. No spectroscopic information is required and there are no invisible channels, such as may occur with spectroscopic detection methods. In addition, the resolution of these machines may be increased almost arbitrarily; indeed, even rotationally inelastic scattering has been studied [66.45]. The disadvantages are complementary to the advantages: the universal detector implies that quantum state resolution is not achieved directly, al-

though in favorable cases the product vibrational states may be resolved in the translational energy distributions [66.21, 46]. In addition, if the product of interest represents a mass that receives interference from one of the beam masses, background interference may be problematic. Kinematic considerations mentioned above may also preclude study of certain systems. However, the kinematic requirements for the Doppler and imaging approach discussed below are complementary to those of the rotatable-detector configuration.

66.2.2 Doppler Techniques

Spectroscopic detection methods in crossed-beam experiments allows the measurement of state-resolved differential cross sections, and thus the ultimate level of insight into the reaction dynamics. A method developed by *Kinsey* and others [66.47, 48] determines differential cross sections by measurement of product Doppler profiles using LIF (called ADDS for Angular Distribution by Doppler Spectroscopy). For a laser directed parallel to the relative velocity vector, a particle scattered with a cm velocity of $\boldsymbol{u}$ perceives the photon as having the Doppler shifted frequency

$$\nu' = \nu \left[1 - (\boldsymbol{u} + \boldsymbol{V}_{\mathrm{cm}}) \cdot \hat{\boldsymbol{n}}/c \right] , \qquad (66.17)$$

where ν is the laser frequency and $\boldsymbol{V}_{\mathrm{cm}}$ is the velocity of the center of mass, both in the laboratory frame of refernce, and $\hat{\boldsymbol{n}}$ is the unit vector in the probe laser direction. For the case of a single possible recoil speed, one may obtain the full differential cross section directly in the cm frame by reconstruction of a single Doppler profile [66.47]. In this case, the angular resolution is a maximum for the sideways scattered products, and a minimum at the poles. An alternative approach is to measure the Doppler profile with a laser perpendicular to the relative velocity vector. This approach (PADDS for Perpendicular ADDS) affords complementary angular resolution, but folds the forward and backward scattered products into a single symmetric component [66.48]. For the case in which the detected product does not possess a known recoil speed (for example if the thermodynamics of the process is not known, or if one probes the atomic fragment in an $A + BC \rightarrow AB + C$ reaction), a single Doppler profile is insufficient to reconstruct the double differential cross sections. Nevertheless, Kinsey's earliest experimental results were for one such example: the reaction $H + NO_2 \rightarrow OH + NO$ [66.49].

More recently *Mestdagh* et al. [66.50] have studied electronically inelastic collision processes using this approach by measuring the Doppler profiles over a range of probe laser angles, as illustrated in Fig. 66.2. A beam of barium atoms is crossed at 90 degrees by a beam of some molecular perturber. At the interaction region, the barium atoms are electronically excited using a narrow band dye laser. Scattered barium atoms that have undergone a specific electronic transition as a result of the collision are probed at the interaction region using a second dye laser, which is scanned across the Doppler profile. The product-flux vs. velocity contour map is then reconstructed by means of a forward convolution simulation procedure analogous to that described in the preceding section.

In addition to state-resolved detection, another difference between the Doppler methods and the traditional crossed-beam configuration is that the kinematic considerations favor detection of fast particles, and almost any system that is spectroscopically suitable may be considered. The primary disadvantage of Doppler methods is the limited angular and translational energy resolution possible. Often, however, modest angular resolution is sufficient to achieve a global picture of the reaction dynamics. Much current work involves the study of photoinitiated reactions in cells, relying on the short excited state lifetimes to guarantee single collision conditions, and using iterative fitting procedures to probe product velocity distributions and angular momentum polarization [66.14]. Angular momentum polarization can have a profound effect on the measured distributions and can afford a powerful additional means of exploring the collision dynamics. Examples of 3- and 4-vector correlation experiments approach a "complete description" of the scattering process (Chapt. 46) [66.50–52].

66.2.3 Product Imaging

Another spectroscopic technique is based on direct imaging of the scattered product distribution. The technique was first used to record state-resolved angular distributions of methyl radicals from the photodissociation of methyl iodide [66.53]. The method has since been widely employed to study photodissociation, and more recently to record state-resolved inelastic scattering in a crossed-beam experiment [66.54]. Recently it has been applied to a crossed-beam reactive scattering system [66.55]. The crossed-beam configuration used by Houston and coworkers is shown schematically in Fig. 66.3. The two skimmed supersonic beams cross at right angles, and scattered products are state-selectively ionized on the axis of a time-of-flight mass spectrometer using resonant photoionization. The ion cloud thus formed continues to expand with its nascent recoil vel-
Fig. 66.2 Schematic view of crossed molecular beam apparatus with LIF-Doppler detection

ocity as it drifts through the flight tube. The ions then strike a microchannel plate coupled to a phosphor screen. The latter is viewed by a video camera gated to record the signal at the mass of interest. The images are thus two-dimensional projections of the nascent three dimensional product distributions.
Fig. 66.3 Schematic view of crossed molecular beam apparatus with product imaging detection

There now exist two alternatives for regenerating the three dimensional distribution from the projection. The first, a tomographic reconstruction using an inverse Abel transform, is widely used in photodissciation studies [66.56, 57]. It is a direct inversion procedure feasible for cases in which the image is the projection of a cylindrically symmetric object, with its axis of symmetry parallel to the image plane. This analysis yields a unique product contour map directly from the image, but it is difficult to incorporate apparatus functions, and is sensitive to noise in the data. The second alternative is a forward convolution fitting method. A Monte Carlo based simulation has the advantage that one may treat the averaging over experimental parameters quite rigorously.

The advantages of the imaging method again derive from its reliance on a spectroscopic probe, so that quantum state resolution is possible and background interference may be avoided. In addition, it possesses a multiplexing advantage since the velocity distribution is recorded for all angles simultaneously. Imaging relies exclusively on photoionization, unlike the Doppler methods which may use either photoionization or LIF. This is somewhat disadvantageous since the available photoionization schemes are limited and often high laser

power is necessary to achieve adequate signal intensity. As a result, background ions can be a problem. In general, resonantly enhanced two-photon ionization, i. e. $[1 + 1]$, detection schemes are thus preferable.

66.2.4 Laboratory to Center–of–Mass Transformation

Angular and velocity distributions measured in the laboratory frame must be transformed to the cm frame for theoretical interpretation. Accounts of this transformation and details concerning the material presented below may be found in [66.58–61], among others. The Newton diagram is useful to aid in visualizing the transformation, and in understanding the kinematics of a given collision system. For the scattering of $F + D_2$ for example, shown in Fig. 66.4, a beam of fluorine atoms with a velocity v_F is crossed by a beam of D_2, velocity v_{D_2}, at 90 degrees. The relative velocity between the two reactants is $g = v_F − v_{D_2}$, and the velocity of the cm of the entire system is

$$V_{cm} = \frac{M_F v_F + M_{D_2} v_{D_2}}{M_F + M_{D_2}} .$$ (66.18)

V_{cm} divides the g into two segments corresponding to the cm velocities of the two reagents. The magnitude of these vectors, u_F and u_{D_2} are inversely proportional to the respective masses. If scattered DF products are formed with a laboratory scattering angle Θ and a laboratory velocity v_{DF} as shown in Fig. 66.4, this corresponds to DF *backscattered* with respect to the incident F atom, in the cm system. It is common to refer the scattering frame direction to the atomic reagent in an $A + BC \rightarrow AB + C$ reaction, for example, to make clear the dynamics of the process. In this case the backscattered DF arises as a result of a direct rebound collision. Some useful kinematic quantities are summarized here. For beams A and BC intersecting at 90 degrees, the an-

gle of the cm velocity vector with respect to A is given by

$$\Theta_{cm} = \arctan \frac{M_{BC} v_{BC}}{M_A v_A} .$$ (66.19)

For an arbitrary Newton diagram with angle α between the two beams the magnitude of the relative velocity is

$$g^2 = v_A^2 + v_{BC}^2 − 2 v_A v_{BC} \cos \alpha ,$$ (66.20)

the relative velocity vector is

$$g = v_A − v_{BC} ,$$ (66.21)

and the collision energy is

$$E_{coll} = \frac{1}{2} \mu_i g^2 ,$$ (66.22)

where μ_i is the reduced mass of the initial collision system. The magnitude of the cm frame velocity of particle A before collision is

$$u_A = \frac{m_{BC}}{m_A + m_{BC}} g .$$ (66.23)

The final relative velocity is

$$g' = v_{AB} − v_C ,$$ (66.24)

with magnitude

$$g' = \sqrt{2 E_{avail}/\mu_F} ,$$ (66.25)

where the available energy E_{avail} is

$$E_{avail} = E_{coll} + E_{int,reac} + E_{exo} − E_{int,prod} ,$$ (66.26)

in which $E_{int,reac}$ is the internal energy of the reactants, E_{exo} is the exoergicity of the reaction, and $E_{int,prod}$ is the internal energy of the products.

One must transform the laboratory intensity $I(\Omega) \equiv d^2\sigma/d^2\Omega$ into $I(\omega) \left(\equiv d^2\sigma/d^2\omega \right)$, the corresponding cm quantity. For the crossed-beam configuration described in Sect. 66.2.1, the laboratory distributions are distorted by a transformation Jacobian that arises because the laboratory detector views different cm frame solid angles depending on the scattering angle and recoil velocity. For the spectroscopic experiments described in Sects. 66.2.2 and 66.2.3, the Jacobian is unity (the cm velocity represents a simple frequency offset of the Doppler profiles, for example); however, the transformation of the scattering distributions from the recorded quantities (2-dimensional projections or intensity vs. wavelength) to recoil velocity distributions may be complex. Two cases must be considered for the
Fig. 66.4 Newton diagram for collision of F with H_2 with superimposed c.m. flux vs. velocity contour map

configuration discussed in Sect. 66.2.1: one in which discrete velocities result (such as elastic or state-resolved scattering experiments), and one in which continuous final velocities are measured. For the first case, the laboratory and cm differential cross sections are independent of the respective product velocities v and u and these quantities are related by

$$\frac{d^2\sigma}{d^2\Omega} = J \frac{d^2\sigma}{d^2\omega} , \tag{66.27}$$

so that the transformation Jacobian is given by

$$J = \frac{d^2\omega}{d^2\Omega} . \tag{66.28}$$

For discrete recoil velocities, the cm solid angle is

$$d^2\omega = \frac{dA}{u^2} , \tag{66.29}$$

where dA is a surface element of the product Newton sphere. The laboratory solid angle corresponding to this quantity is

$$d^2\Omega = \frac{\cos(\boldsymbol{u}, \boldsymbol{v})}{v^2} dA , \tag{66.30}$$

so that the Jacobian for the first case is given by

$$J = \frac{v^2}{u^2 \cos(\boldsymbol{u}, \boldsymbol{v})} . \tag{66.31}$$

For the case of continuous final velocities, the σ are velocity-dependent and are related by

$$\frac{d^3\sigma}{d^2\Omega \, dv} = J \frac{d^3\sigma}{d^2\omega \, du} , \tag{66.32}$$

so that here the Jacobian is given by

$$J = \frac{d^2\omega \, du}{d^2\Omega \, dv} . \tag{66.33}$$

In this case we consider a recoil volume element $d\tau$ (in velocity space), which must be the same in both coordinate frames:

$$d\tau_{cm} = u^2 \, du \, d^2\omega = d\tau_{lab} = v^2 \, dv \, d^2\Omega , \tag{66.34}$$

so that the Jacobian is

$$J = v^2/u^2 . \tag{66.35}$$

The laboratory intensity is then related to that in the cm frame by

$$I_{lab}(v, \Theta) = (v^2/u^2) \, I_{cm}(\theta, u) . \tag{66.36}$$

For a mass spectrometer detector with electron bombardment ionizer, one measures number density of particles rather than flux, so that the recorded signal is given by

$$N_{lab}(v, \Theta) = \frac{I_{lab}(v, \Theta)}{v} = \frac{v}{u^2} \, I_{cm}(u, \theta) . \tag{66.37}$$

The usual flux vs. velocity contour map is a polar plot of the quantity $I_{cm}(u, \theta)$. The product velocity distributions are then

$$I(u) = \int\int I(\theta, u) \, \sin\theta \, d\theta \, d\phi$$
$$= 2\pi \int_0^\pi I(u, \theta) \sin\theta \, d\theta , \tag{66.38}$$

and the translational energy distributions are

$$I(E_T) = I(u) \left| \frac{du}{dE_T} \right| . \tag{66.39}$$

66.3 Elastic and Inelastic Scattering

When particles collide, they may exchange energy or recouple it into different modes, they may change their direction of motion, and they may even change their identity. The study of these processes reveals a great deal of information about the forces acting between the particles and their internal structure. It is useful to begin with a summary of the dominant features of elastic and inelastic scattering.

66.3.1 The Differential Cross Section

Figure 66.5 illustrates the relation between the deflection function χ and the impact parameter b for a realistic potential containing an attractive well and a repulsive core. For large b there is no interaction, hence no deflection. At smaller values of b, the attractive part of the potential is experienced and some positive deflection results. At a smaller value of b, b_r, the influence of the attractive component of the potential reaches a maximum, giving the greatest positive deflection: this is the *rainbow angle* by analogy with the optical phenomenon. There is another value of the b for which point the attractive and repulsive parts of the potential balance, yielding no net deflection. This is the *glory* impact parameter b_g. For yet smaller values of b, the interaction is dominated by the repulsive core and rebound scattering gives a negative deflection function.

Fig. 66.5 Schematic diagram showing the relation between impact parameter b and deflection function χ

The important expressions related to the differential cross section are summarized here [66.62]. For scattering involving an isotropic potential, the deflection angle is $\Theta = |\chi|$. The differential cross section $d\sigma$ gives the rate of all collisions leading to deflection angles in the solid angle element $d\omega$:

$$\frac{dN(\theta)}{dt} \propto I(\theta) \, d\omega = I(\theta) 2\pi \sin(\theta) \, d\theta \, . \quad (66.40)$$

The incremental cross section is $d\sigma = I(\theta) \, d\omega = 2\pi b \, db$, so

$$I(\theta) = \frac{b}{\sin\theta \, (d\theta / db)} \, . \quad (66.41)$$

For classical particles, the relation between the deflection function and the potential is

$$\chi = \pi - 2b \int_{R_0}^{\infty} \frac{dR}{R^2} \left(1 - \frac{V(R)}{E_T} - \frac{b^2}{R^2} \right)^{-1/2} , \quad (66.42)$$

where $V(R)$ is the potential as a function of interparticle distance R, R_0 is the turning point of the collision, and E_T the collision energy.

In the high energy limit, for large $b \approx R_0$,

$$\chi(b, E_T) \propto V(b)/E_T \, . \quad (66.43)$$

For a long-range potential $V(R)$ proportional to R^{-s},

$$E_T^{2/s} \theta^{2(1+1/s)} I(\theta) = \text{const} \, . \quad (66.44)$$

For a potential exhibiting a minimum, the rainbow angle θ_r is proportional to the collision energy, and clearly resolved when the collision energy is 3 to 5 times the well depth. In addition, supernumery rainbows and quantum

mechanical "fast osillations" occur in the $d\sigma$, and these provide a sensitive probe of the interaction. Accurate interatomic potentials are routinely obtained from elastic scattering experiments [66.60, 63].

66.3.2 Rotationally Inelastic Scattering

Classical scattering involving an anisotropic potential results in another rainbow phenomenon, distinct from that seen in pure elastic scattering and notable in that it does not require an attractive component in the potential. These rotational rainbows are equivalently seen in a plot of integral cross section against change in rotational angular momentum Δj, or in the differential cross section for a particular value of Δj. The rotational rainbow peaks arise from the range of possible orientation angles γ in a collision involving an anisotropic potential. When there is a minimum in $d\gamma/d\theta$ for a given Δj, the differential cross section reaches a maximum [66.64]. The rotational rainbow peak occurs at the most forward classically allowed value of the scattering angle, and $d\sigma$ drops rapidly at smaller angles. The rainbow moves to more backward angles with increasing Δj because the larger j-changing collisions require greater momentum transfer, hence must arise from lower impact parameter collisions. For heteronuclear molecules, two rainbow peaks may be observed, corresponding to scattering off either side of the molecule. One can relate the location of the rainbow peak to the shape of the potential using a classical hard ellipsoid model [66.65]:

$$A - B = \frac{j}{p_0} \left[2 \sin \left(\frac{\theta_{r,cl}}{2} \right) \right]^{-1} , \quad (66.45)$$

where j is the rotational angular momentum, p_0 is the inital linear momentum, $\theta_{r,cl}$ is the classical rainbow position, and A and B are the semimajor and semiminor axes of a hard ellipse potential. The classical rainbow positions occur somewhat behind the quantum mechanical and experimental rainbow positions, so the classical rainbow may be estimated as the point at which the peak has fallen to 44% of the experimental value. Real molecular potentials may be far from ellipsoids, however, so detailed quantitative insight into the potential requires a comparison of scattering data with trajectory calculations.

66.3.3 Vibrationally Inelastic Scattering

There has been no direct observation of the differential cross section of T–V or V–T energy transfer involving neutral molecules owing to the small cross sections for

these processes. Integral cross section data are available, however. Above threshold, the latter has shown a linear dependence of σ on collision energy for $\Delta v = 1$, quadratic for $\Delta v = 2$ and cubic for $\Delta v = 3$ [66.66]. In addition, a great deal of information on vibrational relaxation processes has been obtained in cell experiments [66.67].

66.3.4 Electronically Inelastic Scattering

A wealth of information is available on electronically inelastic scattering systems, since these in general exhibit much larger cross sections than V–T processes [66.68, 69]. In addition, spectroscopic methods may be used to overcome some of the background problems that hamper the study of the latter. Often, quenching of electronically excited states involves curve crossing mechanisms, so that very effective coupling of electronic to vibrational energy may occur. Spin-orbit changing collisions of $Ba(^1P)$ with O_2 or NO, for example, occur by a near-resonant process and result in almost complete conversion of electronic energy to vibrational excitation of the product [66.70]. The analogous collisions with N_2 and H_2, however, reveal very repulsive energy release with little concomitant vibrational excitation. Both processes likely occur via curve crossings of the relevant electronic states, but the near-resonant mechanism occurs by way of an ionic intermediate.

66.4 Reactive Scattering

Reactive differential cross sections reveal several distinct aspects of the chemical encounter. The angular distributions themselves may be used to infer the lifetime of the collision intermediate: long-lived complexes exhibit forward-backward symmetry along the relative velocity vector. In this case "long-lived" means on the order of several rotational periods. The rotational period of the complex may thus be used as a clock to study the energy dependence of the intermediate's lifetime. The angular distributions further reveal the relation of initial and final orbital angular momentum. Sharply peaked angular distributions generally indicate strongly correlated initial and final orbital angular momentum vectors. Finally, the product translational energy release contains the details of the energy disposal, and reveals a wealth of information about the thermodynamics of the process, the existence of barriers, and sometimes even the geometry of the transition state. Together, the angular and tranlational energy distributions reveal many of the details of the potential energy surface.

The dynamics of reactive collisions fall broadly into three main categories characterized by distinct angular and energy distributions. The three categories are harpoon/stripping reactions, rebound reactions, and long-lived complex formation. Some reactions may exhibit more than one of these mechanisms at once, or the dynamics may change from one to another as the collision energy is varied.

66.4.1 Harpoon and Stripping Reactions

It was known in the 1930s that collisions of alkali atoms with halogen molecules exhibit very large cross sections and yield highly excited alkali halide products. These observations were accounted for by the *harpoon* mechanism proposed by M. Polanyi. Because alkali atoms have low ionization potentials and halogen molecules large electron affinities, as the alkali atom approaches the molecule, electron transfer may occur at long range. These processes are considered in detail in Chapt. 49 [66.71, 72]. The harpooning distance R_c at which this curve crossing takes place may be estimated simply as the distance at which the Coulomb attraction of the ion pair is sufficient to compensate for the endoergicity of the electron transfer:

$$R_c = e^2/(I_P - A_e) , \tag{66.46}$$

where I_P and A_e represent the ionization potential and electron affinity of the electron donor and recipient, respectively. For R in Å and E in eV, this relation is

$$R_c = 14.4/(I_P - A_e) . \tag{66.47}$$

Owing to the large Coulombic attraction between the ion pair, reaction proceeds immediately following electron transfer. The crossing distance may then be used to estimate the effective reaction cross section. The vertical A_e is not necessarily the appropriate value to use in estimating these crossing distances; stretching of the halogen bond may occur during approach, so the effective A_e is generally somewhere between the vertical and adiabatic values. Often there exists some repulsion between the atoms in the resulting halogen molecular ion, so that electron transfer is accompanied by dissociation of the molecule in the strong field of the ion

pair. The alkali ion, having sent out the electron as the "harpoon", then reels in the negative ion, leaving the neutral halogen atom nearly undisturbed as a spectator. Because these events occur at long range, there is no momentum transfer to the spectator atom, and it is a simple matter to estimate the anticipated angular and translational energy distributions in this *spectator stripping* limit. The product molecule is scattered forward (relative to the direction of the incident atom) and for the reaction $A + BC \rightarrow AB + C$, the final cm velocity for the product AB is given by

$$u'_{AB} = -M_C u_{BC}/M_{AB} ,\qquad (66.48)$$

where u_{BC} is the initial cm velocity of the BC molecule. This spectator stripping mechanism may occur in systems other than harpoon reactions, and is useful to remember as a limiting case.

The likelihood of electron transfer at these crossings may be estimated using a simple Landau–Zener model [66.72] (Chapt. 49). For relative velocity g, impact parameter b and crossing distance R_c, the probability for undergoing a transition from one adiabatic curve to another (that is, the probability for remaining on the diabatic curve) is given by

$$p = 1 - e^{-\delta} ,\qquad (66.49)$$

where

$$\delta = \frac{2\pi H_{12}^2 R_c^2}{g} \left(1 - \frac{b^2}{R_c^2} \right)^{-\frac{1}{2}} ,\qquad (66.50)$$

and H_{12} is the coupling matrix element between the two curves. H_{12} may be estimated from an empirical relation which is accurate within a factor of three over a range of 10 orders of magnitude [66.73]. In atomic units

$$H_{12} = \sqrt{I_1 I_2}\, R_c^* \, e^{-0.86 R_c^*} ,\qquad (66.51)$$

where

$$R_c^* = \left(\sqrt{I_1} + \sqrt{I_2} \right)\qquad (66.52)$$

is the reduced crossing distance, and I_1 and I_2 are the initial and final ionization potentials of the transferred electron. One finds electron transfer probabilities near unity for curve crossing distances below about 5 Å, dropping to zero for crossing at distances greater than about 8 Å. These estimates are based on electron transfer in atom–atom collisions, and it is important to remember that atom–molecule collisions occur on surfaces rather than curves, so the crossing seam may cover a broad range of internuclear distances.

66.4.2 Rebound Reactions

Another common direct reaction mechanism is the *rebound* reaction exemplified by $F + D_2 \rightarrow DF + D$ [66.21]. The cm product flux vs. velocity contour map obtained for this reaction is shown in Fig. 66.4. Owing to the favorable kinematics and energetics in this case, the FD product vibrational distribution is clearly resolved, and peaks at $v = 2$. The dominant $v = 2$ product peaks at a cm angle of 180 degrees (referred to the direction of the incident F atom). This rebound scattering is characteristic of reactions exhibiting a barrier in the entrance channel. Rebound scattering implies small b collisions, and this serves to couple the translational energy efficiently into overcoming the barrier. Small b collisions have necessarily smaller cross sections however, since cross section scales quadratically with b.

66.4.3 Long–lived Complexes

A third important reaction mechanism involves the formation of an intermediate that persists for some time before dissociating to give products. If the collision complex survives for many rotational periods $(\sim 10^{-11}\,\text{s})$, then the cm angular distribution exhibits a characteristic forward–backward symmetry, usually with peaking along the poles. The latter occurs because the initial and final orbital angular momenta tend to be parallel (and perpendicular to the initial relative velocity vector). When there exist dynamical constraints enforcing some other relation, as in the case $F + C_2H_4$, then sideways scattering may be observed, despite a lifetime of several rotational periods [66.74–76]. For some systems exhibiting this long-lived behavior, the rotational period may be used as a *molecular clock* to monitor the lifetime of the complex. By increasing the collision energy until the distribution begins to lose its forward–backward symmetry, one can investigate the internal energy of the system just when its lifetime is on the order of a rotational period.

Systems that have an inherent symmetry may exhibit this forward–backward symmetry in the scattering distributions despite lifetimes that are considerably shorter than a rotational period. This is the case for $O(^1D)$ reacting with H_2, for example [66.77]. This reaction involves insertion of the O atom into the H_2 bond resulting in an intermediate that accesses the deep H_2O well and contains considerable vibrational excitation. Trajectory calculations show that the complex dissociates after a few vibrational periods, but the distribution exhibits forward–backward symmetry because the O atom is equally likely to depart with either H atom.

66.5 Recent Developments

Astonishing progress in reactive scattering methods has continued in the past decade, and a few highlights are summarized here. These advances have taken the form of improvements in detection methods or, in some cases, entirely new experimental approaches.

One of the most important of these is the H atom Rydberg time-of-flight (HRTOF) method [66.78, 79] pioneered by the late Karl Welge and coworkers for the hydrogen exchange reaction. This approach employs a conventional scattering geometry, and is suitable only for experiments yielding product H or D atoms. Despite this narrow focus, owing to the general importance of hydrogen elimination reactions and the remarkable resolution of the technique, this has been an important development. The H or D atom products are excited to long-lived high-n Rydberg states in a $1 + 1'$ excitation scheme in the interaction region. The atoms fly through a field free region and impinge upon a rotatable field-ionization detector. The result is very high velocity resolution, largely because the spreads in the beam velocities make a negligible contribution to the product velocity spread since the H atoms are moving so fast. In addition, the dimensions of the scattering volume and ionization region may easily be made small relative to the flight length. Using this technique, Welge and coworkers achieved fully rotationally-resolved differential cross sections for the hydrogen exchange reaction.

A second, widely-used approach is a variation of the state-resolved Doppler probe in a bulb configuration. This strategy, pioneered by *Hall* at Brookhaven [66.80] and *Brouard* et al. in Oxford [66.81], has been applied most notably to study excited oxygen atom reactions. Although not a true crossed-beam approach, through appropriate exploitation of kinematic constraints, energy conservation, and careful analysis, state-resolved doubly differential cross sections may be obtained, sometimes with additional vector properties as well [66.82].

Another significant new direction in detection strategies is the use of near-threshold VUV product ionization. This is a universal approach, in that little advance spectroscopic information is required, but it is selective in that dissociative ionization is minimized and sometimes isomer-selective detection may be achieved. This approach has been used in synchrotron-based studies of Cl atom reactions [66.83], in transition metal reactions [66.84], and in product imaging studies of oxygen and chlorine atom reactions using the F_2 excimer at 157 nm [66.85]. Inspired by the threshold VUV detection methods, *Casavecchia* and coworkers have recently advanced the use of near-threshold electron impact ionization in a conventional universal crossed-beam configuration [66.86]. Their recent results show the great promise of this technique to deliver higher signal-to-noise and to minimize fragmentation processes in the detection step that may obscure the underlying dynamics.

A final note concerns advances in imaging techniques applied to reactive scattering. Mention has been made of the successful application of the VUV excimer probe for imaging radical products of reaction of Cl and $O(^3P)$ reactions with alkanes. Two significant advances in imaging strategies have made it a very powerful technique. The first of these is "velocity mapping", developed by *Eppink* and *Parker* at Nijmegen [66.87], a simple but important strategy that eliminates spatial blurring in the images. The second is "slicing", or 3-D, methods that allow the velocity-flux contour map to be recorded directly [66.88–90]. This has seen its most beautiful illustration in recent work by *Liu* and coworkers at IAMS in state-resolved detection of methyl radicals following reaction of F atoms with methane [66.91]. Their images provide quantum state correlated differential cross sections for this reaction directly, allowing comparison to theory at an unprecedented level of detail.

67. Ion–Molecule Reactions

The observation of ion–molecule reactions has a history that goes back to the beginning of the twentieth century, when J. J. Thomson discovered that operating his positive ray parabola apparatus in a hydrogen atmosphere produced signals at a mass to charge ratio of 3, which he correctly attributed to the species H_3 [67.1]. Later studies showed that this species was produced by a reaction between the primary ionization product H_2^+ and molecular hydrogen. Most ion–molecule reactions proceed without an activation barrier and their cross sections are governed by the long range attractive potential of the approaching reactants (Sect. 64.2.4). Reaction rates based on long range potential capture models [67.2] predict rates in excess of 10^{-9} cm^{3}molecule^{-1}s^{-1}, corresponding to thermal energy cross sections (Sect. 47.1.7) of $10^{-16}-10^{-15}$ cm^2. The importance of ion-molecule reactions in such widely diverse areas as planetary atmospheres, (Sect. 84.1), electrical discharges and plasmas (Sect. 87.1.4), particularly in semiconductor processing, in the formation of molecules in interstellar space (Chapt. 82), and in flames and combustion

systems (Sect. 88.1), has borne out that prediction. This chapter discusses applications of single–collision scattering methods to the study of reactive collision dynamics of ionic species with neutral partners.

A number of different physical processes can be categorized as ion-molecule reactions, with examples such as

$$A^{\pm} + BC \rightarrow A + BC^{\pm},$$ charge transfer

$$A^{\pm} + BC \rightarrow A + (B+C)^{\pm},$$ dissociative charge transfer

$$A^{\pm} + BC \rightarrow AB^{\pm} + C.$$ particle transfer
The $\pm$ superscript indicates charge appropriate to anions and cations. The parentheses indicate that the charge can reside on either the B or C fragment. Particle transfer reactions often involve the transfer of a hydrogen atom or a proton, but heavy particle <transfer processes are often important ones as well. An interesting example in which new carbon-carbon bonds are formed, termed a

condensation reaction, is the following:

$$C^+ + CH_4 \rightarrow C_2H_3^+ + H.$$
An additional process unique to anionic systems is detachment, occurring when the intermediate collision complex is internally excited above its autodetachment threshold:

$$A^- + BC \rightarrow [ABC^-]^* \rightarrow A + BC + e^-,$$
detachment

$$A^- + BC \rightarrow [ABC^-]^* \rightarrow ABC + e^-.$$
associative detachment
For exothermic reactions at low collision energies where the long range attraction dominates the interaction potential, cross sections are consistent with Langevin orbiting, generally having $E^{-1/2}$ energy dependence.

At higher energies, cross sections drop below this limit, as surface crossings and short-range repulsive features become important. Endothermic reactions exhibit cross section thresholds, as illustrated in Sect. 67.3.4 on the $N^+ + D_2$ system.

Scattering measurements probe the potential energy surface, or surfaces, governing the collision dynamics with techniques that measure the fluxes from specific reactant quantum states into product quantum states, scattering angles, and product translational energies. Scattering experiments define more precisely than in a bulb the initial and final conditions in a collision [67.3]. A scattering experiment measures a cross section (Sect. 91.1.1) rather than a rate constant. The measured cross section represents an average over initial conditions and a sum over final states inherent in the technique used.

Cross sections of various forms can be defined with respect to the rate of formation of product states under single-collision conditions. The total rate of product formation $dN_\pm/dt$ for a beam of ions with number density n_1 intersecting a gas of number density n_2 within a scattering volume ΔV, defined by the overlap of the ion beam with the target gas, is given by

$$dN_\pm/dt = \sigma v_{rel} n_1 n_2 \Delta V , \tag{67.1}$$

where σ is the total reaction cross section (Sect. 47.1.7) and v_{rel} is the relative speed of the collision partners. Using the experimental ion beam current $I_\pm$, cross section σ, neutral number density n_2, and attenuation length L, this expression converts to the particularly useful form

$$dN_\pm/dt = 6.25 \times E - 7 \sigma I_\pm n_2 L \tag{67.2}$$

for computing signal levels, where σ is expressed in Å^2, $I_\pm$ in nA, n_2 in cm^{-3}, and L in cm. An ion beam of current 1 nA, intersecting a target of length 1 cm at a pressure of 10^{-3} Torr, corresponding to a number density of 3.5×10^{13} cm^{-3} at STP, and reacting with a cross section of 1 Å^2 yields a total rate of product formation of 2×10^7 s^{-1}.

The detector observes only a fraction of this total rate. If reaction products are scattered isotropically over 4π steradians in the laboratory, and the detector entrance slit of area dS is located a distance r from the collision center, subtending a solid angle dS/r^2, the fraction of the total signal scattered into the slit is $dS/(4\pi r^2)$ [67.4]. The fraction of the collision volume, or of the product state distribution accessible to a particular experimental method, determines the tradeoffs between resolution and signal level, and therefore the feasibility of a given experiment.

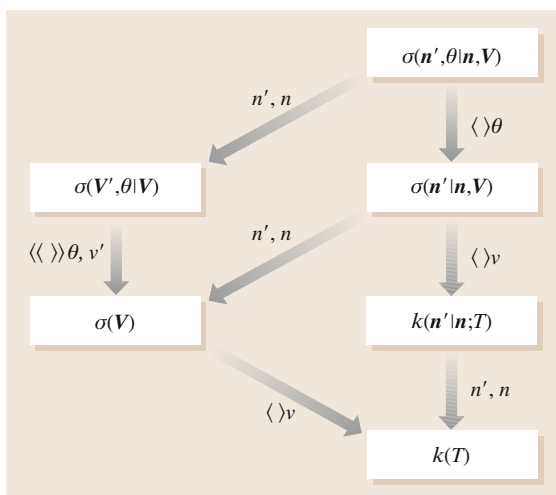
In an "ideal" experiment, one collides reactants, with well specified quantum numbers collectively denoted n, at a precisely defined relative velocity v_{rel}, resolving products in quantum states n' scattered through center-of-mass scattering angle θ. The resulting detailed differential cross section (DCS) (Sect. 47.1.1) is denoted by $\sigma(n', \theta | n, v_{rel})$. However, most experiments involve at least partial averages over initial states and/or summations over final states. Figure 67.1 shows the result of averaging $\sigma(n', \theta | n, v_{rel})$ over θ to yield the state-to-state cross section at fixed v_{rel}, denoted by $\sigma(n'|n, v_{rel})$. Averaging this cross section over a Maxwell–Boltzmann distribution of molecular speeds at a specified temperature T yields the detailed state-to-state rate constant $k(n'|n, T)$, while summation over the final states n' and averaging over the initial states n yields the thermal rate constant $k(T)$. These latter two quantities are thermally averaged, multiple collision properties and not the subject of this chapter, although they play an important role in practical applications. Another pathway for averaging the detailed DCS $\sigma(n', \theta | n, v_{rel})$ arises from averaging over n and summing over n' to yield cross sections differential in product velocity v'_{rel} and θ at fixed v_{rel}, denoted by $\sigma(v'_{rel}, \theta | v_{rel})$. An average over θ and v'_{rel} yields the velocity dependent total cross section $\sigma(v_{rel})$, and its Maxwell-Boltzmann average produces the thermal rate constant $k(T)$ once again. The subject of this chapter is a discussion of the various cross sections σ shown in Fig. 67.1. As one moves from


Fig. 67.1 Relationships among differential and total cross sections, and rate constants. *Brackets* denote averages over indicated variables, or averages over initial states and summations over final states

more highly averaged quantities to the detailed cross sections, more sophisticated reactant preparation and product detection schemes are required to extract the desired information, at the expense of decreased signal levels. Technological advances, particularly in laser preparation of quantum state-selected reactants and in state-specific product detection, have made the "ideal"

experiment a near reality in favorable circumstances, particularly in neutral-neutral interactions, e.g., in experiments on $H + H_2$ and its isotopic variants. This chapter discusses the cross sections $\sigma(\mathbf{n}', \theta | n, \mathbf{v}_{rel})$, $\sigma(\mathbf{v}'_{rel}, \theta | \mathbf{v}_{rel})$, $\sigma(\mathbf{n}' | n, \mathbf{v}_{rel})$, and $\sigma(\mathbf{v}_{rel})$, emphasizing the dynamical information that can be extracted from each kind of measurement.

67.1 Instrumentation

Instrumentation for studying ion-molecule reactions is quite diverse, and numerous literature sources are available for further discussion [67.5]. A typical instrument has an ionization source, a primary

mass selector, a collision region, and detector, consisting of a mass spectrometer or employing a spectroscopic technique allowing molecular identification.

67.2 Kinematic Analysis

The transformation of laboratory measured speeds, angles and intensities to their center of mass (cm) counterparts can be accomplished with appropriate geometric constructions [67.6, 7]. The geometric relationships can be understood by considering a kinematic Newton diagram for the collision process $A + BC$, as shown in Fig. 67.2. The diagram is constructed for the special case in which the reactant beams intersect at 90°. The laboratory scattering angle and velocity are Θ and v respectively, while the corresponding center of mass quantities are θ and u. The beam velocity vectors $\mathbf{v}_A$ and $\mathbf{v}_{BC}$ define the initial conditions, and the relative *velocity vector* $\mathbf{v}_{rel}$ is defined by their vector difference. The velocity $\mathbf{c}$ of the center of mass, or centroid, of the collision system is determined by conservation of linear momentum; the vector $\mathbf{c}$ divides the $\mathbf{v}_{rel}$ in inverse proportion to the masses of A and BC:

$$\mathbf{c} = \frac{m_A \mathbf{v}_A + m_{BC} \mathbf{v}_{BC}}{M}, \quad (67.3)$$

$$\mathbf{u}_A = -\frac{m_{BC}}{M} \mathbf{v}_{rel}, \quad (67.4)$$

$$\mathbf{u}_{BC} = \frac{m_A}{M} \mathbf{v}_{rel}, \quad (67.5)$$

where M is the total mass of the reactants with masses m_A and m_{BC}. An observer moving away from the laboratory origin in the direction of the center of mass vector $\mathbf{c}$ would see the reactants A and BC approach along the direction of $\mathbf{v}_{rel}$, with the products retreating along the direction of $\mathbf{v}'_{rel}$. The angle θ between these vectors defines the center of mass scattering angle. For a single Newton diagram, detection of products

at recoil speed u and scattering angle θ requires that measurements be made at laboratory coordinates (v, Θ). For monoenergetic incident beams, the measurement of both laboratory scattering angle and speed results in a unique lab to cm coordinate transformation. Linear momentum conservation also relates the center of mass speeds of products AB and C to the relative velocity of the separating products according
Fig. 67.2 Kinematic Newton diagram showing laboratory and center of mass velocities and scattering angles

to

$$\boldsymbol{u}'_{AB} = \frac{m_C}{M} \boldsymbol{v}'_{rel} , \qquad (67.6)$$

$$\boldsymbol{u}'_C = -\frac{m_{AB}}{M} \boldsymbol{v}'_{rel} . \qquad (67.7)$$

The final relative kinetic energy of the separating products is

$$\mathcal{T}'_{rel} = \frac{1}{2} \mu' \boldsymbol{v}'_{rel} \cdot \boldsymbol{v}'_{rel} , \qquad (67.8)$$

where μ' is the reduced mass of the products.

The total energy of a collision system is computed from the energies of the incident reactants and the energy accessible to the products:

$$E_{tot} = \mathcal{T}_{rel} + E_{int} - \Delta D_0^o = \mathcal{T}'_{rel} + E'_{int} ; \qquad (67.9)$$

$\mathcal{T}_{rel}$ and E_{int} refer to the incident kinetic and internal excitation energies of the reactants and the primed quantities correspond to the products. ΔD_0^o is the zero point energy difference of reactants and products. Specification of the vibrational and rotational energy of a product determines the relative velocity $\boldsymbol{v}'_{rel}$ with which the products separate, according to

$$\boldsymbol{v}'_{rel} = \left[\left(\frac{2}{\mu'} \right) (\mathcal{T}_{rel} + E_{int} - \Delta D_0^o - E'_{int}) \right]^{1/2} . \qquad (67.10)$$

The quantization of internal energy of the product AB leads to a series of concentric circles about the centroid that describe the loci of final translational speeds for AB produced in specific internal states. An example of the kinematic resolution of product vibrational states in the reaction $O^- + HF \rightarrow F^- + OH$ is shown in Fig. 67.3 [67.8, 9].

At a collision energy of 0.47 eV (45.0 kJ/mol), the laboratory flux distribution shows structure that is attributable to the formation of OH in $v' = 0$, 1, and 2 states. The kinematic Newton diagram at the bottom of the figure shows the concentric circles corresponding to the formation of F^- in concert with OH in specific vibrational states having quantum numbers $v' = 0$, 1, and 2. For laboratory scattering angles in the range $0° \le \Theta \le 11°$ and $80° \le \Theta \le 90°$ energy scans only intersect the kinematic circles corresponding to OH in $v' = 0$ and 1 states, while data in the intermediate range of angles $18° \le \Theta \le 70°$ show contributions from all three states. The laboratory speeds at which these vibrational states appear, for a given Θ, are marked in the figure, showing clear correspondence with the structure in the experimental data. Rotational excitation in the products will broaden the contributions from individual vibrational states in experiments lacking rotational resolution. The best resolution achieved in electrostatic energy analyzers is approximately 5 meV (40 cm^{-1}); and consequently, scattering measurements of product fluxes based on kinetic energy analysis generally do not have rotational state resolution. However, photoelectron spectroscopy measurements on H_2 [67.10] have yielded spectra of H_2^+ energy levels with rotational resolution.

The transformation of intensities and cross sections between laboratory and cm coordinate systems relies on conservation of flux in a transformation between two coordinate systems moving with respect to one another. Figure 67.2 shows the nature of this conservation: in laboratory coordinates, the flux into solid angle $d\Omega$ is given by $I_{lab}(\Omega) d\Omega$, where the laboratory intensity I_{lab} is the flux per unit solid angle, while the corresponding flux in the cm frame is $I_{cm}(\omega) d\omega$, where I_{cm} is the cm flux per unit solid angle. The solid angles subtended by the detector in the laboratory and cm frames expressed in velocity space may be computed from the surface element dS subtended by the detector:

$$d\omega = \frac{dS}{u^2} , \qquad d\Omega = \frac{dS}{v^2} . \qquad (67.11)$$

The flux equality $I_{lab}(\Omega) d\Omega = I_{cm}(\omega) d\omega$ leads to the intensity transformation

$$I_{lab}(v, \Theta) = \frac{v^2}{u^2} I_{cm}(u, \theta) . \qquad (67.12)$$

The widths of the beam velocity distributions must be accounted for in extracting accurate cm cross sections from laboratory data. In the case where the laboratory flux at a given Θ is comprised of contributions from individual quantum states of the products, the laboratory flux is recovered from the relation

$$\begin{aligned} I_{lab}(v, \Theta) = v^2 \int_0^\infty dv_2 f_2(v_2) \int_0^\infty dv_1 f_1(v_1) \frac{\boldsymbol{v}_{rel}}{u^2} \\ \times \left[\sum_{n'} \sigma(\boldsymbol{n}', \theta | \boldsymbol{n}, \boldsymbol{v}_{rel}) \delta(u - u_{\boldsymbol{n}'}) \right] . \end{aligned} \qquad (67.13)$$

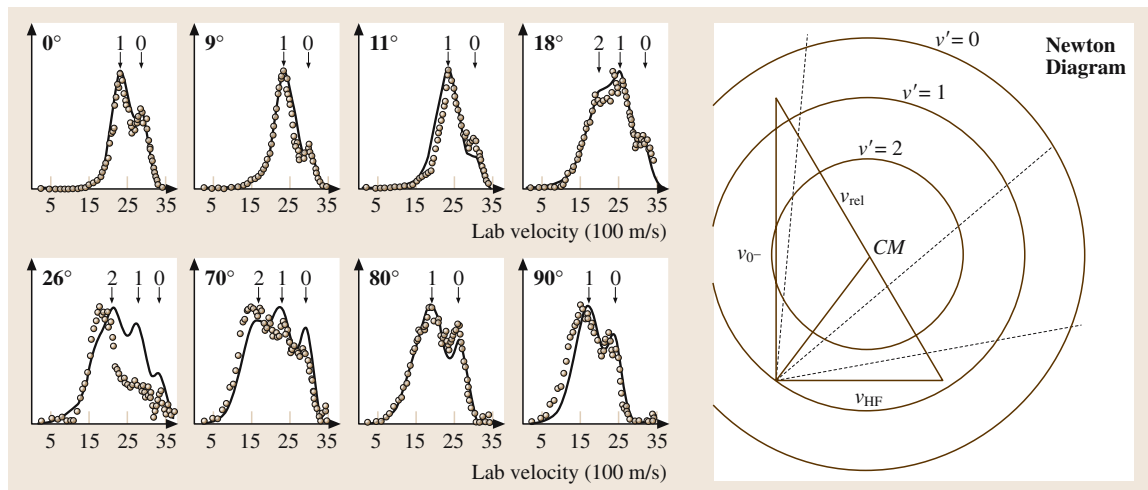
In this expression, the velocity distributions for the primary ion beam and the secondary neutral beam are given by $f_1(v_1)$ and $f_2(v_2)$ respectively. The final product internal states are labeled by the index $\boldsymbol{n}'$; the cm cross section for producing collective quantum state $\boldsymbol{n}'$ is given by $\sigma(\boldsymbol{n}', \theta | \boldsymbol{n}, \boldsymbol{v}_{rel})$ and the cm speed corresponding to the formation of this state is given by


Fig. 67.3 F^- reactive fluxes in the $O^- + HF$ system at a collision energy of 45 kJ/mol. After [67.8, 9] by permission

$u_{n'}$. The solution of this equation for $\sigma(n', \theta|n, v_{rel})$ can be accomplished both by forward convolution integration fitting procedures [67.11] and by iterative unfolding [67.12]. Forward convolution methods assume parametric forms for $\sigma(n', \theta|n, v_{rel})$ that are substituted into (67.13). The parameters are then varied until the calculated fluxes agree with the data within experimental error. Iterative deconvolution methods generally extract

the cm cross section summed over final states,

$$\sum_{n'} \sigma(n', \theta|n, v_{rel}), \qquad (67.14)$$

but the finite energy of the detection scheme also determines whether quantum states are completely resolved or if the data represent a summation over product energy levels.

67.3 Scattering Cross Sections

Measurements of the single-collision cross sections shown schematically in Fig. 67.1 require a variety of sophisticated techniques. Each of these are discussed in the context of measurement techniques and information content, with illustrative examples.

67.3.1 State-to-State Differential Cross Sections

Information most diagnostic of the potential energy surface for chemical reaction comes from $\sigma(n', \theta|n, v_{rel})$. The experimental data of Fig. 67.3 on the $O^- + HF$ system provide an example of a case in which n' refers to product OH vibrations in the ground electronic state, but without resolution of product rotations. Iterative deconvolution of the laboratory fluxes results in a flux distribution that is a sum of cross sections, as described in (67.14). Figure 67.4 shows this distribution in cm velocity space as a function of u and θ. In this representation,

the relative velocity vector lies along the 0° - 180° line, and the symmetric peaks of the data near 0° (forward scattering) and 180° (backward scattering) indicate that the reaction proceeds through a transient collision complex living for at least several rotational periods. The symmetry of the flux distribution with respect to 90° is the most important diagnostic for the participation of a long-lived transient complex. Whether the distribution is forward-backward peaked, as in the present example, or more isotropic reflects the geometry of the complex (i. e., oblate or prolate symmetric top) and the manner in which angular momentum is partitioned in the products [67.13]. In Fig. 67.4, the forward-backward scattering is indicative of the fact that the orbital angular momentum L of the approaching reactants is partitioned preferentially into orbital angular momentum of the products, L', through a near-linear $[O \cdots H \cdots F]^-$ intermediate. The various peaks in the flux distribution of Fig. 67.4 can

be assigned to OH vibrations $v' = 0$, 1, and 2. Integration of the cross sections over the appropriate angular and velocity ranges yields the result $P(v' = 0) : P(v' = 1) : P(v' = 2) = 0.38 : 0.43 : 0.18$.

Crossed–beam experiments (Sect. 60.2.2) with sufficient angular and kinetic energy resolution yield angular distributions for individual vibrational states. Similarly, laser-induced fluorescence experiments [67.15] yield rotational distributions. Recent work on the $Ar^+ + N_2 \rightarrow Ar + N_2^+(v' = 0, J')$ system illustrates this capability [67.16] (Sects. 64.2.1 and 38.4.1). However, these experiments probe N_2^+ in the collision volume, thereby averaging over all possible scattering angles, and are more properly examples of product-state resolved cross sections, discussed in Sect. 67.3.4. Experiments that provide complete product vibrational-rotational state specification and product scattering angles have yet to be carried out.

In the above examples the neutral beam is produced by supersonic expansion, producing reactants in their ground vibrational states, with rotational temperatures of only a few kelvins. Experiments with reactants prepared in excited states, either by laser absorption [67.17] or photoionization, and with full final state selection and angular resolution, remain a major goal of ion-molecule chemistry.

The production of reagent ions in selected vibrational and vibrational-rotational states by resonance enhanced multiphoton ionization (REMPI) (Sect. 74.1.2) has been accomplished in a number of systems [67.17, 18]. The use of photoelectron spectroscopy to assess the purity of the state-selection process is essential [67.19].

67.3.2 Velocity–Angle Differential Cross Sections

The velocity-angle DCS $\sigma(v'_{rel}, \theta | v_{rel})$ obtained by measuring kinetic energy distributions as a function of Θ can be plotted as a distribution in u and θ. Figure 67.5 shows $\sigma(v'_{rel}, \theta | v_{rel})$ for the reaction $C^+ + H_2O \rightarrow [COH]^+ + H$ at a collision energy of 2.14 eV (206.5 kJ/mol) [67.14]. The scattering is predominately backward, and the data indicate a reaction taking place in part through a transient complex, but principally through low impact parameter direct collisions leading to backward scattered products. Collisions leading to such backward scattered products are called rebound collisions and are dominated by the repulsive part of the potential surface. Although the reaction of C^+ with H_2O is exothermic, high kinetic energy release in the rebound component suggests that a potential energy barrier is in the exit channel, i. e., it acts as the products separate.

At lower collision energies, the forward peak in the flux distribution becomes more pronounced for the $C^+ + H_2O$ reaction, suggesting that the reaction is mediated by a collision complex living for a fraction of a rotational period. Under these conditions, it is possible

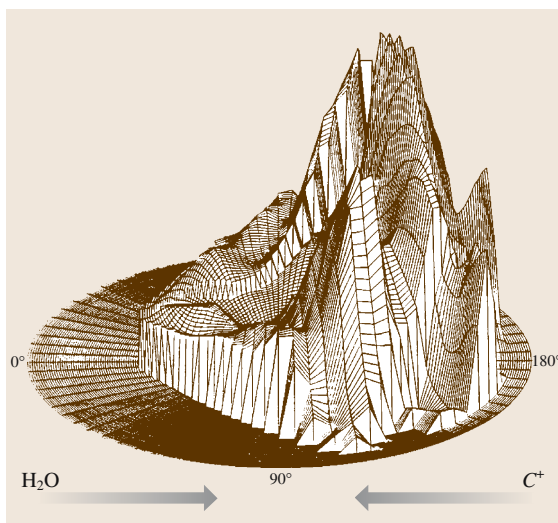
Fig. 67.4 Axonometric plot of F^- fluxes in velocity space in the reaction $O^- + HF \rightarrow OH + F^-$ at 45 kJ/mol. Data from [67.8, 9]


Fig. 67.5 Axonometric plot of $[COH]^+$ fluxes in velocity space in the reaction $C^+ + H_2O \rightarrow [COH]^+ + H$ at 2.14 eV (206.5 kJ/mol). Data from [67.14]

to extract collision complex lifetimes from the angular distribution asymmetry through the osculating model for chemical reactions [67.20]. In this model, the lifetime is a parametric function of the complex's rotational period, evidenced by the forward-backward asymmetry

$$I(180°)/I(0°) = 1/\cosh(\tau_R/2\tau) .\qquad(67.15)$$

In this expression, τ is the lifetime of the complex and τ_R is the rotational period, estimated from the moment of inertia I and the maximum orbital angular momentum L_{max} of the complex. The total reaction cross section σ can be used to estimate this latter quantity from

$$\sigma = \left(\frac{\pi\hbar^2}{2\mu\mathcal{T}_{rel}}\right)(L_{max}+1)^2 .\qquad(67.16)$$

In the present case, the lifetime estimate for the $[CHOH]^+$ complex is less than 1×10^{-13} s (Chapt. 35).

At high energies, rebound collisions dominate the dynamics of the $C^+ + H_2O$ reaction. Another limit often encountered in high energy ion-molecule reactions is the stripping process in which the incoming ionic projectile removes a particle from its molecular collision partner, and the new ionic product travels in the same direction as the incident ionic reactant. The spectator stripping limit [67.22] for a reaction of the type $A + BC \rightarrow AB + C$ corresponds to the case in which the cm speed of product C is unchanged from the cm speed of reactant BC, i.e., C "spectates" as the reaction occurs.

67.3.3 Total Cross Sections with State-Selected Reactants

State-selected cross sections $\sigma(\boldsymbol{n}'|\boldsymbol{n}, \boldsymbol{v}_{rel})$ were first measured by *Chupka* and collaborators [67.23, 24] in the endothermic reaction of $H_2^+ + He \rightarrow HeH^+ + H$, with H_2^+ prepared in states $\upsilon \geq 2$ by photoionization, and HeH^+ detected without product state analysis. Thus, $\boldsymbol{n}'$ represents a summation over all accessible product states in state-selected reactant experiments. At a given vuv ionization wavelength, H_2^+ is prepared, subject to Franck-Condon factor limitations (Sect. 33.6.1), in all possible vibrational states up to the maximum allowed by the photon energy. Therefore, extraction of cross sections for individual vibrational states requires VUV wavelength dependent studies in which the number of reactant vibrational states is increased smoothly from the ground state up to the limit allowed by instrumental resolution or photon sources. A number of reactive and charge transfer systems have been studied

with photoionization techniques at the reactant state-selected level with unresolved product states. Data are typically in the form of $P(\upsilon')$ vs. υ', as a function of collision energy. A comprehensive review by *Ng* is available [67.25].

67.3.4 Product–State Resolved Total Cross Sections

The resolution of product states in cross section measurements can be accomplished in a variety of ways. We will first discuss the case in which the reactants have not been state-selected. In principle, spectroscopic methods such as laser-induced fluorescence can be used for complete product quantum state specification. Earlier reference to N_2^+ vibration-rotation state-resolved charge transfer experiments [67.16] provides an excellent example of the state of the art of such methods, and their extension to chemical reactions represents an important future development. A beautiful example is mass spectrometric detection of N_2^+ in the $Ar^+ + N_2$ charge transfer system [67.21]. Guided ion-beam production and detection methods [67.26] in conjunction with a supersonic beam of N_2 allow 4π detection of the charge transfer products as a function of collision energy, yielding accurate total cross sections. The results, plotted in Fig. 67.6, show thresholds for the production of excited vibrational states of $N_2^+ X^2\Sigma_g$, $\upsilon' = 1, 2$, and 4) as well as the formation of the excited $B^2\Sigma_g$ state. The detection of chemiluminescence from electronically ex-
Fig. 67.6 Energy dependent cross section for production of N_2^+ in states as indicated in the $Ar^+ + N_2$ charge transfer system. After [67.21] by permission

cited states of ion-molecule reactions is also a powerful method for determining such cross sections; methods and results are reviewed in [67.27].

67.3.5 State-to-State Total Cross Sections

The most detailed probe of an ion-molecule reaction is the state-to-state cross section. The measurement of angularly-resolved state-to-state cross sections has only been achieved for reactants in their ground states, but true state-to-state total cross sections have now been measured in a few favorable cases. A particularly novel method for product-state determination with reactant-state selection has been developed [67.25]. In the differential reactivity method, product vibrational states are distinguished by their differing cross sections for charge transfer with selected molecules. Although the method is limited at present because state-selected charge transfer cross sections have been measured in only a few systems, the technique has great potential. The charge transfer reaction $H_2^+ (v) + H_2 \rightarrow H_2 + H_2^+ (v')$, in which H_2^+ is prepared in $v = 0$ and 1 by VUV photoionization, provides a particularly good example of its power. The H_2^+ charge transfer products, formed in states $v' = 0 - 3$, are first mass-analyzed, accelerated to 10 eV, and then passed through a collision cell containing N_2, Ar, or CO, where charge transfer occurs once again. The N_2^+, Ar^+, or CO^+ products are mass analyzed and the cross sections σ_m for forming these ions by charge transfer from the H_2^+ reaction products are measured. The charge transfer cross sections for H_2^+ with these gases have different dependences on v', as shown in Fig. 67.7, and therefore, the gases can be used to probe the product states of H_2^+ formed in the symmetric charge exchange reaction. Letting $X_{v'}$ denote the fraction of H_2^+ formed in the vibrational state v', n denote the number density of the neutral collision gas, and l denote the attenuation length, the following set of simultaneous equations can be solved for $X_{v'}$, since the cross sections $\sigma_{v'}$ are known and the σ_m are measured:

$$X_0 + X_1 + X_2 + X_3 = 1 \qquad (67.17)$$

and, for a particular ion (e.g., N_2^+, Ar^+, CO^+),

$$X_0 nl\sigma_0 + X_1 nl\sigma_1 + X_2 nl\sigma_2 + X_3 nl\sigma_3 = nl\sigma_m . \qquad (67.18)$$

[An equation like (67.18) will exist for each collision gas.] An extensive set of data at collision energies from 2 eV up to 16 eV has been obtained [67.29]. When the reactant ions are in the vibrational ground state, at low kinetic energies the charge transfer product is also in the ground state, indicating that resonant charge transfer is the dominant process. At increasing collision energies, X_1 increases from 0.0 to 0.17. For vibrationally excited H_2^+ reactants, inelastic relaxation to form H_2^+ in $v' = 0$ is important at all collision energies, increasing in magnitude with increasing collision energy. Of particular interest is the fact that inelastic relaxation forming $v' = 0$ is substantially more important than inelastic excitation producing $v' = 1$ or 2. This trend is predicted by theory, but underestimated at lower collision energies.

67.3.6 Energy Dependent Total Cross Sections

Although non-state-selected cross sections, denoted $\sigma(v)$, lack information about product energy disposal, important features of the potential energy surface can be obtained from their measurement. Guided ion beam methods have been especially important in the determination of accurate cross sections, particularly those that employ a supersonic beam rather than a gas as a neutral target. Energy-dependent cross sections provide crucial information on ion and neutral thermochemistry through accurate measurements of reaction thresholds, and help to elucidate important potential surface features such as thresholds, barriers, and crossings [67.30]. A particularly illustrative example of threshold formation concerns the reaction $N^+(^3P) + H_2 \rightarrow NH^+ + H$ and its isotopic variants. This reaction is important at low ($< 0.1\,eV$) collision energies as the first step in the chain reaction that leads to formation of ammonia in dense interstellar clouds, but the bond energy of NH^+ is uncertain enough to prevent knowing whether the above reaction is endothermic or exothermic. Recent total cross section measurements on the isotopic variant $N^+(^3P) + D_2 \rightarrow ND^+ + D$ at very low collision energies now appear to answer this question [67.28]. Figure 67.8 shows experimental results performed on two different instruments, one a guided ion beam-crossed neutral beam machine and the other a guided merged-beam apparatus. The data show a very clear threshold at 15 meV, demonstrating that the reaction is endothermic and allowing for a more accurate estimate of the ND^+ bond energy. This experiment shows that the high energy resolution afforded in total cross section measurements employing crossed and merged beams, rather than thermal collision cells, can answer thermochemical questions of importance in a wide variety of applications, including astrophysics, combustion, electrical discharges, and atmospheric processes.

67.4 New Directions: Complexity and Imaging

The crossed beam technique provides the precise kinematic definition required to extract the most intimate details of reactive collisions. Although the highest resolution examples of the technique involve systems with three or four atoms, several recent examples of systems of greater complexity have appeared in the literature. The multiply-charged $CF_2^{2+} + D_2$ system [67.31] is appreciably more complex experimentally than its singly-charged analog, owing to the possibility of forming two charged fragments with correlated product distributions. The nine-atom $C_2H_2^+ + CH_4$ system has been studied previously with guided ion beam-gas cell methods under conditions where the reactant ions are produced by multiphoton ionization [67.32]. Those early experiments, which yielded total reaction cross sections for vibrational state-selected ions, gave significant indications of mode-selectivity in complex reactions. A more recent study [67.33], conducted without reactant state-selection or product state analysis, maps out product angular distributions and disposal of energy in relative translation with ion trapping techniques that measure longitudinal velocity components directly and provide upper bounds on the transverse velocity components.

The majority of extant crossed beam experimental studies construct three-dimensional velocity space distributions with a series of one-dimensional sections through the full distribution such that, in any interval of time, only a single detection element in velocity space can be measured. Recent advances in imaging methods [67.34–36], in which many velocity space elements can be observed in a single time interval, promise to increase the sensitivity of the crossed beams method by orders of magnitude. The signal gains that can be achieved with the implementation of such multiplex advantage methods will allow the lower reactant and product signal levels associated with increasing state-specification and/or system complexity to be tolerated without undue increases in data acquisition times.

Figure 67.9 shows a schematic of an instrument that illustrates the imaging principle.

As indicated in the diagram, the locus of points of reaction products with a constant center of mass speed is a sphere whose radius increases with time. Individual quantum states of a given reaction product form a set of nested spheres in velocity space. Projecting this set of product spheres onto a detection plane allows all product velocity elements to be observed in a single time window. Application of the inverse Abel transform [67.37] allows the full three-dimensional velocity distribution to be extracted from the two-dimensional projection on the detection plane. Velocity focusing methods [67.38] allow reaction products originating from spatially distinct regions of the collision volume
Fig. 67.9 Schematic of crossed beam imaging instrument. Product flux extracted from the collision volume with a single center of mass speed describes a sphere in velocity space. This flux is projected onto a multichannel plate/phosphor screen detector and recorded with a CCD camera

Fig. 67.10a,b *Panel* (**a**): image of ionic products formed by H_2 ejection from Co^+ C_4H_10 collision complex. *Panel* (**b**): image of ionic products formed by CH_4 ejection from Co^+ C_4H_10 collision complex

that have the same lab velocity components in the plane of the beams to be focused to a single point. Figure 67.10 shows velocity space images of the H_2 and CH_4 elimination products arising from decay of the transient collision complex formed in collisions of Co^+ with iso-butane C_4H_{10} [67.39].

This velocity space image is equivalent to the c.m. cross section expressed in equation (67.14), and can be appropriately averaged over initial states or summed over final states to yield product angular or energy distributions, total cross sections, or rate constants according to the hierarchy of Fig. 67.1. The time window that imaging requires is ideally mated with pulsed molecular beam sources, and thus with pulsed lasers. This last connection opens up a number of possibilities for reactant preparation, including electron impact ionization via pulsed electron beams formed by laser-induced photoemission from metals, pulsed IR laser excitation of ro-vibrationally state-selected molecules, formation of free radicals by UV laser photolysis, and multiphoton ionization preparation of state-selected ions.

As laser-based photolysis, state-selection, and ionization methods continue to advance, additional routes for preparing atomic and molecular ions, free radicals, and clusters with quantum state-specificity will appear. These schemes will enhance all crossed beam methodologies, but will have an especially important impact on methods that exploit time-based snapshots of the velocity space product distribution in coordinate space. Point-by-point methods for reconstruction of the three-dimensional flux distribution in velocity space will continue to play a role in the development of the crossed beam technique, but technological advances in lasers and in imaging systems virtually assure that the most impressive gains in crossed beam technology in the next several years will come from multichannel product detection.

Part F
Quantum Optics

Part F Quantum Optics

68. Light−Matter Interaction

Optical physics is concerned with the dynamical interactions of atoms and molecules with electromagnetic to fields. Semiclassical theories, which study the interaction of atoms with classical fields, are often said to comprise optical physics, while quantum optics treats the interaction of atoms or molecules with quantized electromagnetic fields. A significant part of optical physics and quantum optics is the study of near-resonant atom−field interactions, and concentrates on nonperturbative dynamics, where the effects of the optical fields have to be kept to all orders. The atomic properties themselves are assumed to be known.

The vast majority of problems in light−matter interactions can be treated quite accurately within semiclassical theories. However, an important class of problems where this is not the case are presented in Chapt. 78. While much of optical physics and quantum optics ignores the effects of the electromagnetic fields on the center-of-mass motion of the atoms, important topics such as atomic trapping and cooling (Chapt. 75) and de Broglie optics (Chapt. 77) rely in an essential way on such mechanical effects of light. The present chapter deals with more "traditional" aspects of optical physics, where these effects are ignored.

68.1 Multipole Expansion

Consider a test charge q of mass m localized within an atom and acted upon by an external electromagnetic field with electric field $\boldsymbol{E}(\boldsymbol{r}, t)$ and magnetic field $\boldsymbol{B}(\boldsymbol{r}, t)$. In the multipole expansion formalism [68.1, 2], the electric and magnetic interaction energies between the charge and the electromagnetic field are

$$V_{\mathrm{e}} = V_{\mathrm{E0}}(t) - q \int_0^{\boldsymbol{r}} \mathrm{d}\boldsymbol{s} \cdot \boldsymbol{E}(\boldsymbol{R} + \boldsymbol{s}, t) \,, \tag{68.1}$$

$$V_{\mathrm{m}} = -q \int_0^{\boldsymbol{r}} \mathrm{d}\boldsymbol{s} \cdot \boldsymbol{v} \times \boldsymbol{B}(\boldsymbol{R} + \boldsymbol{s}, t) \,, \tag{68.2}$$

respectively. The material of this chapter is discussed in detail in a number of texts and review articles. We cite such references rather than the original sources whenever possible. These energies correspond to the work done by the electric and magnetic components of the Lorentz force in first moving the charge to a stationary

origin of coordinates at a point $\boldsymbol{R}$ and then to a location $\boldsymbol{r}$ relative to $\boldsymbol{R}$. Here, $V_{E0}(t)$ represents the energy of the charge when located at the reference point $\boldsymbol{R}$. It may be expressed in terms of the electrostatic potential $\phi(\boldsymbol{R}, t)$ as $V_{E0}(t) = +q\phi(\boldsymbol{R}, t)$.

A Taylor series expansion of $V_e(t)$ and $V_m(t)$ about $\boldsymbol{r} = 0$ yields

$$V_e(t) = V_{E0}(t) - q \sum_{n=1}^{\infty} \frac{1}{n!} \left(\boldsymbol{r} \cdot \frac{\partial}{\partial \boldsymbol{R}} \right)^{n-1} \boldsymbol{r} \cdot \boldsymbol{E}(\boldsymbol{R}, t) , \tag{68.3}$$

$$V_m(t) = -\frac{q\hbar}{m} \sum_{n=1}^{\infty} \frac{n}{(n+1)!} \left(\boldsymbol{r} \cdot \frac{\partial}{\partial \boldsymbol{R}} \right)^{n-1} \boldsymbol{\ell} \cdot \boldsymbol{B}(\boldsymbol{R}, t) , \tag{68.4}$$

where $\hbar \boldsymbol{\ell} = \boldsymbol{r} \times \boldsymbol{p}$ is the angular momentum of the test charge relative to the coordinate origin $\boldsymbol{R}$. Here, use of the mechanical momentum $\boldsymbol{p} = m\dot{\boldsymbol{r}}$, instead of the canonical momentum, neglects the electromagnetic component of the momentum responsible for diamagnetic effects.

In addition to the electromagnetic interaction, electrons and nuclei are characterized by a spin magnetic moment $\boldsymbol{m}_s = (q\hbar/2m)g_s \boldsymbol{s}$, where $\boldsymbol{s}$ is the spin of the test charge and g_s its gyromagnetic factor, equal to $2.002\ldots$ for electrons. The factor $q\hbar/2m$ is the particle's magneton. The spin magnetic moment yields an additional term to the magnetic energy V_m, which becomes

$$V_m(t) = -\frac{e\hbar}{2m} \sum_{n=1}^{\infty} \frac{1}{n!} \left(\boldsymbol{r} \cdot \frac{\partial}{\partial \boldsymbol{R}} \right)^{n-1}$$
$$\times \left(\frac{2}{n+1} g_\ell \boldsymbol{\ell} + g_s \boldsymbol{s} \right) \cdot \boldsymbol{B}(\boldsymbol{R}, t) , \tag{68.5}$$

where the orbital g-factor is $g_\ell = q/e$ ($g_\ell = -1$ for an electron). For an ensemble $\{\alpha\}$ of charged particles q_α in an atom, these expressions are to be summed over all particles. Thus, the electric energy becomes

$$V_e(t) = \sum_{\alpha} q_\alpha \phi(\boldsymbol{R}, t) - \sum_{i=1}^{3} \sum_{\alpha} q_\alpha r_i(\alpha) E_i(\boldsymbol{R}, t)$$
$$- \frac{1}{2} \sum_{i,j=1}^{3} \left[\sum_{\alpha} q_\alpha r_i(\alpha) r_j(\alpha) \right]$$
$$\times \frac{\partial}{\partial R_j} E_i(\boldsymbol{R}, t) + \cdots$$
$$\equiv V_{E0}(t) + V_{E1}(t) + V_{E2}(t) + \cdots , \tag{68.6}$$

and the magnetic energy becomes

$$V_m(t) = \sum_{i=1}^{3} B_i(\boldsymbol{R}, t)$$
$$\times \sum_{\alpha} \frac{e\hbar}{2m_\alpha} [g_\ell(\alpha)\ell_i(\alpha) + g_s(\alpha)s_i(\alpha)]$$
$$- \sum_{i,j=1}^{3} \frac{\partial B_i(\boldsymbol{R}, t)}{\partial R_j} \sum_{\alpha} \frac{e\hbar}{2m_\alpha} \left[\frac{2}{3} g_\ell(\alpha)\ell_i(\alpha)r_j(\alpha) \right.$$
$$\left. + g_s(\alpha)s_i(\alpha) \right] + \cdots$$
$$\equiv V_{M1}(t) + V_{M2}(t) + \cdots . \tag{68.7}$$

68.1.1 Electric Dipole (E1) Interaction

For optical fields whose wavelength is large compared with the interacting atom, only the first few terms in the Taylor expansions of $V_e(t)$ and $V_m(t)$ need be retained. The first term, $V_{E0}(t)$, of $V_e(t)$ is the net charge of the atom, which vanishes for neutral atoms. The second term, $V_{E1}(t)$, is the electric dipole interaction energy. Introducing the electric dipole (E1) moment,

$$\boldsymbol{d} = \sum_{\alpha} q_\alpha \boldsymbol{r}(\alpha) , \tag{68.8}$$

or

$$\boldsymbol{d} = \int d^3 r \rho(\boldsymbol{r}) \boldsymbol{r} , \tag{68.9}$$

for a charge distribution, this contribution to the interaction energy may be re-expressed as

$$V_{E1}(t) = -\boldsymbol{d} \cdot \boldsymbol{E}(\boldsymbol{R}, t) . \tag{68.10}$$

The E1 term dominates most optical phenomena.

68.1.2 Electric Quadrupole (E2) Interaction

The $V_{E2}(t)$ contribution to $v_e(t)$, describes electric quadrupole (E2) interactions. In terms of the quadrupole tensor

$$Q = 3 \int d^3 r \rho(\boldsymbol{r}) r_i r_j , \tag{68.11}$$

$V_{E2}(t)$ becomes

$$V_{E2}(t) = -\frac{1}{6} \sum_{i,j=1}^{3} Q_{ij} \frac{\partial}{\partial R_i} E_j(\boldsymbol{R}, t) . \tag{68.12}$$

Alternatively, E2 interactions can be expressed in terms of the traceless quadrupole tensor $Q_{ij}^{(2)} = \int d^3r \rho(\boldsymbol{r}) \times (3r_i r_j - \delta_{ij} r^2)$. E2 interactions are typically weaker than E1 interactions by a factor a_0/λ, where a_0 is the Bohr radius and λ is the wavelength of the transition. Since a_0/λ is very small for optical transitions, E2 interactions are typically neglected in quantum optics.

68.1.3 Magnetic Dipole (M1) Interaction

The first term in the multipole expansion the magnetic interaction (Sect. 68.6) is the magnetic dipole M1 interaction,

$$V_{\mathrm{M1}} = -\boldsymbol{m} \cdot \boldsymbol{B}(\boldsymbol{R}, t) , \qquad (68.13)$$

of a magnetic moment $\boldsymbol{m}$ in a magnetic field, where

$$\boldsymbol{m} = \sum_\alpha \left(\frac{q_\alpha \hbar}{2m_\alpha} \right) [g_\ell(\alpha)\ell(\alpha) + g_s(\alpha)s(\alpha)]$$
$$= -\mu_{\mathrm{B}}(\boldsymbol{L} + 2\boldsymbol{S}) , \qquad (68.14)$$

and we have used the fact that for electrons $g_\ell = -1$ and $g_s \simeq -2$. The Bohr magneton μ_{B} is

$$\mu_{\mathrm{B}} = \frac{e\hbar}{2mc} = \frac{\alpha e a_0}{2} , \qquad (68.15)$$

where α is the fine structure constant. Thus M1 interactions tend to be smaller than E1 interactions by a factor of order $\alpha/2$. The connection between $\boldsymbol{m}$ and angular momentum $\boldsymbol{J}$ is $\boldsymbol{m} = \gamma \boldsymbol{J}$, where γ is the gyromagnetic ratio.

68.2 Lorentz Atom

The Lorentz atom consists of a classical electron harmonically bound to a proton. It provides a framework for understanding a number of elementary aspects of the electric dipole interaction between a single atom and light [68.3–7]. Assuming that the c.m. motion of the atom is unaffected by the field, and neglecting magnetic effects, the equation of motion of the electron is

$$\left(\frac{d^2}{dt^2} + \frac{\Gamma_0}{2} \frac{d}{dt} + \omega_0^2 \right) \boldsymbol{r} = -\frac{e}{m} \boldsymbol{E}(\boldsymbol{R}, t) , \qquad (68.16)$$

where ω_0 is the electron's natural oscillation frequency, and Γ_0 represents a frictional decay rate that accounts for the effects of radiative damping. For the classical Lorentz atom

$$\Gamma_0 = 2\omega_0^2 r_0/3c , \qquad (68.17)$$

where $r_0 = e^2/4\pi\epsilon_0 mc^2$ is the classical electron radius. This damping arises physically from the radiation reaction of the field radiated by the atom on itself. In the E1 approximation, the electric field is evaluated at the location $\boldsymbol{R}$ of the atomic c.m.

68.2.1 Complex Notation

The study of light-matter interactions is simplified by the introduction of complex variables [68.8–11]. For example, an electric field

$$\boldsymbol{E}(\boldsymbol{R}, t) = \sum_{n,\mu} \boldsymbol{\epsilon}_\mu \mathcal{E}_n \cos(\omega_n t) , \qquad (68.18)$$

where $\boldsymbol{\epsilon}_\mu$ is the polarization vector of the field Fourier component at frequency ω_n is expressed as

$$\boldsymbol{E}(\boldsymbol{R}, t) = \boldsymbol{E}^+(\boldsymbol{R}, t) + \boldsymbol{E}^-(\boldsymbol{R}, t) , \qquad (68.19)$$

where the *positive frequency part* of the field is

$$\boldsymbol{E}^+(\boldsymbol{R}, t) = \frac{1}{2} \sum_{n,\mu} \boldsymbol{\epsilon}_\mu \mathcal{E}_n \exp[i(\boldsymbol{k}_n \cdot \boldsymbol{R} - \omega_n t)] . \qquad (68.20)$$

Due to the linearity of (68.16), it is sufficient to study the response of the Lorentz atom to a plane monochromatic electric field of frequency ω, complex amplitude $\mathcal{E}$ and polarization $\boldsymbol{\epsilon}$. Introducing the *complex dipole moment*

$$\boldsymbol{d} = -e\boldsymbol{r} = \boldsymbol{\epsilon} \mathcal{P} \exp[i(\boldsymbol{k} \cdot \boldsymbol{R} - \omega t)] + \text{c.c.} , \qquad (68.21)$$

where $\mathcal{P}$ is in general complex for $\mathcal{E}$ real, and the complex polarizability $\alpha(\omega)$ via $\mathcal{P} = \alpha(\omega)\mathcal{E}$, then

$$\alpha(\omega) = \frac{e^2/m}{\omega_0^2 - \omega^2 - i\gamma\omega} . \qquad (68.22)$$

68.2.2 Index of Refraction

From the Maxwell wave equation

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) \boldsymbol{E}(\boldsymbol{R}, t) = \frac{1}{\epsilon_0 c^2} \frac{\partial^2 \boldsymbol{P}(\boldsymbol{R}, t)}{\partial t^2} , \qquad (68.23)$$

where $\boldsymbol{P}(\boldsymbol{R}, t)$ is the electric polarization, given by the electric dipole density of the medium $\boldsymbol{P} = N\boldsymbol{d}$, N being

the atomic density, the plane wave dispersion relation is

$$k^2 = \frac{\omega^2}{c^2} n^2(\omega) , \tag{68.24}$$

where the index of refraction $n(\omega)$ is

$$n(\omega) = \sqrt{1 + \frac{N\alpha(\omega)}{\epsilon_0}} . \tag{68.25}$$

68.2.3 Beer's Law

Since the polarizability $\alpha(\omega)$ is normally complex, so is the index of refraction. Its real part leads to dispersive effects, while its imaginary part leads to absorption. Specifically, $\mathrm{Re}[n(\omega)] - 1$ has the form of a standard dispersion curve, positive for $\omega - \omega_0 < 0$ and negative for $\omega - \omega_0 > 0$, while $\mathrm{Im}[n(\omega)]$ is a Lorentzian curve peaked at $\omega = \omega_0$. The intensity absorption coefficient $a(\omega)$ is

$$a(\omega) = 2 \, \mathrm{Im}\,[n(\omega)] \, \omega/c \tag{68.26}$$

$$= \frac{2\omega}{c} \, \mathrm{Im}\left[1 + \left(\frac{Ne^2}{m\epsilon_0}\right) \frac{\mathrm{i}\gamma\omega + (\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2} \right]^{1/2} .$$

For atomic vapors, the corrections to the vacuum index of refraction are normally small, so that the square root in (68.26) can be expanded to first order, giving

$$a(\omega) = \left(\frac{Ne^2}{\epsilon_0 mc}\right) \frac{\gamma\omega^2}{\left(\omega_0^2 - \omega^2\right)^2 + \gamma^2\omega^2} . \tag{68.27}$$

The intensity of a monochromatic field propagating along the z-direction through a gas of Lorentz atoms is therefore attenuated according to *Beer's law* given by

$$I(\omega, z) = I(\omega, 0)\,\mathrm{e}^{-a(\omega)z} . \tag{68.28}$$

If the index of refraction at a given frequency becomes purely imaginary, no electromagnetic wave can propagate inside the medium. This is the case for field frequencies smaller than the plasma frequency

$$\omega_\mathrm{p} = \sqrt{\frac{Ne^2}{m\epsilon_0}} . \tag{68.29}$$

While the Lorentz atom model gives an adequate description of absorption and dispersion in a weakly excited absorbing medium, it fails to predict the occurence

of important phenomena such as saturation and light amplification. This is because, in this model, the phase of the induced atomic dipoles with respect to the incident field is always such that the polarization field adds destructively to the incident field. The description of light amplification requires a quantum treatment of the medium, which gives a greater flexibility to the possible relative phases between the incident and polarization fields.

68.2.4 Slowly–Varying Envelope Approximation

Light–matter interactions often involve quasi-monochromatic fields for which the electric field (taken to propagate along the z-axis) can be expressed in the form

$$\boldsymbol{E}(\boldsymbol{R}, t) = \frac{1}{2}\boldsymbol{\epsilon}\mathcal{E}^+(\boldsymbol{R}, t)\,\mathrm{e}^{\mathrm{i}(kz-\omega t)} + \mathrm{c.c.} , \tag{68.30}$$

such that

$$\left|\frac{\partial\mathcal{E}^+}{\partial t}\right| \ll \omega\left|\mathcal{E}^+\right| , \quad \left|\frac{\partial\mathcal{E}^+}{\partial z}\right| \ll k\left|\mathcal{E}^+\right| . \tag{68.31}$$

It is further consistent within this approximation to assume that the polarization takes the form

$$\boldsymbol{P}(\boldsymbol{R}, t) = \frac{1}{2}\boldsymbol{\epsilon}\mathcal{P}^+(\boldsymbol{R}, t)\,\mathrm{e}^{\mathrm{i}(kz-\omega t)} + \mathrm{c.c.} , \tag{68.32}$$

with

$$\left|\frac{\partial\mathcal{P}^+}{\partial t}\right| \ll \omega\left|\mathcal{P}^+\right| . \tag{68.33}$$

Under these conditions, known as the *slowly-varying envelope approximation* ([68.5]), Maxwell's wave equation reduces to

$$\left(\frac{\partial}{\partial z} + \frac{1}{c}\frac{\partial}{\partial t}\right)\mathcal{E}^+(z, t) = -\frac{k}{2i\epsilon_0}\mathcal{P}^+(z, t) . \tag{68.34}$$

Hence, in the slowly-varying envelopes approximation we ignore the backward propagation of the field [68.12]. The slowly-varying amplitude and phase approximation is essentially the same, except that it expresses the electric field envelope in terms of a real amplitude and phase.

68.3 Two–Level Atoms

A large number of optical phenomena can be understood by considering the interaction between a quasi-monochromatic field of central frequency ω and

a two-level atom, which simulates a (dipole-allowed) atomic transition [68.5, 7, 10, 11, 13–17]. This approximation is well justified for near-resonant interactions;

i. e., $\omega \simeq \omega_0$. The next three sections discuss the model Hamiltonian for this system in the *semiclassical* approximation where the electromagnetic field can be described classically. The formal results are then extended to the case of a quantized field, where the electric field is treated as an operator.

68.3.1 Hamiltonian

In the absence of dissipation mechanisms, the dipole interaction between a quasi-monochromatic classical field and a two-level atom is

$$H = \hbar\omega_e |e\rangle\langle e| + \hbar\omega_g |g\rangle\langle g| - \boldsymbol{d} \cdot \boldsymbol{E}(\boldsymbol{R}, t) \,, \quad (68.35)$$

where $|e\rangle$ and $|g\rangle$ label the upper and lower atomic levels, of frequencies ω_e and ω_g, respectively, with $\omega_e - \omega_g = \omega_0$, and $\boldsymbol{R}$ is the location of the center of mass of the atom. The electric dipole operator (68.8), couples the excited and ground levels, and may be expressed as

$$\boldsymbol{d} = \boldsymbol{\epsilon}_{\mathrm{d}} d \left(|e\rangle\langle g| + |g\rangle\langle e|\right) \,, \quad (68.36)$$

where $\boldsymbol{\epsilon}_{\mathrm{d}}$ is a unit vector in the direction of the dipole and d the matrix element of the electric dipole operator between the ground and excited state, which we take to be real for simplicity. We also neglect the vector character of $\boldsymbol{d}$ and $\boldsymbol{E}(\boldsymbol{R}, t)$ in the following, assuming, for example, that both $\boldsymbol{\epsilon}_{\mathrm{d}}$ and $\boldsymbol{\epsilon}$ are parallel to x-axis. The Hamiltonian (68.35) may then be expressed as

$$\begin{aligned} H = \hbar\omega_e |e\rangle\langle e| + \hbar\omega_g |g\rangle\langle g| - d \left(|e\rangle\langle g| + |g\rangle\langle e|\right) \\ \times \left[E^+(\boldsymbol{R}, t) + E^-(\boldsymbol{R}, t)\right] \,, \quad (68.37) \end{aligned}$$

where we have generalized the notation of (68.20) in an obvious way. One can introduce the *pseudo-spin operators*

$$\begin{aligned} s_z &= (|e\rangle\langle e| - |g\rangle\langle g|)/2 \,, \\ s_+ &= s_-^\dagger = |e\rangle\langle g| \,, \end{aligned} \quad (68.38)$$

and redefine the zero of atomic energy to introduce the commonly used form

$$H = \hbar\omega_0 s_z - d \left(s_+ + s_-\right) \left[E^+(\boldsymbol{R}, t) + E^-(\boldsymbol{R}, t)\right] \,. \quad (68.39)$$

68.3.2 Rotating Wave Approximation

Under the influence of a monochromatic electromagnetic field of frequency ω, atoms undergo transitions between their lower and upper states by interacting with either the positive or the negative frequency part of the field. The corresponding contributions to the atomic dynamics oscillate at frequencies $\omega_0 - \omega$ and $\omega_0 + \omega$, respectively, and their contributions to the probability amplitudes involve denominators containing this same frequency dependence. For near-resonant atom-field interactions, the rapidly oscillating contributions lead to small corrections, the first-order one being the Bloch–Siegert shift, whose value near resonance, is $\omega \simeq \omega_0$ [68.17].

$$\delta\omega_{eg} = -\frac{\left(d|E^+|/\hbar\right)^2}{4\omega} \quad (68.40)$$

to lowest-order in $d\mathcal{E}/\hbar\omega$. The neglect of these terms is the Rotating Wave Approximation (RWA). Note that it is normally inconsistent to regard an atom as a two-level system and not to perform the RWA. In the RWA, the atomic system is described by the Hamiltonian

$$H = \hbar\omega_0 s_z - d \left[s_+ E^+(\boldsymbol{R}, t) + s_- E^-(\boldsymbol{R}, t)\right] \,, \quad (68.41)$$

or, in a frame rotating at the frequency ω of the field,

$$H = \hbar\Delta s_z - \frac{1}{2} d \left(s_+ \mathcal{E}\, \mathrm{e}^{\mathrm{i}\boldsymbol{k} \cdot \boldsymbol{R}} + \mathrm{h.c.}\right) \,, \quad (68.42)$$

where $\Delta = \omega_0 - \omega$ is the atom-light detuning. (Note that the alternate definition $\delta = \omega - \omega_0$ is frequently used in the literature.) In the rest of this chapter, we consider atoms placed at $\boldsymbol{R} = 0$.

68.3.3 Rabi Frequency

The dynamics of the two-level atom is conveniently expressed in terms of its density operator ρ, whose evolution is given by the Schrödinger equation

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H, \rho] \,, \quad (68.43)$$

where $\rho_{ee} = \langle e|\rho|e\rangle$ and $\rho_{gg} = \langle g|\rho|g\rangle$ are the upper and lower state populations P_e and P_g, respectively, while the off-diagonal matrix elements $\rho_{eg} = \langle e|\rho|g\rangle = \rho_{ge}^\star$ are called the atomic coherences, or simply coherences, between levels $|e\rangle$ and $|g\rangle$. These coherences play an essential role in optical physics and quantum optics, since they are proportional to the expectation value of the electric dipole operator.

The evolution of $P_g(t)$ and $P_e(t) = 1 - P_g(t)$, is characterized by oscillations at the generalized Rabi frequency

$$\Omega = \left(\Omega_1^2 + \Delta^2\right)^{1/2} \,, \quad (68.44)$$

where the *Rabi frequency* Ω_1 is $\Omega_1 = d\mathcal{E}/\hbar$, (or $\Omega_1 = d\mathcal{E}(\boldsymbol{\epsilon}_d \cdot \boldsymbol{\epsilon})/\hbar$ when the vector character of the electric field and dipole moment are included). Specifically, assuming that the atom is initially in its ground state $|g\rangle$, the probability that it is in the excited state $|e\rangle$ at a subsequent time t is given by Rabi's formula

$$P_e(t) = (\Omega_1/\Omega)^2 \sin^2(\Omega t/2) . \tag{68.45}$$

At resonance ($\Delta = 0$), the generalized Rabi frequency Ω reduces to the Rabi frequency Ω_1. (In addition to the texts on quantum optics already cited, see also [68.18].)

68.3.4 Dressed States

Semiclassical Case

The atomic dynamics can alternatively be described in terms of a *dressed states* basis instead of the *bare states* $|e\rangle$ and $|g\rangle$ (see especially [68.17]). The dressed states $|1\rangle$ and $|2\rangle$ are eigenstates of the Hamiltonian (68.42), and, by convention, the state $|1\rangle$ is the one with the greatest energy. They are conveniently expressed in terms of the bare states via the Stückelberg angle $\theta/2$ as

$$|1\rangle = \sin\theta|g\rangle + \cos\theta|e\rangle ,$$
$$|2\rangle = \cos\theta|g\rangle - \sin\theta|e\rangle , \tag{68.46}$$

where $\sin(2\theta) = -\Omega_1/\Omega$, $\cos(2\theta) = \Delta/\Omega$. The corresponding eigenenergies are

$$E_1 = +\frac{1}{2}\hbar\Omega ,$$
$$E_2 = -\frac{1}{2}\hbar\Omega . \tag{68.47}$$

These energies are illustrated in Fig. 68.1 as a function of the field frequency ω. The dressed levels repel each other and form an anticrossing at resonance $\omega = \omega_0$. As the detuning Δ varies from positive to negative values, state $|1\rangle$ passes continuously from the excited state $|e\rangle$ to the bare ground state $|g\rangle$, with both bare states having equal weights at resonance. The distances between the perturbed levels and their asymptotes for $|\Delta| \gg \Omega_1$ represent the ac Stark shifts, or light shifts, of the atomic states when coupled to the laser. From Fig. 68.1, the ac Stark shift of $|g\rangle$ is positive for $\Delta < 0$ and negative for $\Delta > 0$, while the $|e\rangle$ state shift is negative for $\Delta < 0$ and positive for $\Delta > 0$.

Quantized Field

The concept of dressed states can readily be generalized to a two-level atoms interacting with a single-mode quantized field in the dipole and rotating wave approximations. The atom and its dipole interaction with the

field are still described by the Hamiltonian (68.41), except that the positive and negative frequency components of the field are now operators, and the free field Hamiltonian must be included. The Hamiltonian of the total atom-field system becomes

$$H = \hbar\omega_0 s_z + \hbar\omega\left(a^\dagger a + \frac{1}{2}\right) + \hbar g\left(s_+ a + a^\dagger s_-\right) , \tag{68.48}$$

where the creation and annihilation operators $a^\dagger$ and a obey the boson commutation relation $[a, a^\dagger] = 1$ (Chapt. 6), and the coupling constant

$$g = d\sqrt{\frac{\omega}{2\epsilon_0 \hbar V}} \tag{68.49}$$

is the vacuum Rabi frequency, with V being a photon normalization volume. This Hamiltonian defines the Jaynes–Cummings model, [68.7, 19] which is discussed in more detail in Chapt. 78.

The dressed states of the atom-field system are the eigenstates of the Jaynes–Cummings model. Since, in the RWA, the dipole interaction only couples states of same "excitation number", e.g., $|e, n\rangle$ and $|g, n+1\rangle$, where $|n\rangle$ is an eigenstate of the photon number operator, $a^\dagger a|n\rangle = n|n\rangle$, with n an integer, the diagonalization of the Jaynes–Cummings model reduces to that of the semiclassical driven two-level atom in each of these manifolds. Hence, the dressed states are

$$|1, n\rangle = \sin\theta_n|g, n+1\rangle + \cos\theta_n|e, n\rangle ,$$
$$|2, n\rangle = \cos\theta_n|g, n+1\rangle - \sin\theta_n|e, n\rangle , \tag{68.50}$$

with

$$\tan(2\theta_n) = -2g\sqrt{n+1}/\Delta . \tag{68.51}$$
Fig. 68.1 Dressed levels of a two-level atom driven by a classical monochromatic field as a function of the detuning $\Delta = \omega_0 - \omega$

(The factor of 2 difference between this and the semiclassical case is due to the use of a running waves quantization scheme, while the semiclassical discussion was for standing waves.) The corresponding eigenenergies are

$$E_{1n} = \hbar(n+1)\omega - \hbar R_n \,,$$
$$E_{2n} = \hbar(n+1)\omega + \hbar R_n \,, \tag{68.52}$$

where

$$R_n = \frac{1}{2}\sqrt{\Delta^2 + 4g^2(n+1)} \,. \tag{68.53}$$

Chapter 78 shows that by including the effects of spontaneous emission, this picture yields a straightforward interpretation of a number of effects, including the Burshtein–Mollow resonance fluorescence spectrum. Dressed states also help to elucidate the interaction between two-level atoms and quantized single-mode fields, as occur for example in cavity QED ([68.19] and Chapt. 79). Their generalization to the case of moving atoms offers simple physical interpretations of several aspects of laser cooling, see Chapt. 75 and [68.20].

68.3.5 Optical Bloch Equations

Introducing the density operator matrix elements $\rho_{ab} = \langle a|\rho|b\rangle$, where a, b can be either e or g, as well as the real quantities

$$U = \rho_{eg}\,\mathrm{e}^{\mathrm{i}\omega t} + \text{c.c.} \,,$$
$$V = \mathrm{i}\rho_{eg}\,\mathrm{e}^{\mathrm{i}\omega t} + \text{c.c.} \,,$$
$$W = \rho_{ee} - \rho_{gg} \,, \tag{68.54}$$

the equations of motion for the density matrix elements $\rho_{ij} = \langle i|\rho|j\rangle$ may be expressed, with (68.43), as

$$\frac{\mathrm{d}U}{\mathrm{d}t} = -\Delta V \,,$$
$$\frac{\mathrm{d}V}{\mathrm{d}t} = \Delta U + \Omega_1 W \,,$$
$$\frac{\mathrm{d}W}{\mathrm{d}t} = -\Omega_1 V \,. \tag{68.55}$$

These are the optical Bloch equations, as discussed extensively in [68.5, 17]. Physically, U describes the component of the atomic coherence in phase with the driving field, V the component in quadrature with the field, and W the atomic inversion. The optical Bloch equations have a simple geometrical interpretation offered by thinking of U, V and W as the three components of a vector called the Bloch vector $\boldsymbol{U}$, whose equation of motion is

$$\frac{\mathrm{d}\boldsymbol{U}}{\mathrm{d}t} = \boldsymbol{\Omega} \times \boldsymbol{U} \,, \tag{68.56}$$

where $\boldsymbol{\Omega} = (-\Omega_1, 0, \Delta)$. Thus $\boldsymbol{U}$ precesses about $\boldsymbol{\Omega}$, of length Ω, while conserving its length. The evolution of a two-level atom driven by a monochromatic field is thus mathematically equivalent to that of a spin-$\frac{1}{2}$ system in two magnetic fields $\boldsymbol{B}_0$ and $2\boldsymbol{B}_1\cos\omega t$ which are parallel to the z- and x-axis, respectively, and whose amplitudes are such that the Larmor spin precession frequencies around them are ω and $2\Omega_1\cos\omega t$, respectively. In optics, this vectorial picture is often referred to as the Feynman–Vernon–Hellwarth picture [68.21]. It is very useful in discussing the coherent transient phenomena discussed in Chapt. 73.

68.4 Relaxation Mechanisms

In addition to their coherent interaction with light fields, atoms suffer incoherent relaxation mechanisms, whose origin can be as diverse as elastic and inelastic collisions and spontaneous emission. Collisional broadening is discussed in Chapt. 59, while a QED microscopic discussion of spontaneous emission is described in Chapt. 78 in terms of reservoir theory. One advantage of describing the atomic state in terms of a density operator ρ is that the physical interpretation of its elements allows us phenomenologically to add various relaxation terms directly to its elements.

68.4.1 Relaxation Toward Unobserved Levels

If the relaxation mechanisms transfer populations or atomic coherences toward uninteresting or unobserved levels, their description can normally be given in terms of a Schrödinger equation, but with a complex Hamiltonian. In contrast, if all levels involved in the relaxation mechanism are observed, a more careful description, e.g. in terms of a master equation, is required. Specifically, in the case of relaxation to unobserved levels, the evolution of the atomic density operator, restricted to the

levels of interest, is of the general form [68.16]

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}\left(H_{\mathrm{eff}}\rho - \rho H_{\mathrm{eff}}^{\dagger}\right) , \tag{68.57}$$

where

$$H_{\mathrm{eff}} = H + \hat{\Gamma} , \tag{68.58}$$

H being the atom-field Hamiltonian and $\hat{\Gamma}$ the non-Hermitian relaxation operator, defined by its matrix elements

$$\langle n|\hat{\Gamma}|m\rangle = \frac{\hbar}{2\mathrm{i}}\gamma_n\delta_{nm} . \tag{68.59}$$

Both inelastic collisions and spontaneous emission to unobserved levels can be described by this form of evolution. In the framework of this chapter, inelastic, or strong, collisions are defined as collisions that can induce atomic transitions into other energy levels.

68.4.2 Relaxation Toward Levels of Interest

A master equation description is necessary when all involved levels are observed [68.7, 17]. This master equation can rapidly take a complicated form if more than two levels are involved. We give results only for the case of a two-level atom and upper to lower-level spontaneous decay and elastic or soft collisions; i.e., collisions that change the separation of energy levels during the collision, but leave the level populations unchanged. In that case, the atomic master equation takes the form

$$\frac{\mathrm{d}\rho}{\mathrm{d}t} = -\frac{\mathrm{i}}{\hbar}[H, \rho] - \frac{\Gamma}{2}\left(s_+s_-\rho + \rho s_+s_- - 2s_-\rho s_+\right)$$
$$- \frac{1}{2}\gamma_{\mathrm{ph}}\rho + 2\gamma_{\mathrm{ph}}s_z\rho s_z , \tag{68.60}$$

where the free-space spontaneous decay rate Γ is found from QED to be

$$\Gamma = \frac{1}{4\pi\epsilon_0}\frac{4d^2\omega_0^3}{3\hbar c^3} , \tag{68.61}$$

and γ_{ph} is the decay rate due to elastic collisions.

It is possible to express the classical decay rate (68.17) in terms of the quantum spontaneous emission rate (68.61) as

$$\Gamma = \Gamma_{\mathrm{cl}}f_{ge} , \tag{68.62}$$

where f_{ge} is the oscillator strength of the transition. The various oscillator strengths characterizing the dipole-allowed transitions from a ground state $|e\rangle$ to excited levels $|e\rangle$ obey the Thomas–Reiche–Kuhn sum rule

$$\sum_e f_{ge} = 1 , \tag{68.63}$$

where the sum is on all levels dipole-coupled to $|g\rangle$. Assuming that $\boldsymbol{d}$ and the polarization of the field are both parallel to the x-axis, this gives

$$f_{ge} = \frac{2m\omega_0}{\hbar}|\langle g|x|e\rangle|^2 . \tag{68.64}$$

68.4.3 Optical Bloch Equations with Decay

In general, the optical Bloch equations cannot be generalized to cases where relaxation mechanisms are present. There are, however, two notable exceptions corresponding to situations where

1. the upper level spontaneously decays to the lower level only, while the atom undergoes only elastic collisions;
2. spontaneous emission between the upper and lower levels can be ignored in comparison with decay to unobserved levels, which occur at equal rates $\gamma_e = \gamma_g = 1/T_1$.

Under these conditions, (68.55) generalizes to

$$\frac{\mathrm{d}U}{\mathrm{d}t} = -U/T_2 - \Delta V ,$$
$$\frac{\mathrm{d}V}{\mathrm{d}t} = -V/T_2 + \Delta U + \Omega_1 W ,$$
$$\frac{\mathrm{d}W}{\mathrm{d}t} = -(W - W_{\mathrm{eq}})/T_1 - \Omega_1 V , \tag{68.65}$$

where we have introduced the longitudinal and transverse relaxation times T_1 and T_2, with $T_1 = 1/\Gamma$ and $T_2 = (1/2T_1 + \gamma_{\mathrm{ph}})^{-1}$ in the first case, and $T_2 = (1/T_1 + \gamma_{\mathrm{ph}})^{-1}$ in the second case. The equilibrium inversion W_{eq} is equal to zero in the second case since the decay is to unobserved levels.

68.4.4 Density Matrix Equations

In the general case, it is necessary to consider the density operator equation (68.43) instead of the optical Bloch equations. The equations of motion for the components of ρ become, for the general case of complex Ω_1,

$$\frac{\mathrm{d}\rho_{ee}}{\mathrm{d}t} = -\gamma_e\rho_{ee} - \frac{1}{2}\left(\mathrm{i}\Omega_1^*\tilde{\rho}_{eg} + \mathrm{c.c.}\right) ,$$
$$\frac{\mathrm{d}\rho_{gg}}{\mathrm{d}t} = -\gamma_g\rho_{gg} + \frac{1}{2}\left(\mathrm{i}\Omega_1^*\tilde{\rho}_{eg} + \mathrm{c.c.}\right) ,$$
$$\frac{\mathrm{d}\tilde{\rho}_{eg}}{\mathrm{d}t} = -(\gamma + \mathrm{i}\Delta)\tilde{\rho}_{eg} - \mathrm{i}\frac{\Omega_1}{2}\left(\rho_{ee} - \rho_{gg}\right) , \tag{68.66}$$

where $\gamma = (\gamma_e + \gamma_g)/2 + \gamma_{ph}$, and $\tilde{\rho}_{eg} = \rho_{eg}\, e^{i\omega t}$. In the case of spontaneous decay from the upper to the lower level, these equations become

$$\frac{d\rho_{ee}}{dt} = -\Gamma\rho_{ee} - \frac{1}{2}\left(i\Omega_1^*\tilde{\rho}_{eg} + \text{c.c.}\right),$$

$$\frac{d\rho_{gg}}{dt} = +\Gamma\rho_{ee} + \frac{1}{2}\left(i\Omega_1^*\tilde{\rho}_{eg} + \text{c.c.}\right),$$

$$\frac{d\tilde{\rho}_{eg}}{dt} = -(\gamma + i\Delta)\tilde{\rho}_{eg} - i\frac{\Omega_1}{2}\left(\rho_{ee} - \rho_{gg}\right), \quad (68.67)$$

where $\gamma = \Gamma/2 + \gamma_{ph}$. Equations (68.67) are completely equivalent to the optical Bloch equations (68.65).

68.5 Rate Equation Approximation

If the coherence decay rate γ is dominated by elastic collisions, and hence is much larger than the population decay rates γ_e and γ_g, $\tilde{\rho}_{eg}$ can be adiabatically eliminated from the equations of motion (68.66) and (68.67) to obtain the rate equations (Sect. 68.2)

$$\frac{d\rho_{ee}}{dt} = -\gamma_e\rho_{ee} - R\left(\rho_{ee} - \rho_{gg}\right),$$

$$\frac{d\rho_{gg}}{dt} = -\gamma_g\rho_{gg} + R\left(\rho_{ee} - \rho_{gg}\right), \quad (68.68)$$

and

$$\frac{d\rho_{ee}}{dt} = -\Gamma\rho_{ee} - R\left(\rho_{ee} - \rho_{gg}\right),$$

$$\frac{d\rho_{gg}}{dt} = +\Gamma\rho_{gg} + R\left(\rho_{ee} - \rho_{gg}\right), \quad (68.69)$$

respectively, where the transition rate is

$$R = |\Omega_1|^2 \mathcal{L}(\Delta)/(2\gamma), \quad (68.70)$$

and we have introduced the dimensionless Lorentzian

$$\mathcal{L}(\Delta) = \gamma^2/\left(\gamma^2 + \Delta^2\right). \quad (68.71)$$

The transitions between the upper and lower state are thus described in terms of simple rate equations.

Adding phenomenological pumping rates Λ_e and Λ_g on the right-hand side of (68.68) provides a description of the excitation of the upper and lower levels from some distant levels, as would be the case in a laser. The equations then form the basis of conventional, single-mode laser theory. In the absence of such mechanisms, the atomic populations eventually decay away.

68.5.1 Steady State

In the case of upper to lower-level decay, the state populations reach a steady state with inversion [68.5, 17]

$$W_{st} = -\frac{\Gamma}{\Gamma + 2R} = -\frac{1}{1+s}, \quad (68.72)$$

where s is the saturation parameter. In the case of pure radiative decay, $\gamma_{ph} = 0$, s is given by

$$s = \frac{\Omega_1^2/2}{\Gamma^2/4 + \Delta^2}. \quad (68.73)$$

In steady state, the other two components of the Bloch vector U are given by

$$U_{st} = -\frac{2\Delta}{\Omega_1}\left(\frac{s}{1+s}\right) \quad (68.74)$$

and

$$V_{st} = \frac{\Gamma}{\Omega_1}\left(\frac{s}{1+s}\right). \quad (68.75)$$

U_{st} varies as a dispersion curve as a function of the detuning Δ, while V_{st} is a Lorentzian of power-broadened half-width at half maximum $\left(\Gamma^2/4 + \Omega_1^2\right)^{1/2}$.

68.5.2 Saturation

As the intensity of the driving field, or Ω_1^2, increases, U_{st} and V_{st} first increase linearly with Ω_1, reach a maximum, and finally tend to zero as $\Omega_1 \to \infty$. The inversion W_{st}, which equals -1 for $\Omega_1 = 0$, first increases quadratically, and asymptotically approaches $W_{st} = 0$ as $\Omega_1 \to \infty$. At this point, where the upper and lower state populations are equal, the transition is said to be saturated, and the medium becomes effectively transparent, or bleached. (This should not be confused with self-induced transparency discussed in Chapt. 73.) The inversion is always negative, which means in particular that no steady-sate light amplification can be achieved in this system. This is one reason why external pump mechanisms are required in lasers.

68.5.3 Einstein A and B Coefficients

When atoms interact with broadband radiation instead of the monochromatic fields considered so far, (68.69)

still apply, but the rate R becomes

$$R \to B_{eg}\varrho(\omega) , \tag{68.76}$$

where $\varrho(\omega)$ is the spectral energy density of the inducing radiation. Einstein's A and B coefficients apply to an atom in thermal equilibrium with the field, which is described by Planck's black-body radiation law

$$\varrho(\omega) = \frac{\hbar\omega^3}{\pi^2 c^3}\frac{1}{e^{\hbar\omega/k_B T} - 1} , \tag{68.77}$$

where T is the temperature of the source and k_B is Boltzmann's constant. Invoking the principle of detailed balance, which states that at thermal equilibrium, the average number of transitions between arbitrary states $|i\rangle$ and $|k\rangle$ must be equal to the number of transitions between $|k\rangle$ and $|i\rangle$, one finds

$$\frac{A_{ki}}{B_{ki}} = \frac{\hbar\omega^3}{\pi^2 c^3} , \tag{68.78}$$

where A_{ki} is the rate of spontaneous emission from $|k\rangle$ to $|i\rangle$, and $\Gamma_k = \sum_i A_{ki}$ is the level width.

68.6 Light Scattering

Far from resonance, the approximation of a two- or few-level atom is no longer adequate. Two limiting cases, which are always far from resonance, are Rayleigh scattering for low frequencies, and Thomson scattering for high frequencies.

68.6.1 Rayleigh Scattering

Rayleigh scattering is the elastic scattering of a monochromatic electromagnetic field of frequency ω, wave vector $\mathbf{k}$ and polarization $\boldsymbol{\epsilon}$ by an atomic system in the limit where ω is very small compared with its excitation energies [68.4, 17]. To second-order in perturbation theory, the Rayleigh scattering differential cross section into the solid angle Ω' about the wave vector $\mathbf{k}'$ with $k' = k$, and polarization ϵ' is

$$\frac{d\sigma}{d\Omega'} = r_0^2\omega^4(\boldsymbol{\epsilon}\cdot\boldsymbol{\epsilon}')^2\left(\sum_e \frac{f_{ge}}{\omega_{eg}^2}\right)^2 , \tag{68.79}$$

where r_0 is the classical electron radius, the sum is over all states $|e\rangle$, f_{ge} is the E1 oscillator strength (68.64) and ω_{ge} is the transition frequency. The corresponding total cross section is

$$\sigma = \frac{8\pi r_0^2\omega^4}{3}\left(\sum_e \frac{f_{ge}}{\omega_{eg}^2}\right)^2 . \tag{68.80}$$

68.6.2 Thomson Scattering

Thomson scattering is the corresponding elastic photon scattering by an atom in the limit where ω is very large compared with the atomic ionization energy, yet small enough compared to $\alpha mc^2/\hbar$, that the dipole approximation can be applied. The differential cross section for this process is [68.4, 17]

$$\frac{d\sigma}{d\Omega'} = r_0^2(\boldsymbol{\epsilon}\cdot\boldsymbol{\epsilon}')^2 , \tag{68.81}$$

and the total cross section is

$$\sigma = \frac{8}{3}\pi r_0^2 . \tag{68.82}$$

This is a completely classical result, which exhibits no frequency dependence.

68.6.3 Resonant Scattering

We finally consider elastic scattering in the limit where ω is close to the transition frequency ω_0 between $|g\rangle$ and $|e\rangle$. Provided that no other level is near-resonant with the ground state, the resonant scattering differential cross section is [68.6, 17]

$$\frac{d\sigma}{d\Omega'} = \frac{9}{16\pi^2}\lambda_0^2(\boldsymbol{\epsilon}\cdot\boldsymbol{\epsilon}')^2\frac{(\Gamma/2)^2}{\Delta^2 + (\Gamma/2)^2} , \tag{68.83}$$

where $\lambda_0 = 2\pi c/\omega_0$ is the wavelength of the transition and Γ is the spontaneous decay rate (68.61). The total elastic scattering cross section is

$$\sigma = \frac{3}{2\pi}\lambda_0^2 . \tag{68.84}$$

In contrast to the nonresonant Rayleigh and Thomson scattering cross sections, which scale as the square of the classical electron radius, the resonant scattering cross section scales as the square of the wavelength. For optical to frequencies, $\lambda_0/r_0 \simeq 10^4$, giving a *resonant enhancement* of about eight orders of magnitude. This illustrates why near resonant phenomena, which form the bulk of the following chapters, are so important in optical physics and quantum optics.

69. Absorption and Gain Spectra

This chapter develops theoretical techniques to describe absorption and emission spectra, using concepts introduced in Chapt. 68, and density matrix methods from Chapt. 7. The simplest cases are treated, compatible with the physics involved, and more realistic applications are referred to in other chapters. Vector notation is not used, but it can be inserted as required. Only steady-state spectroscopy is covered; for time-resolved transient techniques see Chapt. 73.

Laser technology has greatly expanded the potential of atomic and molecular spectroscopy, but the same techniques for describing the interaction of light with matter also apply to the traditional arc lamps and flash discharges,

and the more recent synchrotron radiation sources.

In many cases, departures from the thin sample limit, such as beam attenuation, light scattering and radiation trapping (Sect. 69.2) may be important. However, the properties of laser devices themselves depend in an essential way on these effects, making a self-consistent treatment of their properties necessary.

At the other extreme, the spectroscopy of dilute gases is well characterized by ensemble averages over the properties of the individual particles, interrupted by occasional brief collisions. Ensemble averages, however, may no longer apply to recent experiments probing a single atomic particle in a trap, as discussed in Chapt. 75.

69.1 Index of Refraction

As discussed in Sect. 68.2.2, the complex index of refraction for a medium containing harmonically bound charges (electrons) [69.1] with natural frequency ω_0 is

$$
\begin{aligned}
n(\omega) &= \sqrt{1 + \frac{N\alpha(\omega)}{\varepsilon_0}} \approx 1 + \frac{N\alpha(\omega)}{2\varepsilon_0} \\
&= 1 + \frac{Ne^2}{2m\varepsilon_0}\left(\frac{\mathrm{i}\gamma\omega + (\omega_0^2 - \omega^2)}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2}\right) \\
&= n' + \mathrm{i}\,n'' \ .
\end{aligned}
\tag{69.1}
$$

The expansion is valid when the density of atoms N is low.

A plane wave can be written in the form

$$
\mathcal{E} \propto \mathrm{e}^{\mathrm{i}kz} = \mathrm{e}^{\mathrm{i}\omega n z/c} = \mathrm{e}^{\mathrm{i}\omega n' z/c}\,\mathrm{e}^{-\omega n'' z/c} \ .
\tag{69.2}
$$

The absorption of light through the medium then shows a resonant behavior near $\omega \approx \omega_0$ determined by

$$
\begin{aligned}
n'' &= \frac{Ne^2}{2m\varepsilon_0}\left(\frac{\gamma\omega}{(\omega_0^2 - \omega^2)^2 + \gamma^2\omega^2}\right) \\
&\approx \frac{\pi Ne^2}{4m\varepsilon_0\omega_0}\left(\frac{\gamma/2\pi}{(\omega - \omega_0)^2 + \gamma^2/4}\right) \ .
\end{aligned}
\tag{69.3}
$$

This is called an absorptive lineshape. When the single electron is harmonically bound, its interaction with radiation is found in this response. For a real atom, the response of the electron is divided among the various transitions to other states. The fraction assigned to one single transition is characterized by the oscillator strength f_n as discussed in Sect. 68.4.2.

In ordinary linear spectroscopy, the laser is tuned through the resonance $\omega \approx \omega_0$, and the value of ω_0 is

determined from the lineshape (69.3). Several closely spaced resonances can be *resolved* if their spacing is larger than their widths

$$\left| \omega_0^{(1)} - \omega_0^{(2)} \right| > \gamma \ . \tag{69.4}$$

This defines the *spectral resolution* (Chapt. 10).

The velocity of light in the medium is seen to be given by the expression

$$c_{\text{eff}} = \frac{c}{n'} \approx c \left[1 - \frac{Ne^2}{2m\varepsilon_0} \left(\frac{\omega_0^2 - \omega^2}{\left(\omega_0^2 - \omega^2 \right)^2 + \gamma^2 \omega^2} \right) \right] \ . \tag{69.5}$$

This expression shows a *dispersive behavior* around the position $\omega = \omega_0$, where the modification of the velocity disappears. Below resonance $\omega < \omega_0$, the velocity of light is lower than in vacuum. This derives from the fact that the polarization is in phase with the driving field. Thus, by storing the incoming energy, the driving field retards the propagation of the radiation.

For a harmonically bound charge, the refractive index (69.1) always stays absorptive and it is independent of the intensity of the laser radiation. This no longer holds for discrete level atomic systems. In order to see this, we consider the *two-level atom* in Sect. 69.2 (Sect. 68.3).

69.2 Density Matrix Treatment of the Two-Level Atom

The response of atoms to light is conveniently expressed in terms of the density matrix ρ. In addition to the direct physical meaning of the density matrix elements discussed in Sect. 68.3.3, the density matrix formalism is advantageous because the various relaxation mechanisms effecting the atomic resonances can be introduced phenomenologically into its equations of motion (Sect. 68.4), and theoretical derivations often provide *master equations* for the density matrix (Chapt. 7).

The two-level Hamiltonian (68.35) can be written as

$$H = \begin{bmatrix} \hbar\omega_0/2 & -d\mathcal{E}(R, t) \\ -d\mathcal{E}(R, t) & -\hbar\omega_0/2 \end{bmatrix} \ . \tag{69.6}$$

The equation of motion for the density matrix (68.67) is then

$$\frac{d}{dt}\rho_{ee} = -\Gamma\rho_{ee} + \frac{id\mathcal{E}}{\hbar}\cos\omega t \left(\rho_{ge} - \rho_{eg} \right) \ ,$$
$$\frac{d}{dt}\rho_{gg} = \Gamma\rho_{ee} - \frac{id\mathcal{E}}{\hbar}\cos\omega t \left(\rho_{ge} - \rho_{eg} \right) \ ,$$
$$\frac{d}{dt}\rho_{eg} = -(\gamma + i\omega_0)\rho_{eg} + \frac{id\mathcal{E}}{\hbar}\cos\omega t \left(\rho_{gg} - \rho_{ee} \right) \ . \tag{69.7}$$

Here Γ is the spontaneous decay rate given by (68.61) and

$$\gamma = \Gamma/2 + \gamma_{\text{ph}} \ , \tag{69.8}$$

where γ_{ph} derives from all processes that tend to randomize the phase between the quantum states $|e\rangle$ and $|g\rangle$, such as collisions (Chapts. 7 and 19), noise in the laser fields and thermal excitation of the environment

in solid state spectroscopy. The Greek letters Γ and γ correspond to the longitudinal relaxation rate (T_1-process) and the transverse relaxation rate (T_2-process), respectively (Sect. 68.4.3).

In the rotating wave approximation (RWA), discussed in Sect. 68.3.2, the density matrix equations (69.7) become identical to (68.67) with

$$\rho_{eg} = \tilde{\rho}_{eg}\,e^{-i\omega t} \ . \tag{69.9}$$

Using the condition of conservation of probability

$$\rho_{ee} + \rho_{gg} = 1 \ , \tag{69.10}$$

the steady state solutions to (68.67) are [69.2]

$$\rho_{ee} = \frac{\Omega_1^2 \gamma}{2\Gamma} \left(\frac{1}{\Delta^2 + \gamma^2 + \Omega_1^2 \gamma/\Gamma} \right) \ , \tag{69.11}$$

$$\tilde{\rho}_{eg} = \frac{i\Omega_1}{2} \frac{\left(\rho_{gg} - \rho_{ee} \right)}{\gamma + i\Delta}$$
$$= \frac{i\Omega_1}{2} \left(\frac{\gamma - i\Delta}{\Delta^2 + \gamma^2 + \Omega_1^2 \gamma/\Gamma} \right) \ , \tag{69.12}$$

where Ω_1 is the Rabi frequency from (68.44), and $\Delta = \omega_0 - \omega$ is the detuning. The induced polarization is then

$$\mathcal{P} = N\text{Tr}(\hat{d}\rho) = N\text{Tr}\left[\begin{pmatrix} 0 & d \\ d & 0 \end{pmatrix} \begin{pmatrix} \rho_{ee} & \rho_{eg} \\ \rho_{ge} & \rho_{gg} \end{pmatrix} \right]$$
$$= Nd \left(e^{-i\omega t}\tilde{\rho}_{eg} + e^{i\omega t}\tilde{\rho}_{ge} \right)$$
$$= N \left(\alpha\mathcal{E}^{(+)} + \alpha^*\mathcal{E}^{(-)} \right) \ , \tag{69.13}$$

where N is the density of active two-level atoms. Setting

$$\mathcal{E}^{(+)} = \frac{1}{2}\mathcal{E}\,e^{-i\omega t}\,, \tag{69.14}$$

the complex polarization is

$$\alpha(\omega) = \frac{d^2}{\hbar}\left(\frac{i\gamma + \Delta}{\Delta^2 + \gamma^2 + \Omega_1^2\gamma/\Gamma}\right)\,, \tag{69.15}$$

and from (69.1), the complex index of refraction is

$$\begin{aligned}
n(\omega) &= 1 + \frac{N\alpha(\omega)}{2\varepsilon_0}\\
&= 1 + \frac{\pi Ne^2}{4\varepsilon_0 m\omega_0}\left(\frac{f_0}{\pi}\right)\frac{i\gamma + \Delta}{\Delta^2 + \gamma^2 + \Omega_1^2\gamma/\Gamma}\,,
\end{aligned} \tag{69.16}$$

where $f_0 = 2d^2 m\omega_0/\hbar e^2$ is the oscillator strength. Summing over all possible transitions yields the f-sum rule (68.63) (Chapt. 21).

The imaginary part of (69.16) shows exactly the same absorptive behavior as in the harmonic oscillator model of Sect. 69.1 [see (69.3)]. However, the additional factor of $\left(\Omega_1^2\gamma/\Gamma\right)$ in the denominator makes the line

appear broader than in the harmonic case; the line is power broadened. Physically, this derives from a saturation of the two-level system in which the population of the upper level becomes an appreciable fraction of that of the lower level. In the limit $\Omega_1 \to \infty$, (69.16) shows that $n(\omega) \to 1$ and the atom-field interaction effectively vanishes. In this limit, $\rho_{ee} \to \frac{1}{2}$ (69.11), and the field induces as many upward transitions as downward transitions.

When radiation at the frequency ω propagates in a medium of two-level atoms, the energy density is

$$I(z) \propto \mathcal{E}^*\mathcal{E} \propto \exp\left[-\left(\frac{Nd^2\omega}{\hbar\varepsilon_0 c}\right)\frac{\gamma z}{(\omega - \omega_0)^2 + \gamma^2}\right]\,. \tag{69.17}$$

Far from resonance ($|\omega - \omega_0| \gg \gamma$), the medium is transparent; but near resonance, damping is observed. The impinging radiation energy is deposited in the medium and propagation is impeded. This is called radiation trapping. In spectroscopy, the phenomenon is seen as a prolongation of the radiative decay time; the spontaneously emitted energy is seen to emerge from the sample more slowly than the single atom lifetime implies.

69.3 Line Broadening

The effective width of a spectral line from (69.16) is

$$\gamma_{\mathrm{eff}} = \sqrt{\gamma^2 + \Omega_1^2\frac{\gamma}{\Gamma}} \simeq \frac{1}{2}\Gamma + \gamma_{\mathrm{ph}} + \frac{\Omega_1^2}{2\Gamma} + O\left(\Omega_1^4\right)\,. \tag{69.18}$$

The various contributions are as follows [69.3]. The term γ contains all the transverse relaxation mechanisms. If decay to additional levels occurs, these must be included (Sect. 69.4). The term γ_{ph} contains all perturbing effects effecting each single atom. For low enough pressures, collisional perturbations are proportional to the density of perturbing atoms so that

$$\gamma_{\mathrm{ph}} = \eta_{\mathrm{coll}}\,p\,, \tag{69.19}$$

where p is the pressure of the perturbing gas and η_{coll} is a constant of proportionality. This is called collision or pressure broadening (Chapt. 59), whose order of magnitude can be estimated to be the inverse of the average free time between collisions. For high pressure (usually of the order of torrs), the linearity in (69.19) breaks down. When identical atoms collide, resonant

exchange of energy may also take place. The third term in (69.18) is the power broadening term. It derives from the effect of the laser field on each individual atom. All such relaxation processes that are active on each and every individual atom separately are called homogeneous broadening processes. For a detailed discussion of line broadening, consult Chapt. 19.

In contrast to homogeneous broadening, Doppler broadening is characterized by an atomic velocity parameter v which varies over the observed assembly. In a thermal assembly at temperature T (e.g., a gas cell), the velocity distribution is

$$P(v) = \frac{1}{\sqrt{2\pi u^2}}\exp\left(-\frac{v^2}{2u^2}\right)\,, \tag{69.20}$$

where $u^2 = k_B T/M$. A particular atom with velocity v in the direction of the optical beam with wave vector k then experiences the Doppler-shifted frequency $\omega - kv$ relative to a stationary atom, and the effective detuning becomes

$$\Delta' = \Delta + kv\,, \tag{69.21}$$

replacing Δ. The population in the lower level from (69.11) is then

$$\rho_{gg} = 1 - \frac{\Omega_1^2 \gamma}{2\Gamma} \left(\frac{1}{(\Delta + kv)^2 + \gamma^2 + \Omega_1^2 \gamma/\Gamma} \right) .$$

(69.22)

The atoms in the lower level, originally distributed according to (69.20), are now depleted from the velocity group around

$$v = (\omega - \omega_0)/k .$$

(69.23)

The width of the depleted region is given by γ_{eff} of (69.18). This region is called a *Bennett hole*. When the laser frequency ω is tuned, the hole sweeps over the velocity distribution of the atoms. The atomic response is saturated at the velocity group of the hole, indicating that *spectral hole burning* has occurred.

The observed spectrum is obtained by averaging the single atom response (69.15) over the velocity distribution. From the imaginary part, the absorption response is

$$\alpha''(\omega) = \frac{d^2}{\hbar\sqrt{2\pi u^2}} \int\limits_{-\infty}^{+\infty} \frac{\gamma\, \mathrm{e}^{-v^2/2u^2}}{(\Delta + kv)^2 + \gamma^2 + \Omega_1^2 \gamma/\Gamma}\, \mathrm{d}v .$$

(69.24)

In the limits $\Omega_1 \to 0$ (no saturation), and $\gamma \ll ku$ (the Doppler limit), the Lorentzian line shape sweeps over the entire velocity profile, finding a resonant velocity group according to (69.23) as long as $v \le u$. Thus, the linear spectroscopy sees a *Doppler broadened line* of width ku. This is called *inhomogeneous broadening*.

In the unsaturated regime, the atomic response function (69.24) is proportional to the imaginary part of the function

$$V(z) = \frac{1}{\sqrt{2\pi\sigma^2}} \int\limits_{-\infty}^{+\infty} \frac{\exp\left(-x^2/2\sigma^2\right)}{z - x}\, \mathrm{d}x ,$$

(69.25)

at $z = -\Delta - \mathrm{i}\gamma$ and $\sigma = ku$. This is the Hilbert transform of the Gaussian, and its shape is called a *Voigt profile* [69.4]. For $\gamma \ll ku$, it traces over the Gaussian, but for large detunings it always goes to zero as slowly as the Lorentzian, i.e., as Δ^{-1}. The profile has been widely used to interpret the data of *linear spectroscopy*. The function is tabulated [69.5] and its expansion is

$$V(z) = \sqrt{-\frac{\pi}{2\sigma^2}} \sum_{n=0}^{\infty} \frac{\left(\mathrm{i}z/\sqrt{2}\sigma\right)^n}{\Gamma\left(1 + n/2\right)} ,$$

(69.26)

and it has the continued fraction representation,

$$V(z) = \cfrac{1}{z - \cfrac{\sigma^2}{z - \cfrac{2\sigma^2}{z - \cfrac{3\sigma^2}{z - \cfrac{4\sigma^2}{z - \cdots}}}}} .$$

(69.27)

In addition to velocity, any other parameter shifting the individual atomic resonance frequencies ω_0 by different amounts for the different individuals leads to *inhomogeneous broadening*. The detuning Δ is then different for different members of the observed assembly, and a line shape similar to (69.24) applies. The distribution function must be replaced by the one relevant for the problem. In practice a Gaussian is almost always assumed.

An example of inhomogeneous broadening is the influence of the lattice environment on impurity spectroscopy in solids. The resonant light selectively excites atoms at those particular positions which make the atoms resonant. Thus only these spatial locations are saturated, and the phenomenon of *spatial hole burning* occurs. This has been investigated as a method for storing information, signal processing, and volume holography.

It is, however, possible that the effects of collisions can counteract the inhomogeneous broadening. In order to see this we observe that the induced atomic dipole is proportional to the induced density matrix element, from (69.9),

$$\rho_{eg} = \tilde{\rho}_{eg}\, \mathrm{e}^{\mathrm{i}(kz(t) - \omega t)} \propto \mathrm{e}^{\mathrm{i}kvt} .$$

(69.28)

If the atoms now experience collisions characterized by an average free time of flight τ, the phase kvt cannot build up coherently for times longer than this duration, the atomic velocity is quenched on the average, and the full Doppler profile cannot be observed. To see how this comes about, consider a time $t \gg \tau$. During this period the atom experiences on the average $\bar{n} = t/\tau$ collisions. Assuming a Poisson distribution, the probability of n collisions in time t is

$$p_n = \frac{\mathrm{e}^{-\bar{n}}}{n!} \bar{n}^n .$$

(69.29)

Taking the average of (69.28) over the time $t = n\tau$ with the distribution p_n yields

$$\begin{aligned}
\bar{\rho}_{eg} &\propto \sum_{n=0}^{\infty} \mathrm{e}^{\mathrm{i}kv\tau n} \left(\frac{\mathrm{e}^{-\bar{n}}}{n!} \bar{n}^n \right) \\
&= \mathrm{e}^{-\bar{n}} \exp\left(\bar{n}\, \mathrm{e}^{\mathrm{i}kv\tau} \right) \\
&\approx \mathrm{e}^{\mathrm{i}kvt} \exp\left(-\frac{1}{2} t k^2 v^2 \tau \right) .
\end{aligned}$$

(69.30)

This heuristic derivation suggests that for long enough interaction times $(t \gg \tau)$, the large velocity components are suppressed. This tends to prevent the tails of the velocity distribution from contributing to the observed spectral profile. The effect is called *collisional narrowing* or *Dicke narrowing*. It is an observable effect, but the narrowing cannot be very large. To overcome the Doppler broadening one has to turn to nonlinear laser methods (Sect. 69.5).

69.4 The Rate Equation Limit

Consider now a generalized theory for the case of several incoming electromagnetic fields of the form

$$\mathcal{E}(R, t) = \sum_i \frac{1}{2} \mathcal{E}_i(R) \, e^{-i\omega_i t + i\varphi_i} + \text{c.c.} . \qquad (69.31)$$

The index i may range over several laser sources, the output of a multimode laser or the multitude of components of a flashlight or a thermal source. Each component carries its own amplitude $\mathcal{E}_i$.

In steady state, the generalization of (69.12) becomes

$$\rho_{eg} = \frac{i}{2} \sum_i \frac{d\mathcal{E}_i}{\hbar} \frac{(\rho_{gg} - \rho_{ee})}{\gamma + i\Delta_i} \, e^{-i\omega_i t + i\varphi_i} , \qquad (69.32)$$

where the detuning is

$$\Delta_i = \omega_0 - \omega_i . \qquad (69.33)$$

The response of the atom now separates into individual contributions oscillating at the various frequencies ω_i according to

$$\rho_{eg} = \sum_i \rho_{eg}^{(i)} \, e^{-i\omega_i t + i\varphi_i} . \qquad (69.34)$$

This resolution is of key importance to the theory.

With the multimode field, (68.67) for the level occupation probabilities become

$$\frac{d}{dt} \rho_{ee} = -\frac{d}{dt} \rho_{gg}$$

$$= -\Gamma \rho_{ee} + \frac{i}{2} \sum_i$$

$$\times \left(\frac{d\mathcal{E}_i}{\hbar} \, e^{-i\omega_i t + i\varphi_i} \rho_{ge} - \text{c.c.} \right) . \qquad (69.35)$$

Insertion of the steady state result (69.32) into this equation yields a closed set of equations for the level occupation probabilities. These are called *rate equations*.

To justify the above steps, consider the single frequency case again. The off-diagonal time derivatives can be neglected when

$$\left| \frac{d}{dt} \rho_{eg} \right| \ll |\gamma + i\Delta| |\rho_{eg}| . \qquad (69.36)$$

This can be surmised to hold when the phase relaxation contributions to γ are large (69.8) or the detuning $|\Delta|$ is large. Insertion of (69.32) into (69.35) for the single mode case gives

$$\frac{d}{dt} \rho_{ee} = -\Gamma \rho_{ee} - W \left(\rho_{ee} - \rho_{gg} \right) , \qquad (69.37)$$

where the rate coefficient is given by

$$W = 2\pi \left(\frac{d\mathcal{E}}{2\hbar} \right)^2 \frac{\gamma/\pi}{\Delta^2 + \gamma^2} . \qquad (69.38)$$

Multiplying (69.37) by the density of active atoms N then produces the conventional rate equations for the populations $N_{ee} = N\rho_{ee}$ and $N_{gg} = N\rho_{gg}$.

Two physical effects can be discerned in (69.37): *induced* and *spontaneous emission*. The term with Γ gives the spontaneous emission which forces the entire population to the lower level. The terms proportional to W describe induced emission, with upward transitions proportional to $W\rho_{gg}$ and downward transitions proportional to $W\rho_{ee}$. In the absence of spontaneous emission, they strive to equalize the population of the two levels. Using (69.10), the steady-state solution is

$$\rho_{ee} = \frac{W}{\Gamma + 2W}$$

$$= \frac{1}{2} \left(\frac{d\mathcal{E}}{\hbar} \right)^2 \frac{\gamma}{\Gamma} \frac{1}{\Delta^2 + \gamma^2 + (d\mathcal{E}/\hbar)^2 \gamma/\Gamma} . \qquad (69.39)$$

This is clearly seen to agree with the solution (69.11) as is expected in steady state.

Although the rate equations were derived in the limit (69.36), the rate coefficient (69.38) has a special significance in the limit $\gamma \to 0$. In this limit, the factor

$$\frac{1}{\hbar} \lim_{\gamma \to 0} \left(\frac{\gamma/\pi}{\Delta^2 + \gamma^2} \right) = \frac{1}{\hbar} \delta(\Delta)$$

$$= \delta(\hbar\omega - \hbar\omega_0) , \qquad (69.40)$$

enforces energy conservation in the transition. Using the field in (69.14), and the interaction from (69.6), the

off-diagonal matrix element is

$$|\langle e|H|g\rangle| = \frac{1}{2}d\mathcal{E} \; . \tag{69.41}$$

With these results, (69.38) can be written in the form of *Fermi's Golden Rule*

$$W = \frac{2\pi}{\hbar}|\langle e|H|g\rangle|^2 \delta(\hbar\omega - \hbar\omega_0) \; , \tag{69.42}$$

usually derived from time dependent perturbation theory.

Returning to the multimode rate equations, an incoherent *broad band light source* has many components that contribute to the sum over field frequencies. In the case of flash pulses, thermal light sources, or free-running multimode lasers the spectral components are uncorrelated. Inserting (69.32) into (69.35) yields

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho_{ee} = -\frac{\mathrm{d}}{\mathrm{d}t}\rho_{gg}$$
$$= -\Gamma\rho_{ee} + \frac{d^2}{2\hbar^2}\left(\rho_{gg} - \rho_{ee}\right)$$
$$\times \sum_{i,j} \mathcal{E}_i\mathcal{E}_j\, \mathrm{e}^{\mathrm{i}(\omega_j - \omega_i)t}\, \mathrm{e}^{\mathrm{i}(\varphi_i - \varphi_j)} \frac{\gamma}{\Delta_j^2 + \gamma^2} \; . \tag{69.43}$$

The contributions from the different terms $i \neq j$ average to zero either by beating at the frequencies $|\omega_i - \omega_j|$ or by incoherent effects from the random phases φ_j. Thus, only the coherent sum survives to give

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho_{ee} = -\frac{\mathrm{d}}{\mathrm{d}t}\rho_{gg}$$
$$= -\Gamma\rho_{ee} \times \sum_i W^{(i)}\left(\rho_{gg} - \rho_{ee}\right) , \tag{69.44}$$

where the rate coefficients $W^{(i)}$ are given by (69.38) with the appropriate detunings $\Delta_j = \omega_0 - \omega_j$. This is a *rate equation* in the limit of many uncorrelated components of light, i. e., for a *broad band light source*. In this case the incoherence between the different components justifies the use of a rate approach, and no assumption like (69.36) is needed. Thus, the limit $\gamma \to 0$ (69.40) is legitimate, and the $W^{(i)}$ can be calculated in time dependent perturbation theory from Fermi's Golden Rule.

In the limit of an incoherent broad band light source, the sum in (69.44) can be replaced by an integral. In particular, this is allowed for incandescent light sources as used in *optical pumping* experiments [69.6]. Pumping of lasers by strong lamps or flashes are also describable by the same rate equations.

In amplifiers and lasers, the atoms must be brought into states far from equilibrium by incoherent optical excitation or resonant transfer of excitation energy in collisions (Chapt. 70). In the two-level description, the atomic levels are constantly replenished. The normalization condition (69.10) is then no longer appropriate; often the density matrix is normalized so that $\mathrm{Tr}(\rho)$ directly gives the density of active atoms.

With pumping into the levels, one must allow for decay out of the two-level system in order to prevent the atomic density from growing in an unlimited way. This decay takes the atom to unobserved levels. In the rate equation approximation, the pumping and decay processes can be described by terms added to the equations of the form (68.68)

$$\frac{\mathrm{d}}{\mathrm{d}t}\rho_{ee} = \lambda_e - \gamma_e\rho_{ee} \; ,$$
$$\frac{\mathrm{d}}{\mathrm{d}t}\rho_{gg} = \lambda_g - \gamma_g\rho_{gg} \; . \tag{69.45}$$

In a laser, the level $|g\rangle$ is usually not the ground state of the system.

From (69.45), the steady state population is

$$\rho_{gg}^{(0)} - \rho_{ee}^{(0)} = \lambda_g/\gamma_g - \lambda_e/\gamma_e \; . \tag{69.46}$$

A *population inversion* exists when this is negative. The population difference (69.46) is modified when the effects of spontaneous and induced processes are added, as in (69.37). Then the transitions saturate because of the *induced processes*.

Using (69.46) in (69.12), the calculated polarizability without saturation is

$$\alpha(\omega) = \left(\frac{d^2}{\hbar}\right)\left(\frac{\mathrm{i}\gamma + \Delta}{\gamma^2 + \Delta^2}\right)\left(\rho_{gg}^{(0)} - \rho_{ee}^{(0)}\right) \; . \tag{69.47}$$

According to (69.1), the index of refraction is

$$n'(\omega) = 1 + \frac{N\alpha'(\omega)}{2\varepsilon_0}$$
$$= 1 - \left(\frac{Nd^2}{2\varepsilon_0\hbar}\right)\frac{(\omega - \omega_0)}{(\omega - \omega_0)^2 + \gamma^2}\left(\rho_{gg}^{(0)} - \rho_{ee}^{(0)}\right) \; . \tag{69.48}$$

For weakly excited atoms, $\rho_{gg} \approx 1$, and (69.47) agrees with the unsaturated limit of (69.16). The dispersion of a light signal behaving according to (69.48) is called *normal*, i. e., according to the harmonic model in Sect. 69.1. Below resonance ($\omega < \omega_0$), n' is larger than unity, implying a reduction of the velocity of light. As a function of ω, the curve (69.48) starts above unity, and passes below unity for $\omega > \omega_0$. This is *normal dispersion*.

However, for an *inverted medium* $\left(\rho_{gg}^{(0)} < \rho_{ee}^{(0)}\right)$, n' is less than unity for low frequencies and goes through

unity with a positive slope. This is called *anomalous dispersion* and signifies the presence of a *gain profile*. In such a medium, $\alpha'' = \text{Im}[\alpha(\omega)]$ is of opposite sign, as seen from (69.47); in the inverted medium, α'' becomes negative near $\Delta = 0$. From (69.2), this indicates a growing electromagnetic field, i. e., an *amplifying medium*. The amplitude grows, and the assumption of a small

signal becomes invalid. Then saturation has to be included, either at the rate equation level or by performing a full density matrix calculation. This regime describes a laser with *saturated gain*. In steady state, the two levels become nearly equally populated ($\rho_{ee} \approx \rho_{gg}$), and the operation is stable. The theory of the laser is discussed in detail in Chapt. 70.

69.5 Two-Level Doppler-Free Spectroscopy

The *linear absorption* of a scanned laser signal defines *linear spectroscopy* and gives information characterizing the sample. However, Sect. 69.3 shows that inhomogeneous broadening masks the desired information by dominating the line shape. The availability of laser sources has made it possible to overcome this limitation, and to use the *saturation* properties of the medium to perform *nonlinear spectroscopy*. This section discusses how Doppler broadening can be eliminated to achieve *Doppler-free spectroscopy*. Similar techniques may be used to overcome other types of *inhomogeneous line broadening*; a general name is then *hole-burning spectroscopy* (see the discussion in Sect. 69.3). Other aspects of nonlinear matter-light interaction are found in Chapt. 72.

Equation (69.24) shows that a single laser cannot resolve beyond the Doppler width. However, if a strong laser is used to pump the transition, a weak *probe signal* can see the hole burned into the spectral profile by the pump. This technique is called *pump-probe spectroscopy*. Because the probe is taken to be weak, perturbation theory may be used to calculate the induced polarization to lowest order in the probe amplitude only.

In the field expansion (69.31), define the strong pump amplitude to be $\mathcal{E}_1$ and the weak probe $\mathcal{E}_2$ at frequency ω_2. From the resolution (69.34), the component $\rho_{eg}^{(2)}$ carries the information about the linear response at frequency ω_2. If the field $\mathcal{E}_2$ propagates in a direction opposite to that of $\mathcal{E}_1$, its detuning is

$$\Delta_2' = \Delta_2 - kv \tag{69.49}$$

(as compared with $\Delta_1' = \Delta_1 + kv$ for $\mathcal{E}_1$). Since $\omega_1 \simeq \omega_2$, the two k-vectors are nearly equal in magnitude.

The linear response now becomes

$$\rho_{eg}^{(2)} = \left(\frac{\mathrm{i}d\mathcal{E}_2}{2\hbar}\right) \frac{1}{\gamma + \mathrm{i}(\Delta_2 - kv)} \left(\rho_{gg} - \rho_{ee}\right) . \tag{69.50}$$

With only the signal $\mathcal{E}_1$ present, the population difference follows directly from (69.22)). The linear response at frequency ω_2 is then

$$\rho_{eg}^{(2)} = \left(\frac{d\mathcal{E}_2}{2\hbar}\right) \frac{\mathrm{i}\gamma + (\Delta_2 - kv)}{\gamma^2 + (\Delta_2 - kv)^2} \times \left[1 - \frac{\Omega_1^2\gamma}{\Gamma}\right.$$
$$\left. \times \left(\frac{1}{(\Delta_1 + kv)^2 + \gamma^2 + \Omega_1^2\gamma/\Gamma}\right)\right] . \tag{69.51}$$

This is the linear response of atoms moving with velocity v. To obtain the polarization of the whole sample, we must average over the velocity distribution using the Gaussian weight (69.20). The first term in (69.51) gives the linear response in the form of a *Voigt profile*, as discussed in Sect. 69.3. This part of the response carries no Doppler-free information. The second terms contain the nonlinear response. This shows the details of the homogeneous features under the Doppler line shape. For simplicity we assume the Doppler limit, $\gamma \ll ku$, and neglect the variation of the Gaussian over the atomic line shape. We also neglect the power broadening due to the field $\mathcal{E}_1$ and obtain, using (69.13), (69.20), and (69.51),

$$\alpha''(\omega) = -\left(\frac{d^2}{\hbar}\right) \frac{\Omega_1^2\gamma^2}{\sqrt{2\pi}\,\Gamma u}$$
$$\times \int_{-\infty}^{+\infty} \frac{\mathrm{d}v}{\left[(\Delta_2 - kv)^2 + \gamma^2\right]\left[(\Delta_1 + kv)^2 + \gamma^2\right]}$$
$$= -\left(\frac{d^2}{\hbar}\right) \frac{\sqrt{2\pi}\,\Omega_1^2}{4\Gamma ku} \frac{\gamma}{(\omega - \omega_0)^2 + \gamma^2} . \tag{69.52}$$

This denotes the energy absorbed from the field $\mathcal{E}_1$, as induced nonlinearly by the intensity $\mathcal{E}_1^2$. The resonance is still at $\omega = \omega_0$, but with a homogeneous atomic line shape. In the Doppler limit, the Doppler broadening is

only seen in the prefactor

$$\frac{\Omega_1^2}{\Gamma k u} = \left(\frac{\Omega_1^2}{\Gamma \gamma}\right) \frac{\gamma}{ku} , \tag{69.53}$$

which shows that only the fraction (γ/ku) of all atoms can contribute to the resonant response. The first factor on the right-hand side of (69.53) is the dimensionless saturation factor.

The Doppler-free character of this spectroscopy derives from the fact that the two fields burn their two separate Bennett holes at the velocities

$$kv_1 = -\Delta_1 , \qquad \text{and } kv_2 = \Delta_2 . \tag{69.54}$$

When these two groups coincide, i.e., when $v_1 = v_2$, the probe $\mathcal{E}_2$ sees the absorption saturated by the pump field $\mathcal{E}_1$ and a decreased absorption is observed. For $\omega_1 = \omega_2$, the two holes meet in the middle at zero velocity. With two different frequencies, one can make the holes meet at a nonzero velocity to one side of the Doppler profile. The decreased absorption seen in these experiments is called an *inverted Lamb dip* Chapt. 70.

The results derived here are based on a simplified view of the pump-probe response which in turn is based on the rate equation approach. Certain coherent effects are neglected, which would considerably complicate the treatment [69.2]. Section 69.6 discusses these effects in the three-level system where they are more important.

In addition to measuring the probe absorption induced by the pump field, it is also possible to observe

the dispersion of the probe signal caused by the saturation induced by the pump. Assuming that the pump introduces the velocity dependent population difference

$$\rho_{ee} - \rho_{gg} = \Delta\rho(v) , \tag{69.55}$$

then from (69.50), Re(n) is

$$n' = 1 + \frac{Nd^2}{2\hbar\varepsilon_0} \int \frac{\Delta_2 - kv}{(\Delta_2 - kv)^2 + \gamma^2} \Delta\rho(v)\,\mathrm{d}v . \tag{69.56}$$

From (69.2), the phase of the electromagnetic signal feels the value of n' through the factor

$$\mathcal{E} \propto \exp(\mathrm{i}\omega n'z/c) . \tag{69.57}$$

Thus, by modifying $\Delta\rho(v)$, a pump laser can control the phase acquired by light traversing the sample, and thereby control the optical length of the sample.

A real atom has magnetic sublevels, which are coupled to light in accordance with *dipole selection rules* (see the discussion in Chapt. 33). If a pump laser is used to affect populations in the various sub-levels differently, the optical paths experienced by the differently circularly polarized components of a linearly polarized probe signal are different. Thus, its plane of polarization will turn, corresponding to the *Faraday effect*. By tuning the pump and the probe over the spectral lines of the sample, the turning of the probe polarization provides a signal to investigate the atomic level structure. This method of *polarization spectroscopy* can be used both with two-level and three-level systems [69.7].

69.6 Three−Level Spectroscopy

New nonlinear phenomena appear when one of the levels in the two-state configuration, $|e\rangle$ say, is coupled to a final level $|f\rangle$ by a weak probe. This may be above the level $|e\rangle$ (the cascade configuration denoted by $\varXi$) or below $|e\rangle$ (the lambda configuration Λ) (if the third level were coupled to $|g\rangle$ we would talk about the inverted lambda or V configuration) [69.8]. For simplicity, only the $\varXi$ configuration is discussed here.

Assume that the level pair $|g\rangle \leftrightarrow |e\rangle$ is pumped by the field $\mathcal{E}_1$ and its effect probed by the field $\mathcal{E}_2$ coupling $|e\rangle \leftrightarrow |f\rangle$. The dipole matrix element is $d_2 = \langle f|H|e\rangle$. The RWA is now achieved by introducing slowly varying quantities through the definitions

$$\rho_{fe} = \mathrm{e}^{\mathrm{i}(k_2 z - \omega_2 t)}\tilde\rho_{fe} ,$$
$$\rho_{fg} = \mathrm{e}^{\mathrm{i}[(k_1+k_2)z - (\omega_1+\omega_2)t]}\tilde\rho_{fg} , \tag{69.58}$$

and omitting all components oscillating at multiples of the optical frequencies. From the equation of motion for the density matrix, the steady state equations are [69.2]

$$(\Delta_2 + k_2 v - \mathrm{i}\gamma_{fe})\tilde\rho_{fe} = \frac{d_2\mathcal{E}_2}{2\hbar}\rho_{ee} - \frac{d_1\mathcal{E}_1}{2\hbar}\tilde\rho_{fg} ,$$
$$[(\Delta_1 + \Delta_2) + (k_1 + k_2)v - \mathrm{i}\gamma_{fg}]\tilde\rho_{fg}$$
$$= \frac{d_2\mathcal{E}_2}{2\hbar}\tilde\rho_{eg} - \frac{d_1\mathcal{E}_1}{2\hbar}\tilde\rho_{fe} , \tag{69.59}$$

where the second step detuning is now

$$\Delta_2 = \omega_{fe} - \omega_2 . \tag{69.60}$$

These equations contain the lowest order response proportional to $\mathcal{E}_2$, including some coherence effects. The coherence effects remain to lowest order, even when the last term in (69.59) is neglected; in that case, the

solution is

$$
\tilde{\rho}_{fe} = \left(\frac{d_2 \mathcal{E}_2}{2\hbar} \right) \frac{\rho_{ee}}{\Delta_2 + k_2 v - i \gamma_{fe}}
$$
$$
- \left(\frac{d_1 \mathcal{E}_1}{2\hbar} \right) \left(\frac{d_2 \mathcal{E}_2}{2\hbar} \right)
$$
$$
\times \frac{\tilde{\rho}_{eg}}{(\Delta_2 + k_2 v - i \gamma_{fe})}
$$
$$
\times \frac{1}{\left[(\Delta_1 + \Delta_2) + (k_1 + k_2) v - i \gamma_{fg} \right]} . \quad \text{(69.61)}
$$

The result to lowest order in $\mathcal{E}_2$ follows by replacing the density matrix elements for the two-level system $|e\rangle \leftrightarrow |g\rangle$ by their results calculated without this field. This shows that the polarization induced at the frequency ω_2 consists of two parts: one induced by the population excited to level $|e\rangle$ by the field $\mathcal{E}_1$ proportional to ρ_{ee}, and the other one is induced by the coherence $\tilde{\rho}_{eg}$ created by the pump. Retaining only the former produces a rate equation approximation, called a *two-step process*. This misses important physical features which are included in the second term called a *two-photon* or *coherent process*.

In order to see the effects of the two terms most clearly, consider the two-level matrix elements from (69.11) and (69.12) in lowest perturbative order with respect to the pump field $\mathcal{E}_1$, i. e.,

$$
\rho_{ee} = \left(\frac{d_1 \mathcal{E}_1}{\hbar} \right)^2 \frac{\gamma_{eg}}{2\gamma_{ee}} \frac{1}{(\Delta_1 + k_1 v)^2 + \gamma_{eg}^2} ,
$$
$$
\tilde{\rho}_{eg} = \frac{d_1 \mathcal{E}_1}{2\hbar} \frac{1}{\Delta_1 + k_1 v - i \gamma_{eg}} \quad \text{(69.62)}
$$

From (69.61), these matrix elements give

$$
\tilde{\rho}_{fe} = - \left(\frac{A}{\Delta_1 + k_1 v - i \gamma_{eg}} \right) \left[\left(\frac{2\gamma_{eg}}{\gamma_{ee}} \right) \right.
$$
$$
\times \frac{1}{(\Delta_1 + k_1 v + i \gamma_{eg})(\Delta_2 + k_2 v - i \gamma_{fe})}
$$
$$
- \frac{1}{(\Delta_2 + k_2 v - i \gamma_{fe})}
$$
$$
\left. \times \frac{1}{\left[(\Delta_1 + \Delta_2) + (k_1 + k_2) v - i \gamma_{fg} \right]} \right] ,
$$
$$
\text{(69.63)}
$$

where

$$
A = - \left(\frac{d_2 \mathcal{E}_2}{2\hbar} \right) \left(\frac{d_1 \mathcal{E}_1}{2\hbar} \right)^2 . \quad \text{(69.64)}
$$

The imaginary part of this yields the absorptive part of the polarization at the frequency ω_2. The first term

becomes the product of two Lorentzians, and is an incoherent rate contribution. It dominates when the induced population ρ_{ee} decays much more slowly than the induced coherence $\tilde{\rho}_{eg}$, i. e., when $\gamma_{ee} \ll \gamma_{eg}$.

The significance of the second term in (69.63) is evident in the limit when no phase perturbing processes intervene, so that

$$
\gamma_{ee} = \Gamma , \qquad \gamma_{eg} = \frac{1}{2} \Gamma ,
$$
$$
\gamma_{fg} = \frac{1}{2} \gamma_{ff} , \qquad \gamma_{fe} = \frac{1}{2} (\gamma_{ff} + \Gamma) . \quad \text{(69.65)}
$$

For $v = 0$, $\tilde{\rho}_{fe}$ becomes

$$
\tilde{\rho}_{fe} = - \frac{A}{\Delta_1^2 + (\Gamma/2)^2} \left(\frac{1}{\Delta_1 + \Delta_2 - i \frac{1}{2} \gamma_{ff}} \right) . \quad \text{(69.66)}
$$

Neglecting the decay of the final level $|f\rangle$, $\gamma_{ff} \to 0$, the absorption becomes proportional to

$$
\text{Im} (\tilde{\rho}_{fe}) = \frac{\pi |A|}{\Delta_1^2 + (\Gamma/2)^2} \delta (\Delta_1 + \Delta_2) . \quad \text{(69.67)}
$$

In this limit, strict energy conservation between the ground state and the final state must prevail; the final state must be reached by the absorption of exactly two quanta. The delta function in (69.67) indicates precisely this:

$$
\Delta_1 + \Delta_2 = \omega_{fe} + \omega_{eg} - (\omega_1 + \omega_2)
$$
$$
= \omega_{fg} - \omega_1 - \omega_2
$$
$$
= 0 . \quad \text{(69.68)}
$$

The detuning and the width of the intermediate state affect the total transition rate, but not the condition of energy conservation. The presence of the second term in (69.63) makes the resonance contributions at

$$
\Delta_2 = \omega_{fg} - \omega_2 = 0 \quad \text{(69.69)}
$$

cancel approximately. Only a *two-photon transition* remains; in the Λ configuration this would be a *Raman process* (Chapts 62 and 72).

If the velocity dependence in (69.63) is retained, the nonlinear response of an atomic sample must be averaged over the velocity distribution given by the Gaussian (69.20). The computations become involved, but the results show more or less well resolved resonances around the two positions (69.68) and (69.69), i. e., the *coherent two-photon process* and the single step rate process $|e\rangle \to |f\rangle$ appearing due to a previous single step process $|g\rangle \to |e\rangle$; this is the *two-step process*.
